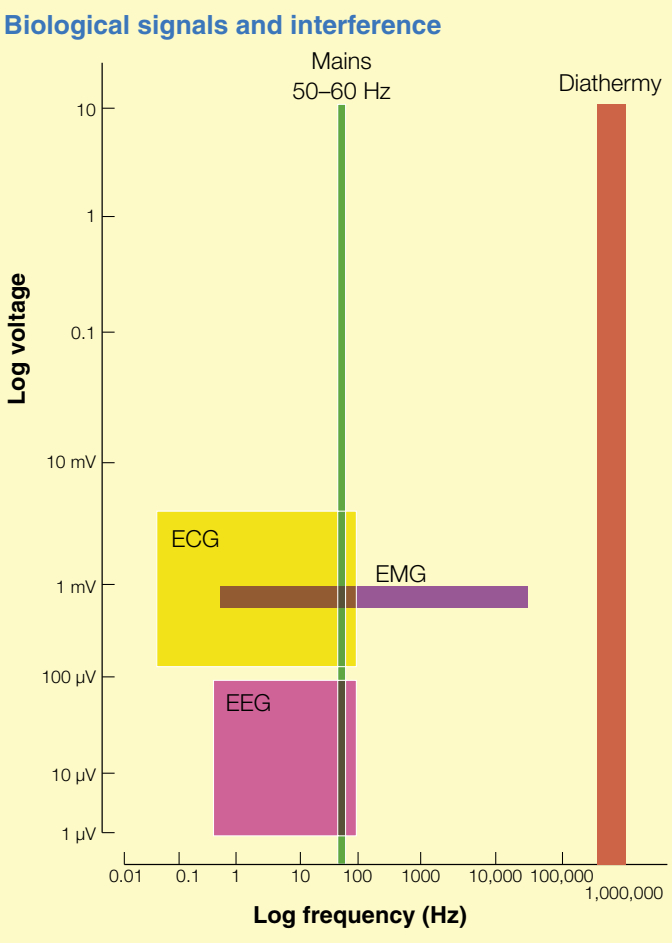
Biological signals and interference



2

DC amplifiers: a very slowly changing signal (e.g. daily variation in body temperature) can be treated as if it were a steady voltage and requires a special type of direct current amplifier. Historically, these were difficult to make free of 'drift'. This is a spurious slow change in the output signal when the input is steady. Drift was usually caused by changes in the temperatures of components within the amplifier causing changes in their resistance, and very long warm-up times were necessary before measurement could begin. With modern integrated circuits, the whole amplifier is formed on a tiny silicon chip which is too small to permit significant temperature differences to occur between closely spaced components.

Differential amplifiers: one type of amplifier widely used for biological signals has two input terminals and amplifies the voltage difference between them, while ignoring a much larger voltage between both terminals and earth. In this way, if two ECG wires run side by side from the patient to the amplifier, the same amount of mains interference is picked up by each wire but is ignored when it reaches the amplifier that is sensitive only to the voltage difference between the ECG patches. The quality of such a device is expressed on a log scale as the common mode rejection ratio, that is the ratio by which the difference signal is amplified more than the common mode.

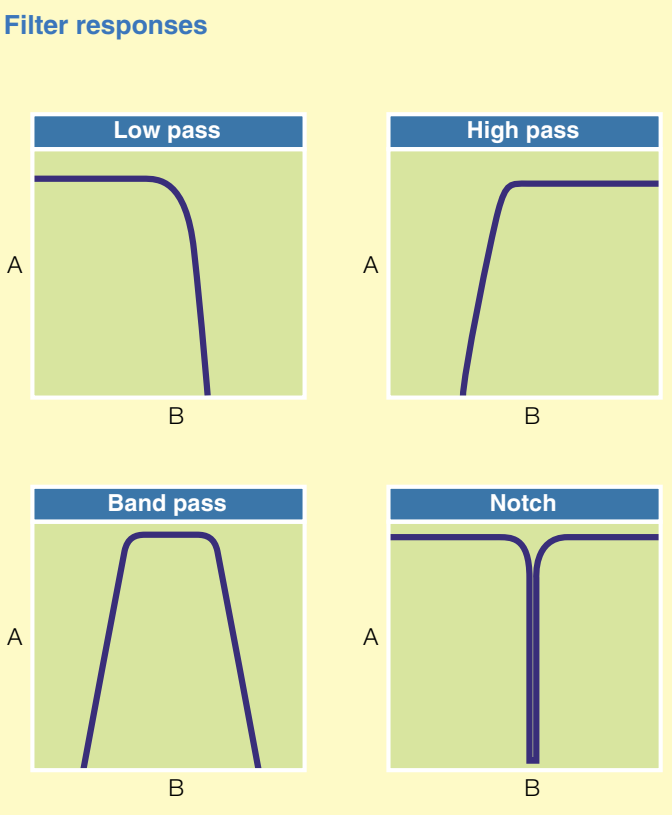
Fourier analysis
Any repetitive waveform can be dissected mathematically and described in terms of various proportions of a set of related frequencies that are multiples (harmonics) of one another. The original waveform can be reassembled from this mathematical recipe. Knowledge of the range of frequencies present in a signal is necessary to design an amplifier that reproduces it faithfully. Among biological signals, the ECG and arterial pulse are repetitive, but random signals such as the EMG and EEG can be analysed in much the same way.

Spectral analysis
It is possible to perform spectral analysis in real time on an EEG signal, and to display the amount of neural activity present in each of several groups of frequencies. The dominant frequencies change and slow with the depth of anaesthesia and this is the basis of the cerebral function monitor.

Processed signals
Additional information can be extracted from signals by computer processing. For example, if the P wave of the ECG is identified, and then the time between it and the corresponding R wave measured for each heartbeat, a beat-to-beat variation in P–R interval emerges, and may give information on the state of autonomic tone and the health of the conducting system.

Filters
Filter circuits pass or block a signal according to its frequency (Figure 3). They can be used to separate interference from a wanted signal provided their frequencies are sufficiently different. Filters are commonly built into amplifiers to suit them to a particular use.

Filter responses



3

A low pass filter allows a low frequency signal to pass through, but obstructs the passage of high frequencies, and a high pass filter does the reverse.

A band pass filter blocks high and low frequencies, but passes a group of frequencies in between.

A notch filter blocks a narrow band of frequencies centred on an interfering signal, for example a 48–52 Hz filter removes mains 50 Hertz interference from an ECG signal, but makes little difference to the fidelity of the recording.

Special techniques
A very small signal can be extracted from large amounts of random electrical 'noise' if the signal can be made to recur regularly. The basis of the evoked auditory response test of cochlear function is to feed precisely regular clicks into the ear through headphones, and then search for equally regular, but small, responses within the EEG. If the EEG is summed for each of a large number of successive short time periods after each click, then random signals will average towards zero, but a constant response will build up in size and become visible through the noise.

Electrical interference
Sources: in electrical terms, the world is a noisy place. In industrial countries most buildings have an electricity supply, are close to roads carrying traffic that emits interference from ignition systems, while radio, television, radar and mobile phone signals are ubiquitous.

In the operating theatre
Mains frequency – so much equipment in theatre is mains powered that wires carrying mains voltage snake everywhere. Each wire emits an electric field fluctuating at 50 Hz (60 Hz in the USA) and a magnetic field the strength of which varies with the current. Any conductor in an electric field has a voltage induced on it, and any conductor exposed to a fluctuating magnetic field also has a voltage induced in it.

High frequency sources – surgical diathermy (Bovie) apparatus is a radio transmitter. The high frequency current has a heating, charring or explosive effect on tissue depending on the power setting, the waveform selected and the current density. A high frequency of 0.5–1 MHz is chosen because, other than heating, it has little or no effect on excitable tissue such as muscle and nerve. In use, surgical diathermy operates at a power level of tens of watts, the wire to the surgeon's handpiece is a transmitting aerial and the current is picked up by any wire nearby. Because the frequency is high compared with any biological signal, it is easily filtered.

MRI: monitoring a patient in an MRI scanner introduces additional problems. The scanner uses a powerful magnet, a radio transmitter and a receiver all aimed at the part of the patient being scanned. The radio frequency is swept rapidly over a range centred on the resonant frequency of water or other molecules of interest in the magnetic field. So the patient and the monitoring leads are at the focus of intense energy fields. One solution is to use a small radio transmitter operating at a non-interfering frequency to take the ECG signal to a monitor outside in the control room. Another is to use fibre-optic leads to bring light to and from the patient's finger for pulse oximetry. The common feature is that metal wires carrying small signals through an intense energy field are avoided.

The MRI scanner is subject to interference from external radio signals, and the whole room is enclosed in a Faraday cage. The walls, floor, ceiling, and doors all contain a conductive copper mesh, and the windows are of special conductive glass. The edges of the doors have a copper strip to complete the cage when they close. Any wires or other metallic parts implanted in a patient can have significant voltages, temperatures or mechanical forces induced in them during scanning. A useful website that gives advice on MRI safety is www.MRIsafety.com. ◆

Anaesthesia Monitoring Techniques

Simon Hughes

Simon Hughes is an RAF Anaesthetic SHO currently working at the Nuffield Department of Anaesthesia, Oxford.

Richard Griffiths is Consultant Anaesthetist at Peterborough District Hospital. He qualified from St Thomas' Hospital, London, and trained in anaesthesia in Nottingham, Leicester and San Francisco. His main interests are vascular anaesthesia and medical education.

Depth of anaesthesia

Most anaesthetics are given without monitoring the effect of the anaesthetic on the target organ. Depending on the stimulus, there is a depth of anaesthesia at which the patient becomes aware. The incidence of awareness or recall during general anaesthesia is about 1/500.

Historical methods

Clinical assessment uses autonomic signs such as pulse, blood pressure, sweating and lacrimation to predict anaesthetic depth. However, autonomic functions are not affected by depth of anaesthesia only, and patients with autonomic neuropathy will not react as predicted.

Tourniquet – Tunstall described inflating a tourniquet to the upper arm above systolic pressure before induction of anaesthesia. This prevents neuromuscular agents reaching the forearm muscles, and the patient's arm moves if anaesthesia is too light. This method is unsuitable for routine use because it indicates awareness once it has occurred, and the time for which the tourniquet can be inflated is limited by neuronal ischaemia from compression.

Electroencephalogram (EEG)

Recording the electrical activity of the brain provides information on depth of anaesthesia. However, the equipment is expensive and skilled operators are required to obtain useful information. Different drugs have varying effects on the EEG. Hypotension, hypoxia, metabolic encephalopathy and cerebral oedema can all depress EEG signal output.

The EEG detects voltages of 1–500 μv. It comprises α, β, θ and δ waves. With increasing depth of anaesthesia there is a progressive increase in signal amplitude and a reduced frequency (burst suppression). The EEG is non-invasive and presents cortical electrical activity derived from summated excitatory and inhibitory postsynaptic activity that is paced by subthalamic nuclei. Fourier analysis is used to separate the raw EEG into a number of component sine waves. The derived parameters, spectral edge frequency and median frequency describe the entire EEG as a single value. Spectral edge frequency is a single value representing the frequency below which 95% of the total power is present. The median frequency is the point at which 50% of the power lies above and below this value. Median frequency has been shown to control closed loop feedback of intravenous drug administration, but no studies have demonstrated the usefulness of spectral edge frequency.

Bispectral index (BIS) is a derived variable that uses information on EEG power and frequency, and includes information derived from the mathematical technique of bispectral analysis (Figure 1). BIS records a state of the brain and not the effect of a particular drug. BIS gives a numerical value and the data are generated over 30 EEG recordings, with the average updated every 2–5 s. A low BIS value indicates hypnosis. BIS decreases during natural sleep, though not to the level produced by anaesthetic drugs.

Evoked potentials

Cortical evoked potentials to auditory, visual or somatosensory stimuli are suppressed in a dose-dependent manner by anaesthetic agents, and correlate well with peroperative wakefulness, awareness and explicit and implicit memory. Voltage potentials are small (1–2 μv) compared with background electrical activity (> 100 μv). Evoked potentials are generated using repeated stimuli, and the electrical responses pre- and post-stimuli are averaged so that only the electrical activity corresponding to the generated stimulus is analysed.

The evoked response is divided into early, mid-latency and late cortical waves. Early waves originate in the brainstem and are unchanged by anaesthesia. Mid-latency waves (40–60 ms post-stimulus) are highly influenced by increasing depth of anaesthesia, particularly the Pa and Nb waves. Anaesthetic agents increase latency and decrease amplitude in a dose-dependent manner. The correlation of mid-latency auditory evoked potentials to depth of anaesthesia approaches that of BIS.

The late cortical response (50–100 ms post-stimuli) reflects activation of the frontal cortex but is heavily influenced by attention, sleep and sedation.

Neuromuscular blockade

Neuromuscular blockade is monitored during surgery to guide repeated doses of muscle relaxants and to differentiate between the types of block. All techniques for assessing neuromuscular blockade use a peripheral nerve stimulator (PNS) to stimulate a motor nerve electrically. The PNS generates a standard electrical pulse, which should be:

- supramaximal to ensure recruitment of all available muscle units
- a square wave of short duration (0.1–0.2 ms) with uniform amplitude (10–40 mA).

The muscle response can be assessed by visual and tactile methods, electromyography, acceleromyography and mechanomyography. Visual observation and palpation of the contracting muscle group are the easiest but least accurate methods of assessing neuromuscular block from PNS stimulation.

Electromyography uses electrodes to record the compound muscle potential stimulated by the PNS. Typically, the ulnar nerve is used and the electrodes are placed over the motor point of adductor pollicis. A drawback is that small movements of the hand can change the response by altering the electrode geometry.

Acceleromyography – acceleration of a distal digit is directly proportional to the force of muscle contraction (because force equals mass times acceleration), and therefore inversely proportional to the degree of neuromuscular block. The transducer uses a piezoelectric crystal secured to the distal part of the digit measured and the PNS provides the electrical stimulus. Accurate and stable positioning of the digit is important for accurate results.

Mechanomyography uses a strain gauge to measure the tension generated in a muscle. A small weight is suspended from the muscle to maintain isometric contraction. The tension produced on PNS stimulation is converted into an electrical signal. Mechanomyography requires splinting of the hand and is generally used for research.

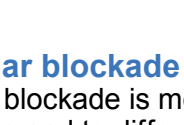
Different modes of PNS stimulation

Single twitch – an electrical pulse is delivered at 1 Hz, and the ratio of the evoked twitch compared with that before muscle relaxation gives a crude indication of neuromuscular blockade (Figure 2). When 75% of the acetylcholine (ACh) receptors on the postsynaptic membrane of the neuromuscular junction are occupied by a neuromuscular blocking agent (NMBA), twitch magnitude starts to decrease. When there is 100% drug occupation, no twitch is elicited.

Pulse patterns

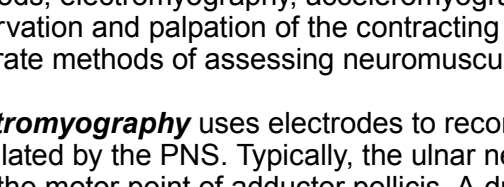
Twitch

- Single twitch
- Used with depolarizing blockade
- Degree of twitch depression used to calculate level of blockade



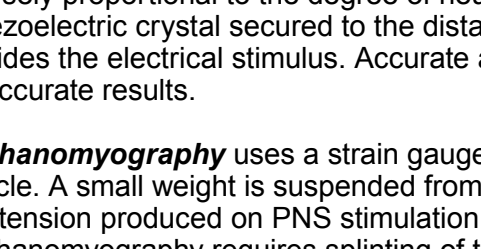
Train of four

- Four single pulses at 2 Hz
- Shows fade
- Ratio of first to fourth twitch used to calculate level of blockade



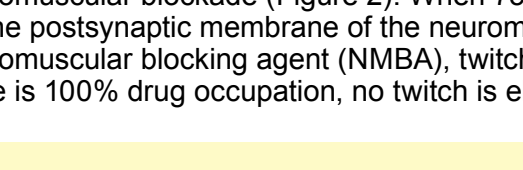
Tetanus

- Sustained burst of pulses at 50 or 100 Hz
- Usually held for around 5 s
- Used to 'kick start' the nerve under deep paralysis



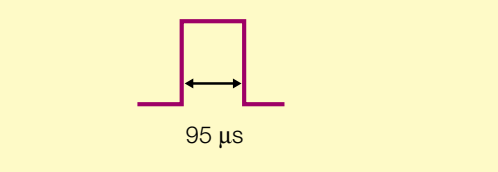
Double burst stimulation

- Two bursts 0.5 s apart
- Either 3 pulses followed by 2 pulses (3:2) or 3 followed by 3 (3:3)
- Used under light paralysis where train of four ratio is difficult to distinguish



Post-tetanic count

- 5 s tetanus followed by 20 pulses at 2 Hz
- Shows fade response earlier than train of four
- Used under deep paralysis to estimate time to recovery



2

Train of four (TOF) – four stimuli are given at a frequency of 2 Hz, potentially eliciting 4 twitches (T1–T4). The ratio T4:T1 indicates the degree of neuromuscular block. Non-depolarizing NMBAs produce a decrease in magnitude of the first twitch compared with a pre-relaxant stimulus, and a progressive reduction in magnitude of T1–T4. The number of elicited twitches indicates the degree of receptor occupancy. Disappearance of T4, T3, T2, T1 corresponds to 75%, 80%, 90% and 100% occupancy. With recovery of neuromuscular function the twitches appear in the reverse order. Accepted values for TOF count are:

- 1 twitch for tracheal intubation
- 1–2 twitches during established anaesthesia
- 3–4 twitches before reversal of neuromuscular blockade is attempted.

Double burst stimulation consists of two bursts of three stimuli at 50 Hz with each triple burst separated by 750 ms. These manifest visually as two separate stimuli (T1 and T2). The ratio is related to the TOF ratio and is easier for the operator to interpret reliably.

Tetanic stimulation at 50 Hz for 5 s produces detectable fade in muscle contraction, the extent of which is related to neuromuscular block. No fade indicates no neuromuscular block. In intense neuromuscular block, TOF stimulation elicits no twitches. Post-tetanic facilitation (PTP) uses tetanic stimulation for 5 s to mobilize presynaptic ACh. Subsequent 1 Hz twitch stimulation can overcome the high concentrations of NMBAs. The number of twitches generated (i.e. the post-tetanic count) reflects the degree of neuromuscular blockade.

Depolarizing NMBAs react differently to the PNS modes of stimulation. They produce equal but reduced twitches in response to single twitch and TOF stimulation (the T4: T1 ratio is 1), reduced but sustained contraction with tetanic stimulation, but do not demonstrate either tetanic fade or PTP.

Temperature

In health, body temperature is maintained at 37 ± 0.2°C. Intraoperative monitoring can be via electrical or non-electrical techniques.

Non-electrical techniques

An aneroid gauge uses the expansion of air with increasing temperature to change the size of a bellows connected to a needle. The needle moves across a calibrated scale to display the temperature.

Liquid thermometers typically rely on the thermal expansion of alcohol or mercury. The liquid is forced into a fine transparent glass tube with an appended scale. An angulation and constriction below the fine-bore tube prevents the liquid retracting into the bulb reservoir until the thermometer is shaken. A short time (2–3 minutes for mercury) is required for complete thermal equilibration between the liquid and the surrounding environment. There is a risk of poisoning if the thermometer breaks and mercury leaks.

Bimetallic strip thermometers comprise two metals with different coefficients of thermal expansion. With a change in temperature one metal changes size more than the other causing the strip to bend; this is displayed via a mechanical linkage on a temperature scale.

Chemical thermometers use liquid crystals composed of chemicals such as cholesterol esters, that change colour with temperature. Typically these scales can be accurate only to 0.5°C. They are used for monitoring skin temperature which may be markedly different from core temperature.

Infrared thermometers use the principle of black body radiation. Only the temperature of that object determines the maximal amount of radiation emitted by a body. The amount of radiation emitted by a surface (e.g. the tympanic membrane) is less than that emitted by a black body at the same temperature. The emissivity of the surface is the ratio of these radiation levels. Thus, measurement of a surface's emitted radiation combined with a pre-existing knowledge of that surface's emissivity can determine the temperature of that surface. Infrared tympanic membrane thermometers are in common clinical use.

Electrical techniques

Thermocouples use the Seebeck effect, whereby a small voltage is produced at a junction between two dissimilar metals, commonly either platinum/rhodium or copper/constantan. The temperature at the junction determines the voltage produced. There is a second junction to complete the electrical circuit. This is either maintained at a constant temperature, to provide a reference level, or has built-in compensation for the reference junction temperature, enabling the first junction to act as a thermometer.

A thermistor is a semiconductor made from tiny beads of heavy metal oxides, which can be incorporated into the tips of fine temperature probes. Electrical resistance of semiconductors decreases exponentially with increasing temperature. Thermistors require signal conditioning and calibration because resistance may alter with time. Thermistors exhibit hysteresis in that their electrical resistance is different at the same temperature depending on whether the temperature is increasing or decreasing.

Platinum wire thermometers – electrical resistance of platinum increases with increasing temperature. The increase is linear in the range 0–100°C. They are accurate to within 0.0001°C, but are fragile.

Respiration

In anaesthesia, ventilatory pattern, gas flow, airway pressure and tidal and minute volumes are measured. Only methods of measuring gas flows and volumes are mentioned here.

Gas flow can be used to derive volume. Flow is laminar or turbulent, and Reynolds number is used to predict the type of flow. Laminar flow is described in the Hagen–Poiseuille equation. Pneumotachographs measure flow by inducing laminar flow through a gauze screen. The screen produces a resistance to flow and thus generates a small pressure difference on either side. This pressure difference is measured with two transducers. These convert pressure into an electrical signal, which is processed to produce a display of flow. The screen is manufactured to provide minimal resistance to respiration, and is heated to maintain a constant temperature. If the screen was allowed to cool in the gas flow this would affect the gas viscosity, altering flow characteristics of the gas and thus affecting accuracy. Warming also prevents condensation developing on the screen, which would increase resistance to flow.

Respirometers can be used to monitor expiratory gas volumes. The most common is Wright's anemometer (Figure 3). Expired gas passes through oblique slits, which creates circular gas flow in a chamber, causing rotation of a double-vaned rotor. The rotor is coupled via a set of linkage gears to a display indicator dial and needle. The respirometer measures gas volume in one direction only. Flow can be calculated by averaging recorded volumes over time. Its advantages are that no power supply is necessary, and the device is lightweight and portable. Owing to the inertia in the system it tends to overestimate higher volumes and underestimate lower volumes. ◆

Basic Measurement Concepts

John Curnow

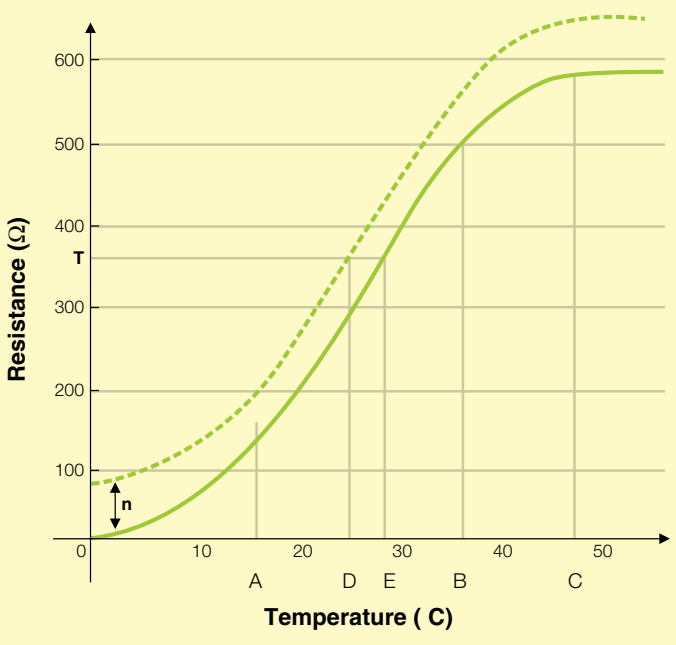
John Curnow is Biomedical Engineer at Derriford Hospital, Plymouth, Devon, UK. His specialist interest is in patient monitoring and the application of computing techniques in medicine.

Anaesthetists commonly record data from patients, intermittently or continuously. Data collection can be as simple as measuring the heart rate by feeling the pulse and counting it over a period of time, through regular intermittent monitoring of blood pressure and heart rate to continuous monitoring of variables using electronic data collection, analysis and storage systems. The general concepts discussed here are mainly related to continuous mon-itoring though some of them also apply to intermittent methods.

Measurement is the interpretation of a feature or function in a way that is repeatable and calibrated so that it can be understood and compared with other measurements taken at different times or by different people and on different patients. In many basic measurement techniques such as measuring length, the device used to make the measurement is calibrated to a national or international standard. This use of a standard to calibrate a measurement is the basis of making it repeatable and accurate so that measurements made by anyone with a calibrated instrument can be compared with other measurements.

For medical monitoring, data are collected directly from the patient using two different systems. If the feature to be monitored is an electrical activity in the body, electrodes are used to collect the data directly. If the feature to be monitored does not produce electrical activity then a transducer is used to collect the data. A transducer measures the feature required and produces an electrical signal proportional to it. For example, a standard method of temperature measurement is to use a thermistor as the sensor. A thermistor is an electronic device that has been specifically designed so that its electrical resistance changes with temperature in a regular and defined way (Figure 1).

Characteristic thermistor curve



See text for explanation

1

This characteristic curve shows several important features. Within the temperature range A to B the change in temperature is directly related to change in resistance and therefore the curve for this part can be represented by a straight line. This is called a linear relationship because it can be represented by the straight line characteristic and therefore the changes in resistance mirror the changes in temperature. Many systems are said to be linear and the linearity of a measurement system is a measure of how well the measured variable and the measurement variable can be represented by a straight line.

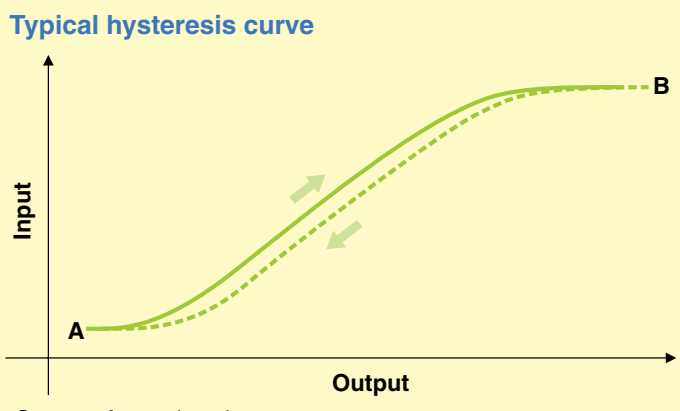
In the temperature ranges zero to A and B to C the characteristic is a curve that follows a fixed mathematical function. In this case, the relationship can be modelled within the electronics of the measurement system to produce a linear relationship and allow monitoring. In the range above C, the curve approximates to a straight horizontal line because there is no change of resistance with change of temperature. The measuring system is said to have reached saturation at point C and no readings can be made above this temperature. Saturation can be a problem to the unwary because the measurement system is apparently giving an acceptable reading although it is wrong. It is always important to identify the maximum value a system should read before using it.

Offset is a change within the transducer that can happen in real systems; it is shown by the dotted curve in Figure 1. In the case shown it represents a vertical shift equivalent to a resistance change of n ohms at each temperature. The effect in this case is to underestimate the temperature as shown by points D and E for a temperature T. It is difficult to identify offset unless a known source at a standard value is available to check the system.

Drift – most transducers used with monitoring equipment have active electronic devices such as a thermistor. These devices are designed to work accurately over a known environmental temperature range. If they are used at environmental temperatures outside this range the results may be incorrect because of drift. Drift can be seen as a change of the characteristic curve and can consist of offsets and/or changes in slope of the characteristic curve. The later will reproduce as an overestimate or under-estimate of temperature that changes across the measurement range of the system. If one or the other of these occurs the final result will be an error in the reading of the measurement that will be difficult to identify. One method of identifying drift is to monitor the expected baseline continuously. If it shows a consistent rise or fall, which is not expected then drift may be the cause.

Hysteresis – some transducers (e.g. pressure measurement transducers) use the mechanical properties of a material as the basic measurement technique. In the case of some pressure transducers a thin metal or plastic membrane is fitted over the end of a small chamber connected to the fluid having its pressure measured. The membrane flexes out as the pressure increases and goes back towards its original position as the pressure falls. The flexing of the membrane is measured using an electrical method. Many solid materials demonstrate a feature called hysteresis when stretched and relaxed repeatedly. A typical hysteresis curve is shown in Figure 2. If the system starts at point A and the input rises, the characteristic will follow the full line to point B where saturation occurs. If the input is then reduced the characteristic will follow the dotted line back to the lower saturation level at A. Therefore, the output value for any input value depends on the direction the input is changing in at the time and means accurate calibration of the output values is impossible. If the input signal is continuously changing, the output will also be a continuously changing value but will appear to read above the expected value during increasing input and below the expected value during reducing input. This will produce a distorted signal shape.

Typical hysteresis curve



See text for explanation

2

Measurement equipment electronics

Most medical measurement equipment depends on electronic systems to process and display the data collected. These electronic systems therefore become part of the overall measurement system. The electronics is often intended to make correction for known consistent errors in the signal produced by the transducer or to make non-linear responses linear.

The bulk of the electronics of a measurement system usually means that electrodes and transducers need long cables to connect them. These cables lie in the general environment and act as an aerial to airborne electrical signals. These signals consist mainly of power line frequency signals and radiofrequency signals. The signal is added to the signal from the electrode or transducer and both signals are presented to the electronics for processing. The unwanted signals are called noise. Other sources of noise are unwanted body potentials such as the muscle activity added to an ECG signal. The level of noise is important when considering the quality of a signal. The signal-to-noise ratio (SNR) is a ratio of the amplitude of the required signal to the amplitude of the noise signal and is used to define the quality of the signal. SNR is equal to 20 $\log_{10}$ (ratio of signal amplitude to noise amplitude measured in volts). A value of 6 dB means the signal is twice the size of the noise, and 60 dB means the signal is 1000 times larger than the noise.

The electronic system can also affect the signals, for example saturation occurs if the signal requires a voltage higher than that available from the electronics. Also the electronics can have thermal drift which can produce the same results as transducer drift. The usual cause is the electronics becoming too hot and it is essential that all vents are kept clear to minimize this effect. ◆

Basic Principles of Lasers

R John Parsons

R John Parsons was appointed Head of Medical Physics and Biomedical Engineering in Plymouth in 1992. He first worked with medical lasers in the 1970s and has taken a great interest in laser safety. He represents the British Medical Laser Association on the BSI committee dealing with Optical Radiation Safety.

The acronym LASER stands for **L**ight **A**mplification by the **S**timulated **E**mission of **R**adiation. Stimulated emission is an atomic process predicted by Einstein in 1917, but it was not until 1960 that the first laser was demonstrated. Lasers produce light of varying frequencies and power depending on their construction. They heat tissue, causing eventual destruction and are used in a variety of medical situations. They pose risks to all present, but by observing local rules they can be used safely with low risk to staff and patients. The three elements needed to make a laser are a medium, a power supply and positive feedback.

A medium that can exhibit stimulated emission implying amplification is required. This process takes place at the atomic level and involves inverting the normal steady-state thermal equilibrium of the medium – 'the population inversion'. Many substances exhibit this phenomenon though usually additional materials are required to make the system work. The laser is normally referred to by the name of the medium used (Figure 1).

Examples of media used in common medical lasers

- Gas – carbon dioxide (mixed with helium and nitrogen), argon, krypton
- Solid – Nd:YAG (neodymium doped yttrium aluminium garnet) crystal, holmium YAG, erbium YAG
- Metal vapour – copper, gold
- Liquid – organic dye
- Semi-conductor

A power supply drives the process. Many types are used including high voltage power supplies, radiofrequency power supplies, flashlight systems and small batteries driving devices like lecture theatre pointers.

Positive feedback: stimulated emission within the optical cavity is seldom sustainable without positive feedback. As the output is in the form of optical radiation this can be achieved by two mirrors placed one at each end of the cavity. One of these is made to have a very high reflectivity whereas the other allows some radiation to be transmitted through it, thus forming the laser output.

Properties
Laser light output has three main properties. It is collimated, coherent and monochromatic.

Collimated refers to the parallel nature of the output. In contrast to the light emanating from a light bulb, that from a laser is almost parallel showing very low divergence. This means that it can be focused using a lens to a very small spot size, greatly increasing the power per unit area. This is exploited in most medical lasers because the energy can be concentrated to affect tissues, up to destruction, with high positional precision. It also means that the light can be 'bundled' into a fibre-optic cable for transmission to otherwise inaccessible places in the body.

Coherent means that all light waves are in step with one another. This is responsible for the proliferation of holograms. They are little used in medicine though they have been extensively researched.

Monochromatic means output of one colour or frequency. This is not strictly true because most lasers emit more than one frequency with each one occupying a narrow band in the spectrum. This output depends on the active medium and can be in the ultraviolet, visible or infrared part of the spectrum (Figure 2).

Output of different media

- Carbon dioxide emits in the far infrared spectrum – invisible
- Neodymium YAG emits in the near infrared spectrum – invisible
- Copper vapour and argon emit in the visible spectrum
- Excimer (excited dimer) lasers emit in the ultraviolet spectrum – invisible

Light–tissue interaction

Light energy impacting on tissue has wide potential for changing tissue components and structures, depending on several factors. The most important of which are the intensity and frequency of the light.

Intensity
As the light intensity increases, different effects dominate, roughly following an order of magnitude scale. Below about 4 J/cm^2 biostimulation at a cellular level occurs. This effect is exploited in physiotherapy applications of low power lasers. If the power level is increased above this figure biosuppression starts to occur.

By about 40 J/cm^2 any sensitizing agents become activated. Ultraviolet therapy using psoralens and sunscreen creams are two examples of this phenomenon. By 400 J/cm^2, with tissue temperatures approaching 60°C, protein denaturization and photocoagulation dominate. Another order of magnitude increase sees the temperature rise to 100°C and vaporization and ablation occur. These descriptions are general and there are variations within an organ and between organs. However, the sequence of events leads from gentle heating to complete destruction.

Most continuous lasers can be 'pulsed' singly or in a repetitive way under user control. The effect of pulsing is to lower the average power delivered and consequently the temperature. During the 'off' phase the tissue has a chance to dissipate the heat and therefore thermal damage to surrounding tissue is reduced.

Lasers described as Q-switched have an internal shutter in the optical cavity which controls the release of the radiation. The energy is stored and then released as a high energy, short duration pulse. The population inversion then collapses briefly (i.e. stimulated emmission ceases) before recovering as the shutter closes. This burst of energy causes non-thermal tissue damage by electromechanical effects. These lasers are widely used in ophthalmology. UV lasers (Excimer) work in a similar way, by a photoablative action in which tissue can be removed in a controlled way with minimal thermal damage.

Frequency (wavelength)
The penetration of light energy into the body depends on its wavelength. At both far infrared and ultraviolet wavelengths light does not penetrate easily because of absorption by water. Absorption is rapid and surface effects dominate. In the visible part of the spectrum the two components mainly responsible for absorption are haemoglobin and melanin. Greater penetration therefore occurs before full absorption takes place. The deepest penetration into tissue takes place towards the red end of the spectrum and into the near infrared. The laser wavelength therefore controls the depth of effect and the type of tissue affected.

A carbon dioxide laser, emitting in the far infrared, is absorbed by water in 1 mm or less and is, therefore, a cutting and vaporising tool. A Nd:YAG laser is absorbed by haemoglobin and melanin about equally with water. It cuts and coagulates to a depth of about 3–5 mm and has the deepest penetration. An argon laser does not penetrate as far but coagulates to a depth of about 2 mm with maximum effect on haemoglobin.

Safety

Lasers are used in many specialties but the most important from an anaesthetic point of view is ENT. The only reported deaths from laser therapies have been associated with ENT and resulted from ignition of tracheal tubes. It is important to be aware of safety considerations with lasers as with all clinical treatments. However, their use is strictly controlled.

All installations using lasers, both public and private, have to have local rules drawn up to define:

- the hazards of the particular laser
- the control of those hazards
- where it can be used
- who can use it
- how it should be used.

The reader is referred to the MDA Guidance Notes for full information on laser use (see Further Reading). It is also important to ascertain the identity of the Laser Protection Adviser. This person has to be appointed by employers wherever a laser that poses a risk to personnel is in use. Their job is to assess the installation for risk, advise on safety measures, oversee the writing of the local rules and investigate all accidents and incidents. In addition, a Laser Protection Supervisor should be appointed in each area, who is responsible for the day-to-day activities of laser use.

Not all lasers are as potentially dangerous as others. There is a complex relationship between frequency, power and time of exposure. Lasers are classified into four main classes (these are further subdivided) from Class 1 (inherently safe) to Class 4 (hazardous). Most medical lasers are Class 4 and thus present the highest level of risk.

The other major risk is to the eyes of all present (including the patient). Stray beams can impinge on the eye and cause permanent damage. Skin exposure can also occur but is not usually so damaging. The Laser Protection Adviser will have specified the type of safety goggles to be worn and the local rules will say that they must be worn. Absorption by goggles is wavelength dependent. Goggles are specific to a laser and should not be moved from one laser to another.

Lasers should be operated by trained personnel only. The training should include safety and clinical training. Everyone present should have had basic safety training. This particularly applies to anaesthetists because they are often 'at the wrong end' of the laser, which means that the beam could easily point in their direction thereby exposing them to a high risk.

The room in which a laser is to be used is designated a 'laser controlled area' and is clearly delineated. Only authorized people should be in the room and other activities minimized. Windows and doors are often blacked out to avoid inadvertent exposure to passers-by. Although the likelihood of this happening is low the potential damage to the eye could be high.

All Class 4 lasers have the potential to ignite suitable materials. Paper drapes and spirit solutions should not be used near lasers but there is an even greater danger in ENT laser surgery. The combination of a tracheal tube, oxygen and the ignition potential of the laser has been responsible for lethal fires in the trachea. Strategies to overcome this have evolved (e.g. Venturi anaesthesia) but strict adherence to the rules is necessary to avoid such problems. ◆

Common Errors in Clinical Measurement

Sarah Ford

Sarah Ford is Consultant Anaesthetist at Derriford Hospital, Plymouth, Devon, UK. She qualified from Otago University, New Zealand, and trained in anaesthesia in south west London. Her current interests are anaesthesia for major spinal surgery and general surgery.

Increasingly sophisticated instruments are being used for monitoring and guiding patient care but the onus is on the observer to be aware of the limitations of measurements and the causes of error.

Confounding errors in clinical measurements are readings that are not true reflections of the underlying signal. They may be caused by instrumental, sampling and patient factors.

The measuring system must be accurate and precise to produce reliable clinical measurements. Accuracy is the difference between the measurement and a 'gold standard' measurement of the underlying signal. Precision is the reproducibility of repeated measurements of the same biological signal. A repeated consistent measurement may be precise but inaccurate, for example an erroneous arterial pressure in an un-zeroed system. A continuous measuring system needs:

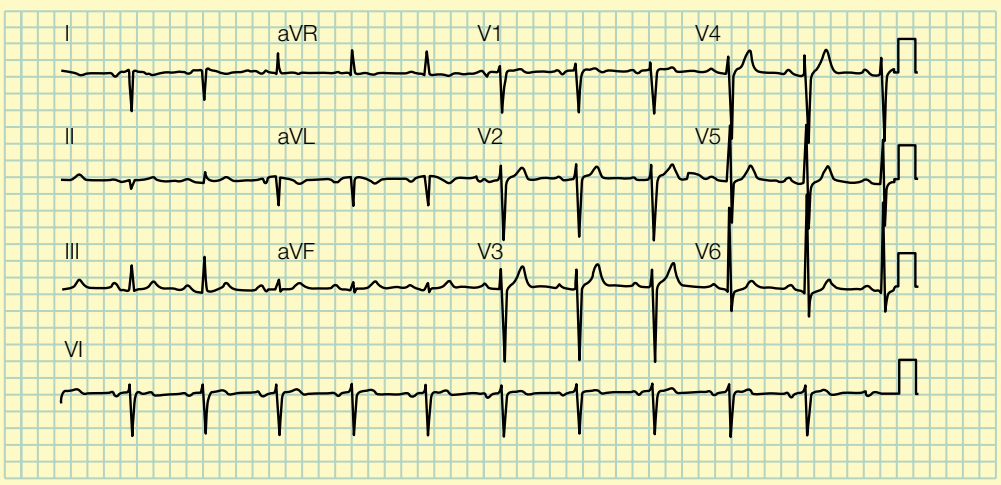
- high signal-to-noise ratio
- good zero stability and constant gain to prevent slow drift
- linearity of amplification over a range of signal
- no amplitude or phase distortion of fundamental frequencies up to the 10th harmonic
- correct calibration by the user.

ECG

The ECG measures potentials of 0.5–2 mV at the skin surface. Noise and interference that obscure these tiny signals are the main cause of a poor ECG trace. The most obvious error is incorrect electrode placement relative to the heart because QRS complexes vary with position of the electrodes (Figure 1). The ECG signal must be isolated from noise and interference before amplification and display (Figure 2).

Incorrect attachment of the arm leads

Incorrect attachment of the arm leads is recognized because of reversal of the axis with Q waves in I and positive QRS in aVR



Speed: 25 mm/s
Limb: 10 mm/mV
Chest: 10 mm/mV
Electrode Off
0.05–150 Hz

1

Interference to ECG signals

Type of interference	Sources	Means of reducing ECG distortion
Electromagnetic induction	Any power leads or lights	Long ECG leads twisted together therefore induced signal rejected as common mode Selective filters in amplifiers
Electrostatic induction and capacitative coupling	Stray capacitances between table, lights, monitors, patients and power leads	Copper screens round ECG leads
Radio interference (> 100 Hz)	Diathermy enters system by: • entering mains supply • direct application by probe • radio transmission via probe and wire	High-frequency filters clean up signal before entering input Filtering power supply of amplifiers Double screen electronic components of amplifiers and earth outer screen Newer machines operate at higher frequencies

2

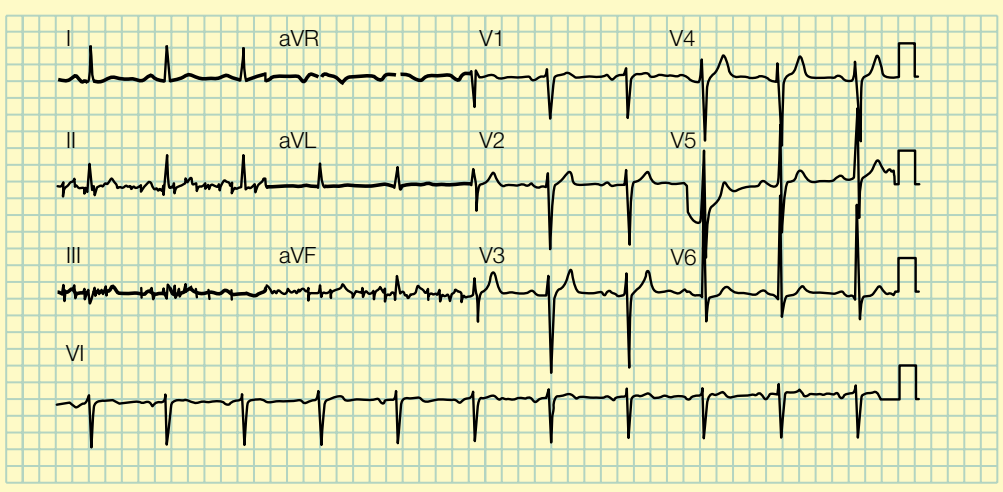
Noise originating from the patient – high frequency electromagnetic activity caused by shivering or movement is filtered by low-pass filters.

Noise originating from the patient–electrode interface – high skin impedance is the most common reason for a poor ECG signal and can be reduced by de-greasing the skin with alcohol. Modern disposable electrodes are made of silver coated with silver chloride with stable impedances reducing slow drift. Gel-impregnated foam pads decrease movement artefact and lower skin impedance.

Noise originating from the environment – the operating theatre is cluttered with sources of AC current that may distort ECG recordings (Figure 3).

Mains frequency interference

Characteristic mains frequency 50 Hz electrical interference visible in all leads



Speed: 25 mm/s
Limb: 10 mm/mV
Chest: 10 mm/mV
Electrode Off
0.05–150 Hz

3

The very small currents caused by capacitative and inductive coupling are exaggerated if electrode impedance is high, causing severe 50 Hz interference. Radiofrequency signals may saturate the input stages of the amplifier and block any output. Newer diathermy machines with higher frequency output may produce less interference.

Modern ECG monitors often allow selection of a diagnostic filtering band up to 100 Hz while the monitoring mode is a narrower band up to 50 Hz, which reduces motion artefact and mains interference. These high pass filters attenuate slow drift and maintain a stable baseline, but low-frequency elements of the ECG, such as the T wave, may appear biphasic or distorted.

Invasive blood pressure measurement

Intra-arterial cannulation with electromechanical transduction provides continuous monitoring of arterial blood pressure with greater accuracy in patients with unstable blood pressures or hypotension. The arterial pressure wave narrows and increases in amplitude in peripheral vessels, so the systolic pressure is higher in the dorsalis pedis than in the radial artery. Improper damping and calibration account for a large percentage of the errors in direct arterial pressure monitoring.

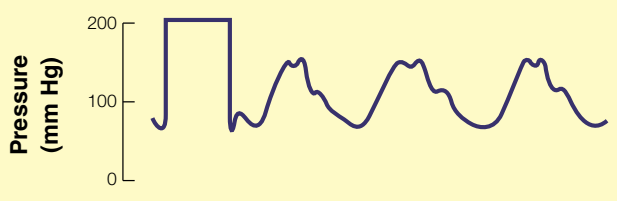
The fluid and diaphragm of the pressure transducer constitute a mechanical system that oscillates at the natural resonant frequency (F_n). This determines the frequency response of the measuring system. Factors that decrease F_n to within the range of frequencies of the arterial waveform result in sine wave oscillations being superimposed on the blood pressure trace. Depending on the shape of the arterial pressure wave, this distortion can introduce a 20–40% overshoot error in systolic blood pressure readings; it is worse with tachycardia. The most common reason for an under-damped spiked arterial trace is soft tubing inserted to extend the arterial line.

Damping results from friction of the fluid moving within the tubing which tends to extinguish any oscillations and decrease the frequency response of the transducer system. Excessive damping causes loss of detail in the waveform and under-estimation of pressures. Air bubbles in the system, clotting or kinking in the cannula and arterial spasm increase damping. The use of relatively wide-bore cannulae and minimizing stopcocks improves the frequency response of the system.

The amount of distortion in a system is assessed by snapping the flush valve and observing the response (Figure 4). Commercial damping devices (Accudynamic) are available to avoid the risks of air embolism. It is essential to calibrate and zero the transducer system correctly to the right atrium. Baseline drift of the transducer's electrical circuits may occur requiring periodic checks and re-zeroing.

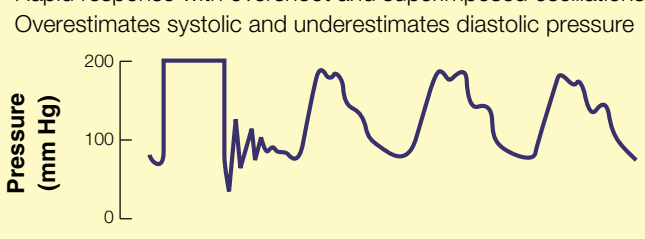
An optimally damped arterial trace

Small overshoot of 7% of the step change with no oscillations then follows arterial trace



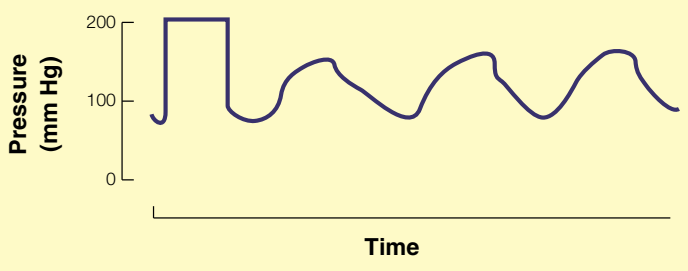
An under-damped arterial trace

Rapid response with overshoot and superimposed oscillations
Overestimates systolic and underestimates diastolic pressure



An over-damped arterial trace

Slow response with no overshoot
Phase shift as response gets slower



4

Non-invasive blood pressure measurement

Indirect methods of blood pressure measurement provide intermittent readings that tend to overestimate at low pressures and underestimate at high pressures. Readings vary according to the site of measurement owing to hydrostatic effects and increased arterial pulse wave velocities in the peripheries.

Manual methods – errors in the auscultatory method occur because of deficiencies in the transmission of sound energy owing to overlong or loose stethoscope tubing. Korotkoff sounds may be difficult to hear in hypotension and arteriosclerosis, resulting in underestimation of blood pressure. Readings in shivering patients require an excessively high occluding pressure and produce pseudohypertension. Further measurement errors may occur due to the auscultatory gap and confusion over whether phase IV or V is to be taken as the diastolic point. Phase V is closer to directly measured diastolic pressure with better inter-observer agreement, but may be absent in high output conditions (e.g. aortic regurgitation, pregnancy or after exercise).

Common sources of error are wrong cuff size, zero and calibration errors in aneroid manometers, and leaks from the pneumatic system that prevent a slow and controlled deflation of the cuff. The width of the cuff should be 20–30% of the circumference of the limb, of which the pneumatic bladder should span at least half and should be centred over the artery. Narrow cuffs yield erroneously high readings while wide cuffs underestimate the pressure.

Automatic methods based on the oscillometric principle rely on a regular cardiac cycle, and inconsistent readings may occur in patients with atrial fibrillation. Over-frequent readings may cause impeded blood flow and can produce inaccurate results. The appropriate cuff size must be used. The apparatus fails to record at pressures below 50 mm Hg.

Systolic pressure correlates well with a bias towards overestimation at low pressures and underestimation at high pressures. Mean arterial pressure shows a less satisfactory correlation with a similar systemic bias as does diastolic pressure. Newer devices deflate the cuff continuously rather than in steps, thus achieving a shorter measurement cycle.

Cardiac output measurement
Thermal indicator dilution with saline at room temperature is used to measure cardiac output. Sources of error relate to incorrect pulmonary artery catheter placement and incomplete mixing of the bolus with venous blood. The thermistor probe must be matched to the cardiac output processor and errors related to data input are reduced due to automated computer control that rejects any artefacts or non-exponential curves. Errors may arise when there is tricuspid incompetence or cardiac arrhythmias, and measurements should be averaged over several beats. Injections during the inspiratory or expiratory phases of mechanical ventilation may vary by up to 50% in calculated cardiac output. To minimize this error, injections are made at end-expiration.

Central venous pressure (CVP)
Low-pressure CVP measurements require that the saline manometer or tip of the stopcock in a transducer system are accurately referenced to the right atrium. If the manubriosternal junction is used the measured pressure is 0.5–1.0 kPa (5–10 cm H_2O) lower. Errors are also caused by the catheter being inserted too far or being blocked.

Pulse oximetry
Oximeters determine the oxygen saturation of haemoglobin by measuring the absorbance of light by arterial blood. The pulse oximeter is accurate to within ± 2% but is less accurate below saturations of 85% (Figure 5). Algorithms in commercial devices are based on studies in volunteers breathing low concentrations of oxygen, and calibration points are in the range 80–100%. Values below 70% are extrapolated from higher readings and may be grossly inaccurate. The absolute measurement of oxygen saturation in arterial blood (SaO_2) may vary between probes due to variability in the centre wavelength of light-emitting diodes (LEDs). This produces probe-to-probe variability in the absolute measurement of SaO_2 but trends are accurate. Sophisticated devices have a mechanism for identifying the sensor LED wavelengths allowing internal correction for different wavelengths.

Erroneous readings during pulse oximetry

Source of error	SpO_2 reading	Note
HbCO	Increase	50% HbCO content SpO_2 reads 95%
MetHb	Approaches 85%	Independent of arterial saturation
Fetal Hb	No effect	Identical to HbA
Sickle Hb	No effect	Right shift of HbO_2 so for given PaO_2, SpO_2 lower than expected
Anaemia	Decrease	Ht < 10% SpO_2 under-reads by 5%
Polycythaemia	No effect	
Methylene blue	Decrease	
Iodocyanate green	Lesser decrease	
Fluorescein	No effect	
Nail polish	Decrease	Especially blue colours

Hb, haemoglobin; HbA, haemoglobin A; HbCO, carboxyhaemoglobin; HbO_2, oxyhaemoglobin; Ht, haematocrit; MetHb, methaemoglobin; PaO_2, partial pressure of oxygen in arterial blood; SpO_2, oxygen saturation

The most common causes of errors are signal artefacts, which produce a poor signal-to-noise ratio. Artefacts have three major sources: ambient light, low perfusion and especially movement. The light detectors cannot differentiate the red light LED wavelength from other sources of light such as infrared heaters and room lights. Manufacturers have incorporated minimum values for signal-to-noise ratios below which the device displays no value for oxygen saturation (SpO_2) and modern oximeters display a low signal strength error message. Patient motion may be the most difficult artefact to eliminate. The device can average its measurements over a longer period to reduce the effect of an intermittent artefact but this slows the response time to an acute change in SaO_2. Increasingly sophisticated algorithms are being incorporated to identify and reject spurious signals.

Pulse oximetry is a global measure of functional oxygen saturation; it reveals nothing about adequacy of ventilation (e.g. patients with supplementary oxygen with a rising $PaCO_2$), or oxygen content (e.g. a grossly anaemic patient with severely deficient oxygen content and delivery to the tissues with normal saturations). Another source of error is a delay in response caused by instrumental and circulatory delay. The delay in response to step reduction in alveolar gas concentration is longer with a finger probe than with a ear probe. Cold-induced vasoconstriction, hypovolaemia and venous engorgement increase the response time. Atrial fibrillation may also cause measurement errors. Signals may be inadequate in the elderly with arterial disease.

Capnography
Modern CO_2 analysers are based on the absorption of infrared light by CO_2 in a gas sample based on the Beer–Lambert law. There are many sources of error. There must be no leaks in the breathing system, the non-rebreathing valve should be functioning perfectly and the inspired gas well mixed and of constant composition.

Errors related to the machine include the overlap of absorption wavebands of different gases so that the nitrous oxide (N_2O) absorbs some of the infrared energy within the CO_2 bandwidth and the CO_2 measurement is falsely high. A second error arises from 'collision broadening' in which the absorption spectrum for CO_2 is widened by the presence of other gases such as N_2O and N_2. The simplest method of eliminating these errors is to calibrate the instrument with gas mixtures containing the same background gas concentration as that to be analysed. Modern infrared analysers provide a simultaneous breath-by-breath analysis of CO_2, O_2, N_2O and the volatile agents. Microprocessor technology can automatically identify and correct for the presence of other gases. Exhaled alcohol can confound vapour concentration in these machines.

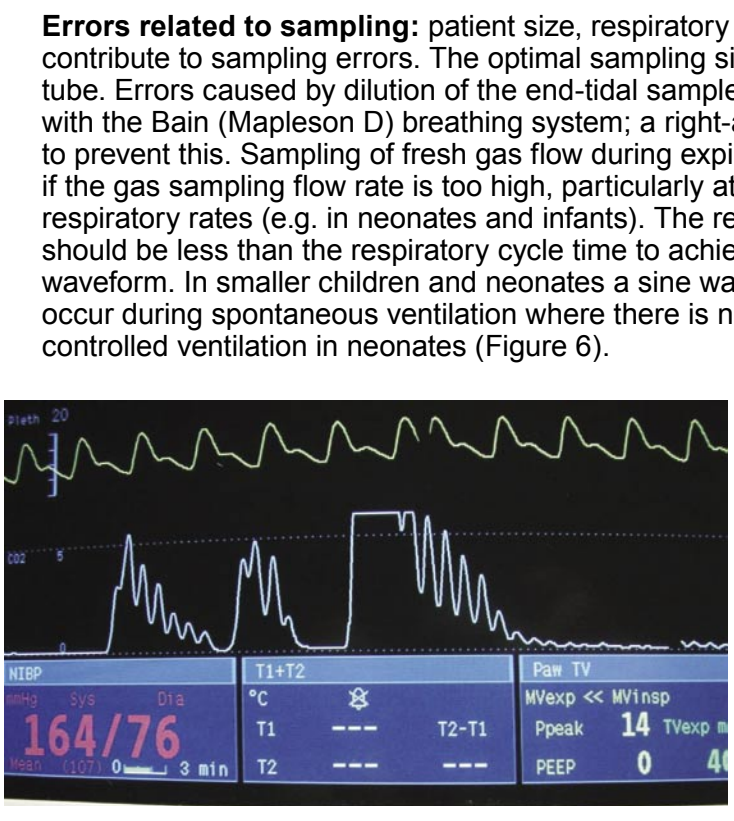
Response time – a capnograph needs a rapid response time because a slow response may result in failure to reach the true maximum values at normal breathing frequencies. This alters the capnogram profile with prolongation of phase II with a steeper phase III (similar to asthma), decreases in peak end-tidal CO_2 measurements and elevation of the baseline during rebreathing.

Water vapour – a slow response time is caused by long tubing and blockage in the sampling line by secretions or condensation of water vapour, hence the water trap. Liquids and particulate matter entering the measuring chamber cause erroneous readings of CO_2 owing to their high infrared absorbance.

Calibration – it is essential to calibrate the machine with the background gas and intended sampling system in place. Modern CO_2 analysers should have a three-point calibration with known concentrations of CO_2 at regular intervals. Frequent calibration checks are necessary to minimize errors from changes in atmospheric pressure.

Ram-gas effect – because infrared analysers act as partial pressure detectors of the number of molecules of absorbent gas in the sample chamber, changes in atmospheric pressure affect output. A pressure drop across the sampling line (e.g. inadequate suction along an extended sampling tube) causes under-estimation of end-tidal CO_2.

Errors related to sampling: patient size, respiratory rate and site of sampling may contribute to sampling errors. The optimal sampling site is at the top of the tracheal tube. Errors caused by dilution of the end-tidal sample by fresh gas flow can occur with the Bain (Mapleson D) breathing system; a right-angled connector should be used to prevent this. Sampling of fresh gas flow during expiration may occur inadvertently if the gas sampling flow rate is too high, particularly at lower tidal volumes and faster respiratory rates (e.g. in neonates and infants). The response time of the analyser should be less than the respiratory cycle time to achieve predictable CO_2 values and waveform. In smaller children and neonates a sine wave type of capnogram can occur during spontaneous ventilation where there is no clear alveolar plateau or with controlled ventilation in neonates (Figure 6).



6 Cardiogenic oscillations in a patient requiring assisted ventilation after opioid administration.

Errors related to the patient: during a prolonged expiration or end-expiratory pause, when the gas flow exiting the trachea approaches zero, the sampling of the monitor may aspirate gas alternately from the trachea and the inspiratory limb causing ripples on the expired CO_2 trace. These are called cardiogenic oscillations and appear during the alveolar plateau in synchrony with the heartbeat and are thought to be due to mechanical agitation of deep lung regions that expel CO_2-rich gas. Such fluctuations are smoothed over when the lung volume is increased by application of positive end-expiratory pressure. In patients with asthma or chronic obstructive airway disease, the end-tidal CO_2 may under-read, especially if the response time is slow.

Gas volumes
Dry spirometers require patient cooperation and depend on voluntary effort. Gas meters such as the Wright respirometer over-read at high tidal volumes and under-read at low tidal volumes because of inertia of the moving parts. ◆

Electricity and Magnetism

Adrian K Dashfield

Adrian K Dashfield is Consultant Anaesthetist at Derriford Hospital, Plymouth, UK. He qualified from Birmingham University Medical School and trained in anaesthesia and pain management in Plymouth, Sheffield and London. His research interests include psychomotor function and anaesthesia and the treatment of neuropathic pain.

Most clinical measuring devices and anaesthetic equipment can be used with no knowledge of electronics. However, an understanding of this subject is necessary to use equipment to its full potential.

Electric charge
Early observations on the effect of electricity involved the production of 'static electricity' by friction when two materials such as glass and silk were rubbed together. These two materials become oppositely charged, the two forms of charge being positive and negative. It was subsequently discovered that the electron was responsible for the negative charge, while the atomic nuclei were found to be positive. The quantity of electricity associated with a body is measured in coulombs (C). 1 C is the charge associated with the electrolytic deposition of 0.001118 g of silver from silver nitrate solution.

Electric current
Electric current is the rate of passage of electric charge. Current is measured in C/s and this unit is called the ampere (1 A = 1 C/s). The ampere is the SI unit, thus 1 C is the charge deposited when 1 ampere flows for 1 second.

Resistance to flow of electricity
When a potential difference between two points on a conductor exists, current flows. The relationship between the current and the potential difference is expressed as Ohm's law. This quantifies the concept of resistance when electrons or ions move through a material under the action of an electric potential difference. This resistance is due to collisions of electrons resulting in heat as energy being imparted to surrounding molecules. Thus, a resistance of R units restricts the current from a source of E volts to I amperes, where:

$$I = E/R$$

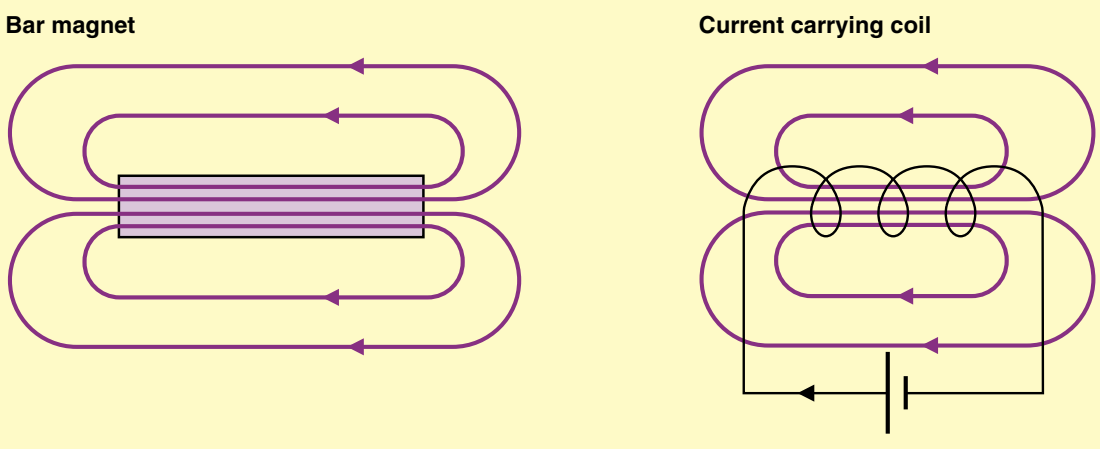
The unit of R is the V/A, which is abbreviated to the ohm (Ω), (1 Ω = 1 V/A).

If two resistors are connected in series the total resistance is the sum of the two. If the resistors are connected in parallel, the combined resistance is:

$$1/R = 1/R^1 + 1/R^2$$

Magnetism
Magnetic fields are regions in which there is attraction and repulsion of magnets and magnetizable pieces of metal. There is interaction with current-carrying conductors in electrical generators and transformers. There is a magnetic field within and around a permanent magnet and a conductor (in the form of turns of wire) carrying current. Imaginary lines indicating the presence of these phenomena, known as magnetic 'flux' (Figure 1) often represent the magnetic field.

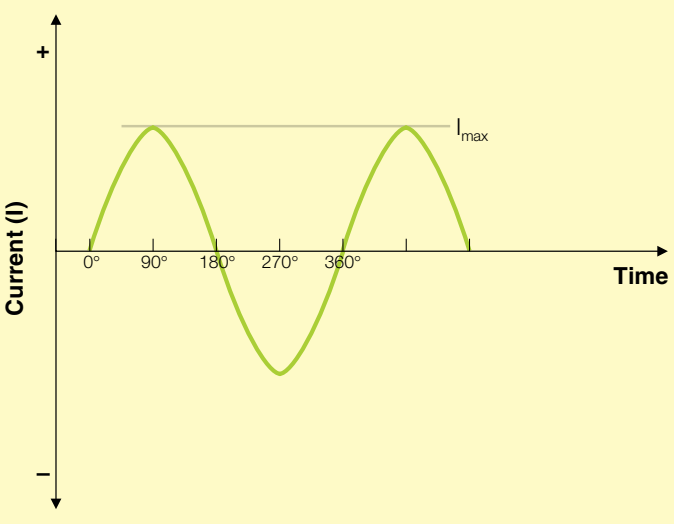
Magnetic flux



1

Electromagnetic induction and generation of electricity
Faraday's law of electromagnetic induction states that when flux linkage between a coil and a magnetic field is varying, an electromotive force (emf) proportional to the rate of change of flux linkage is induced in the coil. When a loop of wire is rotated between the poles of a permanent magnet the flux linkages change continuously. This induces an emf that reverses polarity every 180° of rotation. The flux linkage alternates from maximum when the plane of the coil is at right angles to the flux, through zero when they are coplanar, to a maximum in the reverse direction after 180° of rotation. The easiest way of doing this is to produce the flux by passing current through some other conductor and varying this magnetizing current. The more rapid the change using either method of induction, the larger the emf. This gives rise to a sinusoidally varying emf such as is encountered with alternating current (AC) mains electricity supply (Figure 2). The frequency of the AC is the number of complete cycles per second, expressed in hertz (Hz). Mains electricity is supplied at 50 Hz in the UK and at 60 Hz in the USA. The number of cycles per second is known as the frequency (f). The time T for a complete cycle of alteration is the period or periodic time. Thus f = 1–T. The unit of magnetic flux is the weber (Wb) and is defined so that flux linkage changing at the rate of 1 weber per second (in one turn) causes an emf of 1 volt to appear. Transformers can increase or decrease the size of an alternating emf as required. For transmission of power it is easier to work at high voltages with low currents in the cables. The voltages are brought down to safer values before reaching the consumer.

Alternating current produced by the rotation of a coil in a magnetic field



2

Power
Sources of electrical current such as generators or electric cells are capable of creating excess positive or negative charge at their terminals. They cause separation of charges in otherwise neutral material. The attraction between opposite charges causes the flow of current. The work done by an electrical generator when it drives unit quantity of electric charge around a circuit is known as the emf force. 1 J of work done in driving 1 C of electricity is known as 1 V (1 V = 1 JC).

Power calculations are applied to even the simplest circuit design. Thus, if a 10 Ω resistor rated at 0.5 W passes 1 A through it:

$$W = EI$$

where: W = work in joules; E = potential difference in volts.

From Ohm's law:

$$E = IR$$

where: I = current in coulombs, R = resistance in ohms.

Substituting:

$$W = I^2R = 0.5^2 \times 10 = 2.5 \text{ W}$$

Capacitance
If two conductors of electricity are separated by an insulator, a capacitor is formed. The insulator is known as the dielectric. This simplest form of capacitor consists of two metal plates separated by a thin layer of air. If an emf is applied across the two conductors, the two plates are left in a 'charged' state.

A potential difference is associated with the separated charges that rise to be equal to the emf, at which point the process stops. An 'electric field' is set up in the dielectric in which attraction in a specific direction is experienced by any charged body. Capacitance is the charge stored (in coulombs) per volt of potential difference and is abbreviated to the farad (1 F = 1 C/V).

Three factors determine the capacitance between two bodies. Capacitance increases if the area of the bodies is increased. Decreasing the distance between the bodies intensifies the field and permits more electrons to arrive at one plate and repel from the other. Finally the introduction of an insulating material in place of a vacuum or air can increase capacitance depending on the material used. Capacitance in an electrical circuit is defined as volume taken up per unit change of pressure difference set up.

Impedance
The two electrical energy-storing devices (inductors and capacitors) behave differently from one another as frequency is changed. Electrical circuits may have mixtures of components, resistive and reactive, which are not simply proportional to the current. For mixed circuits the term impedance is used to suggest opposition. ◆

$$\text{Impedance (Z)} = \frac{\text{Size of potential difference across circuit}}{\text{Size of current through it}}$$

Force, Mass and Acceleration

Jeremy A Langton
Richard Struthers

Jeremy A Langton is Consultant Anaesthetist at Derriford Hospital, Plymouth, Devon, UK. He qualified from Guy's Hospital, London, and trained in anaesthesia in London and Leicester. His research interests include airway reflexes and anaesthesia.

Richard Struthers is Specialist Registrar in Anaesthesia in the South West School of Anaesthesia, Plymouth, Devon, UK.

In 1665, Isaac Newton developed the laws of motion that link the movement of a body with the force applied to it – allegedly after noting an apple falling from a tree. These built on the work of Galileo a century earlier and the advances in mathematics at that time. In 1687, in his book *Philosophiae Naturalis Principa Mathematica* Newton published three laws of motion along with laws of fluid dynamics, calculus, gravity and planetary motion. Newton's laws still hold true – and were used to place man on the moon – but Einstein's theories have surpassed them when dealing with forces in astronomy. Advances in quantum physics may provide a theory to link Newtonian physics with theories in particle physics and astronomy.

Newton's first law

An object will continue moving with a constant velocity, or remain at rest, unless acted upon by a resultant force.

This law deals with inertia. A resultant force is the sum of all forces acting on an object. If the forces are balanced there will be no resultant force and no change in velocity. Therefore a change in the velocity of an object needs an unbalanced force.

Newton's second law

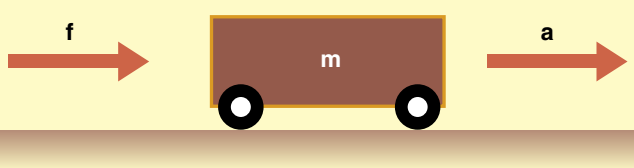
The resultant force acting on a body is proportional to its rate of change of momentum.

This quantifies the change in velocity by looking at changes in momentum. The momentum of an object depends on both its mass and velocity. If the mass is constant then the rate of change in velocity (or acceleration) is proportional to the resultant force (Figure 1). The second law can therefore be reworded as 'An unbalanced force acting on an object causes it to accelerate in the direction of the force at a rate proportional to the force applied and inversely proportional to the mass of the object.' This gives the equation:

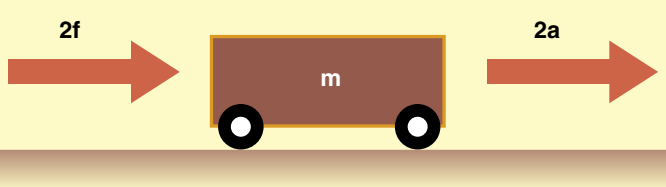
Force = Mass x Acceleration

The SI unit of force, the Newton, is defined as the force needed to accelerate a mass of 1 kilogram by 1 metre per second per second.

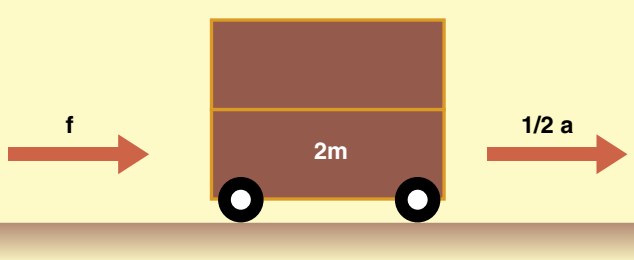
Force = mass x acceleration



a If an unbalanced force f is applied to an object with mass m then it will accelerate in the direction of the force at a rate a



b If twice the force (2f) is applied to the object then it will accerelate at twice the rate (2a)



c If the force f is applied to an object of twice the mass (2m) then it will accelerate at half the rate

Newton's third law

To each action there is an equal and opposite reaction.

This relates to the nature of forces. An action is taken to be a force or a change in momentum. Hence the apple falling from the tree towards the earth exerts an equal force pulling the earth towards it. However, because the mass of the apple is insignificant relative to the mass of the earth we do not see the resultant acceleration of the earth.

The third law also leads to the idea of the conservation of momentum – that after a collision between two bodies the sum of their momentums will be the same as before the collision. ◆

Heat and Thermodynamics

David Birt

David Birt is Consultant Anaesthetist at Derriford Hospital, Plymouth, Devon, UK, and a Surgeon Commander in the Royal Navy. He qualified from St Mary's Hospital, London, and trained in anaesthesia in the South West of England and Glasgow. His special interests include paediatric anaesthesia and regional blockade.

The concepts of heat energy and temperature are easy to confuse. Heat is a measure of the vibrational movement of molecular or atomic particles; it is determined by the kinetic energy in each particle and the number of particles involved. Temperature is a measure of the ability of one object or area to transfer heat to another and is independent of the quantity of matter. Consequently, a small object may be at a higher temperature than a large one, but it does not necessarily possess more heat energy. Like all energy, the derived SI unit for quantifying heat is the joule (J). Temperature is measured by various linear scales but the SI unit is the degree kelvin (K), named after Lord Kelvin, one of James Joule's close associates.

Calorimetry and the laws of thermodynamics

Organic compounds contain chemical potential energy derived originally from photosynthesis. The amount of stored energy can be determined by calorimetry. This process involves the combustion of the compound to carbon dioxide and water in an oxygen-containing chamber surrounded by a known quantity of water or ice. By measuring the rise in the temperature of the water or the quantity of ice that melts, the amount of energy released may be calculated.

In biological systems, the chemical potential energy in certain organic compounds is converted from one form to another. This process is governed by the laws of thermodynamics. There are four laws, including the improbably named zeroth law, but two of them are important in biological systems.

The first law of thermodynamics states that, in a closed system, the total quantity of energy in that system must remain constant. If glucose undergoes combustion to carbon dioxide and water, it produces the same amount of energy whether that occurs with oxygen in a calorimeter or by complex metabolic pathways such as glycolysis and oxidation. Alternatively, if amino acids are metabolized by human metabolic pathways, the end product, urea, possesses chemical potential energy and the amount of energy produced is less than that from complete combustion in a calorimeter. The energy deficit is stored in the urea, however, and the total amount of energy in the system remains constant.

The second law of thermodynamics relates to the entropy, or disorder, of a system. It states that a system's entropy increases if energy is exchanged. Therefore, when two objects exchange heat, the heat flows from the object with the higher temperature to that with the lower, until equilibrium is reached at the highest level of entropy. The transfer of this heat is achieved by the mechanisms described in Figure 1. In anaesthetic practice, heat loss occurs through a combination of these mechanisms. Conduction occurs between a patient and his surroundings, convection then assists heat transfer to the wider environment, while radiation heat loss occurs from skin and visceral surfaces.

Some physical mechanisms of heat transfer

Mechanism	Description	Comments
Conduction	The flow of heat energy through solid matter from places of high temperature to those of lower temperature without movement of the matter itself	• The rate and magnitude of conductive heat transfer across an object is determined by its shape, the temperature gradient across it and the thermal conductance of the substance from which it is made
Convection	The flow of heat energy through a liquid or gaseous fluid from places of higher temperature to places of lower temperature by movement of the fluid itself	• In contrast to conductive heat transfer, convection involves the higher energy molecules retaining their heat energy, moving within the medium, and carrying heat energy with them • The two basic forms are natural convection, when the fluid movement is maintained by its tendency to move as it warms, and forced convection, when the fluid movement is assisted
Radiation	The flow of heat from places of higher temperature to places of lower temperature by means of electromagnetic waves	• Radiation is independent of fluid movement and is the only means of transferring heat across a vacuum • All visible objects emit radiation in the form of light waves but as temperature increases, both the range of frequencies and the quantity of emitted radiation increase

Deriving mechanical work from heat

Mechanical work can be derived from heat energy. As heat energy is applied, individual particles of matter vibrate with greater amplitude and the distance between them increases. This results in expansion. Inevitably, heat is lost from such a system but, in obedience to the first law of thermodynamics, the total energy in the system remains constant. Therefore, the heat input equals the heat output plus the amount of work done. Complete conversion of heat to mechanical work without the loss of some energy to the surroundings is impossible. This principle is applied to thermostats and vaporizers that use bimetallic strips or in heat engines, the most familiar of which is the internal combustion engine. ◆

Mathematical Concepts

John Curnow

John Curnow is Biomedical Engineer at Derriford Hospital, Plymouth, UK. His specialist interest is in patient monitoring and the application of computing techniques in medicine.

Science uses mathematics to model theories and to provide methods that allow theories to be applied to solve practical problems. Anaesthetists as members of a science-based profession can gain insight into their subject and produce better forecasts of the probable outcomes using mathematics and mathematical modelling.

Mathematics describes processes using algebraic equations and solves the problems using numeric methods. The general form of a mathematical algebraic equation is written as y = fn(x) where fn(x) is called the function of x. A function is a basic mathematical method used to describe how the value of a variable y is controlled by the value of another variable x. In general, the variable x is the variable the researcher has control over, and it can be given values that can be used to calculate the value of y. If a graphical representation of the function is being drawn it is usual practice for the controlled variable x to be represented by the horizontal axis and the variable y by the vertical axis.

Indices

The use of indices is one of the shorthand methods used in mathematics. If a mathematical equation requires a number of multiplications of the same variable (i.e. n.n.n) this is written as n^3 where the 3 is called the index of n. The general form is written n^x. If the value of x is less than 1 it represents a root of the number n, which is the basic number that if multiplied by itself 1/x times, gives n as the answer. Thus $n^{1/2}$ indicates the square root of n and $n^{1/3}$ the cube root of n. If the index is negative it implies it is the reciprocal of the result that is needed (i.e. $x^{-n} = 1/x^n$).

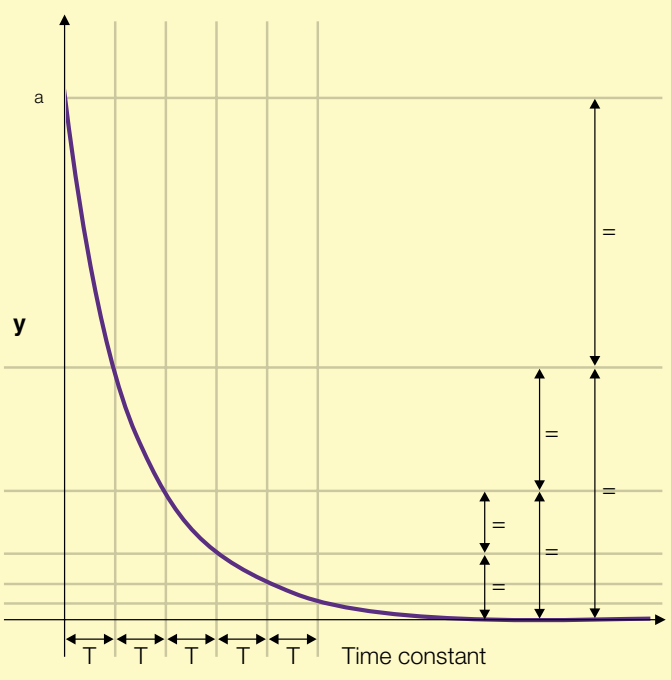
Any value of x can be used and the value of the function for simple values of x such as 2 or 3 can be found in tables. Computers and calculators have inbuilt methods for calculating n^x for any real value of n and x.

Exponential

Exponential functions are common in medicine and anaesthesia; examples include the growth of a bacterial colony and the charging and discharging of a capacitor in a defibrillator. A specific form of the index method, briefly described above, is the exponential where n is replaced by e (Euler's number) more commonly called the natural number which has a value of 2.718. The general, mathematical equation for an exponential is $y = a.e^x$. The main properties of the function are a which represents the initial value of y, and x which is the power or index. Values for the function e^x can be found in mathematical tables and are available on calculators and computers.

The index of e, in many applications of this equation will be a time period and the equation can then be written as $y = a.e^{\lambda.t}$. Where a is the initial value of y and λ is a constant for the particular exponential function which is called the time constant. The time constant is related to an important value of an exponential curve, the half-life T by the equation $T = 0.693/\lambda$ making the above equation $y = a.e^{t/T}$. At any point on an exponential curve, a point T seconds later will have a y value half of that at the initial point as shown in Figure 1. In general the value of y halves every T seconds along the curve and thus is a useful way to plot an exponential curve (Figure 1). One application of the exponential function in medicine is in modelling radioactive decay of radioisotopes. In this case the time constant is called the half-life of the isotope and it represents the time taken for the isotope activity to reach half its value.

Exponential curve $y = a.e^{-t/T}$



See text for explanation

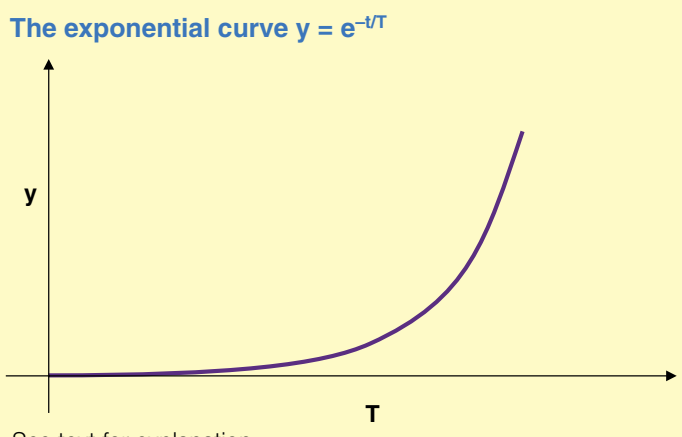
1

As an application of the exponential function consider the discharge of a capacitor through a resistor. This follows an exponential function where the initial amplitude of the potential across the capacitor is V volts and it follows an exponential curve towards zero. The time constant of this circuit is C.R seconds, where C is the capacitance of the capacitor in farads and R is the resistance of the resistor in ohms. An application of this in equipment used by anaesthetists is the simple capacitor discharge defibrillator. In this case, the discharge resistor is usually considered to be the patient circuit resistance consisting of electrode and patient resistance between the two paddles and the charge time is set by an internal resistor.

Logarithms

The logarithm is a mathematical method used to make calculations of index representations easier. If $y = a^x$ then the logarithm is defined such that $x = \mathrm{Log}_a(y)$ where a is called the base of the logarithm. The most common base used for logarithms is 10. Logarithms are used extensively in the modelling of data and to transform data when producing graphs. A graph of a function that follows an exponential function for instance can be plotted as a straight line if the natural logarithm of the function is drawn. This is easier to use and allows certain features such as the time constant to be identified simply. Figure 2 displays the graph of $e^{t/T}$, it would be difficult to identify the time constant of the process from this. Figure 3 displays the graph of $\mathrm{Ln}\ (e^{t/T})$, which is a straight line. The time constant is the slope of this line and is easy to measure.

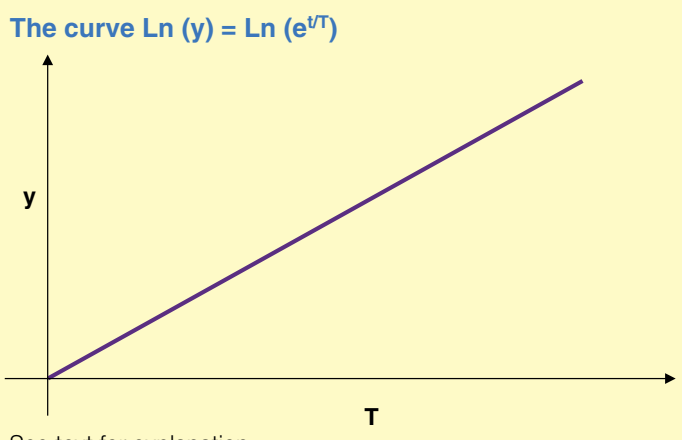
The exponential curve $y = e^{-t/T}$



See text for explanation

2

The curve $\mathrm{Ln}\ (y) = \mathrm{Ln}\ (e^{t/T})$



See text for explanation

3

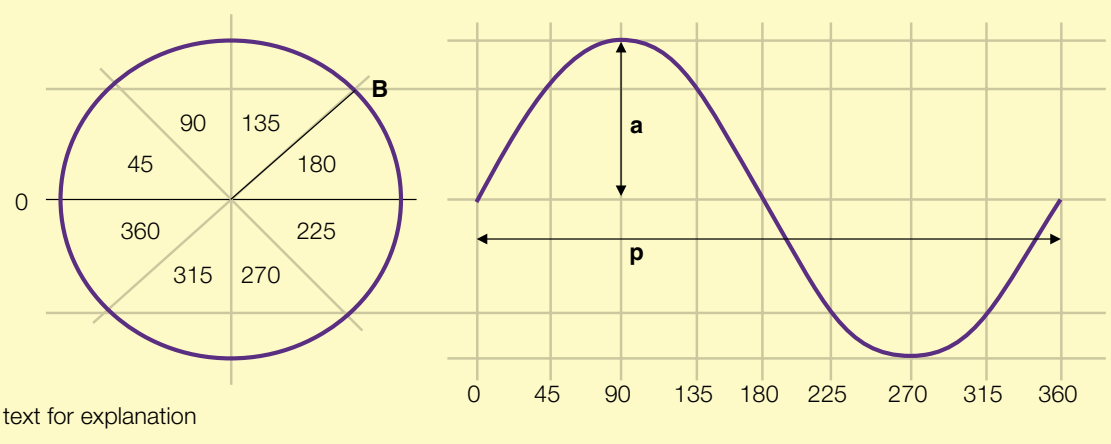
An example of the use of a natural logarithm plot to display an exponential function and allow easier understanding and data calculation is in the modelling of pharmacokinetics and pharmacodynamics. Each compartment of the model is plotted as a logarithm of the plasma concentration against time. The model can be fitted to real data collected from patients to show the interaction of each compartment to the whole model.

Sinusoid

Some functions are regularly thought of by their graphical representation and can also be described by a specific mathemat-ical function. A sinusoidal waveform is shown in Figure 4 with the two main features of the sinusoid, a the amplitude which is the maximum positive and negative excursion of the waveform and p the cycle length of the waveform. The horizontal axis of the graph can be a time scale with the waveform showing the amplitude change with time. In this case the cycle length is called the period of the waveform. The frequency, or number of cycles per second f of the waveform is defined by f = 1/p where p is measured in seconds, the unit of frequency is the hertz where 1 hertz is the frequency of a waveform with a period of 1 second.

A sinusoid can be plotted from circular motion. If you view a rotating object from one side as shown in Figure 4, the position of a point on the circumference 'B' plotted against angle of rotation or time assuming the point is moving at constant speed around the circumference, will follow a sinusoidal waveform as shown. If the horizontal axis represents the angle of rotation of the point from its start point then one cycle or one period is represented by one rotation or an angle of 360°.

Sine wave



See text for explanation

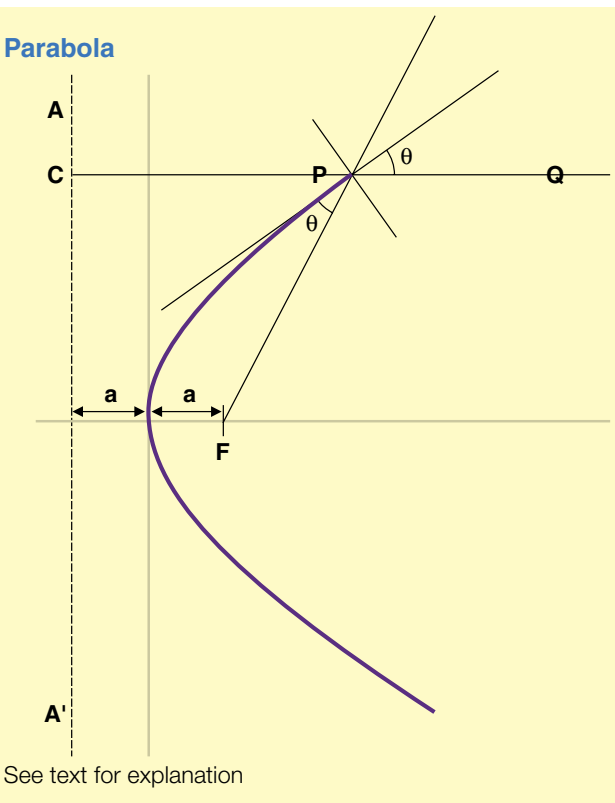
4

The sine wave is most commonly found as the wave shape of the mains electricity supply. In the UK, the frequency is 50 Hz, which gives a period for each complete wave of 1/50 s or 100 ms. The potential is usually quoted as 230 V, which is the root mean square value. For a sine wave this is calculated as peak value divided by 1.414 ($2^{½}$). Therefore, the peak value of each cycle of the mains supply is 230 x 1.414 or 325 V.

Parabola

The conic sections (circle, ellipse, hyperbola, parabola) are standard curves that are the boundary shapes of cutting a circular cone at different angles to its axis. Each conic section has a set of features that describe it. For the parabola (Figure 5), the point F is called the focus of the parabola, the line AA' is called the diretrix of the parabola and these form the basis for its construction. The distance from the directrix to the y axis and the focus to the y axis are equal and represented by 'a'. The parabolic shape is defined such that the distance from any point on the curve is equal distance from the line AA' the directrix represented by PC and F the focus, represented by PF which gives PC = PF.

Parabola



See text for explanation

5

The parabola has a unique feature demonstrated at point P. The line from F the focus to P the point of interest has an angle θ to the tangent to the curve at the point. A line drawn at the equal angle away from the point in the opposite direction PQ will always be parallel to the axis of the parabola. This means that if a reflector for any radiation is designed to have a parabolic cross-section any radiation coming from the focus will be 'focused' into a parallel beam and any radiation that enters such a reflector parallel with the axis will be 'focused' to a point at the focus of the parabolic cross-section.

A parabola is the shape of a reflector used for many different radiations from light through radiowaves to microwaves. A specific application is in spotlights used to intensify light in one area such as in theatre lamps where each light source has its own parabolic reflector. Because the lamp is not a point source the beam will diverge a little, but the main beam will be focused. ◆

Measurement of Gas Concentrations

Chris Seavell

Chris Seavell is Consultant Anaesthetist at Derriford Hospital, Plymouth, Devon, UK. He qualified from Bristol University and trained in anaesthesia in the South West and Wessex, UK, and Perth, Western Australia.

Accurate, fast, continuous measurement of inspired and expired gases and volatile agents is vital to the safe practice of modern anaesthesia. The technology required is readily available in compact form. The user should check the manufacturer's handbook to determine which method is utilized in the equipment being used.

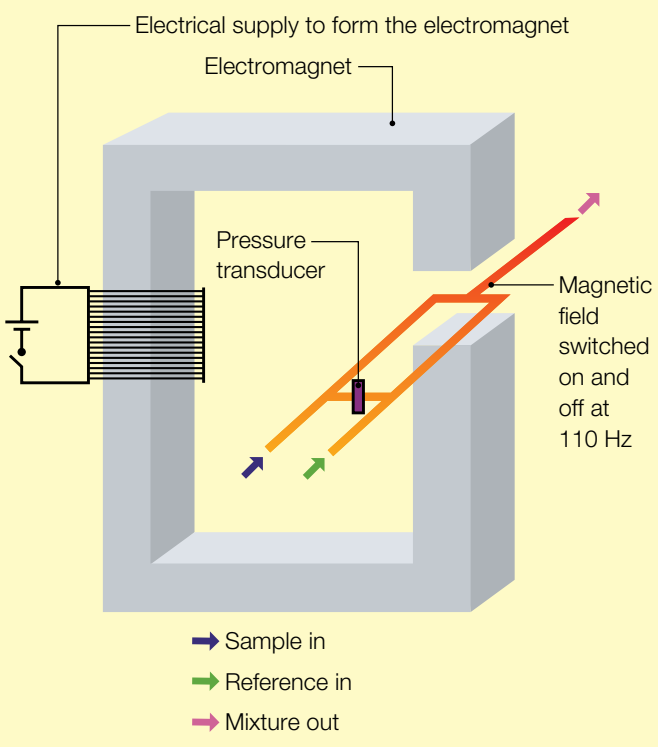
Oxygen concentration measurement

The three methods commonly used are the paramagnetic technique, the fuel cell (galvanic cell) and the polarographic cell (Clark's electrode).

Paramagnetic technique

Oxygen is unique among anaesthetic gases because it has unpaired electrons in its outer shell. This makes it paramagnetic – attracted into a magnetic field. Most other gases, including nitrogen, are diamagnetic and are repelled from a magnetic field. The Pauling apparatus was the first to use the paramagnetic technique. A sample of gas is drawn into a chamber containing a sealed, glass, nitrogen-filled dumb-bell arrangement, suspended in a powerful permanent non-homogeneous magnetic field by a small wire. Oxygen in the sample is attracted to the magnetic field, thus displacing the spheres. To improve accuracy, the displacement of the spheres can be prevented by an electric current applied to the dumb-bell arrangement such that the current required is proportional to the oxygen concentration. This is the principle of null deflection. Datex has refined this technique (Figure 1) so that the gas sample is drawn into a pneumatic bridge at the same rate as a sample of air (i.e. reference value of 21% O_2). An electromagnet is placed over the junction of these two tubes and switched on and off at 110 Hz. If the two samples contain a different oxygen concentration, a pressure difference is produced because of the paramagnetic properties of oxygen. This pressure difference is detected by a transducer and is proportional to the difference in oxygen concentration between the two samples. From this, the oxygen concentration of the sample can be calculated and displayed.

Datex paramagnetic analyser



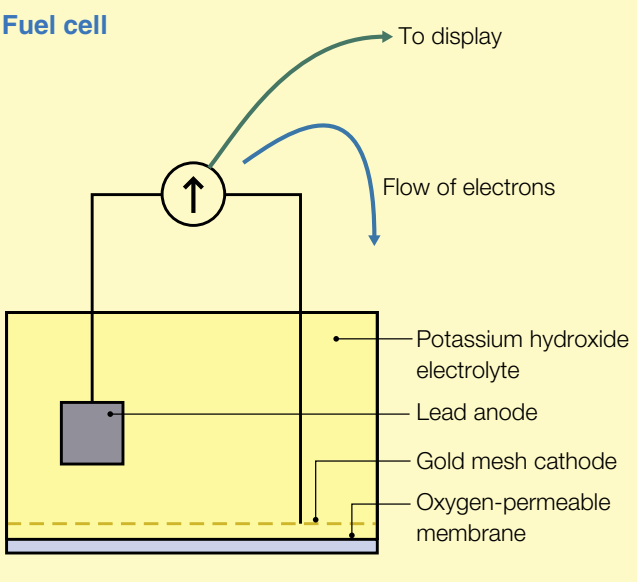
1

Fuel cell (galvanic cell)

The fuel cell is effectively a battery requiring oxygen for a current to flow (Figure 2). Oxygen from the sample being analysed diffuses through the base membrane and is consumed at the gold mesh cathode:

$$O_2 + 4e^- + 2H_2O \rightarrow 4(OH)^-$$

Fuel cell



2

The electrons are supplied from the reaction at the anode:

$$Pb + 2(OH)^- \rightarrow PbO + H_2O + 2e^-$$

The voltage produced is thus proportional to the concentration of oxygen. This device has to be temperature compensated and eventually wears out. If the gas sample is supplied under pressure the fuel cell reads erroneously high (the Ram-gas effect).

Polarographic cell (Clark's electrode)

Oxygen diffuses through a membrane and combines with elec-trons supplied by a voltage of about 0.6 v. The small current produced is amplified and displayed as oxygen concentration. Temperature compensation is required. This device is seldom used for analysis of gas concentrations though it is still used for the estimation of the concentration of oxygen in blood.

Measurement of N_2O, CO_2 and volatile agents

Infrared absorption spectroscopy

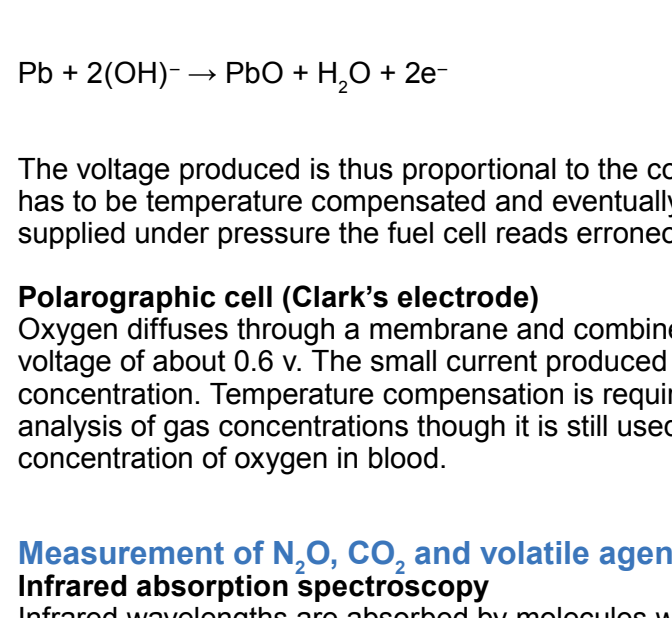
Infrared wavelengths are absorbed by molecules with two or more different atoms such as carbon dioxide (CO_2), nitrous oxide (N_2O) and volatile agents. Each molecule has a unique 'fingerprint' wavelength absorption pattern. Absorption is proportional to the concentration present and follows the Beer–Lambert law:

$$A = \varepsilon dC = \log \frac{I_0}{I_I}$$

where A is absorption, ε is molar extraction coefficient, d is path length through which radiation passes, C is concentration of sample, I_0 is incoming intensity and I_I is exit intensity.

The basic components of infrared spectroscopy are described in Figure 3. A unit consists of an infrared source, measuring chamber, a filter and a detector/amplifier. In an infrared analyser measuring only one gas, a single filter is used, but to allow measurement of several different gases and vapours simultaneously the filter is made up of several different rotating windows, each of which allows only infrared radiation at the peak absorption wavelength of the gases under test. For example, 4.3 μm for CO_2, 3.9 μm for N_2O and 3.3 μm for volatile agents (monitors capable of differentiating between different volatile agents use several different wavelengths between 3.24 and 3.39 μm). Rotating filters also cause a changing signal to strike the detector, which makes it easier to amplify. When CO_2 absorbs infrared wavelengths its vibrational energy increases. This can be passed on to N_2O allowing CO_2 to absorb more infrared wavelengths. This appears as if the spectrum is broadened and is called 'collision broadening'. It is compensated for automatically in new monitors.

Principles of infrared spectroscopy



3

The absorption of each of the wavelengths is measured by the detector and compared with reference data to allow display of the concentrations of gases and volatile agents. The system allows rapid detection of CO_2, N_2O and volatile agents though larger molecules such as the volatile agents have a slightly slower response time of about 750 ms compared with 250 ms for CO_2 and N_2O. Alcohol has a similar absorption spectrum to the volatile agents and high expired concentrations of alcohol can cause interference.

Piezoelectric effect

Quartz crystals can be set to oscillate at high frequency when placed in an electric field. They can be coated with an oil that absorbs volatile agents. Through the absorption process, the set frequency of the crystals changes, allowing rapid measurement of volatile concentration. Neither CO_2 nor N_2O can be measured in this way and the method is unable to distinguish between different volatile agents.

Photoacoustic spectroscopy

If N_2O, CO_2 and volatile agents are irradiated with pulsatile infrared radiation they absorb energy (see above) and expand causing a pressure increase. This can be detected by a microphone and the concentration displayed. As with infrared spectroscopy, a rotating filter is used to produce the desired frequency. Photoacoustic spectroscopy seldom requires recalibration and can produce fast response times.

Raman scattering

When N_2O, CO_2 and volatile agents are irradiated with an argon laser (488 nm) they each give off a characteristic set of different wavelength energies. These 'new' wavelengths are filtered out from the argon laser and passed through another series of filters, specific to each gas being tested, to identify each agent.

Interferometry

Two parallel beams of light pass through sample chambers, one containing air and the other the anaesthetic mixture. There is a difference in velocity of light through the two chambers so that when the beams are brought back together an interference pattern is seen. The amount of shift of the pattern is proportional to the concentration of anaesthetic gas. The interferometer can only provide a one-off measurement of a known gas; however it is cheap, portable and accurate and can be used to calibrate vaporizers.

Mass spectrometry

A sample is continuously drawn into a chamber from where a few molecules are allowed to diffuse into a near vacuum ionization chamber. Here, the sample is hit by a stream of electrons, which causes some of the molecules to become charged. These charged particles are accelerated by a negatively charged plate and are separated out by molecular weight in one of two ways. In a magnetic mass spectrometer a powerful magnet bends the line of trajectory, the lightest particle being bent the most. The particles are detected by a series of up to six plates each sampling different molecular weights. In a quadruple mass spectrometer, four charged rods are arranged in parallel around the line of accelerated particles. By varying the charge on the rods, only particles of a certain mass pass through to a detector plate. In both methods, the ionization process breaks some molecules down into smaller components (cracking pattern) thus allowing differentiation of molecules with the same molecular weight (e.g. CO_2 and N_2O with a molecular weight of 44). Mass spectrometry can rapidly (less than 0.1 s) measure several different gases simultaneously and requires only small samples. However, spectrometers are bulky and costly and seldom used in theatre.

Clinical aspects

Sampling

Clinical uses of capnography are given in Figure 4. The gas to be analysed can be sampled by sidestream or mainstream analysis (Figure 5).

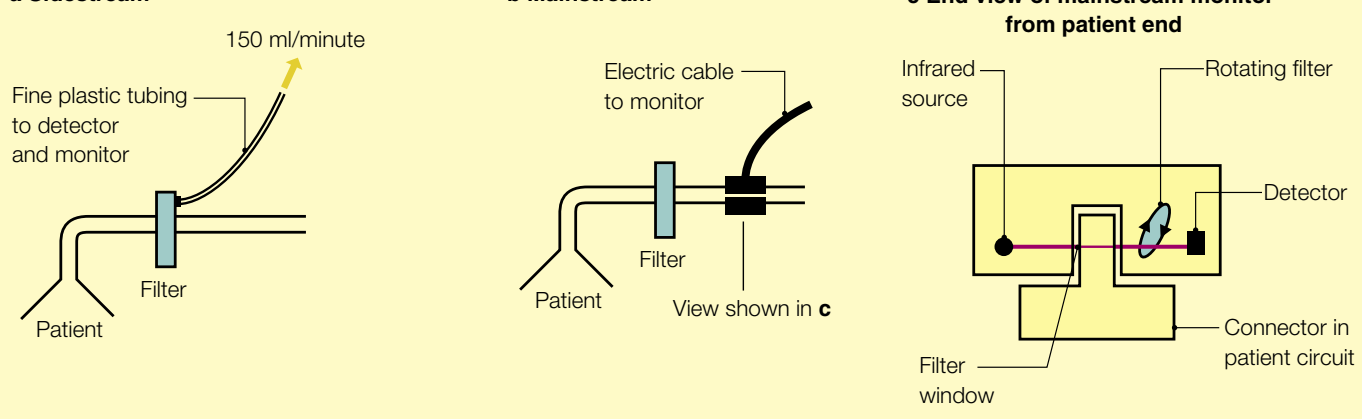
Sidestream analysis: gas is drawn off continuously usually at about 100–150 ml/minute from the breathing circuit, into the detectors inside the monitor. For accuracy, only the tubing provided by the manufacturer should be used. Depending on the technique used for detection, the sample gas may be returned to the breathing circuit, thus preventing a leak. This allows low flows to be used in a circle system.

Clinical uses of a constant carbon dioxide trace

- Respiratory rate
- End-tidal CO_2 estimates hypo- or hyperventilation (increased (alveolar–arterial) difference with significant lung disease)
- Indication of ventilation to perfusion mismatch (sloping up slope)
- Detection of oesophageal intubation
- Can act as a disconnect alarm if correctly set
- Detection of rebreathing (sloping down slope and eventually raised baseline – pattern depends on circuit)
- Reveals wear off of paralysis – regular pattern of CO_2 is interrupted and dips may appear in the expired trace
- Sudden loss of trace
  - Disconnection
  - Cardiac arrest
  - Gas/fluid emboli
- Rising CO_2 – part of diagnosis of malignant hyperthermia

4

Sidestream and mainstream gas analysis



5

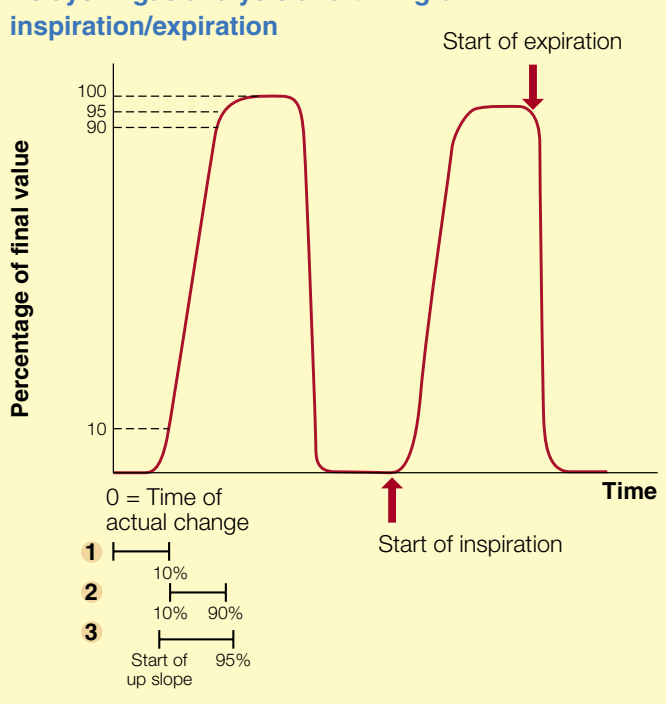
Advantages

- There is a lightweight connector to the breathing circuit and no bulky detector in the circuit (major factor).
- Multi-analysis is possible via the same circuit tube (e.g. N_2O, CO_2 and volatiles).

Disadvantages

- The lag time (Figure 6) from the sample leaving the breathing circuit to the monitor is long.
- Water vapour contamination occurs if the take-off point is placed in the circuit between the patient and a filter or if no filter is used.
- Mixing of fresh gas flow and expired gas can occur in the sample tubing, especially at small tidal volumes and in spontaneous ventilation, producing erroneously low end-tidal readings; to prevent this, the sample tubing take-off point should be as close to the patient's trachea as possible.

Delays in gas analysis and timing of inspiration/expiration



1 Delay time – time of actual change to 10% rise (increased with sidestream analysis)
2 Rise time – from 10% to 90% value (prolonged with V/Q mismatch)
3 Response time – first upward movement to 95% value

6

Mainstream analysis: the gas to be analysed does not leave the patient circuit, but a detector is placed into the sample. This technique can be used with a fuel cell attached to the common gas outlet or with infrared radiation detection for CO_2.

Advantages

- immediate readings
- no water vapour contamination possible
- no gas lost from circuit.

Disadvantages

- bulky attachment at patient end of circuit (major factor)
- only one gas can be measured at a time
- needs a clean window to prevent erroneous readings.

Sources of error

Potential sources of errors linked to the instrument are calibration error, electrical error, alcohol contamination or collision broadening. Errors related to the sampling technique include incorrect sampling tubing, water or secretion contamination, mixing of fresh and expired gas and the Ram-gas effect. If the patient has a high alveolar–arterial (A–a) difference the equipment may under-read end-tidal values. ◆

Measurement of pO_2, pCO_2, pH, Pulse Oximetry and Capnography

Jonathan Ingham
Peter D Macnaughton

Jonathan Ingham is Consultant in Intensive Care Medicine and Anaesthesia at Torbay Hospital, Devon, UK. He qualified from Oxford University and trained in anaesthesia in Portsmouth, Plymouth and Perth, Australia.

Peter D Macnaughton is Consultant in Intensive Care Medicine and Anaesthesia, Derriford Hospital, Plymouth, UK. He qualified from Westminster Medical School and trained in anaesthesia and intensive care in London, Bristol and Sydney, Australia. His research interests are acute lung injury and applied respiratory physiology.

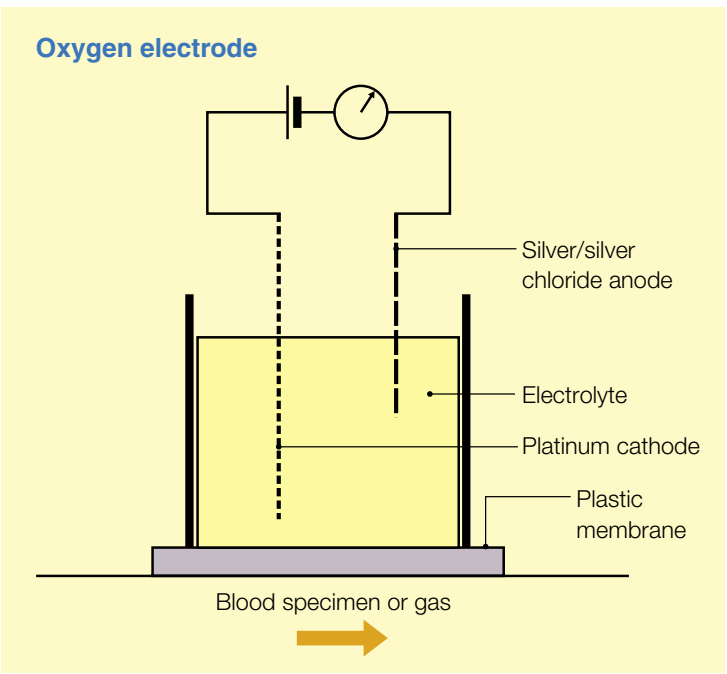
The assessment of respiratory function and metabolic state with blood gas analysis, combined with continuous monitoring from pulse oximetry and capnography is routinely performed in patients during anaesthesia, in resuscitation and in the critically ill.

Blood gas measurement
Blood gas analysers report a wide range of results, but the only parameters directly measured are the partial pressures of oxygen (pO_2) and carbon dioxide (pCO_2) and blood pH. The haemoglobin saturation (HbO_2%) is calculated from the pO_2 using the oxygen-dissociation curve and assumes a normal P50 and that there are no abnormal forms of haemoglobin. Some blood gas analysers incorporate a co-oximeter that directly measures the various forms of haemoglobin including oxyhaemoglobin, total haemoglobin, carboxyhaemoglobin and methaemoglobin. The actual bicarbonate, standard bicarbonate, and base excess are calculated from the pH and pCO_2 using the Siggard-Anderson nomogram derived from a series of *in vitro* experiments relating pH, pCO_2 and bicarbonate.

Practical precautions: a heparinized, freshly drawn, bubble-free, arterial blood sample is required. Heparin is acidic and if too much is present, the measured pCO_2 and calculated bicarbonate are spuriously reduced. Delay in measurement allows continued metabolism by the erythrocytes and reduces pH and pO_2 and increases pCO_2. Keeping the specimen on ice allows accurate measurement to be delayed for up to 1 hour. Air bubbles introduce error and cause a fall in pCO_2 and an increase in pO_2.

The polarographic (Clark) oxygen electrode measures the oxygen partial pressure in a blood or gas sample. A platinum cathode and a silver/silver chloride anode are placed in a sodium chloride electrolyte solution, and a voltage of 700 mv is applied (Figure 1). The following reactions occur.

- At the cathode: $O_2 + 2H_2O + 4e^- = 4OH^-$.
- In the electrolyte: $NaCl + OH^- = NaOH + Cl^-$.
- At the anode: $Ag + Cl^- = AgCl + e^-$.

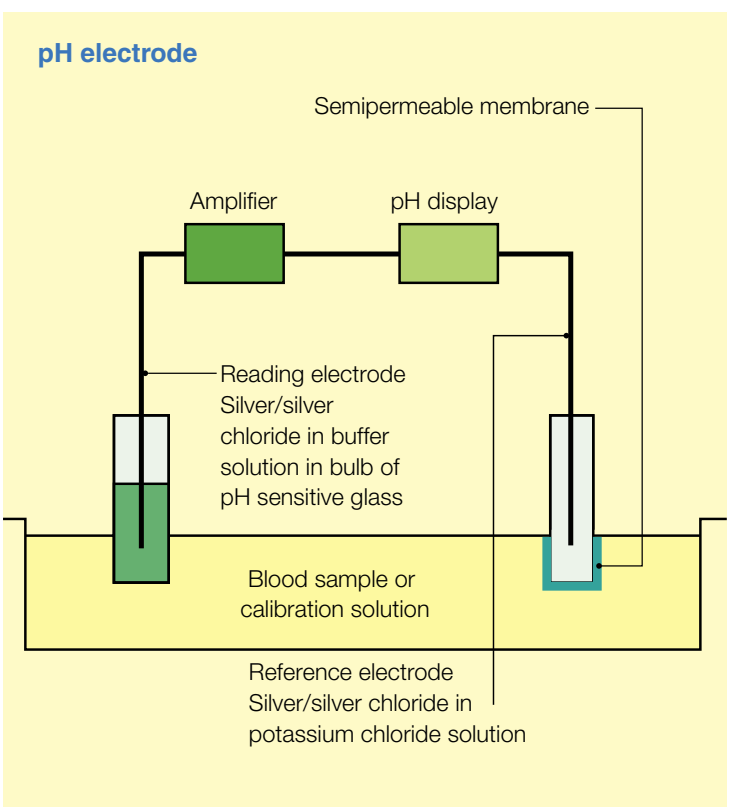


1

Electrons are taken up at the cathode and the current generated is proportional to oxygen tension. A membrane separates the electrode from blood, preventing deposition of protein but allowing the oxygen tension in the blood to equilibrate with the electrolyte solution. The electrode is kept at a constant temperature of 37°C and regular checks of the membrane are required to ensure it is not perforated or coated in proteins. Sampling two gas mixtures of known oxygen tension allows calibration.

pH electrode: if a glass membrane separates two solutions of different hydrogen ion concentration a potential difference develops that is proportional to the hydrogen ion gradient between the two. A potentiometric electrode is designed to measure the potential between the sample and a buffer solution.

A measuring silver/silver chloride electrode is encased in a bulb of special pH-sensitive glass and contains a buffer solution that maintains a constant pH (Figure 2). This glass electrode is placed in the blood sample and a potential difference is generated across the glass, which is proportional to the difference in hydrogen ion concentration. The potential is measured between a reference electrode (in contact with the blood via a semi-permeable membrane) and the measuring electrode. Both electrodes must be kept at 37°C, clean and calibrated with buffer solutions of known pH.



2

The Severinghaus or carbon dioxide electrode is a modified pH electrode in contact with sodium bicarbonate solution and separated from the blood specimen by a rubber or Teflon semi-permeable membrane. Carbon dioxide, but not hydrogen ions, diffuses from the blood sample across the membrane into the sodium bicarbonate solution, producing hydrogen ions and a change in pH.

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

Hydrogen ions are produced in proportion to the pCO_2 and are measured by the pH-sensitive glass electrode. As with the pH electrode, the Severinghaus electrode must be maintained at 37°C, be calibrated with gases of known pCO_2 and the integrity of the membrane is essential. Because diffusion of the CO_2 into the electrolyte solution is required the response time is slow at 2–3 minutes.

Hypothermia, pH-stat, and alpha-stat: the solubility of all gases, including CO_2 and O_2, in blood increases with a fall in temperature. Thus, hypothermia causes the pO_2 and pCO_2 to fall and the pH to rise. As analysis of a sample taken from a hypothermic patient occurs at 37°C, the pO_2 and pCO_2 results are artificially high. The result can be corrected to represent the pH, pO_2 and pCO_2 at the patient's temperature. In practice such correction is unnecessary. When cardiopulmonary bypass was developed it was thought that the reduction in $PaCO_2$ during hypothermia would result in cerebral vasoconstriction. In pH-stat management, CO_2 was added to the oxygenator to maintain a temperature-corrected $PaCO_2$ of 5.3 kPa and a pH of 7.4. The alternative and now standard strategy is that of alpha-stat in which a non-temperature corrected $PaCO_2$ of 5.3 kPa and a pH of 7.4 is maintained. The true value of $PaCO_2$ is lower than this but the associated alkalosis is thought to aid enzyme function during hypothermia.

Pulse oximetry
Pulse oximeters provide a safe, reliable and non-invasive method of continuous arterial oxygen saturation monitoring. They are standard monitors during anaesthesia and in the ICU. Haemoglobin saturation is measured from the absorption of light emitted from a probe placed on a digit or ear lobe.

The probe contains two high intensity, monochromatic, light- emitting diodes, one emitting red light (660 nm) and the second infrared (940 nm) on one side and a photodetector on the other to measure the amount of light transmitted through the finger. The saturation of haemoglobin is calculated from the absorption at the two different wavelengths. The diodes are switched on in sequence with a pause with both diodes off. This pause allows the photocell and microprocessor to compensate for any ambient light. By analysing the pulsatile changes in light absorption, the absorption by venous blood and tissue is deducted and arterial saturation measured. The measurements are plotted against a standard calibration curve, determined by direct measurements of the arterial oxygen saturation of normal resting healthy volunteers.

Limitations and errors: pulse oximetry is accurate above 90% oxyhaemoglobin saturation, but much less so below 70%, and inaccurate below 50%. Pulse oximeters estimate arterial haemoglobin oxygen saturation (SaO_2) and not arterial oxygen tension (PaO_2). Because of the shape of the oxygen-dissociation curve, large changes in PaO_2 may occur at the extremes of the curve with minimal change in SaO_2. They have a response time of 10–30 s, depending on the signal averaging time, circulation time and the site of the probe.

Increase in the non-pulsatile component of light absorption through nail varnish or dirt increases error. Skin colour does not influence accuracy. Excess ambient light, infrared heaters and diathermy also interfere with accuracy. Hyperbilirubinaemia does not affect accuracy, nor anaemia unless the haematocrit is below 10%. Low peripheral perfusion due to low cardiac output or vasoconstriction interfere with accurate detection of arterial pulsations, as do atrial fibrillation or other arrhythmias.

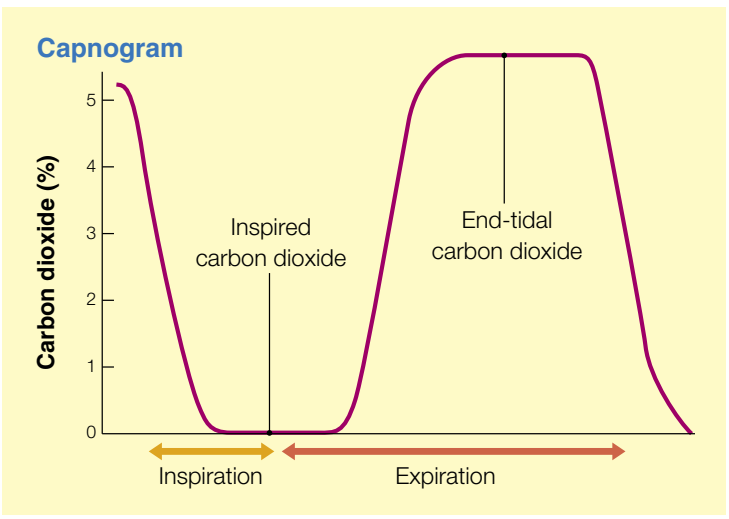
Carboxyhaemoglobin has a similar absorbance to oxyhaemoglobin and gives a falsely high reading for SaO_2. Methaemoglobin has an absorption that is similar at 660 and 940 nm and produces a SaO_2 towards 85%. The intravenous dyes methylene blue and indocyanine green also lead to falsely low values. Fetal haemoglobins do not cause error. A co-oximeter can measure carboxyhaemoglobin and methaemoglobin by analysing the absorption of at least three different wavelengths of light by blood *in vitro*.

Capnography
Capnography is a standard method of monitoring during anaesthesia and is increasingly used in the ICU. It describes the continuous measurement of expired carbon dioxide tension at the airway to allow the monitoring of the end-tidal CO_2 tension. An analyser with a rapid response time is required and most devices measure CO_2 tension from the absorption of infrared light, though other techniques such as mass spectrometry can be used.

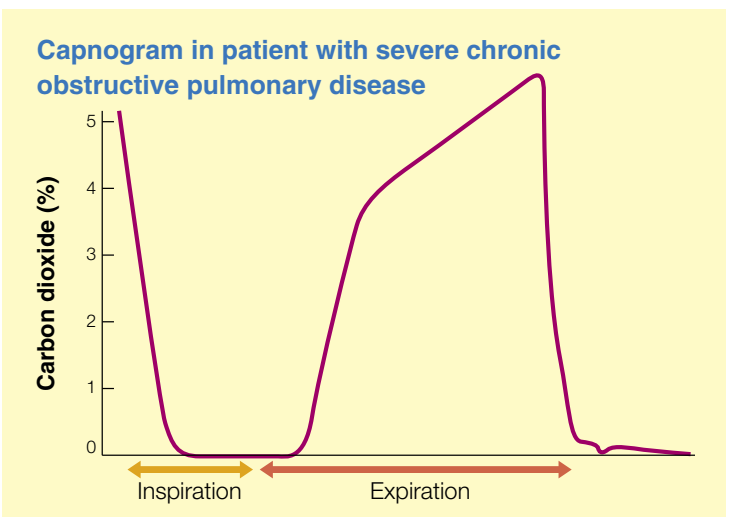
Sidestream sampling is most common and describes the technique of continually aspirating a sample of gas from the respiratory circuit which is then fed through the analyser. The gas is either returned to the respiratory circuit or scavenged. Sidestream capnography is favoured during anaesthesia owing to the convenience of a lightweight attachment to the airway but may be troublesome due to sampling line blockage by water vapour following protracted use.

Mainstream sampling – the analyser head is attached directly to the airway and the gas is analysed within the respiratory circuit through a clear window or cuvette. In the ICU where inspired gases are often humidified actively, mainstream may be more reliable than sidestream capnography.

Capnogram: a typical capnogram is shown in Figure 3. During inspiration the CO_2 tension should be neligible unless there is rebreathing. Dead space gas is exhaled first, it contains no CO_2, and is followed by alveolar gas and a rapid rise in CO_2 which reaches a clear plateau in normal lungs and is termed the end-tidal CO_2 tension. However, if there is significant inhomogeneity of ventilation within the lungs no clear plateau is discernible and an accurate end-tidal CO_2 cannot be measured (Figure 4). This occurs in obstructive airway disease and asthma. If tidal volumes are very small there is inadequate distinction between dead space and alveolar gas resulting in an indistinct expiratory plateau and the end-tidal CO_2 tension is inaccurate.



3



4

End-tidal CO_2: in normal lungs the end-tidal CO_2 tension is 0.5–0.8 kPa less than the arterial CO_2 tension and is a useful non-invasive estimate of arterial CO_2. The difference between end-tidal and arterial CO_2 is increased if there is mismatch of ventilation and perfusion within the lung, as occurs in lung disease. In these circumstances, the end-tidal CO_2 may markedly underestimate arterial CO_2 tension. A reduction in lung perfusion increases alveolar dead space and results in an end-tidal CO_2 tension considerably lower than the arterial CO_2 tension. This may occur in pulmonary emboli, low cardiac output states, hypotension and following the application of high levels of positive end-expiratory pressure during mechanical ventilation. A sudden drop in end-tidal CO_2 during anaesthesia may reflect a decrease in cardiac output or pulmonary embolism (e.g. thrombus, gas, fat). Monitoring end-tidal CO_2 is useful during cardiopulmonary resuscitation for assessing adequacy. The causes of changes in end-tidal CO_2 are summarized in Figure 5. ◆

Changes in end-tidal carbon dioxide ($ETCO_2$)

Increased $ETCO_2$

Decreased alveolar ventilation
- Reduced respiratory rate
- Reduced tidal volume
- Increased equipment dead space

Increased CO_2 production
- Fever
- Hypercatabolic state

Increased inspired pCO_2
- Rebreathing
- CO_2 absorber exhausted
- External source of CO_2

Reduced $ETCO_2$

Increased alveolar ventilation
- Increased respiratory rate
- Increased tidal volume

Reduced CO_2 production
- Hypothermia
- Hypocatabolic state

Increased alveolar dead space
- Reduced cardiac output
- Pulmonary embolism
- High positive end-expiratory pressure during intermittent positive-pressure ventilation

Sampling error
- Inadequate tidal volume
- Water blocking sampling line
- Air entrainment into sampling line

Measurement of Temperature and Humidity

John Bernard Carlisle

John Bernard Carlisle is Consultant Anaesthetist at Torbay Hospital, Devon, UK. He is an editor of the Cochrane Anaesthesia Review Group (CARG). In addition to evidence-based medicine, he is interested in the preoperative preparation and perioperative optimization of patients.

The temperature of matter is equal to the mean translational kinetic energy of its particles.

Thermodynamic principles
Energy (E) can perform work. It exists in discrete quantities as the photons of electromagnetic radiation ($E = h\nu$; where h is Planck's constant and ν is the electromagnetic frequency) or the mass of quarks and leptons ($E = mc^2$; where m is mass and c is the velocity of light).

A mass in motion has more energy than a mass at rest (kinetic energy = $\frac{1}{2}mv^2$; where m is mass and v is velocity). Atomic or molecular internal energy can displace the centre of the mass (translation) or not (vibration or rotation around interatomic bonds).

Kinetic temperature is the translational component of internal energy. The atoms or molecules of two substances with the same temperature have the same mean translational kinetic energy. For an ideal monatomic gas all the internal energy is translational kinetic energy, the mean value of which determines the temperature. The kinetic energies of atoms at thermal equilibrium follow a statistical distribution defined by the Maxwell–Boltzmann equation. The mean atomic kinetic energy is $\frac{1}{2}kT$ in one dimension and kT in three dimensions (where T is temperature in Kelvin, k is Boltzmann's constant 1.4×10^{-23} J/K). The speed of gas particles depends on their mass and temperature ($kT = \frac{1}{2}mv^2$). For air (average molecular mass 29) the mean molecular speed at room temperature is 466 m/s (1679 km/hour). At atmospheric pressure a gas molecule in air would be expected to collide with another every 2×10^{-10} s.

Heat is the transfer of energy quanta that change internal molecular energy. Heat quanta increase all three kinetic modes (vibration, rotation, translation), while temperature measures only the translational component of internal energy. Heat and temperature are not usually simply related, particularly for phase changes; for instance, five times as much heat energy (2260 kJ) is required to vaporize 1 kg of water at 100°C (no temperature change) as to increase the temperature of the same water from 0°C to 100°C (419 kJ).

Energy quanta are transferred by particle collision or electromagnetic radiation (emr). The absorption of emr that increases temperature is efficient at wavelengths between 1000 nm and 1×10^6 nm (infrared).

The international standard measurement scale for temperature is the Kelvin (K). The reference point for this scale is the triple point of water at 273.16K. Pure water freezes at 273.15K (0.00°C) and boils at 373.125K (99.975°C) at standard pressure (International Temperature Scale 1990 or ITS-90).

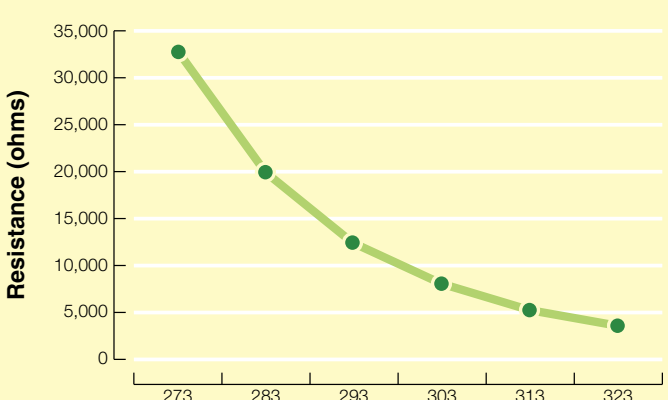
Thermometers
Thermometers measure their own temperature resulting from the net gain or loss of heat (radiation and molecular collision). Thermometer temperature is signalled in one of two ways.

- Physical thermometers signal the density change of a gas, liquid or solid with temperature (e.g. bulb thermometers, Galileo thermometers, gas expansion gauge sensors, acoustic sensors) or a phase change, usually solid to liquid, as in 'dot matrix' thermometers.
- Electrical thermometers signal changes in the energy of electrons. There are a variety of methods for measuring electron energy, including changes in potential difference (thermocouple, thermopile, transistor), conductivity (thermistors, resistance temperature detectors, electrical noise thermometers), capacitance (pyroelectric crystals in emr sensors), inductance and colour.

Thermistors are temperature-dependent semiconductors. Negative thermal conductivity thermistors (Figure 1) are made from metal oxides (cobalt, copper, manganese, nickel), positive thermal conductivity thermistors from barium titanate.

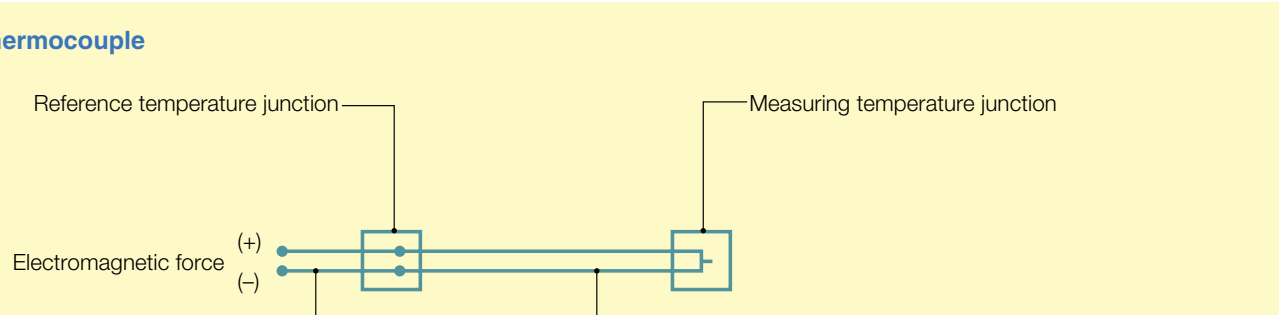
Thermocouples generate a temperature-dependent electromagnetic force at the junction of two different metals (Seebeck effect) (Figure 2).

Negative temperature coefficient thermistor



1

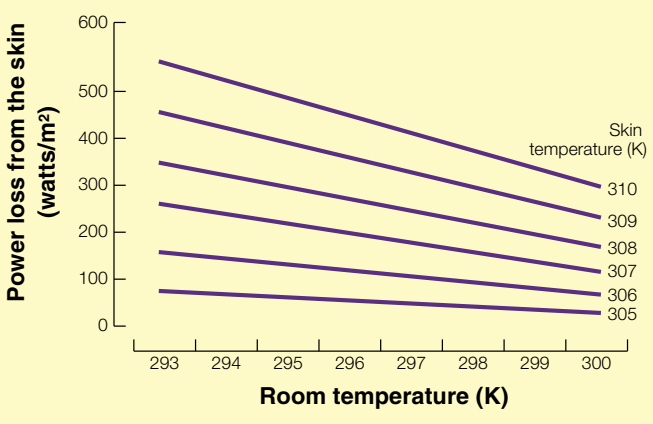
Thermocouple



2

Infrared sensors detect the electromagnetic energy radiated from the body (whole body thermography) or from parts of the body (e.g. tympanic membrane thermometers). Skin absorbs and emits almost all of its thermal energy (emissivity 0.97). The radiated energy flux (power per unit area) depends on the temperature obeying the Stefan–Boltzmann law = $e \times \sigma \times (T^4_{hot} - T^4_{cold})$ (Figure 3) where e is emissivity (perfect black body = 1), σ is the Stefan–Boltzmann constant 5.7×10^{-8} W/m^2/K^4, T is the temperature (K).

Effects of room and skin temperature on radiative heat loss

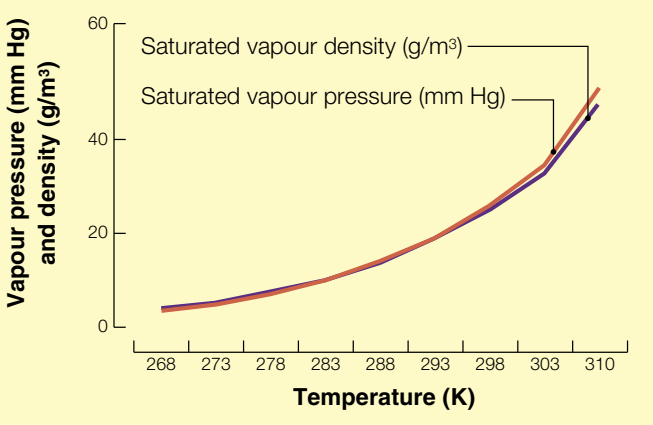


3

Technical specifications should detail range, precision, time constant to reach thermal equilibrium, sensitivity to emr interference (1 m long leads are subject to radiofrequency interference and heating), applications and requirement for recalibration. Thermometers are subject to damage and inaccuracy over time. Calibration laboratories should fulfil national (National Measurement Accreditation Scheme) and international (ISO/IEC 17025) standards, using Standard Platinum Resistance Thermometers (SPRTs) and fixed-point isothermal cells.

Humidity
Humidity is the vapour density of water in air (g H_2O/m^3 air). The water molecules in a closed container of air and fluid water have a spectrum of translational kinetic energies determined by the Maxwell–Boltzmann equation. At thermal equilibrium the saturated vapour density (SVD) has a corresponding saturated vapour pressure (SVP); both increase non-linearly with temperature. VP (mm Hg) = $7.5 \times 10^{-6} \times$ VD (g/m^3) $\times$ R $\times$ T where R is the specific gas constant for water (462 J/kg/K) and T is the temperature (K) (Figure 4).

Variation of saturated vapour pressure and saturated vapour density of water with temperature



4

Relative humidity (RH) is the measured vapour density of water divided by the SVD, expressed as a percentage. Compression or cooling of gas increases RH. Excess water vapour condenses when the RH of cooled gas exceeds 100% (dew point).

Measuring water vapour density in air
Primary hygrometers use fundamental thermodynamic principles. They include gravimetric hygrometers, electrolytic hygrometers (the electrolytic current is proportional to the humidity), chilled mirror hygrometers (dew point detected by cooling the air) and psychrometers.

Psychrometers compare the temperatures of two thermometers; one has a dry bulb, a wet wick encloses the second. The wet bulb is cooled by water evaporation (latent heat of vaporization) until the SVD is reached. The difference in thermometer temperatures depends on the RH of the sampled air. Absolute humidity (for mirror hygrometers and psychrometers) is calculated using the temperature of the dry bulb. Psychrometers calculate the water vapour pressure from:

$$VP = SVP_{Tw} - [\gamma \times (T_d - T_w)]$$

Rearranged this shows that wet bulb temperature increases with increasing humidity:

$$T_w = T_d - [(SVP - VP)/\gamma]$$

When the sample air is saturated (SVP–VP = 0) wet and dry bulb temperatures are equal. Where: VP is actual vapour pressure, SVP_{Tw} is saturated vapour pressure (kPa) at wet bulb temperature, T_W and T_d are wet and dry bulb temperatures (K). γ is the psychometric variable that relates the heat energy lost from the wet bulb by water vaporization to the temperature measured. $\gamma = P \times C_p / (0.622 \times L)$ where P is atmospheric pressure (kPa), C_P is the heat capacity of the thermometer (J/kg/K) and L is the latent heat of vaporization for water at T_W (J/kg).

Secondary hygrometers depend on observed changes in the properties of materials with humidity. They include physical properties (oscillating crystal frequency, fibre tension, weight) or electrical properties (capacitance, resistance, impedance). A gravimetric hygrometer measures the difference in weight between an untreated and a desiccated sample of gas (using P_2O_5).

Permeable capacitive hygrometers measure the variation in capacitive charge by the effects of water vapour on the dielectric constant of the material between the capacitor plates. The charge, $C = \varepsilon A/d$. Area (A) and plate separation (d) are fixed, so the charge is proportional to the dielectric constant (ε).

Water molecules can also be measured using mass spectrometry, absorption spectrophotometry or Raman spectroscopy. Absorption spectrophotometers measure the absorption of photons by water molecules in the gas sample between the emitter and detector. Wavelengths used to detect water vapour are either in the ultraviolet (λ 121.56 nm) or infrared (λ 2.5 μm) parts of the spectrum. The electrical current (I) generated by the photodetector = $I_0 \exp^{[-k\ d\ VD]}$ where VD is the vapour density, d is the path length, I_0 is the current produced in the absence of water and k is the absorption coefficient of the photons by water vapour.

Calibration: the National Physical Laboratory (NPL) holds the UK's international standard, calibrating hygrometers between –60°C and 60°C in dew point at standard pressure (error ± 0.003 to 0.84°C in dew point depending on conditions). Commercial calibration laboratories use a transfer standard (usually a chilled mirror hygrometer) that has been calibrated against an NPL standard.

Hygrometers also need to be recalibrated at regular intervals (traceable to the NPL standard). Most hygrometers are calibrated at 25°C. Sensor precision decreases away from the calibration temperature; the efficacy of any electronic compensation for this imprecision is likely to decrease with time. Contamination of the analysed gas (particulates, inorganic salts, organic compounds) reduces hygrometer precision, particularly as they accumulate on or in the sensor. ◆

Measurement of Volume and Flow in Gases

Fred Roberts

Fred Roberts is Consultant Anaesthetist at the Royal Devon and Exeter Hospitals. His clinical interests are anaesthesia for obstetric and ENT surgery. He is a Primary FRCA examiner.

The ability to measure gas flows and volumes accurately is essential to the anaesthetist, both for precise delivery of gas mixtures and for monitoring respiratory volumes in the ventilated or spontaneously breathing patient. Gases are fluid, compressible and usually invisible, which makes them difficult to measure. Gas volumes (and associated flows) can be measured directly using a system with a calibrated chamber, but in clinical practice, measurement is usually made indirectly, using a property of the gas that changes in parallel to flow or volume and which can be more easily determined.

Scientific principles

To understand the working principles of the various devices used for measurement, a few aspects of the relevant basic science must be considered. Gas flow conventionally refers to volume flow per unit time (Q) rather than linear velocity (v) of the flowing gas.

Relationship between flow and volume: for gas delivery systems (e.g. oxygen flowmeters), flow is generally constant and the relationship between flow and volume is expressed by $V = Q\,t$, where V is volume, Q is flow and t is time.

In a physiological setting (e.g. tidal volume) flow is seldom constant and thus volume must be calculated by integrating the measured flow rate with respect to time. In a graph plotting flow against time, this represents the area under the curve; if the data are recorded electronically it is usually computed.

Types of flow: the influence of many of the variables that determine flow depends on whether flow is laminar or turbulent. Several factors determine which type of flow predominates, and these are amalgamated into Reynolds' number (Re), a dimensionless value that can be calculated for a smooth parallel-sided tube by:

$$Re = \frac{v\,\rho\,d}{\eta}$$

where v is linear velocity, ρ is density, d is diameter and η is viscosity. At an Re less than 2000 flow will probably be laminar; an Re over 2000 indicates flow is likely to be turbulent.

Laminar flow is efficient, with layers passing smoothly over each other producing a parabolic (bullet-shaped) flow profile, with the greatest velocity centrally. It is determined by the Poiseuille–Hagen formula:

$$Q = \frac{P\,\pi\,r^4}{8\,\eta\,l}$$

where: P is pressure drop, r is the radius of the tube and l is the length of the tube. Important features are that flow is:

- directly proportional to the pressure drop
- proportional to the fourth power of the radius
- related to the viscosity but not the density of the gas.

Turbulent flow is less efficient, with multiple eddy currents occurring in the overall direction of flow. Because of the variable nature of turbulence, there is no precise and comprehensive equation to calculate flow, but turbulent flow is related to the:

- square root of the pressure drop
- density of the gas rather than its viscosity.

If flow is being calculated by measuring one of the above variables, unforeseen changes in any of the others will compromise accuracy. Changes could occur directly, such as by alteration in gas composition, or indirectly, such as temperature variation causing a change in viscosity.

Working principles

Direct measurement: gas volumes (and associated flows) can be measured directly using bulk filling of an enclosed space of known volume. Instruments using direct measurement include the gas meter, vitalograph and water-displacement spirometer. Because of the logistical problems of such devices, their use in clinical practice is limited.

Indirect measurement: for clinical use, measurement is usually made indirectly, using a property of the gas that changes in parallel to flow or volume and which can be more easily determined.

Pressure drop across a resistance – as flow occurs through a resistance, a pressure drop occurs. This effect can be used to calculate flow by:

- keeping the resistance constant and measuring the pressure change as the flow varies, as in a pneumotachograph
- having a constant pressure drop and varying the resistance in a measurable way (e.g. bobbin rotameter).

Mechanical movement – flowing gas has kinetic energy related to its velocity, which can be converted into a measurable value by:

- rotation of a vane (e.g. a spirometer)
- bending a flexible obstruction, transducing this to produce an electrical signal.

Heat transfer – gas flowing past a heated element acts to cool it, as in a hot-wire anemometer.

Ultrasound interference – the velocity of an ultrasound signal is increased by a gas flowing alongside it in the same direction, and decreased if the gas is flowing against it.

Ideal features of a device used for gas flow or volume measurement in clinical practice include:

- accurate across a wide range of flows
- unaffected by changes in gas temperature or composition
- low resistance so that it can be used in a spontaneously breathing patient
- minimal impairment of performance with prolonged use.

Measurement site: for measuring tidal volume, it is important that the characteristics of the breathing system are taken into consideration when deciding where to measure. For a semi-closed rebreathing system (any of the Mapleson A–F classification), measurement must be made at the distal end of the system, adjacent to the mask or tracheal tube, or the fresh gas flow may produce an addition to the tidal volume.

With some older designs of circle system, circulating fresh gas flow could erroneously increase the tidal volume when measured within the circle and the only reliable site was distal to the Y-piece. With improved circle design, appropriate placement of flow sensors adjacent to the unidirectional valves enables the tidal volume to be measured accurately within the circle in the inspiratory or expiratory limb.

Intensive care ventilators are non-rebreathing systems, and measurements can be made accurately in the inspiratory or expiratory parts of the system. In practice, both inspiratory and expiratory tidal volumes are usually measured, because clinically important discrepancies between them can occur, for example a leak caused by lung pathology or the use of an uncuffed tube.

Specific devices

Most devices for measuring gas flow and volume measure the whole gas flow, though some incorporate a mechanism for splitting the flow and then measure only a part of it, extrapolating from this sample to calculate the whole flow. Devices may be designed to measure primarily flow or volume, though the two are closely related and information about both may be readily obtained. Some devices also give other clinical data, such as inspiratory pressure and information about the pattern of flow.

Gas meter

A gas meter acts as a volumetric turnstile, with sequential filling of internal chambers of known volume and recording the number of times each has been filled. They are classified as dry or wet, depending on whether an underwater seal is used in the mechanism. They have a substantial resistance and are cumbersome, thus largely restricting use to industrial applications.

Vitalograph

The vitalograph is used specifically to record a single vital capacity breath. Its design uses an expanding bellows with a recording pen attached and a motor to move the paper at constant speed. Volume is displayed on the y-axis and time on the x-axis, so that the pattern of expiration is shown as well as the volume.

Water-displacement spirometer

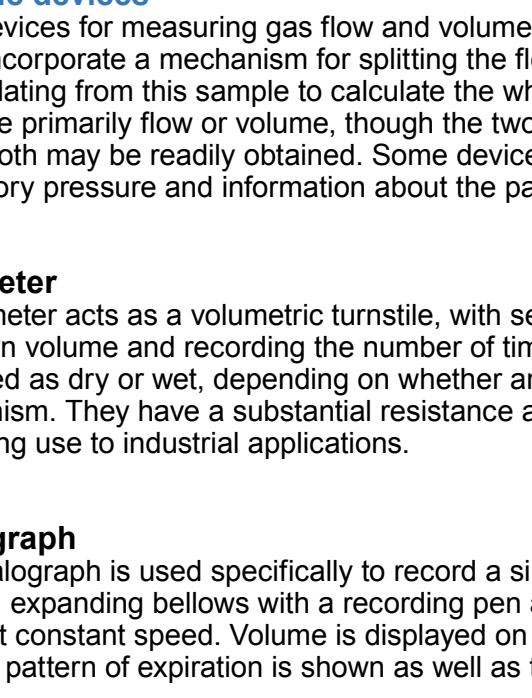
A water-displacement spirometer involves directing gas (usually respiratory gas) into an inverted bell chamber that is immersed in water but free to move up and down via a pulley as the volume of gas in the chamber varies. This movement is linked to a recording system calibrated to display the volume change. It is accurate, but is impractical for everyday clinical use because of its size and it is used mainly as a research instrument.

Pneumotachograph

In a pneumotachograph, a resistance is put in the gas pathway and the resulting pressure drop across it measured rapidly and accurately using a differential pressure transducer, from which flow rate and volume are calculated.

For improved accuracy, the resistance is usually designed to produce laminar flow, so that the flow rate is directly proportional to the measured pressure drop. This is achieved using a series of small-bore tubes arranged in parallel (Figure 1), through which the gas flow must pass. A heating element is sometimes incorporated to prevent the build-up of condensation that could compromise accuracy. The total resistance added by the pneumotachograph should be small so that it can be used in a spontaneously breathing patient.

Pneumotachograph



1

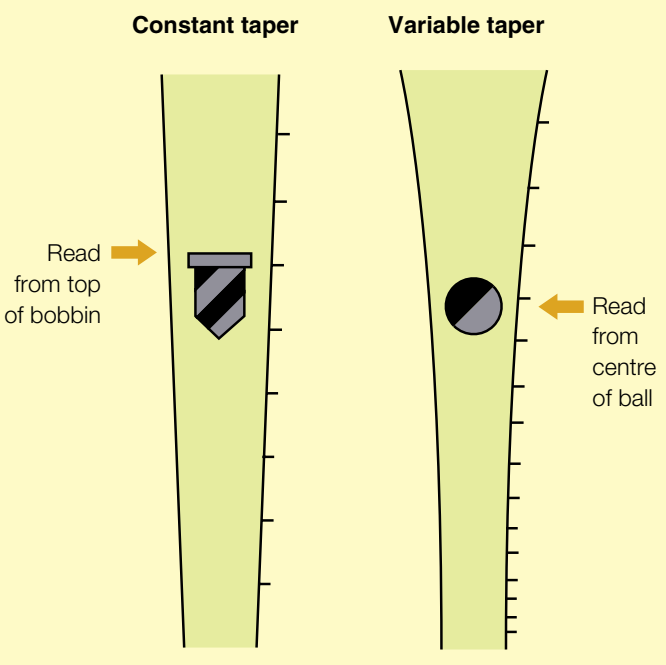
Measurement can be made at various points in the breathing system or ventilator, and a pair of sensors is often used so that inspired and expired tidal volumes can be measured independently. Alternatively a single sensor may be used at the Y-piece, when a sampling port is usually included for gas analysis. In addition to the differential pressure across the chamber, the absolute pressure in the airway can be easily measured. When linked to the recorded tidal volume, compliance can be calculated and displayed in real time.

Rotameters

Rotameters are widely used in gas delivery systems for continuous flow measurement. Several designs have been used, though now almost all use a vertical tapered tube containing a bobbin or ball (Figure 2) which is supported by the gas flow as it passes upwards through the tube. The weight of the bobbin (and thus the pressure drop required to support it) is constant, but as the flow increases its position in the tube rises, lowering the resistance as a larger pathway is created alongside the bobbin.

Amalgamation of the space for gas flow around the bobbin to equate to a simple pathway reveals that at the bottom of the flowmeter the resulting dimensions lead to laminar flow but at the top of the tube produce turbulent flow. The physical characteristics of the gas that determine the resulting flow are therefore viscosity at the bottom and density at the top of the tube. The main implication of this is that calibration of rotameters is gas-specific and for accuracy its use must be restricted to that gas. Calibration is usually done to read the flow rate from the top of a bobbin but the centre of a ball.

Rotameters



2

The range of gas flow measurements can be increased by using two tubes (one for low and one for high flow rates), or by varying the taper so that a greatly increased diameter results at the top of the tube.

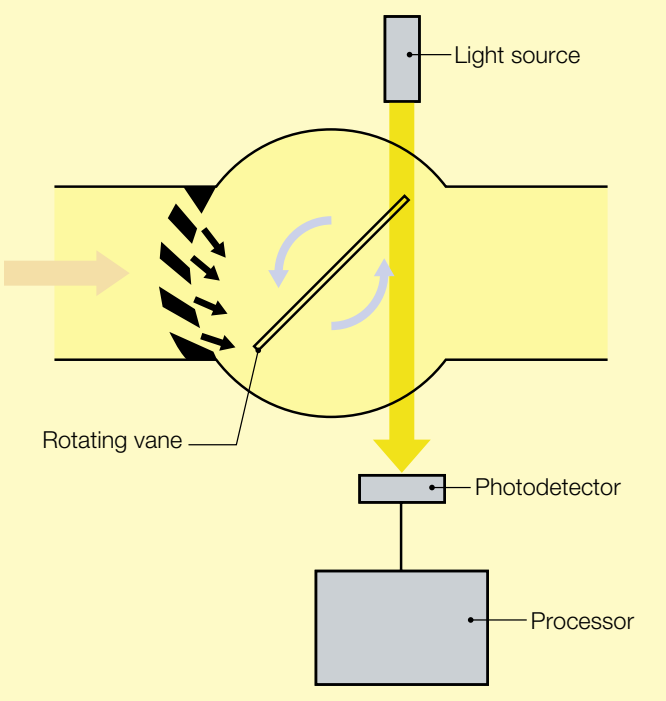
Inaccuracy results from anything that causes the bobbin to stick in the tube, including dirt or static electricity. To prevent build-up of static, the inside walls of a rotameter and its mounting points are made of conductive material. To demonstrate that the bobbin is not stuck, it has angled flutes to produce rotation, which is made easier to see by appropriate colouring.

Back pressure caused by downstream resistance also leads to an inaccurately low reading on a rotameter, though the actual flow is the same as that shown before the resistance was applied.

Vane meters

The most common vane meter is the Wright's spirometer, in which the gas flow is directed tangentially to strike a rotating vane in the gas pathway (Figure 3). Originally this rotation was linked mechanically to a needle and the volume read from the adjacent dial, but modern versions use a light source and photodetector positioned across the vane to count its rotation. The Wright's spirometer tends to under-read at low flows (because of friction) and to over-read at high flows (because of momentum).

Wright's spirometer (electronic)



3

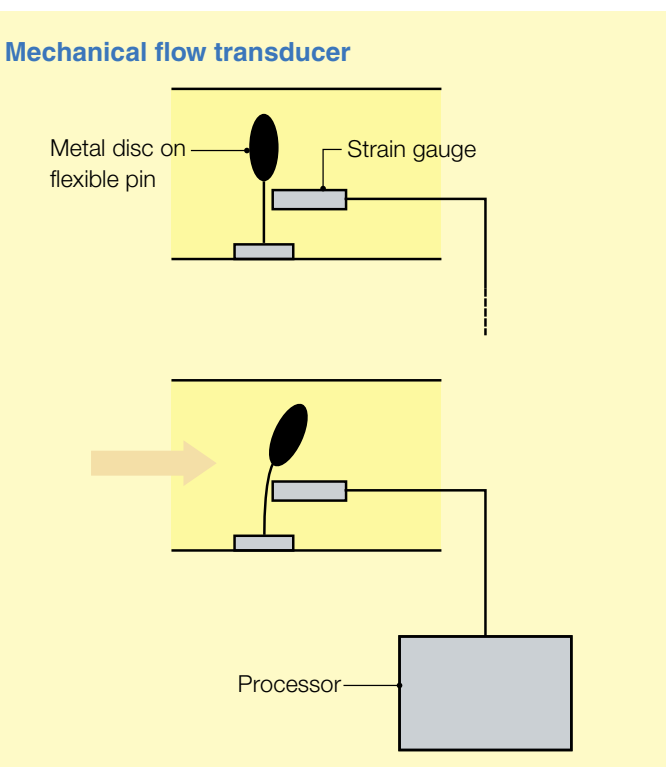
The peak flow meter is a specialized vane meter that measures the maximum flow rate only, without calculation of the associated volume. It is modified so that movement of the vane by expiratory gas results in a steadily enlarging pathway for gas escape. The final position to which the bar has moved corresponds to the peak expiratory flow rate.

Its clinical use is to assess conditions such as asthma, where the problem is largely confined to airway resistance, which limits the expiratory flow rate. Although its use is limited in this respect, it is a very simple and reliable bedside test.

Mechanical flow transducers

Another device using mechanical movement is the flow transducer used in the Siemens Servo™ 300 and 900 series intensive care ventilators. The gas flow is split so that measurement is made in a small side channel using a thin metal disc supported on a flexible pin, resembling a lollipop (Figure 4). The disc is placed in the measuring channel at right angles to the direction of gas flow, which results in it being bent backwards by the flow. A strain gauge situated immediately behind the pin is compressed as it is bent, with a force dependent on the flow. The resulting electrical signal is processed to calculate the flow rate with a high degree of accuracy.

Mechanical flow transducer

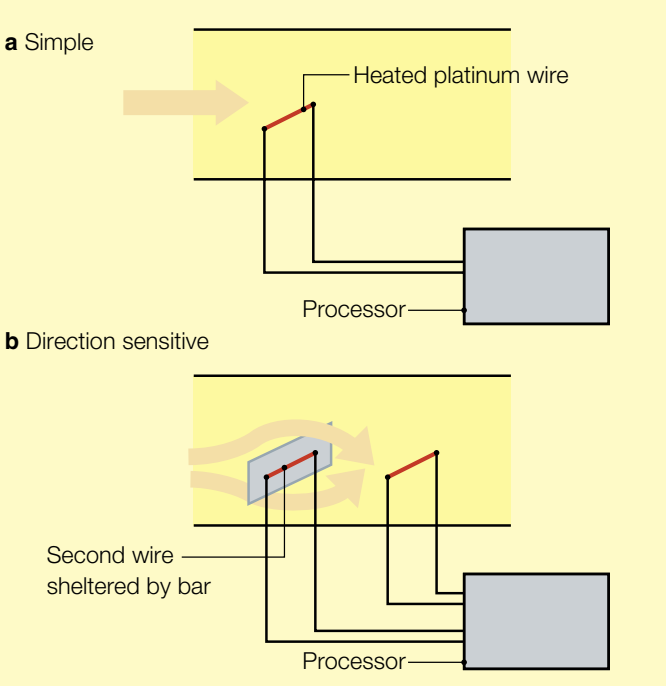


4

Hot wire anemometer

In this device an electrically heated wire is placed in the gas pathway, which is cooled by the gas flow (Figure 5). The degree of cooling depends on the gas flow rate, which can thus be calculated. A modification of this device uses a heated screen or film instead of a wire.

Hot wire anemometer



5

The hot wire (usually platinum) has an operating temperature as high as 400°C, and is incorporated into a balanced Wheatstone bridge circuit. Cooling the wire changes its resistance and unbalances the bridge. Most designs work on the constant-temperature system, whereby a correcting current is applied through the hot wire to compensate for the cooling effect of the gas, maintaining a constant wire temperature and thus restoring the balance in the Wheatstone bridge. This current is measured and from it the gas flow rate is determined. To compensate for changes in the gas temperature, a second wire is usually incorporated, which is maintained at ambient temperature. Minor corrections are also made according to the gas composition, to accommodate the variation in specific heat capacity, but hot wire anemometry is generally extremely accurate.

This cooling effect occurs with flow in either direction, and so to measure exhaled tidal volume the hot wire anemometer is placed in the expiratory limb of the circuit. It can be modified to provide information about the direction of flow by using an additional heated wire placed just downstream from a small bar, as shown in Figure 5b. This bar shelters the wire from the full cooling effects of flow in one direction but not the other, and thus inspiratory and expiratory flows can be calculated separately. For this purpose the sensor must be placed in the Y-piece of the circuit. This technique is particularly useful for neonatal ventilation.

Ultrasonic flowmeter

6

Ultrasonic flowmeters

Ultrasonic flowmeters work on the principle that when an ultrasound signal is being transmitted within a flowing gas, its velocity changes in proportion to that of the gas flow. When the gas flow and ultrasound signal are in the same direction, an increase in signal velocity occurs. Conversely, when the signal is against the direction of gas flow, its velocity decreases. The usual design is to incorporate a pair of ultrasound beams aimed in opposite directions, each with a sensor. The beams can be situated either directly along the line of flow (within the lumen of the tubing) or tangentially across it (Figure 6). When no flow is present the velocity of the two beams is equal, and pulses of ultrasound arrive at the sensors simultaneously. When flow occurs there is a time difference between signal detection at the sensors, from which the gas velocity and flow rate can be calculated. ◆

Martin B Walker is Consultant in Neuroanaesthesia and Intensive Care at Derriford Hospital, Plymouth, UK. He qualified from St Thomas' Hospital Medical School, London; and trained at St Bartholomew's Hospital, London; Southwestern Medical Centre, Dallas; and Oxford. His interests include multimodality monitoring of brain-injured patients.

In 1733, Stephen Hales first measured arterial blood pressure in animals by the direct cannulation of an artery. In 1828, Poiseuille used a mercury manometer to measure blood pressure. Subsequently non-invasive measurement of arterial blood pressure developed. However, direct monitoring of the arterial blood pressure using cannulation of an artery provides the most information on a continuous beat-to-beat basis. Arterial blood pressure monitoring is performed in critical care areas and operating theatres to monitor patients with actual or potential haemodynamic instability.

The preferred site of insertion of the intra-arterial cannula is the radial artery, because it is not an end-artery, it is readily observed for complications and it is in a relatively clean location. Alternative sites include the femoral, brachial and dorsalis pedis arteries. Arterial pressure monitoring can be complicated by haemorrhage, air embolism, thrombosis, infection and inadvertent intra-arterial drug administration.

Indications for arterial pressure monitoring

Direct arterial blood pressure monitoring provides a continuous record of arterial pressure, but also facilitates repeated blood sampling for blood gas and acid–base analysis as well as standard laboratory investigations. Relative indications for its use include:

- patients with organ failure or impairment in a critical care area
- major surgery with a significant risk of major blood loss or haemodynamic instability
- patients with significant cardiac disease undergoing non-cardiac surgery for which close monitoring of their haemodynamic status is required
- manipulation of intracranial pressure and/or cerebral perfusion pressure
- induced systemic hypotension or hypothermia
- severe morbid obesity or burns of the extremities (or other tissue damage) if non-invasive blood pressure cuffs cannot be used
- high risk of significant cardiac dysrhythmia
- inter- and intra-hospital transfer of intubated and ventilated patients.

Equipment used for arterial pressure monitoring

A purpose-built pressure transducer system is required to provide a continuous and accurate arterial waveform. The lumen of the artery is cannulated with a Teflon or polyurethane cannula which is connected to an electronic pressure trans-ducer by non-compliant fluid-filled tubing. A continuous flush system prevents occlusion of the cannula with clots by flushing saline (with or without low-dose heparin) at a constant rate of 1–3 ml/hour. This constant flow is generated by a syringe driver or more commonly with a pressurized bag of fluid (usually 300 mm Hg). The transducer should be placed at the level of the right atrium and the transducer zeroed to atmospheric pressure. This provides the reference point for measuring blood pressure. For monitoring cerebral perfusion pressure, the reference point is altered to a fixed point relating to the intracranial contents, traditionally the external auditory meatus.

Damping or resonance of the monitoring system can cause a decrease or an increase of the pulse pressure around an unaltered mean arterial pressure. This can result in erroneous analysis of the information provided. Clots, air bubbles or a kinked cannula can cause damping. Hyper-resonance is the result of long connecting lines, small tubing or an oversized cannula for the size of vessel. It occurs when the rapidity of the pressure change approaches the natural resonant frequency of the system, producing a distorted and falsely amplified signal.

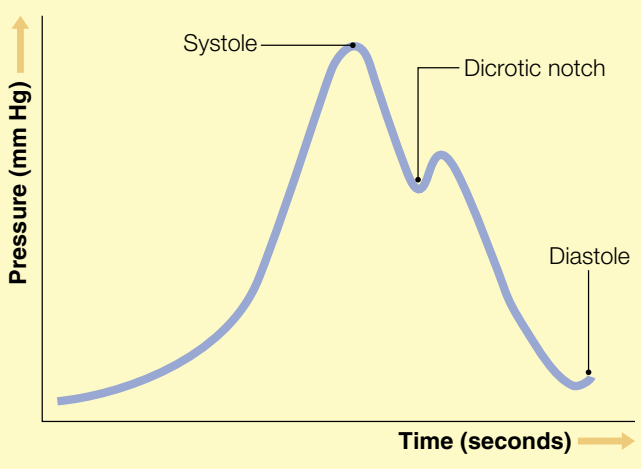
Transducer physics

Left ventricular systole produces a pressure wave within the bloodstream that is propagated along the aorta to the peripheral arteries. The transmission velocity of the wave is considerably faster than that of the actual forward flow of the blood. This pressure wave is transmitted through the cannula in the artery via the fluid-filled tubing to the transducer interface. The mechanical motion of the fluid in the tubing is converted into electrical signals by a mechanoelectrical transducer. The transducer contains a chamber with a diaphragm in its base providing the interface with the fluid. Mechanical motion of the fluid moves the diaphragm in the chamber. Sensing elements attached to the diaphragm measure small changes in resistance and convert this movement into an electrical signal. The small electrical signals that are generated by the pressure transducer are amplified and processed before being displayed on the monitor screen. Individual monitors can display the arterial pressure values on a beat-to-beat basis or averaged over time.

Interpretation of arterial waveform

The waveform of normal individuals has a higher peak pres-sure in large peripheral arteries than in the aorta, but the mean and diastolic pressures are unchanged (Figure 1). The dicrotic notch and pulse pressure also become more prominent peripherally.

Arterial pressure waveform



1

The pressure waveform not only gives systolic and diastolic pressures but also allows indirect assessment of myocardial performance, vascular resistance and intravascular volume. The upstroke of the arterial waveform (dP/dT) gives an indication of myocardial contractility except in patients with aortic stenosis. The area under the arterial pressure waveform from the beginning of the upstroke to the dicrotic notch (closure of the aortic valve) reflects the left ventricular stroke volume. This is also an indication of blood volume. The systolic blood pressure can vary considerably during the respiratory cycle if the patient is hypovolaemic. A reduction of systemic vascular resistance results in a lowering of the position of the dicrotic notch within the waveform. It is important to realize that factors within the monitoring system can impair the accurate assessment of the shape of the waveform. A horizontal line drawn dividing the waveform such that the area above and under the line is equal gives the mean arterial pressure. This is continuously calculated and displayed by all modern monitors. The mean arterial pressure is commonly used for setting a target for an individual patient, such as cerebral perfusion pressure following brain injury or a systemic mean arterial pressure for a critically ill patient with organ failure. The mean arterial pressure can also be calculated by adding one-third of the pulse pressure to the diastolic pressure.

Additional information: analysis of the arterial waveform using standard patient monitors or more advanced dedicated monitoring devices can provide additional information:

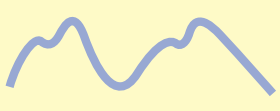
- heart rate (useful during electrical interference and patient shivering)
- limited analysis of heart rhythm
- cardiac output.

The cardiac output can be calculated using software that measures the appropriate area under the curve to determine stroke volume and multiply this by the heart rate. Two current commercial monitors that perform arterial waveform analysis and generate continuous cardiac output values both use a calibration of the calculated output. One system uses lithium chloride dilution (LiDCO, LiDCO Ltd, UK) and the other uses transpulmonary thermodilution (PiCCO, PULSION Medical UK Ltd).

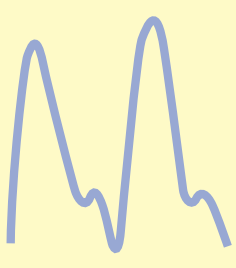
Abnormal waveforms are characteristic of some disease states (Figure 2). ◆

Abnormal arterial waveforms

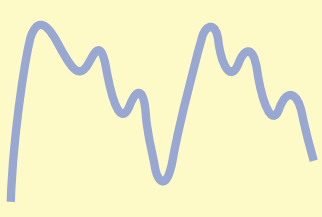
Anacrotic: aortic stenosis



Collapsing: hyperdynamic circulation (e.g. sepsis, anaemia, aortic regurgitation, hyperthyroidism, arteriovenous fistula, pregnancy)



Bisferiens: aortic stenosis with aortic regurgitation



Alternans: left ventricular failure

Monitoring Central Venous Pressure

Vijaya Esuvaranathan
Martin B Walker

Vijaya Esuvaranathan is Specialist Registrar at Derriford Hospital, Plymouth, UK. She qualified from the Flinders University of South Australia, Adelaide, and trained in anaesthetics in Singapore and the South West rotation in Plymouth. Her interests include paediatric anaesthesia and intensive care medicine.

Martin B Walker is Consultant in Neuroanaesthesia and Intensive Care at Derriford Hospital, Plymouth, UK. He qualified from St Thomas' Hospital Medical School, London; and trained at St Bartholomew's Hospital, London; Southwestern Medical Centre, Dallas; and Oxford. His interests include multimodality monitoring of brain-injured patients.

Central venous pressure (CVP) was first measured by Stephen Hales in 1733 in a mare. It was first measured in man by Frey in 1902 but it was not until 1910 that the technique was used clinically. The development of the first plastic (polythene) intravenous catheter in 1945 led to a surge in the use of CVP monitoring. In 1952, Aubaniac described using central venous catheters for cannulation of the subclavian vein to resuscitate wounded soldiers on the battlefield.

Monitoring CVP as a reflection of the right atrial pressure is now commonly used in the management of patients on the wards, those undergoing major surgery, during resuscitation and in the critical care environment. The triad of cardiac contractility, preload and afterload maintain the circulatory dynamics of a patient. These factors determine blood pressure, cardiac output and therefore tissue perfusion. The CVP is commonly used to evaluate preload and thus the volume status of the patient.

Indications for CVP monitoring

Cannulation of a central vein is indicated for transvenous pacemaker insertion, drug or parenteral nutrition admin-istration, poor peripheral venous access, renal support and CVP monitoring.

Assessment of circulatory volume – monitoring CVP is indicated in patients in whom large fluid shifts are occurring or are anticipated. However, it is only one component of haemodynamic monitoring that enables assessment of the circulatory volume; the patient's clinical condition and underlying disease process should also be considered.

Venous air embolism – maintaining a positive venous pressure at the level of the surgery helps to prevent venous air embolism by ensuring that there is no negative pressure gradient. Monitoring CVP facilitates this, but care must be taken that the patient's cardiac status permits the maintenance of a relatively high CVP. Monitoring CVP may then facilitate aspiration of the air embolus via the central venous cannula. Venous air embolism is associated with intracranial surgery, spinal procedures, caesarean section and other operations in which large veins may demonstrate a negative pressure gradient.

Clinical use of CVP monitoring

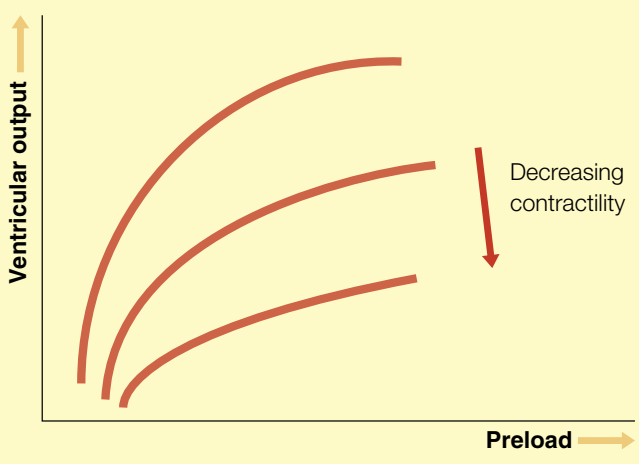
Monitoring CVP is useful for assessing the haemodynamic status of a patient. Absolute values are of little use, it is more important to study CVP trends with fluid challenges and not to use individual values in isolation. The CVP should be used in conjunction with clinical observation of peripheral perfusion; the rate, volume and pressure of the arterial pulse; and the state of hydration.

The underlying principle of using CVP monitoring to determine circulatory volume status is the use of repeated fluid challenges. The CVP is a dynamic measurement and is measured before, during and after administration of a fluid challenge. The fluid is given as aliquots of 100–250 ml of crystalloid or colloid given rapidly via a large-bore intravenous cannula. If the CVP does not increase with a bolus of fluid, it implies that the patient is hypovolaemic. If there is a sustained increase in the CVP, it is likely that the patient is approaching relative fluid overload. This may be isolated hypervolaemia, but may indicate poor myocardial contractility. If the increase is temporary, and the CVP falls back to the previous level, the patient is isovolaemic.

The Starling relationship

Frank Starling, and later others, described the relationship of preload as right atrial pressure to ventricular output (Figure 1). Muscle fibre length and tension are closely related. In the heart, myocardial fibre length and tension determine ventricular volume and ventricular pressure, respectively. The resting tension of cardiac muscle corresponds to the end-diastolic pressure and is dependent on the degree of filling (preload). The end-diastolic volume determines the stroke volume of the heart. Thus the CVP, being almost equal to right atrial pressure (which in turn approximates to right ventricular end-diastolic pressure) becomes the monitor of right heart preload in the absence of tricuspid outflow obstruction.

Starling relationship



Preload determines ventricular output with decreasing contractility. As the preload increases in a poorly contracting heart, the ventricular output decreases

1

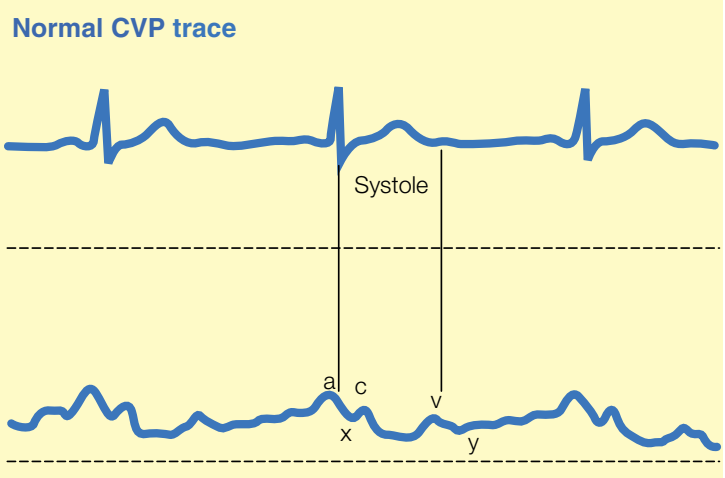
CVP measurement

The patient should lie flat with the reference level being a point level with the right atrium. This is traditionally taken to be the mid-axillary line. The mean CVP should then be measured with the patient in expiration. A wide range of normal values is quoted (usually 0–10 cm H_2O). In spontaneously breathing, isovolaemic, healthy individuals negative values can be seen during inspiration. In the past, CVP monitoring was performed with a water manometer, but this technique is now generally limited to ward use. In theatres and critical care areas this method has been superseded by the use of electronic transducers measuring the CVP in mm Hg (1 mm Hg = 1.3 cm H_2O).

The CVP trace

The normal CVP trace has three positive waves (a, c and v) and two negative deflections (x and y) (Figure 2). Each wave and descent represents distinct elements of the cardiac cycle and may be altered in cardiac disease (Figure 3).

Normal CVP trace



See text for explanation

2

Features of the CVP trace

a wave
- Represents right atrial contraction
- Begins before the first heart sound
- Absent in atrial fibrillation
- Inconsistent in various heart blocks
- Large a waves are seen in tricuspid stenosis, right ventricular hypertrophy, pulmonary stenosis and pulmonary hypertension
- Cannon (giant) a waves occur when the right atrium contracts against a closed tricuspid valve as in complete heart block

c wave
- Caused by bulging of the tricuspid valve into the right atrium during the onset of ventricular contraction
- Occurs after the first heart sound and the QRS complex

x descent
- Produced by atrial relaxation and a downward displacement of the tricuspid valve during ventricular systole
- Absent in tricuspid regurgitation

v wave
- Occurs during right atrial filling with a closed tricuspid valve
- Large v wave seen with tricuspid regurgitation

y descent
- Produced by opening of the tricuspid valve and flow into the right ventricle

3

Factors that increase CVP – causes of an increased right-sided preload produce a rise in CVP. This can occur acutely with any cause of raised intrathoracic pressure (e.g. tension pneumothorax, Valsalva manoeuvre), impaired cardiac function, venoconstriction, relative volume overload or significant intra-abdominal hypertension. Chronic elevation of the CVP is associated with right ventricular dysfunction, obstruction of the superior vena cava (as occurs with intrathoracic malignancy), pulmonary hypertension and chronic respiratory disease.

Factors that decrease CVP include right-sided preload reduction. This occurs when venous return is reduced during hypovolaemia or venodilatation and as a normal variation during the inspiratory phase of spontaneous ventilation.

Factors that cause a false CVP reading – before any monitoring variable is acted on, spurious values must be excluded. During CVP monitoring of a correctly located cannula, spurious volumes can result from inaccurate positioning of the transducer and kinking or occlusion of the central venous cannula. In the presence of hypovolaemia, the vessel wall can be sucked against the monitoring port of the cannula resulting in falsely elevated readings. Rapid infusion of fluids during CVP monitoring can also result in spurious elevation of the CVP. ◆

Physical Principles of Defibrillators

David J Williams
Fiona J McGill
Hywel M Jones

David J Williams is Clinical Fellow in Cardiothoracic Anaesthesia at the Royal Brompton Hospital, London. He graduated from Birmingham University Medical School and completed his CCST in anaesthesia in South Wales. He spent 18 months in Adelaide doing research in diving and hyperbaric medicine.

Fiona J McGill is Specialist Registrar in Anaesthesia at the Royal Gwent Hospital, Newport, Wales. She graduated from the University of Wales College of Medicine, Cardiff.

Hywel M Jones is Associate Medical Director (Teaching) and Sub Dean of Medicine, Gwent Clinical School, University of Wales College of Medicine. He is a Primary FRCA Examiner for the Royal College of Anaesthetists. He graduated from the University of Wales College of Medicine, Cardiff.

Defibrillation is the application of a preset electrical current across the myocardium to cause synchronous depolarization of the cardiac muscle with the aim of converting a dysrhythmia into normal sinus rhythm. Over 135,000 people die annually following acute myocardial infarction. The main cause of sudden death is ventricular fibrillation; the only effective treatment for which is early defibrillation. The defibrillator was invented in 1932 by Dr William Bennett Kouwenhoven.

Capacitors

The most important component of a defibrillator is a capacitor that stores a large amount of energy in the form of electrical charge, then releases it over a short period of time. A capacitor consists of a pair of conductors (e.g. metal plates) separated by an insulator (called a dielectric). Conductors lose and gain electrons easily, and therefore allow current to flow; whereas insulators do not lose their electrons, and hardly allow any current to flow. The maximum working voltage is the voltage that when exceeded causes the dielectric to break down and conduct, often with catastrophic results.

The unit of electric charge (Q) is the coulomb (C). 1 coulomb is the quantity of electricity transported in 1 s by a current of 1 ampere (A) and is equivalent to 6.24 x 10^{18} electrons (Figure 1).

Key formulae and definitions

Current is charge per second	A = Q/s
Power is energy (or work) per second	W = J/s
Power is current x potential difference	W = AV
Stored charge	Q = CV
Stored energy	J = CV
Delivered energy	J = QV/2

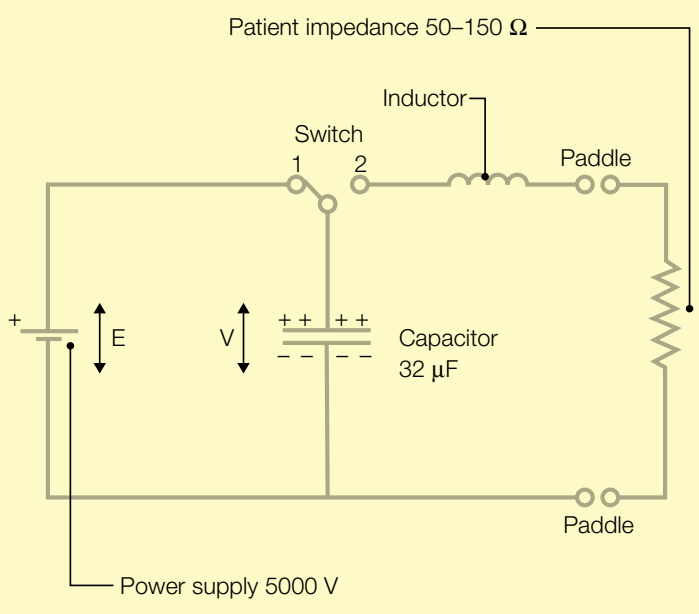
C, capacitance in farads; Q, charge in coulombs; V, potential difference in volts; J, energy (or work) in joules; W, power in watts; A, current in amperes

1

Capacitance (C) is the ability to store charge. A capacitor has 1 farad of capacitance if a potential difference of 1 volt is present across its plates, when a charge of 1 coulomb is held by them (i.e. C = Q/V). Capacitors typically have values of microfarads ($\mu F = 10^{-6} F$), nanofarads ($nF = 10^{-9} F$) or picofarads ($pF = 10^{-12} F$). For a simple capacitor, the capacitance is proportional to the area over which the plates overlap (A), inversely proportional to their distance apart (D), and related to the di-electric constant (E_o). Thus $C \alpha A/D. E_o$

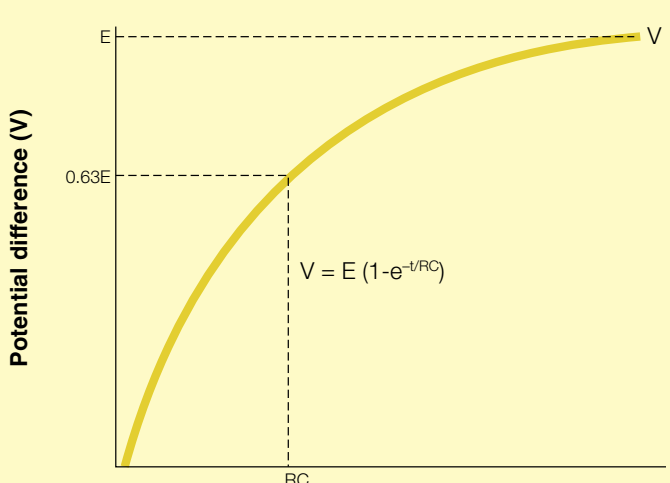
Figure 2 shows a defibrillator. When the switch is in position 1, direct current (DC) from the power supply is applied to the capacitor. Electrons flow from the upper plate to the positive terminal of the power supply and from the negative terminal of the power supply to the lower plate. Therefore current flows and a charge begins to build up on each electrode of the capacitor, with the lower plate becoming increasingly negatively charged, and the upper plate increasingly positively charged. As the charge builds up on the plates, it creates a potential difference across the plates (V), which opposes the electromagnetic force of the power supply (E). Initially when there is no charge on the plates, V is zero and it is easy to move electrons onto the plates. As V increases, however, it opposes further movement of electrons, and increasing work must be done to move more electrons onto the plates. The work done (W) to move charge (Q) through a potential difference V is: W = VQ. Charging a capacitor is therefore an exponential process, with a time constant determined by the capacitance and the resistance of the circuit through which the current flows (Figure 3). When V equals E, the current ceases to flow and the capacitor is fully charged. In this example, the amount of charge stored (Q = CV) is 32 μF x 5000 V = 160 mC.

Mechanism of action of a defibrillator



2

Charging a capacitor



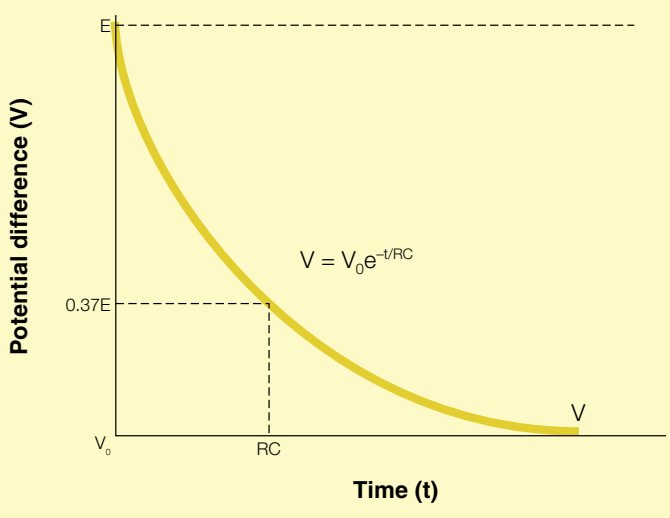
RC is the time constant, and is the time taken for the potential difference across the plates (V) to reach 63% ($1^{-1/e}$) of the value of the electromotive force of the power source (E)

3

Work must be done against the field to store charge in the capacitor. The charged capacitor is therefore a store of potential energy, which may be released on discharge. Theoretically, the amount of energy stored in a capacitor is CV.

When the paddles are applied to the patient's chest and the switch is moved to position 2, a circuit is completed. Electrons stored on the lower (negative) plate of the capacitor are able to pass through the patient and back to the upper plate. Thus, curent flows, stored electrical energy is released, and the potential difference across the plates (V) falls to zero (i.e. the capacitor is discharged). The rate of discharge declines as the potential difference across the plates falls; it is an exponential process (Figure 4) with a time constant determined by the capacitance and the resistance of the circuit through which the current flows.

Discharging a capacitor



4

The energy delivered may be calculated from: Energy (J) = ½ x stored charge (Q) x Potential (V) (i.e. Energy = QV/2). Thus, 400 J = ½ x 160 mC x 5000 V. The apparent loss of half of the stored charge on discharge is due to circuit resistance, radiation and arcing of switch contacts.

Inductors

For successful defibrillation, the current delivered must be maintained for several milliseconds. However, the current and charge delivered by a discharging capacitor decay rapidly and exponentially. Inductors are therefore used to prolong the duration of current flow. They are coils of wire that produce a magnetic field when current flows through them. When current passes through an inductor, it generates a flow of electricity in the opposite direction which opposes current flow as predicted by Faraday's law of electromagnetic induction. This opposition to current flow is called inductance (L) and is measured in henries (H). Inductors typically have values of microhenries (μH).

Power supply

Step-up transformers are used to convert the mains voltage of 240 V AC to 5000 V AC. This is then converted to 5000 V DC by a rectifier. In practice, a variable voltage step-up transformer is used so that different amounts of charge may be selected by the clinician. The control switch is calibrated in energy delivered to the patient (J), because this determines the clinical effect. If a mains supply is unavailable, most defibrillators have internal rechargeable batteries. These supply DC, which is then converted to AC by means of an inverter, and then amplified to 5000 V DC by a step-up transformer and rectifier as above.

Patient factors

Successful defibrillation depends on delivery of the electrical charge to the myocardium. Only part of the total current delivered (about 35 A) flows through the heart. The rest is dissipated through the resistance of the skin and the rest of the body. The impedance of skin and thoracic wall act as resistances in series, and the impedance of other intrathoracic structures act as resistances in parallel with the myocardium. The total impedance is about 50–150 Ω, however, repeated administration of shocks in quick succession reduces impedance.

Safety

Patient: before administering the charge, it is essential to make the correct diagnosis to avoid defibrillating a patient who is already in sinus rhythm. If a defibrillator monitor is being used, check that the leads are correctly connected, and whether the device is monitoring from the paddles or from chest electrodes.

The paddles should be placed across the long axis of the heart to facilitate effective defibrillation. The paddles should not be placed over transdermal patches, because they may block current delivery or if they contain an inflammable substance (e.g. glyceryl trinitrate) may result in burns or explosion. The paddles should not be placed near metal objects, either on the surface of the skin (e.g. ECG leads or electrodes, skin clips, jewellery), or subcutaneously (e.g. implanted pacemakers), because the current follows the path of least resistance through the metal, resulting in arcing, heating or burns. The paddle size should be appropriate for the patient (typically 13 cm diameter for adults): large enough to prevent burns but small enough to deliver an adequate current density.

Conductive gel pads and firm pressure (about 10 kg force) are used to improve electrical contact between the paddles and the patient's chest. Liquid electrode gel should not be used, because excess may cause arcing across the surface of the chest wall or the operator's hands.

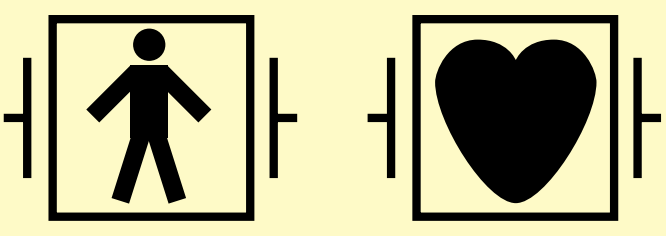
All sources of oxygen must be removed from the patient during defibrillation, because it supports combustion if arcing occurs.

Staff should not touch the bed, patient or any equipment connected to the patient during defibrillation. Fluids may conduct electricity, therefore it is important to ensure that the immediate area is clean and dry. The defibrillator should not be charged until the paddles are applied to the patient's chest, because accidental discharge from open paddles may cause injury or death. The operator must not touch any part of the paddle electrodes. Before administering the charge, the operator must shout "Stand clear!" and check that all staff have done so.

If the defibrillator is charged but a shock is no longer indicated, it should be discharged through the defibrillator internally by turning the control knob to zero before removing the paddles from the patient's chest: charged paddles should never be returned to the defibrillator.

International Electrotechnical Committee (IEC) symbols for 'defibrillator safe' equipment

The two symbols outside each square indicate that equipment is protected from damage if the patient to whom it is connected receives cardiac defibrillation



a Equipment meeting IEC type BF leakage current requirements

b Equipment meeting IEC type CF leakage current requirements

5

Equipment that does not have the 'defibrillator protected' symbol (Figure 5) should be disconnected from the patient before de-fibrillation to prevent damage, heating or arcing effects. The de-fibrillator should never be discharged with the paddles shorted together, as this may cause burning and damage to the electrical contacts. ◆

Physics of Gases

Alexander P L Goodwin

Alexander P L Goodwin is Consultant in Anaesthesia and Intensive Care at the Royal United Hospital, Bath, UK. He qualified from St Thomas' Hospital Medical School, London, and after serving in the Royal Navy for 7 years completed his anaesthetic training in Cambridge and Oxford.

In whichever state a substance exists, it is made up of the same atoms or molecules. The difference between a solid and liquid, and a liquid and gas is the strength of the forces attracting the molecules and atoms to each other. These interparticular forces in a solid hold the molecules together in a lattice. When a solid is heated the kinetic energy of the individual molecules increases, leading to an increase in their vibrational energy, causing them to move apart and the substance to melt. When the molecules in a liquid acquire further kinetic energy, they break away from the interparticular forces and the substance becomes a gas. The kinetic theory accounts for all three states of matter by assuming that above absolute zero, molecules are in continual motion – they have kinetic energy. The molecules exert forces of attraction on each other and so possess potential energy. At small separations the forces must be repulsive, because if the attractive force were to exist down to zero separations, matter would collapse in on itself.

When a liquid and gas coexist, as occurs in a cylinder of *Entonox* (a 50:50 mixture of oxygen and nitrous oxide), molecules enter the liquid as well as leaving it. When the rate at which molecules are leaving and entering the liquid phase becomes equal, the vapour above the liquid is said to be saturated. When a liquid reaches its boiling point all the molecules are transferring into vapour. The terms gas and vapour are synonymous but vapour relates to the gaseous phase at a temperature and pressure close to that at which the gas would condense into a liquid.

In a gas, the atoms collide with each other and their surroundings, and thus a force is exerted. The force exerted over an area equals pressure.

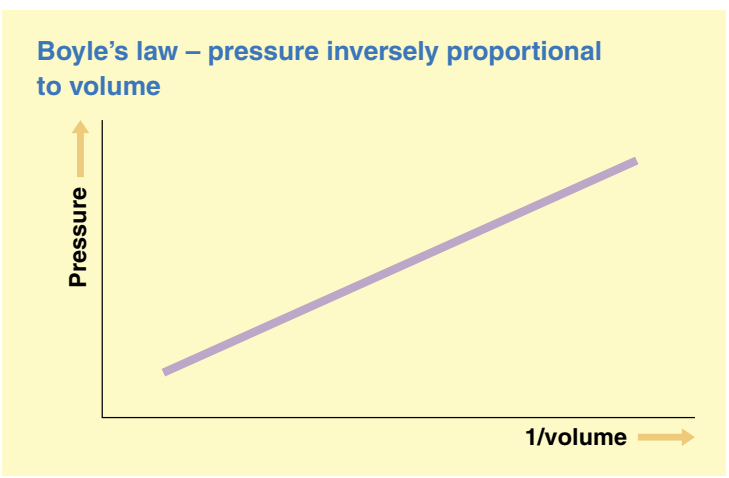
Absolute and relative pressure

Atmospheric pressure at the surface of the earth is due to the gravitational force exerted on air molecules. The pressure depends on air density, which depends on altitude and weather conditions. (Absolute pressure = gauge pressure + atmospheric pressure.)

Zero gauge pressure is equal to atmospheric pressure. If this were not so, empty cylinders would collapse in on themselves. Anaesthetists tend to ignore absolute pressure and record gauge pressures such as ventilator and gas-cylinder pressures, arterial blood pressure and venous pressures.

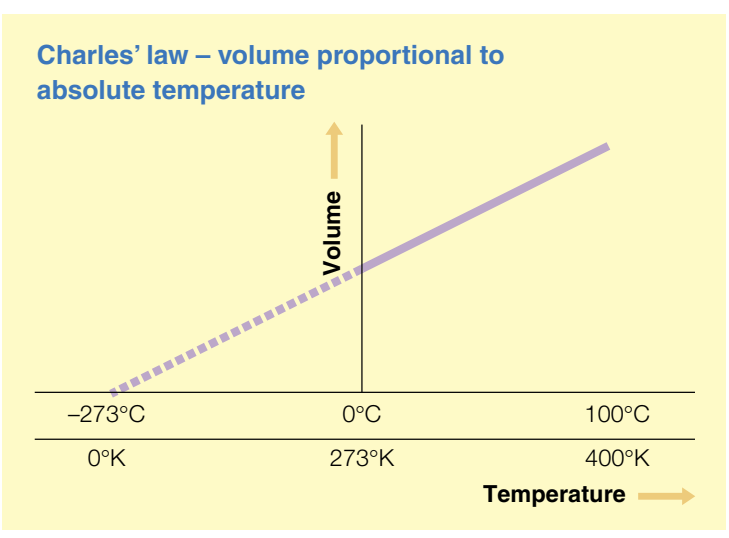
The gas laws

Boyle's law (Figure 1) – at a constant temperature, the volume of a mass of gas is inversely proportional to the pressure (PV = Constant).



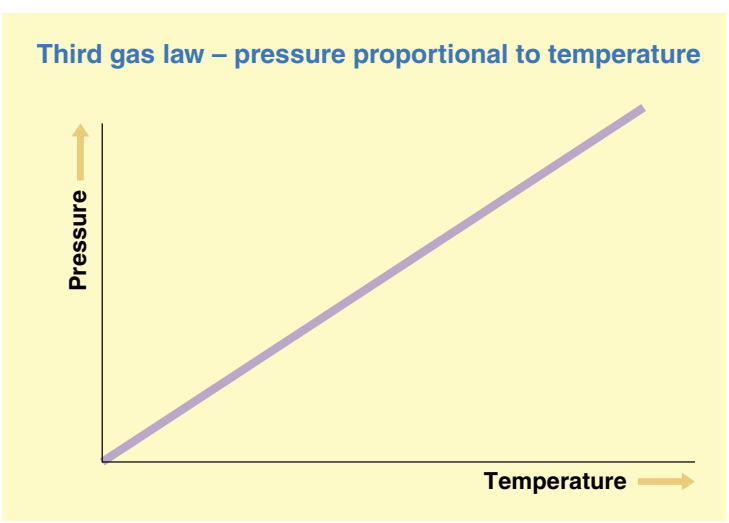
1

Charles' law (Figure 2) – at a constant pressure the volume of a gas is directly proportional to its absolute temperature (V/T = Constant). Volume is proportional to temperature. Gases expand when they are heated and become less dense, thus hot air rises.



2

The third perfect gas law (Figure 3) – at constant volume the absolute pressure varies directly with absolute temperature (P/T = Constant). Pressure is proportional to temperature. An example is the hydrogen thermometer. A constant volume of hydrogen when heated produces a change in pressure.



3

Standard temperature and pressure (STP) – it is important to specify the temperature and pressure at which the measurement of a volume is made. Standard temperature and pressure is defined as 273.15°K (0°C) and 101.325 kPa (760 mm Hg).

The practical effects of temperature change include:

- change in vaporization rates of volatile agents
- increased temperature reduces the density of fluids
- increased temperature reduces the viscosity of liquids
- increased temperature increases the viscosity of gases (increased molecular activity).

Adiabatic changes in a gas

Applying the three gas laws, for a change to occur in the state of a gas, heat energy is either added or taken away from the gas. If the state of a gas is altered without a change in heat energy it is said to undergo adiabatic change. If a compressed gas expands adiabatically, cooling occurs as seen in the cryoprobe. Energy is required as the gas expands to overcome van der Waal's forces. No heat exchange occurs between the gas and its surroundings because the source of energy is from the molecule's own kinetic energy, thus the gas cools as it expands. Conversely, if a gas is rapidly compressed its temperature rises (the Joule–Kelvin principle). When a cylinder connected to an anaesthetic machine is turned on too quickly the temperature rises in gauges and pipelines and in the presence of oil or grease may lead to a fire or explosion.

Dalton's law of partial pressures

In a mixture of gases, the pressure each gas exerts is the same as that which it would exert if it alone occupied the container.

Avogadro's hypothesis

Equal volumes of gases at the same temperature and pressure contain equal numbers of molecules. As the mass of molecules present in a fixed volume varies depending on the individual gas, the number of molecules present is expressed as a mole. A mole is the quantity of a substance containing the same number of particles as there are atoms in 0.012 kg of carbon 12. The number of particles is 6.022×10^{23}. One mole of gas at standard temperature and pressure is contained in a volume of 22.4 litres.

A clinical application would be to calculate the volume of nitrous oxide in a cylinder. A nitrous oxide cylinder contains 2.2 kg of nitrous oxide. The molecular weight of nitrous oxide is 44. One mole is 44 g. At STP we know that 44 g occupies 22.4 litres, therefore 2200 g occupies 22.4 x 2200/44 = 1120 litres.

The universal gas equation (the ideal gas law)

If the perfect gas laws and Avogadro's hypothesis are combined PV/T = Constant. For one mole of gas, PV/T equals the universal gas constant R. The equation can be rearranged to PV = nRT (the universal gas equation) where n equals the number of moles present. The practical application of this law is the use of pressure gauges to assess the contents of a cylinder. The volume, temperature and gas constant remain the same and pressure is therefore proportional to n, the number of moles.

Temperature scales – the triple point of water

Different thermometers use particular thermometric properties. For example, a mercury-in-glass thermometer uses the change in length of a column of mercury confined to a capillary tube of uniform bore; a platinum thermometer uses the increase in resistance with increasing temperature.

To establish a temperature scale it is necessary to make use of fixed points: a fixed point is the single temperature at which it can be confidently expected that a particular physical event always takes place.

The ice point is the temperature at which pure ice can exist in equilibrium with water at standard atmospheric pressure.

The steam point is the temperature at which pure water is in equilibrium with its vapour at standard atmospheric pressure.

The triple point of water is that unique temperature at which pure ice, pure water and pure water vapour can exist together at equilibrium. The triple point is particularly useful, because there is only one pressure at which all three phases (solid, liquid and gas) can be in equilibrium with each other.

Critical temperature

The critical temperature is the temperature above which a gas cannot be liquefied however much pressure is applied (for CO_2 Tc = 31.1°C).

Critical pressure is the minimum pressure that causes liquefaction of a gas at its critical temperature (for CO_2 pc = 73 atm).

Specific critical volume is the volume occupied by 1 kg of a gas at its critical temperature and pressure.

Therefore one can define a gas as a substance in the gaseous phase above its critical temperature. Vapour is the term applied to a substance in the gaseous phase below its critical temperature. Thus, simply increasing the pressure can liquefy a vapour, but not a gas. The relationship between pressure, volume and temperature is displayed as a family of isotherms (Figure 4).

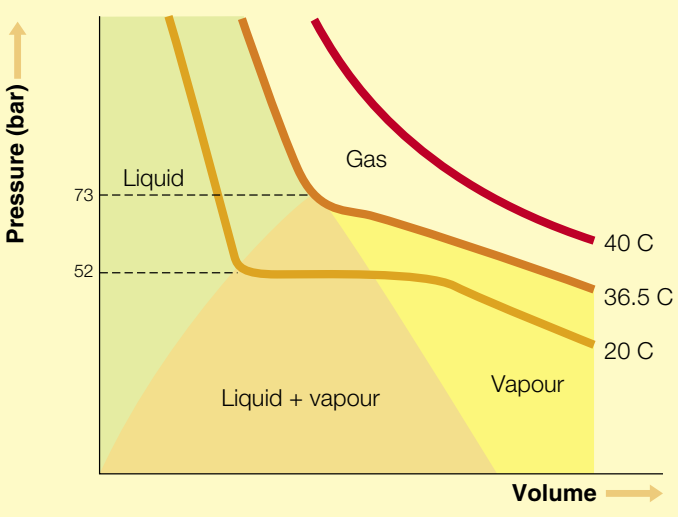
Oxygen, nitrogen and hydrogen are traditionally called permanent gases, because it was thought they could not be liquefied. This is because each of these gases has a critical temperature below room temperature (oxygen –118°C, nitrogen –146°C, hydrogen – 240°C).

Poynting effect (overpressure effect) – the critical temperature and pressure of a gas may be affected when it is mixed with another gas. For example, in a cylinder of *Entonox*, the new critical temperature of nitrous oxide (known as the pseudo-critical temperature) changes to –6°C. Therefore, precautions regarding the cooling of cylinders should be taken into account.

Density and viscosity of gases – fluid flow

Liquids and gases are fluids. The density of a substance is the mass per unit volume ($kg/m^3 = \rho$) (silver, 10500; water, 1000; oxygen, 1.43; air, 1.29; helium, 0.18; hydrogen, 0.09).

Isotherms of nitrous oxide



The isotherm at 40 C is above the critical temperature of nitrous oxide (36.5 C) and threfore obeys Boyle's law. As the volume decreases the pressure rises. At the critical temperature 36.5 C there is a critical pressure at which nitrous oxide becomes a liquid. Liquids are relatively incompressible and therefore a decrease in volume leads to a dramatic rise in pressure. At 20 C as the nitrous oxide is compressed some of it liquefies at a pressure of 52 bar (saturated vapour pressure of nitrous oxide). Further reduction in volume causes more vapour to condense with no change in pressure. When all the vapour is condensed to liquid a rapid rise in pressure is seen with further decrease in volume.

4

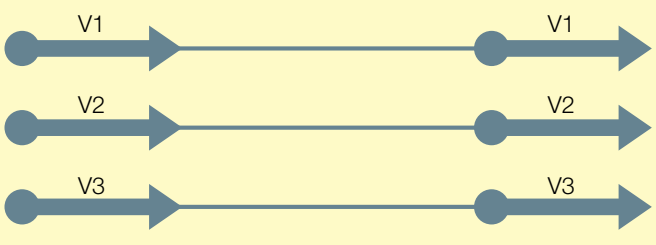
If a fluid is viscous it offers resistance to the motion of any solid through it or to its own motion past a solid body. In both these circumstances (except where the fluid is a gas of very low density) the layer of fluid in immediate contact with the solid is stationary. The motion causes adjacent layers of fluid to move past each other. An internal friction offers resistance to the motion of one layer of fluid past another, and this is the origin of viscous force. In liquids, the internal friction is due to intermolecular forces of attraction. In gases, the friction is due to the interchange of molecules between different layers. This results in the average speed of molecules in adjacent layers changing.

If the flow of a fluid is steady (also known as streamline flow, orderly flow and uniform flow) all the fluid particles that pass any given point, follow the same path at the same speed – they have the same velocity. The path followed by a particle of the fluid is called the line of flow of the particle.

In steady flow, streamlines coincide with the lines of flow. A streamline is a curve whose tangent at any point is along the direction of the velocity of the fluid particle at that point. Streamlines never cross.

Laminar flow is a special case of steady flow in which the velocities of all the particles on any given streamline are the same, though the particles of different streamlines may move at different speeds (Figure 5).

Streamlines of a liquid in laminar flow



Velocities V1, V2 and V3 are not necessarily equal

5

Poiseuille's formula – when considering a viscous liquid undergoing steady flow through a pipe of circular cross-section, the velocity varies from a maximum at the centre of the tube to zero at the walls. Poiseuille originally described the relationship between flow and the properties of the fluid as:

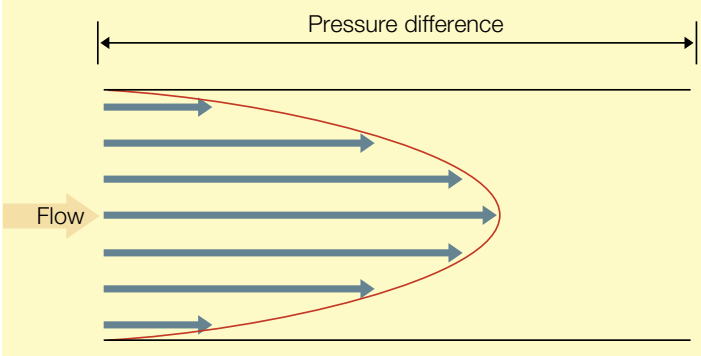
$$Q = \frac{kr^4p}{\eta l} \qquad \text{mathematical analysis shows that } k = \frac{\pi}{8} \text{ therefore}$$

$$Q = \frac{\pi r^4 p}{8\eta l}$$

where: Q is flow; η is viscosity; p/l is the pressure gradient; r is the radius of the tube. The formula applies only to Newtonian fluids (in which viscosity is constant) undergoing steady flow. This applies to all gases and some fluids. Water is a Newtonian fluid; blood is non-Newtonian.

The flow profile of a viscous fluid flowing in a pipe of circular diameter is conical (Figure 6). The fluid flows in a series of concentric cylinders. All the particles within an individual cylinder flow at the same speed. The speed of the cylinder adjacent to the wall of the pipe is zero, and the speeds increase towards the centre.

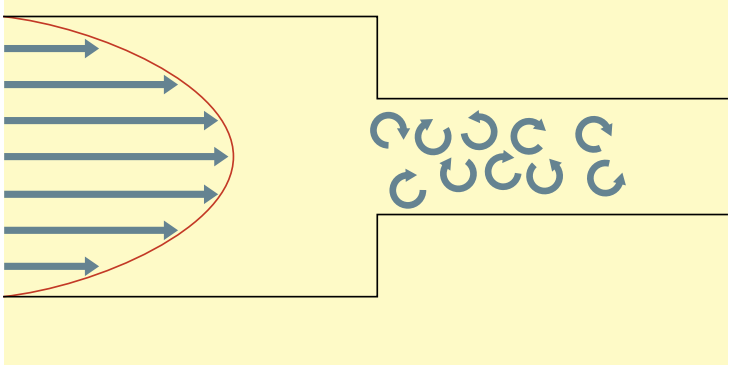
Velocity profile at laminar flow



6

Turbulent flow is also known as disorderly flow. In this type of flow the speed and direction of the fluid particles passing any point varies with time. When laminar flow encounters a constriction, fluid velocity increases and turbulent flow occurs (Figure 7). At turbulent flows the resistance is higher than for a similar laminar flow. The variation in fluid velocity is different in turbulent flow and flow is no longer directly proportional to pressure. The property of a fluid that dictates the degree of turbulent flow is density.

Transition from laminar to turbulent flow



7

The ability to predict the onset of turbulent flow is aided by calculating the Reynolds number (Re). If the Reynolds number exceeds 2000, then turbulent flow is likely to occur. When flow is turbulent there is a change in viscous forces and an increased pressure change along a tube:

$$Re = \frac{v\,\rho\,d}{\eta}$$

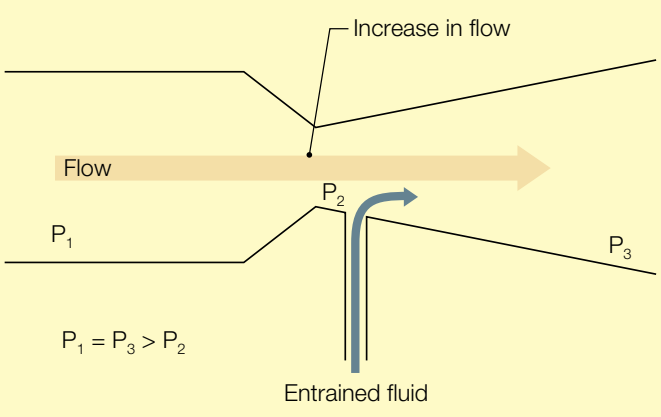
where: v is linear velocity of fluid; ρ is density; d is the diameter of the tube; η is viscosity. The effect of density (mass/volume) on flow is evident in the use of helium and oxygen to promote flow in patients with upper airway obstruction. The density of air is 1.29, of oxygen 1.43 and helium 0.18 at STP.

The Bernoulli equation states that for an incompressible, non-viscous fluid undergoing steady flow, the pressure plus the kinetic energy per unit volume plus the potential energy per unit volume is constant at all points on a streamline:

$$P + \tfrac{1}{2}v^2 + \rho gh = \text{Constant}$$

where: P is the pressure within the fluid; v is the velocity of the fluid; ρ is the density of the fluid; g is acceleration due to gravity; h is the height of the fluid above some arbitrary reference line. It follows from Bernoulli's equation that whenever a flowing fluid speeds up, there is a corresponding decrease in the pressure and/or the potential energy of the fluid and an increase in kinetic energy. If the flow is horizontal the whole of the velocity increase is accounted for by a decrease in pressure as the total energy must remain constant.

Principle of Venturi



8

A Venturi tube has a constriction in which the bore gradually decreases and then increases (Figure 8). At the narrowest point the pressure drops as the flow of a fluid through the constriction increases. In medicine, applications include oxygen masks and nebulizers. Everyday applications include an aerofoil, spinning ball, filter pumps, Bunsen burners and carburettors. ◆

Processing, Storage and Display of Physiological Measurements

John Curnow

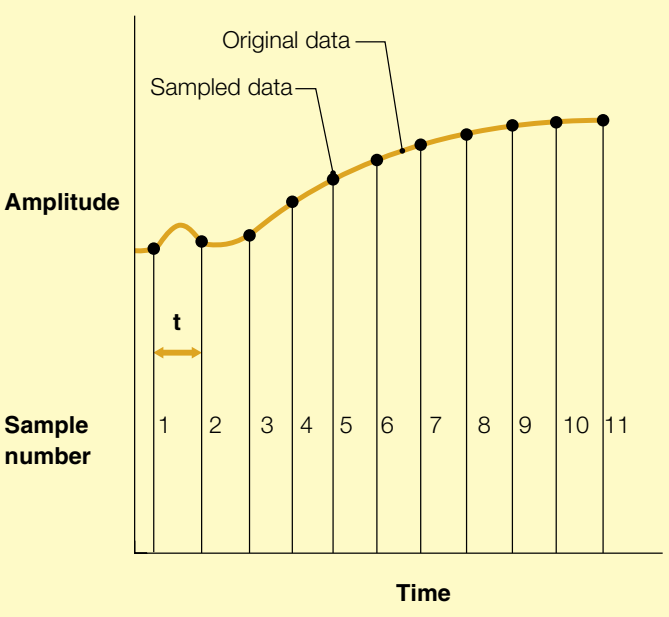
John Curnow is Head of the Biomedical Engineering Group at Derriford Hospital, Plymouth, UK. He gained a degree in electrical engineering from Bath University. He has worked in biomedical engineering for over 30 years. His special area of interest is in developing novel methods for clinical measurements.

The collection, display, analysis and storage of physiological data from patients are important functions for all anaesthetists. Modern electronic patient-monitoring equipment provides these functions, but to understand the final data it is important to have an understanding of the underlying functions involved in each process. Methods of collecting data from patients have changed little in recent years. Analogue electronic data proportional to the physiological variable being measured are the source of most of the signals collected.

Data collection and analysis

The use of micro-computing technology in monitors makes it easier to analyse data, but the data have to be digitized. Digitization consists of taking the instantaneous value, or sample, of the signal at fixed time points and storing these numbers as representation of the signal as shown in Figure 1. The time between each sample is the sample period (t seconds) and its inverse is the sampling frequency or sampling rate (f = 1/t Hz). The shorter the time between each sample or the faster the sampling frequency the closer the series of numbers can replicate the original data. However, there is always a limit on the storage space for the data and, partly for this reason, the sampling rate is kept as low as possible. There is an optimum minimum sampling frequency that allows mathematical reconstruction of the original signal defined by the sampling theorem, called the Nyquist frequency, which is twice the maximum frequency present in the signal. In Figure 1, the data from sample 1 to sample 3 are sampled too slowly and it can be seen that some information is lost, such as the peak between samples 1 and 2, while the data from sample 3 to sample 11 could be sampled at a slower rate without loss of information.

Comparison of sampled data and continuous analogue data



t, time between each sample

1

Digitization is achieved using an analogue to digital converter (ADC) that reads the instantaneous value of a signal when triggered and represents it as a fixed accuracy number. There are two limitations to using digital data. The accuracy of the value is set by the smallest change in signal the ADC can detect, which is often about 1/4096 of the maximum signal size including signal noise and offset. The accuracy of the amplitude data is ± 0.5 v where v is the minimum amplitude change that the ADC can measure. The timing accuracy is set by the sample period and any times must be defined as ± 0.5 t, where t is the sample period.

The raw sampled data collected from the patient can be analysed to extract more useful information in the form of features extracted from the data. Analysis often identifies individual waveform groups in the continuous trace such as an ECG complex within a whole ECG trace. Features are then extracted, such as peak values, mean values and time intervals between known landmarks on the trace. Also, more complex features and interrelationships of multivariate signal features can be calculated. This is usually achieved using signal processing techniques such as digital filters, neural networks and fuzzy logic. Modern signal processing techniques have improved the quality of feature identification and thus improved the quality of the data. Also, the newer methods combined with fast processor speeds have allowed the real time extraction of features such as heart rate variability and EEG frequency spectrum analysis, which require more complex calculations to be performed for their identification.

Data storage

The sampled data that represent the signal and the values of extracted features are usually stored in the short term, and sometimes in the long term, in the monitor. Short-term storage is usually on electronic memory chips. This type of storage is usually used to hold the sampled data long enough for its analysis and display. However, memory chips require power to continue to store data. Therefore, data can be stored only while the system is switched on. In some cases, a battery supply is used to keep the memory active when the rest of the system is switched off. However, long-term storage is not feasible in this way. If the data collection is a single operation such as intermittent collection of blood pressure, the data are held in the memory at least until the next sample period. With many systems, raw digitized data are collected and the features immediately extracted and represented by new numeric values, and it is only these feature values that need to be stored longer term, so the sampled data are erased immediately.

If data have to be stored for months or years, the usual method is to store the information on a disk storage system as used on a PC. The drive may have a removable floppy disk that can store a small amount of data or it may have a hard disk on which large amounts of data can be stored. The floppy disk has the advantage that it can be removed and more disks inserted. Thus, for the storage of relatively small amounts of data, specific to one condition or patient, a floppy disk could be ideal. However, to store large amounts of data and data on multiple patients a hard disk is more suitable. The hard disk may be on a network such as a central station or even a network server rather than within the monitor itself.

The disk system uses magnetic methods of data storage, therefore over years the data quality reduces until it can no longer be read. For long-term data storage it is better to use optical data storage such as CD or, for large amounts of data, a DVD disk.

Data display

The raw data collected and the results of analysis by a monitoring system can be displayed in several different ways. The method of display depends partly on the use to be made of the data and on the type of data.

A basic system may display a set of numeric values for predefined features of the data. The display is often made up of a series of seven segment displays which allows easily identifiable numerals to be displayed. Many bedside blood pressure and oxygen saturation monitors use this type of display where a single set of values is needed for ward observations.

When a similar type of instrument is being used with an anaesthetized patient and regular updates of the values are being taken, then a small screen using liquid crystal display (LCD) may be used to provide a time series chart of the values to allow trends to be detected easily. This type of display allows a number of predefined displays to be used with graphical and alphanumeric displays combined. An example is a pulse oximeter with a numeric display of the most recent value and a trend chart of values over the past hour.

Multivariate monitoring systems, which are typically used during surgery and in the ICU, have a display monitor screen. These screens provide a larger display area and allow a variety of layouts of data with combinations of graphical displays for real time, trend and numeric values. The displays can usually be modified by the user to provide a preferred layout that can be stored and recalled whenever the specific user uses the monitor. The monitor may use a cathode ray tube as the screen or modern systems use colour LCD screens where each dot of the screen is made of three diodes of red, green and blue which are controlled to produce the required colour at each picture cell or pixel.

Modern trends to networked patient management systems are providing entry for patient monitoring data directly to the patient record. This type of system can provide a complex display of monitored data, laboratory results and diagnostic images. ◆

SI Units: Fundamental and Derived

Jeremy A Langton
Richard Struthers

Jeremy A Langton is Consultant Anaesthetist at Derriford Hospital, Plymouth, Devon, UK. He qualified from Guy's Hospital, London, and trained in anaesthesia in London and Leicester. His research interests include airway reflexes and anaesthesia.

Richard Struthers is Specialist Registrar in Anaesthesia in the South West School of Anaesthesia, Plymouth, Devon, UK.

The decimal metric system originates from the creation of the prototype metre and kilogram during the French Revolution at the end of the 18th century. The Systéme International d'Unités (SI) was adopted in 1960 after a meeting of the Conférences Générales des Poids et Mesures (CGPM) – an international convention of 50 member states including all the major industrialized nations.

The system defines seven fundamental units (Figure 1) that are dimensionally independent. The fundamental units can be algebraically combined to create derived units (Figure 2). These derived units can be named and given symbols and can then be used to derive further units. The SI also defines prefixes (Figure 3) for multiples and submultiples of SI units to avoid very large or small numbers and defines the correct usage of SI notation. The prefix attaches directly to the name or symbol of a unit.

Fundamental units

Dimension	SI unit	Symbol
Time	Second	s
Length	Metre	m
Mass	Kilogram	kg
Electrical current	Ampere	A
Thermodynamic temperature	Kelvin	K
Amount of substance	Mole	mol
Luminous intensity	Candela	cd

3

In the UK, the National Physical Laboratory (NPL) is responsible for national standards in measurement and is a member of the conference maintaining the SI units.

Fundamental SI units

Six of the fundamental SI units are based on physical properties of defined systems and therefore are reproducible to a high degree of certainty in any suitably equipped laboratory. The unit of mass (the kilogram) is still dependent on comparison with the original kilogram, which is theoretically at risk of changing over time.

Time (second s)
The second corresponds to the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the caesium-133 atom. Caesium atoms can flip between two energy states by microwave stimulation. In an atomic clock, an oven boils off caesium atoms, which are then magnetically gated to isolate those in one energy state. These are subjected to microwaves to energize them further and a second magnetic gate is used to send those that have flipped energy states to a detector.

The second measured by this technique is accurate to about 2 parts in 10^{15} – equivalent to 1 second in 15 million years. These atomic clocks calibrate Coordinated Universal Time (UTC) which is broadcast globally by radio and navigation satellites.

Length (metre, m)
The metre is the length of the path travelled by light in a vacuum during a time interval of 1/299 792 458 of a second. At NPL the metre is measured through the wavelength of the 633 nm radiation from an iodine-stabilized helium-neon laser, with an accuracy of about 3 parts in 10^{11}. This is equivalent to measuring the earth's mean circumference to an accuracy of about 1 mm.

Mass (kilogram, kg)
The kilogram is defined by the international prototype of the kilogram. The kilogram was originally the mass of 1 litre of water at its freezing point. In 1799 a platinum ingot was cast as the prototype and in 1879 Johnson Matthey and Co. of London successfully cast an ingot of a more stable alloy of platinum and iridium which was then regarded as the standard.

In 1889, 40 copies of the kilogram were made and distributed to national standards laboratories worldwide to be their primary standard. The UK received Kilogram 18, which is now kept at NPL.

Masses can be compared at NPL on a precision balance to an accuracy of 1 microgram. Because mass still requires comparison to a standard it might be regarded as less satisfactory than the other fundamental units.

Electric current (ampere, A)
The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 metre apart in a vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per metre of length.

The ampere is measured at NPL using a current-weighing and induced electromagnetic potential (EMP) method. It is accurate to 0.08 μA.

Thermodynamic temperature (kelvin, K)
The kelvin is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water. The triple point of water is the unique temperature and pressure in a special water cell at which all three phases of water coexist (about 0.01 K above water's freezing point). This can be measured accurately to about 1 mK. From this point, gas and radiation thermometers can be calibrated.

As well as thermodynamic temperature (T) measured in kelvin the SI also recognizes celsius temperature (t) defined by $t = T – 273.15$.

Amount of substance (mole, mol)
The mole is the amount of substance of a system that contains as many elementary entities as there are atoms in 0.012 kilogram of carbon 12. Measurements of the amount of a substance are often made without referring to this definition. Methods are used that give results in moles using measurements made with other SI units.

Luminous intensity (candela, cd)
The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz and that has a radiant intensity in that direction of 1/683 Watt per steradian.

NPL uses a cryogenic radiometer that equates the heating effect of optical radiation with that of electric power. It has an uncertainty of 0.02%.

Derived SI units

Derived units are those which may be expressed in terms of multiplication or division of fundamental units. Certain derived units have been named and given special symbols and may be further combined to express other derived units.

As an example, the SI unit of force, the Newton (N), is defined as the force needed to accelerate a mass of one kilogram by one metre per second per second. Thus one Newton equals one kilogram metre per second squared.

Pressure is defined as the force applied per unit area. The SI unit of pressure, the Pascal (Pa), is therefore derived from Newtons per square metre. Thus one Pascal equals one Newton per square metre or one kilogram per metre per second squared. The use of derived units reduces the number of such longwinded units. ◆

Thermal Energy and States of Matter

David Birt

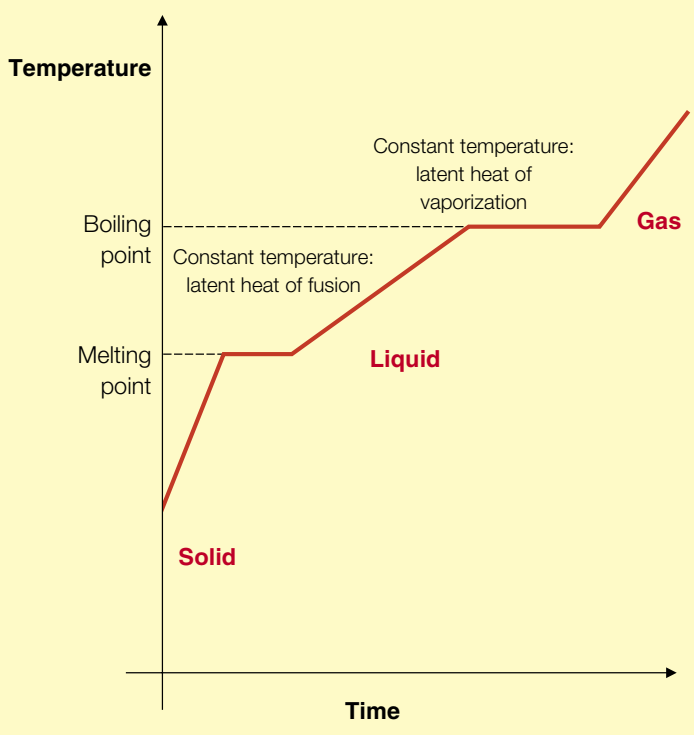
David Birt is Consultant Anaesthetist at Derriford Hospital, Plymouth, Devon, UK, and a Surgeon Commander in the Royal Navy. He qualified from St Mary's Hospital, London, and trained in anaesthesia in the South West of England and Glasgow. His special interests include paediatric anaesthesia and regional blockade.

Molecular and atomic particles in close proximity exert attractive and repulsive electrical forces on each other. The particles oscillate around a fixed position but, as long as the attractive and repulsive forces are in equilibrium, the matter retains its shape and volume and exists as a solid. Thermal energy is a measure of the vibrational kinetic energy possessed by such particles. If the thermal energy level increases, the particles oscillate with greater amplitude and become able to move freely over short distances. The substance becomes liquid because the particles are in company with each other for such a short time that the attractive forces fail to gain a grip. The distance between the particles, however, remains small and although liquid matter has no shape it retains its volume. If more thermal energy is given to the particles, some of them will oscillate with such vigour that they will escape from the influence of the attractive electrical forces. Once clear, they move freely in the space available above the liquid and the matter exists as a gas.

Melting point and latent heat

If a liquid is to solidify, it must lose energy. When this occurs, the temperature of the liquid falls to a level at which an additional quantity of energy must be lost by the particles as they form a coherent structure. At this stage the substance is at its freezing point and, instead of causing a fall in temperature, further loss of energy causes fusion. Likewise, when a solid is supplied with thermal energy, it reaches its melting point and the temperature stops rising as the supplied energy is required to enable particles to break away from the fused structure. These events all occur at the same temperature and the quantity of energy released or required is known as the latent heat of fusion. When matter changes from liquid to gas, a similar phenomenon occurs at the boiling point, and the energy required is the latent heat of vaporization (Figure 1).

Variation in temperature of a substance as it is heated at a constant rate through its states of matter



1

Vapour pressure

When evaporation occurs from the surface of a liquid in a closed vessel, the particles that have left the liquid collide with the wall of the vessel and create pressure. This is known as the vapour pressure and it occurs in addition to any existing atmospheric pressure.

The particles evaporate from the liquid until a stage is reached when they leave and enter the liquid at the same rate. A state of dynamic equilibrium then exists and the number of particles in the space above the liquid has reached a maximum. The vapour is therefore saturated and the vapour pressure exerted at this point is the saturated vapour pressure.

Colligative properties

If the substance in question is a solution, the response to changes in thermal energy is influenced by the number of solute particles present. These altered responses are known as colligative properties and are independent of the chemical properties of the solute. Melting point, osmotic pressure and vapour pressure are all influenced in this way and by comparing them with the corresponding properties of the pure solvent, it is possible to determine the number of solute particles present.

Since osmotic pressure also depends on the number of particles present in solution, colligative properties may be used to determine the osmolality of a solution. An osmometer applies colligative principles by using the depression of a solution's freezing point to calculate its osmolality. The resulting 'real' measurement takes account of the incomplete electrolyte dissociation that occurs in organic solutions such as plasma. ◆

Acid–Base Balance: Maintenance of Plasma pH

John C Atherton

John C Atherton is Senior Lecturer in Physiology at Manchester University. He graduated from Newcastle on Tyne and gained his PhD at Manchester. His research interests focus on renal physiology with particular interest in urinary concentrating mechanisms, renal function in pregnancy and assessment of nephron function.

Maintenance of plasma pH ($-\log_{10}[H^+]$) within the range 7.38–7.42 is an essential requirement for life, because many metabolic processes (e.g. enzymatic reactions) are exquisitely sensitive to changes in H^+ concentration. The range compatible with life is 7.00–7.70 (i.e. a 5-fold change in H^+ concentration). The intracellular H^+ concentration is higher (about pH 7.00) than that in extracellular fluid (ECF), but it is sensitive to changes in extracellular H^+ concentration. ECF is normally alkaline. This narrow pH range must be maintained in the face of the production of large quantities of volatile acid from cellular metabolism (mainly CO_2) and non-volatile acid from the metabolism of fats and certain proteins. The main problem encountered in the homeostatic control of plasma pH is the defence of the alkaline environment in the face of this massive, daily acid load.

Volatile acid: in terms of the total acid production, CO_2 provides the largest contribution at 15–20 mols/day. This can occur either by hydration of CO_2 to form the weak, volatile carbonic acid (equation 1) or by hydroxylation of CO_2 following the splitting of water (equation 2). The products of both reactions are H^+ and HCO_3^-.

$$CO_2 + H_2O = H_2CO_3 = H^+ + HCO_3^- \quad (1)$$
$$H_2O = OH^- + H^+$$
$$OH^- + CO_2 = HCO_3^- \quad (2)$$

Production of this amount of acid would certainly change the plasma pH if it were not for the fact that most of the CO_2 is excreted from the lungs.

Non-volatile acids contribute much less to daily acid production. Such acids include sulphuric acid from sulphur-containing amino acids (e.g. cysteine, methionine), hydrochloric acid from cationic amino acids (e.g. lysine, arginine) and phosphoric acid from the metabolism of phospholipids and phosphorylated amino acids (e.g. phosphoserine). In addition, faecal loss of HCO_3^- from gastrointestinal secretions can be regarded as a significant (and variable) contribution to non-volatile acid production. Metabolism of anionic amino acids (e.g. aspartic, glutamic) and some organic anions (e.g. citrate) yield HCO_3^-, which will partially offset some of the non-volatile acid production. The contribution of non-volatile acids to total acid production depends on dietary composition. If meat is a major component of the diet, non-volatile acids are significant (about 50 mmol/day), whereas this value is lower if vegetables and fruit are the major components.

Buffer systems in body fluids

A buffer system consists of an undissociated weak acid (HA) and its base (A^-), and can be represented by:

$$HA = H^+ + A^- \quad (3)$$

Following the addition of a strong acid, some of the H^+ is mopped up through the formation of more HA and thus the change in free H^+ is limited. Conversely, the decrease in H^+ caused by the addition of strong alkali is limited by freeing H^+ from the weak acid. The main buffer systems in body fluids are given in Figure 1. The main buffer system in plasma is bicarbonate/carbonic acid, therefore pH can be represented using the Henderson–Hasselbalch equation:

$$pH = pK' + \log_{10}\frac{\text{buffer salt}}{\text{weak acid}} = \log_{10}\frac{[HCO_3^-]}{[H_2CO_3]} \quad (4)$$

where pK' is the apparent dissociation constant.

Since there is little H_2CO_3, the acid moiety of the system is primarily CO_2 which is proportional to the partial pressure of CO_2 (pCO_2 mm Hg). Thus:

$$pH = 6.1 + \log_{10}\frac{[HCO_3^-]}{0.03 \times pCO_2} \quad (5)$$

where 0.03 is the solubility coefficient of CO_2 in plasma

$$= 6.1 + \log_{10}\frac{24 \text{ mmol/litre}}{(0.03 \times 40 \text{ mm Hg}) \text{ mmol/litre}} = 7.4$$

Defence mechanisms

Defence of the alkaline environment is achieved through the operation of three basic mechanisms.

- Physicochemical buffering (i.e. removal of the H^+ by the various reactions listed in Figure 1) is instantaneous but only limits the fall in pH.
- Respiratory compensation is rapid (in minutes) and operates via the control of plasma pCO_2 through changes in alveolar ventilation and subsequent evolution of CO_2; plasma pH is returned towards the normal values, but acid–base status cannot be corrected completely.
- Renal compensation is slower (measured in hours or days) and operates via the control of plasma bicarbonate through changes in the renal secretion of H^+, reabsorption and production of bicarbonate; acid–base status can be corrected.

Main buffer systems in body fluids

Blood

• Plasma proteins	HPr	=	Pr^-	+	H^+
• Haemoglobin	HHb	=	Hb	+	H^+
• Bicarbonate	H_2CO_3	=	HCO_3	+	H^+

Interstitial fluid

• Bicarbonate	H_2CO_3	=	HCO_3	+	H^+

Intracellular fluid

• Proteins	HPr	=	Pr	+	H^+
• Phosphate	H_2PO_4	=	HPO_4	+	H^+

Disturbances in acid–base balance

It is evident from equations 4 and 5 that disturbances in acid–base balance can occur via changes in either the numerator (plasma HCO_3^- concentration) or the denominator (plasma pCO_2). Respiratory disturbance occurs if the primary change is altered pCO_2 whereas metabolic (non-respiratory) disturbance occurs if the primary change is altered plasma HCO_3^-. Thus, if pCO_2 is either increased (e.g. asphyxia, chronic pulmonary disease, voluntary hypoventilation) or decreased (e.g. anxiety attacks, rapid ascent to high altitude, voluntary hyperventilation), these disturbances are referred to as respiratory acidosis and respiratory alkalosis, respectively. If plasma HCO_3^- is decreased by addition of non-volatile acids (e.g. uncontrolled diabetes mellitus, renal failure, severe diarrhoea, ammonium chloride ingestion) or increased (e.g. excessive vomiting, sodium bicarbonate ingestion for chronic dyspepsia), these disturbances are referred to as metabolic acidosis and metabolic alkalosis, respectively.

Compensatory responses to these changes can also be predicted from equations 4 and 5. Thus, increasing or decreasing pCO_2 can be compensated for by decreasing or increasing plasma HCO_3^-, whereas acid-induced changes in plasma HCO_3^- can be compensated for by opposite changes in pCO_2. In other words, primary respiratory disturbances are compensated for by metabolic responses, and primary metabolic disturbances by respiratory responses.

Respiratory acidosis

Increasing pCO_2 will lead to a reduction in pH (i.e. the equilibrium in equation 1 is shifted to the right with an increase in H^+ concentration). The plasma bicarbonate buffer system cannot be used to compensate for this change because to do so would need the equilibrium simultaneously moving to the left (i.e. in a direction opposite to that which is causing the change). However, some H^+ will be taken up by non-bicarbonate buffers (plasma proteins and phosphates) with a subsequent small elevation in plasma HCO_3^-. CO_2 readily diffuses across all cell membranes, including capillary and RBC membranes. Thus, interstitial fluid H^+ will increase and thereby lower pH to a large extent because the concentration of non-bicarbonate buffers is low. However, the haemoglobin buffer system will make a significant contribution. Thus, the increasing intracellular CO_2 will be hydrated or hydroxylated in the presence of the catalytic enzyme, carbonic anhydrase, with the end products being H^+ and HCO_3^-. The former will be buffered by the haemoglobin system and the latter will be exchanged for Cl^- across the cell membrane (known as the chloride shift). Thus the first line of defence (physicochemical buffering) will limit but not restore plasma pH.

It should be evident that the second line of defence, respiratory compensation, cannot contribute since the primary cause of the change in pH is respiratory.

The third line of defence, renal compensation, will be important; H^+ will be excreted and plasma HCO_3^- will be increased by the renal tubular cells reclaiming virtually all the filtered HCO_3^- and producing HCO_3^-. As stated above, it can take days to compensate fully for the increase in CO_2. Hence, primary respiratory disturbances are followed by a few days of lowered plasma pH before compensation occurs.

Respiratory alkalosis

Decreasing pCO_2 will lower the denominator of equation 4, hence pH will become more alkaline. Again the plasma bicarbonate buffer system cannot contribute H^+ since this would require a simultaneous shift in the equilibrium (equation 1) to the right. Non-bicarbonate buffers will contribute by releasing H^+ and produce a small reduction in plasma HCO_3^- which will restrict, but not prevent, the rise in pH. Respiratory compensation cannot contribute since the primary disturbance is respiratory. Renal compensation will be important in lowering plasma HCO_3^- by reducing HCO_3^- reabsorption and production by the renal tubular cells.

Metabolic acidosis

Increased production or addition of non-volatile acid to plasma will lower pH. However, the change in pH will be limited by both HCO_3^- and the non-bicarbonate buffer systems:

$$H_2SO_4 + 2NaHCO_3 = Na_2SO_4 + 2H_2CO_3 \quad (6)$$
$$2H_2CO_3 = 2H_2O + 2CO_2$$

Thus, the added H^+ will be buffered so the concentrations of Hb^-, plasma proteins and HCO_3^- will be reduced. The H_2CO_3 so formed will dissociate into CO_2 and H_2O; the CO_2 will be rapidly excreted by alveolar ventilation. In addition, the increase in plasma H^+ will stimulate alveolar ventilation so that a further reduction in pCO_2 occurs. Although these compensatory changes minimize any change in pH, full compensation to return acid–base status to normal requires renal excretion of H^+, and tubular reabsorption and production of HCO_3^-.

Metabolic alkalosis

Following the addition of $NaHCO_3$ or the removal of H^+ through excessive vomiting, the sequence of change is the reverse of that described for the addition of acid. Non-bicarbonate buffers will contribute as will alveolar hypoventilation to minimize the change in pH. Renal compensation will occur through the excretion of HCO_3^-.

Role of the kidneys in regulation of plasma pH

The involvement of the kidneys in acid–base balance is primarily through the reabsorption of filtered HCO_3^- and the excretion of H^+ leading to production of HCO_3^- to replenish buffer stores depleted during buffering of non-volatile acids (i.e. the reverse of the reaction represented in equation 6).

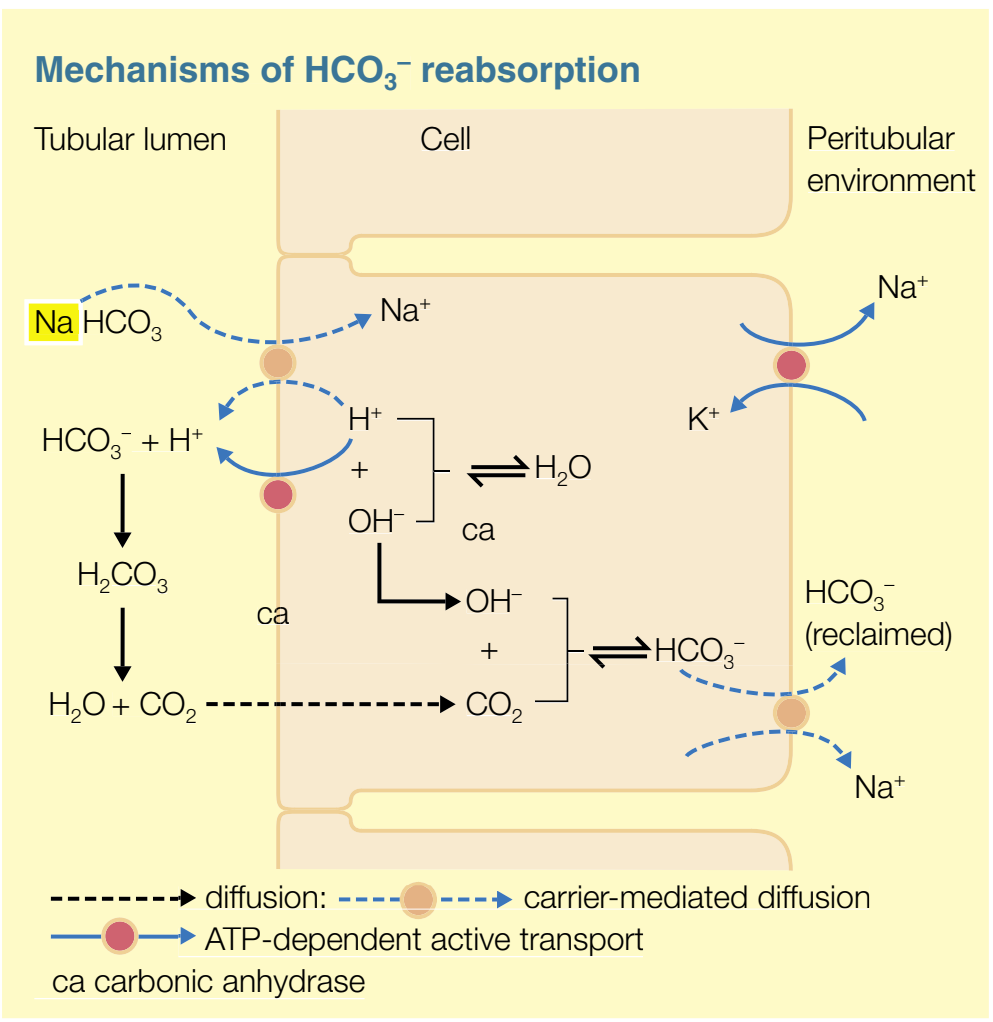
Reabsorption of filtered HCO_3^-: daily filtered HCO_3^- (calculated as glomerular filtration rate x plasma HCO_3^- concentration) approximates 4–5 moles. Renal reabsorption of this ion is in excess of 99.9% of the filtered load. If this high percentage reabsorption did not occur, bicarbonate stores in the body would soon be depleted.

In terms of the contributions of the different nephron segments, 70–85% of the filtered load is reabsorbed in the early part of the proximal tubule. The contributions of the loop of Henle, distal tubule and collecting duct are 15–20%, 3–5% and 1–2% of the filtered load, respectively.

The mechanisms for the reclamation of the filtered HCO_3^- are shown in Figure 2. Intracellular H^+, formed from the splitting of H_2O, is secreted into the tubular lumen by either passive Na^+/H^+ exchange using a protein carrier, or active transport via the energy-requiring proton pump (H^+-ATPase). A third mechanism (H^+/K^+-ATPase) operates in the α intercalated cells in the collecting duct but, quantitatively, this is far less important than the other two mechanisms.

Secreted H^+ combines with filtered HCO_3^- in the tubular lumen to form H_2CO_3 which dissociates to CO_2 and H_2O. The presence of carbonic anhydrase in the luminal cell membrane (proximal tubule and thick ascending limb of the loop of Henle) ensures that this dissociation occurs rapidly. The CO_2 formed diffuses into the cell where it is hydroxylated by OH^- (catalysed by carbonic anhydrase) to form HCO_3^-, which moves across the basolateral cell membrane into the peritubular environment on either Na^+-HCO_3^- co-transporters or Cl^--HCO_3^- ion exchangers.

The rate of HCO_3^- reabsorption appears to be influenced by a number of factors including the amount filtered, ECF volume and arterial pCO_2. Thus, if the amount filtered is increased by increasing the filtered load, total reabsorption is increased. Following ECF volume expansion, reabsorption is reduced. The mechanisms by which these changes occur are uncertain, but the fact that Na^+ reabsorption is similarly affected suggests that HCO_3^- and Na^+ might be linked. The influence of arterial pCO_2 on HCO_3^- reabsorption is thought to be by changes in the filtered load and by a direct effect on the active pumps for H^+ secretion.



2

Production of HCO_3^-: the secretion of H^+ as described above does not lead to net excretion because the CO_2 formed within the tubular lumen is returned to the cell where more H^+ is formed and then secreted. However, H^+ can be excreted either as neutral ammonium salts (e.g. $(NH_4)_2SO_4$) or as acid buffer salts (NaH_2PO_4). The latter is also referred to in some texts as the excretion of titratable acid. Both these routes for H^+ excretion lead to the formation of one new HCO_3^- for every H^+ secreted.

Excretion of NaH_2PO_4: the mechanisms involved in the formation and excretion of NaH_2PO_4 are shown in Figure 3. H^+ secreted into the lumen, combines with the filtered neutral buffer salt (NaH_2PO_4) to form the acid buffer salt. Intracellular splitting of water to form the H^+ for secretion provides OH^- which combines with CO_2 to form HCO_3^- which moves into the peritubular environment with Na^+ released from the neutral salt. Formation of HCO_3^- by this mechanism occurs in the proximal tubule, distal tubule and collecting duct. Note that unlike the reclamation of filtered HCO_3^- (Figure 2), HCO_3^- is newly formed and thus will replenish some of the HCO_3^- utilized in buffering non-volatile acid (equation 6).

The rate of excretion of titratable acid will be influenced by the availability of the urinary buffers, the pK of these buffers and tubular fluid pH. The minimal tubular fluid pH is about 4.4. This probably represents the maximum gradient against which H^+ ions can be excreted. At this pH, it is likely that the buffering capacity afforded by the neutral phosphate buffers (pK = 6.8) will have been exceeded; in other words, all the phosphate will be in the acid form (NaH_2PO_4). Under these conditions, increases in H^+ excretion would occur by increasing plasma PO_4^- concentration (thus filtered load) or if other urinary buffers were available. Creatinine is such a buffer (pK about 5), but it is present only in low concentrations and, therefore, will not make a significant contribution.

Clearly, if these were the only mechanisms available for H^+ ion excretion, urinary pH would soon decrease to the minimal value (i.e. there would be little further net secretion of H^+ and both extracellular and intracellular acidosis would occur) with the pH decreasing well below the range compatible with life. The fact that this does not occur indicates that other mechanisms by which H^+ can be excreted with minimal changes in urinary acidification are involved.

Excretion of ammonium buffer salts: the mechanisms involved in the formation and excretion of NH_4^+ salts are shown in Figure 3. H^+ produced within the cell combines with NH_3 to form NH_4^+. This occurs either within the cell as in the proximal tubule, or in the collecting duct lumen.

In the proximal tubule, NH_3 is derived from deamination of glutamine and NH_4^+ gains access into the tubular lumen by replacing H^+ on the Na^+/H^+ exchanger in the apical membrane. This NH_4^+ can be reabsorbed from the thick ascending limb of the loop of Henle, perhaps by replacing K^+ on the triple transporter ($Na^+/K^+/2Cl^-$) in the apical membrane. Since water is not reabsorbed in the thick ascending limb of the loop of Henle, NH_4^+ reabsorption will contribute to the single osmotic effect which is multiplied by countercurrent multiplication. A steep corticopapillary concentration gradient for NH_4^+ will be produced with the highest value in papillary interstitial fluid. As with all buffer systems, the NH_4^+/NH_3 system exists as two moieties, so the concentration of NH_3 increases with NH_4^+ concentration. This high concentration will promote NH_3 diffusion into the collecting duct lumen where it will combine with secreted H^+ to form the impenetrable NH_4^+ – a process known as diffusion trapping or non-ionic diffusion. In the α intercalated cells of the collecting duct H^+ is secreted either by H^+-ATPase or the active H^+/K^+ exchanger, both of which are found in the apical membrane. The rapid removal of NH_3 as NH_4^+ maintains the favourable gradient for NH_3 diffusion, thereby enabling secreted H^+ to be removed. As with the excretion of titratable acid, Figure 3 shows that secretion of both NH_4^+ in the proximal tubule and H^+ in the collecting duct results in the production of HCO_3^- which moves, with reabsorbed Na^+, into the peritubular environment (i.e. H^+ excretion leads to replenishment of the HCO_3^- buffer stores depleted by addition of non-volatile acids).

The rate of NH_4^+ excretion appears to be influenced by urinary pH, and the severity and duration of the acidosis. The first appears to modify NH_3 secretion and the second appears to be related to the quantity of intracellular NH_4^+ produced in the proximal tubules.

Action Potential: Generation and Propagation

Anthony C Wareham

Anthony C Wareham was Senior Lecturer in Physiological Sciences at the University of Manchester until taking early retirement in April 2001. He obtained his BSc in Zoology and his PhD from Durham University. His research interests focus on the electrophysical properties of skeletal muscle during development, denervation and disease, particularly muscular dystrophy.

Nerve and muscle cells have a highly developed ability to generate and propagate electrical impulses. An impulse, the action potential, is a reversal of the potential developed across the cell membrane at rest.

Resting membrane potential

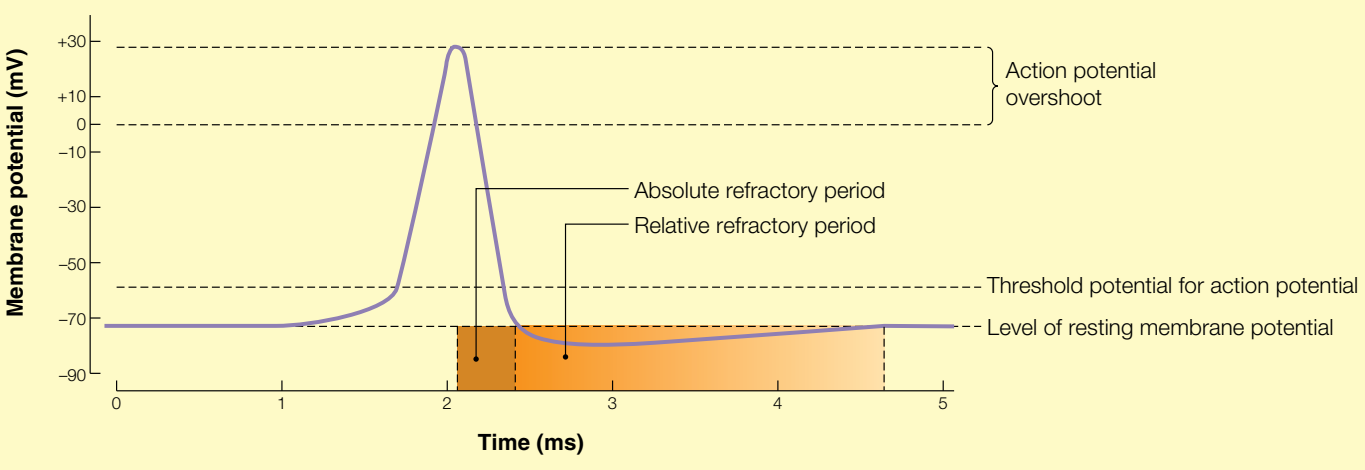
Electrically excitable cells normally have a potential of 70–90 mV across their cell membranes, with the inside negative. The K^+ concentration inside the cell is 28–30 times greater than that outside, whereas the Na^+ concentration is about 14 times greater outside. These differences are generated and maintained by the Na^+/K^+ pump. However, it is the presence in the membrane of Na^+ and K^+ leak channels, which are passive and always open, that allows the generation of the membrane potential. Because the membrane is 100 times more permeable to K^+ than to Na^+ there is a greater tendency for K^+ to diffuse out of the cell than for Na^+ to diffuse in. Such a net movement of positive charge out of the cell sets up a potential difference across the membrane with the inside negatively charged. When the difference is great enough (–70–90 mV), the negativity inside is sufficient to prevent any further net outward movement of K^+. At this point an electrochemical equilibrium is established. Thus, the resting membrane potential is sensitive to change in the extracellular K^+ concentration because this upsets the established equilibrium and leads to an adjustment of K^+ distribution, reflected in a change in resting membrane potential. Therefore, hyperkalaemia results in membrane depolarization and hypokalaemia in hyperpolarization. Since there are also Na^+ leak channels, there is a small resting Na^+ permeability and consequent slight depolarization at rest that modifies the K^+ electrochemical equilibrium and reduces the magnitude of the resting membrane potential by a few millivolts. A major value of the resting membrane potential is that it can be changed transiently, simply by altering the membrane ion permeability, and thus can generate electrical signals. Usually these are not propagated but serve to transduce sensory stimuli and to generate synaptic potentials such as the end-plate potential at the neuromuscular junction. The main exception is the action potential, which is bigger than any synaptic potential and is propagated.

Generation of the action potential

An important property of the cell membrane of electrically excitable cells is the possession of two types of voltage-gated ion channels. These are the voltage-gated Na^+ and voltage-gated K^+ channels that respond to depolarization by opening and allowing either Na^+ or K^+ to diffuse down their chemical gradients. Thus, when the Na^+ channel opens there is a net diffusion of Na^+ into the cell and when the K^+ channel opens there is a net diffusion of K^+ out of the cell. At the resting membrane potential most voltage-gated channels are closed. Other types of ion channels are opened, or gated, by chemical transmitters (e.g. by acetylcholine at the neuromuscular junction).

When an excitatory stimulus of adequate strength, a threshold stimulus (one that takes the membrane potential to –60–55 mV), is applied to a resting nerve or muscle cell, it results in the activation or opening of all the voltage-gated Na^+ channels at the point of stimulation. This results in an inward rush of Na^+ down its concentration gradient. Such inward movement of positive charge depolarizes the membrane and typically generates a positive potential of about 30–40 mV. This is the depolarizing phase of the action potential which, because it takes the membrane from its negative resting value across zero potential to a positive value, is said to ‘overshoot’. Generation of this overshoot is fast, typically taking less than 1 ms (Figure 1). To act as an effective signalling system it is essential that the membrane potential is returned to its resting value quickly. To understand how this is achieved requires a knowledge of some of the properties of voltage-gated Na^+ and K^+ protein channels.

Changes in membrane potential during a neuronal action potential



A skeletal muscle action potential is similar except that the resting membrane potential is 10–15 mV more negative and it may last for 5 ms

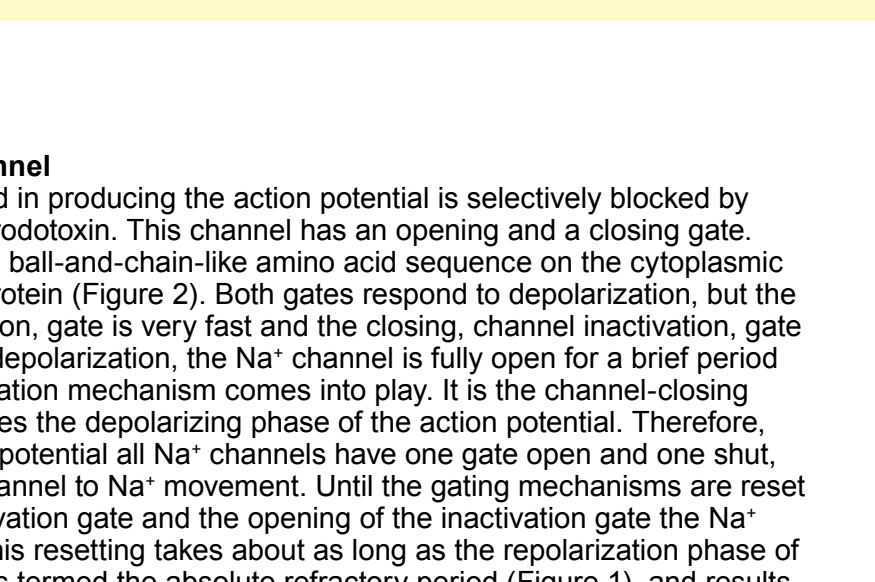
Voltage-gated Na^+ channel

The Na^+ channel involved in producing the action potential is selectively blocked by the puffer fish poison tetrodotoxin. This channel has an opening and a closing gate. The inactivation gate is a ball-and-chain-like amino acid sequence on the cytoplasmic surface of the channel protein (Figure 2). Both gates respond to depolarization, but the opening, channel activation, gate is very fast and the closing, channel inactivation, gate is slower. Therefore, on depolarization, the Na^+ channel is fully open for a brief period of time before the inactivation mechanism comes into play. It is the channel-closing mechanism that terminates the depolarizing phase of the action potential. Therefore, at the peak of the action potential all Na^+ channels have one gate open and one shut, effectively closing the channel to Na^+ movement. Until the gating mechanisms are reset by the closing of the activation gate and the opening of the inactivation gate the Na^+ channel is inexcitable. This resetting takes about as long as the repolarization phase of the action potential and is termed the absolute refractory period (Figure 1), and results in action potentials being unitary events, with no possibility of summation.

Voltage-gated K^+ channel

The K^+ channel involved in excitation is different from the Na^+ channel because it is not blocked by tetrodotoxin but by tetraethyl ammonium ions and it does not have an inactivating mechanism but only an activation or opening mechanism, initiated by depolarization (Figure 2). However, its activation mechanism is delayed so, although it is activated at the same time as the Na^+ channels, it takes longer to open. It is fully open at the peak of the action potential just as the Na^+ channel is inactivated. At this stage, the inside of the cell is positive and, with the high internal K^+ concentration, there is both an electrical and chemical force driving K^+ out of the cell. Such outward movement of positive ions drives the membrane potential in a negative direction, leading to repolarization of the resting membrane. The K^+ channel also closes quite slowly and there is thus an extended period of high K^+ permeability after an action potential that may last for several milliseconds and is termed the relative refractory period (Figure 1). During this period, owing to the high resting K^+ permeability, the membrane is electrically stable and requires a larger stimulus to reach threshold for a further action potential to be generated.

Ion movements during an action potential



Changes in membrane permeabilities to Na^+ (green) and K^+ (red) during an action potential, shown in black. Associated figures indicate the states of Na^+ and K^+ voltage-gated channels at different stages of the action potential. The Na^+ channel is always shown on the left of the K^+ channel.
ECF, extracellular fluid; ICF, intracellular fluid

Membrane currents

There is a high density of voltage-gated Na^+ and K^+ channels in the excitable cell membrane. The sum of their individual activities is measured as membrane currents and it is these currents flowing across the resistance of the cell membrane that can be recorded as depolarizations. A threshold stimulus activates sufficient Na^+ channels to lead to a strong inward Na^+ current. This inward current activates further Na^+ channels in the area in a positive feedback manner until all are activated and the peak inward Na^+ current is flowing. The action potential is a single all-or-none event. Suddenly the inactivating mechanism of Na^+ channels stops the inward Na^+ current. This is the point where the K^+ channels are fully open and there is a strong outward K^+ current flowing. This current stops quite slowly, after which the resting permeabilities of the membrane are re-established. The action potential is brief, lasting 0.5–1 ms in large axons and up to 5 ms in skeletal muscle fibre. Because action potentials are unitary all-or-nothing events, stimulus intensity in the nervous system is coded by the frequency of action potentials transmitted and not by the magnitude of the signal. Thus, the nervous system is a frequency-modulated signalling system.

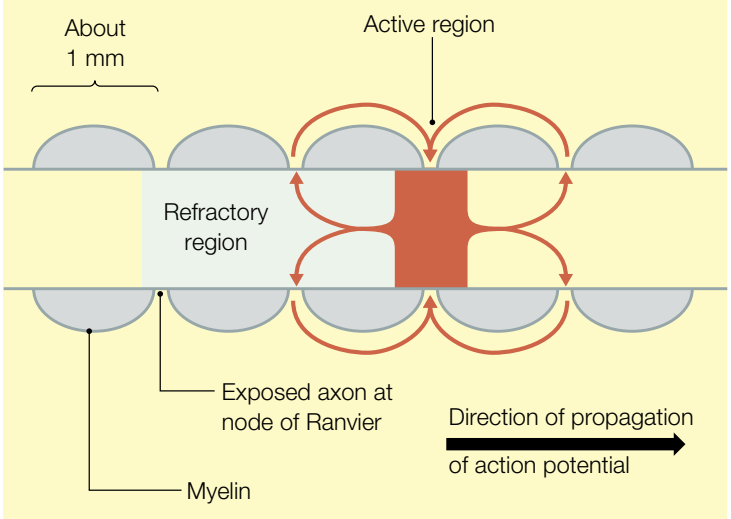
Membrane ion movements

These membrane currents result from the movement of ions into or out of the cell. However, it is important to realize that the cell does not fill up with Na^+ during the action potential. It is best to consider that the events of the action potential concern only the membrane and the ions on its surfaces. Thus, while there is a massive, but brief, increase in Na^+ permeability to generate the action potential, the number of ions that move into the cell during this increase is small in comparison to the volume of the cell. It is the movement of these positive ions that generates the inward current and not their total concentration in the cell. It can be calculated that such Na^+ influx results in a minute increase in the whole cell Na^+ concentration. Because of this, the Na^+/K^+ exchange mechanism in the membrane is not directly involved in the generation of the action potential. It is not necessary to remove all the influxing Na^+ before another action potential can occur. In fact, tens of thousands of normal action potentials may be generated in a cell whose Na^+/K^+ pump has been blocked. The role of the pump is to maintain ion gradients across the membrane and it will eventually remove the Na^+ that enters during excitation. However, its rate of pumping is relatively slow and it plays no part in the repolarization phase of the action potential.

Propagation of the action potential

At the site of action potential generation, the inside of the cell is positive. The area of membrane around this is at rest and inside is negative. Such a difference in polarity results in the movement of positive ions away from and negative ions towards the activated area. Similar but opposite effects occur outside the cell membrane. This leads to the generation of electrotonic potentials flowing through regions of the membrane adjacent to the active areas driving the resting membrane potential towards the threshold for activation. Where this electrotonic current is intense enough, voltage-gated Na^+ channels are activated and another action potential is generated. In this way, the action potential appears to move along the cell membrane (Figure 3). In fact, it is being generated wherever there are voltage-gated Na^+ channels. In the case of muscle cells and unmyelinated neurons this is all over the surface membrane. In myelinated axons, Na^+ channels occur only at the nodes of Ranvier and therefore this is where the subsequent action potential is generated. The electrotonic potentials flowing around an activated node are sufficiently intense to reach, with the help of the insulating properties of myelin, the next node of Ranvier (about 1–2 mm apart) at a sufficient intensity to cross the threshold. The action potential thus appears to ‘skip’ down the myelinated axon and results in saltatory conduction (from the Latin *saltare* to leap or dance). An action potential proceeds away from the site of initial generation and cannot reverse direction because of the absolute refractory period of the membrane previously activated (Figure 3). In electrical terms, the generation of an action potential is relatively slow and therefore propagation down a muscle fibre or unmyelinated axon is slow (about 1 m/s). However, in a myelinated axon, because the electrotonic potentials spread very rapidly, and because an action potential is generated only at discrete portions of the axon, conduction velocity is relatively quick; in large type A fibres it is up to 140 m/s. ◆

Propagation of an action potential in a myelinated axon



The active region where an action potential is occurring, shown in red, is associated with electrotonic potentials that are strong enough to activate the membrane 1 mm away at the next node of Ranvier. The direction of propagation is ensured by the refractory nature of the activated membrane. Electrotonic potentials travel much faster than an action potential, therefore myelination significantly increases conduction velocity

Adrenocortical Hormones

Adrian Heald

Adrian Heald is Locum Consultant Endocrinologist at Hope Hospital, Salford, UK. He qualified from the University of Oxford and trained in endocrinology in Manchester. His research interests include the IGF system in relation to the epidemiology of diabetes and cardiovascular disease.

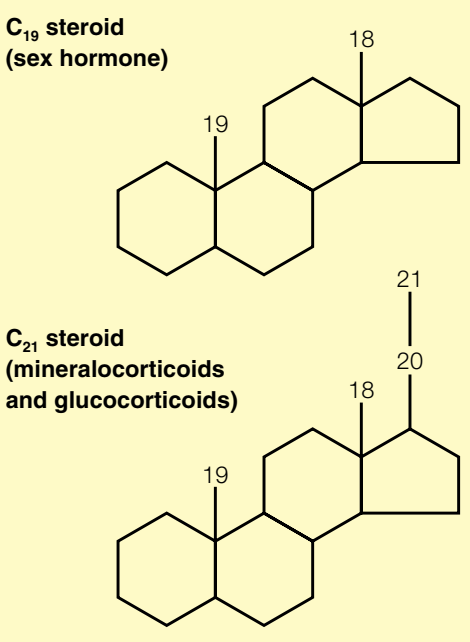
If adrenocortical disorders are untreated they are associated with significant morbidity and mortality, however, effective treatments are available that can dramatically alter the course of the disorder. Thus, a high index of clinical suspicion coupled with use of established algorithms for investigation is an appropriate clinical strategy.

Adrenal cortex

Mineralocorticoids (aldosterone) and glucocorticoids (cortisol)

Synthesis and release: all the hormones of the adrenal cortex are derived from cholesterol. This can be synthesized in the gland or taken up from the circulation. The mineralocorticoids and glucocorticoids have 21 carbon atoms in their chemical structure and may be called C_{21} steroids (Figure 1). The sex hormones, which are normally synthesized in small amounts relative to gonadal production, are mainly androgens, contain 19 carbon atoms and may be called C_{19} steroids.

Basic structures of the steroid hormones

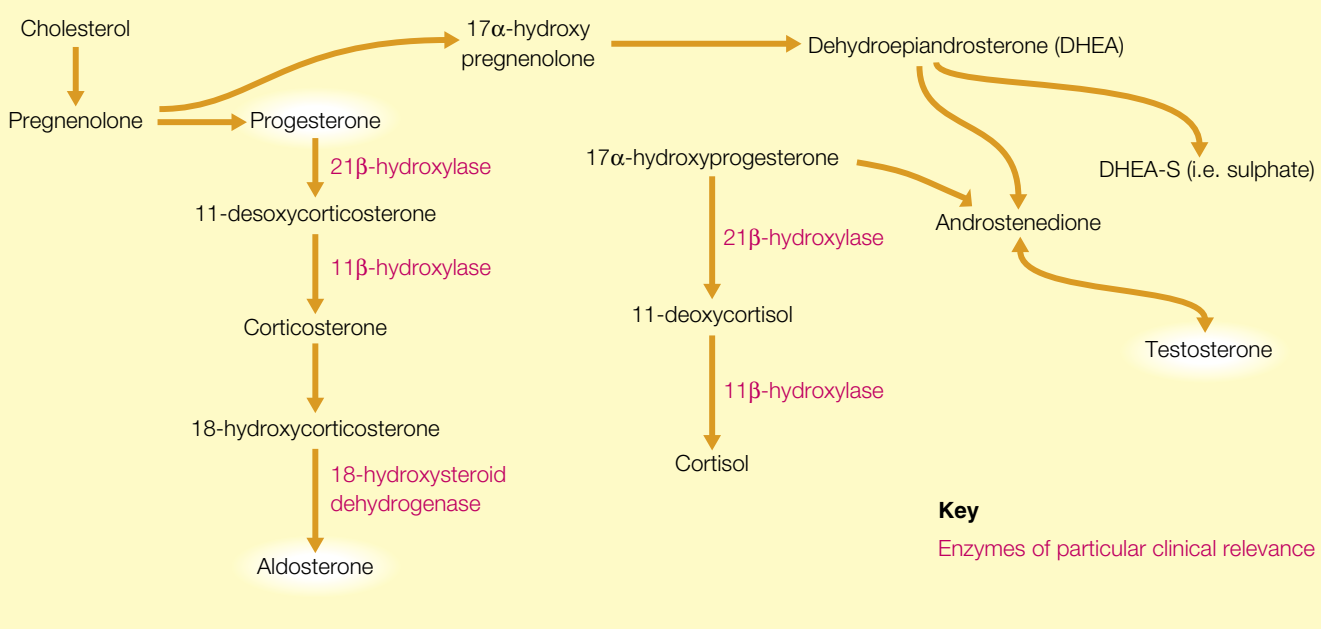


1

The most important mineralocorticoid in humans is aldo-sterone. It is synthesized from cholesterol which is converted to pregnenolone and then to progesterone (Figure 2). The enzyme 18-hydroxysteroid dehydrogenase is present only in the zona glomerulosa therefore aldosterone can be synthesized only in this part of the adrenal cortex. Cortisol synthesis is also via hydroxylation of progesterone with 17α-hydroxylase. This enzyme is present only in the zona fasciculata and reticularis of the adrenal cortex (Figure 2). Of the androgens secreted by the adrenal cortex, dehydroepiandrosterone (DHEA) is the most important. Significant quantities of adrenal androgens are produced only if the adrenal cortex is hyperactive in disease or when there is deficiency of specific enzymes leading to diversion of substrate down alternative pathways, for example in 21-hydroxylase deficiency, the most common form of congenital adrenal hyperplasia.

In the healthy individual, the secretion of cortisol follows a diurnal rhythm following that of cortisol release from the anterior pituitary. Adrenocorticotrophic hormone (ACTH) and cortisol levels rise during the hours of sleep and reach their highest levels in the morning soon after waking.

Principal metabolites produced in the synthesis of corticosteroids in adrenal glands



2

Actions

Aldosterone – the principal effect of aldosterone is to stimulate sodium absorption from the distal convoluted tubule of the kidney. Its release is stimulated by several factors including:

- a direct effect of plasma sodium (decrease) and potassium (increase)
- either a generalized fall in systemic blood pressure or a decrease in blood volume (secondary to haemorrhage or salt and water loss). This causes a decrease in renal arteriolar blood pressure which stimulates renin release and causes angio-tensin II levels to rise via the renin–angiotensin system. This in turn stimulates aldosterone production in the zona glomerulosa
- ACTH release from the anterior pituitary.

Cortisol – the effects of cortisol are:

- stimulation of hepatic gluconeogenesis and antagonism of peripheral action of insulin and glucose uptake
- stimulation of protein catabolism
- some mineralocorticoid activity on salt and water balance, an effect that is particularly important when the hormones are produced in excess.

Other effects of cortisol may be observed when the hormone is produced in excess:

- decreased growth hormone secretion by the anterior pituitary
- inhibition of the healing process in tissues
- immunosuppression.

Hyperaldosteronism

In primary hyperaldosteronism there is autonomous secretion of excess aldosterone by the adrenal cortex (unilateral adenoma) or bilateral adrenal hyperplasia. In secondary hyperaldosteron-ism, the high aldosterone production is induced by elevated levels of angiotensin II resulting from high plasma renin activity.

Primary hyperaldosteronism – patients present with hypertension caused by salt and water retention. There is often hypokalaemia and sometimes alkalosis. Confirmation of the diagnosis is by measurement of supine renin and aldosterone levels. Typically there is increased plasma concentration of aldosterone with low or suppressed plasma renin activity. Differentiating between an aldosterone-secreting adenoma (Conn's syndrome) and idiopathic adrenal hyperplasia is crucial and requires MRI scanning of the adrenals, bilateral adrenal vein catheterization or adrenal scintigraphy with ^{131}I- or ^{75}Se-labelled precursors of aldosterone.

Treatment of bilateral hyperplasia is with spironolactone, an aldosterone antagonist often combined with an ACE inhibitor. Treatment of Conn's adenoma is initially with spironolactone to normalize blood pressure and potassium levels, followed by surgical removal.

Secondary hyperaldosteronism – patients have high levels of aldosteronism and renin. Common causes are diuretic therapy, congestive cardiac failure, cirrhosis of the liver and ascites and nephrotic syndrome.

Adrenocortical insufficiency

Primary insufficiency is caused by disease of the adrenal gland (Addison's disease) which presents with glucocorticoid and mineralocorticoid deficiency. The causes of primary adrenal insufficiency are given in Figure 3. Secondary insufficiency follows absent or low levels of ACTH. It presents principally with glucocorticoid deficiency. This may result from disease of the anterior pituitary or suppression of the hypothalamo-pituitary system during long-term administration of exogenous steroids.

Causes of primary adrenal insufficiency

Chronic primary adrenal insufficiency

- Autoimmune adrenalitis, associated with circulating adrenal autoantibodies and other autoimmune disorders (e.g. pernicious anaemia, hypothyroidism and premature ovarian failure (autoimmune spectrum disorder))
- Tuberculosis of the adrenal gland
- Infiltration of the adrenal glands with metastatic tumour or amyloid
- Haemochromatosis

Acute primary adrenal insufficiency

- Any case of chronic primary adrenal insufficiency when subject to significant physiological stress
- Septicaemia with adrenal haemorrhage usually caused by meningococcal septicaemia (Waterhouse-Friderichsen syndrome)

3

Patients with the acute condition present with vomiting, abdominal pain, hypotension, dehydration and prostration (Addisonian crisis). The chronic condition has an insidious onset with fatigue, anorexia, weight loss, postural hypotension, hypoglycaemia and increased pigmentation in exposed areas and in the palmar creases and buccal mucosa.

Diagnosis is by the demonstration of impaired output of cortisol in the presence of a high circulating ACTH concentration. In the chronic situation, impaired cortisol may become apparent only on stimulation with exogenous ACTH (synacthen test) in which failure of basal cortisol levels to rise significantly is a reliable marker for insufficiency of cortisol production.

The treatment of an acute Addisonian crisis is with high-dose intravenous hydrocortisone, 100 mg q.d.s., together with intra-venous normal saline. As soon as the patient improves they may be given oral therapy with hydrocortisone, 20–30 mg/day, often supplemented with fludrocortisone, 50–100 μg/day). This is also the treatment in the non-critical case.

The diagnosis of adrenal insufficiency in the context of a pituitary tumour is by a short synacthen test or an insulin tolerance test (with induction of hypoglycaemia to act as a stimulus to adrenal cortisol production). Treatment of the condition is with glucocorticoid (hydrocortisone) replacement alone. In order to avoid secondary adrenal insufficiency in patients maintained on corticosteroid therapy for other reasons, any reduction in steroid dose must be made over a period of months with close monitoring of the patient's condition.

All patients on maintenance steroid therapy are at risk in physiologically stressful situations such as infection, operation or trauma, because they are unable to mount an adequate adrenal steroid response. At such times the dose of hydrocortisone should be increased. For simple surgical procedures or routine labour, hydrocortisone, 100 mg, should be given at induction or at the start of labour. In major operations, hydrocortisone, 100 mg every 6 hours, should be given perioperatively and postoperatively with dose reduction by 50% every 1–2 days thereafter.

Cortisol excess (Cushing's syndrome)

Cushing's syndrome is caused by excessive levels of gluco-corticoids. These may be secreted by the adrenal cortex or be derived from administered corticosteroids. Excessive secretion of cortisol may be caused by increased ACTH production by the anterior pituitary (Cushing's disease) or ectopic production of ACTH most commonly by an oat cell carcinoma of the lung. It may also result from independent hypersecretion of cortisol by the adrenal gland caused by adenoma or carcinoma.

Typical features are a red 'moon face,' purple striae on the lower abdomen and upper thighs, thin skin that bruises easily, hypertension, centripetal obesity with proximal muscle wasting giving a 'lemon on a stick' appearance, a fat pad between the shoulders (buffalo hump) and in women hirsutism and acne due to excess androgen production. There is sodium retention and potassium loss, the latter leading to hypokalaemia, impaired glucose tolerance or frank diabetes mellitus (type II), because of the counter-regulatory effects of cortisol on insulin action, and with osteoporosis.

Confirmation of the diagnosis of Cushing's disease is by 24-hour urine collection which shows a raised level of free cortisol and by the overnight dexamethasone suppression test in which a midnight dose of dexamethasone, 1 mg, fails to suppress the 9 a.m. cortisol level. Differentiation between pituitary- dependent Cushing's syndrome and adrenal Cushing's syndrome or ectopic ACTH production is by the 48 hour high-dose dexamethasone test which involves 6 hourly administration of dexamethasone, 2 mg. In pituitary Cushing's syndrome the cortisol level is suppressed after 48 hours but not in Cushing's syndrome of adrenal or ectopic origin. MRI scanning of the pituitary is the primary radiological investigation for suspected ACTH-secreting pituitary tumours. The most definitive test for the differential diagnosis is the measurement of ACTH levels in the inferior petrosal venous sinuses after corticotrophin-releasing hormone stimulation (given peripherally).

CT/MRI scanning of the adrenal glands is used to localize an adrenal tumour. Isotope scanning with ^{131}I-labelled cholesterol is sometimes used to confirm that an identified adrenal adenoma is a functioning cortisol-producing tumour.

Pituitary dependent Cushing's syndrome is treated by transphenoidal surgery often followed by external beam radiotherapy. Previously, bilateral adrenalectomy was the treatment of choice but this may result in increased growth of the pituitary tumour with very high levels of ACTH and hyperpigmentation (Nelson's syndrome). Benign tumours of the adrenal should be treated by surgical removal of the affected gland. Treatment of adrenal carcinoma is by surgical removal and administration of the adrenolytic agent o,p′-DDD. Most patients die within 2 years of diagnosis.

Congenital adrenal hyperplasia
Congenital adrenal hyperplasia comprises a set of inherited disorders of adrenal steroidogenesis. Most arise from congenital enzyme defects that impair the synthesis of cortisol and aldosterone. Depending on the precise enzyme defect there may be production of excess androgens and/or excessive secretion of mineralocorticoids other than aldosterone. Plasma levels of ACTH are raised with resulting hyperplasia of the adrenal glands.

21-hydroxylase deficiency is the most common defect and is an autosomal recessive disorder. In the absence of this enzyme there is failure of conversion of progesterone to the precursor of aldosterone and of 17-hydroxyprogesterone to the precursor of cortisol (Figure 2). The excess substrate allows enhanced synthesis and secretion of androgens in response to increased ACTH drive.

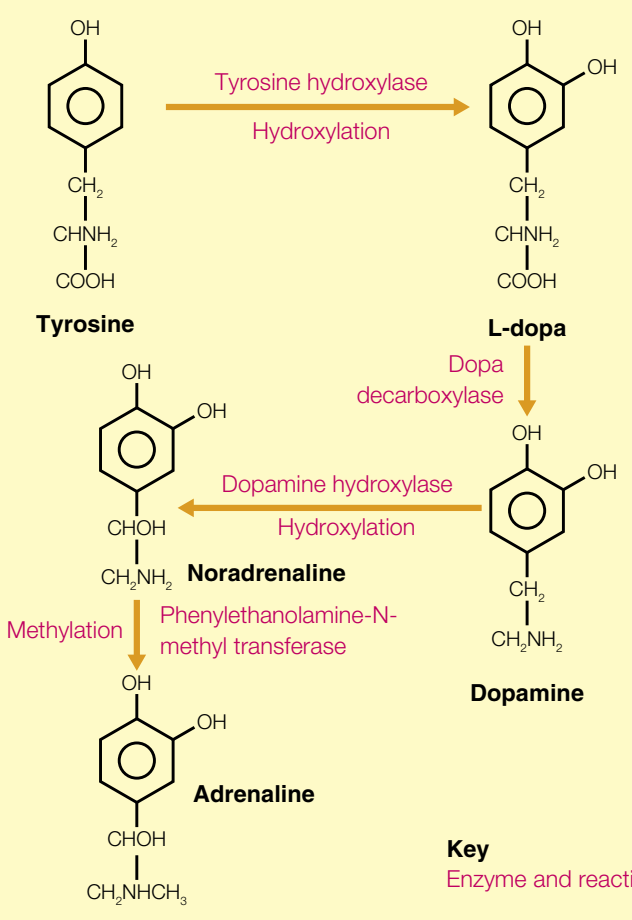
Boys present with pseudo-precocious puberty and girls with masculinization (fusion of the labia and clitoromegaly) if the disorder manifests *in utero* or virilization (hirsutism, muscle hypertrophy, clitoral enlargement and coarseness of the voice) if the disorder presents later.

Diagnosis is by demonstration of a raised plasma level of 17-hydroxyprogesterone. Treatment is with the glucocorticoids dexamethasone or prednisolone given as a morning dose and then a late evening dose to suppress the overnight release of ACTH.

Adrenal medulla
The adrenal medulla is embryologically derived from the neural crest and secretes catecholamines of which adrenaline is predominant, the remainder being noradrenaline. The adrenal medullae are not essential for life because their function is compensated for by increased sympathetic activity.

Catecholamines
The catecholamines, dopamine, noradrenaline and adrenaline, are synthesized within the adrenal medulla in addition to sympathetic postganglionic nerve endings and the brain. The synthetic pathway is shown in Figure 4 and originates with the amino acid tyrosine (mainly derived from the diet). This is hydroxylated to L-dopa which is decarboxylated to dopamine. This can be converted to noradrenaline by hydroxylation and on to adrenaline by methylation.

Principal features of the synthesis of noradrenaline and adrenaline



4

The catecholamines are stored in granules within the chromaffin cells of the adrenal medulla. Their release is stimulated by acetylcholine from preganglionic sympathetic nerve endings.

Phaeochromocytoma
Phaeochromocytoma is potentially lethal if untreated but eminently curable once identified. 90% of phaeochromocytomas arise in the adrenal and 10% are malignant. There is an association with multiple endocrine neoplasia type 2 (MEN 2), the other features being medullary thyroid carcinoma and parathyroid hyperplasia.

Most tumours secrete noradrenaline and adrenaline. Large tumours secrete almost entirely noradrenaline. Diagnosis is by the measurement of metadrenaline and normetadrenaline in a 24-hour urine sample collected with acid preservative. Localization is by CT/MRI scanning or by isotope scanning with ^{131}I metaiodobenzylguanidine (MIBG), an analogue of noradrenaline. This is particularly useful in the localization of extra-adrenal phaeochromocytomas. Treatment is initially medical, with combined α- and β-adrenoreceptor blockade (e.g. phenoxybenz-amine plus propranolol) followed by surgical removal in a specialist unit. Recently, this has been successfully carried out laparoscopically. Careful preoperative preparation is vital. During the operation any marked elevation of blood pressure caused by sudden release of catecholamines can be overcome by the intravenous administration of the α-blocker phentolamine.◆

Applied Cardiovascular Physiology

Roger Hainsworth

Roger Hainsworth is Professor of Applied Physiology at the University of Leeds and Honorary Consultant Clinical Physiologist. He trained at Leeds Medical School and San Francisco Cardiovascular Research Institute, USA. His research interests centre around the control of the cardiovascular and respiratory systems in normal subjects, patients with cardiorespiratory diseases and animal models. For several years he served as examiner for the Royal College of Anaesthetists.

Exercise

Physical exercise involves complex coordinated responses involving the locomotor, respiratory and cardiovascular systems. The first cardiovascular changes are initiated by a central drive, which starts either in anticipation of, or at the start of, exercise and leads to a decrease in cardiac vagal activity and an increase in sympathetic activity. Though an increase in heart rate may be the first observable change, the main factor causing the cardiovascular responses is the increase in muscle work. The increased metabolic activity by the working muscle results in the local build-up of the various metabolic products, including adenosine and phosphates, potassium, carbon dioxide and lactate. The consequent vasodilatation results in a large increase in blood flow in the working muscle with a greatly enhanced filling of veins. The rhythmically contracting muscle alternately compresses and relaxes compression of veins, and venous valves ensure that blood return to the heart is enhanced. Cardiac filling is also enhanced by the 'thoraco-abdominal' pump mechanism whereby alternating pressure gradients between the thorax and abdomen effectively pump blood into the right atrium.

The role of the heart is essentially to respond to the increased inflow. A reduction in vagal activity and increased activity in the sympathetic nerves increase both rate and force of ventricular contractions. The increase in cardiac output is achieved mainly through the increase in heart rate (Figure 1) though, particularly for endurance athletes, the increased stroke volume is also important. It should be noted that an increase in heart rate *per se* does not necessarily increase cardiac output. It is the enhanced venous inflow and the shortening of systolic time by sympathetic drive that allows the heart to fill adequately so that the increase in rate is not offset by a decrease in stroke volume.

The generalized increase in sympathetic drive results in vasoconstriction in regions of the body not involved in the exercise and has the effect of diverting the blood to exercising regions. Sympathetic vasoconstrictor nerves have little effect on flow to exercising muscle and there is no evidence for the existence of vasodilator nerves to human muscle. Blood pressure, particularly systolic, increases in proportion to the exercise intensity and systolic pressure may reach 200 mm Hg in maximal exercise.

Training causes widespread changes to improve exercise performance (Figure 1). In trained muscle, there are increases in mitochondrial oxidative enzymes and in capillary density, which together with increased muscle mass, increase oxygen extraction. The resting heart rate is reduced and stroke volume increases. During exercise, the maximal heart rate is mainly age-dependent, but the relative increase is greater in athletes. Other effects of endurance training are increases in red cell count and plasma volumes, and in cardiac mass and volume. Inactivity, particularly bed rest and weightlessness in space, results in opposite changes (see below).

Responses to exercise in a healthy young subject and a trained endurance athlete

	Healthy subject at rest	Athlete at rest	Maximum exercise	
			Healthy subject	Athlete
Heart rate (beats/minute)	70	50	200	200
Stroke volume (ml)	70	100	100	200
Cardiac output (litre/minute)	5.0	5.5	20	40
Total muscle blood flow (litre/minute)	1.0	1.2	15	35
Volume of oxygen utilization (litre/minute)	0.25	0.30	3.0	6.0

Haemorrhage

The cardiovascular effects of haemorrhage are dependent on the volume of blood lost and the rate at which the loss occurred. A slow gastrointestinal bleed or heavy menstrual loss results in anaemia and the main effect of this on the cardiovascular system is to cause an increase in cardiac output to maintain a normal oxygen delivery. A rapid loss of up to 0.5 litre may be unnoticed though the effects of posturally related blood shifts may be enhanced. Larger and rapid bleeds invoke reflex responses and, if sufficiently severe, result in shock.

Because most of the blood volume (about 70%) is contained in veins, and veins are readily able to reduce their volume by passive recoil and by active constriction in some veins, it is venous volume that is mainly reduced following blood loss. The reduced venous volume leads to a decrease in cardiac filling and consequently (Starling's law) a reduced stroke volume and cardiac output. Blood pressure is well maintained, and mean pressure may even increase. In moderate haemorrhage, the smaller stroke volume results in a reduction in arterial pulse pressure and it is this that alters the pattern of baroreceptor discharge, and leads to increases in vascular resistance and heart rate. The small rapid pulse and the cutaneous vasoconstriction are observable clinically. More severe, hypotensive haemorrhage affects chemoreceptors and results in further vasoconstriction and hyperventilation. Severe systemic hypotensive haemorrhage may result in cerebral ischaemia and a very intense vasoconstriction. Other responses to haemorrhage involve the endocrine system and increased secretion of cortisol, adrenal catecholamines, renin–angiotensin–aldosterone and vasopressin.

Following an acute haemorrhage, the blood volume is largely restored within a few hours by absorption of fluid from the tissues into the capillaries. This occurs because precapillary arteriolar vasoconstriction reduces capillary hydrostatic pressure, leaving the protein oncotic pressure relatively unopposed. Regeneration of protein by the liver and increased formation of RBCs by the bone marrow have a longer time course.

Severe, untreated hypotensive haemorrhage may lead to irreversible changes and death. Tissue hypoperfusion results in hypoxia and acidosis, and a point may be reached when replacement of the lost blood fails to restore blood pressure. Hypoperfusion of the intestine may lead to bacteria and toxins entering the circulation, with disastrous consequences. Nitric oxide is synthesized and this causes relaxation of vascular smooth muscle and severe hypotension. Myocardial function may be depressed, causing cardiac failure. Blood clotting is abnormal, with both disseminated intravascular thromboses and widespread haemorrhages occurring. Renal failure also occurs. Irreversible shock is fatal, and the aim of treatment of haemorrhage must be to prevent this from occurring.

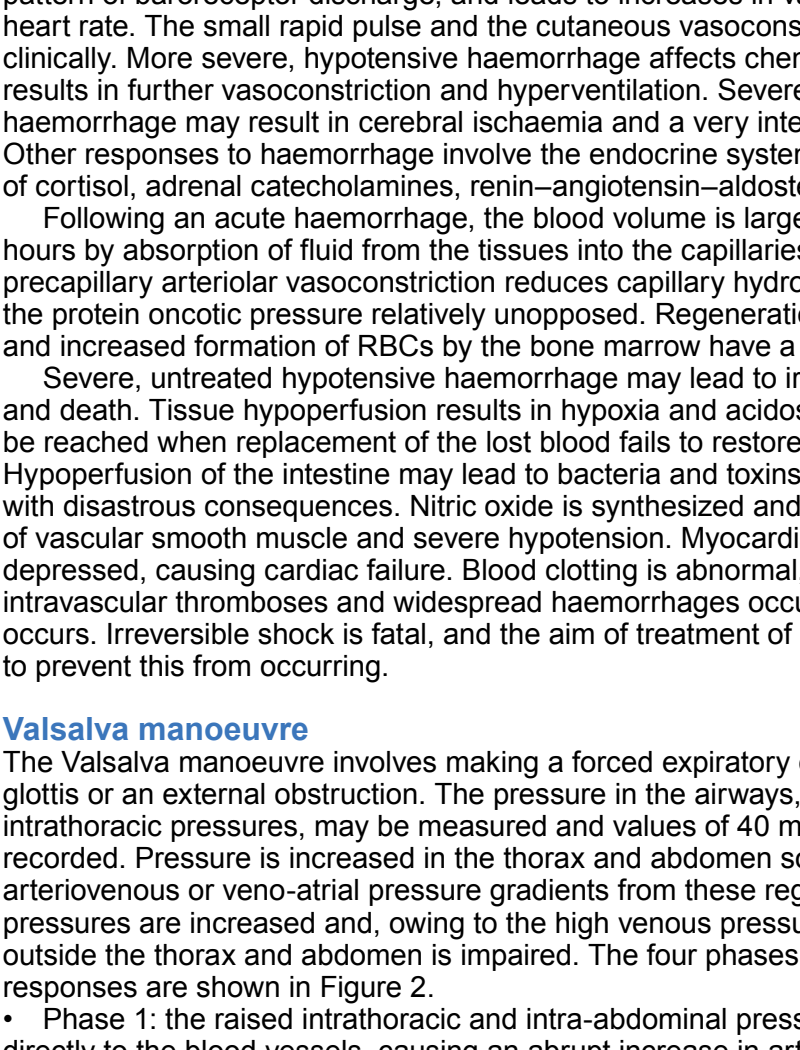
Valsalva manoeuvre

The Valsalva manoeuvre involves making a forced expiratory effort against a closed glottis or an external obstruction. The pressure in the airways, and therefore intrathoracic pressures, may be measured and values of 40 mm Hg or more are recorded. Pressure is increased in the thorax and abdomen so that it has little effect on arteriovenous or veno-atrial pressure gradients from these regions. Absolute vascular pressures are increased and, owing to the high venous pressure, inflow of blood from outside the thorax and abdomen is impaired. The four phases of the blood pressure responses are shown in Figure 2.

- Phase 1: the raised intrathoracic and intra-abdominal pressures are transmitted directly to the blood vessels, causing an abrupt increase in arterial pressure.
- Phase 2: pressure (particularly pulse pressure) decreases due to decreased stoke volume resulting from the reduced inflow from veins draining limbs and head. This partly recovers owing to venous pressures increasing and to baroreceptor-mediated vasoconstriction.
- Phase 3: a fall in pressure occurs as the arterial compression is released.
- Phase 4: an overshoot occurs owing to the increased venous return following relief of the obstruction being pumped by the heart into a constricted circulation. There is usually reflex bradycardia in phase 4.

The Valsalva manoeuvre can be used as a test for normal autonomic control and baroreceptor reflexes. In autonomic disorders, the recovery of pressure in phase 2 and the overshoot in phase 4 are absent.

Valsalva manoeuvre



There are four phases. **1** Compression of intrathoracic and intra-abdominal arteries causes blood pressure to increase.
2 Decreased inflow from outside the thorax and abdomen results in decreased venous inflow and there are decreases in stroke volume, pulse pressure and mean pressure, followed by partial recovery due to reflexes and high venous pressures.
3 Pressure falls as compression of arteries is removed.
4 Overshoot as high venous inflow is pumped into constricted circulation. There may be a reflex bradycardia.

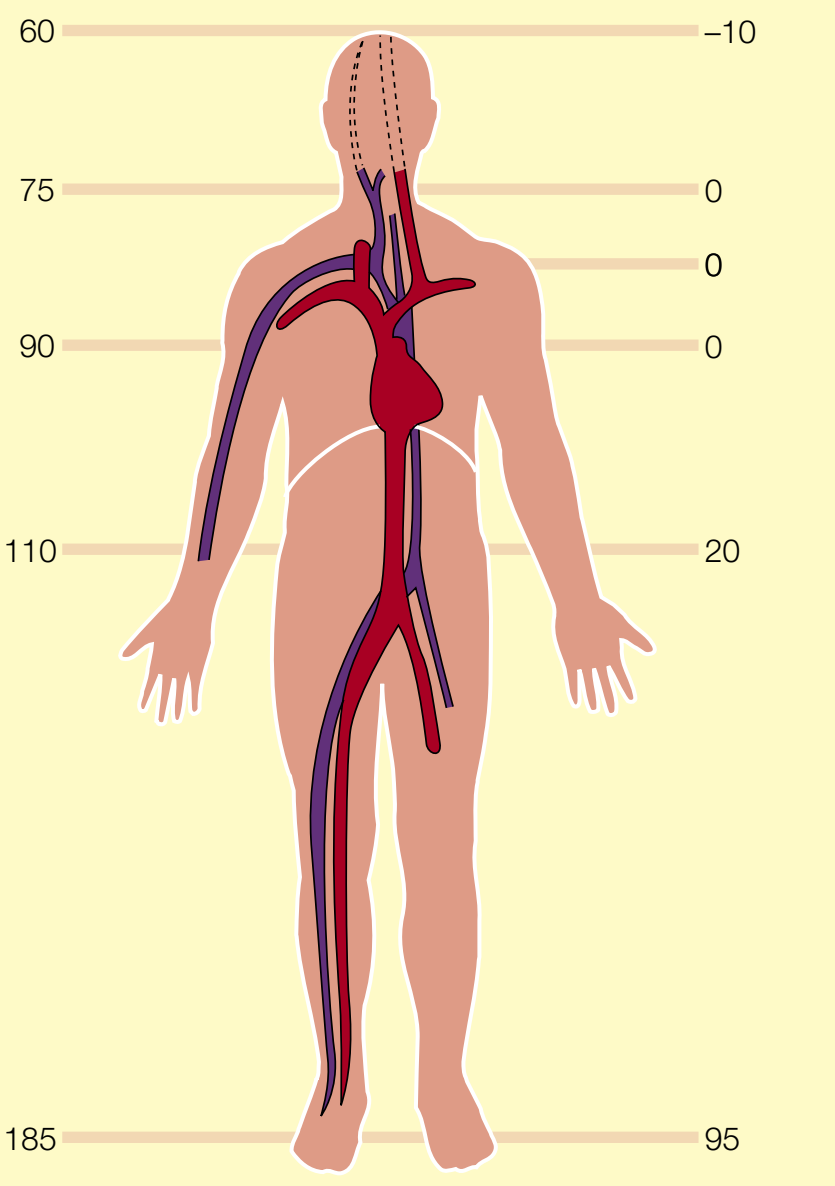
Responses to postural change

Figure 3 gives examples of typical arterial and venous pressure in a person standing motionless. Gravity imposes large pressure gradients, for example the low cerebral perfusion pressure and the high subdiaphragmatic venous pressures. The venous gradients result in the translocation of 0.5 litre or more from the central circulation into dependent veins. Of equal importance is the progressive loss of fluid from the dependent, distended capillaries to the tissues. This also can amount to another 0.5 litre or more within 5 minutes of being upright. The venous pooling and fluid loss result in cardiac output falling by about 25%.

The responses depend on whether the subject stands actively or is tilted using a tilt table. Active standing involves muscular exercise and there may also be some degree of straining (see above). Typically, there is an initial heart rate increase followed by a short-lasting, but often sharp, fall in blood pressure due at least partly to vasodilatation in the working muscle. Passive head-up tilting does not normally lead to a fall in blood pressure but diastolic pressure usually increases with little change in systolic pressure. The fall in pulse pressure, despite the unchanged or even increased mean pressure, provides the change to baroreceptor stimulation. Reflex responses cause vascular resistance and heart rate to increase.

Prolonged standing, particularly standing still so that the 'venous pump' is ineffective, or head-up tilting may lead to venous pooling and capillary fluid loss progressing to the point at which venous return is inadequate and syncope results. Syncope is often associated with a vasovagal reaction where sympathetic vasoconstrictor drive abruptly ceases, causing inappropriate vasodilatation, and vagal activity markedly increases, causing bradycardia or even asystole. On becoming supine, venous return increases and recovery is normally rapid.

Arterial and venous pressures in a motionless upright individual



Gravity causes pressure gradient along vertical axis of body. Arterial pressure is particularly low in the head and vulnerable to further falls. Venous pressures are high in abdomen and legs, resulting in accumulation of blood in distended veins and increased fluid loss from dependent capillaries.

3

Weightlessness

The problems encountered during gravitational stress are avoided when the individual is recumbent, immersed in water or in space away from earth's gravity. Several adaptive changes take place, particularly over the first few days, as the result of the absence of hydrostatic pressure gradients. There is no longer the accumulation of blood and tissue fluid in dependent regions, and the blood volume in the thorax and upper parts of the body increases. The increase in thoracic blood volume is at least partly responsible for inducing a diuresis as the result of atrial receptor stimulation. This causes a decrease in extracellular fluid volume including blood volume. Cardiac output decreases and there is also some evidence for impairment of cardiovascular reflexes. Prolonged weightlessness leads to muscle deconditioning and wasting. There is also a slow but persistent demineralization of the bony skeleton.

Changes caused by weightlessness are largely adaptive processes to the absence of work by the cardiovascular and locomotive systems against gravitational forces and, therefore, result in few problems while the subject is in the weightless state. On returning to gravity, however, the adaptive changes result in the subject being unable to induce normal responses. The smaller blood volume, the increased amount of venous pooling in the deconditioned individual and the impaired cardiovascular reflexes result in a greatly impaired orthostatic tolerance, with a greatly increased risk of fainting.

Astronauts attempt to minimize these effects by taking regular exercise while weightless and attempting to expand blood volume by drinking large quantities of saline before returning to earth.

RBCs (erythrocytes)

Characteristics, formation and destruction

The average red cell count is 5.4 x 10^{12}/litre in men and 4.5 x 10^{12}/litre in women. Each RBC is a biconcave disc, which has an average diameter of 7.2 μm and is 2 μm thick at its edges. RBCs lack intracellular organelles. The shape of the RBC is physiologically important, because it maintains a high surface area:volume ratio, which aids transmembrane diffusion (particularly of oxygen), while minimizing the intracellular distance over which oxygen must diffuse to combine with haemoglobin (see below). The shape of the RBC, together with the considerable flexibility of its plasma membrane, also allows the cell to flex and distort, which is often necessary as it traverses the capillaries. The normal shape of the cell is maintained by a membrane skeleton, consisting of four proteins, of which spectrin is the most abundant. A deficiency of these proteins leads to an abnormal shape; for example, a deficiency of spectrin, which is found in hereditary spherocytosis, results in RBCs that are more spherical than normal.

Because they lack intracellular organelles, RBCs have a limited life in the circulation (about 120 days) and must derive energy anaerobically through the glycolytic (Embden–Meyerhof) pathway. About 5% of glycolysis also occurs through the hexose monophosphate shunt, using glucose-6-phosphate dehydrogenase (G6PD), and resulting in the generation of NADPH. G6PD deficiency makes RBCs extremely susceptible to damage by oxidants, resulting in haemolytic anaemia.

The events leading to the death of RBCs remain obscure but, at the end of their life, they are removed by macrophages of the reticuloendothelial system, especially in the bone marrow, and also in the liver and spleen. This removal appears to be triggered by changes in the membrane that alter its flexibility, and any disease that leads to a change in this (e.g. hereditary spherocytosis) results in an accelerated removal of the cells and haemolytic anaemia.

In health, the continuous removal of old RBCs is balanced by the formation of new cells (erythropoiesis). In the early fetus until about 7 months' gestation, erythropoiesis is performed by the liver and spleen. After that time, and throughout childhood and adult life, the bone marrow becomes the sole site of erythropoiesis. Whereas in children all bone marrow is capable of erythropoiesis, in adults it is limited to the marrow of the bones of the trunk and the proximal end of long bones. Within the marrow, RBCs are derived from common pluripotent cells that give rise to a series of progenitor (committed stem) cells which, in turn, form the several blood cell types. The progenitor cells of the erythroid series divide and differentiate into pronormoblasts, which are large cells with a large central nucleus. Through a number of cell divisions, the pronormoblasts give rise to series of progressively smaller normoblasts, which become invested with haemoglobin. In the final stage of maturation, the nucleus is extruded and immature RBCs – reticulocytes – are released into the bloodstream. The rate of erythropoiesis is regulated by the hormone erythropoietin, which is a glycoprotein hormone secreted by the peritubular network of the kidney. Erythropoietin increases RBC formation by enhancing the proliferation of the erythroid progenitors and their differentiation into pronormoblasts. The sole regulator of erythropoietin secretion appears to be the rate of oxygen delivery to kidney; erythropoietin production increases as oxygen delivery falls. A fall in oxygen delivery can occur not only with deficient oxygenation of the blood, but also in haemoglobin deficiency (anaemia) or in the presence of an abnormal haemoglobin which is unable to give up oxygen normally.

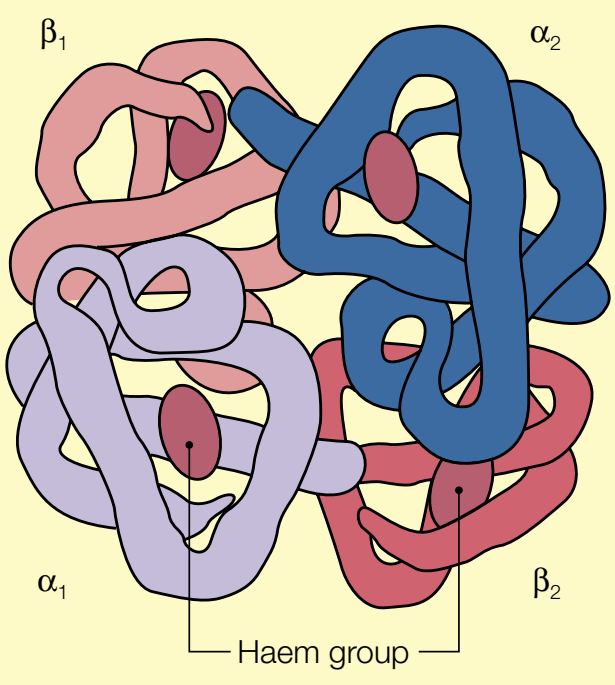
Functions

Functionally, the most important contents of the RBC are carbonic anhydrase and haemoglobin. Carbonic anhydrase catalyses the hydroxylation of carbon dioxide to H^+ and HCO_3^-. The HCO_3^- formed in the RBC then diffuses into the blood plasma in exchange for Cl^- (the chloride shift) and accounts for 90% of the way in which carbon dioxide is carried in blood. The major role of haemoglobin derives from its ability to combine reversibly with oxygen. In addition, it is responsible for the carriage of a small proportion of carbon dioxide in the blood (as carbamino compounds) and it is a buffer, accepting the H^+ released with HCO_3^- formation (see above).

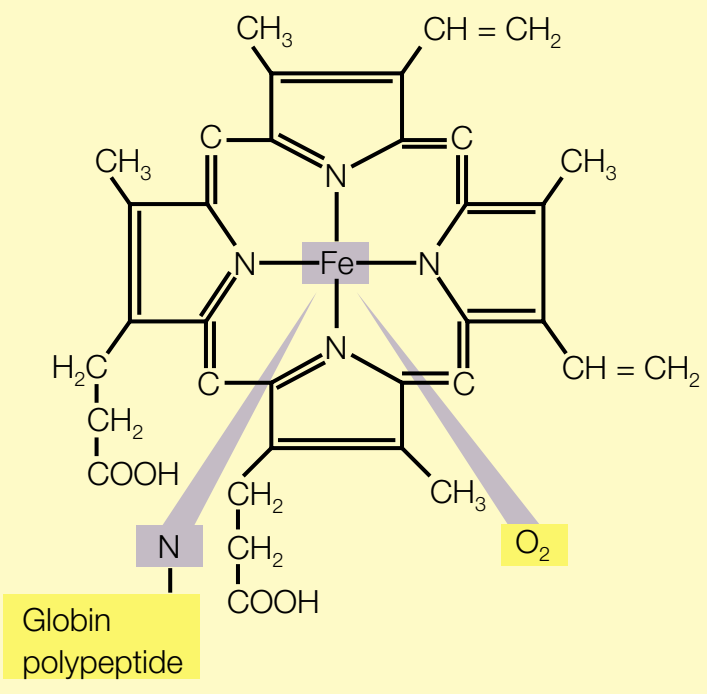
Haemoglobin has a molecular mass of 64,450 and its concentration in blood is normally about 16 g/dl in men and 14 g/dl in women. Physiologically, it exists as a tetramer. Each of the four subunits consists of a polypeptide (globin) chain conjugated to the iron-containing porphyrin, haem, in which the iron is found in the reduced Fe^{2+} state (Figure 1). In the tetramer, there are two pairs of globin chain which differ in their amino-acid sequence. In adults, most haemoglobin (96–98%) possesses two α and two β chains, and is referred to as HbA ($\alpha_2\beta_2$). In addition, there are also small amounts (1–3%) of HbA_2, in which the β chains are replaced by δ chains. In fetal haemoglobin (HbF; $\alpha_2\gamma_2$), the β chains are replaced by γ chains, which results in the higher binding affinity of HbF for oxygen. Most HbF synthesis is switched to HbA production 6–8 months postnatally, though very small amounts of HbF synthesis persist into adult life. The genes for the γ, δ and β chains are situated on chromosome 11, whereas the α gene is found on chromosome 16, where it is duplicated (α_1 and α_2 genes). As with any other genetically determined trait, mutants can arise, resulting in the formation of abnormal or deficient haemoglobin (see below).

In the oxygenation of haemoglobin, each haem moiety binds one oxygen molecule (Figure 1), and thus 1 mole of the tetramer can bind 4 moles of oxygen. The binding of oxygen to one subunit causes an allosteric change in the remainder of the molecule. In the deoxy state, the haem is in the tense or T state, and there are numerous salt bridges between the four globin chains. When oxygen binds to one haem, some salt bridges are broken, leading to a small movement of the globin chains. This causes haem to change to its relaxed or R state, which favours oxygen binding. In this way, binding of one oxygen molecule favours binding of further oxygen until all haem moieties are saturated, which explains the sigmoid shape of the oxyhaemoglobin dissociation curve. As the haemoglobin gives up its oxygen to the tissues, the salt bridges re-form. The resulting movement of the globin chains causes haem to revert to its T state and allows 2,3-diphosphoglycerate (2,3-DPG) to gain access to a central cavity in the haemoglobin molecule. 2,3-DPG decreases the affinity of haemoglobin for oxygen and a rise in the intracellular concentration of 2,3-DPG thus shifts the oxyhaemoglobin dissociation curve to the right.

Model of the adult haemoglobin (HbA) molecule



Chemical structure of the haem moiety showing bound oxygen



Anaemia

Anaemia is normally defined as a haemoglobin concentration of less than 13.5 g/dl in men and 11.5 g/dl in women. It has a number of causes, which can be categorized into anaemias resulting from:

- a decreased life-span of the RBC – haemolytic anaemias
- impairment of RBC formation.

These anaemias are in addition to the anaemia that will follow some hours after a haemorrhage. The haemolytic anaemias include those in which a congenital defect results in abnormal RBCs that are removed by the recticuloendothelial system at an accelerated rate (e.g. hereditary spherocytosis, G6PD deficiency, sickle cell anaemia). In addition, acquired defects (e.g. haemolytic transfusion reaction, some drugs, malaria) can also lead to premature destruction of RBCs.

Anaemias resulting from impairment of RBC formation are equally varied in cause. They are most commonly caused by a deficiency of one of the factors required for normal erythropoietic activity (e.g. iron deficiency, which is required for haemoglobin synthesis, and vitamin B_{12} or folate deficiency, which is required for incorporation of thymidine into DNA). In addition, they can be caused by diseases of the bone marrow – the aplastic anaemias, which can be congenital, acquired or secondary. Causes of secondary damage to marrow include ionizing radiation, cytotoxic drugs such as busulphan and cyclophosphamide, chemicals such as benzene, and myeloid leukaemia, though the latter only rarely results in aplastic anaemia.

Haemoglobinopathies: over 500 haemoglobinopathies, which result from the formation of an abnormal globin chain, have been reported. Most are rare, asymptomatic and harmless, and result from a single-point mutation in one of the globin genes, giving rise to a single amino-acid substitution in one of the globin chains. Some of the more commonly occurring haemoglobinopathies are summarized in Figure 2. Of these, the most common and clinically significant is sickle cell haemoglobin (HbS). HbS is far less soluble and, in the deoxygenated state, crystallizes and then polymerizes into long chains, causing distortion of the RBC into a characteristic sickle shape.

Common haemoglobin variants caused by a single amino-acid substitution on the β chain

Haemoglobin variant	Amino-acid substitution[1]	Clinical abnormality
HbS	GLU(6) → VAL	Sickling of RBCs on deoxygenation due to haemoglobin polymerization, leading to severe haemolytic anaemia and painful crises
HbC	GLU(6) → LYS	Decreased solubility of haemoglobin and reduced RBC flexibility on deoxygenation, leading to mild haemolytic anaemia
HbD	GLU(121) → GLN	Mild haemolytic anaemia
HbE	GLU(26) → LYS	Small RBCs with low intracellular haemoglobin concentration, but seldom anaemia
HbM (Milwaukee)	VAL(67) → GLU	Oxidation of iron in haem to Fe^{3+}, known as methaemoglobinaemia

[1]The amino acid shown before the arrow is the amino acid (and its position on the β chain) that is substituted by the amino acid indicated after the arrow. GLU, glutamic acid; VAL, valine; LYS, lysine; GLN, glutamine.

In an individual homozygous for the HbS gene, more than 80% of circulating haemoglobin is HbS. Such individuals have sickle cell anaemia, which is a haemolytic anaemia resulting from accelerated destruction of the sickled cells, with sickling occurring even at oxygen tensions normally found in venous blood. The individual may also suffer painful crises due to sickled cells blocking the microcirculation and causing tissue infarction. Such crises can be triggered by infection, dehydration, acidosis, and conditions that can cause further deoxygenation of haemoglobin. Careful management of such individuals during general anaesthesia is critical.

Heterozygous individuals have the sickle cell trait. They are generally asymptomatic and do not usually suffer sickling because the RBCs contain less than 45% HbS. Severe hypoxia (haemoglobin saturation < 40%) can, however, still result in sickling in these individuals, who should be considered 'at risk' during general anaesthesia.

As yet, there is no cure for sickle cell anaemia, though treatment with hydroxyurea, which increases HbF production, has been shown to decrease the number of crises. In addition, recent research has attempted transplants of healthy stem cells into the early fetus, before erythropoiesis is transferred to the bone marrow and immunity has developed. These stem cells would then divide further, produce normal RBCs and, it is hoped, might eventually displace native stem cells possessing the sickle cell gene.

Thalassaemia: in this condition, either α or β chain synthesis is decreased due to gene deletions. Since the αgene is duplicated, in α-thalassaemia one, two, three or four genes can be deleted. α^+ and α^0 thalassaemia, in which there is deletion of one or two genes, respectively, are usually asymptomatic. When three genes are deleted, which is termed HbH disease, there is a chronic haemolytic anaemia and, when four genes are deleted, there is usually intrauterine death (Hb Bart's hydrops foetalis syndrome).

β thalassaemias are classified as β thalassaemia major, in which the individual is homozygous, and β-thalassaemia trait, in which the individual is heterozygous. The trait normally results in no or mild anaemia, whereas the major condition results in a severe anaemia as a result of precipitation of the abnormal haemoglobin. The trait can coexist with other haemoglobin variants (e.g. HbS, HbE and HbD).

WBCs (leucocytes)

Unlike RBCs, WBCs are not homogeneous, but are differentiated on the basis of their physiological function and histology. They are broadly divided into lymphocytes, monocytes and granulocytes. Granulocytes, which derive their name from the presence of cytoplasmic granules, are further subdivided into neutrophils, eosinophils and basophils by the staining affinity of the granules. In health, the normal total white cell count is about 4–11 x 10^9/litre.

Like RBCs, WBCs are formed initially from pluripotent stem cells in the bone marrow. These give rise to separate progenitor cells for the eosinophils and basophils, and a common progenitor for monocytes and neutrophils. The two types of lymphocytes also arise from a common progenitor in bone marrow, but postnatally many lymphocytes are formed at other sites.

Neutrophils

Neutrophils are the most abundant WBCs, contributing 50–70% of the total circulating leucocyte population, and have a half-life of about 7 hours. They are easily identifiable in a blood smear by virtue of their multilobular nucleus.

Neutrophils are phagocytic cells and are the body's first line of defence against bacterial infection. In bacterial infection, they migrate through the capillary endothelium (diapedesis) and are attracted towards bacteria or the site of an inflammatory response by chemotactic substances released from damaged tissues and by components of the plasma complement system, particularly C5a. The neutrophils then bind to and phagocytose the bacterium or damaged cell. The binding is facilitated by bacteria that have been opsonized (coated) by antibodies of the IgG class, or by the C3b complement component. (Neutrophils possess receptors for C3b and the Fc component of IgG.) Once ingested by the neutrophil, the foreign material within the phagocytic vacuole is killed and ingested by two pathways, one being oxygen-dependent and the other non-oxygen-dependent. In the oxygen-dependent pathway, superoxide and hydrogen peroxide, which are oxidants that kill bacteria, are generated through activation of a NADPH oxidase. In addition, hydrogen peroxide reacts with myeloperoxidase in the neutrophil to convert intracellular halides to hypothalous acids that also kill bacteria. The non-oxidative pathway involves a fall in pH and release of lysosomal enzymes into the phagocytic vacuole.

Monocytes

Monocytes constitute about 5% of circulating WBCs and are identifiable in a blood smear by their large central nucleus that is oval or indented. They spend only about 72 hours in the circulation before they migrate into the tissues to become tissue macrophages, an important component of the reticuloendothelial system. They may remain in the tissues for several months.

Like neutrophils, monocytes are phagocytic, and kill and digest microorganisms and cellular material using mechanisms similar to those used by neutrophils. In addition, they play a role in presenting foreign antigens to the immune system (see below).

Eosinophils

Eosinophils are so called because of the affinity of their cytoplasmic granules for acidic dyes. They constitute about 2% of circulating WBCs, but their number increases in patients with allergic diseases. The half-life of eosinophils in the circulation is about 6 hours, after which they enter the tissues. They are especially abundant in the mucosa of the respiratory and gastrointestinal tracts, where they probably have a role in mucosal immunity.

Eosinophils participate in the killing of parasites that are too large to be ingested by phagocytes and regulate immediate-type hypersensitivity (allergic) reactions, releasing leukotriene C_4 and platelet activating factor (PAF), which are both inflammatory mediators.

Basophils

Basophils are often absent from the bloodstream. They are similar to mast cells, and contain heparin and histamine. When coated with IgE, basophils can react with specific antigens and are essential for immediate-type hypersensitivity reactions. Once activated, they release histamine, leukotrienes and proteases, which are inflammatory mediators.

Lymphocytes

Circulating lymphocytes are divided into three groups: T cells (60–80%); B cells (30%); and null cells (2–10%). Although postnatally some lymphocytes are formed from stem cells in the bone marrow, most are formed in the lymph nodes, thymus and spleen from cells that originally came from bone marrow, and enter the circulation via the lymphatics. T cells undergo some transformation in the thymus before their appearance in peripheral blood. In birds, there is also processing of B cells by the bursa of Fabricius, but whether or not there is any equivalent processing of B cells in man is unclear.

The plasma membranes of lymphocytes possess specific antigen-recognizing receptor molecules. Thus, they participate in, and give specificity to, immune responses.

B cells are responsible for antibody secretion (i.e. humoral immunity) and thus aid in defence against bacterial infection. Their membrane receptor is similar in structure to the antibody that they will secrete and which will recognize a specific antigen. On exposure to antigen, B cells that recognize that antigen release several cytokines that cause them to proliferate and differentiate into antibody-secreting plasma cells or into so called memory B cells. With primary antigen exposure, the specific antibody released from the plasma cell is usually an IgM. In a secondary response, when the memory B cells are activated and differentiate into plasma cells, most antibody secreted is IgG. Recognition of the specific antigen by the B cell can be aided by antigen-presenting cells and helper T cells (see below).

The physiology of T cells is complex. They are responsible for cell-mediated immunity and thus participate in delayed hypersensitivity reactions and transplant rejection. In addition, cell-mediated immunity is a major defence against viral and fungal infections. Several types of T cell are found. First, they are subdivided by the presence or absence of one of two cell-surface protein markers termed CD4 and CD8. CD4+ cells (possessing the CD4 marker) are further divided into helper cells and memory cells. CD8+ cells are subdivided into suppressor cells and cytotoxic cells. Unlike B cells, T cells are unable to bind to antigen in free solution, and the antigen must be 'presented' to the T cell in association with proteins of the major histocompatibility complex (MCH). Two classes of MCH protein exist. Class I MCH proteins are present on the surface of all nucleated cells and are recognized by CD8+ cells, whereas class II MCH proteins are recognized by CD4+ cells and are present on the surface only of certain cells, including specialized macrophages, termed antigen-presenting cells (APCs).

Helper cells 'help' in the immune response to bacterial infection. Once bacteria have been engulfed by APCs, peptide products of the digested antigen are complexed by class II MCH proteins on the cell surface. Helper cells possessing receptors specific to the antigen bind the MCH-antigen complex, which activates the helper cell. On activation, the helper cell releases various cytokines (in particular interleukin 2), and results in the proliferation of other T cells (including memory cells) and activation of further APCs. Helper cells also participate in the differentiation of B lymphocytes into plasma cells.

Cytotoxic cells play a major role in defence against viral infection. Once a cell is infected by a virus, some viral proteins are broken down to peptides which complex with MCH I proteins on the cell surface. Here, the antigen associated with MCH I is 'recognized' by cytotoxic cells, which then become activated and secrete cytotoxic substances that lyse and thus kill the infected cell. Suppressor cells, which are activated by the same mechanism but more slowly, 'switch off' cytotoxic and helper cells when the infection is no longer a threat. Memory T cells, like those of B cells, differentiate into effector cells on subsequent exposure to the antigen.

Null cells include natural killer (NK) and killer (K) cells. The function of NK cells is similar to that of cytotoxic cells, though they are activated by a different process, and they kill tumour cells and cells with a viral infection. K cells lyse cells that have been coated with antibody and antibody-coated viruses. Together the NK and K cells thus form the first line of defence against viral infection.

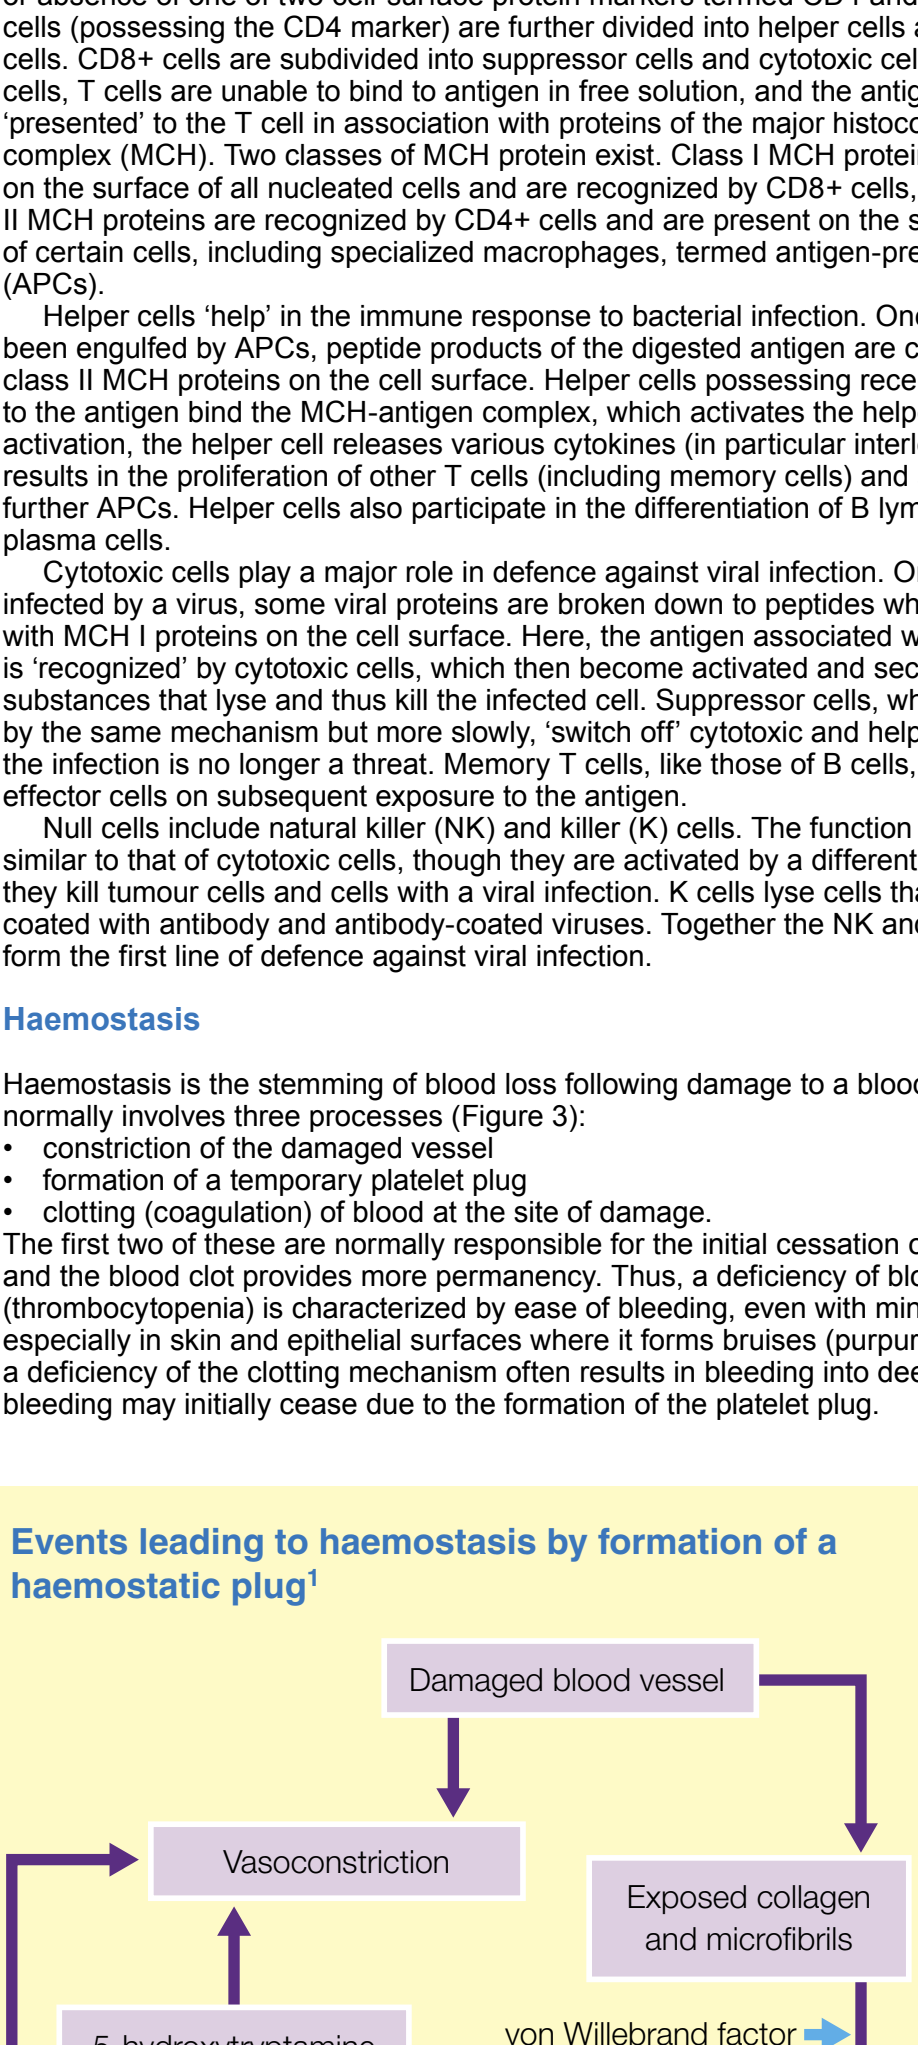
Haemostasis

Haemostasis is the stemming of blood loss following damage to a blood vessel; it normally involves three processes (Figure 3):

- constriction of the damaged vessel
- formation of a temporary platelet plug
- clotting (coagulation) of blood at the site of damage.

The first two of these are normally responsible for the initial cessation of blood loss, and the blood clot provides more permanency. Thus, a deficiency of blood platelets (thrombocytopenia) is characterized by ease of bleeding, even with minor damage, especially in skin and epithelial surfaces where it forms bruises (purpura). By contrast, a deficiency of the clotting mechanism often results in bleeding into deep tissues and bleeding may initially cease due to the formation of the platelet plug.

Events leading to haemostasis by formation of a haemostatic plug[1]



[1]Green arrows indicate positive feedback activation

Platelet function and formation of the platelet plug
The normal platelet count is about 3 x 10^{11}/litre. Platelets are incomplete cells formed from megakaryocytes in the bone marrow. Formation of platelets involves 'pinching off' bits of cytoplasm from the megakaryocyte, with each megakaryocyte giving rise to about 1000 platelets.

The structure of platelets is complex. Normally they are discoid in shape and bounded by a complex plasma membrane. This membrane is extensively invaginated, forming a canalicular system, and contains numerous glycoproteins (GP), including GPIa, GPIb and GPIIb/IIIa, that act as adhesion molecules and play an important part in platelet function. Intracellularly, the platelet contains numerous microfilaments, a dense tubular system and two types of granules:

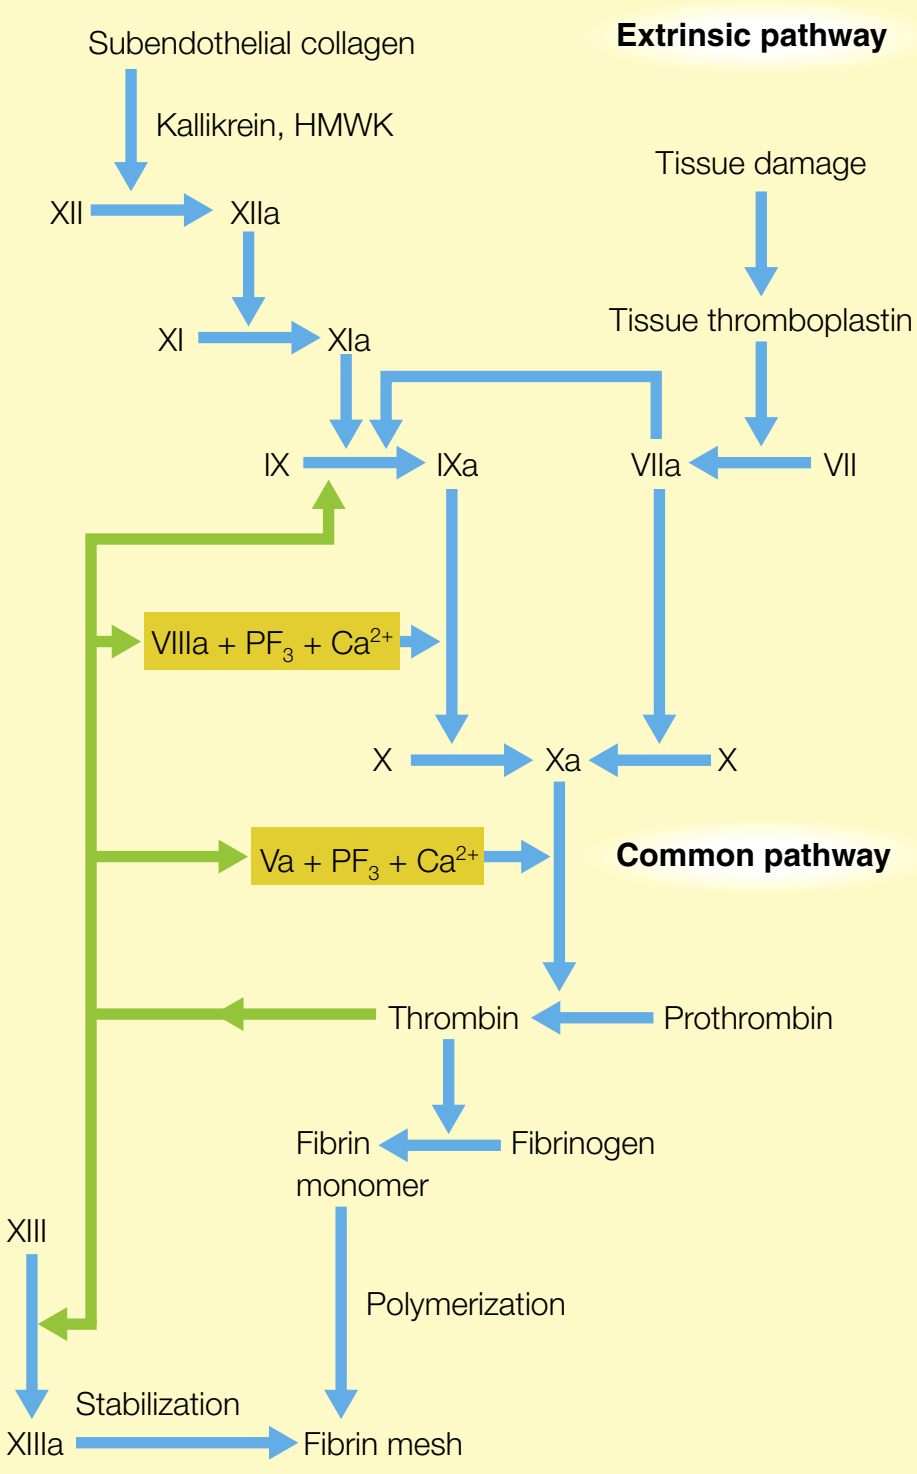
- α-granules, which contain fibrinogen, von Willebrand factor (vWF), a heparin antagonist (PF_4) and a platelet growth factor
- dense-granules, which contain certain adenosine nucleotides (including ADP) and 5-HT.

Normally, platelets do not adhere to the smooth endothelial lining of blood vessels. When the vasculature is damaged, however, this exposes the blood to subendothelial collagen and microfibrils. Platelets bind to this collagen via GPIa and further binding is facilitated by vWF. vWF forms a bridge between subendothelial microfibrils and platelets via the membrane GPIb. Binding of GPIa and GPIb exposes GPIIb/IIIa, which binds fibrinogen and vWF. Following this adhesion, the platelet becomes activated, changes shape to become more spherical, and sends out pseudopodia that enhance platelet–platelet interaction (platelet aggregation). Platelet aggregation is aided by fibrinogen that binds to GPIIb/IIIa and forms a bridge between adjacent platelets. On activation, platelets also release their granules (platelet release reaction). The 5-HT which is released acts as a potent vasoconstrictor. In addition, there is exposure of a membrane phospholipid, platelet factor 3 (PF_3) and release of arachidonic acid from the phospholipids. The arachidonic acid is converted within the platelet to thromboxane A_2 (TxA_2), which is a potent vasoconstrictor and aids the localized vasoconstriction. In addition, TxA_2, together with ADP released from the dense granules, further enhances platelet activation, aggregation and release (Figure 3). In this way, an aggregate of platelets that plugs the damaged blood vessel is rapidly built up. Spreading of this plug away from the site of injury is prevented by the production of prostacyclin (PGI_2), which is a potent inhibitor of platelet aggregation and release, in the normal endothelium in adjacent areas. (The release and aggregation reactions are also inhibited by aspirin, which inhibits TxA_2 synthesis, and thus explains, in part, the anticoagulant activity of aspirin.)

Coagulation
The platelet plug provides a nidus around which the blood clots form a more definitive haemostatic plug. The fundamental reaction in the formation of the blood clot is the conversion of the soluble plasma protein fibrinogen into insoluble fibrin under the action of thrombin. Thrombin splits off two polypeptide chains from the fibrinogen molecule to form fibrin monomer, which polymerizes to form a meshwork of strands. Initially, the strands are held together weakly by hydrogen bonds, but activation of factor XIII by thrombin leads to the formation of covalent cross-bridges between fibrin chains, thus strengthening them.

The conversion of prothrombin, the inactive precursor of thrombin, to thrombin involves a series of plasma serine proteases (collectively referred to as clotting factors) that normally exist in an inactive, proenzyme form, becoming activated in a cascade sequence. As shown in Figure 4, classically, the activation of the clotting factors proceeds down two pathways that converge at factor X to a common pathway. The intrinsic pathway can be activated *in vivo* by exposure of blood to collagen in the subendothelium. This activates the first factor in this pathway, factor XII, which can also be activated by exposure of blood to any electronegative wettable surface (e.g. glass). The extrinsic pathway is activated by release of lipoproteins, referred to as tissue thromboplastin or tissue factor, from damaged tissue. Although initially it was thought that the two pathways operated independently, this is now known not to be the case and interactions occur. Thus, as indicated in Figure 4, active factor VII formed in the extrinsic pathway can directly activate factor IX, thus bypassing the early stages in the intrinsic pathway. In addition, thrombin has positive feedback effects, since thrombin activates factors V and VIII, which act as co-factors in the formation of thrombin and factor Xa, respectively, and factor IX. Blood platelets also play an essential role in clotting since they provide phospholipid PF_3 and activation of factor X by factor IX and the conversion of prothrombin to thrombin by factor X take place, in part, on the surface of platelets in association with PF_3. In this association, the relevant co-factor (V or VIII) in the reaction is bound to PF_3 along with calcium ions, and greatly increases the activity of the co-factor.

The clotting cascade



The active form of the various clotting factors is suffixed 'a'. Green arrows show some of the positive feedback actions of thrombin. Reactions shown in yellow boxes take place on the surface of platelets in association with the platelet, platelet factor 3 (PF_3), and calcium ions. HMWK, high molecular weight kininogen.

4

Tests for clotting deficiency
Two tests are commonly used to detect clotting deficiency.

- The activated partial thromboplastin time (APTT) is a measure of the integrity of the intrinsic pathway and is performed by mixing blood with kaolin (which provides an electronegative surface), a phospholipid (as a substitute for PF_3) and calcium. The normal APTT is 30–32 seconds.
- The prothrombin time measures the integrity of the extrinsic pathway and is performed by adding blood to tissue thromboplastin derived from brain tissue and calcium. Since there are differences in the efficacy of different batches of the thromboplastin, the test is also run against an international reference standard. The prothrombin time is then expressed as a ratio, the international normalized ratio (INR), in which the time for the sample blood to clot is expressed relative to the control sample. In oral anticoagulant therapy (e.g. with warfarin), the dose is adjusted to maintain the INR in the range 2–4.

Anticlotting mechanisms and fibrinolysis
In vivo, there is a natural tendency for blood to clot. This is balanced by various naturally occurring anticoagulants. The most important of these is antithrombin III, which inhibits the activity of factors IX, X, XI and XII as well as thrombin. This inhibition is greatly facilitated by heparin.

Coagulation is also inhibited by thrombomodulin, which is secreted by intact endothelial cells and binds thrombin. The thrombomodulin–thrombin complex then activates a proenzyme protein C, found in plasma, to its enzymatic form and this, together with a co-factor protein S in plasma, results in the inactivation of factors V and VIII. Therapeutically, warfarin is used as an anticoagulant. This coumarin derivative is a vitamin K antagonist – vitamin K being required in the synthesis of several of the clotting factors (prothrombin and factors VII, IX and X).

Fibrinolyis, the dissolution of fibrin also occurs, through the action of plasmin, which degrades fibrin and fibrinogen into fibrin-degradation products. Plasmin is present in plasma as an inactive precursor, plasminogen. Its conversion to plasmin is brought about primarily by tissue-type plasminogen activator (t-PA), a protein released from endothelium. The activity of t-PA is inhibited in plasma due to the presence of plasminogen activator inhibitor-1 (PAI-1). However, this inhibitor is itself inhibited by activated protein C.

Body Temperature and its Regulation

Andrew Sean Weller

Andrew Sean Weller is a Senior Scientist at the Defence Evaluation and Research Agency (DERA) Centre for Human Sciences (CHS). He obtained his doctorate investigating the influence of cold exposure on thermoregulation and metabolism in man at the University of Nottingham, UK. His current research interests are centred around mechanisms of fatigue during exercise in environmental extremes.

Man is a homeotherm and as such deep body (core) temperature must be maintained within narrow limits throughout life, despite greater fluctuations in the ambient temperature. Although core temperature fluctuates by about 0.5°C throughout the day, only during prolonged exercise, illness and extreme exposure to hot and cold environments will it deviate outside the normal range of 36.1–37.8°C. Core temperature is normally in a state of dynamic equilibrium as a result of a balance between factors that add and subtract body heat. These factors are evident in the body heat balance equation:

Heat storage = metabolic heat production ± conductive, convective and radiant heat exchange – evaporative heat loss

Man is a homeotherm and as such deep body (core) temperature must be maintained within narrow limits throughout life, despite greater fluctuations in the ambient temperature. Although core temperature fluctuates by about 0.5°C throughout the day, only during prolonged exercise, illness and extreme exposure to hot and cold environments will it deviate outside the normal range of 36.1–37.8°C. Core temperature is normally in a state of dynamic equilibrium as a result of a balance between factors that add and subtract body heat. These factors are evident in the body heat balance equation:

Conductive, convective and radiant heat exchange are positive if heat is gained from the environment, and negative if heat is lost to the environment. Heat storage is zero (i.e. core temperature is constant) when heat production is balanced by heat loss.

Hyperthermia is associated with a net increase in body heat content (i.e. positive heat storage), whereas hypothermia is associated with a net decrease in body heat content (i.e. negative heat storage). Homeostasis of body core temperature is accomplished through two parallel processes: behavioural temperature regulation and physiological temperature regulation. Behavioural temperature regulation operates through conscious behaviour and may employ any means available. Physiological temperature regulation operates through responses that do not rely on conscious voluntary behaviour.

Effector responses

sThe physiological effector responses facilitating homeostasis of body core temperature may be described in terms of their ability to influence heat loss and heat production.

Heat loss

The surface of the body exchanges heat with the environment by conduction, convection, radiation and evaporation.

- Conduction involves the transfer of heat from one material to another through direct molecular contact. For example, the heat generated deep in the body core can be conducted through adjacent tissue until it reaches the body surface. It can then be conducted to clothing or air that is in direct contact with the skin. Conversely, if the matter in direct contact is hotter than the skin, heat will be conducted to the skin.
- Convection involves the transfer of heat by the motion of a gas or liquid across the heated surface. For example, air circulates around the body (even when trapped in clothing layers) and sweeps away the air molecules that have been warmed by contact with the skin. The greater the movement of air (or liquid, such as water), the greater the rate of heat removal by convection. In combination with conduction, convection can also cause the skin to gain heat in a hot environment. Although conduction and convection continuously remove heat when skin temperature is higher than air temperature, their contribution to overall heat loss is relatively low (about 10–20%). However, due to the high specific heat capacity of water, the rate of heat loss by conduction and convection is considerably greater in cold turbulent water compared with air at an equivalent temperature.
- Radiation is the primary means of dissipating heat at rest and, at normal room temperature (about 21–25°C), the nude body may lose up to 60% of its excess heat by this means. Radiant heat is emitted as infrared rays and the body continuously radiates heat to cooler objects (e.g. clothing and walls), but it may also gain radiant heat from warmer surrounding objects. The sun is a powerful radiator and direct exposure to it may cause heat gain.
- Evaporation accounts for about 20% of heat loss at rest, but may increase to about 80% during exercise. Thermal energy is required to transfer water from the liquid to the vapour state. Thus, when water vaporizes from body surfaces (e.g. lungs, mucosa and skin), the heat required to drive the process is removed from the surface, thereby cooling it. In the absence of sweating, water is lost by diffusion through the skin (insensible heat loss) and accounts for about 10% of heat loss, irrespective of the level of activity. However, as body temperature rises, sweat production increases and may reach a rate of 2–3 litres/hour for a short time. Sweating requires the active secretion of fluid by sweat glands which are under sympathetic control. However, high sweat rates do not necessarily translate into high cooling rates, if sweat evaporation is restricted. This is evident when the ambient vapour pressure is high (i.e. high relative humidity), or when clothing that is relatively impermeable to water vapour transfer is worn.

Heat loss by conduction, convection and radiation is largely determined by the temperature difference between the skin surface and the environment. To help explain heat exchange, the body is divided into two compartments: a core of deep tissues (e.g. brain, thoracic and abdominal organs) and a shell of peripheral tissues (e.g. subcutaneous fat and skin). The insulating capacity of the shell may be altered by vasomotor control and this contributes to core homeothermy. In a hot environment (and particularly during exercise), above a threshold body core temperature, active vasodilatation occurs which increases skin blood flow and reduces tissue insulation. This ensures that blood carries heat from the core to the skin, which has two effects. First, skin temperature is increased and thus the potential for dry heat loss (i.e. through conduction, convection and radiation) is maximized. Second, if sweating occurs, it delivers the heat necessary to evaporate the sweat. Although venomotor changes are not usually thought of as being thermoregulatory responses, dilation of superficial veins increases the efficiency of heat convection from core to skin by the blood. In the limbs, deep veins receive blood from the muscles, whereas superficial veins receive blood primarily from the skin; there are also many communicating veins between the deep and superficial veins. Unlike the deep veins, the superficial veins are relatively well innervated by sympathetic fibres. Consequently, dilation of superficial veins favours the return of blood via these vessels and increases the time available for heat exchange between the blood and skin. Both these effects promote the transfer of heat from the core to skin. However, in a cold environment, enhanced sympathetic activity causes vasoconstriction, which reduces the cutaneous blood flow and increases tissue insulation. Skin temperature, and therefore dry heat exchange, will be reduced. Although this heat-conserving mechanism helps to maintain body core temperature, the reduction in peripheral temperature (especially in the extremities) will result in discomfort and reduced performance of fine motor tasks, and may lead to peripheral cold injury (i.e. frost bite).

In a cold environment, clothing is an important component of temperature regulation in humans. The skin loses heat to the air layers trapped in the clothing; the clothes in turn pick up heat from the inner layer and transfer it to the external environment. The thermal insulating value of clothing is primarily determined by its thickness. If the thermal insulation of clothing is inadequate and when vasoconstriction is maximized, the ability to maintain thermal balance largely depends on the thickness of the subcutaneous fat layer. Individuals with a relatively thick layer of subcutaneous fat are able to maintain a large thermal gradient between the core and skin surface. This is particularly important during immersion in cold water, which has high thermal conductivity.

Heat production

Although heat conservation by enhanced vasoconstriction is an important physiological adjustment to cold stress, unless the cold stress is mild, the body must additionally increase its rate of heat production through shivering to maintain thermal balance. Shivering thermogenesis is controlled by motor innervation, and many aspects of this process are unusual and complicated. It is an involuntary response of skeletal muscles which are normally under voluntary control. Shivering can be influenced by conscious control, and it can start or stop abruptly irrespective of changes in skin temperature. Heat production is optimized during shivering as it has low mechanical efficiency and most of the heat generated appears as heat. However, compared with vasomotor responses, it is an energy-demanding process, the increase in blood flow to the shivering musculature will reduce tissue insulation, the associated limb movement will increase convective heat loss, and the performance of fine motor tasks will be impaired. Shivering thermogenesis can potentially increase the rate of heat production up to five times the resting level during cold exposure, although typically, three- to four- fold increases are observed.

Non-shivering thermogenesis is the increase in heat production independent of muscle activity. The site and mechanism of non-shivering thermogenesis in man is controversial. However, it is likely to be confined to the release of the hormones adrenaline, noradrenaline and thyroxine, which all increase the metabolic rate. Nevertheless, the contribution of non-shivering thermogenesis to heat production in the cold is minimal compared with shivering thermogenesis.

Body temperature heterogeneity

Fundamental to the study of temperature regulation is the assessment of body core temperature (the regulated variable). However, there is no one representative body core temperature, because the temperatures of sites within the body core are slightly different from each other. Nevertheless, temperatures at all sites are within about 1°C of central blood temperature at thermal steady state. Brain temperature cannot be measured directly in man, and body core temperature is usually measured at the oesophagus, rectum, mouth, tympanum and auditory meatus.

Oesophageal temperature, which is assessed by a sensor passed through the nose and throat to the level of the left atrium, is recognized as the best non-invasive index of body core temperature, because it responds rapidly to changes in central blood temperature. However, it cannot be tolerated for long periods, and it is influenced by anything ingested while measurements are being made.

Rectal temperature, which is measured by placing a flexible sensor 5–20 cm beyond the anal sphincter, is about 0.2–0.5°C higher than the temperature of the blood leaving the left side of the heart, and responds more slowly to thermal transients (it has a time lag of 5–10 minutes). However, it is well tolerated for long periods and is recognized as a reliable measure
of body core temperature in conditions of thermal steady state.

Sublingual temperature is widely used in the clinical setting because the tongue's high blood flow makes it an efficient heat exchanger with central blood and it is convenient to measure. However, oral temperature may be biased by head and facial skin temperature.

Tympanic temperature is assessed by a sensor placed on the tympanic membrane, which is uncomfortable and may occasionally result in damage to the membrane. Consequently, most researchers have chosen to measure the temperature of the external auditory meatus. Owing to the large temperature gradient along the wall of the meatus, the sensor must be placed near the tympanic membrane and insulated from the environment with a plug of cotton wool. The temperature of the tympanic or auditory meatus responds faster to changed core temperature than rectal temperature and, because this region receives the same blood supply (internal carotid artery) as the hypothalamus, it has been suggested that it is a valid measure of the blood influencing the central thermoreceptors (see page 197).

Although skin temperature is not the regulated variable, it contributes to the effector responses both directly and indirectly. Skin temperature influences the effector response even if the temperature at the site where the effector response is measured is unchanged. Therefore, the skin temperature over the rest of the body contributes to the reflex control of the effector response. Consequently, the contribution of the skin temperature to thermoregulation is usually expressed in terms of a suitably weighted mean temperature. This is more important in a cold environment, where skin temperature varies substantially between extremity and proximal body sites.

Physiological temperature regulation

Most physiologists subscribe to a theory of body temperature regulation, with properties similar to a servomechanism. The key elements of this classic biological control system are evident in Figure 1. Perturbations in body temperature (i.e. body core and skin temperature) arising from changes in metabolic rate (exercise being the most powerful influence) or changes in the external environment are sensed by thermoreceptors and sent to a controller or integrator within the CNS. The central controller compares this afferent information with a reference (or set point) and generates an error signal (load error signal). This load error signal activates corrective effector responses influencing heat loss and heat production via efferent pathways. As a result of controller action, body temperature is kept close to, and may even return to, its original value before the perturbation.

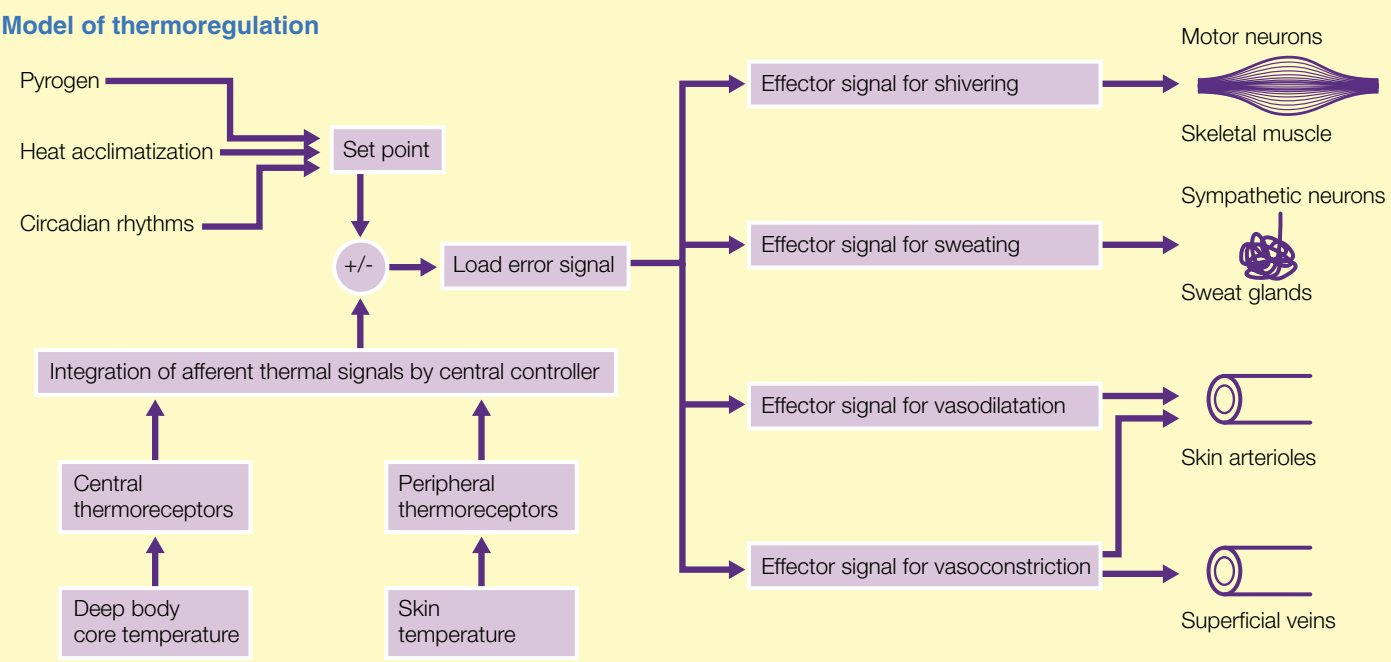
Although the exact neurophysiological mechanisms responsible for this complicated biological control system have not been fully elucidated, the following features are known. The firing rates of thermoreceptors reflect the temperature of the regional blood supply. Warm and cold sensitive thermo-receptors are grouped into those located within the core (central thermoreceptors), and those in skin and certain mucous membranes (peripheral thermoreceptors). Central thermoreceptors are unevenly distributed, though they are concentrated in the hypothalamus, where much of the integration also occurs. With regard to investigation, minor temperature changes in the anterior preoptic area of the hypothalamus induce substantial changes in thermoregulatory effector responses. However, the hypothalamus cannot account for all thermoregulatory integration and control, and other, unidentified, structures within the CNS are also likely to be involved. Other core sites that have been shown to display thermosensitivity include the spinal cord, the heart and major blood vessels. The peripheral thermoreceptors

are characterized by a sudden discharge frequency on stimulation followed by a rapid adaptation to a new static discharge. The transient discharges that occur at the beginning of heating and cooling give the central integrator information about changes in skin temperature as they occur. This feature may be responsible for the sensitivity of sweating not only to skin temperature, but also to the rate of change in skin temperature. The distribution of warm and cold receptors varies in different regions of the body surface, and is dense in the facial skin.

Temperature regulation is an example of a 'proportional control system', which means that the magnitude of changes in responses are proportional to the displacement of the regulated variable from some basal value. For sweating, skin blood flow and forearm venous volume, the response depends on both body core and mean skin temperature. Each response has a core threshold, which is influenced by the mean skin temperature. At any given mean skin temperature, each response is proportional to body core temperature, and increasing the mean skin temperature lowers the threshold level of core for the response (therefore increasing the response at any given core temperature). A change of 1°C in core temperature elicits about a nine-fold greater change in thermoregulatory response as does a 1°C change in mean skin temperature. However, as skin temperature varies over a wider range than core temperature, the importance of mean skin temperature in thermoregulatory control is greater than the 9:1 ratio suggests. The responsiveness of the thermoregulatory system to changes in core temperature is necessary to keep the controlled variable relatively constant, and the system's sensitivity to mean skin temperature allows it to respond appropriately to large changes in environmental temperature while permitting little change in core temperature.

The notion of a single load error signal in thermoregulation is supported by the similar contributions of core and mean skin temperature as inputs to all the heat-dissipating responses, and by the fact that thresholds for different thermoregulatory responses are altered simultaneously and by approximately the same degree by factors such as fever, circadian rhythms and heat acclimatization. The simultaneous shift in the thresholds for a collection of thermoregulatory responses represents a shift in thermoregulatory 'set point'. Ion concentrations, osmolality and vascular pressures may also influence the thermoregulatory set point.

Model of thermoregulation



Modified from Sawka M N, Wenger C B. Physiological Responses to Acute Exercise-Heat Stress. In: Pandolf K, Sawka M, Gonzalez K eds. *Human Performance Physiology and Environmental Medicine in Terrestrial Extremes.* Indianapolis: Benchmark, 1988: 97–151.

Examples of set point shifts

In pyrogen-induced fever, the thermoregulatory set point rises, initially causing a negative load error. This inhibits heat dissipating responses and stimulates heat production. The relationship between metabolic rate and core temperature, and skin blood flow and core temperature, are shifted during fever. Core temperature rises to correct the load error and achieve a new thermal balance in which heat production and heat loss are similar to prefebrile levels. The circadian rhythm in core temperature is also the result of a shift in set point. Core temperature and thresholds for forearm vasodilatation sweating follow each other during a 24-hour cycle. Heat acclimatization is a physiological procedure that decreases the thermoregulatory set point. A reduction in resting core temperature is associated with reduced thresholds for sweating and peripheral vasodilation.

It has been suggested that the increase in core temperature during exercise is an example of an increase in set point. However, core temperature increases during exercise because of increased heat production, which facilitates a sustained load error signal (not corrected as in fever), that is sufficient to drive heat loss responses at a rate to attain a new thermal steady state.

Fluid is continually being exchanged between the vascular space and the interstitium, and is returned to the vascular space via the lymph. The net balance of this movement determines the amount of fluid in the tissue. If there is too little fluid in the tissue, it becomes dehydrated, while excessive fluid collection causes oedema. Knowledge of the forces governing this movement, and the ability to define the alteration that has occurred, increases our understanding of the patient's condition and enables the response to treatment to be predicted.

Site of fluid exchange: capillaries and post-capillary venules

Fluid exchange between the vascular and interstitial spaces occurs at the capillaries and post-capillary venules, where the barrier between the blood and interstitial fluid is sufficiently narrow to allow exchange of a number of substances. The walls of these vessels are made up of a single layer of endothelial cells and their basement membrane. In addition, there is a network of fibrous molecules or glycocalyx coating the endothelial cells. Furthermore, the interstitium contains a meshwork of long-chain polymers (glycosaminoglycans, proteoglycans and glycoproteins), which can also contribute to the barrier in some tissues. The end result is a barrier that allows water and small solutes to pass through, but severely restricts the movement of larger molecules (e.g. the larger proteins). The degree of restriction depends, to some extent, on the type of capillary (see below) and the effects of a range of vasoactive mediators, such as histamine, bradykinin, 5-HT and even noradrenaline from the sympathetic nerves.

The capillaries fall into three classes.

- In continuous capillaries, the endothelium forms a continuous layer with narrow clefts between the cells giving 'tight' junctions. Such capillaries are found in skin, muscle, fat and connective tissues, with 'super tight' junctions in the brain.
- In fenestrated capillaries, the endothelial cells are perforated by small pores or fenestrae, allowing relatively free passage of salts and water. These capillaries are found in tissues that transport fluid, such as renal glomeruli, gut mucosa and exocrine glands.
- In discontinuous capillaries, wide, leaky, intercellular gaps permit easy transfer of larger proteins and even RBCs. These capillaries are found in tissues such as liver, spleen and bone marrow.

Fluid movement across the capillary wall

The traditional view

Movement of fluid across the walls of the capillaries and post-capillary venules is governed by a group of four forces known collectively as Starling forces (named after the physiologist who first described them). These forces can be subdivided into two groups – hydraulic or hydrostatic pressures and osmotic or oncotic pressures.

The fluid in the capillary is subject to hydraulic or hydrostatic pressure (Pc), which forces fluid across the wall and out of the capillary. This is opposed by the hydrostatic pressure in the interstitial fluid outside the capillary (Pi), which attempts to force fluid into the capillary.

The capillary wall acts as a semipermeable membrane, which produces much greater restriction on the movements of larger protein molecules than water. As a result, the protein in the plasma exerts an osmotic (often called oncotic) pressure (πc) to draw water into the capillary. This, in turn, is offset by the oncotic pressure of the interstitial fluid (πi), which also contains some protein.

The net force driving water out of the capillary is the difference between the hydrostatic pressure gradient across the wall (attempting to move fluid out) and the oncotic pressure gradient (attempting to draw fluid in). Finally, the rate at which water moves across a given area of capillary wall is dependent not only on the net force (described above), but also on the permeability of the capillary wall to water, which is expressed as the capillary filtration coefficient (Kc). The net rate of fluid movement out of the capillary is represented by Equation 1.

Flow per unit area = $Kc [(Pc – Pi) – (\pi c – \pi i)]$ 1

where: Kc = capillary filtration coefficient, Pc = capillary hydrostatic pressure, Pi = interstitial hydrostatic pressure, πc = capillary oncotic pressure, and πi = interstitial oncotic pressure.

By convention, physiologists consider movement of fluid out of the capillary; thus, Equation 1 has a positive value if fluid is moving out of the capillary and a negative value if fluid is moving into the capillary. The significance of the permeability of the capillary wall is emphasized by considering the different types of capillaries; the continuous capillaries have a fairly low capillary filtration coefficient, while that of the fenestrated capillaries is high.

Equation 1 allows calculation of the transcapillary movement of fluid at any single point on the capillary wall. However, since blood is flowing along the capillary, down its hydrostatic pressure gradient, the hydrostatic pressure will fall from the arteriolar to the venular end of the capillary (Figure 1a). Most physiology textbooks argue that fluid moves out of the capillary at the arteriolar end, but is drawn back in at the venular end, with any excess fluid being returned to the cardiovascular system via the lymph.

Filtration–reabsorption pattern along the length of an 'average' capillary

a Traditional view

Traditional view with filtration at the arteriolar end and absorption at the venular end. The net effect is a small degree of filtration with return via lymph

1

Recent developments

Magnitude of lymph flow: most general textbooks of physiology argue that the Starling forces lead to the production of about 4 litres of lymph per day in a 'normal' adult; this figure is derived from measurements of lymph in the thoracic ducts. However, the rate of lymph production and the flow in the pre-nodal afferent vessels is likely to be substantially higher (Figure 2), because up to 50% of the water is reabsorbed into capillaries from the lymph in the lymph nodes (again under the influence of Starling forces). This results in a reduction in lymph volume being delivered to the post-nodal (efferent) vessels and an increase in its protein concentration. As a consequence of this finding and recent advances in techniques for measuring interstitial pressures, the idea of net filtration at the arteriolar end and absorption of fluid at the venular end of capillaries has been reconsidered. Current ideas suggest that, in a large number of capillaries, there is little reabsorption under normal conditions. The balance is therefore shifted much more in favour of filtration than was thought previously, accounting for the higher rate of lymph production. As will be shown below, these new ideas represent a development of the Starling hypothesis rather than a contradiction.

Overview of the extravascular circulation of fluid in a 65 kg adult

2

Interstitial forces: most general textbooks of physiology view the interstitial forces as negligible. However, this is an oversimplification – not only do they make a significant contribution to the transcapillary movement of fluid, but they are also variable and thus provide a dynamic modulation of flow. Our appreciation of the importance of the extravascular forces has been increased by the advent of new techniques to measure these pressures accurately. The following section will consider the interstitial oncotic and hydrostatic pressures.

Interstitial oncotic pressure – it has been known for many years that plasma proteins are found in peripheral lymph. These proteins enter the lymph by leaking out of the capillaries into the interstitium and so the capillary wall, in most cases, is not completely impervious to the proteins. This occurs because the 'pores' in most capillary walls are small enough to make it extremely difficult for the proteins to leak out, but not so small as to make a slight leak impossible. This effect can be quantified by assessing the ratio of the oncotic pressure actually exerted by a given concentration of protein to the oncotic pressure exerted if the membrane was perfectly semipermeable (impermeable to the protein, but permeable to water). This ratio is called the reflection coefficient. A perfect semipermeable membrane would therefore have a reflection coefficient of 1, while a coefficient of 0 would indicate that the membrane was freely permeable to the solute, which would therefore exert no osmotic effect. Most continuous and fenestrated capillaries have a reflection coefficient of 0.8–0.95, with values of 1 being found in only a few areas (e.g. the brain). Because the reflection coefficient is less than 1, the oncotic pressure exerted by the proteins is proportionately less than it would be otherwise, and the Starling equation needs to be modified to take this into account (Equation 2).

Flow per unit area = $Kc [(Pc – Pi) – (\pi c – \pi i)]$ 2

where: Kc = capillary filtration coefficient, Pc = capillary hydrostatic pressure, Pi = interstitial hydrostatic pressure, πc = capillary oncotic pressure, πi = interstitial oncotic pressure and πi = reflection coefficient.

In a number of tissues (e.g. muscle, skin), because of the protein leak into the interstitium, the interstitial oncotic pressure is 30–60% of the plasma oncotic pressure, which is higher than previously reported. The magnitude of the forces favouring movements of water back into the capillary is therefore diminished compared with the traditional view.

Interstitial fluid pressure is defined as the interstitial pressure that is not attributable to the oncotic pressure exerted by the interstitial proteins. It is difficult to measure accurately because the interstitial space consists of a mesh of small molecular chains, the glycosaminoglycans, and water, which together constitute a gel. Recent measurements of the interstitial fluid pressure indicate that it is zero or negative (subatmospheric) in many normal tissues, and therefore can contribute to 'sucking' water from the capillary to the interstitium. This is because the interstitial glycosaminoglycans exert their own osmotic effect.Gravity has little effect on this pressure because of the gel-like composition of the interstitium. Thus, tissue fluid pressure contributes little to driving fluid back into the capillaries in a number of normal tissues, even when the tissue is below heart level with respect to gravity, and in some circumstances may aid movement of fluid out of the capillary.

Old versus new: a shift in balance

Current ideas suggest that the forces favouring movements of water into the capillary (see Equation 2) are smaller than originally thought. Consequently, it is now considered that, at steady state, there is net filtration along almost the entire length of the capillary in many tissues (Figure 1b), rather than filtration at the arteriolar end and absorption at the venular end (Figure 1a). This explains why the filtration of fluid into tissues is much greater than was originally supposed. However, it should be stressed that it is possible to achieve net absorption during transient non-steady states in most tissues, and sustained absorption in some tissues (see below).

Interdependence of filtration rate and Starling forces: changes from the steady state

Interstitial oncotic pressure helps to determine, and is affected by, the capillary filtration rate. A change in filtration rate would alter the amount of water added to the interstitium, the interstitial protein concentration and thus the interstitial oncotic pressure. Conversely, any alteration in the interstitial oncotic pressure would change the filtration rate (see Equation 2). This interdependence promotes stability within the tissue and leads to a buffering of any change in filtration rate as a consequence of altered intravascular forces. To illustrate this, two situations will be considered.

A fall in capillary hydrostatic pressure (Pi) leading to transient fluid absorption (e.g. following haemorrhage): during mild or moderate haemorrhage, the arterial baroreceptor reflex maintains mean arterial blood pressure. However, this reflex results in an increase in sympathetic vasoconstrictor drive to the arterioles. The consequent increase in arteriolar vascular resistance leads to a fall in the downstream capillary hydrostatic pressure (see Equation 2). This can be sufficient to reduce the force moving water out of the capillary (Pc – Pi) below that favouring inward movement (πc – πi), leading to net absorption. However, the absorptive state is usually transient, because the removal of water from the interstitium in turn causes the interstitial oncotic pressure to rise, thus opposing capillary absorption and re-establishing filtration, albeit at a reduced rate. This effect is also aided by tissue dehydration causing a reduction in the interstitial hydraulic pressure. Although the absorptive state is transient, some studies have shown it to be sufficient to add up to about 500 ml of interstitial water to the plasma over about 30 minutes. Finally, it is important to note that some tissues with active arteriolar vasomotion, such as skin and skeletal muscle, spend considerable time in the non-steady state, alternating between absorption during arteriolar constriction and filtration during arteriolar dilatation. This mechanism may help to remove considerable quantities of fluid from the interstitium.

Increases in capillary hydrostatic pressure (Pc) causing increased filtration: mean capillary hydrostatic pressure can be elevated either as a result of reduced arteriolar constriction or increased venous pressure (e.g. as a consequence of heart failure). The result of this increase in hydrostatic pressure (see Equation 2) is to increase net filtration. However, the increased filtration is soon buffered, because the resulting addition of water to the interstitium decreases interstitial oncotic pressure and thus reduces one of the forces favouring movement of water out of the capillary. A new steady state is therefore re-established, albeit at a slightly elevated level of filtration.

Sustained absorption

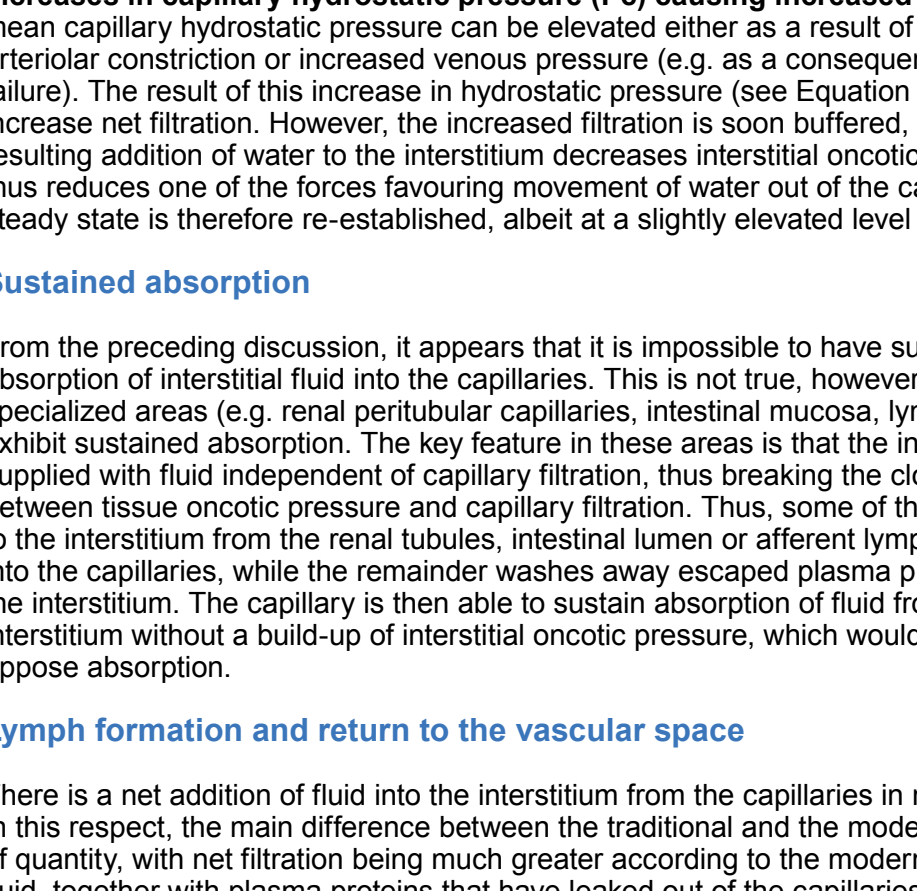
From the preceding discussion, it appears that it is impossible to have sustained absorption of interstitial fluid into the capillaries. This is not true, however, as some specialized areas (e.g. renal peritubular capillaries, intestinal mucosa, lymph nodes) exhibit sustained absorption. The key feature in these areas is that the interstitium is supplied with fluid independent of capillary filtration, thus breaking the close relationship between tissue oncotic pressure and capillary filtration. Thus, some of the fluid added to the interstitium from the renal tubules, intestinal lumen or afferent lymph is absorbed into the capillaries, while the remainder washes away escaped plasma proteins from the interstitium. The capillary is then able to sustain absorption of fluid from the interstitium without a build-up of interstitial oncotic pressure, which would otherwise oppose absorption.

Lymph formation and return to the vascular space

There is a net addition of fluid into the interstitium from the capillaries in most tissues. In this respect, the main difference between the traditional and the modern view is one of quantity, with net filtration being much greater according to the modern view. This fluid, together with plasma proteins that have leaked out of the capillaries, must now be removed from the interstitium by the lymphatic system to prevent build-up of interstitial fluid and tissue oedema.

The lymphatic system consists of the afferent lymphatic vessels, lymph nodes and the efferent lymphatic vessels, with the largest lymphatic vessel being the thoracic duct which ultimately returns fluid to the blood. The filtrate initially enters the fine lymphatic capillaries, which are similar in appearance to blood capillaries in that they consist of an endothelial cell layer, but they also have large intercellular pores and are thus highly permeable to both water and larger molecules, such as protein. The capillaries merge with the larger afferent lymphatic trunk, and fluid movement is aided along the vessel by contractions of smooth muscle within the lymphatic vessel (Figure 3). Where the lymph vessels travel through skeletal muscle, activity in surrounding skeletal muscle also aids fluid movement analogous to the muscle pump moving blood in the veins. These contractions transiently increase pressure within segments of the lymphatic vessels and, because of the presence of one-way valves in the lymph vessels, the fluid can only move away from the lymphatic capillaries (Figure 3) and is returned to the blood circulation mainly via the thoracic duct.

Lymphatic system



Interstitial fluid and proteins enter the low pressure terminal lymphatic and are propelled forward through the one-way valves towards the thoracic ducts by contraction of surrounding smooth and skeletal muscle

Clinical sequelae

The Starling forces are important in a number of clinical situations and responses associated with daily life in addition to acute hypovolaemia (e.g. following haemorrhage) and heart failure, which have already been discussed. It must, however, be acknowledged that clinical reality is often complex and the following descriptions are, of necessity, simplified.

Orthostasis

The effect of gravity can cause marked changes in the fluid content of tissues. Venous blood and lymph being columns of fluid, unlike interstitial fluid, are particularly affected by gravitational forces. Thus, in the upright individual, blood and lymph pool in the veins and lymphatic vessels, respectively. During quiet standing or sitting, this is unopposed and capillary hydraulic pressure is increased, leading to elevated net capillary filtration (see Equation 2). The increased capillary filtration is further enhanced by increased leakage of albumin from the capillary, partly because of increased convection with the increased movement of fluid through the large pores, and partly because of increased permeability to albumin as a consequence of enhanced sympathetic activity. The increased permeability to albumin, in turn, increases filtration because of a reduction in the difference between capillary and interstitial oncotic pressure, and a reduced reflection coefficient. The increased filtration, coupled with an initial reduction in lymph drainage, leads to increased fluid content of the dependent tissues, which continues until tissue expansion causes a sufficient increase in interstitial hydraulic pressure to return filtration to normal levels. Many readers will have been painfully aware of this when re-applying shoes at the end of a long flight. A recent study indicated that as much as 20% of the plasma volume may move out of the vascular space after 15 minutes of quiet standing.

Increased capillary permeability following trauma

Following trauma, there can be periods of tissue hypoxia as a result of hypovolaemia and haemodynamic changes initiated by the response to tissue injury and subsequent nociception. This, coupled with subsequent reperfusion during resuscitation, can lead to reperfusion injuries and an inflammatory response. In some circumstances, the inflammatory response can become widespread. Additionally or alternatively, there may be an inflammatory response in the lungs leading to adult respiratory distress syndrome. One consequence of the inflammatory response is increased vascular permeability to protein. The increased leakage of protein from the vasculature causes a reduction in the forces opposing filtration of fluid out of the capillary and thus tissue oedema. Following burn injuries, this is a particular problem at the sites of the burn, and to a lesser extent elsewhere, due to the presence of circulating vasoactive agents, leading to oedema with a high albumin content.

Reduction in plasma protein concentration

There are a number of situations in which plasma protein levels are reduced markedly. In nephrotic syndrome, there is a sudden reduction in plasma albumin (and thus plasma oncotic pressure) with profound proteinuria and loss of albumin into the interstitial fluid. In other situations, the liver is unable to synthesize adequate quantities of plasma proteins for a variety of reasons, including severe malnutrition with a carbohydrate-rich, protein-poor diet (kwashiorkor). Predictably, the reduced plasma oncotic pressure leads to increased capillary filtration (see Equation 2) and tissue oedema.

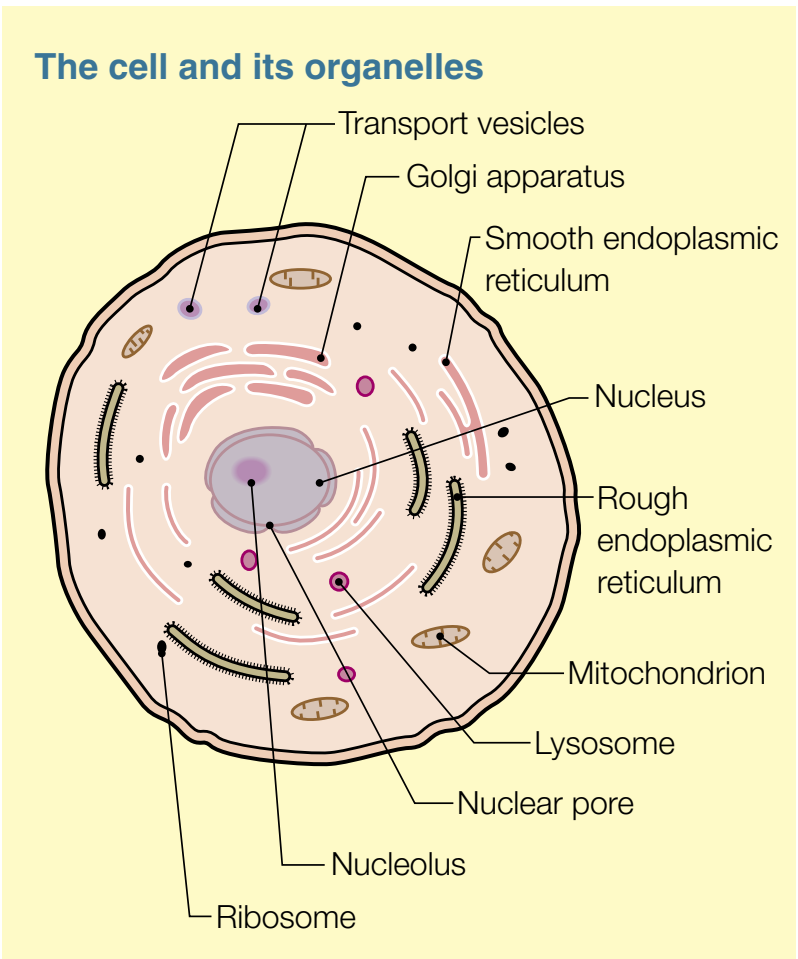
Cell biology

Cells are the individual units of life. They are made up of protoplasm surrounded by a membrane that separates them from their environment. Cells contain structures or organelles that carry out functions vital for the cell's survival. Each structure or organelle is also surrounded by, or composed of, membrane which allows compartmentalization of the various cell functions. Protoplasm within the cell is known as cytoplasm. Cells also contain genetic material that directs activity, and machinery for obtaining energy. Energy in the form of nutrient macromolecules is taken into vacuoles by the process of endocytosis and digested by enzymes contained in lysosomes. Energy is released in discrete packages of ATP via aerobic respiration in the mitochondria.

Cell theory states that all organisms are made up of cells and their products; new cells arise only from existing cells; all cells have the same fundamental make-up and chemical processes; the activity of the organism results from the interdependence and cooperative work of groups of cells.

The eukaryotic cell is divided into two regions: the nucleus, a spherical or oval structure usually situated near the centre containing the genetic material, and the cytoplasm in which lie the other organelles and the fluid surrounding them (the cytosol). Metabolic processes within the cell synthesize (and degrade) proteins for use by the cell or for export. These processes are catalysed by enzymes, which are proteins. Cells differ in their structure depending on their function and no cell can be described as typical. However, there are features common to most cells and the various organelles are found in most body cells (Figure 1).



1

Cell membranes

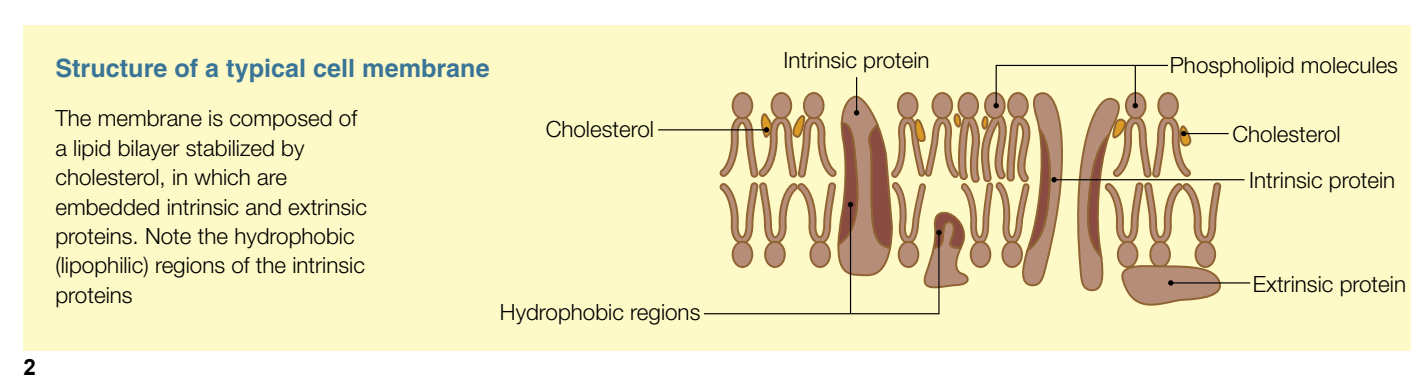
The membranes surrounding the nucleus and the organelles are composed typically of 50% protein and 50% lipid, though the precise proportions vary depending on the cell's function. At one extreme, the membranes of Schwann cells, which provide support and insulation for neurons, are only 18% protein whereas the inner mitochondrial membrane, with its mass of enzymes involved in energy metabolism, is 76% protein. Carbohydrate is also found bound to proteins (glycoproteins) and to lipids (glycolipids) but constitutes only 2–10% of the membrane. The membrane is a selective barrier between the cell and its surrounding medium; it regulates the passage of substances between the cell and its environment. It also detects chemical messengers arriving at the cell surface (e.g. hormones), provides links to adjacent cells and anchors various intra- and extracellular proteins and filaments involved in the generation and transmission of force.

The amphipathic features of the phospholipid molecules that make up most of the structure of a membrane are discussed on page 149. It is this propensity to form bilayered sheets that constitutes the structure of the membrane. Each of the phospholipid molecules can rotate on its own longitudinal axis and move around rapidly within the sheet. They can also move between the two layers of the sheet, but this is less common because it involves the hydrophilic head of the molecule moving across the inner hydrophobic region of the membrane. The fatty acid molecules can also flex and the whole structure is very fluid. It is stabilized, in part, by cholesterol (Figure 2), which may contribute up to 20% of the total lipid. This is a weak amphipathic molecule; it has an -OH group attached but is otherwise hydrophobic. The -OH group lies in the hydrophilic surface of the membrane and its hydrophobic ring structure interacts with the hydrocarbon chains of the phospholipid molecules. Other phospholipids in the membrane include phosphatidylethanolamine, phosphatidylserine, phosphatidyl-inositol and sphyngomyelin. These phospholipids are not distributed evenly throughout the membrane; the composition of the inner and outer membranes often differs.

Protein molecules are embedded in, or lie on the surface of, the phospholipid layers and contribute to the functional characteristics of the membrane. They form the receptors for chemical signals (e.g. hormones) and channels that open and close to allow passage of specific ions (e.g. Na^+, K^+) (Figure 2). Membrane proteins are of two types, intrinsic (or integral) and extrinsic (or peripheral). Intrinsic proteins lie embedded in, and many span the full thickness of, the membrane, allowing transduction of signals and passage of ions and molecules from the outside to the inside of the cell. The intrinsic proteins account for about 70% of total membrane protein. They are amphipathic molecules with their hydrophobic side chains buried in the lipid bilayer and their hydrophilic parts exposed to the aqueous regions outside the bilayer, or buried within the folds of the protein molecule itself. Like the lipid molecules they can move around within the cell membrane, though their freedom of movement may be controlled by interaction with extrinsic or peripheral proteins on the membrane surface or with components of the cytoskeleton of the cell (see page 155). This two-dimensional model of a bilayered phospholipid membrane with embedded proteins is known as the fluid mosaic model.

Extrinsic or peripheral proteins do not lie within the lipid parts of the membrane. They are not amphipathic but hydrophilic and lie on the surface, mostly on the cytoplasmic surface attached via hydrostatic and hydrogen bonds to the polar parts of intrinsic membrane proteins and to the polar phosphate heads of the phospholipids. These are relatively weak interactions, therefore it is much easier to separate extrinsic proteins from cell membranes compared with intrinsic molecules.

Most carbohydrates associated with cell membranes (90%) are found on the surface and in the external half of the bilayer (Figure 2). They are hydrophilic structures and unlike proteins, which are constituted by the folding of a linear molecule, carbohydrates are made up of multiple branching structures. They are associated mainly with proteins in the cell membrane (glycoproteins) though some are associated with lipid molecules (glycolipids). They are important in cell-to-cell recognition processes and, in conjunction with the proteins, function as membrane receptors for extracellular chemical messengers (e.g. hormones). The branching structure provides infinite possibilities in the construction of specific receptor sites.



2

The nucleus

The nucleus is the site where the nucleic acids – deoxyribo-nucleic acid (DNA) and ribonucleic acid (RNA) – are made. DNA makes up the chromosomal material. A gene is a portion of DNA containing the instructions for assembly of a particular polypeptide that makes up a protein. The genome comprises all the genes. DNA contains the instructions for synthesizing the proteins and other macromolecules that the cell needs to carry out its specific function in the body. The instructions are taken to the organelles via RNA. DNA is necessary for the independent existence and function of the cell and for cell reproduction. It is a long unbranched molecule composed of a double strand of bases in the form of an alpha helix. The DNA from one cell, if unravelled, would be about 1 m long. The DNA is tightly packed into the nucleus wrapped round proteins known as histones. Histones have positively charged side chains that bind to negative ions on the phosphate groups of the DNA. DNA is packed to form the chromosomes, of which the human cell has 23 pairs. In the resting state, DNA is relatively uncoiled and the chromosomes are unrecognisable. It is only when the cells divide that individual chromosomes become apparent.

RNA is synthesized in the nucleus from DNA. It travels as messenger RNA (mRNA) via pores in the nuclear membrane to ribosomes, structures that synthesize protein and are composed of ribosomal RNA (rRNA) and protein.

The nucleolus is a prominent area within the nucleus not surrounded by membrane, but composed of large loops of DNA and concerned with the synthesis of rRNA.

The nuclear membrane is a double membrane which appears to be continuous with the endoplasmic reticulum. Ribosomes are attached to its outer layer on its cytoplasmic face. The nuclear membrane contains pores about 9 nm in diameter through which small molecules can pass.

The cytosol

The cytosol contains the various organelles, the precursors for macromolecules to be synthesized by the cell, enzymes and energy stores in the form of glycogen and lipid droplets containing triglycerides. 20% of the cytosol is protein and it forms a highly viscous solution.

Ribosomes and endoplasmic reticulum

Ribosomes are the protein-making structures of the cell. They may be free in the cytosol or attached to the endoplasmic reticulum (ER) forming the 'rough' ER. If they occur in groups in the cytosol they are known as polysomes. Ribosomes are composed of roughly equal weights of rRNA and protein. mRNA takes the information about the precise make-up of a protein (polypeptide) from the nucleus to the ribosome, and transfer RNA (tRNA) transfers the appropriate amino acids to the ribosome.

The ER is a complex interconnected system of folded membranes enclosing a space or lumen. Rough ER has ribosomes attached to it and is concerned with protein synthesis. Smooth ER is concerned with lipid synthesis. Rough ER is prominent in cells that secrete polypeptide hormones and smooth ER in cells that synthesize and secrete steroid hormones. In muscle cells, the ER is important in the storage of calcium ions.

Many ribosomes that occur free in the cytosol become attached to the ER when they become involved in protein synthesis. Polypeptides, synthesized by ribosomes attached to the ER, are formed from amino acids in the cytosol. The polypeptide chain is extruded into the lumen of the ER and may be modified by the addition of carbohydrate to become a glycoprotein. Proteins synthesized by free ribosomes remain in the cytoplasm. Proteins destined to be membrane proteins are trapped in the wall of the ER during synthesis which prevents further movement of the polypeptide into the ER lumen.

Lipids are synthesized in the smooth ER. They are formed from precursors in the cytosol by enzymes that are part of the ER membrane. They may be complexed with proteins in the lumen of the ER to form lipoproteins. Completed proteins destined for export are moved in vesicles formed from the ER membranes to the Golgi complex for processing before export out of the cell, or for storage if the protein is to be used in the cell. Likewise, lipids synthesized in the smooth ER are transported to the Golgi apparatus before moving to the cell membrane or the membranes of other organelles in the cell.

Golgi complex

The Golgi complex is a collection of smooth membranes that look like flattened sacs. Its function is to modify macromolecules synthesized in the ER before they are transported to the cell surface or returned to the cytosol. One side of the complex faces the ER with transition vesicles shuttling synthesized molecules between the two structures. The mature face of the Golgi apparatus faces the plasma membrane, particularly in secretory cells. Secretory vesicles move the newly processed molecules from the Golgi complex towards the cell membrane for export. The modification that occurs in the Golgi complex involves largely polysaccharide chains added to the polypeptides in the ER. The precise size and shape of the complex varies between different types of cells.

Exocytosis, endocytosis and membrane recycling

The cell extrudes macromolecules by the process of exocytosis; the substance is transported in a membrane-bound vesicle to the surface and extruded. The membrane of the vesicle may then form part of the cell membrane. Likewise, during endocytosis, when macromolecules are ingested, part of the cell membrane becomes internalized. It may ultimately be returned to the plasma membrane or directed to the lysosomes with its ingested particle for digestion where it might also be broken down into its component proteins and lipids, which then become deposited in the precursor pool in the cytoplasm.

Lysosomes
Lysosomes are membrane-bound vesicles that contain about 50 digestive enzymes. They allow cells to break down any macromolecule in the body, but are kept within these membrane-bound organelles that originate from the Golgi complex. The enzymes they contain originate from the rough ER. They fuse with the endocytotic vesicles to digest substances taken in by the cell, but are also used in the breakdown and recycling of the cell's organelles.

Peroxisomes
Peroxisomes form as buds from the ER and contain catalase, which degrades hydrogen peroxide, a potentially harmful by-product of oxidative reactions. They were originally defined as organelles that carry out oxidation reactions leading to the production of hydrogen peroxide. A number of substances are oxidized in peroxisomes, including uric acid, amino acids and fatty acids.

Mitochondria
The mitochondrion is the powerhouse of the cell and provides it with energy. It is a double-membraned structure, cylindrical, and about 0.5–1 μm in diameter. The outer membrane is smooth and unfolded but the inner membrane has well-developed infoldings or cristae that project into the lumen thereby increasing the surface area. Most of the body's energy is obtained by the oxidation of carbohydrate, fat and protein. The greatest energy (ATP)-producing mechanism is the Krebs' tricarboxylic acid cycle. This occurs in the mitochondrial matrix, which contains about 120 different enzymes, some RNA and a few DNA molecules. Oxidative phosphorylation, the final stage of the ATP production process, takes place on the inner folded wall of the mitochondrion.

The cytoskeleton
Special proteins in the cytosol (tubulin, actin and myosin) form microtubules, intermediate filaments and microfilaments, which constitute a cytoskeleton and give the cell its shape. They maintain the position of the internal organelles and mediate movement of both the cell and the organelles within the cell. Microtubules are dynamic structures and their distribution within the cell is subject to change with circumstances, whereas the intermediate filaments are more stable. Myosin is seen mainly in muscle cells but it also occurs in non-muscle cells.

Gene function and gene expression

The molecular basis of the different tissues is in the structure of their proteins. Proteins are made by the cell. Cells of different tissues make or express different proteins. The instructions for each cell are contained in the DNA in the chromosomes. All cells of an organism have the same set of chromosomes constituting the genome. Thus, potentially every cell in the body could make all, and the same, proteins, but they all make different ones. Each cell therefore has more information than it needs and most of it is suppressed. Only certain genes in each cell are used to make the proteins appropriate to that particular cell's function.

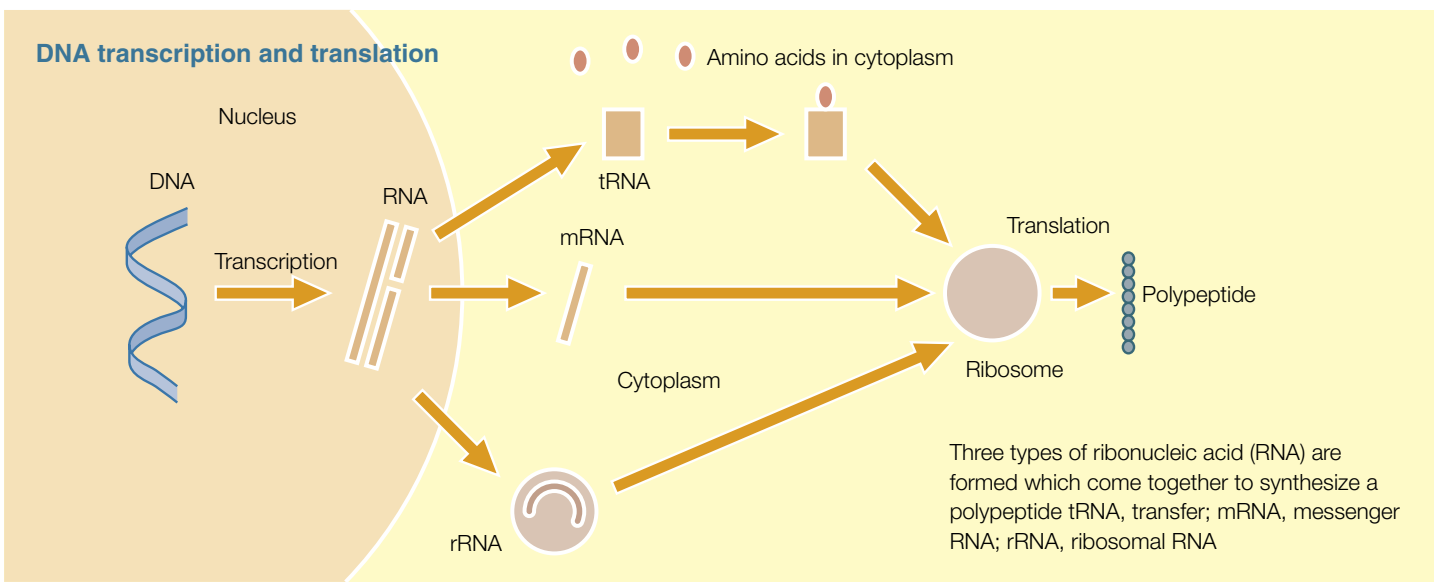
The nucleic acids are composed of nucleotides of which there are four types. Combinations of these nucleotides code for the 20 different amino acids and the order in which they are arranged to form polypeptides and thus proteins. A nucleotide is made up of phosphate groups, a sugar (ribose or deoxyribose) and a specific chemical group called a base (a nitrogen-containing ring structure derived from either purines or pyrimidines), so called because they are all proton acceptors. In DNA, the pyrimidine bases are thymine and cytosine and in RNA they are uracil and cytosine. The purine-derived bases in both DNA and RNA are adenine and guanine. The nucleotides are linked to form DNA and RNA via the phosphate groups attached to carbons 3 and 5 of each sugar molecule (Figure 3). Thus, any nucleotide chain (i.e. any gene) has a 3' end and a 5' end. Nucleotides forming nucleic acids each have only one phosphate group. The phosphate and deoxyribose groups, the so-called sugar–phosphate backbone of the nucleic acid, form the strands of the double helix and are oriented so that their bases are inside the column of the helix and close to the bases from the other strand. Hydrogen bonds can thus form between the bases in the two strands. Each turn of the helix has 10 base pairs. The variable part of the nucleic acid, corresponding to the amino acids that make up a protein (i.e. the order of the amino acids in the polypeptide chain) is the sequence of bases. The bases forming the links across the double helix do so specifically with only one of the other bases – adenine with thymine and guanine with cytosine. Each amino acid that will eventually go to make up the protein is coded for by a sequence of three bases. There are 64 possible combinations of three of each set of four bases and 20 common amino acids. Of the 64 possible triplet combinations, 61 specify a particular amino acid and some amino acids are specified by more than one triplet. The triplet specifying methionine has a special role in starting polypeptide synthesis and the three sets of triplets that do not specify any amino acids are used to stop synthesis.

The information required for protein synthesis is transferred to the ribosome by mRNA following the process of DNA transcription (i.e. the synthesis of the various types of RNA from the DNA template). Each of the bases on the DNA molecule binds only with its corresponding pair and so acts as a template for synthesis of RNA, though adenine in DNA links to uracil in RNA (instead of thymine). rRNA is synthesized in the nucleolus whereas tRNA and mRNA are synthesized in other parts of the nucleus. Several RNA molecules may be synthesized on a single DNA template at the same time. Transcription of a given gene starts when the RNA polymerase binds to a 'promoter' site on the DNA. This is a specific sequence of nucleotides immediately before the 3' end of the gene and it stops when it reaches the 'terminator' site, again a specific sequence of nucleotides towards the 5' end. The promoter sequence determines which strand of the double-stranded DNA is transcribed.

This process of DNA transcription is carried out by an enzyme – RNA polymerase. There are three types of polymerase – one for each type of RNA. RNA undergoes further processing (post-transcriptional modification) in the nucleus and other chemical groups are added to each end. In the RNA strand there are sequences of nucleotides that have no useful information; these are known as introns. They are cut out and the remaining lengths of RNA are spliced together before being exported to the cytoplasm as mature RNA.

RNA is thus synthesized from the DNA template by this process of transcription. Each triplet of bases on the DNA represents a specific amino acid. Following transcription the corresponding series of three bases on the RNA is known as a codon.

Protein synthesis



3

The several steps that involve the translation of the information in the mRNA into the synthesis of a polypeptide take place in the ribosome following the instructions contained in the mRNA (Figure 4). Free amino acids in the cytoplasm are coupled to the 3' end of the ribose ring of the tRNA. This coupling involves an enzyme (amino acyl-tRNA synthetase – AAS) and the expenditure of energy. Each molecule of tRNA has two important sites: one for the attachment of the amino acid, the other for the anti-codon, the triplet of bases complementary to a codon on a molecule of mRNA. For an amino acid to participate in protein synthesis it has to be attached to tRNA and each amino acid has its own AAS and one specific tRNA. mRNA binds to the ribosome, and tRNA molecules transport their amino acids to the ribosome where the polypeptide is assembled. The polypeptide is assembled in accordance with the sequence of codons on the mRNA. The amino acids are joined by peptide bonds by peptide transferase and the tRNA is ejected. Several ribosomes may attach to a single mRNA strand forming a polysome. Translation of the mRNA and polypeptide synthesis cease when a stop codon is encountered in the mRNA sequence. Polypeptides also undergo some degree of post-translational modification in the Golgi apparatus before they become mature proteins.

Gene expression is regulated at the level of transcription rather than translation (i.e. RNA formation rather than protein synthesis). This is performed by repressor and inducer molecules that prevent or allow transcription to occur (i.e. turn the gene on or off), though the mechanism is unclear.

Structure of the DNA helix

The sugar–phosphate backbone, the 3' and 5' ends of the nucleotide chain and the interrelationships of the bases are shown. A, adenine; G, guanine; T, thymine; C, cytosine

The Cell Membrane and Receptors

James Waterhouse

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Sciences, Liverpool John Moores University. He qualified as an animal physiologist from Oxford University and gained his DPhil there. His research interests are circadian rhythms, with particular reference to jet lag and assessing the clock-driven components of measured circadian rhythms.

The cell membrane, the plasmalemma, separates the intracellular fluid (ICF) from the surrounding extracellular fluid (ECF), and acts as an interface between the cell's environment and its contents. Because the ICF and ECF differ in composition, the cell membrane must act as a barrier; however, the metabolism of the cell requires the entry of raw materials and the exit of waste products, therefore the membrane must also allow certain substances to cross it. Cells that manufacture a product that is required elsewhere, have to secrete it across the cell membrane in some way. The cell membrane is also the link between the anatomical structures inside the cell (the microtubules and microfilaments of the cytoskeleton) and those outside it (the basal lamina and other cells), and is the site where external signals first exert their influence on the cell.

It is not surprising, therefore, that the structure of the cell membrane is complex, and that into this complexity is also built specificity, by which only some cells respond to a particular stimulus, and those cells that do respond do so in a specific way.

Membrane composition and the role of lipid

The cell membrane is composed of about equal amounts, by weight, of phospholipids and protein, with a small amount of carbohydrate. The molecular weight of the phospholipids is much less than that of the proteins and there are about 50 phospholipid molecules for each protein molecule. The exact properties of the membrane bilayer depend on the nature of the lipids involved, and change according to the amount of cholesterol, the length and the degree of branching of the lipid chains, and the level of unsaturation of the lipids. The lipids from cell membranes in different regions of the body differ also; for example, those in the brain contain sphingomyelins. The mixture of lipids is such that the cell membrane behaves as a solid just below its melting point; its molecules do not lose their parallel alignment, but the whole is to be regarded as a vibrating rather than a static structure.

The lipid bilayer forms a barrier between the ICF and the ECF to the passage of water-soluble molecules in either direction. However, such a barrier is leaky to small molecules such as water. Some of this leak is probably through gaps that form transiently between the vibrating lipid molecules. If there is an osmotic gradient across the membrane, there is a net flux of water by osmosis; if there is no such gradient, water movement across the membrane occurs, but is equal in both directions (i.e. there is a dynamic equilibrium between influx and efflux). Other small molecules, including the dissolved oxygen, carbon dioxide and nitrogen also pass across the cell membrane, possibly by the same mechanism. However, for other water-soluble substances, including ions, glucose and amino acids, the membrane forms a barrier. For these substances to cross the membrane requires various channels and carriers, which are made of protein.

Role of proteins in the cell membrane

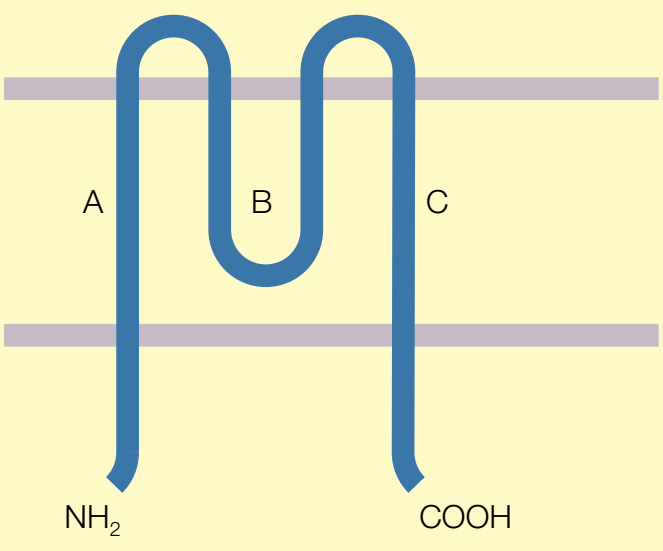
As well as providing a barrier to the free passage of water-soluble molecules, the membrane allows the passage of specific ions and other water-soluble substances; it is selectively permeable. These functions are achieved by the proteins of the cell membrane, which provide the required receptor and channel specificity. The main roles of proteins in allowing the transfer of specific molecules across the membrane are as channels (pores), carriers, receptors, and in the processes of endocytosis, pinocytosis and exocytosis. Proteins also have an important structural role and, in conjunction with carbohydrate moieties, have a role in the immune system.

Transmembrane channels

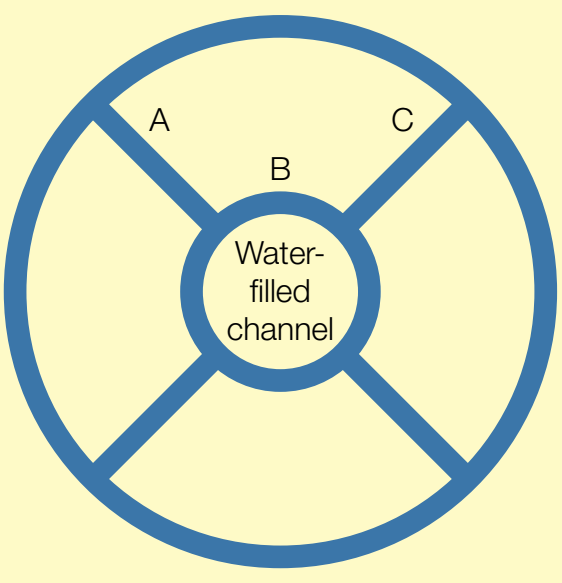
The best known transmembrane channels allow the passage of Cl^-, Na^+, K^+ and Ca^{2+} ions. These channels are fundamental to the functioning of excitable tissues. The channels differ not only in their specificities, but also in whether they are normally open or closed, and in the kind of stimulus that can cause them to open or close. The channels are produced by a set of subunits, each of which spans the membrane and produces a hydrophilic region in the membrane. A set of subunits (generally four or more) combines to form a hydrophilic, water-filled channel or pore, through which a specific ion can pass when the channel is open (Figure 1). The detailed properties of a channel that give it its specificity are not fully understood. Important factors appear to be the size of the channel and its charge, and also the distribution of charge density along the channel. At a physiological pH, some amino acids show a net positive, and some a net negative, charge; these are responsible for the charge along the channel.

The main chloride channel is always open, allowing the movement of Cl^- ions down their electrochemical gradient. The sodium, potassium and calcium channels, by contrast, are often shut, and are said to be gated. Channels can be opened either by changes in the electrical potential across the membrane (voltage-gated), by chemical signals, transmitters or hormones reaching the cell (ligand-gated), or by both mechanisms (Figure 2). For voltage-gated channels, the gate (which determines if the channel is open or closed) is probably a charged part of the protein molecule that is free to swing and whose position is determined by the prevailing electrical gradient. The ligand-gated channels are considered further when the action of membrane receptors is discussed.

Simple ion channel



The position of one subunit in the membrane. It spans the membrane several times. Regions A and C are lipophilic, and region B contains a hydrophilic section that forms part of the wall of the channel

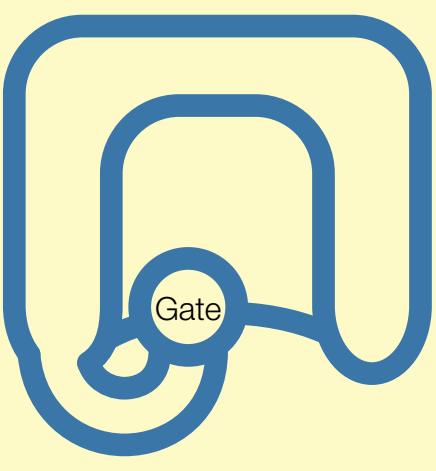


Four subunits combine to form a water-filled channel. The positions of the parts of the subunit (A–C) are shown

1

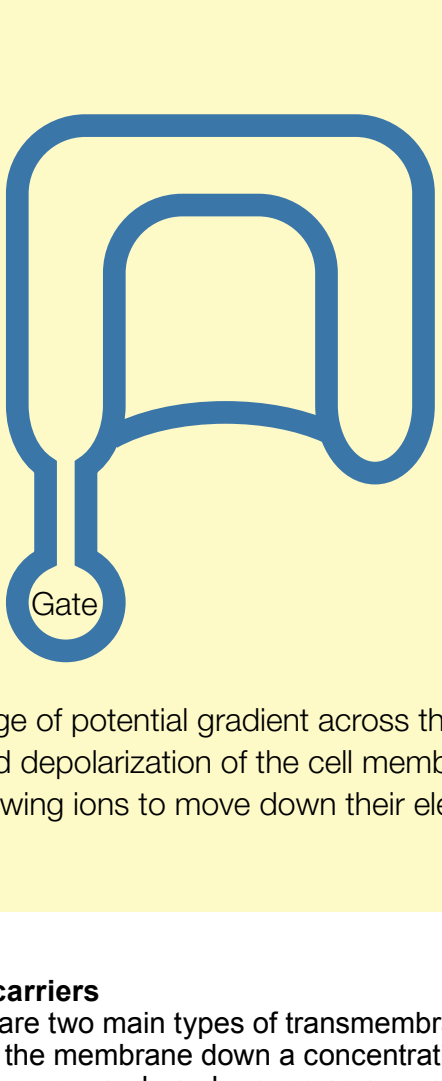
Voltage-gated channel

Closed channel



The gate blocks the channel and prevents ion movement

Open channel



Following a change of potential gradient across the channel (a supra-threshold depolarization of the cell membrane), the gate swings open, allowing ions to move down their electrochemical gradient

2

Transmembrane carriers

Functionally, there are two main types of transmembrane carriers. The first transfers substances across the membrane down a concentration gradient by facilitated diffusion. It does not require energy, and can be seen as a means to overcome the impermeability of the membrane conferred by its lipid structure. Well-known examples are those that involve the transfer of glucose and amino acids into the cell. The molecule seems to be passively transferred to the inside of the cell by conformational changes in the molecule-receptor complex.

The second type of carrier transfers molecules against a concentration gradient, and thus requires energy. The best-known example is the membrane-bound Na^+/K^+-activated ATPase (the sodium pump), which exchanges $3Na^+$ on the cytoplasm side of the cell for $2K^+$ in the ECF. Because the pump moves more positive charges out of the cell than into it, it is also described as an electrogenic system.

Membrane receptors

There are also receptors on the outer surface of the cell membrane, the function of which is to bind with external signals from, for example, blood-borne hormones or neurotransmitters. With blood-borne hormones, the specificity of the receptor–hormone interaction arises from the complex structures of the hormone and its receptor. For neurotransmitters, the receptor–transmitter complex is likely to be formed only in the localized regions into which the transmitter is released. These receptors sometimes contain carbohydrate moieties.

After binding to the receptor has taken place, one change that can occur is the opening of a calcium channel (a ligand-gated channel), allowing calcium influx. Another change is to initiate a series of events that begins with the activation of G proteins (proteins associated with the inner surface of the cell membrane). These G proteins then activate 'second messengers', the effects of which spread into the cytoplasm. Among these second messengers are derivatives of inositol phosphate, but one of the best known is cyclic AMP. This is formed by the action of the enzyme adenylyl cyclase, another protein found at the inner surface of the membrane. Second messengers often cause the release of intracellular calcium. The properties of the different types of membrane transport proteins are summarized in Figure 3.

Some roles of transport proteins

Channels

- Open (Figure 1)
- Voltage-gated (Figure 2)
- Ligand-gated: after binding to the receptor, the ligand causes the channel to open

Carriers

- Facilitated transport: the molecule that is to be carried, after binding with the receptor, causes a conformational change in the complex. The molecule moves down a chemical (diffusion) gradient, no energy being required
- Active transport: the process is the same as that in facilitated transport, except that the molecule moves against an electrochemical gradient. Energy is therefore required and is obtained from the breakdown of ATP, often by the carrier itself, part of which is an ATPase

Receptors

- After the ligand has bound to the receptor, G proteins are activated on the inner surface of the cell membrane. This causes the release of second messengers.
  Two common possibilities are:
  - release of inositol triphosphate from the cell membrane, which diffuses into the cytoplasm causing the release of calcium from the endoplasmic reticulum
  - activation of membrane-bound adenylyl cyclase, which converts ATP into cAMP, leading to the activation of protein kinases which diffuse through the cytoplasm

Endocytosis, pinocytosis and exocytosis

Endocytosis and pinocytosis are processes by which portions of the ECF and its contents can be transported into or out of the cell. A common example of endocytosis is the ingestion of material by phagocytosis. An example of exocytosis is the secretion of stored products, (e.g. hormones). In endocytosis, the cell membrane engulfs the material that is to be taken in and forms a vesicle round it. The process is initiated by an interaction between the signal molecule(s) and a specific membrane protein, some of which are called clathrins. The vesicle can then be discharged into the cytoplasm. Pinocytosis is similar, except that the vesicle contains only ECF and the proteins involved are caveolins; vitamins are taken up by this method. In exocytosis, the process is essentially the same but in the opposite direction; a secretory vesicle, bounded by a structure like the cell membrane, fuses with the inside of the cell membrane with the help of a docking protein. The process is often initiated by a secretagogue that causes calcium influx. This promotes the movement of vesicles to the exit site, a process that involves microfilaments and microtubules, and the proteins kinesin and dynein.

These three processes enable relatively large amounts of material to cross the membrane without allowing continuity between the ECF and ICF. If continuity occurred, it might damage the cell, allowing unwanted material to enter, or required material to escape. This would have catastrophic consequences for ionic gradients.

Structural and immune functions

The proteins in the cell membrane add structural stability to it, and can be considered as a type of scaffolding. In addition, other proteins (cell adhesion molecules) bind cells together at tight junctions, gap junctions, desmosomes and terminal bars. Laminins are proteins that bind the cell membrane to the basement membrane, and other proteins anchor the cell membrane to the internal cytoskeleton.

The external part of the cell membrane contains complex glycoproteins that extend into the ECF. They are the cell's natural antigens, and are the basis of the recognition of self by the immune system.

Modification of membrane function

The membrane is a dynamic interface between the ICF and ECF. There is some regulation of membrane function; for example, frequent exposure of a cell to a particular secretagogue can decrease the sensitivity of the cell to this signal (down-regulation), because it decreases the number of free receptor molecules on the outer surface of the cell membrane (internalization). Exocytosis increases the amount of cell membrane; therefore, the membrane has to be recovered to form more intracellular structures for refilling with transmitter or secretory material.

Transport processes, both those involving carriers and channels, can be modified by natural substances as well as by drugs. Insulin, for example, changes the properties of the glucose carrier, and aldosterone increases the number of functional sodium pumps in the kidney. Many drugs modify membrane function, such as ouabain (the sodium pump), tetrodotoxin (the sodium channel) and atropine (muscarinic receptors).

Characteristics of Special Circulations

Roger Hainsworth

Roger Hainsworth is Professor of Applied Physiology at the University of Leeds and Honorary Consultant Cinical Physiologist. He trained in Leeds and San Francisco. His research interests centre around the control of the cardiovascular and respiratory systems in normal subjects and patients with cardiorespiratory diseases.

Blood flow through any region is controlled by physical principles. Poiseuille's equation, which relates to the laminar flow of a Newtonian fluid through a non-distensible tube, is given as:

$$Q = \frac{(P_1 - P_2)}{\eta \times l} \times r^4$$

where: Q = flow, $P_1 - P_2$ = the pressure gradient, η = viscosity, l = length of the tube and r = radius of the tube.

However, Poiseuille's equation can be used only in a descriptive sense in relation to the cardiovascular system. This is partly because blood is not a Newtonian fluid and its viscosity varies with the velocity of movement, largely as a result of the axial streaming of the cells. Furthermore, the vascular system is not a single tube, but a complex system of interconnecting tubes of various diameters. Nevertheless, the equation provides an insight into the main factors influencing blood flow.

Pressure gradient is the driving force for blood flow and an adequate arterial pressure is essential. In many situations (e.g. in the skin and liver), P_1 and P_2 represent arterial and venous pressure, respectively, with P_2 being usually much lower than P_1. In other regions, the pressure gradient may not be arterial–venous, but be related more to capillary pressure which, importantly, may be influenced by the tension in the surrounding tissues. This particularly applies to blood flow to contracting muscle, including that to the left ventricle.

Poiseuille's equation emphasizes the importance of vessel radius, because this is raised to the fourth power. The most significant vessels in this respect are normally the precapillary resistance vessels (essentially microscopic arteries and arterioles), because they contain a high proportion of vascular smooth muscle and are under neurochemical control. The largest pressure drop occurs across these vessels. There is usually a minimal flow-related pressure drop along the conducting arteries and veins. However, this is not always the case, particularly when conducting arteries are narrowed by disease. In the coronary arteries, for example, a narrowing of about 70% of the diameter allows adequate flow during resting conditions with a relatively small pressure gradient, but during increased demand when the precapillary vessels dilate, flow through the narrowed segment becomes the limiting factor.

The diameter of the lumen of resistance vessels is dependent on the degree of contraction of the vascular smooth muscle. There is usually an inherent muscle tone which can be enhanced or inhibited by neural, humoral or local chemical influences. The principal vasomotor nerves are sympathetic vasoconstrictors. These supply most regions of the body and their activity is largely dependent on reflex inputs, particularly from baroreceptors. Vasomotor nerves are noradrenergic, though their effects may be modulated by the co-transmitters, ATP and neuropeptide Y. Vasodilator nerves also exist in some regions. Parasympathetic nerves cause increases in blood flow in association with glandular secretion. Cholinergic sympathetic vasodilator nerves are found in the cutaneous circulation and blood flow increases with sweating. However, contrary to previously held views, there are no cholinergic sympathetic vasodilator nerves supplying skeletal muscle in humans. Circulating hormones, particularly catecholamines, angiotensin II and vasopressin, have widespread actions. Noradrenaline is a vasoconstrictor, but adrenaline has different actions in that it dilates vessels supplying muscle and mainly constricts those elsewhere.

Flow through highly metabolically active regions, such as working muscle, including the myocardium, is mainly regulated by local mechanisms. These mechanisms are essentially the results of metabolism, which reduces oxygen tension and increases the production of metabolites. The principal vasodilators are carbon dioxide, adenosine, phosphates, and potassium and hydrogen ions. Osmotic forces increase as large molecules are broken up into smaller molecules. The local temperature also increases. These factors combine to cause relaxation of vascular smooth muscle and an increase in flow. A metabolic mechanism can also explain autoregulation of flow. An increase in perfusion pressure immediately leads to an increase in flow, which washes out metabolic products, thereby reducing their local concentration. Flow is therefore restored close to its former level. The other hypothesis for autoregulation is myogenic, whereby vascular muscle reacts by contracting when its tension increases.

When considering the factors influencing regional flow, it is important to recognize that the vascular endothelium is a source of potent vasoactive substances. Endothelial-derived relaxing factor, believed to be nitric oxide, is one such substance. It is released in response to shear stress or pulsatility of the blood and has potent effects on vascular smooth muscle. Other agents released by the endothelium include endothelin, a potent vasoconstrictor, and prostaglandins.

Both neurohumoral and local factors influence the state of constriction of resistance vessels in most vascular beds, and the resultant tone is a balance between local factors (mainly dilator) and neural control (mainly constrictor). The relative importance of the various factors differs widely in the various regions and at different times in the same region.

Coronary circulation

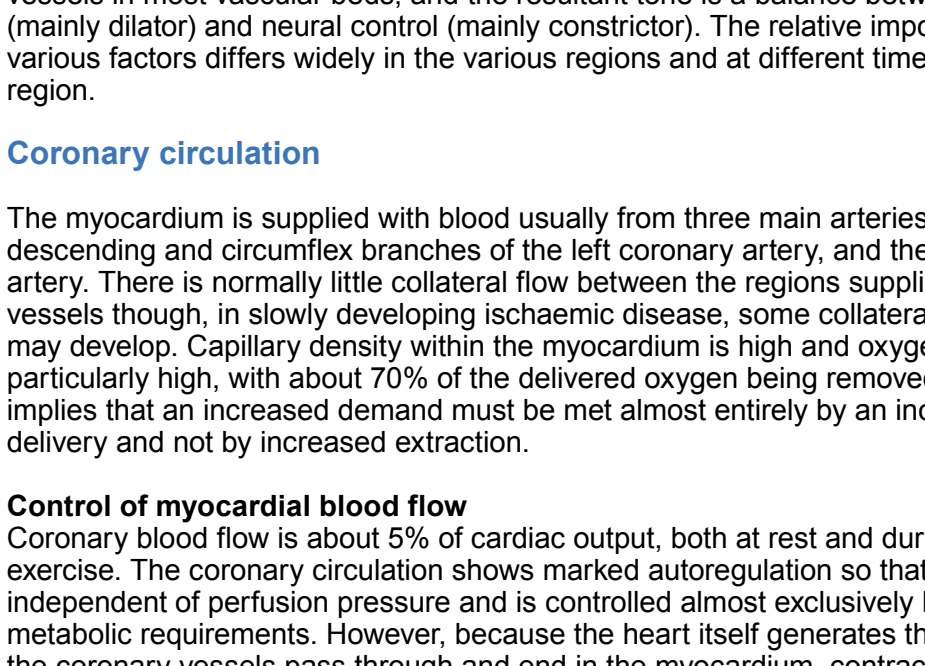
The myocardium is supplied with blood usually from three main arteries: the anterior descending and circumflex branches of the left coronary artery, and the right coronary artery. There is normally little collateral flow between the regions supplied by these vessels though, in slowly developing ischaemic disease, some collateral circulation may develop. Capillary density within the myocardium is high and oxygen extraction is particularly high, with about 70% of the delivered oxygen being removed at rest. This implies that an increased demand must be met almost entirely by an increase in oxygen delivery and not by increased extraction.

Control of myocardial blood flow

Coronary blood flow is about 5% of cardiac output, both at rest and during exercise. The coronary circulation shows marked autoregulation so that flow is largely independent of perfusion pressure and is controlled almost exclusively by myocardial metabolic requirements. However, because the heart itself generates the pressure, and the coronary vessels pass through and end in the myocardium, contraction of the heart has a major effect on the phasic characteristics of flow, particularly flow to the left ventricle (Figure 1). The high intramyocardial tension, especially at the start of systole, prevents and may even transiently reverse coronary flow. Flow is, therefore, maximal in early diastole when perfusion pressure is greatest and intra-myocardial tension relaxes. Coronary flow is thus dependent on both diastolic pressure and its duration. Intra-myocardial tension increases from epicardium to endocardium. Normally, this has little effect on flow, but when flow is restricted by coronary disease, it is the inner wall of the ventricle that is most susceptible to ischaemia.

Activity in cardiac nerves has little direct effect on coronary flow; activity in sympathetic and parasympathetic nerves causes small decreases and increases in flow, respectively. These effects are, however, transient because of the associated changes in cardiac work, which have far more potent effects. Increases in the metabolic activity of the myocardium result in decreases in tissue oxygen tension and increases in the concentrations of metabolic products, of which adenosine is a particularly potent vasodilator. The magnitude of this dilatation can be appreciated by considering that the changes required when going from rest to exercise typically cause a five-fold increase in both cardiac output and coronary flow, accompanied by a marked reduction in diastolic duration. Coronary flow is almost linearly related to heart rate and is also affected by arterial blood pressure due to its effect on cardiac work. Both of these factors are increased by exercise, which explains why stress testing is an effective method for assessment of coronary insufficiency.

Pressures in the aorta and left ventricle, and flow in left coronary artery during the cardiac cycle



Vertical lines A–B indicate the ventricular isovolumic contraction phase and C the onset of ventricular diastole. Note that coronary flow abruptly ceases during isovolumic contractions and is greatest during diastole

1

Cerebral circulation

The brain is supplied with blood through the carotid and vertebral arteries, which anastomose in the circle of Willis. This anastomosis may allow for adequate flow if one vessel is obstructed, though with age and vascular disease adequate perfusion may be dependent on the patency of all vessels. Perfusion pressure is the arterial–venous difference and the effects of gravity need to be considered when the body position changes. Cerebral venous sinuses, unlike other veins, do not collapse at low pressures so that, in the upright position, perfusion may be assisted by negative venous pressures.

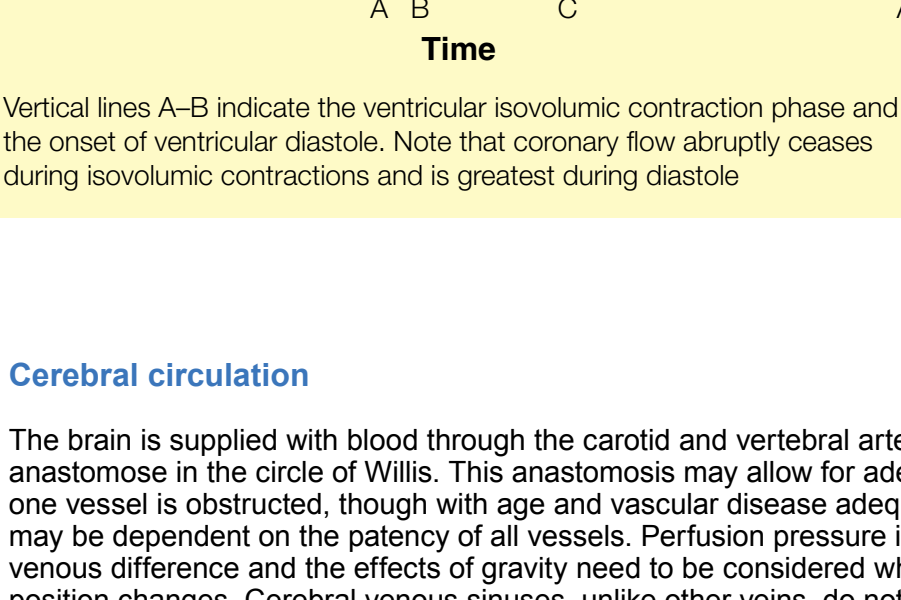
Control of cerebral blood flow

Cerebral blood flow is about 55 ml/minute/100 g, which is about 15% of the resting cardiac output. Flow overall normally remains relatively constant, though localized increases in flow occur in response to various activities. For example, shining a light in the eye causes hyperaemia in the visual cortex.

The cerebral circulation is autoregulated; flow is relatively constant at mean pressures of 60–130 mm Hg. Innervation of cerebral vessels is relatively weak, though there may be cerebral vasospasm in some circumstances. The level of carbon dioxide in the cerebral blood does, however, have a marked effect on cerebral flow. An increase in the partial pressure of carbon dioxide from its normal level of 5.3 kPa to 7 kPa doubles the flow, whereas a decrease to about 3 kPa reduces the flow by half. The level of carbon dioxide influences autoregulation of cerebral flow (Figure 2). During hypercapnia, autoregulation is largely lost, whereas during hypocapnia blood flow remains low at all perfusion pressures.

It should be noted that the brain can tolerate complete ischaemia for only a few seconds and a 50% reduction in flow results in consciousness starting to be lost. This level could be reached by hyperventilation or by a fall in mean cerebral arterial pressure to about 40 mm Hg. In the upright position, this is equivalent to a brachial pressure of about 60 (80/50) mm Hg.

Effects of cerebral perfusion pressure and arterial carbon dioxide on cerebral blood flow



During normocapnia (partial pressure of carbon dioxide, 5.3 kPa), there is effective autoregulation of flow at pressures above 60 mm Hg. During hypercapnia, autoregulation is largely lost and flow markedly increases. During hypocapnia, flow remains low at all pressures

2

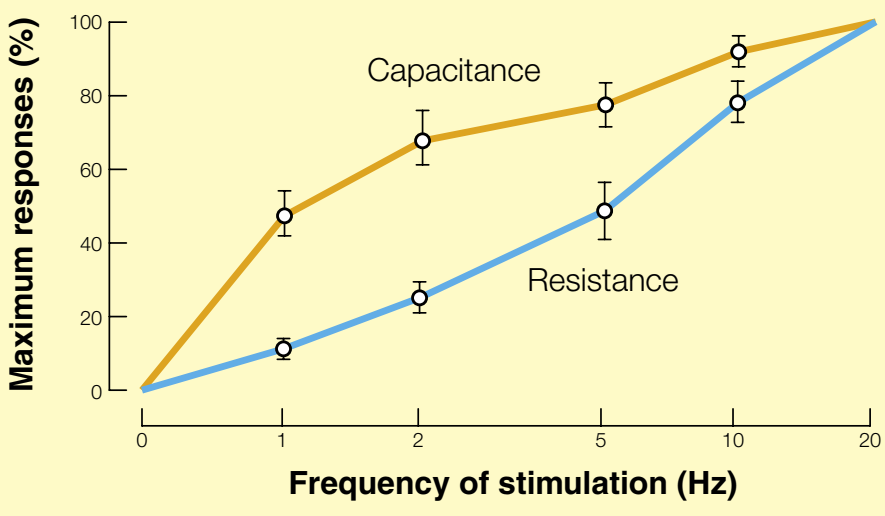
Hepatosplanchnic circulation

The gastrointestinal tract from stomach to large intestine receives blood from the coeliac, and the superior and inferior mesenteric arteries. Splanchnic blood flow, which is about 1.2 litres/minute, passes through the portal vein to the liver. Hepatic arterial flow is about 0.4 litres/minute and the combined outflow is through the hepatic veins. The hepatosplanchnic circulation provides for the secretory and absorptive functions of the digestive system. It is also a large vascular bed, which is important in reflex circulatory control.

Control of splanchnic flow
Splanchnic flow increases in response to food in the gastro-intestinal tract. This is partly due to local mechanisms resulting from the increased metabolic activity associated with secretion, digestion and absorption. Humoral factors, such as gastrin, cholecystokinin and insulin, cause vasodilatation, and food products, particularly glucose and fatty acids, also contribute.

Apart from increases in flow due to food digestion, splanchnic flow is regulated by sympathetic vasoconstrictor nerves which in turn are controlled by reflexes, particularly baroreceptors. The high resting splanchnic blood flow means that it has the potential to be significant in the control of total peripheral vascular resistance. Of particular importance, however, is its role in vascular capacitance. The hepatosplanchnic circulation contains about a quarter of the blood volume. The capacitance vessels (veins) are highly distensible so they can passively constrict or expand if blood is transferred to or from other regions, or if blood volume changes. They also possess adrenergic innervation, which can cause active constriction and thereby enhance inflow to the heart; this is a capacitance effect. The gut vessels are highly distensible and are responsible for most of the 'passive' volume changes in the region. This region accounts for most of the active capacitance of the body, with the liver being of particular importance. One feature of the responses to sympathetic nerve stimulation is that, at low levels of activity, capacitance responses dominate and only at higher levels do resistance vessels show large changes (Figure 3).

Capacitance and resistance in the hepatosplanchnic circulation to graded stimulation of efferent sympathetic nerves



Total responses at stimulation frequency of 16 Hz are taken as 100%. Note that at low frequencies (1–2 Hz) capacitance responses predominate, whereas higher frequencies are needed to induce large responses of vascular resistance

3

Renal circulation

The blood flow to the kidneys is about 1.2 litres/minute and is extremely high in relation to their size. Renal arteries supply the glomerular capillaries via afferent arterioles and then drain to efferent arterioles. This arrangement maintains the high glomerular capillary pressure required for filtration. Efferent arterioles supply the peritubular capillaries, which drain into the renal veins. Juxtaglomerular cells synthesize and release renin in response to decreases in local blood pressure, decreases in sodium delivery (actually detected by cells in the macula densa of the distal convoluted tubules) and to sympathetic nerve stimulation.

Control of renal blood flow
Renal blood flow is autoregulated and is thus largely independent of blood pressure down to mean levels of about 80 mm Hg. Myogenic mechanisms are thought to be involved, but there is also a tubuloglomerular feedback mechanism whereby the flow of fluid in the distal tubule is sensed by the macula densa. This regulates various vasodilator or vasoconstrictor factors that act on afferent arterioles to control both blood flow and glomerular filtration. The agents responsible are not precisely known, though angiotensin II, prostaglandins and adenosine have been implicated. Sympathetic nerve activity reduces renal blood flow mainly by constriction of afferent arterioles. This effect may be augmented by angiotensin II, formed as a result of increases in renin release.

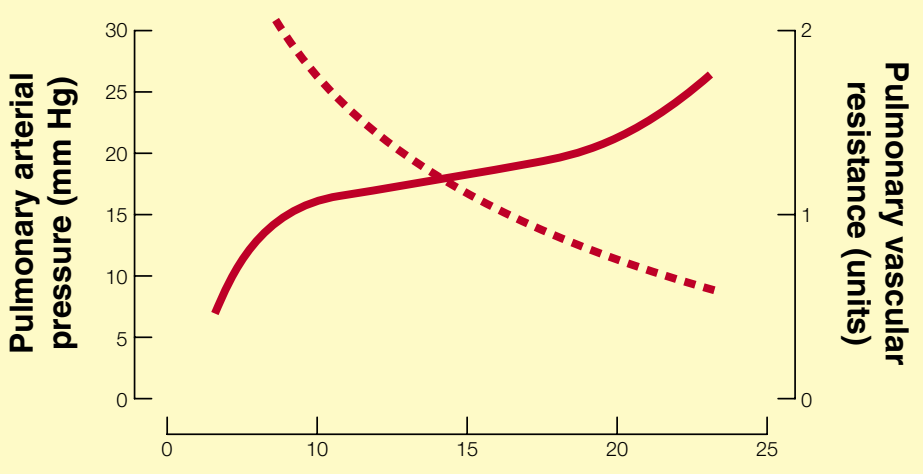
Pulmonary circulation

The pulmonary vascular bed is a low-resistance network in series with the systemic circulation, but with only about one-sixth of the arterial pressure. Because pulmonary arterial pressure is so low (systolic pressure about 20 mm Hg), both pulmonary pressures and flow are greatly influenced by gravity so that, at rest in the upright position, there is little or no flow at the apices, and the greatest flow at the bases. The uneven distribution of flow is partly, but not completely, offset by a similar distribution of ventilation. Pulmonary capillary pressure is about 10 mm Hg, which is considerably less than plasma colloid osmotic pressure. Nevertheless, some filtration does take place, resulting in lymph formation. This is because the tissue protein concentration in the lungs is high, thereby reducing the absorptive gradient.

The volume of blood in the pulmonary circulation is about 0.5 litres. This can vary to allow for changes in blood distribution. For example, standing upright or the Valsalva manoeuvre results in most of this blood being transferred elsewhere. The reservoir function also allows for temporary imbalances between the right and left ventricles as occurs at the start of exercise.

Factors influencing pulmonary vascular resistance
Unlike regions of the systemic circulation, overall pulmonary flow is not regulated but depends solely on systemic flow. The characteristics of the pulmonary circulation allow flow to be increased five-fold with only a small change in arterial pressure (Figure 4). This is partly because of the high degree of distensibility of the pulmonary vessels and also because a small pressure change results in more perfusion of the apical regions. Pulmonary arterioles possess some smooth muscle, which has sympathetic innervation. Stimulation of peripheral arterial chemoreceptors results in pulmonary vasoconstriction. Hypoxia also increases pulmonary vascular resistance by a direct effect on the blood vessels. This is the opposite of what occurs in the systemic circulation. Localized hypoxic vasoconstriction has the beneficial effect of diverting blood away from inadequately ventilated regions. Generalized hypoxia, however, leads to pulmonary hypertension and possibly oedema; this can be countered by administration of oxygen.

Effects of changes in pulmonary blood flow (cardiac output) on pulmonary artery pressure and pulmonary vascular resistance



Resistance is perfusion pressure (pulmonary artery – left atrial pressure). Note that increasing cardiac output from resting levels (typically 5 litres/minute) to exercise levels (25 litres/minute) is associated with only a small increase in pulmonary arterial pressure ▬ and a large decrease in pulmonary vascular resistance ▪ ▪ ▪

Digestive Functions

Adrian Thomas

Adrian Thomas is Consultant Paediatric Gastroenterologist at Booth Hall Children's Hospital, Manchester. He qualified from Manchester where he also completed an honours BSc in physiology. His training in paediatric gastroenterology was completed in Manchester, London, and Sydney, Australia. His research interests include inflammatory bowel disease and nutritional support.

Most foods cannot be absorbed in the form in which they are present but require digestion into smaller compounds that can be more easily absorbed. The basic process of digestion for the three major foods (carbohydrates, proteins, fats) is hydrolysis. Most absorption takes place in the small intestine and the absorptive surface is increased about 1000-fold by:

- valvulae conniventes (mucosal folds)
- villi (finger-like projections composed of epithelial cells, blood supply and a central lacteal)
- microvilli (finger-like projections on the surface of epithelial cells).

Absorption of ions and water

Sodium is actively transported from inside the epithelial cell through the basal and lateral cell walls into the paracellular spaces. Intracellular sodium is replaced by sodium from the chyme moving down the electrochemical gradient. In addition, some potassium and hydrogen ions are transported in the opposite direction in exchange for sodium ions, and some chloride ions are transported in the same direction with the sodium ions. Osmotic equilibrium is maintained by water following sodium through the epithelial membrane. In the colon, the junctions between the epithelial cells are much tighter than those in the small intestine. This prevents back diffusion of ions and water, allowing more complete absorption of sodium, especially when under the influence of aldosterone.

A typical adult ingests 2000 ml/day of fluid. In addition, about 7000 ml/day of fluid is secreted into the gastrointestinal tract. Of this 9000 ml, only about 1500 ml enters the colon and only about 200 ml is lost in the stool. Similarly 5–8 g/day of sodium is ingested and 20–30 g/day is secreted into the gastrointestinal tract, but less than 0.5% is lost in the faeces. If the absorptive mechanisms are overwhelmed (e.g. in severe diarrhoea) dehydration and electrolyte depletion can occur rapidly.

The epithelial cells in the ileum and large intestine can absorb chloride ions in exchange for bicarbonate ions, which are secreted. Calcium, iron, magnesium, potassium, phosphate and other ions are all actively absorbed from the small intestine.

Carbohydrates

The main carbohydrates in the diet are sucrose, lactose, starch and cellulose (Figure 1). However, cellulose cannot be digested by humans.

Starch is digested by salivary amylase (ptyalin) in the mouth and upper stomach. Ptyalin is inhibited by the low gastric pH but carbohydate digestion is continued in the small intestine by pancreatic amylase, which is more powerful than salivary amylase. Starch digestion produces maltose and short chains of glucose molecules. These, together with ingested sucrose and lactose, are broken into monosaccharides by luminal enzymes (lactase, sucrase, maltase, α-dextrinase). Fructose crosses the epithelium by facilitated diffusion, while glucose and galactose undergo secondary active transport coupled to sodium. Thus, the final products of carbohydrate digestion are all monosaccharides, which are absorbed immediately into the portal blood. Most ingested carbohydrate is digested and absorbed in the first 20% of the small intestine.

Carbohydrates in food

Monosaccharides	Disaccharides	Polysaccharides
Glucose	Sucrose (glucose + fructose)	Starch
Fructose	Lactose (glucose + galactose)	Cellulose
Galactose	Maltose (glucose + glucose)	Glycogen

1

Proteins

Pepsin precursors (pepsinogen I and II) are activated by gastric acid and inactivated by alkali in the duodenum. Proteins are broken down to peptides in the stomach and by the major proteo-lytic pancreatic enzymes (trypsin, chymotrypsin, proelastase) in the small intestine. The peptides are further digested to free amino acids by carboxypeptidase (pancreatic), aminopeptidase and several dipeptidases (in the small intestinal brush border). D amino acids are absorbed by passive diffusion. L amino acids are actively absorbed by basic, neutral and amino acid transporters (the latter two are coupled with sodium). Dipeptides and tripeptides are absorbed by secondary active transport coupled with hydrogen ions, are hydrolysed to amino acids in the epithelial cell, then enter the blood by facilitated diffusion. Occasionally, large peptides and whole proteins are absorbed intact by endocytosis and subsequent exocytosis. This can result in severe allergic reactions and declines with age. Overall about 50% of digested protein originates from food, 25% from digestive juices and 25% from desquamated cells.

Fats

Triglycerides are the main dietary fat. They are emulsified by bile salts, lecithin and monoglycerides and the process is assisted by agitation in the small intestine. Procolipase is secreted by the pancreas and is activated by trypsin. It displaces emulsifying agents and binds lipase to the fat droplets. Lipase (lingual, gastric, pancreatic) produces free fatty acids, glycerols, monoglycerides and diglycerides. Cholesterol esters and phospholipids are hydrolysed by pancreatic cholesterol ester hydrolase and phospho-lipase A_2 to release cholesterol, monoglycerides and fatty acids. Lipids and bile salts interact to produce micelles, which contain fatty acids, monoglycerides and cholesterol. Micelles facilitate fat digestion in three ways:

- they lower the concentration of monoglycerides and free fatty acids thereby allowing triglyceride hydrolysis to continue
- they move down the concentration gradient to the brush border where the lipids diffuse into the epithelial cells and are esterified
- they are essential for cholesterol absorption.

The bile salts are released back into the chyme and are re-absorbed in the terminal ileum, to be re-used to form micelles. Medium chain fatty acids (10–12 carbon atoms long) enter the portal blood directly. Longer fatty acids are re-esterified to triglycerides and together with cholesterol esters are coated with protein, cholesterol and phospholipid to form chylomicrons, which enter the lymphatics within the villi. Fat absorption occurs mainly in the proximal small intestine but also, to some extent, in the ileum. Overall, about 95% of ingested fat is digested and absorbed.

Malabsorption

The causes of malabsorption are summarized in Figure 2. ◆

Reasons for malabsorption

Loss of absorptive surface
- Surgical resection of small intestine (short bowel syndrome)
- Villous atrophy (e.g. coeliac disease)

Specific enzyme defects
- Lactase deficiency

Motility disorders
- Intestinal pseudo-obstruction

Inflammatory disorders
- Crohn’s disease

Pancreatic insufficiency
- Cystic fibrosis

Hepatobiliary dysfunction
- Cirrhosis

Gastrointestinal Secretions and Vomiting

Adrian Thomas

Adrian Thomas is Consultant Paediatric Gastroenterologist at Booth Hall Children's Hospital, Manchester. He qualified from Manchester where he also completed an honours BSc in physiology. His training in paediatric gastroenterology was completed in Manchester, London and Sydney, Australia. His research interests include inflammatory bowel disease and nutritional support.

The two main gastrointestinal secretions are mucus and digestive enzymes. There are numerous pits or crypts throughout the gastrointestinal tract containing specialized secretory cells (e.g. crypts of Lieberkuhn in the small intestine). Tubular glands are present in the stomach (e.g. oxyntic glands) and proximal duodenum. Specialized glands include the salivary glands, pancreas and liver.

The presence of food in the gastrointestinal tract causes direct stimulation of mucous (goblet) cells and nearby glands, which release digestive enzymes. The mucus protects the epithelium and acts as a lubricant. Mucous cells and glands are also stimulated by local enteric reflexes in response to distension or irritation. Parasympathetic stimulation increases secretion from salivary, oesophageal, gastric, pancreatic, duodenal Brunner's and distal large intestinal glands. Secretion from the rest of the small intestine and proximal large intestine is controlled predominantly by local neural and hormonal stimuli. Sympathetic stimulation alone slightly increases gastrointestinal secretion, but in the presence of parasympathetic or hormonal stimulation can reduce secretion because it induces constriction of splanchnic blood vessels.

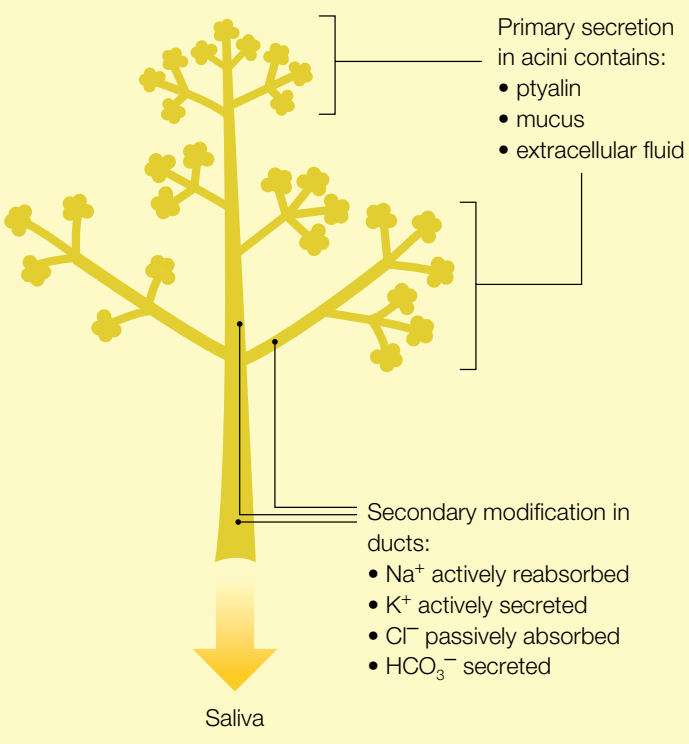
Basic mechanism of glandular secretions
Organic substances: synthesis of enzymes and other organic substances takes place in the endoplasmic reticulum of glandular cells. These are modified in the Golgi apparatus and stored in secretory vesicles until neural or hormonal signals induce their release by exocytosis.

Water and electrolytes: hormonal or neural stimulation is thought to initiate active transport of chloride across the basal membrane, positive ions then follow the electrical gradient, the increased intracellular osmolality draws in water, resulting in increased intracellular pressure and cell swelling. This disrupts the secretory border allowing leakage of water and electrolytes.

Saliva
Saliva helps to maintain oral hygiene because it:
- washes away bacteria and food
- contains bactericidal agents (e.g. thiocyanate)
- contains proteolytic enzymes (e.g. lysozyme)
- contains antibodies.

Saliva comprises a serous secretion containing ptyalin and a mucous secretion. The parotid gland secretes only serous fluid, the submandibular and sublingual glands secrete both and the numerous buccal glands secrete only mucus. Together they secrete 800–1500 ml/day of saliva. Ptyalin and/or mucin are secreted in the acini (Figure 1); as the fluid passes through the ducts, sodium is actively reabsorbed in exchange for potassium, bicarbonate is secreted and chloride is reabsorbed. Therefore, saliva contains high concentrations of potassium and bicarbonate and low concentrations of sodium and chloride. When the rate of salivation is increased, the rate of flow through the ducts also increases, reducing reabsorption and secretion.

Salivary gland



1

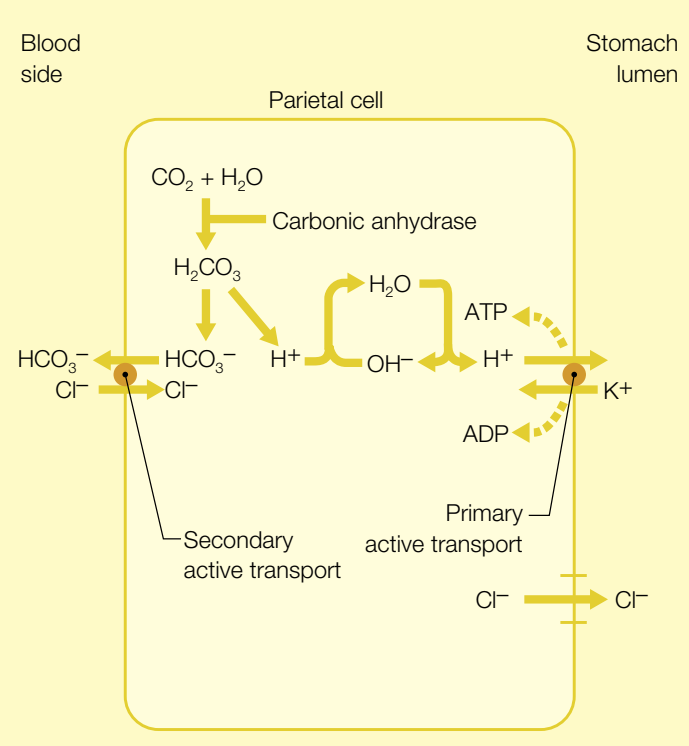
Regulation of secretion: the salivary glands are controlled mainly via the parasympathetic nervous system from the superior and inferior salivary nuclei in the brainstem. They are influenced by the adjacent medulla and pons, which are stimulated by taste and touch sensors in the mouth, tongue and pharynx. They are also influenced by the appetite area in the amygdala, prefrontal cortex and adjacent hypothalamus. Reflex salivation also occurs in response to gastrointestinal irritation.

Gastric secretion
Mucous cells line the gastric mucosa. Oxyntic (gastric) glands occur in the fundus and body of the stomach. The pyloric glands are confined to the antrum.

Mucous cells secrete large amounts of viscid alkaline mucus to protect the gastric mucosa from acid.

Oxyntic glands contain three types of cells: mucous neck cells (secreting mainly mucus but also some pepsinogen), peptic (chief) cells (secreting pepsinogen) and parietal (oxyntic) cells (secreting hydrochloric acid and intrinsic factor). The basic mechanism of pepsinogen and mucus secretion is described above. Pepsinogen is activated to pepsin in the presence of hydrochloric acid and pepsin. In an acid environment, pepsin is a powerful proteolytic enzyme. Intrinsic factor is necessary for absorption of vitamin B_{12} in the terminal ileum. During the secretion of hydrochloric acid (Figure 2) hydrogen ions from water in the parietal cell are actively secreted into the gastric lumen in exchange for potassium ions. The remaining hydroxyl ions are neutralized by hydrogen ions from carbonic acid. Bicarbonate ions diffuse from the cell to the extracellular fluid in exchange for chloride ions. Chloride ions are also transported into the lumen. Water passes into the lumen by osmosis.

Secretion of hydrochloric acid by parietal cell



2

Pyloric glands contain mainly mucous cells, but also secrete gastrin and small amounts of pepsinogen.

Regulation of gastric secretion: acetylcholine, gastrin and hist-amine bind to specific receptors on the secretory cells. Acetylcholine stimulates secretion of pepsinogen by the peptic cells, hydrochloric acid by the parietal cells and mucus by the mucous cells. Gastrin and histamine stimulate secretion of hydrochloric acid by the parietal cells but have little effect on the other cells. Amino acids, caffeine and alcohol also have weak stimulatory effects on gastric secretion.

Acid secretion – neural stimulation of acid secretion is initiated by higher CNS centres via the vagus nerve or by local reflexes. Local reflexes are triggered by gastric distension, acid pH and products of protein digestion. The nerves release acetyl-choline, except for those supplying the gastrin-secreting cells (G cells) in the pyloric glands where an intermediate neuron secretes gastrin-releasing peptide. Gastrin enters the bloodstream and travels to the oxyntic glands in the body of the stomach where it stimulates the parietal cells to release hydrochloric acid and to a lesser extent the peptic cells to release pepsinogen. Acetylcholine, gastrin and histamine alone have little effect on gastric secretion. Histamine is continually present in small amounts and exerts its effect via the H_2-receptors on the parietal cells. This, together with vagal stimulation (either from higher CNS centres or local reflexes when food enters the stomach), releases gastrin and acetylcholine thus promoting large quantities of gastric acid to be released. Excess acidity produces neural inhibition of gastric secretion and blocks the secretion of gastrin from the G cells.

Pepsinogen secretion – pepsinogen is released from the peptic cells in response to neural stimulation (releasing acetylcholine) and the presence of gastric acid.

Phases of gastric secretion
Cephalic phase – this results from the thought, sight, smell or taste of food. Neural stimuli arise in the cerebral cortex, appetite centre or hypothalamus and are transmitted through the vagus.

Gastric phase – food entering the stomach elicits long vaso-vagal reflexes, local enteric reflexes and release of gastrin. This phase accounts for about 70% of total gastric secretion.

Intestinal phase – food mixed with gastric secretions (chyme) entering the proximal small intestine can stimulate modest gastric
secretion. Mechanisms include duodenal gastrin release, absorbed amino acids, other hormones and reflexes.

Inhibition of gastric secretion: although chyme stimulates gastric secretion during the intestinal phase, it inhibits it during the gastric phase. This is initiated by the enterogastric reflex and gastrointestinal hormones, including secretin, in response to distension, hyper- or hypo-osmolar fluid, acid, protein breakdown products, fat or irritation in the duodenum.

Exocrine pancreatic secretion
The exocrine pancreas is structurally similar to the salivary glands. Digestive enzymes are secreted by the pancreatic acini and sodium bicarbonate is secreted by the ductules and ducts leading from the acini. Secretion is stimulated primarily by chyme in the duodenum.

Pancreatic enzymes: the pancreas secretes enzymes for:
- protein digestion (trypsin, chymotrypsin, carboxypeptidase)
- carbohydrate digestion (pancreatic amylase)
- fat digestion (pancreatic lipase, cholesterol esterase, phospho-lipase).

The proteolytic enzymes are produced in inactive forms (trypsinogen, chymotrypsinogen, procarboxypeptidase) which become active only in the gastrointestinal tract. Trypsinogen is converted to trypsin by enterokinase. Trypsin converts chymo-trypsinogen to chymotrypsin, other proenzymes into active forms and can also activate trypsinogen (autocatalysis). The pancreatic enzymes are prevented from activation before reaching the gastrointestinal tract (which would cause destruction of the pancreas) by trypsin inhibitor.

Bicarbonate ions produced from carbon dioxide and water by carbonic anhydrase, are actively secreted (in exchange for chloride ions) by the ductular epithelial cells. The remaining hydrogen ions are exchanged for sodium ions in the bloodstream, the sodium ions continue into the duct to maintain electrical neutrality. Water follows by osmosis.

Regulation of secretion: pancreatic secretion is stimulated by acetylcholine (from parasympathetic nerves), cholecystokinin (from proximal small intestine when food enters) and secretin (from proximal small intestine when acid enters). Acetylcholine and cholecystokinin primarily stimulate the production of pancreatic enzymes from the acinar cells whereas secretin primarily stimulates the production of large quantities of sodium bicarbonate solution by the ductal cells, which is largely responsible for neutralizing the gastric acid. Pancreatic secretion occurs in three phases: cephalic, gastric and intestinal in the same way as gastric secretion.

Intestinal secretions
Mucus is secreted by Brunner's glands in the proximal small intestine. Throughout the intestine are numerous crypts of Lieberkuhn containing goblet cells (which produce mucus) and, in the small intestine, enterocytes (which produce large quantities of water). Enterocytes in the small intestinal villi also produce peptidases, disaccharidases and lipase.

Nausea and vomiting

Nausea is a conscious awareness of arousal of the vomiting centre or related areas of the brain. It often precedes vomiting and may be initiated by higher CNS centres or local irritation in the gastrointestinal tract.

Vomiting can be initiated by overdistension or irritation of the upper gastrointestinal tract, resulting in afferent impulses transmitted via the parasympathetic (vagus) and sympathetic nervous systems to the vomiting centre in the medulla. It can also be initiated by stimulation of other areas of the brain, especially the chemoreceptor trigger zone.

Certain drugs (including morphine) induce vomiting by direct stimulation of this area. In motion sickness, impulses arise from receptors in the labyrinth and are transmitted to the vestibular nuclei, then the cerebellum, before reaching the chemoreceptor trigger zone and eventually the vomiting centre. Higher CNS centres can also stimulate the vomiting centre (e.g. in states of psychological distress).

The vomiting centre initiates vomiting by transmitting impulses via cranial nerves V, VII, IX and X to the upper gastrointestinal tract and through the spinal nerves to the diaphragm and abdominal muscles. Antiperistalsis begins as far distally as the terminal ileum and rapidly propels the contents of the small intestine back to the stomach and duodenum, which contract vigorously. The vomiting centre then initiates a deep inhalation, opening of the upper oesophageal sphincter, closure of the glottis and lifting of the soft palate to prevent nasal reflux. The diaphragm and abdominal muscles contract and the lower oesophageal sphincter relaxes allowing vomiting to occur. ◆

Gut Motility, Sphincters and Reflex Control

Adrian Thomas

Adrian Thomas is Consultant Paediatric Gastroenterologist at Booth Hall Children's Hospital, Manchester. He qualified from Manchester where he also completed an honours BSc in physiology. His training in paediatric gastroenterology was completed in Manchester, London, and Sydney, Australia. His research interests include inflammatory bowel disease and nutritional support.

The gastrointestinal tract is made up of layers of serosa, longitudinal muscle, circular muscle, submucosa and mucosa. The muscle layers are composed of bundles of smooth muscle fibres joined together at multiple points so that action potentials can travel along the length of the gastrointestinal tract. The two basic types of electrical activity are slow waves and spike potentials (spikes). Slow waves are minor depolarizations (5–15 millivolts) occurring 3–12 times/minute. They mainly modify the spikes and cause contractions only in the stomach. Spikes occur when the resting membrane potential becomes more positive than about –40 millivolts. The frequency varies from 1 to 10 spikes/minute and is regulated by the slow waves. The higher the slow wave potential rises above –40 millivolts the greater the spike frequency. Many factors influence the resting membrane potential. Gastrointestinal hormones, acetylcholine, parasympathetic stimulation and stretching of the muscle make it more positive and more excitable whereas noradrenaline, adrenaline and sympathetic stimulation make it more negative and less excitable. Muscle contraction is initiated by calcium entering the muscle fibres.

Gastrointestinal movements and secretions are controlled by the enteric nervous system. This comprises two plexuses:
- the myenteric (or Auerbach's) plexus between the longitudinal and circular muscle layers
- the submucosal (or Meissner's) plexus in the submucosa.

The plexuses are influenced by the sympathetic and para-sympathetic innervation of the gastrointestinal tract.

The two types of movement in the gastrointestinal tract are propulsive or peristaltic and mixing movements or local constrictive movements). Peristalsis is a ring of contraction moving from the proximal gastrointestinal tract distally; the usual stimulus is distension of the lumen.

Chewing and swallowing

Chewing (mastication) breaks food up into small particles, increasing the surface area for digestion and absorption. Swallowing is a complex action requiring the coordinated activity of 26 muscles of the mouth, pharynx and oesophagus, six cranial nerves, the brainstem and cerebral cortex. It consists of two voluntary phases (oral preparatory, oral) and two involuntary phases (pharyngeal, oesophageal). In the oral preparatory phase, food is formed into a bolus. In the oral phase, the bolus is propelled backwards by the tongue. When the bolus passes the anterior fauces into the pharynx the swallowing reflex is triggered and from this point the process is involuntary. In the pharyngeal phase, the soft palate rises against the posterior pharyngeal wall to prevent aspiration into the nasopharynx. The bolus is propelled by the peristalsis of the pharyngeal constrictors to the cricopharyngeal sphincter, which then relaxes. The larynx is raised, closing the glottis, which is then covered by the epiglottis, preventing food entering the trachea. In the oesophageal phase, the upper oesophageal (pharyngo-oesophageal) sphincter relaxes and a wave of peristalsis then propels food down the oesophagus, the lower oesophageal (gastro-oesophageal) sphincter relaxes and food enters the stomach. Receptive relaxation occurs in the stomach and duodenum so that they become relaxed before the peristaltic wave reaches them and they are ready to receive food.

A number of factors help to prevent reflux of irritant gastric or small intestinal juice back into the oesophagus. The lower oesophageal sphincter is usually constricted (except during swallowing). Increased intra-abdominal pressure (especially when walking or coughing) causes the intra-abdominal portion of the oesophagus to collapse.

Motor function

The stomach

The stomach has three main motor functions.

Storage: food entering the stomach induces relaxation of the muscular wall via a vasovagal reflex. This allows the stomach to expand to accommodate food up to a volume of about 1.5 litres.

Mixing: food is mixed with gastric secretions by means of mixing or constrictor waves. These are weak peristaltic waves originating from slow waves occurring in the stomach wall. They are each 15–20 seconds long and spread towards the antrum. Some of these peristaltic waves become more intense (constrictor rings) and force the antral contents towards the pylorus. The pylorus contracts to slow gastric emptying and results in further mixing of gastric contents.

Emptying: the more intense peristaltic waves promote antral emptying. As the stomach empties, these constrictor rings begin further up in the body of the stomach promoting further gastric emptying. The pylorus allows fluid, but not usually solid, gastric contents to enter the duodenum. The rate of gastric emptying is regulated by gastric (weak influence) and duodenal (strong influence) factors.

Gastric factors include the gastric food volume and gastrin, which is released in response to gastric stretching, and the presence of certain foods. Carbohydrates remain in the stomach for the shortest time, proteins are intermediate and fats remain for the longest time.

Duodenal factors include enterogastric neural reflexes. These are stimulated by the acidity and osmolality of duodenal juice, the presence of digested proteins, duodenal distension and irritation. Cholecystokinin and other hormones (released particularly in response to duodenal fats) also have a role.

Small intestine

Mixing (segmentation) contractions: distension with chyme elicits regularly spaced contractions each 20–30 seconds. When relaxation occurs in these areas, contractions occur in intervening areas. These alternating contractions mix the chyme with small intestinal secretions and help to propel it distally.

Propulsive movements: peristalsis spreads chyme throughout the absorptive surface of the small intestine and propels it towards the ileocaecal valve. This slows the flow of chyme, often for several hours, until the next meal is eaten and the gastroenteric (gastroileal) reflex increases ileal peristalsis. Peristalsis slows from the proximal to the distal small intestine. Most peristaltic waves last for 3–10 cm and small intestinal transit time is 3–5 hours. Peristaltic activity is promoted by the entry of chyme into the duodenum, by the gastroenteric reflex secondary to gastric distension and by various gastrointestinal hormones including gastrin and cholecystokinin. Secretin and glucagon inhibit small intestinal motility. During fasting a 'migrating motor complex' or peristaltic wave passes down the upper gastrointestinal tract every 90 minutes to prevent any accumulation of secretions. Severe intestinal inflammation can result in intense and rapid peristalsis (peristaltic rush).

Ileocaecal valve

The ileocaecal valve slows the flow from the ileum to the caecum and prevents backflow from the caecum into the ileum. Distension or irritation of the caecum results in a reflex increase of tone in the ileocaecal valve and inhibition of ileal peristalsis, thereby delaying ileal emptying.

Colon

Proximal colonic movements are slow, which promotes reabsorption of fluid and electrolytes. Simultaneous contractions of the circular muscle and longitudinal muscle strips (taeniae coli) result in outward bulging of the bowel wall in between (haustrations). As in the small intestine, alternating areas of contraction and relaxation result in mixing of the colonic contents. Slow forward propulsion also occurs. In the distal colon, modified peristaltic waves or 'mass movements' 1–3 times/day move the faeces towards the rectum. These movements are initiated by colonic inflammation and by gastrocolic and duodenocolic reflexes resulting from gastric and duodenal distension following meals.

Defecation

The internal anal sphincter consists of circular involuntary smooth muscle whereas the external anal sphincter consists of striated voluntary muscle, which is continually contracted unless consciously inhibited. Faeces entering the rectum, initiate an intrinsic defecation reflex mediated by the myenteric plexus. This results in peristalsis in the descending colon/rectum and relaxation of the internal anal sphincter. The intrinsic defecation reflex is weak and usually requires reinforcement by a parasympathetic defecation reflex, mediated via the sacral segments of the spinal cord and the pelvic nerves. This amplifies the peristaltic waves and relaxes the internal anal sphincter. Deep inhalation, closure of the glottis and contraction of the abdominal muscles are also initiated via the spinal cord. Defecation can be inhibited by conscious control over the external anal sphincter.

Gastrointestinal hormones

Several hormones influence gastrointestinal motility and secretions. The two main 'families' of gastrointestinal hormones are gastrin and secretin. The gastrin family includes gastrin and cholecystokinin (CCK), which are polypeptides with the same terminal five amino acids. The secretin family includes secretin, glucagon, glicentin, vasoactive intestinal peptide (VIP) and gastric inhibitory peptide (GIP), which all have similar structures. The functions of the most important gastrointestinal hormones are summarized in Figure 1. ◆

Principal gastrointestinal hormones

	Gastrin	Cholecystokinin (CCK)	Secretin
Where produced	Gastric antrum	Small intestine	Small intestine
Stimuli for release	Peptides and amino acids in stomach	Amino acids and fatty acids in small intestine	Acid pH in small intestine
Effect on stomach	Stimulates acid secretion and growth	Inhibits acid secretion	Inhibits acid secretion
Effect on exocrine pancreas	Stimulates growth	Stimulates growth and enzyme secretion Potentiates secretin	Stimulates growth and bicarbonate secretion Potentiates CCK
Effect on hepatobiliary system		Potentiates secretin Stimulates gallbladder contraction	Stimulates bicarbonate secretion
Effect on intestine	Stimulates small intestinal growth, motility, colonic motility

Hormonal Control of Metabolism: Regulation of Plasma Glucose

Anna Casey

Anna Casey is Senior Research Scientist at the Defence Evaluation Research Agency, UK Ministry of Defence. She obtained her doctorate in metabolic physiology from the University of Nottingham Medical School. Her research interests include skeletal muscle energy metabolism and fatigue, nutrition and ergogenic aids.

Blood glucose concentration represents the net flux of glucose entering and leaving the blood. Glucose is delivered to the blood from the liver following ingestion of carbohydrate, from the breakdown of glycogen (the storage form of glucose) and from endogenous glucose synthesis. Glucose is removed from the blood by a number of organs and tissues, notably the brain, skeletal muscle, liver and adipose tissue. With this variety of means of entry and exit from the blood, and the complications arising from too high or too low a glucose concentration, the regulation of blood glucose is complex.

Many factors affect the delivery of glucose to, and its removal from, the blood. These include dietary carbohydrate and fat, the circulating free fatty acid concentration, exercise, hypoxia and the actions of several hormones. The postprandial blood glucose concentration is about 4–5.5 mmol/litre or 70–100 mg/100 ml, but arterial concentrations vary throughout the day from about 3.5 mmol/litre after exercise to 9 mmol/litre following a meal. For the purposes of this article, it is the plasma fraction of blood glucose that is of most interest, because the plasma glucose concentration is the driving force behind the diffusion of glucose molecules across the capillary wall into the interstitial space.

Glucose disposal

The plasma glucose concentration is regulated by the opposing actions of a number of hormones (Figure 1), the net effect of which depends on their relative concentration in the blood at a given time. Some, such as insulin, promote the clearance of glucose from the plasma, while others, including glucagon, growth hormone, and catecholamines, stimulate the production and release of glucose into the blood.

The most important hormone involved in the regulation of plasma glucose is insulin, a polypeptide secreted by the β-cells of the islets of Langerhans in the pancreas. It promotes the uptake of glucose from plasma, and is used parenterally in the treatment of diabetes mellitus. A rise in plasma glucose concentration, for example after a meal, stimulates the release of a number of gut hormones, known as incretins, which promote insulin secretion by pancreatic β-cells. Glucagon-like peptide-1-(7-36)amide (GLP-1), and glucose-dependent insulinotropic peptide (GIP), secreted from endocrine cells in the intestinal mucosa, are the incretins of major interest. GLP-1 is released within a few minutes of carbohydrate ingestion, mediated by an unknown signalling pathway, and may form the first line of defence against hyperglycaemia. This is followed by a sharp decline in GLP-1 release, the timing of which is related to the glucose load (i.e. the larger the glucose load, the slower the decline in GLP-1 release)

Tight control of GLP-1 helps to prevent excessive insulin secretion and the development of hypoglycaemia. GLP-1 also inhibits the release of glucagon, and probably downregulates gastric emptying of carbohydrates. Insulin secretion is also regulated by somatostatin, a pancreatic hormone, which is released in response to increases in the plasma concentration of glucose, amino acids and fatty acids, and which acts locally within the pancreas to inhibit insulin secretion.

An increase in circulating insulin promotes the uptake of glucose into insulin-sensitive tissues, primarily skeletal muscle, liver and adipose tissue. Skeletal muscle is the primary site of insulin-stimulated glucose disposal in the fed state. As a consequence, the insulin sensitivity of skeletal muscle, which accounts for about 40% of body mass, is an important factor in the regulation of the plasma glucose concentration. The rate of glucose uptake from the plasma is largely dependent on the transfer of glucose across the plasma membrane of the muscle fibres (sarcolemma). Glucose transport across the sarcolemma occurs by facilitated diffusion, involving at least two glucose transporter isoforms, GLUT-1 and GLUT-4. The GLUT-4 isoform has emerged as the most important transporter in skeletal muscle. It is located in an intracellular compartment, and translocates to the plasma membrane in response to insulin and muscle contractions. The fastest rate of glucose uptake from the plasma occurs within the first few hours after muscular exercise. During this period, insulin sensitivity of the muscle is acutely increased, as is the number of GLUT-4 transporters in the sarcolemma.

The action of insulin is mimicked by a number of related peptides. Insulin-like growth factor 1 (IGF-1) is a peptide with similar (though less potent) effects to insulin, the expression and secretion of which is regulated by growth hormone. The primary site of IGF-1 production was thought to be the liver, but it is now clear that IGF-1 is produced by several tissues, including skeletal muscle and adipose tissue. A large, acute dose of IGF-1 produces hypoglycaemia, but prolonged IGF-1 therapy reduces hyperglycaemia in type 1 and type 2 diabetes mellitus, and in some insulin-resistance states. The effects of IGF-1 and insulin on glucose disposal are additive.

Proinsulin, the insulin precursor, is cleaved within β-cells releasing equimolar amounts of insulin and connecting(C)-peptide into the circulation. The concentration–time curve of plasma C-peptide is often used as a marker of insulin secretion, and C-peptide itself is traditionally thought to be biologically inactive. However, there is some evidence to suggest that C-peptide stimulates plasma glucose uptake into skeletal muscle in a dose-dependent manner. The mechanism is unclear, but it is known that binding to insulin receptors on the plasma membrane does not occur. Unlike IGF-1, the effects of C-peptide and insulin are not additive.

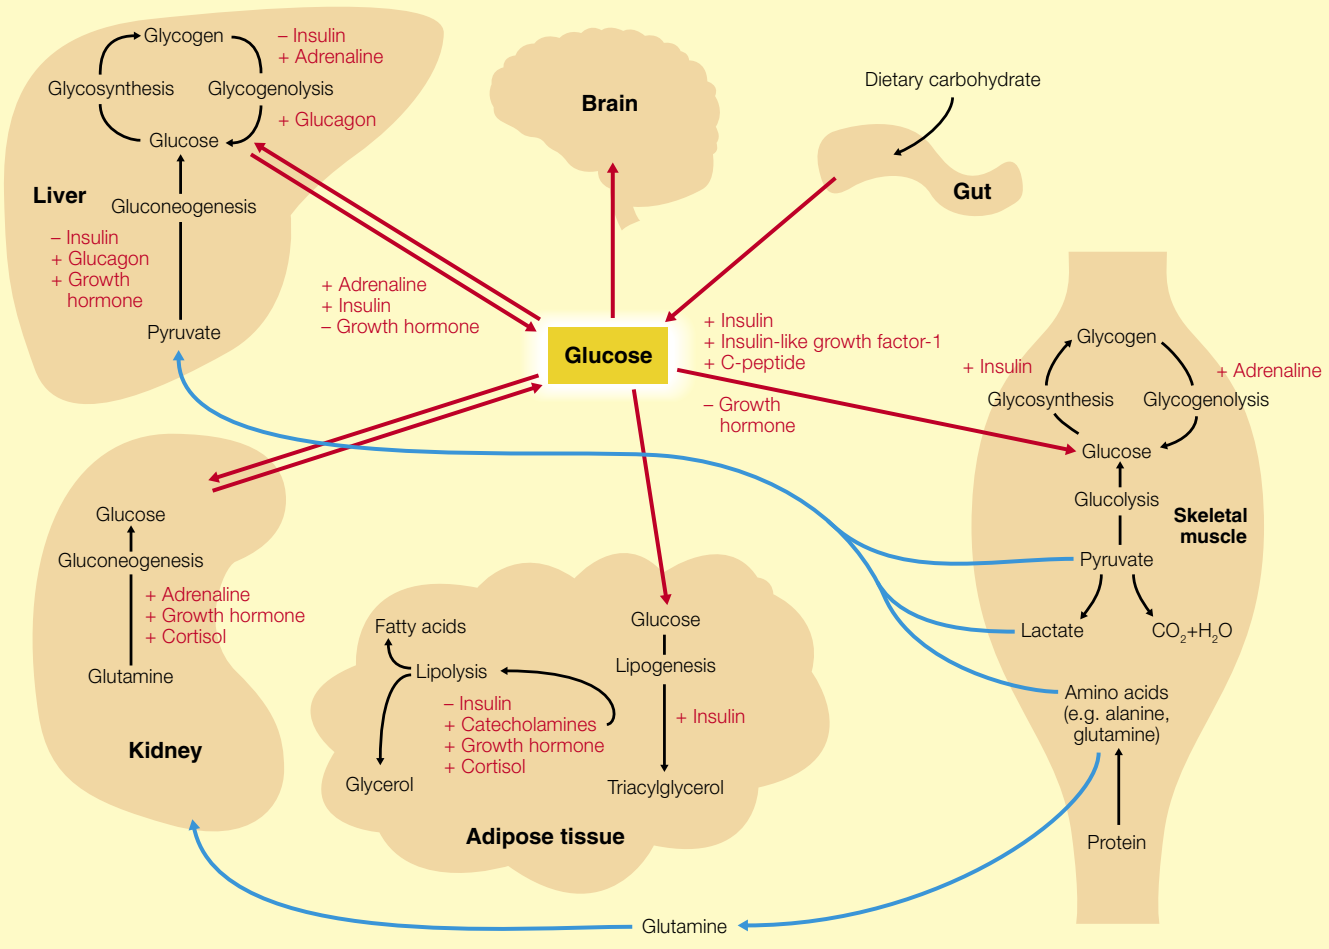
Recently, interest has surrounded the role of leptin, a hormone produced by adipose tissue which acts via the hypothalamus to decrease food intake and to regulate energy stores. Leptin is also reported to have peripheral effects, including stimulation of lipolysis, and insulin-like, though probably indirect, effects on plasma glucose uptake. This increase in glucose disposal appears to be independent of changes in food intake, and is likely to be secondary to a leptin-mediated decline in muscle triglyceride levels.

In contrast to muscle, the plasma membranes of hepatic cells are freely permeable to glucose, enabling a rapid response to changes in blood glucose availability. An increase in plasma insulin concentration reduces the rate of hepatic glycogenolysis (the breakdown of glycogen to glucose) and gluconeogenesis (glucose synthesis from non-sugar sources), thereby inhibiting the production and release of free glucose into the circulation.

Once inside a cell, glucose is phosphorylated to form glucose-6-phosphate (G6P), a process that traps the glucose molecule and prevents it from recrossing the plasma membrane. In the liver, this is a reversible reaction, allowing free glucose to leave the cell and re-enter the circulation, but the requisite enzyme, glucose-6-phosphatase, is missing from skeletal muscle, thus muscle G6P is not a source of free glucose. Instead, G6P either enters glycolysis, resulting in the formation of pyruvate which is oxidized or converted to lactate, or it is converted to glycogen and stored as a future source of energy.

One of the major functions of insulin is the activation of glycogen synthase, the rate-limiting enzyme in glycogen synthesis, by means of a signalling cascade that begins with the binding of insulin to receptors on the plasma membrane. The long-held view is that insulin does not enter the cell and exert any direct effects, though there is some evidence to the contrary.

Hormonal regulation of plasma glucose



1

Glucose production

A fall in plasma glucose concentration evokes a number of counter-regulatory measures designed to restore plasma glucose levels, and avoid the debilitating and potentially fatal effects of hypoglycaemia. At the most basic level, this response involves an increase in the release of glucose into the circulation, and a decrease in tissue glucose uptake.

In healthy individuals, a common cause of a fall in plasma glucose concentration is prolonged exercise. Exercise presents a considerable challenge to glucose homeostasis, because it is common for values to fall below 3.0 mmol/litre at the end of prolonged, fatiguing exercise, and values as low as 2.5 mmol/litre have been recorded. Muscle glycogen is an important fuel for this type of exercise, but stores are limited, and it is now clear that, as the availability of muscle glycogen declines, oxidation of carbohydrate from alternative sources is increased to meet the energy demands of muscle contraction. Plasma glucose is the major source, and it is supplied to skeletal muscle via carbohydrate ingestion, hepatic glycogenolysis and/or gluconeogenesis from 3-carbon precursors, including alanine, glycerol, lactate and pyruvate. In contrast to glycogenolysis, which is rapid, gluconeogenesis is a lengthy process that takes place over several hours. In the absence of exogenous carbohydrate, therefore, hepatic glycogenolysis is the principal means of maintaining euglycaemia during exercise, and the rate of glycogenolysis is directly related to the hepatic glycogen content. However, the store of liver glycogen is also limited and, as exercise progresses, the plasma glucose concentration soon falls in the absence of carbohydrate ingestion.

The key processes described above are skeletal muscle glycogenolysis, hepatic glycogenolysis, and hepatic gluconeogenesis. The existence of muscle gluconeogenesis is debatable, but there is evidence to suggest that glucose synthesis from lactate may occur when the muscle glycogen concentration is low and the lactate concentration is high, for example after exercise. Quantitatively, however, gluconeogenesis is more important during prolonged fasting and starvation. These processes are controlled by several hormones released in response to stressors such as exercise, and to a fall in plasma glucose concentration, notably adrenaline, noradrenaline, glucagon, cortisol, somatostatin and growth hormone (Figure 2).

Role of the principal hormones in regulating plasma glucose

Effects of a rise in plasma glucose

Hormone	Main effects
Increase in insulin	• Peripheral glucose uptake increases • Glycogen synthesis increases • Hepatic glycogenolysis and gluconeogenesis decrease • Lipogenesis increases • Lipolysis decreases
Increase in GLP-1	• Insulin secretion increases • Glucagon secretion decreases
Increase in glucose-dependent insulinotropic peptide	• Insulin secretion increases
Increase in insulin-like growth factor-1	• Peripheral glucose uptake increases
Increase in C-peptide	• Skeletal muscle glucose uptake increases?
Increase in somatostatin	• Insulin secretion decreases

Effects of a fall in plasma glucose

Hormone	Main effects
Increase in glucagon	• Insulin secretion decreases • Hepatic glycogenolysis and gluconeogenesis increase
Increase in adrenaline	• Insulin secretion decreases • Skeletal muscle and hepatic glycogenolysis increase • Hepatic glucose release increases • Renal gluconeogenesis increases
Increase in growth hormone	• Lipolysis increases • Peripheral glucose uptake decreases • Hepatic gluconeogenesis increases
Increase in cortisol	• Potentiates effects of glucagon and adrenaline
Decrease in insulin	• Hepatic glycogenolysis increases

2

The catecholamine hormones, adrenaline and noradrenaline, are secreted by the adrenal medulla in response to stress. Catecholamines inhibit insulin secretion, thereby helping to preserve plasma glucose. Adrenaline activates adenyl cyclase, an enzyme in the plasma membrane, which leads to the activation of phosphorylase, the enzyme controlling glycogenolysis in muscle and liver tissues. An increase in plasma catecholamines also activates hepatic glucose-6-phosphatase, resulting in the rapid conversion of G6P to glucose, and the release of glucose into the circulation. In the absence of glucose-6-phosphatase, muscle G6P enters glycolysis, resulting in the formation of pyruvate. If it is not used as a substrate for oxidative metabolism, pyruvate is converted to lactate, which is transported to the liver and used as a precursor for hepatic gluconeogenesis.

Hepatic glucose production is regulated by anterior pituitary growth hormone, which stimulates hepatic gluconeogenesis, and reduces hepatic and peripheral (principally muscle) insulin sensitivity. The subsequent impairment of glucose uptake is probably secondary to a growth hormone-mediated increase in lipolysis, rather than a direct effect on glucose transport and metabolism. Glucagon, secreted by pancreatic α-cells, has a similar inhibitory effect on insulin secretion, and stimulates hepatic glycogenolysis and gluconeogenesis very rapidly – hence its use in the treatment of hypoglycaemia resulting from exogenously administered insulin. Unlike adrenaline, glucagon has no effect on muscle glycogenolysis. Blunted glucagon responses to hypoglycemia are noted in adults a few years after developing type 1 diabetes mellitus, and the problem seems to be worse in children, in whom impaired autonomic responses appear to reduce or abolish the glucagon response, even following profound nocturnal hypoglycaemia. Cortisol, a corticosteroid hormone secreted by the adrenal cortex, and the most potent of the naturally occurring glucocorticosteroids, potentiates the effects of glucagon and adrenaline on hepatic gluconeogenesis.

In the post-absorptive state, the kidney, another gluconeogenic organ, accounts for about 20% of plasma glucose disposal. This decreases by a small amount during hypoglycaemia. More importantly, renal glucose release has been shown to increase three-fold under these conditions, suggesting that the role of the kidney in the counter-regulation of hypoglycaemia has been underestimated. Animal studies suggest that renal gluconeogenesis is probably stimulated by adrenaline, with additional effects of growth hormone and cortisol after 2–3 hours. In humans, adrenaline, but not glucagon, has been shown to increase renal gluconeogenesis, probably by increasing the fractional extraction of primarily glutamine.

Hypothalamic and Pituitary Function

Adrian Heald

Adrian Heald is Locum Consultant Endocrinologist at Hope Hospital, Salford, UK. He qualified from the University of Oxford and trained in endocrinology in Manchester. His research interests include the IGF system in relation to the epidemiology of diabetes and cardiovascular disease.

Hypothalamus

The hypothalamus can be regarded as the coordinating centre of the endocrine system. It consolidates signals from higher cortical centres, autonomic afferents, environmental cues (e.g. light, temperature) and peripheral endocrine feedback. It delivers precise signals to the pituitary gland which releases hormones that influence most of the endocrine systems in the body. The hypothalamus is also involved in several neuroendocrine functions including temperature regulation, control of appetite and regulation of the autonomic nervous system.

The hypothalamic hormones are small peptides. They are secreted in a pulsatile fashion and reach their target cells rapidly and in high concentration via the hypothalamo-hypophyseal portal venous circulation. The anterior pituitary lacks a major direct arterial supply and is bathed in a dense capillary network of blood containing hypothalamic hormones released from the median eminence of the hypothalamus, together with paracrine and autocrine factors released from the anterior pituitary cells. The capillary plexus empties into the petrosal sinuses and then into the internal jugular veins. The concentration of hormones in the petrosal sinuses is therefore representative of anterior pituitary production and the petrosal sinuses may be catheterized to assess pituitary function. Control of anterior pituitary hormone production is by negative feedback from hormones produced in target endocrine glands in the periphery and by hypothalamic releasing or release-inhibiting factors that are subject to negative feedback from the periphery.

Anterior pituitary hormones

Adrenocorticotrophin (ACTH)

ACTH stimulates the adrenal cortex to secrete cortisol, adrenal androgens and mineralocorticoids. Corticotrophin releasing hormone (CRH) from the hypothalamus and antidiuretic hormone (ADH) stimulate ACTH secretion.

Structure: ACTH is a 39 amino acid peptide. It is synthesized as part of a large precursor molecule pro-opiomelanocortin (POMC) (241 amino acids). Derivatives of POMC are ACTH, β-lipotrophin (β-LPH) (which is converted to lipotrophin and β-endorphin) and melanocyte stimulating hormone (α-MSH). The first 18 amino acids of ACTH have full biological activity and the first 24 amino acids are identical in all mammals. Synthetic $ACTH_{(1–24)}$ (synacthen) has a longer half-life than native ACTH. Concentrations of β-LPH are increased in renal failure because of slower clearance. The hyperpigmentation observed in ACTH hypersecretion, for example in Addison's disease and uraemia, is a result of the MSH-like activity of β-LPH and ACTH on melanocytes.

Secretion*:* ACTH is secreted in bursts that are maximal in the last hours before waking and in the first hour after waking. Light is one of the most important regulators of the circadian rhythm of ACTH. Activators of ACTH secretion are hypoglycaemia (used in the insulin tolerance of cortisol reserve), fever and stress (psychological or physical).

ACTH actions: immediate actions include stimulation of the initial and rate-limiting step of conversion of cholesterol to pregnenolone with increased supply of free cholesterol ester for cortisol biosynthesis. Prolonged actions include increased adrenal protein synthesis including the enzymes involved in steroidogenesis.

ACTH deficiency presents almost exclusively as the resulting cortisol deficiency. Cortisol is necessary to maintain blood pressure and is involved in the maintenance of hepatic glucogenesis and in salt and water balance. In the most severe form this leads to vascular collapse and death. In the less severe form, there is postural hypotension, tachycardia and hyponatraemia. Baseline screening for ACTH deficiency with a short synacthen test is recommended in all patients with pituitary adenoma.

ACTH excess: increased circulating ACTH from the pituitary represents about 60% of cases of Cushing's syndrome. Ectopic ACTH secretion with consequent glucocorticoid excess is characterized by a short history, pigmentation, weight loss, profound muscle weakness, hypokalaemia and plasma ACTH concentrations greater than 200 ng/litre.

Prolactin

Prolactin is a 199 amino acid peptide. It is synthesized from the fifth week of gestation.

Regulation: prolactin release is under tonic hypothalamic inhibition by dopamine. Probable releasing factors are thyro-tropin releasing hormone (TRH) and vasoactive intestinal peptide (VIP). Oestrogen positively regulates prolactin gene expression (levels of prolactin rise during menarche and pregnancy).

Actions*:* prolactin stimulates initiation and maintenance of lactation (this also requires oestrogen, progesterone and several placental mammotrophic hormones). It regulates hypothalamic dopamine turnover and suppresses gonadotropic releasing hormone (GnRH) secretion in the hypothalamus.

Hyperprolactinaemia results in galactorrhoea (spontaneous or expressible), oligomenorrhoea, decreased libido and headaches. It is caused by disruption of the hypothalamus or hypothalamo-hypophyseal stalk by tumour or trauma, prolactin-secreting adenoma, drugs that decrease dopamine synthesis (e.g. neuroleptics), nipple stimulation, stress and primary hypothyroidism.

Growth hormone (GH)

The gene for GH is located on chromosome 17. GH is a single- chain 191 amino-acid non-glycosylated peptide. It exists in several forms including 22 kDa, 20 kDa and at least one acidic form. Oligomers exist in the peripheral blood. Abnormalities in the cDNA encoding the GH receptor result in the GH resistance of Laron dwarfism. A high-affinity binding protein exists leading to a ten-fold longer half-life for bound GH.

Regulation: GH releasing hormone increases transcription of GH messenger RNA. Somatostatin regulates the timing and amplitude of GH pulses. Insulin-like growth factor-I inhibits GH synthesis. GH secretion is greatest during adolescence and decreases with age. GH secretion rises during sleep and is augmented in fasting, stress, exercise, anorexia nervosa, type I diabetes mellitus and hepatic cirrhosis.

Actions: the somatomedin hypothesis proposes that IGF-I is the mediator of GH effects at the cellular level. The effects of GH are anabolic (positive nitrogen balance), lipolytic (redistributed body fat) and decreased carbohydrate utilization.

Growth hormone imbalance in children leads to short stature with low growth velocity in the absence of a systemic cause. In adults, GH deficiency (often secondary to pituitary tumours or pituitary surgery) results in decreased energy, centripetal obesity and affective disturbance. Symptomatic growth hormone deficiency following pituitary surgery and radiotherapy can be treated with daily GH supplementation. GH excess in children (if acquired before epiphyseal fusion) causes gigantism. In adults it causes acromegaly with progressive increase in the size of hands and feet, thick greasy skin, macroglossia and prognathism, hypertension and glucose intolerance.

Glycoprotein hormone family

The glycoprotein hormone family includes thyroid stimul-ating hormone (TSH), luteinizing hormone (LH) and follicle stimulating hormone (FSH). The α subunit is common to all three hormones, while the β subunit confers biological specificity.

TSH: thyrotrophs are the least common anterior pituitary cell type (5%). TRH stimulates TSH release. Intracellular tri-iodothyronine (T3) regulates TSH release but plasma thyroxine (T4) correlates better with TSH levels in health and hypothyroidism (T4 correlates better in hypothyroid patients receiving thyroxine replacement). In the treatment of primary hypothyroidism with thyroxine, levels of TSH may lag behind changes in serum T4 levels.

Deficiency occurs relatively late in the development of hypopituitarism. The clinical presentation of TSH deficiency is of thyroxine deficiency with lethargy, weight gain, constipation and cold intolerance.

LH, FSH and β-human chorionic gonadotropin (hCG): both LH β subunits and FSH β subunits are composed of 115 amino acids and have two carbohydrate side-chains. The structure of the β subunit of LH is similar to hCG except that the β subunit of hCG has an additional 32 amino acids and additional carbohydrate residues.

GnRH interacts with a membrane receptor to regulate LH and FSH synthesis and release. The timing of GnRH pulses is crucial. One GnRH pulse per hour maintains LH and FSH pulse secretion, above this level LH is preferentially stimulated; while one GnRH pulse every 3 hours causes FSH to be preferentially stimulated.

Oestradiol and androgens suppress GnRH secretion by the hypothalamus. Progesterone slows the GnRH pulse generator.

Inhibin suppresses LH and FSH secretion. It is a member of a large family of glycoprotein hormones including transforming growth factor (TGF)-β and mullerian inhibiting substance that are important in cellular differentiation. It is synthesized by the Sertoli cells of the testis, granulosa cells of the ovary, placenta, pituitary gonadotrophs and the brain. Thus, it may operate as a gonadal feedback hormone and locally in the hypothalamus and pituitary in a paracrine fashion.

In women, gonadotrophin deficiency leads to ovarian hypofunction with anovulation and consequent amenorrhoea and infertility, together with decreased oestrogen production leading to premature menopause with flushing/sweating, vaginal dryness and increased risk of osteoporosis in the long term. In men, it results in testicular hypofunction with infertility, diminished libido and decreased energy.

Posterior pituitary

The posterior pituitary secretes two major peptides: antidiuretic hormone (ADH) and oxytocin. Both are synthesized in the magnocellular neurons of the supraoptic and paraventricular nuclei of the hypothalamus. Both are nonapeptides. The precursor molecule includes a specific neurophysin which is the carrier protein within the neuronal tracts. The molecular weight of ADH is 1.084 kDa and of oxytocin is 1.007 kDa. Both circulate unbound to proteins and have half-lives of 5–15 minutes.

ADH

Control of secretion: the principal determinant is osmolality, sensed in the organum vasculosum of the lamina terminalis. Increased plasma osmolality leads to an increase in ADH release which reduces water excretion and leads to lower plasma osmolality. Decreased blood pressure or blood volume leads to an increase in ADH. This is mediated by baroreceptors in the carotids, aorta, heart and great veins.

Actions: the main action is the reduction of solute-free water excretion. This effect is mediated by the receptor coupled to adenylate cyclase in the distal collecting tubule and leads to an increase in the permeability to water of the distal convoluted tubule and the collecting duct. ADH stimulates ACTH combined with chronic renal failure (V_{1B} receptor). At high concentration it contracts blood vessels, gut and renal tract (V_{1A} receptor).

Deficiency of ADH leads to diabetes insipidus. This presents with polyuria, excessive thirst and polydipsia developing after pituitary tumour, pituitary surgery or recent head injury. The diagnosis is confirmed by a water deprivation test with failure to concentrate urine after dehydration but concentration of urine after desmopressin. Treatment is with desmopressin (DDAVP), which is usually administered intranasally.

Excess ADH causes the syndrome of ADH excess. This presents with hyponatraemia (serum sodium less than 130 mmol/litre) with inappropriately low plasma osmolality and inappropriately high urine osmolality. Clinical features become increasingly severe as the serum sodium decreases, ranging from mild drowsiness to convulsions, coma and death. There are many causes, including pneumonia, lung neoplasm, brain tumour or abscess, head injury, subarachnoid haemorrhage and drugs (particularly carbamazepine and selective serotonin reuptake inhibitors).

Oxytocin

Oxytocin production is controlled by stimulation of the nipple and cervical distension of the pregnant uterus (Ferguson reflex). It causes contraction of the myoepithelial cells around the breast ducts and contraction of the uterine myometrium in labour and expulsion of the placenta.

There is low affinity of oxytocin to the V_2 vasopressin receptor. Therefore, it is suggested that care is taken when oxytocin infusion is administered with large amounts of intravenous fluid because this could lead to hyponatraemia. ◆

The Immune System

Peter J Wood

Peter J Wood is Lecturer in Immunology in the School of Biological Sciences, University of Manchester, UK. He obtained a BSc in Pharmacology from Liverpool University and a PhD in Immunology from London University. His research interests focus on immunological events in insulin-dependent diabetes mellitus and in graft rejection.

The mammalian immune system has evolved to provide protection against infectious agents (pathogens). Although the immune system may provide protection against tumours, the main evolutionary driving force has been the battle with pathogens.

Innate and specific immunity

The immune system has historically been divided into the innate and specific systems. The innate immune system includes:

- physical and chemical barriers to infection (e.g. skin, hydrochloric acid in the stomach)
- cells (e.g. macrophages, neutrophils, mast cells)
- soluble factors (e.g. the complement proteins, acute phase proteins).

The cellular components of the specific immune system are the lymphocytes. Lymphocyte precursors originate from the bone marrow and some differentiate in the thymus into T lymphocytes which are responsible for cellular immunity. Other lymphocyte precursors differentiate into B lymphocytes in the fetal liver and after birth in the bone marrow. B lymphocytes are responsible for humoral immunity. Most of the processing of lymphocytes occurs during fetal and neonatal life, but there is a slow continuous production of new lymphocytes from stem cells in adults. After differentiation, the lymphocytes migrate to the lymph nodes and other lymphoid tissue. The two main types of T cells are CD4 and CD8. Although morphologically indistinguishable the three types of lymphocyte perform different functions. One of the main features distinguishing specific from innate immunity is that specific immunity is not present before infection. Following initial infection with a pathogen it takes about 4 days to produce antibody against it.

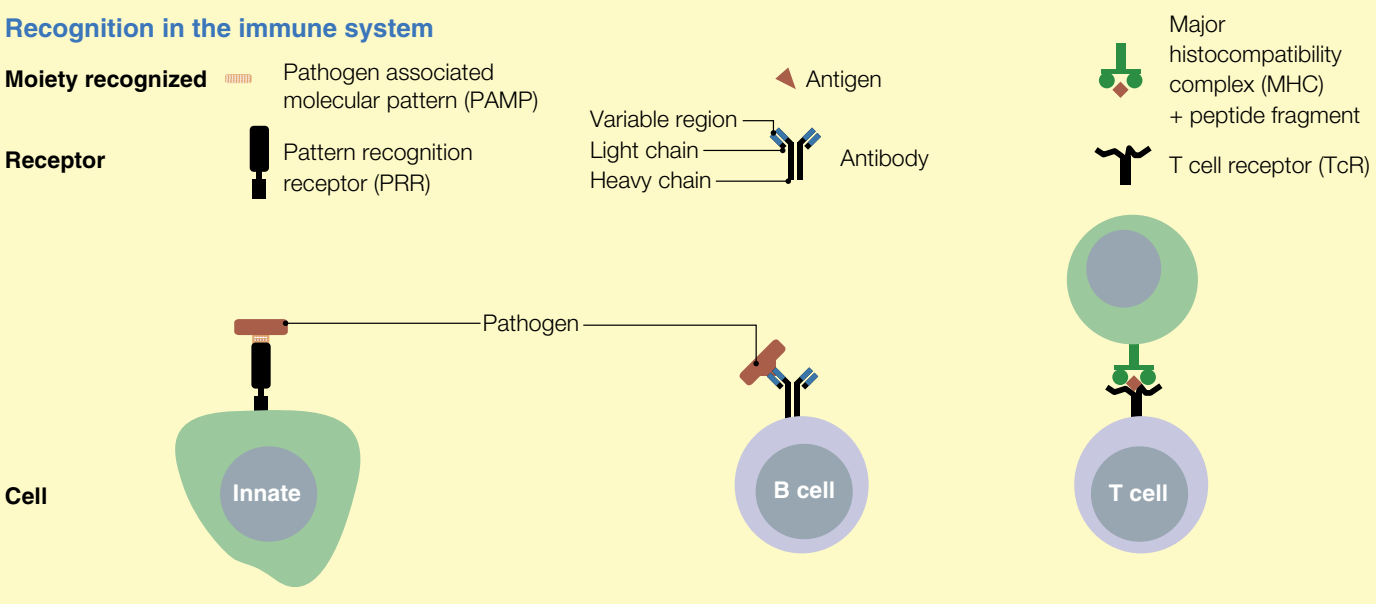
The innate immune system used to be regarded as a primitive defence system of limited effectiveness, found in vertebrates and invertebrates. The specific immune system is found in vertebrates only and was thought to be the main defence mechanism. It is now known that the innate immune system does more than provide the first line of defence and plays an important role in determining the type of specific immune response that is mounted against infectious agents.

Self/non-self discrimination

Both the innate and specific immune systems can distinguish between foreign entities (e.g. pathogens) and the body's cells and tissues. Recognition is achieved by molecules of the immune system that bind only to foreign molecules associated with pathogens and not to self-molecules.

Innate immune system: cells and proteins of the innate immune system can recognize certain molecules on the surface of path-ogens (pathogen-associated molecular patterns – PAMPs) as foreign. PAMPs are large molecules with a significant non-protein component and examples include lipopolysaccharides, peptido-glycans, lipotechoic acids and mannans. They are found only on microbes and are essential for microbial survival, therefore they cannot stop manufacturing them as a way of avoiding recognition by the innate immune system. The cell receptors that recognize PAMPs are called pattern-recognition receptors and include toll-like receptors and lectins such as the mannose receptor (Figure 1). Soluble factors recognizing PAMPs include mannose-binding lectin and C-reactive protein.

Recognition in the immune system



There is a limit to the number of receptors that can evolve to recognize foreign PAMPs and, given the quicker replication of pathogens compared with mammals, some pathogens will evolve ways of escaping recognition by the innate immune system. For example, avirulent streptococci are recognized and eliminated by the innate immune system and therefore do not cause disease. However, virulent streptococci synthesize a waxy carbohydrate outer coat that is not recognized by the innate immune system and therefore to eliminate them a specific immune response is required.

Specific immune system

B lymphocytes and antibody – B lymphocytes have antibody molecules on their cell surface. Antibody molecules consist of two identical heavy chains and two identical light chains forming a Y-shaped structure (Figure 1). Each heavy chain molecule consists of a variable (V) region at the N-terminal amino acid end and a constant region at the C-terminal end consisting of three domains. Light chains have a variable region and a constant region consisting of one domain. The variable regions of the heavy and light chain fold together to form a structure that is responsible for recognizing and binding to molecules on a microbial cell surface or soluble protein made by a microbe. The molecules to which antibody binds are called antigens. Special molecular mechanisms cause part of the gene coding for the V region of the antibody to be randomly altered. Therefore each antibody molecule has a different amino acid sequence in the part of the molecule that recognizes antigen and thus each antibody can bind to some antigens but not others. Enzyme digestion can split antibodies into an antigen-binding fragment (Fab) and a crystallizable fragment (Fc). There are a number of different classes of antibody (IgM, IgG, IgA, IgE, IgD). The class is determined by the Fc region of the heavy chain. There are also two types of light chain called κ and λ. Each class of heavy chain can associate with either κ or λ light chains. The class of heavy chain determines the function of the antibody, the light chain type has no effect on function.

T lymphocytes have receptors for antigen on their surface. Although related to antibody, the T cell receptor for antigen (TcR) is coded for by different genes. The TcR consists of two transmembrane glycoprotein chains (α and β), linked by disulphide bonds. The chains have a constant region proximal to the cell surface and a V region distal to the cell surface. Different V regions are generated on different T cells by the same molecular mechanisms used by B cells, therefore different T cells recognize different antigens.

The TcR does not recognize intact antigen (as antibody does) but recognizes fragments of peptides, 8–20 $\alpha\alpha$ in length derived from microbial proteins. The TcR does not recognize these peptide fragments in isolation but in association with self-molecules of the major histocompatibility complex (MHC) (Figure 2). The MHC is a complex of over 100 genes located on chromosome 6 in humans, where it is also called HLA. There are three classes of MHC.

- Class I MHC genes are called HLA-A, HLA-B and HLA-C. They code for similar proteins with the same function.
- Class II MHC includes three genes (HLA-DP, HLA-DQ, HLA-DR). They code for proteins with similar structure and function.
- Class III MHC genes code for a variety of products, most of which have immune function but which are not related to each other. Examples include the cytokine tumour necrosis factor-α (TNF-α) complement components C2 and C4 and heat shock proteins.

Antigen processing and the major histocompatibility complex (MHC)

The peptide fragments are generated from whole protein by antigen processing (see Figure 2). This involves proteolytic degradation of the whole protein. The two proteolytic pathways deal with extracellular and intracellular antigen in different ways. Extracellular antigen is taken up by endocytosis (phagocytosis, pinocytosis or receptor-mediated endocytosis) into an endocytic vesicle and is degraded by the lysosomal pathway. The antigen peptide fragments generated associate with class II MHC in special transport vesicles and the peptide/class II MHC complex is transported to the cell surface. Intracellular antigens, produced in the cytosol, are degraded in special proteolytic structures called proteosomes. The fragments generated are transported to the rough endoplasmic reticulum where they associate with class I MHC and are transported to the cell surface. CD4 T cells recognize antigen in association with class II MHC and CD8 T cells recognize antigen in association with class I MHC. ◆

Immunological Response to Infection: Inflammatory and Adaptive Immune Responses

Peter J Wood

Peter J Wood is Lecturer in Immunology in the School of Biological Sciences, University of Manchester, UK. He obtained a BSc in Pharmacology from Liverpool University and a PhD in Immunology from London University. His research interests focus on immunological events in insulin-dependent diabetes mellitus and in graft rejection.

When a microbe enters the body, it or its products encounter tissue macrophages. If the macrophage recognizes the pathogen it is activated to release a range of factors.

- Nitric oxide causes vasodilatation and has antimicrobial activity.
- Oxygen radicals have antimicrobial activity.
- Prostaglandins and leukotrienes are important inflammatory mediators that cause vasodilatation and increased vascular permeability, and are chemotactic for (attract) neutrophils and eosinophils.
- Platelet-activating factor causes platelet aggregation and is chemotactic for neutrophils and eosinophils.
- Cytokines are hormone-like molecules involved in immune responses. They are small proteins and act in an autocrine and paracrine manner but seldom in an endocrine fashion. Three of the most important cytokines secreted by macrophages in an inflammatory response are interleukin-1 (IL-1), interleukin-6 (IL-6) and tumour necrosis factor-α (TNF-α).

Tissue damage and damage to the endothelium, which often accompany infection, result in activation of the clotting, kinin, fibrinolytic and complement systems. Activation of these systems leads to the generation of factors with many biological functions (Figure 1) including vasodilatation, increased vascular permeability and activation of mast cells. Activated mast cells degranulate, releasing the contents of their granules into the surrounding tissue. The granules contain histamine, heparin and degradative enzymes. Histamine is a powerful mediator of vasodilatation and increased vascular permeability. The net result is increased blood flow to the area and the recruitment of blood proteins and cells to the site. Cytokines released in the area increase the expression of adhesion molecules on the endothelium, and chemokines (chemotactic cytokines) attract neutrophils and monocytes to the site. The neutrophils and monocyte/macrophages attempt to phagocytose and kill the infectious microbes and monocyte/macrophages also remove dead cells and damaged tissue.

Systems activated during inflammatory responses

System	Component cleavage product	Function of component or
Clotting	Hageman factor	Activates clotting, fibrinolytic and kinin systems
	Fibrin	Forms clot
	Fibrinopeptides	Increase vascular permeability, neutrophil chemotaxis
Kinin	Bradykinin	Vasodilatation, smooth muscle contraction, pain
Fibrinolytic	Plasmin	Breaks down clots, activates complement system, activates Hageman factor
Complement	C1	Binds to antibody (C1q). Serine proteases (C1r,C1s)
	C4	Inflammatory mediator (C4a), binds C2
	C2	Serine protease (C2a)
	C3	Activates mast cells (C3a) Opsonin (C3b)
	C5a	Activates mast cells, chemotactic for neutrophils, monocytes, eosinophils and basophils
	C5–C9	Formation of pores in microbial cell walls causing cell lysis

Acute phase response

If the inflammatory response is large enough, cytokines produced by macrophages appear in the bloodstream in sufficient concentrations to affect other tissues and organs.

Brain – IL-1 acts on the hypothalamus to stimulate prostaglandin secretion which causes fever, somnolence and anorexia.

Bone marrow – IL-6 and TNF-α stimulate stromal cells and macrophages in the bone marrow to release factors that stimulate increased production of leukocytes.

Liver – IL-6 stimulates hepatocytes to produce increased amounts of acute phase proteins, which are secreted into the blood and travel to sites of inflammation. Plasma levels of some of these proteins increase 100–1000-fold:

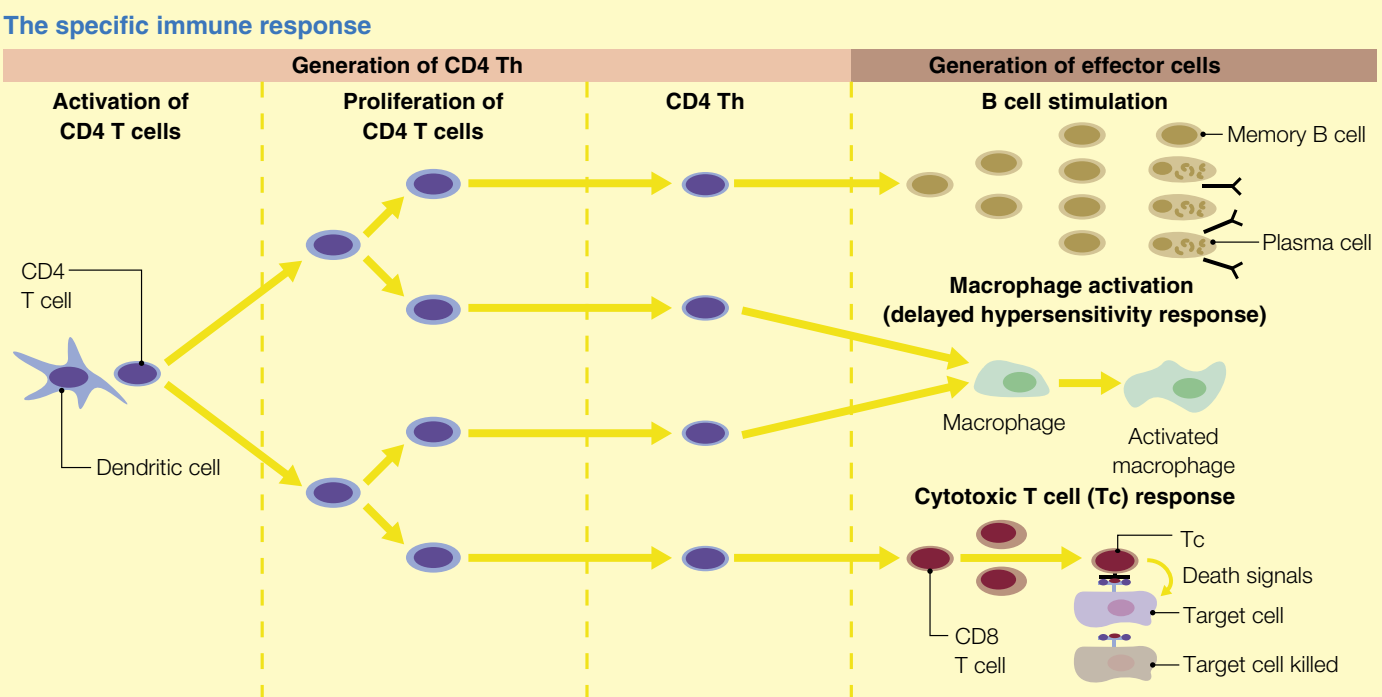
- serum amyloid A inhibits fever and platelet activation and provides a negative feedback loop
- C-reactive protein binds to phosphoryl choline present on bacteria and some fungi and can act as an opsonin in a similar fashion to antibody (see below). Plasma levels of other factors increase only 2–5-fold:
- fibrinogen is involved in clotting and some of its breakdown products (the fibrinopeptides) are chemotactic for (attract) phagocytes (Figure 1)
- complement protein C3 has a number of biological activities including activation of mast cells and promoting phagocytosis (Figure 1)
- mannose-binding lectin can bind mannose-containing molecules on the surface of microbes and activate complement.

Generation of the specific immune response

The local inflammatory and acute phase responses may be enough to resolve an infection. If not, the next response of the immune system is to generate a specific immune response, which can be divided into two stages (Figure 2):

- activation of CD4 T cells so that they divide and differentiate into helper T (Th) cells
- generation of effector cells and molecules that mediate the removal or neutralization of the pathogen (the generation of these cells is controlled by Th cells produced in the first stage of the response).

The specific immune response



Generation of Th cells

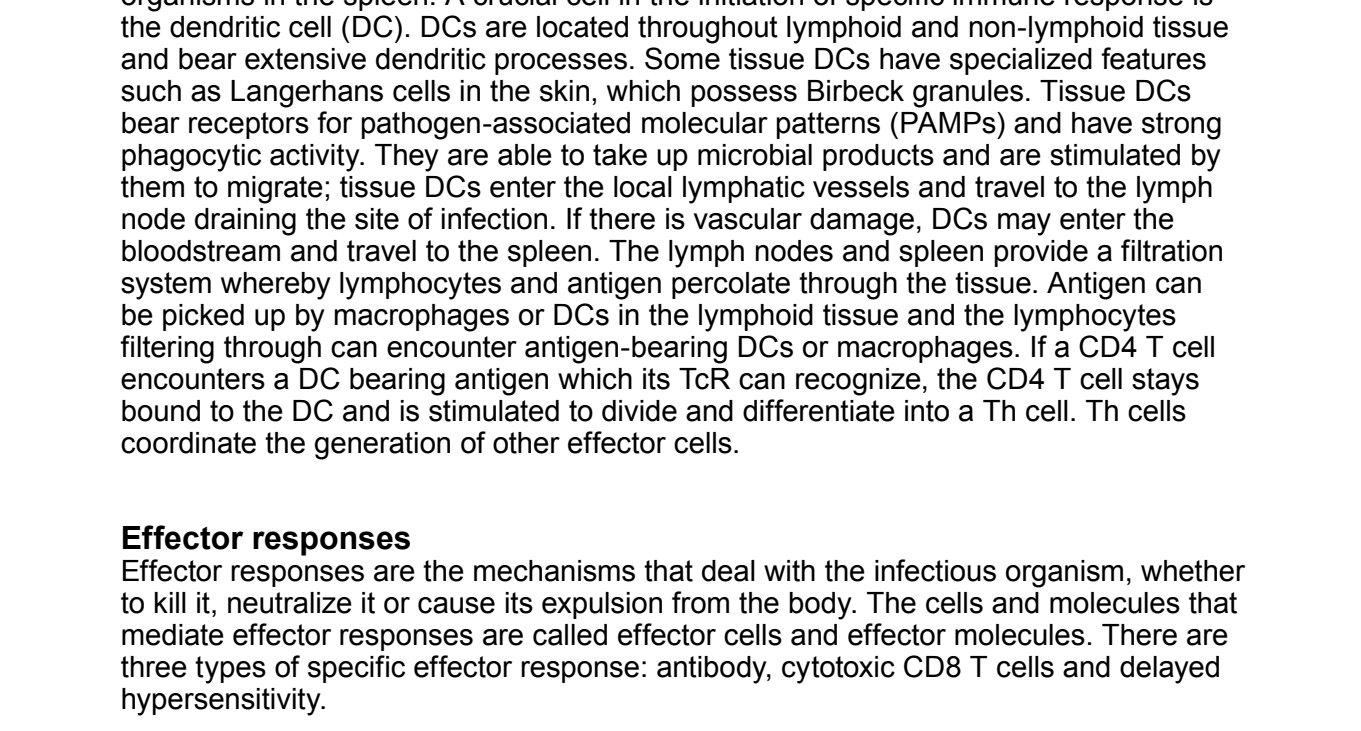
Specific immune responses occur in specialized lymphoid tissue. Responses against tissue pathogens generally occur in lymph nodes and responses against blood-borne organisms in the spleen. A crucial cell in the initiation of specific immune response is the dendritic cell (DC). DCs are located throughout lymphoid and non-lymphoid tissue and bear extensive dendritic processes. Some tissue DCs have specialized features such as Langerhans cells in the skin, which possess Birbeck granules. Tissue DCs bear receptors for pathogen-associated molecular patterns (PAMPs) and have strong phagocytic activity. They are able to take up microbial products and are stimulated by them to migrate; tissue DCs enter the local lymphatic vessels and travel to the lymph node draining the site of infection. If there is vascular damage, DCs may enter the bloodstream and travel to the spleen. The lymph nodes and spleen provide a filtration system whereby lymphocytes and antigen percolate through the tissue. Antigen can be picked up by macrophages or DCs in the lymphoid tissue and the lymphocytes filtering through can encounter antigen-bearing DCs or macrophages. If a CD4 T cell encounters a DC bearing antigen which its TcR can recognize, the CD4 T cell stays bound to the DC and is stimulated to divide and differentiate into a Th cell. Th cells coordinate the generation of other effector cells.

Effector responses

Effector responses are the mechanisms that deal with the infectious organism, whether to kill it, neutralize it or cause its expulsion from the body. The cells and molecules that mediate effector responses are called effector cells and effector molecules. There are three types of specific effector response: antibody, cytotoxic CD8 T cells and delayed hypersensitivity.

Antibody response: B cells that encounter antigen for which their surface Ig is specific are guided by chemokines to the region of the lymph nodes or spleen where CD4 T cell–DC interactions take place. This brings into proximity the B cells and Th cells. B cells express class II major histocompatibility complex (MHC)/antigen on their surface and if the Th cell is specific for the class II MHC/antigen it will be stimulated to produce cytokines which will cause proliferation and differentiation of the B cell. Interaction of CD40 on the B cell surface with CD154 on the Th cell surface is also required for all but IgM production. The proliferating B cells and some of the Th cells form a structure called a germinal centre in the lymph node or spleen. In germinal centres, B cells divide rapidly and undergo class switch and somatic mutation in their Ig genes. Class switch means that instead of expressing IgM and IgD on their cell surface, B cells express IgG, IgA or IgE. This is due to a change in the constant region of the H-chain but it is important to appreciate that the V region, and hence antigen specificity, of the B cell does not change during class switch. Somatic mutation within the Ig genes is a mechanism that results in the production of antibody with much higher affinity (stronger binding) for the antigen. High affinity antibody is more efficient at carrying out the biological activities of antibody listed below. The final step in the B cell response to antigen is differentiation into plasma cells or memory B cells (Figure 2). Plasma cells secrete large amounts of antibody. Memory B cells, because they have already undergone class switch and somatic mutation, provide increased numbers of high affinity B cells. They are long lived and ensure that if the same pathogen is encountered again there is a faster, bigger and better antibody response. Antibody is able to provide protection in a number of ways (Figure 3).

Antibody effector mechanisms



Opsonization – phagocytes have receptors for the Fc part of the antibody molecule. Antibody bound to a microbe can be bound to the phagocyte, promoting uptake and phagocytosis.

Neutralization – by binding to toxins, viruses or bacteria, antibody can prevent them binding to cellular receptors thereby preventing entry into cells.

Activation of complement – the complement system is a cascade of proteins that have a number of biological functions (Figure 1). Antibody binding to antigen undergoes a conformational change that enables the Fc part of the antibody to bind the first component of complement C1, leading to activation of later components. Complement can also be activated in an antibody-independent fashion by the acute phase protein, mannose-binding lectin, and by certain microbial products (e.g. zymosan in yeast cell walls).

Antibody-dependent cell-mediated cytotoxicty (ADCC) – macrophages and natural killer (NK) cells (a type of lympho-cyte) have receptors for the Fc part of the antibody. Antibody bound to an organism can be bound by the macrophage or by the NK cell, which triggers the cell to kill the organism in an extracellular manner. Macrophages and NK cells can kill infected host cells and tumour cells by ADCC. There is evidence that eosinophils can kill helminth worms *in vitro* in the same way.

Generation of CD8 cytotoxic T cells: Th cells also help in the generation of CD8 cytotoxic T cells (Tc), which are capable of killing other cells expressing antigen on class I MHC (Figure 2). In the lymph node or spleen, DCs expressing antigen on their class II MHC to CD4 T cells can also express antigen derived from the same pathogen on their class I MHC. If a CD8 T cell, percolating through the lymph node or spleen, has a TcR specific for the antigen plus class I MHC it will bind to it and receive a signal for activation. The cytokine, IL-2, secreted by the CD4 T cell stimulates the CD8 T cell to divide and differentiate into a Tc. The Tcs migrate through the body and if they encounter any cell type expressing the same antigen on its class I MHC they kill the cell.

Delayed hypersensitivity (DTH) responses: initially considered a pathological response, DTH is now recognized as an important protective response against some intracellular pathogens, especially those that can live in macrophages. Usually DTH responses are generated in response to tissue-dwelling pathogens. Th cells generated in the lymph node draining the site of infection re-enter the bloodstream and travel to the site of infection where they leave the bloodstream and enter the tissue. Infected macrophages, present at the site of infection, can present antigen on class II MHC on their cell surface and this stimulates the Th cells to release cytokines. Among these cytokines, TNF-α increases the expression of adhesion molecules on the local endothelium thereby aiding the recruitment of monocytes from the blood. The monocytes and tissue macrophages are activated by other cytokines, particularly interferon-γ and TNF-α to differentiate into activated macrophages which are better able to kill the pathogens (Figure 2). However, extensive activation of macrophages can also lead to tissue damage and hence the original description of the response as a hypersensitivity reaction. Much of the damage caused in chronic infections (e.g. tuberculosis, leprosy) is due to DTH reactions. ◆

Immunology of Transplantation

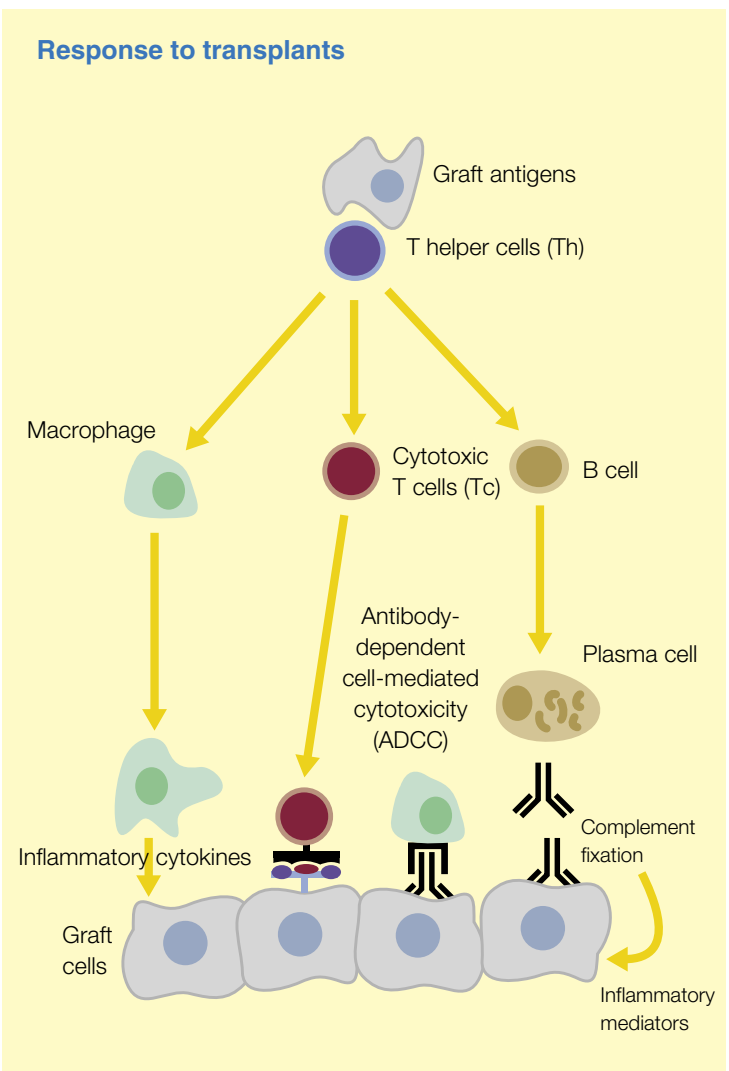
Peter J Wood

Peter J Wood is Lecturer in Immunology in the School of Biological Sciences, University of Manchester, UK. He obtained a BSc in Pharmacology from Liverpool University and a PhD in Immunology from London University. His research interests focus on immunological events in insulin-dependent diabetes mellitus and in graft rejection.

The immune response to transplants is fundamentally no different from that previously described for pathogens elsewhere. The main difference is in the nature of the antigens. Cells of a transplant bear both class I and class II major histocompatibility complex (MHC) molecules on their surface. Because of the enormous variation of class I and class II genes between individuals, unless the transplant is from a relation, it almost certainly bears variants of class I and class II molecules that are not possessed by the transplant recipient. For reasons that are not fully understood, foreign MHC molecules stimulate a much higher number (10–100-fold) of T cells than foreign antigen presented by self-MHC and therefore the immune response against foreign MHC transplantation antigens is much stronger than that seen against pathogens. In addition to foreign MHC molecules (major transplantation antigens), transplants have many proteins that are a variant of the recipient's equivalent proteins. These are called minor transplantation antigens and, though they do not stimulate as strong an immune response as foreign MHC, they can stimulate rejection of the transplant, unless the response against them is suppressed.

Transplants stimulate the same type of effector responses as pathogens (see page 130). In non-immunosuppressed patients antibody is produced particularly against class I MHC, but also against class II MHC and other unidentified antigens on the graft. CD4 T cells respond to foreign class II MHC on the graft and also to minor histocompatibility antigen presented by self class II MHC, and develop into helper T (Th) cells. Similarly CD8 T cells respond to foreign class I MHC and develop into cytotoxic T cells (Tcs).

Therefore, damage to the graft can be brought about by antibody-mediated damage, CD8 Tc killing of graft cells and Th-mediated induction of delayed hypersensitivity (DTH) responses (Figure 1). Histologically, graft rejection resembles DTH most closely, but it is likely that without immunosuppression all three types of effector response will be brought against the graft.



1

Types of graft rejection

Hyperacute rejection occurs within minutes or hours of a vascularized graft and is caused by pre-existing antibodies against the graft which bind to the transplant, activating the complement and clotting pathways, leading to massive clotting throughout the graft. It is prevented by matching blood types and testing the recipient for pre-existing antibodies against the graft (cross-matching).

Acute rejection is the result of the generation of an immune response against the graft as described above. It is treated with immunosuppressive drugs. Without immunosuppression, acute rejection occurs 1–2 weeks after transplantation.

Chronic rejection is a major cause of later graft loss and is seen as slow deterioration of graft function, usually beginning years after transplantation. Although it differs from organ to organ, one of the main features is arterial intimal thickening due to myofibroblast migration and proliferation. This results in progressive narrowing of the arterial lumen, which eventually becomes occluded, leading to tissue anoxia. Current immunosuppressive drugs do not prevent chronic rejection. ◆

Inflammatory Response: Vascular Endothelium

Emrys Kirkman
Marina Sawdon

Emrys Kirkman is Lecturer in Physiology at the University of Durham, UK. He has a PhD from Manchester University and worked at the Royal Free Hospital School of Medicine, London, and the MRC Trauma Group, Manchester. His research interests include trauma-induced changes in cardiovascular control mechanisms, the underlying central nervous pathways and the resulting alterations in haemodynamics and oxygen transport.

Marina Sawdon is a cardiovascular physiologist studying for a PhD at the University of Durham. She graduated from the University of Durham. Her research interests include the cardiovascular and pulmonary responses to trauma.

The vascular endothelium forms a barrier between the blood-borne leucocytes, which play a key role in the inflammatory response, and the underlying tissue. Current ideas suggest that the endothelium orchestrates the inflammatory process, directing the leucocytes to the site of tissue damage or infection to produce a localized response while preventing the spread of the inflammation. As part of this response, the endothelium at the site of inflammation becomes damaged, with both the leucocytes and the endothelial cells providing essential ingredients for this damage. Provided this process remains localized it is beneficial because it plays a part in removing infected or devitalized tissue and leads to healing. However, if the process becomes unregulated and widespread it leads to whole-body inflammation, coagulopathy and organ dysfunction associated with the systemic inflammatory response syndrome (SIRS) and eventually multi-organ failure and death. This contribution discusses the localized process, the potential for spreading of the response and the consequent problem with vascular control and oxygen delivery to cells.

Endothelium–leucocyte interaction

Movement of leucocytes from the blood stream into the damaged and/or infected tissue is an essential part of the inflammatory process. It takes place mainly across the wall of the post-capillary venules, though in some areas, such as the lungs, the process can also occur in the capillaries. The entire process is depicted in Figure 1 and involves complex interactions between the endothelium and the leucocytes. There is a carefully timed sequence of molecular expression and regulation leading to the key steps of leucocyte margination (attraction to the endothelium), rolling (along the endothelium) and finally transmigration (penetration) between the endothelial cells into the tissue.

Leucocyte margination, rolling and transmigration through the endothelium

1

Leucocyte margination and rolling

An essential first step for leucocyte margination and rolling is the appearance of a group of glycoproteins known as selectins on the surface of both the endothelial cells and the leucocytes. Of particular importance are three selectins: P- and E-selectins on the endothelium and L-selectin on neutrophils. The appearance of the selectins on the cell surfaces, in turn, can be triggered by a variety of pro-inflammatory mediators.

In some organs, such as the lungs, a number of injurious stimuli can result in the activation of resident macrophages to produce pro-inflammatory mediators such as tumour necrosis factor (TNFα) and interleukin-1 (IL-1). These mediators, as well as histamine, thrombin-activated complement, leukotrienes and oxygen radicals, cause the endothelial cells to re-distribute P-selectin, normally stored in Wiebel–Palade bodies within the cell, to the cell surface. Expression of P-selectin in this way is normally maximal within 20 minutes of stimulation and declines after 1 hour. By contrast, expression of E-selectin requires *de novo* synthesis and E-selectin is not seen at the cell surface until 2 hours after stimulation. A complementary ligand (binding molecule) for P-selectin, P-selectin glycoprotein ligand 1 (PSGL-1), is found on the surface of neutrophils (and other cells such as monocytes, natural killer cells and memory T lymphocytes). L-selectin on the leucocytes is thought to act as a ligand for both P- and E-selectins.

As a consequence of the interaction between endothelial cell P- and E-selectins with leucocyte PSGL-1 and L-selectin there is a series of intermittent low-affinity binding between the leucocytes and the endothelium leading to leucocyte margination to the endothelium and subsequent rolling along the endothelium. Concurrent with this series of pro-inflammatory events, the host activates a series of anti-inflammatory processes that limit margination and rolling. These include secretion of endocrine substances (e.g. glucocorticoids, IL-10) and paracrine/autocrine substances (e.g. adenosine, nitric oxide (NO), prostacyclin (PGI_2), lipocortin-1).

At this point, the balance of the pro- and anti-inflammatory mechanisms decides whether the inflammatory process proceeds to the next step of transmigration (penetration) or is stopped by detachment of the leucocytes from the endothelium.

Leucocyte activation and transmigration

Assuming that the inflammatory response proceeds, the next step is transmigration. The first step involves an interaction between a further group of endothelial and leucocyte surface molecules to produce high-affinity binding and an arrest of the rolling behaviour. The molecules on the endothelial cells belong to the immunoglobulin supergene family and include intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2), vascular cell adhesion molecule 1 (VCAM-1) and platelet-endothelial cell adhesion molecule 1 (PECAM-1). The best studied of these is ICAM-1, the expression of which is up-regulated by TNFα and IL-1 within 6–9 hours of the stimulus. ICAM-1, in turn, becomes bound to members of the β_2-integrin family of adhesion molecules on the leucocytes, examples of which are leucocyte function associated antigen 1 (LFA-1 or CD11a/CD18) found on all leucocytes, and macrophage-1 antigen (Mac-1 or CD11b/CD18) found particularly on monocytes and neutrophils.

Endothelial cells that have been activated to express ICAM-1 also express chemokines such as IL-8, which leads to activation of the adherent leucocytes. The endothelial cells retract resulting in gaps between the cells, which increase vascular permeability and lead to local oedema. Facilitated by the gaps between the endothelial cells the leucocytes transmigrate out of the blood vessel into the tissue. This process is aided by PECAM-1, which is found along the intercellular junctions of the endothelial cells and is under the control of chemotactic factors such as IL-8 and complement C5a.

The entire process leads to damage of the endothelial cells, with both the activated neutrophils and the endothelial cells playing a role as described in the next section.

Endothelial cell damage

Evidence suggests that the endothelial cells are damaged by the pro-inflammatory cytokines (e.g. TNFα, IL-1), which serve as triggers for the endothelial–leucocyte interaction, as well as by the activated neutrophils. The cytokines are thought to induce apoptosis (programmed cell death) in the endothelial cells.

The interaction between the activated neutrophils and the endothelial cells is better understood. The mechanism underlying the killing of endothelial cells by activated adherent neutrophils is summarized in Figure 2. The neutrophil secretes an enzyme, elastase, which enters the endothelial cell to convert an intracellular enzyme xanthine dehydrogenase (XD) to xanthine oxidase (XO). XO in turn acts on xanthine (a breakdown product of adenosine triphosphate, ATP) to form the superoxide O_2* which in turn reduces bound Fe^{3+} to Fe^{2+}. Fe^{2+} then reacts with hydrogen peroxide (produced by the neutrophils) to yield the highly cytotoxic oxygen free radical HO* within the endothelial cell, causing damage and death.

Neutrophil-induced endothelial cytotoxicity is limited by nitric oxide (NO*). This is formed in the endothelial cell by nitric oxide synthase (NOS) from L-arginine. The protective effect of NO* is twofold. Firstly, it reduces the adhesion between the endothelial cell and the neutrophil. Secondly, NO* scavenges O_2*, forming the peroxynitric anion ONOO*, thus attenuating the formation of Fe^{2+} which is needed to form the cytotoxic oxygen free radical. Endothelial cells from different tissues have different abilities to form NO* and hence different vulnerabilities to injury by oxidants and neutrophil-mediated killing.

Mechanism of neutrophil-induced killing of endothelial cells

2

Natural mechanisms limiting inflammation

Although the inflammatory response is destructive locally, it is beneficial to the whole organism because it is the first step towards healing, provided it is localized and prevented from causing secondary damage elsewhere. It is therefore not surprising that there are several powerful mechanisms that down-regulate the pro-inflammatory mechanisms. Among the most studied mediators are the cytokines IL-10 and IL-13 and secretory leucocyte protease inhibitor (SLPI).

IL-10 and IL-13, in the lung, have been shown to act on alveolar macrophages to reduce the secretion of TNFα and IL-1. SLPI acts on the vascular endothelium to reduce the expression of ICAM-1 and hence reduce neutrophil adhesion. This effect is thought to be mediated by a modulation of the signal transduction mechanism in the endothelial cell, which leads to the activation of NFκB (a transcription factor involved in the production of adhesion molecules). By preventing the activation of NFκB there is a reduced expression of ICAM-1. This effect of SLPI appears to be part of a physiological mechanism limiting inflammation, because blockade of SPLI leads to an enhancement of lung vascular damage (increased permeability) during an inflammatory response.

Widespread inflammation and SIRS

Despite the mechanisms limiting inflammation there are circumstances when the inflammatory response becomes widespread. The precise mechanism is unclear and is likely to be multi-factorial. Some studies have suggested that the endothelium plays a role in this widespread response, with aberrant adhesion molecule expression causing pathological interaction between endothelium and leucocytes. The resulting endothelial damage causes widespread tissue damage and oedema, limiting oxygen delivery to the cells and an exacerbation of the problem. A confounding factor in these cases is disseminated intravascular coagulation (DIC), which again involves the endothelium.

Disseminated intravascular coagulation

Post-mortem findings from victims of SIRS indicate widespread fibrin microthrombi even in vessels with intact endothelium. This has led to the suggestion that the endothelial anti-coagulant mechanisms have become disrupted. Under normal circumstances, the endothelium possesses three anticoagulant mechanisms.

- Cell surface expression of thrombomodulin providing a negative feedback mechanism for thrombin generation, and activated protein C-induced degeneration of an inhibitor of plasminogen activator, thus promoting plasmin formation and hence fibrinolysis.
- Heparin sulphate, which is associated with the endothelial cell surface.
- Secretion of prostacyclin (PGI_2) and adenosine, which inhibits platelet aggregation.

A disturbance of these mechanisms leads to the anticoagulant role of the endothelium being attenuated and reduced fibrino-lysis. Concurrently, the pro-inflammatory cytokines induce the synthesis and surface expression of tissue factor, which in turn causes the endothelium to initiate the extrinsic coagulation cascade giving widespread, unopposed, pro-coagulant activity. The resulting impairment of microvascular flow causes further reduction in tissue oxygenation and hence additional tissue damage.

Impairment of local vasomotor control

The vascular endothelium plays an important physiological role in regulating arteriolar vascular resistance and hence microcirculatory haemodynamics. A detailed description of this role is beyond the scope of this review, however, there are a number of excellent accounts of this topic (see Further Reading). Briefly, the endothelium secretes a number of vasoactive agents, some of which are vasodilator (e.g. NO) and some of which are vasoconstrictor (e.g. endothelin).

NO is among the most thoroughly studied of these mediators. It has been implicated in vascular regulation and dysregulation during sepsis (the systemic inflammatory response to infection). With regard to normal vascular regulation there is a basal synthesis and release of NO by endothelial cells. The NO then diffuses to the underlying smooth muscle cells where it activates guanylate cyclase leading to an elevation of guanosine 3',5'-cyclic monophosphate (cGMP), triggering a series of intracellular events culminating in falls in free calcium levels and hence muscle relaxation. Thus, in arterioles, NO causes vasodilatation and a fall in vascular resistance.

The physiological release of NO by endothelial cells is modulated by a number of chemical (e.g. acetylcholine, 5-HT, thrombin) and mechanical (e.g. shear stress) influences on the endothelium, serving to 'fine tune' local vascular resistance and hence blood flow. In sepsis it has been argued that there is an overproduction of NO and hence widespread vasodilatation.

NO is produced from L-arginine by the action of the enzyme nitric oxide synthase (NOS). There are three isoforms of NOS:

- eNOS found in the endothelium
- nNOS in neurons
- iNOS, an inducible form found in a number of locations (e.g. macrophages, smooth muscle, endothelium).

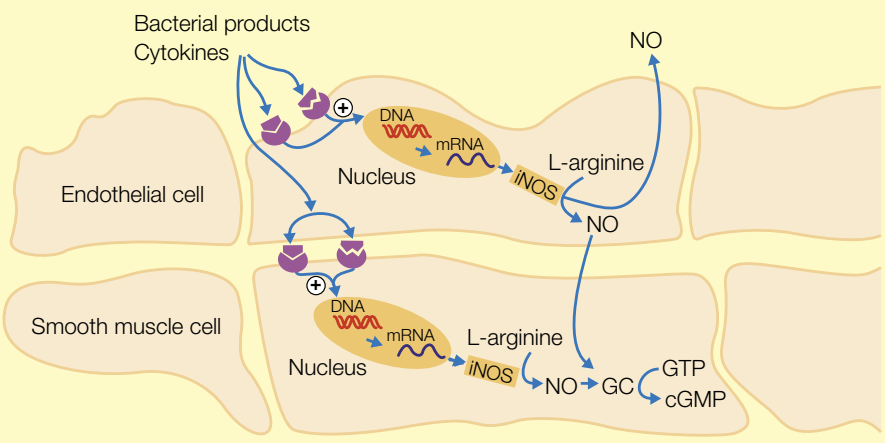
eNOS and nNOS are constitutive enzymes and are sometimes grouped under the title cNOS. In contrast, the expression of iNOS is induced by several stimuli such as those associated with inflammation and sepsis (Figure 3).

Expression of iNOS

Nitric oxide–cGMP pathway producing vascular smooth muscle relaxation

iNOS is not usually present under normal physiological conditions but is induced during inflammation and sepsis

cGMP, cyclic guanosine monophosphate; GC, guanylate cyclase; GTP, guanosine triphosphate; LPS, lipopolysaccharides (endotoxin); NOS, nitric oxide synthase.



Induction and activation of iNOS during sepsis

Adapted from: Kirkeboen K A, Strand O A. The Role of Nitric Oxide in Sepsis – An Overview. *Acta Anaesthesiol Scand* 1999; **43:** 275–88.

There are several important differences between cNOS and iNOS, perhaps the most important of which is that cNOS generally produces small amounts of NO and the rate of secretion is rapidly controlled. By contrast, iNOS produces much greater amounts of NO, and its activation is sustained sometimes for several days. During widespread inflammation and sepsis it is argued that the pro-inflammatory cytokines (e.g. TNFα, IL-1) as well as bacterial components such as endotoxin lead to the induction of iNOS over a period of several hours, thereby causing excessive production of NO. This may produce extensive vasodilatation, a fall in total peripheral resistance and hypotension. Additionally, widespread vasodilatation is likely to be detrimental for matching regional oxygen delivery to demand because it may lead to a 'stealing' of blood flow from areas which most need it to those that do not.

The role and potential therapeutic treatment of NO over-production in human sepsis is currently a 'hot topic'. The balance of evidence suggests that there is overproduction of NO, though this is not universally accepted. The therapeutic potential is more contentious. A large number of animal and a small number of human studies have investigated the effects of NOS inhibition using analogues of L-arginine (e.g. L-NAME, L-NMMA) which affect both cNOS and iNOS, and more selective inhibitors of iNOS. These studies have produced mixed results ranging from benefit to no effect and even increased mortality. Perhaps this is not surprising given the complexity of the system in which NO is widespread and subserves many functions.

Current issues include the relative importance of NO during sepsis in different species, type of inhibitory agent and dose used and whether they are given as a series of boluses or a continuous infusion.

One final area of concern is that some studies have indicated that inhibition of cNOS by L-NAME in healthy volunteers had differential effects on vascular resistance in various organs possibly involving vasoconstriction in the splanchnic and renal circulations but not in skeletal muscle or skin. If this finding was also true in sepsis then any increase in total peripheral resistance (and hence blood pressure) would result in a redirection of blood flow from vital organs with a greater need for oxygen towards skeletal muscle and skin where the need for oxygen might be less. The end result is a potential hypoperfusion of gut and kidney and resulting organ damage. This potential problem emphasizes the danger of becoming fixated on attempts to improve arterial blood pressure when the main concern should be ensuring adequate regional blood flow and oxygen delivery to meet tissue demand.

Intermediary Metabolism

Iain Campbell

Iain Campbell is Reader in Anaesthesia at the University of Manchester and Honorary Consultant Anaesthetist at the University Hospitals of South Manchester. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

Energy is obtained from the oxidation of the macronutrients carbohydrate, fat and protein. The structure of these macro-nutrients and the whole body quantification of their metabolism are described on page 115. The end-products of fat and carbohydrate metabolism are carbon dioxide and water only. The end-products of protein metabolism are carbon dioxide, water and a number of nitrogen-containing compounds excreted in the urine, mainly urea, but also creatinine, uric acid and ammonia. About 80% of urinary nitrogen is normally present as urea.

Energy release

Energy released by oxidation is not used directly by the cells but goes into the formation of bonds between phosphoric acid residues and certain organic compounds and is thus 'stored' as discrete packets. When these bonds are hydrolysed the energy is released for use in muscle contraction, membrane transport or protein synthesis.

'Oxidation' involves the loss of electrons, but organic molecules do not give up electrons easily and oxidation of a complex molecule such as glucose normally involves the loss of an entire atom, usually hydrogen. The oxidation (dehydrogenation) of a compound such as glucose results in the production of the low-energy compound carbon dioxide and the acceptance of electrons (hydrogen atoms), ultimately by oxygen, to produce water. As hydrogen ions are released in the intermediate parts of the oxidation process they are taken up transiently by co-enzymes, most commonly flavine adenine dinucleotide (FAD, derived from vitamin B2) to form FADH2 and nicotinamide adenine dinucleotide (NAD, derived from nicotinamide also a B group vitamin) to form NADH. ATP is synthesized from a series of electron transport proteins situated on the inner wall of the mitochondrion, the flavoprotein-cytochrome (respiratory) chain. The electrons (hydrogen atoms) enter this enzyme chain via FADH2 and NADH. They are passed down the respiratory chain, from one enzyme to the next, each enzyme having a greater affinity for electrons than the previous one. Free energy is released and is used to drive hydrogen ions (protons) across the inner mitochondrial membrane into the intermembrane space to create an electrochemical gradient across the inner membrane. The protons then pass back down this gradient into the mitochondrion, driving a reversible ATPase in the membrane. It is this ATPase that synthesizes ATP from ADP and inorganic phosphate.

Other high-energy phosphate compounds are also used as immediate sources of energy; they include creatine phosphate, large quantities of which are found in muscle, as well as other purines and pyrimidines (e.g. guanosine triphosphate, cytidine triphosphate, inosine triphosphate). 90% of whole body oxygen consumption in the basal state is mitochondrial and 80% of it is coupled to ATP synthesis. About 30% of ATP is used for protein synthesis, 25% by Na/K ATPase in cell membranes, 10% for gluconeogenesis and 3% for ureagenesis. ATP is also the precursor for cyclic AMP

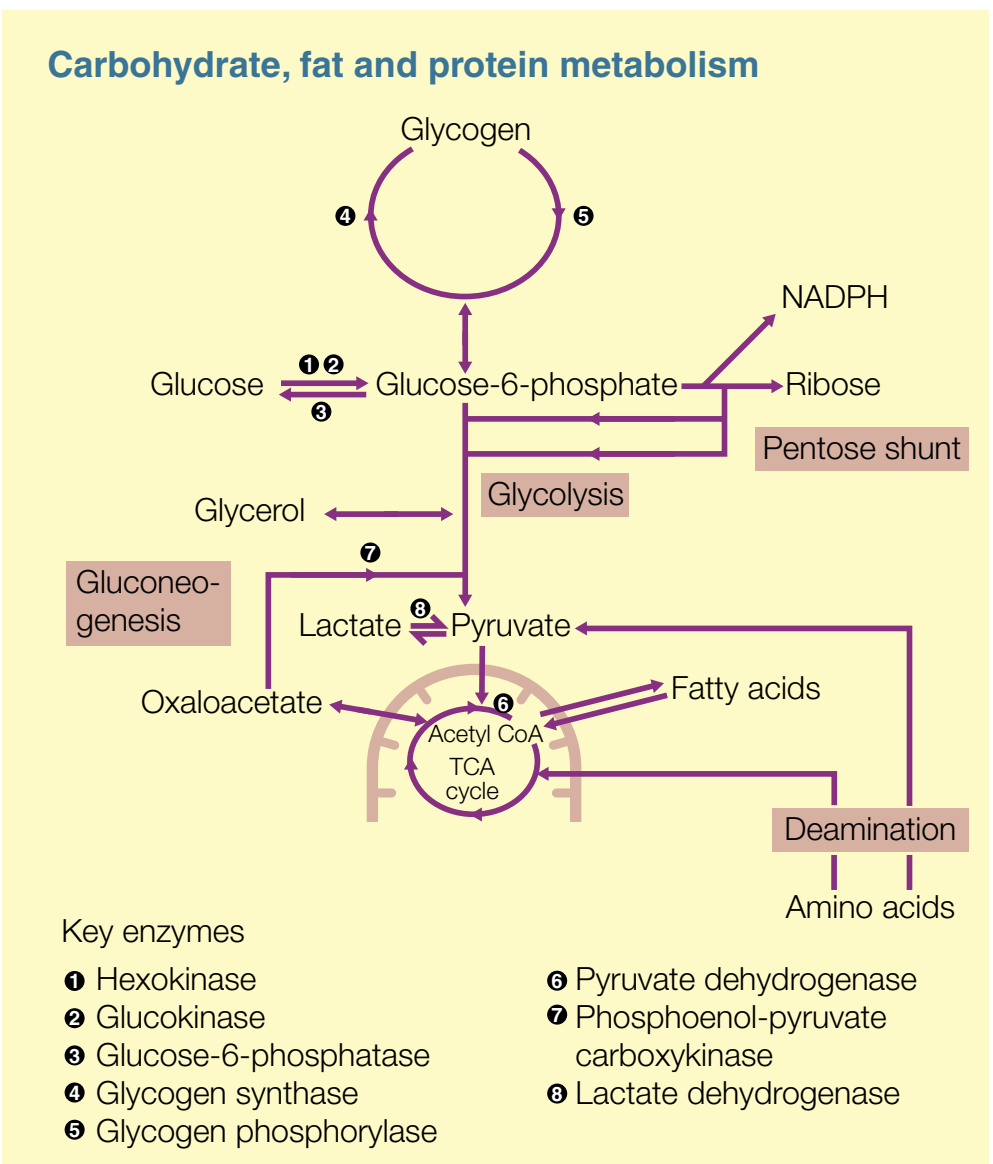
Carbohydrate, fat and protein metabolism

Carbohydrate is the immediate most usable form of energy, fat is the body's main energy store and protein constitutes the structure of the body.

Carbohydrate metabolism

The principal carbohydrate is glucose, but other monosaccharides include fructose and galactose. Glucose is absorbed from the gastrointestinal tract via the portal vein. It passes to the liver where in times of excess, such as after a large meal, some is synthesized into glycogen. The rest passes into the general circulation where it is metabolized in the tissues, or may be stored as glycogen, particularly in muscle. In starvation, most tissues, including muscle (both skeletal and cardiac), can obtain their energy needs from fatty acids alone, but some, such as the CNS and RBCs are obligatory users of glucose.

Glucose is oxidized via two sequential metabolic pathways – the Embden–Meyerhof or glycolytic pathway, which occurs in the cytoplasm, and the Krebs' or tricarboxylic acid (TCA) cycle, which takes place in the mitochondria (Figure 1).



1

Glycolysis is the first stage of glucose breakdown; it is a six-stage metabolic pathway in which metabolism of one molecule of glucose results in the production of two molecules of pyruvate, which enter the TCA cycle. Absorbed glucose is phosphorylated in the tissues by hexokinase (and in the liver by glucokinase) to glucose-6-phosphate (G6P), which is then either converted to glucose-1-phosphate prior to glycogen synthesis or enters the glycolytic pathway. During the course of glycolysis the 6-carbon molecule is split into two 3-carbon fragments – glyceraldehyde-3-phosphate and dihydroxyacetone. Dihdroxyacetone phosphate undergoes isomerization to glyceraldehyde-3-phosphate and it is this 3-carbon molecule that eventually forms pyruvate, but dihydroxyacetone can also be converted to glycerol and thus provides a link with fat metabolism, though, in terms of energy flux, this pathway is minor.

Most of the reactions in glycolysis are reversible, but some are not and these irreversible reactions direct the flow of metabolites through the system. Reversal of these steps in the pathway requires different enzymes.

- The conversion of glucose to G6P by hexokinase (or glucokinase). This is reversed by glucose-6-phosphatase.
- The conversion of fructose-6-phosphate to fructose 1:6 diphosphate in the middle of the glycolytic pathway by phosphofructokinase. This is reversed by fructose 1:6 di-phosphatase.
- The conversion of pyruvate (3 carbons) to acetyl CoA (2 carbons; 1 molecule of carbon dioxide is released) by pyruvate dehydrogenase for entry into the TCA cycle. This step cannot be reversed.

Four molecules of ATP are produced in glycolysis, but two are used in the process so the net gain in glycolysis is two molecules of ATP. 36 molecules are eventually synthesized from the complete oxidation of a molecule of glucose via the glycolytic pathway and the TCA cycle so these two represent about 5% of the total amount of energy ultimately available.

Pentose monophosphate shunt is an alternative pathway for glucose metabolism. This starts with G6P and its main function is to supply pentose sugars, essential in the synthesis of nucleotides and nucleic acids, as well as reduced nicotinamide-adenine dinucleotide phosphate (NADPH), a phosphorylated form of NADH used in a number of biosynthetic pathways. Excess ribose-5-phosphate not required for nucleotide synthesis returns to the glycolytic pathway as fructose-6-phosphate and phosphoglyceraldehyde. The pentose shunt does not use ATP or oxygen. Whether glucose is metabolized via this route or via the glycolytic pathway appears to depend on whether the cell is engaged in biosynthesis (e.g. fatty acid synthesis).

TCA cycle is a sequence of reactions that result in the production of most of the ATP derived from both fat and carbohydrate oxidation. The reactions occur within the matrix of the mitochondrion. With carbohydrates, pyruvate is transported across the inner mitochondrial membrane and is then oxidatively decarboxylated to acetyl CoA. This reacts with the 4-carbon acid oxaloacetate to produce the 6-carbon tricarboxylic acid citrate. In a subsequent series of seven reactions, oxaloacetate is regenerated and two carbon dioxide molecules are produced. A number of other intermediate compounds are generated (oxoglutarate, malate, fumarate) but the oxidation of the acetyl groups to carbon dioxide is coupled to the reduction of NAD and FAD to NADH and FADH2 which enter the flavoprotein-cytochrome chain in the mitochondrion to produce ATP.

Entry of glucose into the cells is via a number of specialist receptors. Some such as GLUT4 in muscle are insulin dependent, others such as GLUT 2 in the liver are not and glucose follows the concentration gradient. Hexokinase activity is not affected by insulin but glucokinase activity is and insulin stimulates both glycolysis and glycogen synthesis. Glycogen is a branched glucose polymer and is synthesized from glucose by glycogen synthase. Glycogen is a short-term store or buffer for glucose and, in the short term, maintains blood glucose levels in the absence of a glucose intake. Glycogen breakdown to glucose is performed by glycogen phosphorylase which is converted from its inactive b form to its active a form via cyclic AMP and protein kinase A which catalyses the phosphorylation and activation of phosphorylase. Protein kinase also inhibits glycogen synthase, which is active in its dephosphorylated form and inactive when phosphorylated. The balance of glycogen synthesis (glycogenesis) and glycogen breakdown (glycogenolysis) is determined by the balance of the anabolic hormone insulin and the catabolic hormones glucagon, adrenaline and noradrenaline. The balance of insulin and glucagon controls the normal cycle of glycogen synthesis/breakdown, the catecholamines come into play during 'stress'.

Muscle does not contain glucose-6-phosphatase, therefore muscle glycogen does not contribute to blood glucose levels. When muscle glycogen is mobilized the glucose is metabolized by glycolysis. In severe exercise or 'shock' the rate of glycolysis exceeds the oxygen supply and the rate at which pyruvate enters the TCA cycle. Pyruvate goes to form lactic acid, catalysed by the enzyme lactate dehydrogenase. Pyruvate receives hydrogen ions from NADH with the consequent development of a metabolic acidosis. When the oxygen supply is restored to balance the rate of substrate utilization (the 'shock' is treated, or the intensity of exercise diminishes) pyruvate is resynthesized.

Fat metabolism

Fatty acids are also metabolized in the mitochondrion via the TCA cycle. Two carbon fragments at a time are split off the fatty acid chain from the carboxyl end (see page 116) by the process of β oxidation to form acetyl CoA which then enters the TCA cycle. Short and medium-length fatty acid chains can enter the mitochondrion directly, but the long chain molecules need to be bound to carnitine before they can cross the inner mitochondrial membrane. When large quantities of acetyl CoA from fat become available ketone bodies (acetoacetic acid and β-hydroxybutyric acid) are formed. They are synthesized in the liver from free fatty acids and are seen most commonly in starvation, but pathologically in diabetes. In starvation they are used by many tissues in place of glucose, but in diabetic ketoacidosis, in which they are produced in huge quantities, they contribute to a metabolic acidosis. Acetoacetic acid is formed from the condensation of two molecules of acetyl CoA. It is converted to β hydroxybutrate and to acetone (excreted in the breath).

Fatty acids can be synthesized (lipogenesis) from acetyl CoA in the presence of excess glucose, which may occur if a high glucose intravenous feed is given in excess of requirements. High insulin concentrations in response to the glucose load stimulates the process. Lipogenesis occurs principally in the liver and in adipose tissue and takes place in the cytosol. NADPH derived from the pentose phosphate pathway is involved as the source of hydrogen. Fatty acid synthesis stops when the carbon chain reaches 16C and, in adipose tissue depots, fatty acids combine with glycerol to form triglyceride.

Whether or not lipogenesis takes place is determined also by the patient's nutritional status and is most evident in the well-nourished individual with a high proportion of carbohydrate in the diet. In the presence of a fat intake of more than 10–15% of the diet there is little conversion of carbohydrate to fat.

Protein metabolism

Proteins are made up of chains of amino acids. Interconversions can take place between amino acids and products of fat and carbohydrate metabolism involving transfer of the amino groups to other ketoacids by transamination, or oxidative deamination can take place with the formation of N_H^4+ which is in equilibrium with ammonia. Most of the N_H^4+ formed by deamination in the liver is converted to urea. Removal of the amino group from amino acids produces the corresponding ketoacids, most of which undergo oxidative metabolism via pyruvate or the various intermediates in the TCA cycle. Some amino acids are ketogenic in that their ketoacids are converted to acetoacetate, but most are glucogenic and are converted to glucose via gluconeogenesis.

Gluconeogenesis occurs in the liver and the kidney as part of the normal adaptation to starvation and in response to stress. The driving force is the fall in insulin and the rise in the counter-regulatory hormones (glucagon, adrenaline, noradrenaline, cortisol) and, in trauma and sepsis, the release of cytokines that affect peripheral and hepatic metabolism. All of the TCA cycle intermediates potentially act as gluconeogenic precursors but, as stated earlier, the reaction catalysed by pyruvate dehydrogenase which takes pyruvate into the TCA cycle is irreversible. The key enzyme for gluconeogenesis is phosphoenolpyruvate carboxy-kinase, which converts oxaloacetate to phosphoenolpyruvate, the final product of the glycolytic pathway before pyruvate. Glucose is then synthesized via reversal of the various steps in glycolysis, bypassing the 'irreversible' ones referred to earlier.

Amino acids are transferred to the liver and kidney, about 50% of them as alanine (the amino acid corresponding to pyruvate) and glutamine (the amino acid corresponding to α-ketoglutarate, a constituent of the TCA cycle). Transamination takes place in the periphery, mostly by transfer of amino groups from the branch chain amino acids, valine, leucine and isoleucine. Other gluconeogenic precursors are lactate and glycerol. Lactate is synthesized to glucose in the liver and glycerol via dihydroxyacetone phosphate, one of the constituents of the glycolytic pathway.

Ions: Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-

C Douglas Thake

C Douglas Thake is part-time Lecturer at Coventry University, Coventry, UK. He qualified from King's College, London, with an MSc in Human and Applied Physiology. His current research interests include human responses to acute and chronic hypoxia.

Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, and HCO_3^- are ions present within all body fluids. Ions are substances that conduct an electrical current in solution and they are often referred to as electrolytes. The balance of ion species between the inside and the outside of the cell is of fundamental importance to physiological function (Figure 1).

The kidney is pivotal in controlling the total body electrolyte content, while transmembranous pumps in conjunction with the physical properties of the cell membranes govern their distribution. The organization of these systems enables the body to take advantage of the electrochemical properties of ions in order to maintain equilibrium.

Summary of the roles of ions

Na^+
- Major determinant of extracellular fluid (ECF) volume and osmolality
- Actively transported from cells – high concentration in ECF, low concentration in intracellular fluid (ICF)
- Resting cell membrane is relatively impermeable to Na^+
- In excitable cells the large concentration gradient for Na^+ to move intracellularly is utilized for propagation of the action potential

K^+
- Major determinant of ICF volume and osmolality
- Actively transported into cells – low concentration in ECF, high concentration in ICF
- Diffusion of K^+ out of the cell is responsible for the resting membrane potential

Ca^{2+}
- Regulates cell metabolism
- Serves as the link between electrical activity in muscle and contraction
- Influences neuromuscular excitability
- Required for blood clotting

Mg^{2+}
- Activates intracellular enzyme systems, including glycolysis, oxidative phosphorylation and protein synthesis
- Required for the function of the Na^+/K^+ pump
- Influences neuromuscular excitability

Cl^-
- Predominantly in the ECF accompanying Na^+
- Present in gastric juice as hydrochloric acid
- Important in secreting and absorbing cells in the kidney and alimentary tract

HCO_3^-
- Primarily found in the ECF
- Principal role in the transport of CO_2 from the tissues
- Important in the regulation of blood pH

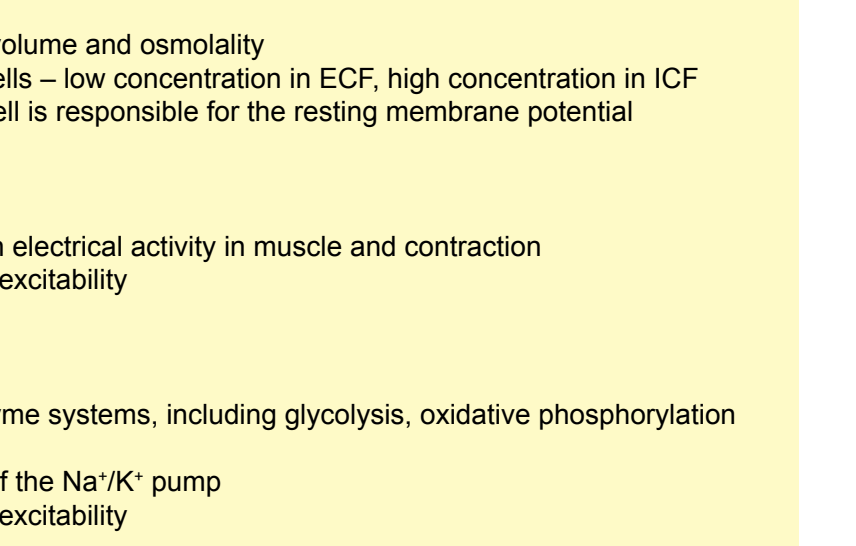
1

Ionic contents of body fluid compartments

The distribution of ions between the major body fluid compartments – the extracellular fluid (ECF) and the intracellular fluid (ICF) – determines their volume (Figure 2). Osmotic forces, primarily generated by the electrolytes, drive water across the semipermeable cell membrane that separates the ECF and ICF. Therefore, the osmolality of the ECF and ICF is equal; the normal range is 275–290 mosmol/kg. However, owing to the differential permeability of the cell membrane and specific transport mechanisms, the electrolyte content of each compartment is different (Figure 3). The most striking contrast is that the concentrations of the predominant ions in each compartment (Na^+ in the ECF and K^+ in the ICF) are nearly opposite.

Distribution of body water in adults

a Total body water expressed as a percentage of total body weight. In women, the total body water accounts for a smaller proportion of body weight because they have more adipose tissue than men. **b** Total body water comprises extracellular fluid (ECF) and intracellular fluid (ICF). **c** ECF is subdivided into interstitial fluid (ISF) and the intravascular compartment or plasma. There is no gender variance in the percentage of body weight taken up by the ECF.



2

Ionic composition of the extracellular fluid (plasma) and the intracellular fluid

Extracellular fluid – Plasma			Intracellular fluid	
Cations	**Concentration (mmol/litre)**		**Cations**	**Concentration (mmol/litre)**
Na^+	130–155	Capillary membrane / Interstitial fluid / Cell membrane	Na^+	10–35
K^+	3.2–5.5		K^+	150–155
Ca^{2+}	2.1–2.9		Ca^{2+}	< 0.1
Mg^{2+}	0.7–1.5		Mg^{2+}	12–28
Anions			**Anions**	
Cl^-	95–110		Cl^-	3–10
HCO_3^-	23–32		HCO_3^-	7–20
PO_4^{3-}	0.7–1.6		PO_4^{3-}	31–105

The capillary membrane is freely permeable to all plasma solutes except protein and lipids. The cell membrane is a selectively permeable barrier that is freely permeable to water

3

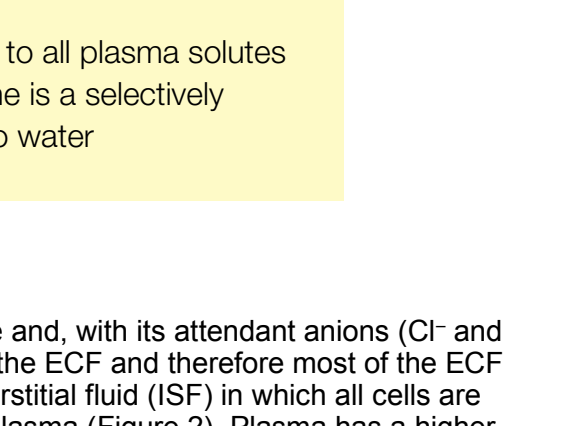
ECF
Na^+ is the main determinant of the ECF volume and, with its attendant anions (Cl^- and HCO_3^-), accounts for 90–95% of all solutes in the ECF and therefore most of the ECF osmolality. ECF can be subdivided into the interstitial fluid (ISF) in which all cells are bathed and the intravascular compartment or plasma (Figure 2). Plasma has a higher protein content than ISF; this does not equilibrate because the capillary endothelium, which separates the two compartments, is not freely permeable to protein. Since, at an arterial pH, protein bears multiple negative charges, electrical neutrality is maintained across the two subcompartments by a redistribution of ions; a slight increase in Na^+ and K^+, and a slight decrease in Cl^- and HCO_3^- in plasma compared with ISF.

ICF
Intracellular osmolality, and thus volume, is determined by the main ICF ion, K^+. There is a large concentration gradient for K^+ to diffuse out of the cell and for Na^+ to move into the cell (Figure 3). However, these ions do not equilibrate because their distribution across the cell membrane is maintained by the Na^+/K^+ pump (Figure 4). The exact composition of the ICF is not consistent across all cell types. In muscle, the most prevalent cell in humans, the Na^+ and Cl^- concentration is 3–4 mmol/litre. In comparison, the Na^+ and Cl^- content of RBCs is 20 and 90 mmol/litre, respectively. The Cl^- concentration is greater than that of Na^+ because during the transport of CO_2, Cl^- enters the RBC in exchange for HCO_3^-.

ICF ions are not always distributed evenly throughout the cell. Ca^{2+} is sequestered in the sarcoplasmic reticulum of muscle cells and is released into the ICF in response to a muscle membrane action potential. The increased Ca^{2+} concentration in ICF activates myofibrillar ATPase that results in contraction. At rest, the cell Ca^{2+} concentration is only 0.1 µmol/litre and a high concentration gradient exists for Ca^{2+} to move from the ECF to the ICF compartment.

Distribution of Na^+ and K^+ across the cell membrane

The intracellular K^+ concentration is maintained by active transport of K^+ in exchange for Na^+ (in a ratio of 3:2). The immediate ionic asymmetry across the cell membrane results from the resting cell membrane being relatively permeable to K^+, but not to Na^+. K^+ moves down a concentration gradient out of the cell and establishes a cell membrane potential difference (–70 to –90 mV in excitable cells, nerve and muscle)



4

Na^+/K^+-ATPase pump

Na^+/K^+-ATPase is a transmembranous enzyme that plays a central role in regulating the internal environment of every body cell. This enzyme acts as a Na^+/K^+ pump that utilizes energy from the hydrolysis of ATP to transport $2K^+$ into the cell and $3Na^+$ out of the cell, against their respective concentration gradients. In humans, the work of the Na^+/K^+ pump is responsible for 45% of the resting metabolic rate. Other primary cation pumps that operate in the body include; H^+/K^+-ATPase; Ca^{2+}/H^+-ATPase, Na^+/H^+-ATPase and Ca^{2+}/Mg^{2+}-ATPase.

The Na^+/K^+ pump usually maintains the osmolality between the fluid compartments. If the pump becomes impaired, such as in hypoxia and septicaemia, Na^+ will accumulate within the cell. This sets up an osmolar gradient across the compartments causing the cell to swell. To compensate, K^+ diffuses down its electrochemical gradient from the intracellular to the extracellular compartment resulting in hyperkalaemia.

The primary functions of tissues specialized in ion transport (brain, kidney, intestine, muscle) depend on the Na^+/K^+ pump, the concentrations of which are over 100 times greater than in other cells, generating dramatic osmolar gradients. For example, the Na^+/K^+ pump on the basolateral surface of epithelial cells lining the proximal tubule of the kidney, maintains a low intracellular Na^+ concentration. This facilitates the active reabsorption of Na^+ (about 25,000 mmol/day), and the co-transport of glucose and amino acids with Na^+ from the tubule lumen. By the same mechanism, the Na^+/K^+ pumps on the basolateral surface of enterocytes enable nutrient molecules to be co-transported with Na^+ from the small intestine. Being an osmotically active transportable solute, Na^+ also has a major influence on water absorption.

Generation of membrane potentials
The characteristics of the cell membrane are of prime importance in the generation of membrane potentials. The resting cell membrane is relatively impermeable to Na^+ and relatively permeable to K^+. K^+ diffuses out of the cell along its electrochemical gradient, generated by the Na^+/K^+ pump. As Na^+ cannot readily move into the cell, the membrane becomes polarized where the inside is negative with respect to the outside (Figure 4). The magnitude of the potential difference depends on the particular cell type; it is greatest in excitable cells ranging from –70 to –90 mV in nerve and muscle, and is lower in nonexcitable cells, for example –40 mV in the hepatocytes of the liver.

The large concentration gradient required for Na^+ to move intracellularly is utilized by phasic changes in the permeability of the cell membrane to Na^+, which results in transient membrane depolarization and the transmission of an action potential. Changes in plasma Na^+ concentration have little effect on the resting membrane potential. Both decreases and increases in the K^+ concentration of ECF (hypokalaemia and hyperkalaemia, respectively) affect the resting cell membrane potential, particularly of nerve and myocardium, resulting in muscle weakness and cardiac arrhythmias.

The excitability of cell membranes is influenced by the presence of other ions, in particular Ca^{2+} and Mg^{2+}. Both hypocalcaemia and hypomagnesaemia result in neuromuscular hyperexcitability and cardiac arrhythmias, and are often associated with hypokalaemia. Conversely, hypercalcaemia and hypermagnesaemia both increase the threshold for membrane depolarization.

Ions and acid–base balance

Ion shifts occur in response to changes in H^+ concentration, in order to maintain electrical neutrality between the body fluid compartments. Acidosis causes H^+ to enter cells and displace K^+, leading to hyperkalaemia. Alkalosis causes K^+ to move from the ECF into cells, resulting in hypokalaemia.

The plasma calcium concentration is directly influenced by the pH of the ECF. About 40% of the plasma calcium is bound to plasma proteins, 10% is complexed with bicarbonate, citrate and phosphate, and the remaining 50% exists as Ca^{2+} and constitutes the physiologically active component. As the Ca^{2+} binding to protein is modulated by pH, the plasma Ca^{2+} concentration rises and falls in response to acidosis and alkalosis, respectively.

Some ions function directly as buffers. HCO_3^- is quantitatively the most important buffering mechanism within the ECF, and is also of prime importance in the transport of CO_2 from the tissues to the lungs. HCO_3^- and H^+ are created by the dissociation of carbonic acid, which is formed by the hydration of CO_2. This reversible reaction system is catalysed by the enzyme carbonic anhydrase, the presence of which is of prime importance in RBCs and renal tubular epithelium.

$$CO_2 + H_2O \longleftrightarrow H_2CO_3 \longleftrightarrow H^+ + HCO_3^-$$

The unique aspect of the carbonic acid–bicarbonate buffer system is that carbonic acid can be rapidly excreted in the form of CO_2 in response to an increase in H^+ concentration. The kidneys are involved in the longer-term control of this buffer system by regulating plasma HCO_3^- concentration and excreting H^+. Importantly, organic acids other than carbonic acid can be eliminated from the body only by the kidneys. Electrical balance is maintained by the reabsorption of Na^+ when H^+ is actively secreted into the tubule lumen of the kidney. Other interconnected blood-buffering systems, including haemoglobin, plasma proteins and phosphates are important in limiting changes in blood H^+ concentration but cannot be regulated in response to blood pH changes.

A disruption in the reabsorption of HCO_3^- along the proximal tubule can lead to a depletion of both Na^+ and HCO_3^- in the ECF. A reduction in ECF Na^+ results in ECF volume depletion. In response, the kidney increases Na^+ reabsorption, which is reabsorbed as NaCl. This leads to effective replacement of HCO_3^- deficit with Cl^- giving rise to hyperchloraemia and low bicarbonate.

Ion reserves
Only a certain amount of each element within the body is exchangeable with the ions in the body fluid compartments. Exchangeable ions act as buffers in response to changes in plasma ion concentrations. The primary reservoir for Na^+, K^+, Ca^{2+} and Mg^{2+} is bone. Normal ECF electrolyte concentrations are achieved through a variety of complex mechanisms, for example the ECF Ca^{2+} concentration is controlled by the interaction of calcitropic hormones with bone, kidney and intestine similar to that of Mg^{2+}.

The ECF ion concentration does not necessarily reflect the total body electrolyte content; for example, only 1–2% of total body K^+, the major cation of the ICF, is present in the ECF. An abrupt decrease in the plasma K^+ concentration should be considered as acute hypokalaemia, whereas a prolonged reduction may be termed chronic hypokalaemia, which reflects a reduction in the total body stores as well as plasma levels. As there are no regulatory mechanisms for controlling the intake of electrolytes, the kidneys function to regulate the ionic balance between input and output.

Na^+ balance: plasma Na^+ concentration is a reflection of both total body Na^+ and total body water. The plasma osmolality is determined by the ratio of Na^+ and water, whereas the ECF volume is determined by the absolute amounts of Na^+ and water that are present. Plasma volume and osmolality homeostasis, are primarily maintained by the kidneys. Total body sodium and hence ECF volume, is regulated by maintaining the balance between sodium input and output. Since the body cannot directly monitor total body sodium, indicators of extracellular volume, atrial stretch, renal perfusion and blood pressure act as signals of total body sodium to the kidneys. Plasma osmolality is sensed by osmoreceptors in the hypothalamus. These receptors affect both water excretion and water intake by influencing antidiuretic hormone secretion and thirst, respectively. Hypernatraemia and hyponatraemia simply indicate that relatively more or less Na^+ is present per unit volume of body fluid. These terms give no insight into any change in the volume of body fluid compartments.

K^+ balance: is regulated by K^+ secretion in the kidneys and is mediated by aldosterone, which conserves Na^+ and promotes K^+ excretion. The regulation of the ratio of intracellular and extracellular K^+ is a function of the Na^+/K^+ pump. To an extent, uptake or release of K^+ from cells buffers changes in the concentration of the ECF K^+.

Macronutrients, Minerals, Vitamins and Energy

Iain Campbell

Iain Campbell is Reader in Anaesthesia at the University of Manchester and Honorary Consultant Anaesthetist at the University Hospitals of South Manchester. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

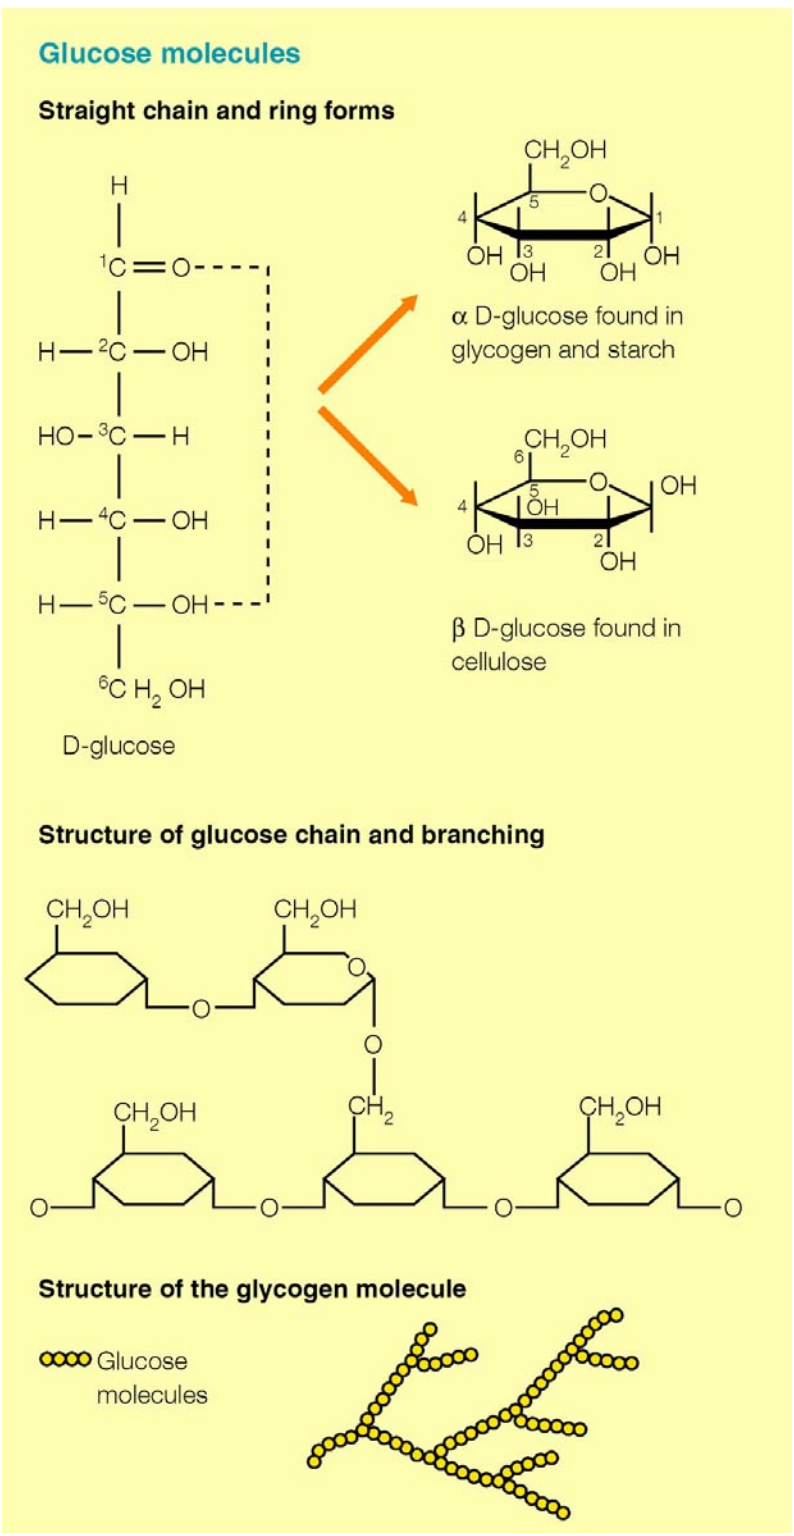
Macronutrients

Carbohydrate, fat and protein make up most of the body's soft tissue structure. These complex molecules are also the form in which protein and energy are ingested (macronutrients). What allows their formation is the ability of the carbon atom to form four bonds at once. In simple terms, carbohydrate, usually in the form of glucose (or glycogen), is the energy substrate for immediate use, fat in the form of adipose tissue represents the long-term energy store, and proteins form the 'living' tissue. Carbohydrate, in combination with protein (glycoproteins) and with fat (glycolipids) is also important in the structure of membrane receptors for hormones and other transmitter molecules, and fat is a major structural component of cell membranes. In this article the structure of carbohydrate, fat and protein and their role in the provision of energy are discussed; their metabolic interrelationships are discussed elsewhere.

Carbohydrates
Carbohydrates are classified in three broad groups – mono-saccharides, disaccharides and polysaccharides. They have the general molecular formula $(CH_2O)n$, where n denotes the number of carbon atoms, with an H and an OH group attached to each carbon (Figure 1). Monosaccharides may have three carbons (triose), four (tetrose), five (pentose) or six (hexose). Triose sugars (e.g. glyceraldehyde) are important in intermediary metabolism, such as glycolysis, and pentoses in the pentose shunt, but it is the hexose sugar, glucose, that is the basic unit of carbohydrate storage and energy provision.

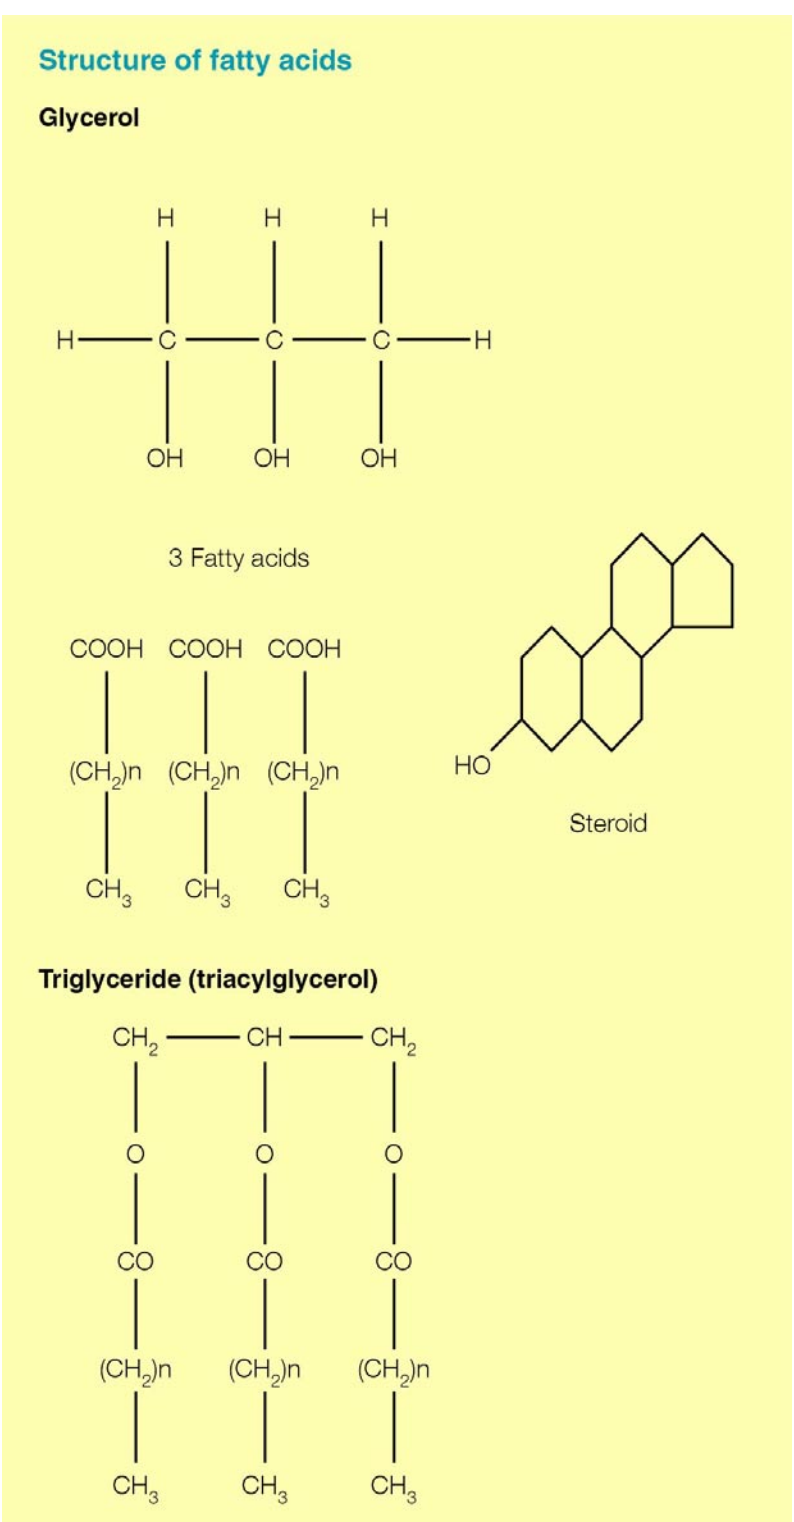
Glucose can exist in a straight chain form or as a ring (Figure 1); the aldehyde group on C_1 reacts with the hydroxyl group on C_5 to form a stable covalent bond and gives rise to a six-member ring (Figure 1). In solution, the two forms are in equilibrium but the ring structure predominates. Conventionally, glucose is seen as a flat structure at right angles to the plane of the page with hydrogen atoms and hydroxyl groups above and below the plane of the ring (Figure 1). Pentoses (e.g. ribose and deoxyribose in nucleic acids) form five-member rings as do some hexoses (e.g. fructose). The presence of an asymmetric distribution of atoms or groups around the carbon atoms allows the formation of isomers. In glucose, the biologically important ones arise from the disposition of the H and OH groups around C_5 and C_1. The asymmetry around C_5 denotes the D or L forms, dependent on the rotatory effect they have on polarized light. Most of the glucose in animals is in the D configuration (hence the term dextrose, commonly used for glucose) and the enzymes responsible for its metabolism are specific for this configuration. The isomerism of H and OH around C_1 (α or β) is important in the formation of bonds between glucose units (see later).

Two monosaccharides can combine to form a disaccharide – maltose from two glucose units, lactose from glucose and galactose and sucrose from glucose and fructose. Glucose units can join at C_1 and C_4 to form chains or at C_1 and C_6 to form branching molecules (Figure 1). Starch is the principal carbohydrate store in plants and is made up of a mixture of non-branching chains of α D-glucose (amylose) and of branched chains of 24–30 glucose molecules, the branching occurring at the 1:6 linkage. Glycogen is the carbohydrate store in the animal body (animal starch). It is found predominantly in muscle and liver and has a similar composition to starch but is a much more highly branched structure (Figure 1) of variable and even indeterminate molecular weight. Cellulose found in plants is also made up of glucose units and these are also linked at C_1 and C_4. The glucose making up cellulose is the β isomer of C_1 (see above) and animals do not have an enyme to break this linkage; cellulose is therefore indigestible by enzymes, though it is broken down by fermentation.



1

Fats
Fats (lipids) differ from other macronutrients in that they are poorly soluble in water, but highly soluble in organic solvents such as ether or acetone. Like carbohydrates they are composed of carbon, hydrogen and oxygen (Figure 2), but the proportion of oxygen atoms to carbon and hydrogen is lower than in carbohydrate.



2

Fatty acids are chains of carbon atoms to which hydrogen atoms are attached with a carboxyl group (COOH) at one end. The carbon atoms are lipophilic and the COOH group hydrophilic. Two of the most common fatty acids in animal cells are palmitic (16C chain) and stearic (18C) acid. Fatty acids are distinguished from one another by the number of carbon atoms in the chains and the number of double bonds. When only single bonds exist the acid is said to be saturated; palmitic and stearic acids are both saturated acids. With one or more double bonds (C=C) the fatty acid is said to be unsaturated. Fatty acids are classified into families according to the position of their first double bond, counting from the noncarboxyl end of the fatty acid molecule. The terms n-3 (or omega-3), n-6 or n-9 denote the three main families. Unsaturated fatty acids include oleic (n-9; one double bond), linoleic (n-6; two double bonds) and arachidonic acids (n-6) which contain four double bonds. Arachidonic acid is an intermediary metabolite in the synthesis of prostaglandins, a group of substances that have a wide range of physiological effects. Dietary n-3 fatty acids (e.g. α linolenic acid found in fish oil) have come to prominence over the last decade for their ability to dampen down inflammatory processes and form part of the lipid structure of cell membranes

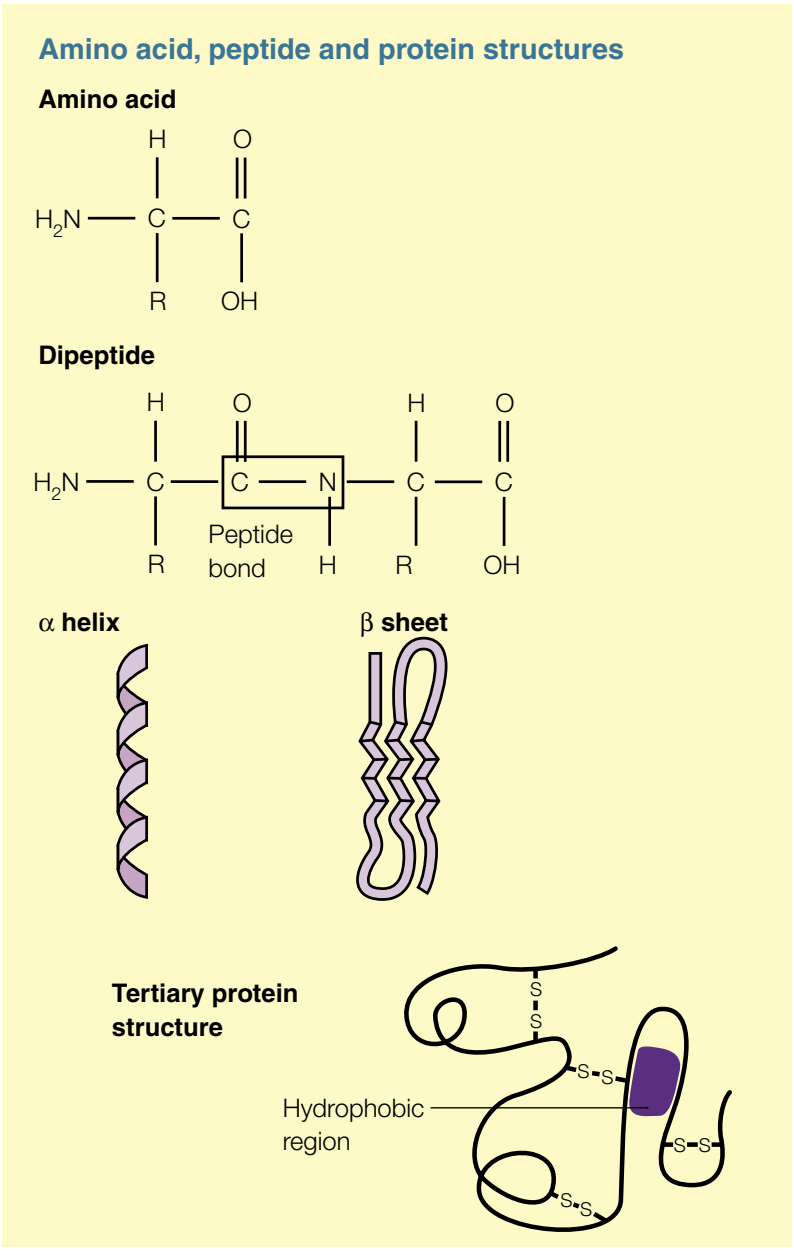
Triglycerides: glycerol is a molecule with three carbon atoms each with an OH group attached. These can form bonds with the COOH groups of the fatty acids to form triglyceride (Figure 2) which makes up adipose tissue. It is in this form that fatty acids are stored until they are required for energy. When needed as an energy source the glycerol–fatty acid bonds are hydrolysed and the fatty acids are released into the circulation loosely bound to albumin as free (or non-esterified) fatty acids.
Phospholipids are important in the formation of cell membranes. The parent compound is glycerol-3 phosphate in which, instead of the OH group on the C_3 of glycerol being linked with a fatty acid, it combines with a phosphate group (PO_4) to form phosphatidic acid and the addition of another chemical group (e.g. choline, serine, inositol) produces a phospholipid. The glycerol phosphate part of this molecule is extremely hydrophilic and the fatty acid part hydrophobic and it is these features that contribute to the structure of cell membranes.

Steroids have a variety of roles including the stabilization of cell membranes and the formation of various hormones, such as male and female sex hormones and the corticosteroids. The steroid nucleus is made up of four interlocking rings of carbon atoms and is amphipathic; the hydrophilic region is an OH group, the main structure of the molecule being lipophilic (Figure 2).

Proteins
Proteins constitute the fundamental structure of a living organism. They have different levels of organization and it is this that determines protein shape; a protein's shape or conformation determines its function. The basic constituent of protein is the amino acid of which 20 are available to make proteins.

Amino acids: the general structure of an amino acid is shown in Figure 3. It consists of an asymmetric carbon atom (the α carbon) with both an amino group (NH_2) and a carboxyl group (COOH) attached, and a side-chain. This gives rise to two isomers D and L, but only the L amino acids are constituents of proteins. At body pH, both the amino and the carboxyl groups are charged. The side-chains distinguish the various amino acids from each other. They are linked by peptide bonds formed between the carboxyl and the amino groups of adjacent amino acids. Two amino acids linked form a dipeptide (Figure 3), three a tripeptide, a chain of eight a polypeptide and proteins are typically made up of 50–2500 amino acids. The number and order of the sequence is what characterizes the protein. Conventionally the amino group is considered to be the start of the chain and the carboxyl group the end (Figure 3).

Amino acids are broadly classified into two groups according to the polarity or hydrophilicity of their side-chains (i.e. water- or fat-soluble). Some amino acids fulfill roles other than protein structure. They include ornithine, citrulline and argininosuccinate (which participate in the formation of urea), tyrosine (which is involved in the formation of thyroid hormones) and glutamate (used in the synthesis of neurotransmitters).



3

Protein structure: the primary structure of protein is the sequence in which amino acids join together in chains. These chains are folded on each other, side-chains of the various amino acids linking and giving the protein its ultimate shape, as discussed above (Figure 3). The secondary structure is formed by folding the chain into a specific conformation. This occurs spontaneously as the various side-chains interact with each other. The precise conformation of this secondary structure is predictable and determined by the sequence of amino acids in the polypeptide.

There are a variety of ways in which interactions occur between side-chains to produce the folding. They include hydrogen bonding, the formation of covalent bonds between amino acids and carboxyl groups and between sulphur atoms in the sulphur-containing amino acids (cysteine, methionine), and the disposition of the hydrophilic and hydrophobic groups within the structure of the protein. In general, hydrophobic (lipophilic) groups find a place within the protein molecule and interact with each other (clump together), while the polar groups are on the outside of the molecule and interact with the aqueous environment.

Insulin is an example of the simplest of protein structures, consisting of two polypeptide chains joined by two covalent linkages between cysteine residues within each of the two chains. There are several types of secondary protein structure and these may occur within the same polypeptide chain. In the β helix, the polypetides adopt a spiral shape largely because of the formation of hydrogen bonds. In the α pleated sheet, regions of the polypeptide chain lie alongside one another forming a corrugated surface, hairpins and loops where regions of the polypeptide chain form tight bends and random coils in which there is no recognizable structure, though for any one protein this apparently random structure is always the same. More complex protein molecules have several of the above structures, all within the same polypeptide. This is called the tertiary structure with β helices folded on themselves and lying in close association with β sheets or 'random' coils. Some globular molecules, of which haemoglobin is an example, may consist of several of the above lying in close proximity and linked with each other. This constitutes a so called 'quaternary structure'.

Minerals

A number of minerals are required for normal metabolism and have to be provided in the diet. Some such as calcium, phosphorus, magnesium and sodium have major roles in normal physiology (e.g. bone structure, maintenance of cell membrane potentials) and are required in large quantities. Others such as copper, zinc, selenium, fluorine and chromium are required only in small quantities and are known as micronutrients or trace elements or minerals. Deficiencies in these elements have characteristic effects; lack of zinc causes skin ulcers and depressed immunity, copper deficiency causes anaemia, chromium lack causes insulin resistance, lack of fluorine is associated with dental caries. Some minerals, such as zinc and selenium, are important in the acute phase (systemic inflammatory) response to trauma and infection where circulating concentrations decrease as they are redistributed to active tissues. There is some evidence that supplementation with trace elements can reduce infection rates and promote healing.

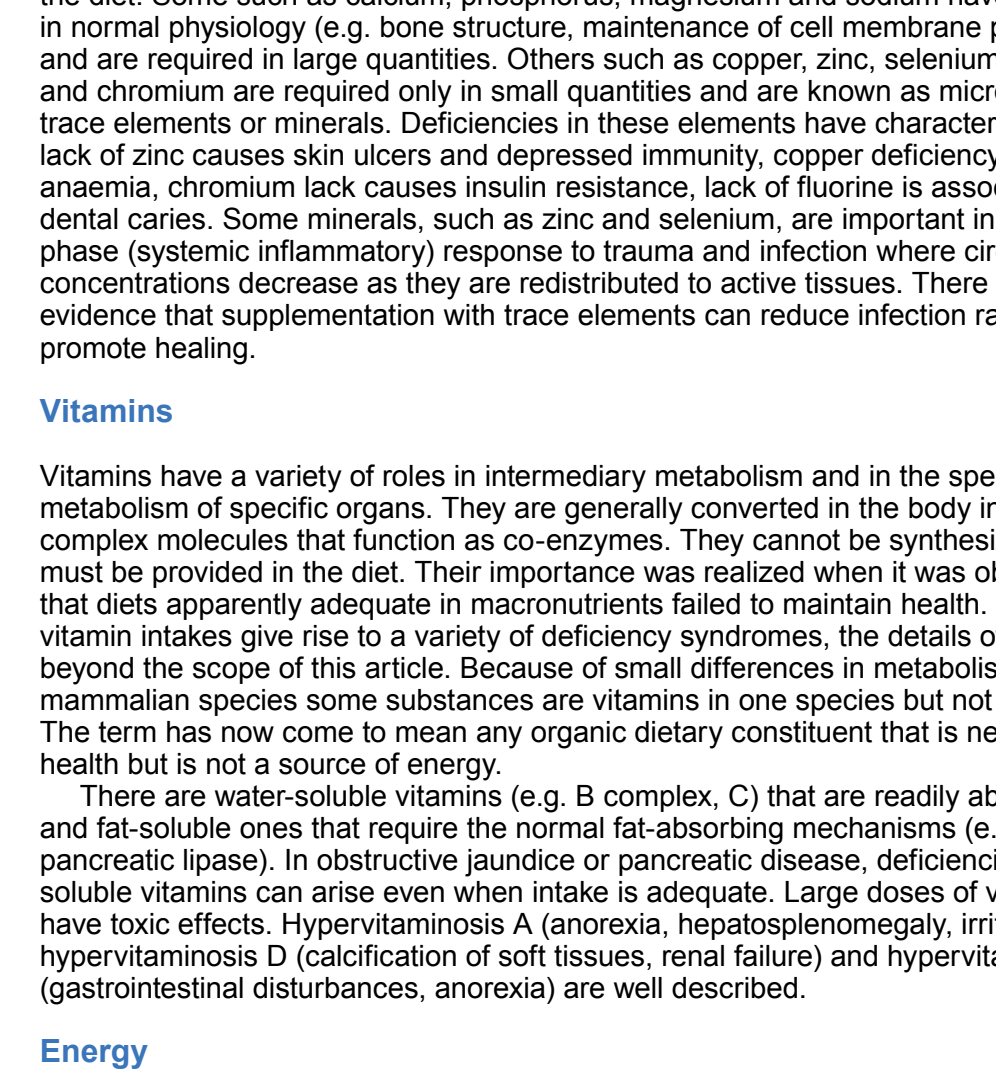
Vitamins

Vitamins have a variety of roles in intermediary metabolism and in the specialized metabolism of specific organs. They are generally converted in the body into more complex molecules that function as co-enzymes. They cannot be synthesized and must be provided in the diet. Their importance was realized when it was observed that diets apparently adequate in macronutrients failed to maintain health. Inadequate vitamin intakes give rise to a variety of deficiency syndromes, the details of which are beyond the scope of this article. Because of small differences in metabolism between mammalian species some substances are vitamins in one species but not in another. The term has now come to mean any organic dietary constituent that is necessary for health but is not a source of energy.

There are water-soluble vitamins (e.g. B complex, C) that are readily absorbed, and fat-soluble ones that require the normal fat-absorbing mechanisms (e.g. bile, pancreatic lipase). In obstructive jaundice or pancreatic disease, deficiencies of fat-soluble vitamins can arise even when intake is adequate. Large doses of vitamins have toxic effects. Hypervitaminosis A (anorexia, hepatosplenomegaly, irritability), hypervitaminosis D (calcification of soft tissues, renal failure) and hypervitaminosis K (gastrointestinal disturbances, anorexia) are well described.

Energy

Energy used by the body is obtained from the oxidation of the macronutrients, 10–15% from protein oxidation, the rest from fat and carbohydrate in roughly equal proportions. The summary equations for fat and carbohydrate are given in Figure 4 in which the energy released is given in units of heat. For technical reasons, heat has always been the traditional unit of energy. Energy is the ability to do work and the unit of work (or energy) is the Joule. This is defined as the work done when a force of 1 Newton (1 kg/second^2) moves through a distance of 1 metre. The calorie is the heat/energy required to raise the temperature of 1 g of water by 1°C. In human metabolism, the conventional unit is the kilocalorie – 1000 times the calorie. The relationship between calories and Joules is given by the mechanical equivalent of heat: 1 calorie = 4.2 Joules. Energy is expended in the maintenance of basal metabolism (i.e. the energy expended in keeping the body alive), in the conduct of external work and in thermoregulation (maintenance of body temperature in the face of thermal (cold) stress).



4

Energy intake

The energy values of the various macronutrients can be determined by bomb calorimetry. This entails burning (oxidizing) the dried foodstuffs in an atmosphere of pressurized oxygen and measuring the heat given off. Carbohydrate and fat produce average values of 4 and 9 kcal/g and, because these substances are oxidized completely in the body to carbon dioxide and water, these figures are the same values as are available to the body. In contrast, bomb calorimetry of protein produces 5.4 kcal/g but only about 4 kcal/g are available for metabolic use; oxidation of protein is only partially complete in the body and energy-containing products of metabolism (e.g. urea, creatinine) are excreted in the urine.

Energy derived from bomb calorimetry is described as gross energy and energy available for metabolism as metabolizable energy. Energy available for metabolism is modified further by absorption. In a normal, mixed Western diet about 95% of ingested food is absorbed, though for high-fibre diets the figure is nearer 92%.

In clinical practice, a patient's energy intake is normally assessed by measuring and recording what they eat then calculating the nutrient content (energy, vitamins, minerals) from tables that list the constituents of the various foodstuffs. These values are derived from bomb calorimetry and chemical analysis.

Measuring oxygen consumption and energy expenditure

Energy expenditure can be derived from the measurement of oxygen consumption and carbon dioxide production – indirect calorimetry. VO_2 can be measured with a traditional carbon dioxide absorption technique using a closed-circuit spirometer, or calculated from the analysis of inspired and expired gas volumes. Thus:

$$VO_2 = (V_I \times F_IO_2) - (V_E \times F_EO_2)$$

$$VCO_2 = V_E \times F_ECO_2$$

where V_I and V_E are inspired and expired volumes and FO_2 and FCO_2 the fractional concentrations of inspired and (mixed) expired oxygen and carbon dioxide, respectively. It is simple to measure VCO2. However, measurement of V_{O2} requires the measurement of inspired and expired volumes separately because the expired volume is usually lower than the inspired volume (RQ is normally 0.7–1). This is technically difficult and it is normal practice to measure one and calculate the other from the inspired and expired nitrogen ($_{NI}$ and $_NE$) concentrations. Nitrogen is not measured but is assumed to constitute all the non-$_O2$, non-C_O2 gas in the two volumes. Thus $_{VE}$ = $_VI$ x $_NI/_NE$. This is known as the Haldane transformation. It has limitations in ventilated patients who require high inspired concentrations of oxygen, and at an $_FI_{O2}$ of 1 it does not work. In practice, most indirect calorimeters that use this technique cease to function properly at an $_FI_O2$ of about 0.6–0.7. The use of the Haldane transformation assumes that the system is in a 'steady state' and that 'nitrogen' (non-$_O2$, non-C_O2) does not take part in gas exchange.

Total 24-hour energy expenditure generally depends on how active an individual is. Most energy expended in any given period is that used to maintain basal expenditure such as the work of breathing, heart beat, maintenance of cell membrane potentials and the multitude of other energy-consuming reactions used in the maintenance of life. In a bed-bound individual this may constitute 90% of total expenditure. In a manual labourer it may be only 50%. Factors that raise metabolic rate other than activity are the energy cost of digestion, absorption and assimilation of food, exposure to cold and body temperature. A high-protein meal stimulates metabolism more than fat or carbohydrate. Thus, to measure basal energy expenditure (oxygen consumption) a subject should be fully rested after an overnight fast and be in a thermoneutral environment. Basal energy expenditure can also be predicted from a number of equations, the Harris–Bennedict equation is probably the best known, but in the UK the Schofield equation has been introduced recently. The variables they include are measures of body size (height and weight), gender and age. Metabolic rate decreases with age and for a given body weight is lower in women because of the higher proportion of body fat. Body temperature also affects metabolic rate. A change in core temperature of ^{1}oC is said to increase or decrease metabolic rate by 13%, though more recent measurements made in the clinical environment indicate that this figure may be nearer 6–7%.

Cold stress raises energy expenditure by inducing shivering or increasing muscle tone. Another thermogenic mechanism is non-shivering thermogenesis seen in hibernating rodents and in humans in the first 6 months of life. The site of this increased heat production is brown adipose tissue, found over the kidneys and around the great vessels. It is brown owing to the large numbers of mitochondria that are ‘uncoupled’ (i.e. instead of synthesizing ATP they produce heat). The process is under the control of the sympathetic nervous system.

Muscle

Anthony C Wareham

Anthony C Wareham was Senior Lecturer in Physiological Sciences at the University of Manchester until taking early retirement in April 2001. He obtained his BSc in Zoology and his PhD from Durham University. His research interests focus on the electrophysiological properties of skeletal muscle during development, denervation and disease, particularly muscular dystrophy.

Morphology

Skeletal muscle

A skeletal muscle is composed of thousands of elongated muscle fibres running in parallel. Fibres are multinucleate cells, formed from the fusion of single nucleated myoblasts. In healthy fibres, the nuclei lie peripherally just under the cell membrane. In large limb muscles, fibres may reach a length of 30 cm with a diameter of 100 μm. The cell membrane (the sarcolemma) surrounds the cytoplasm (the sarcoplasm). The sarcoplasm contains several hundreds to thousands of contractile elements, the myofibrils, each of which is 1–2 μm in diameter. A myofibril is compartmentalized into as many as 10,000 repeating units called sarcomeres joined together by dense material at Z lines. These repeating units in myofibrils endow the muscle fibre with repeated cross striations (easily seen under the light microscope), which leads to the alternative term striated muscle for skeletal muscle. The sarcolemma is invaginated at each sarcomere to form blind-ending transverse tubes (t-tubules) that run into the centre of the fibre and have a crucial role in the activation of contraction. Running longitudinally between the repeating t-tubules are blind-ending membrane tubes or sacs called the sarcoplasmic reticulum. The ends of the tubes of the sarcoplasmic reticulum, terminal cisternae, abut closely to the membranes of the t-tubules, forming triads. A triad is part of a t-tubule and the terminal cisternae on either side and is the site of excitation–contraction coupling.

Fibres are categorized by their speed of contraction, from slow to fast. Primarily, speed of contraction depends on the activity of myosin ATPase. Slow fibres receive a plentiful blood supply and have oxidative metabolism whereas fast fibres can operate anaerobically and do not have such a rich blood supply. All human muscles are composed of a mix of slow and fast fibres, the ratio depending on their function and the amount and type of exercise.

Smooth muscle

Smooth muscle fibres are not striated. They are smaller than striated fibres (5–10 μm in diameter, 30–200 μm long) forming small cells, tapering at each end. They have only one, centrally located nucleus. Cells do not contain ordered sarcomeres, nor is the cell membrane invaginated into t-tubules. The sarcoplasmic reticulum system is present but not as well developed as in striated fibres. The cell surface forms folds or pits called calveolae, which are thought to function in a similar way to t-tubules, and which are associated with tubules of the sarcoplasmic reticulum.

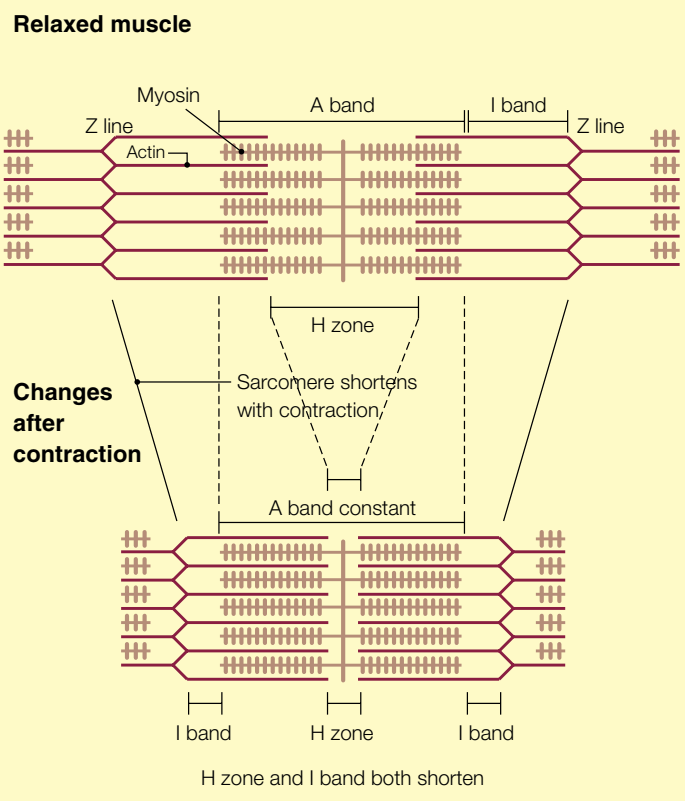
The most common type of smooth muscle is visceral (single unit) muscle, which is composed of smooth muscle cells tightly bound together with gap junctions to form a continuous network. Gap junctions connect the cells together electrically so that an action potential generated in one cell is transmitted to all other cells in the network. Since any smooth muscle cell can be spontaneously active, a sheet of visceral muscle is normally partly contracted and has tone. It is found in the walls of small arteries and veins and lining the hollow viscera. Multi-unit smooth muscle is less common. It consists of individual fibres, each with their own motor nerve endings, and does not function as a network. Multi-unit fibres are found in the walls of large arteries and large airways, in erector pili muscles attached to hair follicles, and in the intrinsic eye muscles.

Ultrastructure

Striated muscle

The contractile proteins are myosin (molecular weight 450 kDa) and actin (molecular weight 43 kDa). Within a sarcomere, filaments of actin are attached to the Z line by actinin. Lying between the thin actin filaments are thick myosin filaments that are not firmly attached to anything. They are kept in place by huge elastic protein molecules of titin (the largest known protein with 25,000 amino acids) which stretch from one Z line to the next. The action of titin and nebulin (an inelastic giant protein lying alongside actin filaments and attached to one Z line of each sarcomere) ensures that actin and myosin exist in a very ordered way (Figure 1). Associated with actin filaments are two inhibitory proteins, troponin and tropomyosin, which prevent any uncontrolled reaction with myosin. The partial overlapping of actin and myosin results in distinct banding across each sarcomere (visible only under the electron microscope) of light areas (I band) where there is no overlap and dark areas (A band), where there is overlap. Actin filaments do not extend across the sarcomere, therefore the central region of the A band is lighter (H zone). The reaction between actin and myosin is responsible for the production of force and movement as the two types of filament are able to slide along each other, thus drawing the Z bands together and shortening each sarcomere and consequently the whole muscle fibre (Figure 1).

Banding patterns seen in striated muscle



1

Smooth muscle

The contractile proteins, actin and myosin, are arranged in long bundles that extend diagonally around the cell, forming a lattice around the central nucleus. Owing to the oblique arrangement of filaments, smooth muscle cells become globular when they contract, rather than simply shortening. Actin filaments are not attached to Z lines but to dense bodies of protein in the cytoplasm at one end and to protein plaques in the cell membrane at the other end. Myosin filaments lie bundled within the long actin filaments. The ratio of actin to myosin filaments is 12:1 compared with 4:1 in skeletal muscle. Smooth muscle does not contain the inhibitory proteins troponin and tropo-myosin.

Proteins involved in contraction

Myosin has at least 10 isoforms. Each myosin molecule consists of two heavy (2000 amino acids) alphahelical protein chains, wound together to form a rod-like tail, and two tadpole-like heads, S1, each connected to a flexible neck, S2. The S1 portion contains the active site that reacts with actin and the S2 portion allows movement of the head. Two lightweight protein chains are associated with each S1 head. Their function is unknown in striated muscle but in smooth muscle they regulate contraction. One molecule of myosin is 150 nm long. About 250 molecules make up a thick filament in a sarcomere. The molecules are wound together in such a way that the S1 heads are clustered at each end of the thick filament, resulting in the central portion being just a bundle of myosin tails.

Actin: the actin molecule is a globular protein (G-actin). The actin of the thin filament in a sarcomere is a polymerized form called F-actin. The thin filament is composed of two F-actin filaments wound together like two strands of beads. Each ‘bead’ of G-actin in the filament has a binding site for a myosin S1 head.

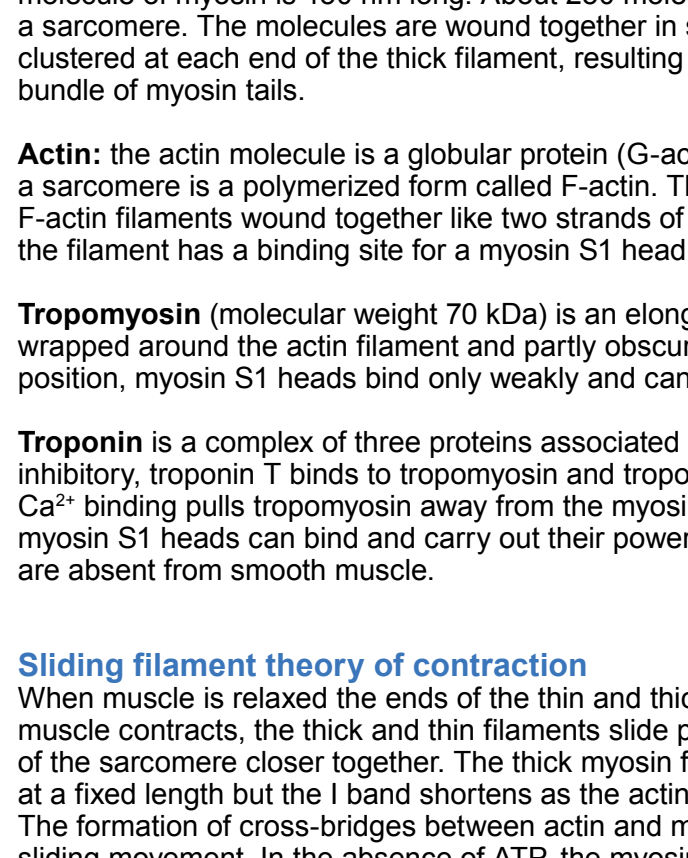
Tropomyosin (molecular weight 70 kDa) is an elongated protein polymer that is wrapped around the actin filament and partly obscures the binding sites. In such a position, myosin S1 heads bind only weakly and cannot create a power stroke.

Troponin is a complex of three proteins associated with tropomyosin. Troponin I is inhibitory, troponin T binds to tropomyosin and troponin C binds reversibly to Ca^{2+}. Ca^{2+} binding pulls tropomyosin away from the myosin-binding sites. In such a position, myosin S1 heads can bind and carry out their power stroke. Troponin and tropomyosin are absent from smooth muscle.

Sliding filament theory of contraction

When muscle is relaxed the ends of the thin and thick filaments overlap slightly. As the muscle contracts, the thick and thin filaments slide past each other, moving the Z lines of the sarcomere closer together. The thick myosin filaments, seen as the A band, stay at a fixed length but the I band shortens as the actin slides into the myosin (Figure 1). The formation of cross-bridges between actin and myosin provides the power for this sliding movement. In the absence of ATP, the myosin S1 head is tightly bound to actin, called the rigor state. ATP, normally present in abundance in resting muscle, binds with the S1 head and releases it from actin (Figure 2). The nucleotide binding site on the S1 head hydrolyses ATP to ADP and inorganic phosphate; both are retained at the site. The energy released rotates the S1 head on the flexible S2 region and it binds to a new site on the actin, one or two positions away from the G-actin where it started. At this point the S2 region is like a stretched spring ready to shorten. The power stroke begins when inorganic phosphate is released and the S2 region pulls the actin filament towards the centre of the sarcomere (Figure 2). To end the contractile cycle, myosin releases ADP and the myosin head is firmly bound to actin. The cycle continues to operate as long as the binding sites for cross-bridge formation are exposed. Therefore, control of contraction is linked to the regulation of troponin and tropomyosin. The contraction cycle is similar in smooth muscle even though it does not have sarcomeres, but the regulation of the cycle is different.

Development of the power stroke of the contractile cycle



2

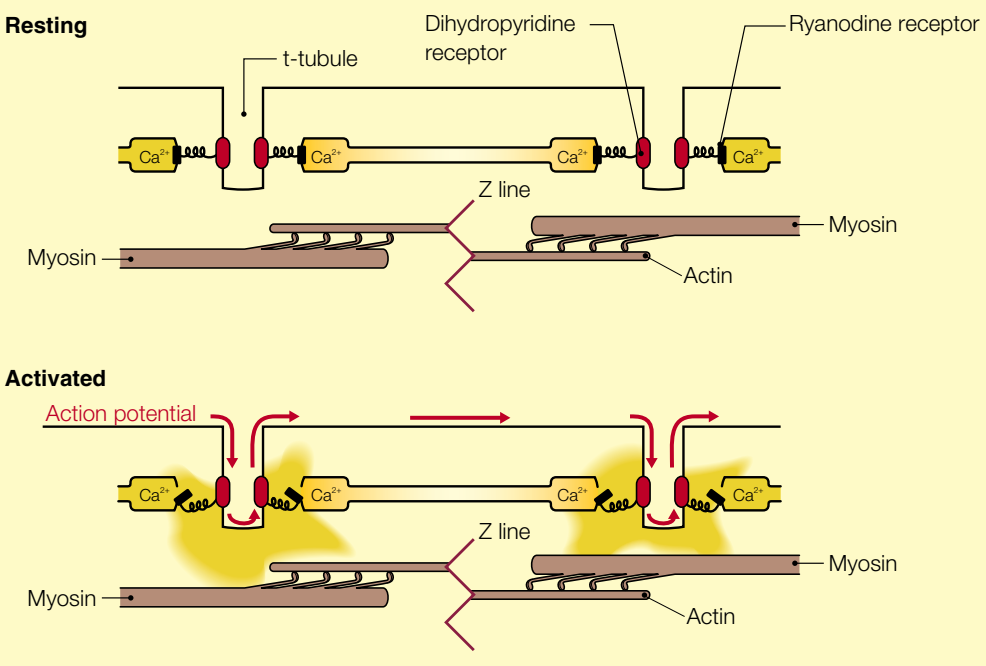
Excitation–contraction coupling

Skeletal muscle

The sarcoplasmic reticulum contains a high concentration of calcium owing to the activity of an inwardly directed calcium pump. The release of this calcium is the link between a muscle action potential and contraction. The sarcolemmal action potential travels into the centre of a muscle fibre along t-tubules. At each triad, the depolarization activates voltage-sensitive dihydropyridine (DHP) binding calcium channels. These activate ryanodine-binding calcium channels on the sarcoplasmic reticulum membrane. This activation, caused by either a physical link between the two types of calcium channel or calcium entering via the activated DHP channel, opens the ryanodine calcium channels and releases calcium from the sarcoplasmic reticulum (Figure 3). The calcium binds to troponin C, which moves tropomyosin on actin, exposes the actin binding sites and starts the contraction cycle. Provided the sarcoplasmic calcium concentration is kept high, by the repeated arrival of action potentials in the t-tubules, the contraction cycle continues. However, as soon as the action potentials cease, calcium is rapidly sequestered back into the sarcoplasmic reticulum system, tropomyosin returns to cover the actin binding sites and the muscle relaxes.

Excitation–contraction coupling

Excitation–contraction coupling is caused by the release of Ca^{2+} from the terminal cisternae of the sarcoplasmic reticulum



3

Smooth muscle

In smooth muscle, initiation of the contraction cycle is different from that of skeletal muscle because it may take up to 500 ms after a smooth muscle action potential to produce the peak of tension. There are several reasons. Some of the calcium required to initiate the contraction cycle comes from the extracellular medium and some from the sarcoplasmic system, therefore the diffusion path is greater. A major cause of delay is that myosin in smooth muscle must be phosphorylated for the activation of myosin ATPase. The pairs of myosin lightweight chains that appear to have no function in striated muscle regulate this process in smooth muscle. Calcium binds to calmodulin, which activates calmodulin-dependent myosin light chain kinase. This catalyses phosphorylation of the myosin S1 site allowing myosin ATPase to be activated and starts the contraction cycle between actin and myosin. Myosin is dephosphorylated by phosphatases in the cell but this does not necessarily lead to relaxation. There appears to be a latch bridge mechanism by which dephosphorylated myosin cross-bridges remain attached for some time after the cell calcium concentration has fallen, producing sustained contractions with little energy expenditure. Smooth muscle is unique in other ways because it is activated by stretch in the absence of external innervation and can adapt its tone to remain constant in the face of different amounts of stretch. ◆

Neurological and Humoral Control of Blood Pressure

Emrys Kirkman
Marina Sawdon

Emrys Kirkman is Lecturer in Physiology at the University of Durham, UK. He has a PhD from Manchester University and worked at the Royal Free Hospital School of Medicine, London, and the MRC Trauma Group, Manchester. His research interests include trauma-induced changes in cardiovascular control mechanisms, the underlying central nervous pathways and the resulting alterations in haemodynamics and oxygen transport.

Marina Sawdon is a Cardiovascular Physiologist studying for a PhD at the University of Durham. She graduated from the University of Durham with first class honours. Her research interests include the cardiovascular and pulmonary responses to trauma.

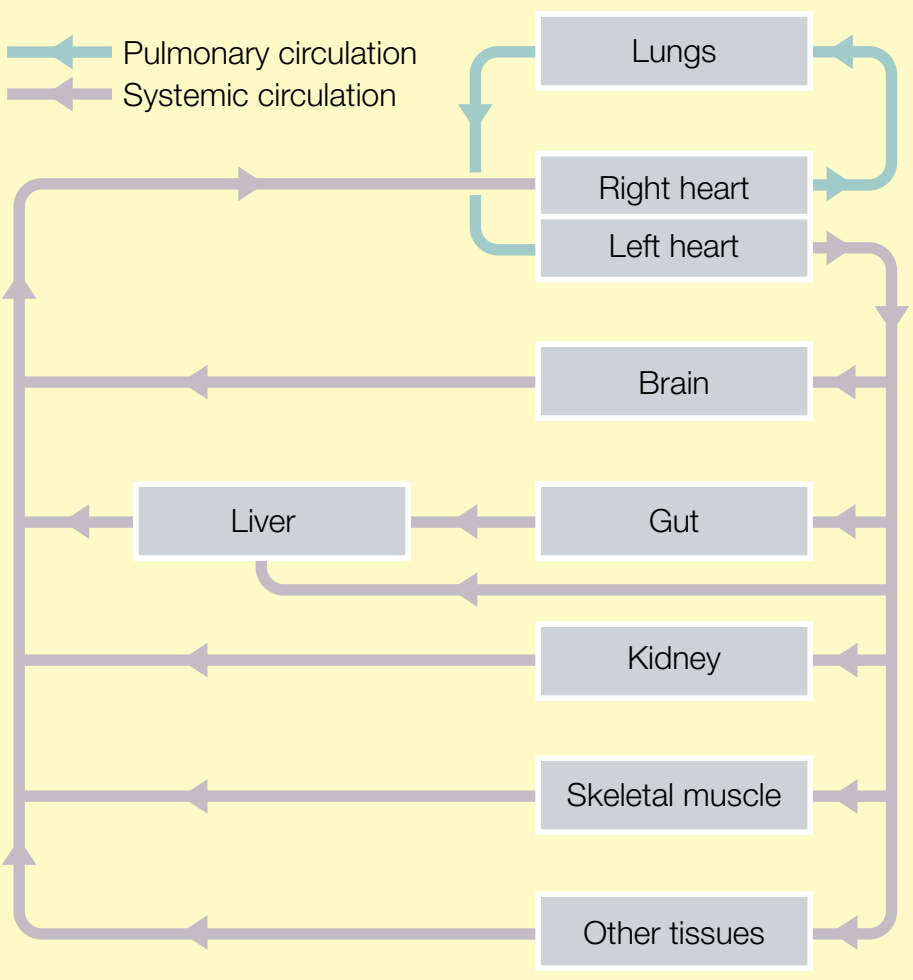
Systemic arterial blood pressure, flow and blood volume are closely regulated by a group of interrelated mechanisms. Perhaps the most important mechanism in the moment-to-moment control of arterial blood pressure is the arterial baroreceptor reflex. This reflex influences blood pressure by modifying a series of cardiovascular parameters: heart rate, cardiac stroke volume and peripheral vascular resistance. The key to understanding how the arterial baroreceptor reflex controls blood pressure is the interrelationship between these parameters as shown by the following equations:

Blood Pressure	= Cardiac Output x Total Peripheral Resistance	1
Cardiac Output	= Heart Rate x Stroke Volume	2
Resistance	$\alpha \frac{1}{(\text{Arteriolar Radius})^4}$	3

The baroreceptor reflex uses negative feedback to maintain constant arterial blood pressure. This normally ensures an adequate pressure to drive blood through individual vascular beds without it becoming high enough to damage the circulation. In simple terms, the vascular beds can be viewed as the blood vessels and circulation through different types of tissue, such as the gut and muscle (Figure 1). There are two circulations in the body: the pulmonary circulation and the systemic circulation. The systemic circulation is made up of a number of vascular beds arranged in parallel. The overall vascular resistance (total peripheral resistance in Equation 1) depends on the vascular resistance of all these beds. Because the beds are arranged in parallel, it is possible to regulate blood flow through specific beds to suit their needs at any given time without causing a similar change in others. For example, blood flow through skeletal muscle is increased during exercise, while that through the gut is reduced, whereas when the same individual is resting postprandially, blood flow through skeletal muscle falls and that to the gut and liver increases. This regulation of blood flow depends on an interplay between reflexes initiated on a whole-body basis.

Thus, blood pressure is dependent on blood flow and vascular resistance. Arterial blood pressure is maintained constant by the regulation of overall flow (cardiac output) and total peripheral resistance. Blood flow through individual organs depends on the peripheral pressure across that vascular bed (difference between arterial and venous pressure) and the vascular resistance. It is important to note, however, that there are some special cases where additional factors are important (e.g. in the cerebral circulation).

The parallel arrangement of some of the vascular beds in the systemic circulation



1

Vascular resistance

The primary site of vascular resistance is the arterioles, which collectively offer the greatest resistance to blood flow. Resistance is dependent on the radius of the lumen of the blood vessel (Equation 3) and, because this is an inverse relationship to the fourth power, a small change in radius leads to a large change in resistance. The change in the radius of the arteriole is brought about by the smooth muscle that forms part of the vessel wall. The activity of the smooth muscle is influenced by substances released from the nerves innervating the muscle and by blood-borne substances, some of which act directly on the smooth muscle and some of which act initially on the endothelium, which in turn modifies smooth muscle activity and thus vascular resistance.

The arteriole is broadly composed of an outer adventitial layer, a medial layer and a single layer of endothelial cells lining the lumen of the vessel. The vascular smooth muscle cells are small, mononucleated and spindle-shaped, and are arranged in a circular layer around the arteriole in the medial layer, so that when they contract they reduce the radius of the vessel. There is a close association between the endothelium and the smooth muscle cells. Indeed, the endothelium plays an important role in regulating the contractile state of the smooth muscle cells (see *Anaesthesia and Intensive Care Medicine* **2:2:** 77). The arteriole is primarily innervated by the autonomic nervous system; parasympathetic fibres play almost no role in modifying vascular resistance to control arterial blood pressure.

In most organs, the primary transmitter released by the sympathetic nerves is noradrenaline, though there are many other co-transmitters including ATP, neuropeptide Y and adrenaline (Figure 2).

There is clear evidence of sympathetic cholinergic fibres, which release acetylcholine and innervate the resistance vessels of skeletal muscle in some species (e.g. cats), but the evidence is more controversial in man and they are thought not to exist in the rat. The sympathetic fibres run along the adventitial layer forming a plexus. The fibres, now with multiple varicosities along their length, run on into the media and end primarily on the outer surface of the smooth muscle layer without penetrating it. Transmitter is released from the varicosities in response to an action potential travelling along the nerves, and diffuses to reach the smooth muscle cells in the media (Figure 2).

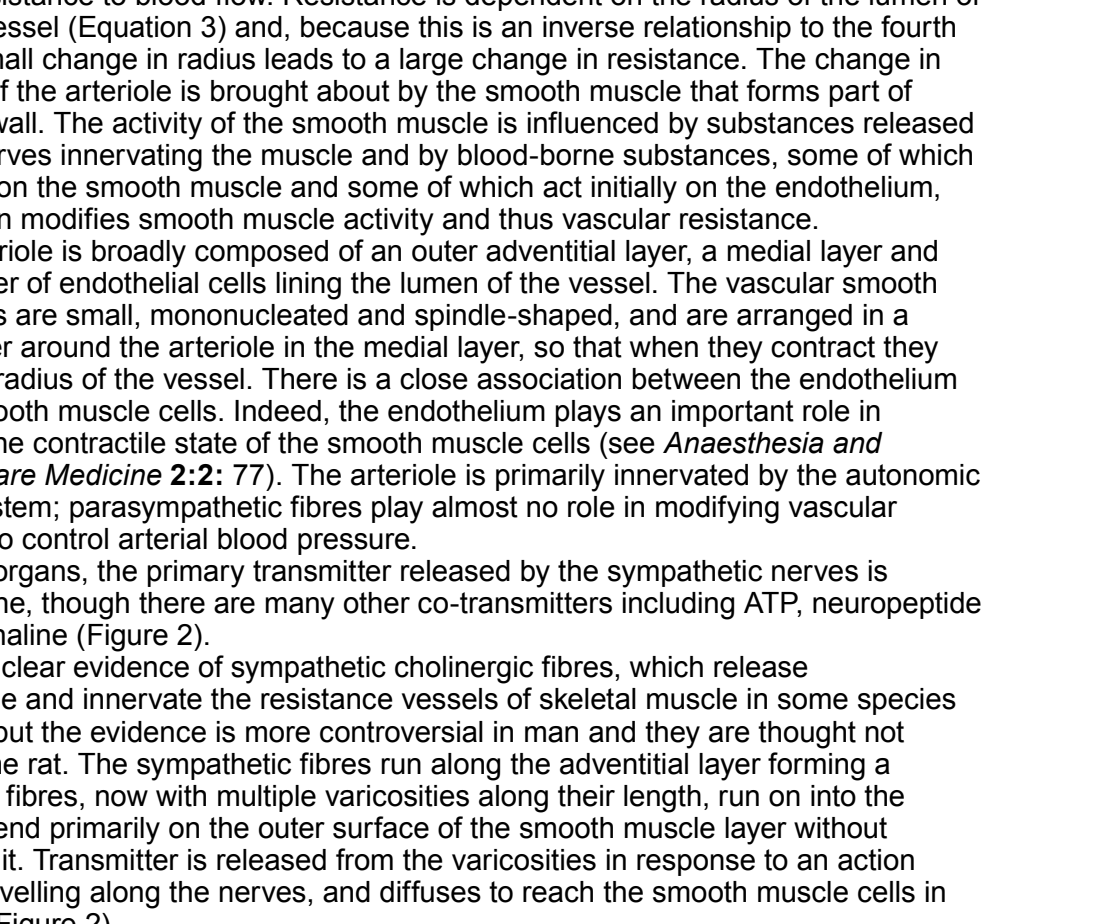
2

Vascular smooth muscle contraction

Vascular smooth muscle contraction takes place by the sliding of actin and myosin filaments over one another. Although there are many similarities between vascular smooth muscle and cardiac and skeletal muscle, there are also some important differences. Compared with skeletal muscle, smooth muscle contracts very slowly, develops high forces and maintains force for long periods of time with low use of ATP.

The sliding of actin and myosin filaments is controlled by the intracellular free calcium ion concentration. The calcium enters the cell via voltage-gated calcium channels and receptor-operated calcium channels (pharmacomechanical coupling), and by release from the sarcoplasmic reticulum (Figure 3). Neurohumoral agents, such as noradrenaline, cause contraction of the vascular smooth muscle primarily by pharmacomechanical coupling. For example, noradrenaline binds to α adrenoceptors on the muscle fibre membrane, which is linked to a membrane-bound regulatory protein called G-protein (guanine nucleotide binding protein). This, in turn, leads to the activation of phospholipase C causing hydrolysis of membrane-bound phosphatidyl inositol bisphosphate to yield inositol triphosphate and diacylglycerol. Inositol bisphosphate then causes the release of calcium from the sarcoplasmic reticulum, which ultimately leads to smooth muscle contraction, reduction in vessel radius and thus increase in vascular resistance.

Excitation–contraction coupling in vascular smooth muscle



ATP, adenosine triphosphate; GP, guanine nucleotide binding protein; PL-C, phospholipase C; PIP_2, phosphatidyl inositol biphosphate; IP_3, inositol triphosphate; DG, diacylglycerol.

Calcium and calmodulin activate myosin light chain kinase, which phosphorylates myosin LC_{20} resulting in cross-bridge recycling

3

Blood-borne substances
Blood-borne substances diffuse into the smooth muscle layer across the endothelial layer. Some, such as adrenaline, act directly on the smooth muscle. Vascular β_2 adrenoreceptors are more sensitive to adrenaline than are α adrenoreceptors. Therefore, at low doses or in vascular beds such as skeletal muscle where β_2 adrenoreceptors predominate over α adrenoreceptors, adrenaline causes vasodilatation. However, at high doses or in vascular beds with a predominance of α adrenoreceptors, adrenaline causes vasoconstriction. Other substances, such as acetylcholine, ATP, 5-HT and substance P, are released as paracrine agents from the endothelial cells in response to stimuli such as a shear stress or hypoxia (Figure 2), and act on neighbouring endothelial cells to cause release of endothelium-derived relaxing factor (EDRF), which is now known to be nitric oxide. This in turn diffuses into the smooth muscle layer ultimately to cause a reduction in intracellular calcium ion levels, muscle relaxation and thus vasodilatation, and a fall in vascular resistance.

The vascular smooth muscle is therefore constantly under the influence of competing drives and the degree of contraction is the result of the balance of these forces. Generally, there is a tonic basal activity in the sympathetic vasoconstrictor nerves which helps to maintain a degree of vascular tone. By contrast, the sympathetic cholinergic fibres, whenever present, are normally silent and only contribute to vascular regulation during exceptional circumstances, such as the visceral alerting response of the defence reaction (see below).

Arterial baroreceptor reflex

The arterial baroreceptor reflex is a negative feedback reflex, so that any change in arterial blood pressure is detected and a response initiated to reverse the change.

Arterial baroreceptors
Arterial blood pressure is detected by a group of receptors known as the arterial baroreceptors (sometimes called the high-pressure baroreceptors). The baroreceptors are found in parts of the arterial tree with a specialized elastic structure. The main areas are the carotid sinuses at the bifurcation of the internal and external carotid arteries, and the aortic arch (Figure 4), though some are also found along the common carotid arteries, particularly at the origin of the thyroid arteries.

The position and nerve supply of the aortic and carotid baroreceptors

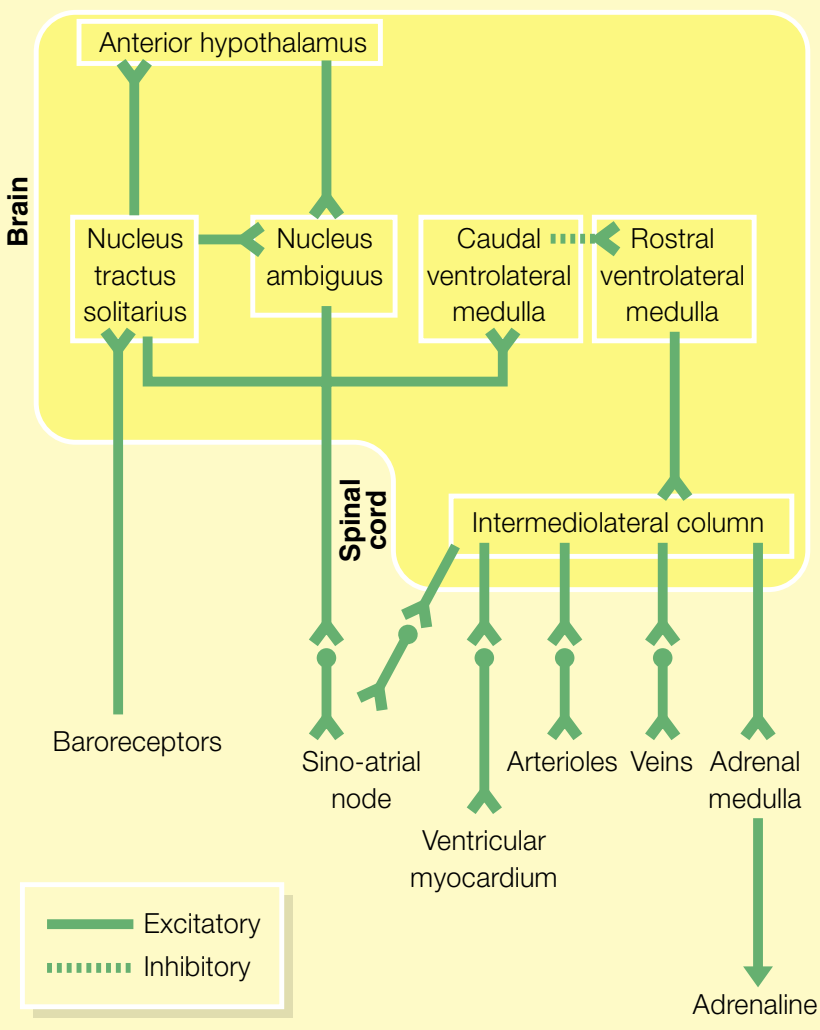
4

These receptors are slowly adapting mechanoreceptors represented by nerve endings in the medio-adventitial junction of the barosensitive area. They do not respond to arterial blood pressure *per se*, but rather to the stretch of the arterial wall produced by the intravascular pressure. They are active at normal arterial blood pressures. A rise in arterial blood pressure will cause the receptors to produce an increased frequency of action potentials, while a fall in arterial blood pressure causes an unloading of the receptors and a reduction in action potential frequency. Since they are mechanoreceptors, any mechanical deformation of the barosensitive areas can cause a burst of action potentials to be generated and provoke a baroreceptor reflex response. Although such mechanical interference does not normally occur, it can be seen in clinical practice (e.g. during carotid sinus massage).

Baroreceptor afferent information is conveyed to the brain via myelinated and unmyelinated fibres in the sinus nerve (a branch of the glossopharyngeal nerve) from the carotid sinus and via the vagus nerve from the aortic arch. The cell bodies of these sensory afferents are found in the petrosal and nodose ganglia (from the carotid sinus and aortic arch, respectively). The afferent axons continue into the medulla where the first synapse of the baroreceptor reflex is found (Figure 5).

Baroreceptor reflex arc



5

CNS connections and efferent pathways
The primary relay of the baroreceptor reflex is found in the nucleus tractus solitarius in the medulla (Figure 5). Older physiology textbooks argue that the baroreceptor reflex is integrated in a brainstem 'vasomotor centre'. Although this represents a convenient 'black box' when describing cardiovascular control mechanisms, current evidence argues against this concept and suggests that cardiovascular control is achieved via a number of interrelated pathways.

The efferent pathways mediating the baroreceptor reflex are carried in the vagus nerve (parasympathetic) to the heart (primarily the sino-atrial and atrioventricular nodes), influencing heart rate and the sympathetic nerves to the heart (affecting both heart rate and force of ventricular contraction) and the vasculature. In addition, the adrenal medulla releases adrenaline into the bloodstream to affect both heart and vasculature (see above). The vagus nerve originates from the nucleus ambiguus (NA) and dorsal vagal motonucleus (DVN) in the medulla. There is both a segmental pathway from the nucleus tractus solitarius to the vagal outflow nuclei (NA and DVN) and a longer one, which ascends to the anterior hypothalamus, synapses and descends again to the vagal outflow nuclei. Increased baroreceptor afferent activity arising in the nucleus tractus solitarius leads to excitation of these secondary pathways, which in turn excite the vagal motor neurons, causing increased vagal efferent activity to the heart (Figure 5).

The sympathetic nerves originate from the intermediolateral column of the spinal cord, with pools of neurons that innervate different organs grouped at various levels along the cord. The sympathetic motor neurons receive a tonic descending excitatory drive from a group of neurons in the rostral ventrolateral medulla (RVLM). There is a high degree of viscerotopic organization here, with neurons innervating sympathetic outflow neurons being grouped together according to the type of vascular bed they influence. The RVLM receives an input from a group of neurons in the caudal ventrolateral medulla (CVLM), which receives an input from the nucleus tractus solitarius (Figure 5). Activation of the baroreceptor afferents innervating the nucleus tractus solitarius causes excitation of neurons projecting to the CVLM, which in turn causes excitation of neurons projecting from the CVLM to the RVLM. This causes increased release of transmitter in the RVLM, however, this is an inhibitory transmitter, possibly −aminobutyric acid, which therefore causes inhibition of RVLM neurons. This leads to less activity from the RVLM to the intermediolateral column and thus to reduced excitation of the sympathetic outflow from the intermediolateral column with a consequent reduction in sympathetic efferent activity (Figure 5).

Response to a rise in blood pressure
A rise in arterial blood pressure will cause increased activity in the baroreceptor afferent fibres and, via the central nervous connection described above, lead to increased vagal efferent activity to the heart and reduced sympathetic efferent activity to both heart and blood vessels. Increased vagal activity to the heart will, in turn, cause a bradycardia as will a reduction in the tonic sympathetic activity to the sino-atrial node. In addition, the reduced sympathetic efferent activity to the ventricles will cause a reduction in the force of contraction and, thus, in cardiac stroke volume. Together, these effects will reduce cardiac output (Equation 2). Finally, the reduced sympathetic activity to the vasculature will cause vasodilatation and a fall in vascular resistance (Equation 3). The reduced cardiac output and vascular resistance will together return blood pressure back to its original level (Equation 1).

Response to blood loss
In a young, healthy individual, the response to haemorrhage initially involves a tachycardia and a rise in peripheral vascular resistance to maintain arterial blood pressure (Figure 6). This response is mediated via the arterial baroreceptor reflex and is the classical response to unloading the baroreceptors (decreased vagal and increased sympathetic activity). In many cases, however, there is no fall in mean arterial blood pressure. If blood pressure has not changed, how do the baroreceptors become unloaded because, as mentioned earlier, they respond to the stretch of the arterial wall produced by the intravascular pressure? The baroreceptors respond not only to the absolute or mean pressure, but also to the pulse pressure (difference between systolic and diastolic pressures). Thus, during a mild haemorrhage, there is a reduction in pulse pressure (because stroke volume is reduced). This unloads the baroreceptors and leads to the tachycardia and elevated peripheral resistance, which helps maintain mean arterial blood pressure.

Finally, the aim of the response, namely that arterial blood pressure is maintained constant to preserve blood flow, should be considered. This reveals an apparent paradox, because part of the baroreceptor reflex response involves increased vascular resistance, which would itself cause reduced flow. The answer to this lies in the parallel arrangement of the vascular beds in the systemic circulation. The sympatho-activation is not uniform to all vascular beds; those with the greatest dependence on oxygen generally are subject to the least vasoconstriction, while areas less dependent on oxygen, or more tolerant to transient reductions in oxygen delivery, have the greatest constriction. The baroreceptor is therefore able to deliver the blood to those areas which need it the most.

Changes in heart rate, systolic arterial blood pressure, cardiac output, peripheral vascular resistance and right atrial pressure during a controlled haemorrhage (venesection) and subsequent faint

Regulation of blood volume

Although a detailed discussion of blood volume regulation is beyond the scope of this review, it is pertinent to discuss briefly the effect of the baroreflex on the short-term control of blood volume. It should be noted, however, that this does not include the role of the baroreceptor reflex in the long-term (definitive) correction of blood volume, which involves the kidneys.

In a normal individual, it is estimated that 60–70% of the blood volume at any one time is contained within the veins. It is also known that the veins, especially those of the splanchnic circulation, are very sensitive to low levels of sympathetic activity. It has been suggested that the earliest response to blood loss would be a sympathetically-induced constriction of the veins (veins as well as arterioles receive a sympathetic efferent supply). While this would have only a small effect on the resistance of these vessels, it has been shown that it would have a much greater effect on capacitance, mobilizing an estimated 5 ml blood/kg body weight. Arteriolar vasoconstriction upstream would also reduce blood flow into the veins and thus, it is argued, would produce a further reduction in capacitance of approximately the same magnitude.

Finally, arteriolar constriction leads to a fall in capillary hydrostatic pressure. This disturbs the Starling forces that govern the net movement of fluid across the capillary wall and leads to a transient mobilization of interstitial fluid into the vascular space, with a fall in haematocrit.

Other reflexes influencing the cardiovascular system

Although the arterial baroreceptor reflex is considered to be the principal mechanism regulating the cardiovascular system, there are many other cardiovascular reflexes and responses mediating the neurological and humoral control of blood pressure and blood flow. These mechanisms are able to interact and enable one to predominate. Thus, for a resting individual, the baroreceptor reflex is probably one of the most important regulatory mechanisms, but this changes in other circumstances.

Severe haemorrhage

The response to progressive haemorrhage initially involves a baroreflex-mediated tachycardia in order to maintain blood pressure (Figure 6). As the haemorrhage progresses and becomes severe, however, there is a reflex increase in vagal tone to the heart and thus bradycardia, and sympatho-inhibition leading to a fall in vascular resistance and severe hypotension. At this point, the patient usually faints. This second phase is not the result of the baroreceptor reflex failing, but is due to the activation of a second ‘depressor’ reflex which seems to predominate over the baroreceptor reflex. Until recently, it was thought that this second reflex was a consequence of stimulating mechanoreceptors in the cardiac ventricular wall, which send afferent information via cardiac afferent C fibres in the vagus. More recent evidence argues against this being the afferent pathway, which is currently unknown. It is thought that this reflex may help protect the heart from ischaemic damage when coronary perfusion is low.

Visceral alerting response of the defence reaction

The visceral alerting response of the defence reaction prepares an individual to fight or flee from a threatening stimulus. It is characterized by a rise in both heart rate and blood pressure, with vasoconstriction due to sympatho-activation in many organs such as gut and kidney, but vasodilatation in skeletal muscle. The muscle vasodilatation results from an inhibition of the sympathetic vasoconstrictor activity and elevated blood adrenaline levels in this bed. In addition, the sympathetic cholinergic vasodilator fibres, in species where they exist, are activated. The benefit of this pattern of response is that there is an effective diversion of blood flow towards skeletal muscle in preparation for the increased demand during the ensuing vigorous muscular activity. This pattern is at variance with the baroreceptor reflex (increased blood pressure should cause a bradycardia and sympatho-inhibition in the vital organs as well as skeletal muscle). However, during the visceral alerting response, the baroreceptor reflex is temporarily inhibited at a number of sites in the medulla including the nucleus tractus solitarius and nucleus ambiguus.

Organization of the Body: Control of the Internal Environment

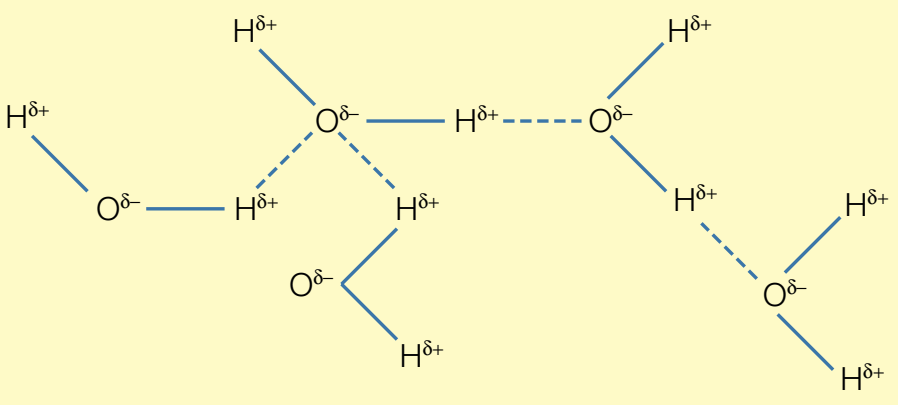
Iain Campbell

Iain Campbell is Reader in Anaesthesia at the University of Manchester and Honorary Consultant Anaesthetist at the University Hospitals of South Manchester. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

Polar and non-polar molecules

The mammalian cell comprises 70% water, 15% protein, 7% nucleic acids, 2% carbohydrate, 2% lipid, 1% inorganic ions and 3% other small molecules. The predominant substance, water, is made up of two atoms of hydrogen and one of oxygen and is described as 'polar.' A polar molecule has an overall charge, or an uneven distribution of charge on its surface. The most polar of small particles are ions (e.g. Na^+, K^+) which have lost an electron from their outer shell. However, even covalently bound molecules (e.g. water) demonstrate polarity by virtue of the uneven distribution of their electron 'cloud.' In water, the oxygen atom pulls electrons towards itself so the electron cloud is more dense over that part of the molecule, which is thus relatively more negative than it is over the hydrogen atoms. The partial negative charge over the oxygen atom is attracted to the partial positive charge over the neighbouring hydrogen atoms, and this weak 'hydrogen bonding' keeps the molecules together (Figure 1) and gives water its principal characteristic (i.e. a liquid, which, for the size of its molecule, has a relatively high boiling point).

Interactions between water molecules



Owing to the polarity of the water molecule (i.e. an uneven distribution of negative and positive charge) hydrogen bonding occurs between neighbouring molecules. This bonding is weak and bonds are constantly being formed and broken, but it accounts for the fact that water is a liquid whereas larger non-polar molecules such as methane and carbon dioxide are gases

1

The polarity of water contrasts with that of organic molecules, made up entirely of carbon and hydrogen ions (e.g. methane) which are non-polar. The carbon–hydrogen bonds lead to an even distribution of electrons so that the molecules do not interact with each other. Polar and non-polar compounds do not mix well; the water molecules bond together and exclude the non-polar substances, which may pack together because of their lack of interaction. There is some attraction between non-polar compounds, however, as a result of random variations in the density of the electron cloud, which results in minor transient degrees of polarity inducing opposite charges in neighbouring molecules and transient attractions between them; these are known as van der Waal forces. Their effects are small compared with the exclusion by water.

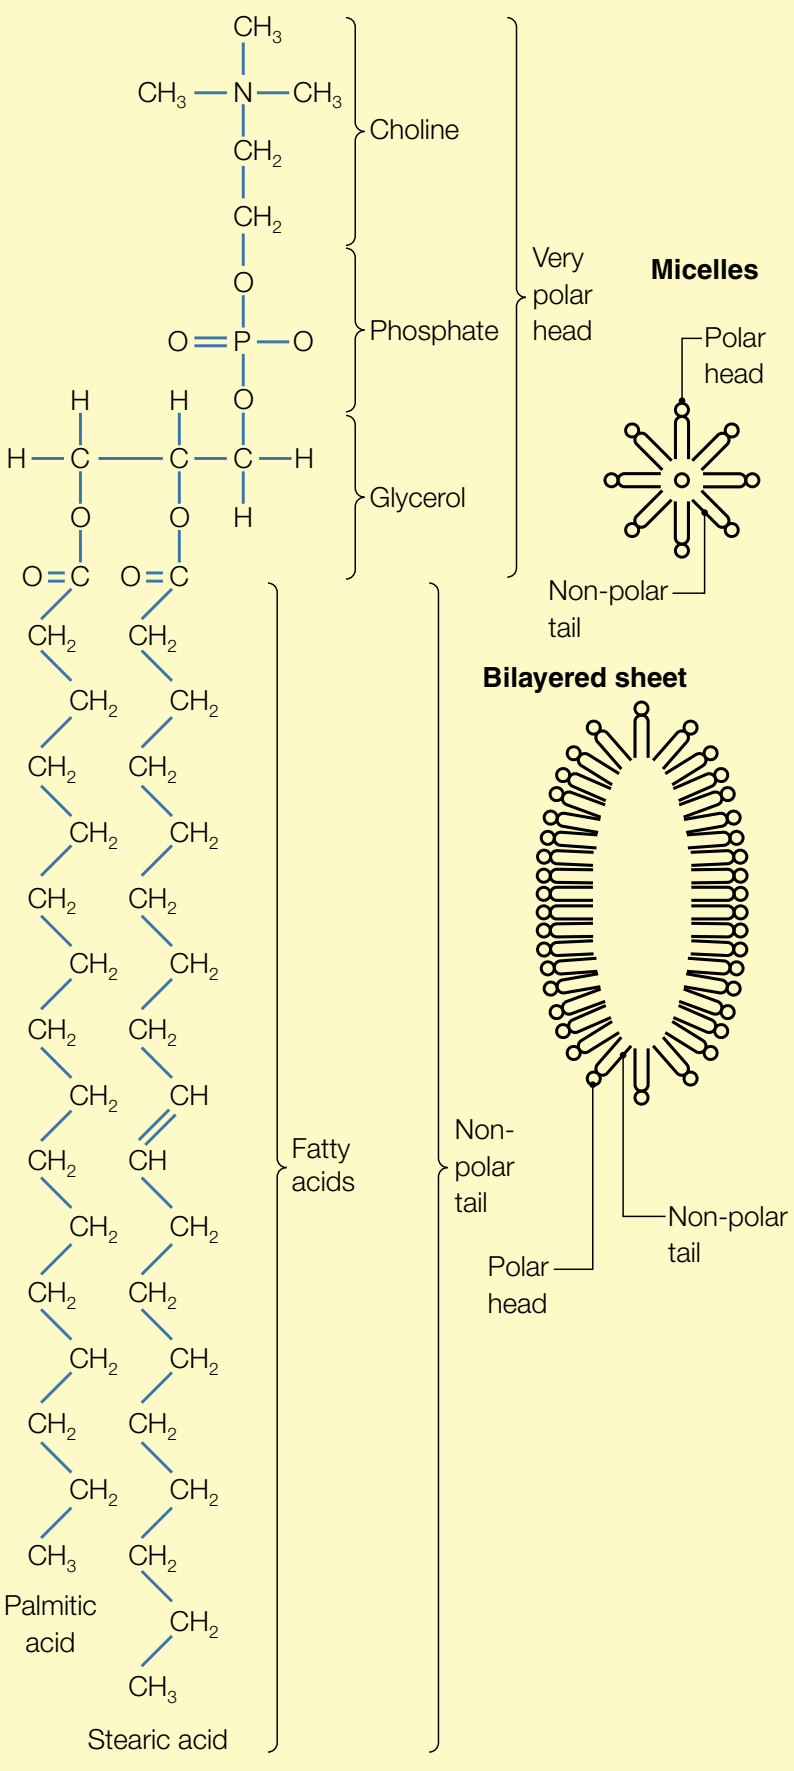
The state of polarity results from the fact that, compared with hydrogen, certain atoms are always electronegative. Biochemically, the important polar atoms are oxygen, phosphorus and nitrogen along with certain functional groups based on these atoms – the hydroxyl group (OH), the amino group (NH_2) and the orthophosphate group (OPO_3). Thus polar compounds, such as glucose (with a large number of OH groups), lactic acid (with a COO group) and other small metabolites, including most amino acids, form hydrogen bonds and are water-soluble.

Molecules that have both polar and non-polar regions, are partly soluble and partly insoluble in water and are described as 'amphipathic.' Amphipathic molecules submersed in an aqueous environment generally take up one of two configurations.

- As micelles they form spherical droplets with their polar heads facing outwards and their hydrophobic tails together in the centre.
- As bilayered sheets or membrane, their water-soluble heads are in the aqueous environment and their hydrophobic tails form the substance of the membrane. An obvious example of this is the phospholipids that make up cell membranes (Figure 2).

Cell membranes comprise two layers of these compounds, with the water-soluble polar phosphate head presented to the aqueous environment and the two layers of hydrophobic non-polar hydrocarbon lipid tails making up the body of the membrane. The structure and function of cell membranes is discussed on page 152. Molecules passing through such membranes have to traverse both the hydrophilic regions (comprising the polar phosphate heads of the phospholipid molecules) and the thickness of the hydrophobic interior (comprising the hydrocarbon chains of the fatty acids). Specific carrier proteins are embedded in the body of the membrane to facilitate these processes. Membrane transport is discussed on page 153, but in general, hydrophobic lipid-soluble substances traverse membranes more easily than do polar water-soluble ones.

Molecular structure of phospholipids



2

Body water volumes

In the young adult male, 60% of the body is water; 40% intracellular fluid (ICF) and 20% extracellular fluid (ECF). Of the ECF, 5% is intravascular and 15% extravascular or interstitial (i.e. between the cells). The composition of the ECF resembles that of sea water but is more dilute.

The volumes of the various fluid compartments can be measured using dilutional techniques (Figure 3). A known amount of tracer, which remains in the compartment being measured, is injected or ingested. The volume of dilution (V) can be calculated from the total amount injected (M), from its final dilution in the compartment into which it is injected (m/unit volume) less the amount excreted (E) over the time it takes for mixing to occur: V= M-E/m.

The tracers commonly used for total body water measurement are tritiated or deuterated water, sodium bromide is used for ECF volume, and Evans' blue dye, labelled albumin, or red blood cells, with appropriate corrections made for haematocrit, are used for plasma. Plasma is normally 93% water. ICF volume is calculated from the difference between total body water and ECF volume.

The interstitial ECF bathes the outside of the cells and provides their immediate environment. The intravascular ECF provides the transport system for nutrients and waste products. The ECF is ultimately a medium of exchange between the cells and the external environment. Its principal cation is sodium. Interstitial ECF normally contains little or no protein. Other types of ECF, in addition to plasma, include lymph and CSF and transcellular fluid (e.g. eye humours). ECF makes up the immediate environment of the cells and its nature and composition is tightly controlled by the mechanisms discussed below (page 151). In contrast, the ICF is rich in potassium and poor in sodium. It contains protoplasm, a complex mixture of substances that includes most of the protein in the body and which shows the features of life:

- organization into specific structural units
- ability to enter into chemical activities that include the transformation of energy and the maintenance or synthesis of the protoplasm itself
- ability to respond to changes in the environment
- ability to grow and reproduce.

Tissues, organs and organ systems

Cells are units of protoplasm bounded by phospholipid membranes formed by the interaction of hydrophobic and hydrophilic molecules. Life as a single-celled organism is obviously vulnerable to the vicissitudes of the environment. It is directly exposed to the external world and does not have the physiological resources to protect itself. In multicellular organisms, the cells have differentiated to perform different functions and have taken on different roles such as movement, digestion and reproduction. When groups of cells are closely associated functionally they form a tissue of which there are four types.

Epithelial tissue comprises close-packed sheets of cells that cover the body surfaces and line the various cavities, tubes and hollow viscera. Apart from its structural role, epithelium may also secrete, absorb and filter.

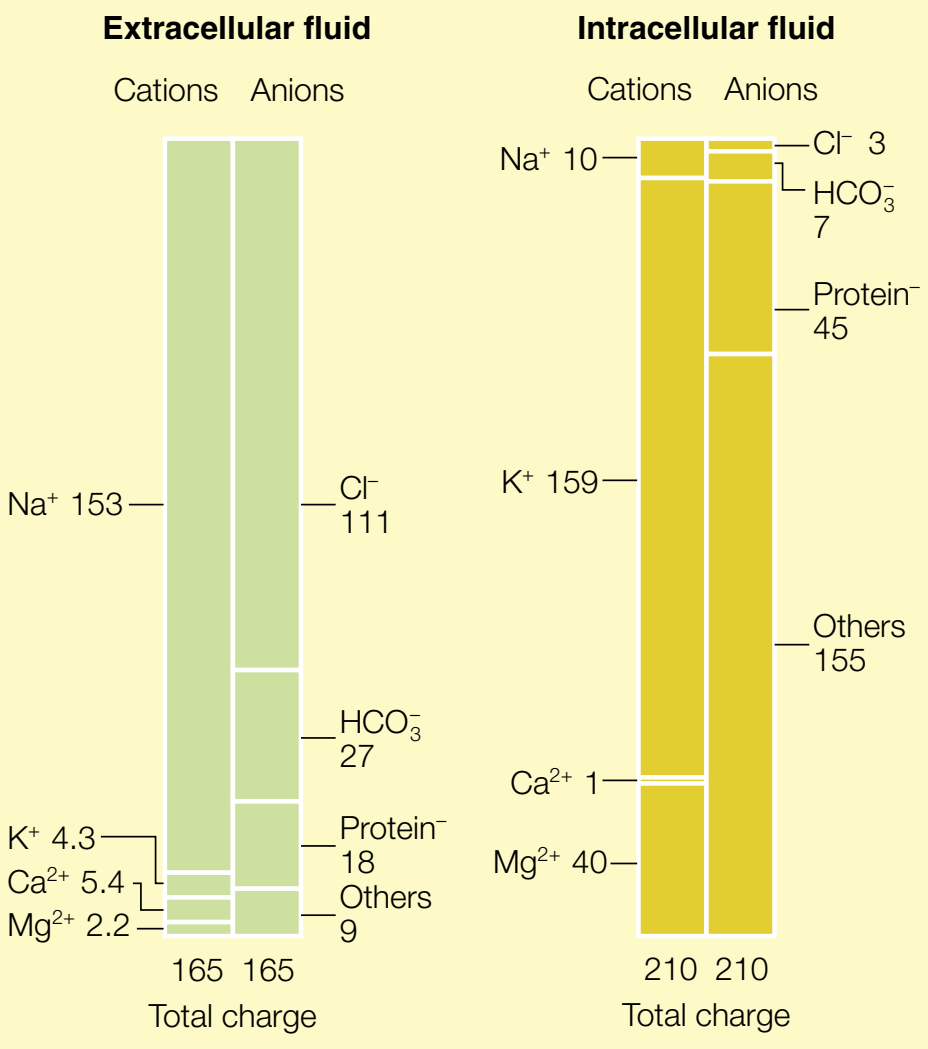
Connective tissue is the most widely distributed tissue in the body. Its cells are loosely arranged and separated by intercellular matrix, which contains fibres, soluble protein and crystalline complexes. It supports and partitions nearly all components of the body and its rearrangement determines growth. Connective tissue includes bone, cartilage, ligaments, blood and adipose tissue.

Muscle – there are three types of muscle. Skeletal muscle enables the body to move and react to external stimuli. Smooth muscle, in part, forms the walls of the gastrointestinal tract, the blood vessels and other hollow viscera (e.g. bladder, uterus). Cardiac muscle pumps blood round the cardiovascular system.

Nervous tissue constitutes the central (brain and spinal cord) and peripheral nervous systems (somatic and autonomic). Neurons are associated with glial tissue, which provides them with structural and metabolic support.

Tissues form organs and a variety of tissues may contribute to the formation of one organ (Figure 4). The gastrointestinal tract and cardiovascular systems, for example, are made of muscle lined by epithelium. The epithelium of the gastrointestinal tract secretes digestive juices and absorbs nutrients, and is under central (autonomic) nervous control with neural networks within the wall of the gut. Organs that share in the performance of related tasks are grouped into systems. These are classified as the cardiovascular, respiratory, gastrointestinal, nervous, locomotor, genitourinary and reticuloendothelial systems.

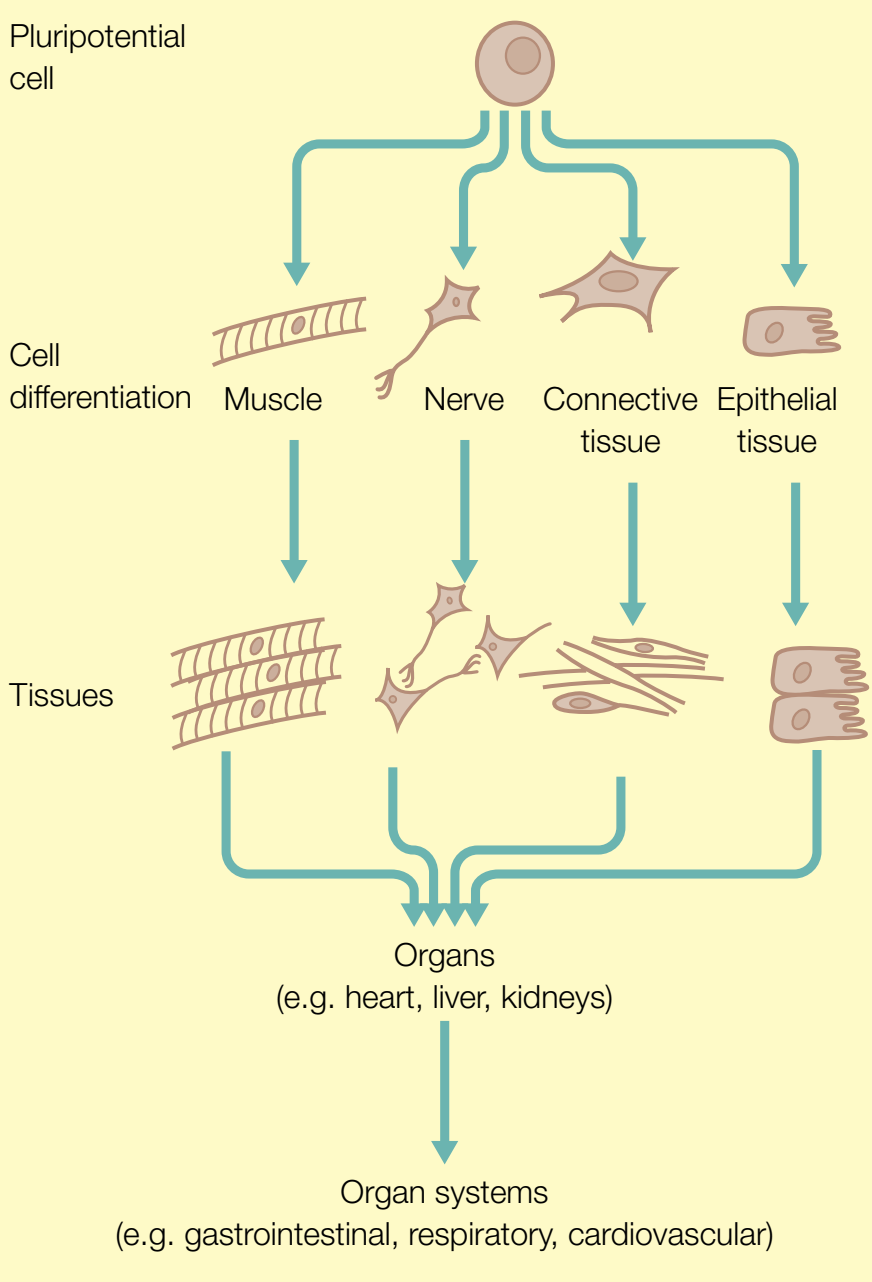
Constitution of intracellular fluid (muscle) and extracellular fluid (plasma water) and the tracers used to measure the various compartments



Figures are ionic concentrations in mmol/kg water. Total ionic concentrations are greater for intracellular fluid because many of the intracellular anions such as protein are polyvalent molecules. 'Other' intracellular anions are mainly organic phosphates such as creatine phosphate and ATP

3

Organization of the body from cells to organ systems



4

Control of the internal environment – homeostasis

For a living organism to function optimally, the internal environment (the composition of the ECF) has to be kept constant in terms of the Po_2, PCo_2, pH, osmotic pressure, temperature and concentrations of the various hormones, substrates, waste products and ions. Poikilotherms (e.g. reptiles) are unable to regulate their body temperature and are therefore sensitive to environmental conditions, but mammals maintain their body temperature in the face of wide variations in environmental temperatures and thus remain active under a variety of conditions.

Outside these tightly controlled conditions, function is suboptimal. The molecular basis for this is in the configuration of proteins. Proteins form the structural components of cells, the enzymes that catalyse biochemical reactions and the receptors and channels in cell membranes that connect the inside of the cell and the ECF. To function properly each protein has its own particular configuration or shape, which is a function of pH, temperature and ionic concentration. When conditions move outside of a relatively narrow range, protein configuration is altered and the ability to function properly is diminished or may be lost. Homeostatic mechanisms maintain the stability of the internal environment. They operate principally through the endocrine and nervous systems.

Control systems possess sensors to monitor variables and effectors to enable a response to alterations in that variable. The desired range of any variable is set, usually in the CNS, and any movement outside that range activates mechanisms that bring the variable back within range. For example, a rise in body temperature brought about by exercise results in peripheral vasodilatation and, depending on the severity of the exercise, sweating. This produces increased heat loss and a tendency for body temperature to return to normal. Most control systems are of the negative feedback type and work to restore the variable to the normal value. Some, however, incorporate positive feedback and these tend to destabilize. An example of this is seen when a rise in body temperature increases metabolic rate and thus heat production and raises body temperature further.

Sensors are situated centrally, usually in the hypothalamus, but there are peripheral sensors such as those for Po_2 and blood pressure which are part of, and transmit their signals via, the autonomic nervous system. Stimuli that activate the endocrine system may also be detected in the CNS or by special cells in the periphery, such as those in the pancreas that detect changes in blood sugar. The mechanisms that correct homoeostatic disturbances may be endocrine or neural, but generally the two systems work together.

Osmolarity and Partitioning of Fluids

Ian Campbell

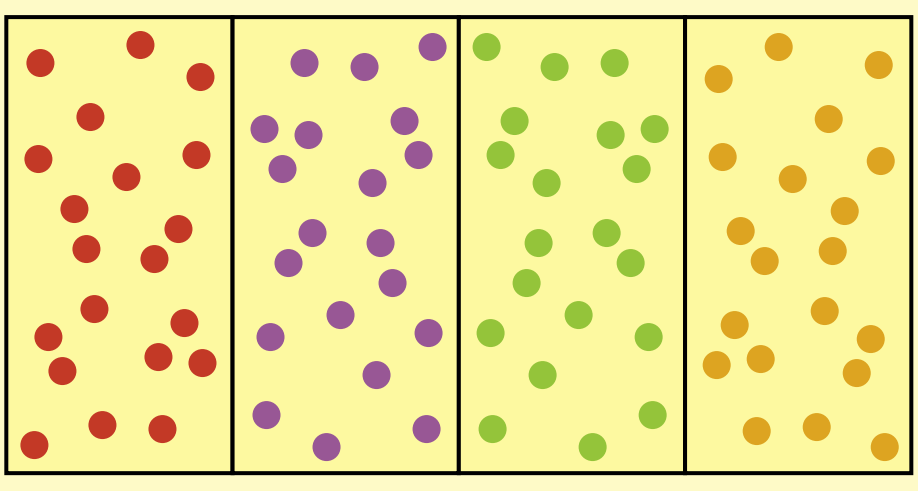
Iain Campbell is Reader in Anaesthesia at the University of Manchester and Honorary Consultant Anaesthetist at the University Hospitals of South Manchester. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

Diffusion

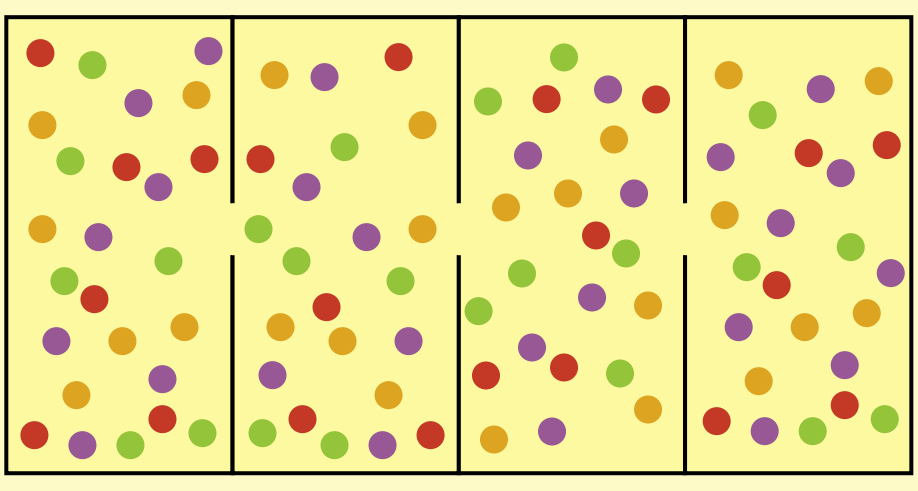
Substances move down concentration gradients. In nature, all molecules are in motion. The rapidity of the motion is proportional to the thermal energy (temperature) of the substance. In fluids (gases and liquids), this movement is random (Brownian motion). When fluids are mixed together, they diffuse down their own concentration gradients and come to a dynamic equilibrium such that the concentrations of the various substances in all parts of the medium are the same (Figure 1). The rate at which they come to equilibrium at a given temperature depends on their relative concentrations and, in the case of solutions, the solubility of the solute in the solvent. Gas molecules also diffuse in proportion to their own concentration gradients (partial pressures), as if they were the only type of molecule present, to become evenly distributed throughout the gas mixture, each contributing its own partial pressure to the whole.

Dynamic quilibrium

Four closed containers holding different gases



The resulting equilibrium if the gases are allowed to mix



Fluids move down their own concentration gradients and come to a dynamic equilibrium with concentrations dispersed equally throughout the medium

1

Diffusion of water (osmosis)
When two aqueous solutions of different concentrations are separated by a semipermeable membrane (permeable to water but not the solute), water moves from the weaker solution to the stronger one by the process of osmosis. In doing so it is moving down its own concentration gradient (i.e. from the solution with the higher water concentration to the solution with the lower water concentration).

The osmotic concentration of a solution depends on the number of particles present. Thus, in a molar solution of glucose, where the molecule stays intact, the osmotic effect is less than that of a molar solution of sodium chloride where the molecule dissociates. Osmotic concentrations are expressed in units called osmoles; in physiological solutions, which are usually weak, the unit is the milliosmole. The relationship between the molarity of a solution and its osmolarity depends on the number of particles derived from each molecule. Thus:

milliosmoles = millimoles x n
where n is the number of particles into which the solute dissociates.

For example, the osmotic concentration of a 60 mmol/litre glucose solution is 60 mosmoles/litre, but the osmotic concentration of a 60 mmol solution of sodium chloride is 120 mosmoles and a 30 mmol solution of calcium chloride is 30 x 3 = 90 mosmoles because calcium chloride dissociates into three particles.

Osmotic pressure is the force that water exerts in passing from a weak solution to a strong one. The osmotic pressure of a solution is given by:

$\pi = RTC$
where π *is* the osmotic pressure, R the ideal gas constant (0.082 litre.atmospheres/degree.mole), T the absolute temperature and C the concentration of a solute expressed in mosmoles/litre.

For a molar solution at 0°C (273° absolute) the osmotic pressure is 22.4 atmospheres. The osmotic pressure of a solution depends on the number of particles in the solution and not on the nature of the solute. The osmotic pressure of pure water is zero.

Osmolarity – the osmolarity of a solution can be measured directly using an osmometer. The freezing point of water is depressed when solutes are present, the extent of the depression being directly proportional to the amount of solute (number of particles), regardless of the nature of the solute. Osmometers work on the principle of freezing point depression. They are usually calibrated to give a readout of mosmoles. The osmolarity of body water is close to 300 mosmoles/litre.

Osmolality is often confused with osmolarity. Osmolality is expressed as osmoles/kg of solvent and osmolarity as osmoles/litre of solution. Biological solutions are mainly water therefore the two terms are virtually identical.

Regulation of cell contents

Most cell membranes are permeable to water, but cells control the amount of water that enters. They do this by adjusting their osmolarity by regulating, directly and indirectly, the amount of solute within the cell. The principal solutes are Na^+, K^+ and Cl^-, but they also include proteins, organic phosphates (e.g. ATP) and other metabolic intermediates. Charged ions do not move freely across the cell membrane; they pass via channels and carrier proteins, but water follows along the osmotic gradient to maintain the same osmotic pressures inside and outside the cell.

If an animal cell is placed in a solution that is hypo-osmolar, water enters the cell until the osmotic pressure inside the cell is the same as that outside. This causes the cell to swell. The RBC is capable of the largest increase in volume (up to 67% of its original), because of its shape, but most cells can accommodate only small changes. In extreme cases, holes develop in the cell membrane and the cell loses its intracellular contents, or bursts. At an osmolarity of 150 mosmoles, about 50% of RBCs lyse. In hyperosmolar solutions, water passes from the cell to the surrounding medium and the cell shrinks.

The electrochemical gradient
Ions are charged and therefore, in addition to following their concentration gradients, their direction of movement is influenced by electrical gradients. The tendency of Na^+ to move to the inside of a cell is favoured both by the concentration gradient (Na^+ concentration is low) and by the electrical gradient (the inside of the cell is negatively charged which attracts the positively charged Na^+), therefore both the electrical and chemical (concentration) gradients are in the same direction. In contrast, K^+ tends to move out of the cell, down its concentration gradient, but is opposed by its electrical gradient because the outside of the cell is positive relative to the inside. The electrochemical gradient is the combination of these chemical (concentration) and electrical forces. The two may favour movement in the same direction or oppose each other.

Weak acids and bases
At body pH, organic acids and bases exist in ionized and non-ionized forms. The non-ionized form passes relatively easily through membranes and, once on the other side of the membrane, it may ionize, to give up an H^+ in the case of an acid, or to accept an H^+ in the case of a base. This ionization prevents diffusion back through the membrane and it remains 'trapped' on the other side. An example of this is the role of NH_3 in the control of urinary pH. NH_3, a weak base, diffuses from the cells into the lumen of the kidney tubule where it buffers an H^+ to become NH_4^+. Because NH_4^+ is highly charged, it is unable to diffuse back and is therefore excreted in the urine.

Movement of substances across membranes

Substances pass through cell membranes by passive or active movement. They may move through a membrane in one direction by a passive process and in the other direction by an active one.

Passive movement
Passive transport of a substance occurs down a concentration gradient by simple diffusion, facilitated diffusion, or osmosis, in the case of water, and does not involve the expenditure of energy. It usually results in a less concentrated state overall. Facilitated diffusion allows for faster transfer of solutes across membranes than simple diffusion, but the system can become saturated if all the binding sites on the proteins become occupied. Unlike simple diffusion, the process is also specific because it involves binding of specific solutes to specific sites on the proteins.

Cell membranes are lipid bilayers and are selectively permeable because they are permeable to nonpolar molecules, but not to highly polar or charged molecules (e.g. ions). Lipid-soluble (nonpolar) molecules cross cell membranes by diffusion (i.e. from an area of high concentration to an area of low concentration), though their rate of movement through the bilayer may be slowed compared with their movement across the aqueous phase on either side. The two principal factors that affect movement through the membrane are solubility in the bilayer and the size of the molecule. Thus, small lipid-soluble molecules diffuse the most easily and large polar ones with the greatest difficulty. The exception to this is water, which is polar but manages to cross membranes freely, possibly via 'water channels.' Small water-soluble molecules (e.g. urea, glycerol) also diffuse relatively freely throughout the intra- and extracellular fluid.

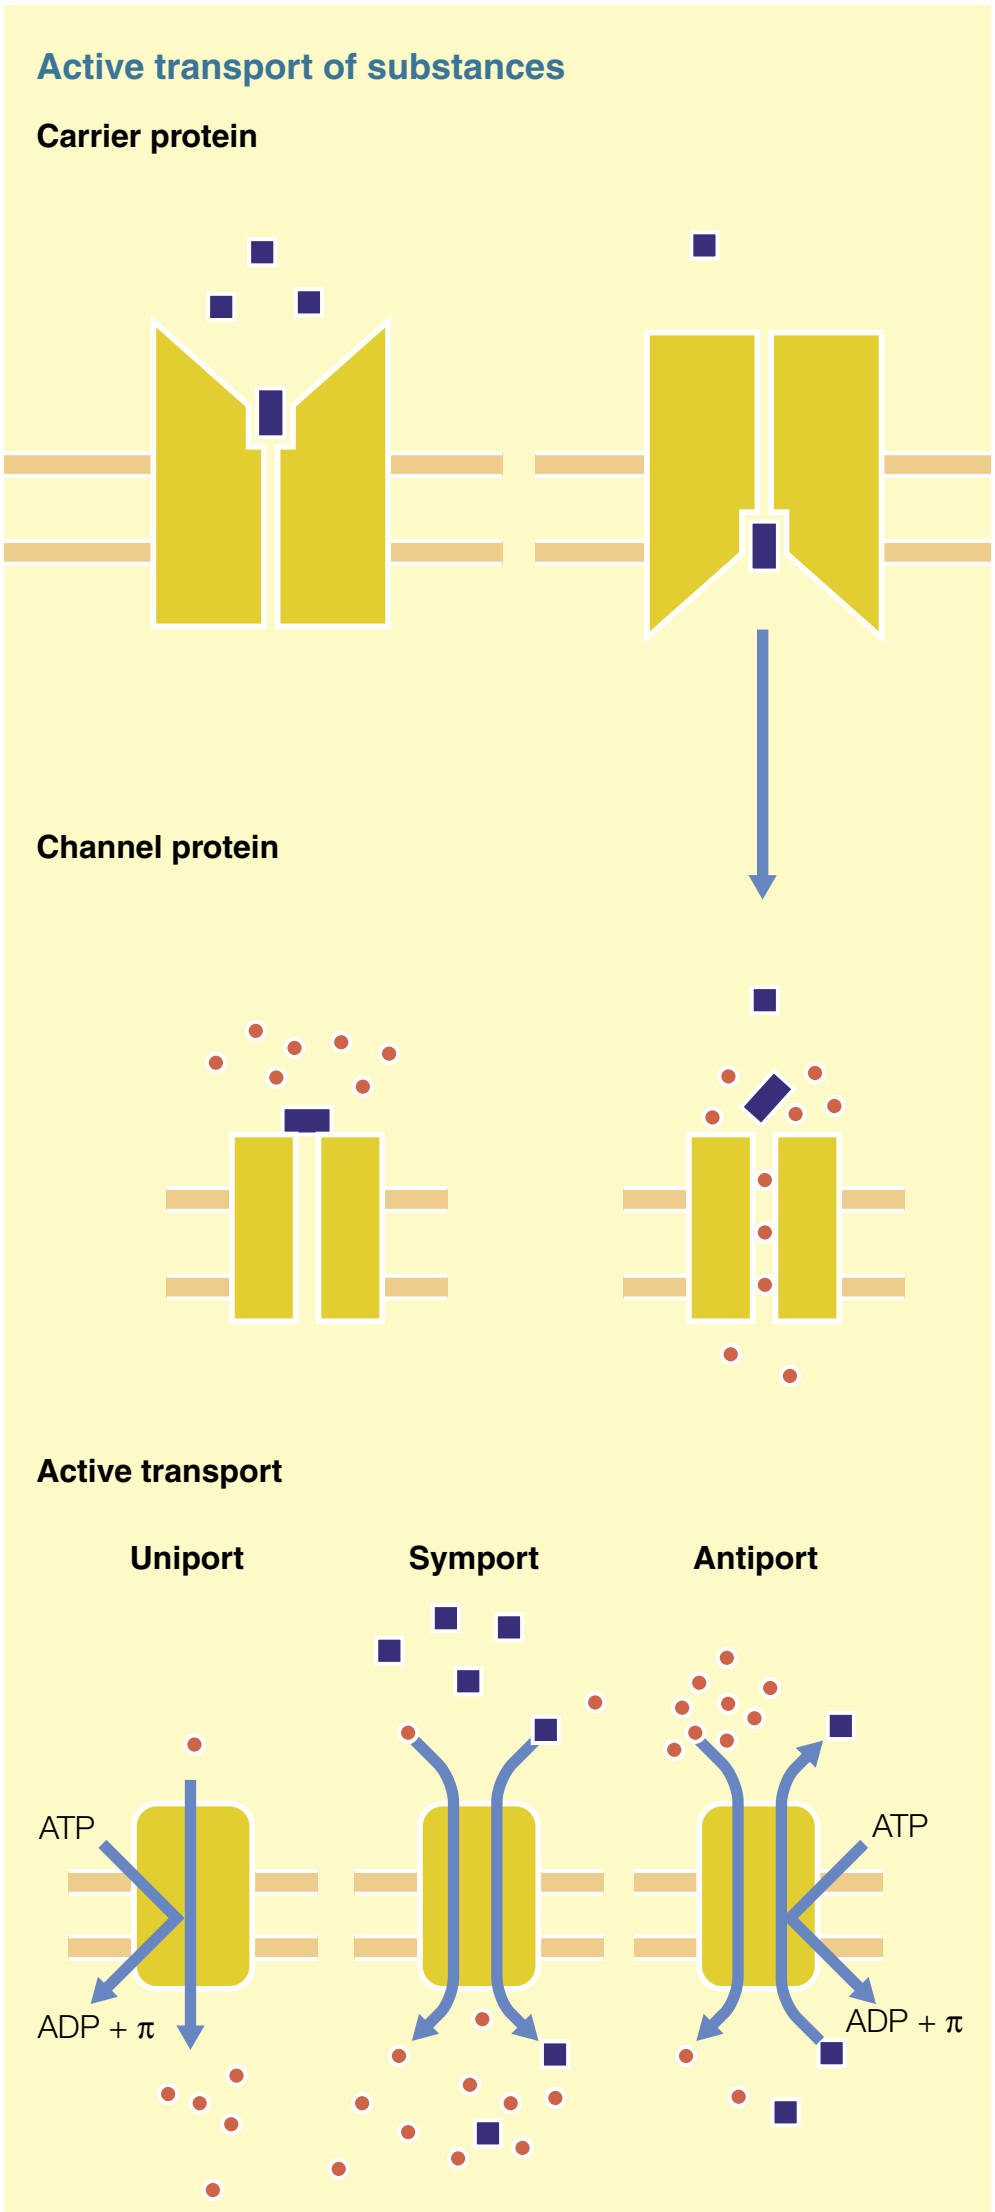
Carrier and channel proteins: strongly charged molecules (e.g. ions) and large water-soluble ones (e.g. amino acids, glucose) pass through membranes via specific carrier or channel proteins that span the bilayer by a process of facilitated diffusion (Figure 2). The intrinsic membrane proteins that act as carriers or channels move the solutes from one side of the membrane to the other and shield them from the lipid molecules. It is a passive process, following the electrochemical gradient, but differs from simple diffusion in a number of ways:

- it allows a high rate of transport
- it is saturable
- it is highly specific to the solute
- it can be blocked by competitive inhibitors.

Carrier proteins bind to a solute causing a conformational change in the protein. The solute then moves to the other side of the membrane where its concentration is low and it dissociates from the binding site. The protein reverts to its previous conformation and the process is repeated.

Channel proteins transfer ions from one side of the membrane to the other (more rapidly than carrier proteins do) and protect them from the surrounding lipid. This method of transport applies particularly to Na^+ and K^+, and the ions probably interact with charged groups in the channel, which quickens the transfer process. These channels are often held closed by 'gates' which open when certain voltages are detected in the surrounding membrane.

Active transport (Figure 2)
The movement of a solute across a membrane against a concentration gradient requires energy, usually in the form of ATP. When movement of the solute is coupled directly to an energy-yielding reaction, the process is known as primary active transport. When not coupled directly to an energy-yielding reaction, it is known as secondary active transport. Active transport generally results in a more concentrated state.



Molecules soluble in water move across membranes via carrier or channel proteins, either passively down their concentration gradient or against their concentration gradients. The latter movement involves the expenditure of energy (hydrolysis of ATP) either in the transport of a molecule (uniport), or the transport of two molecules in different directions (antiport). Symport usually exploits existing electrochemical gradients, but these are established by the expenditure of energy

Primary active transport: one type of ion can be transported singly across a membrane against its concentration gradient involving the expenditure of energy. The best known example of primary active transport is the Na^+/K^+-ATPase pump. Removal of a phosphate group from the ATP molecule provides energy to drive $3Na^+$ ions out of the cell and $2K^+$ ions into it, in both instances against the concentration gradient. Phosphorylation of the carrier protein is Na^+ dependent. This leads to a change in protein configuration which drives Na^+ out of the cell. The subsequent dephosphorylation triggered by the binding of K^+ allows the protein to return to its original configuration and moves the bound K into the cell.

Secondary active transport is energy dependent, but not coupled directly to the energy-producing reaction. A common example is a transport system driven by the energy stored in the electrochemical gradient of another solute, the gradient having been established by energy-consuming mechanisms. In animal cells, the solute is most commonly Na^+ moving intracellularly, the gradient having been established by the Na^+/K^+-ATPase pump.

Movement of solutes in the same direction as Na^+ is described as symport, coupled or co-transport. Movement in the opposite direction is known as antiport, exchange or counter transport. Na^+ binds to the protein carrier and this encourages binding of the solute even though the concentration may be low. A conformational change in the carrier then results in transport of the Na^+ and the solute through the membrane. With co-transport both Na^+ and solute move in the same direction, with exchange transport they move in opposite directions. The Na^+ then dissociates from the carrier because it is in a region of low Na^+ concentration and this causes the solute to dissociate from the transport protein, even though it is now in a region of higher concentration. Symport usually exploits ionic gradients, but counter transport may be linked to ATP hydrolysis.

Pain, Spinal Cord and Senses

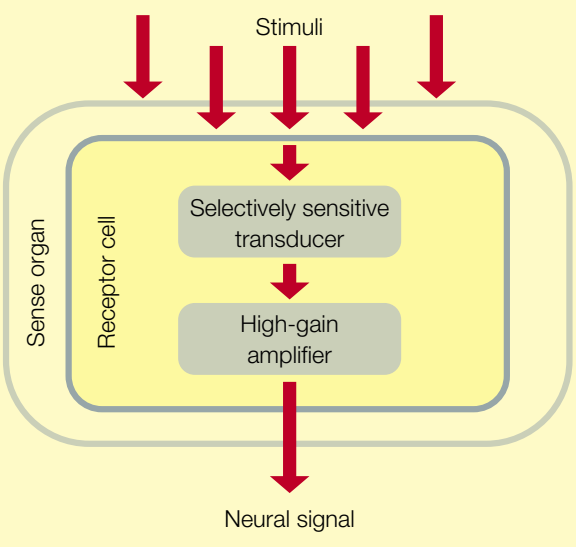
Chris J D Pomfrett

Chris J D Pomfrett is Lecturer in Neurophysiology Applied to Anaesthesia at the University of Manchester, UK. He qualified from Queen Mary College and the Medical College of St Bartholomew's Hospital, London. He has conducted research into cortical visual processing during anaesthesia and determining the depth of anaesthesia using measurements taken from the brainstem.

Pain

Pain is the perception of noxious stimulation by the CNS (Figure 1). Specific nociceptors encode noxious stimuli, but these are painful only if the CNS receives the information and reacts appropriately. If patients are given adequate levels of hypnotic agent and are therefore insensitive to noxious stimuli, or if they are given analgesics or local anaesthetics that block the transmission of nociceptor-sourced information, pain is not experienced even though the noxious stimulation is profound. Similarly, it is possible to induce states of intoxication or euphoria whereby noxious stimuli are perceived but are not interpreted as painful or of emotional importance. As a result, the threshold for a noxious stimulus to be perceived as painful depends on the individual and on the behavioural context of the stimulus. Since pain is a percept, it is also possible for the brain to be fooled into perceiving pain in the absence of nociception.

Typical receptor cell



1

Surgical anaesthesia can be considered as chemically induced hypnosis in balance against the arousing effects of noxious stimulation on the CNS. Hypnotic anaesthetic agents lower cerebral metabolism, whereas ascending interneurons relaying the presence of noxious stimulation to the CNS potentially increase metabolic activity. By using appropriate analgesia, the threshold for perception of pain can be raised and therefore the level of hypnotic required to achieve a desired depth of anaesthesia can be reduced. It is difficult to assess the depth of analgesia accurately, and no commercial technique has been validated that measures the adequacy of analgesia.

Pain is generally classified depending on its duration and patient tolerance.
Acute – lasts for up to a few days and is mild or severe in magnitude. Nociceptive inut is presumed.

Sub acute – lasts a few days to months.

Recurrent acute – persistent nociceptive input from an underlying chronic process (e.g. arthritis).

Ongoing acute – uncontrolled cause with continuous nociceptive input.

Chronic – usually lasts more than 6 months. There is no peripheral nociceptive input. Pain can be enhanced by sensory input. Adequate patient coping.

Chronic intractable benign pain syndrome (CIBPS) – chronic pain with poor patient coping. Pain becomes the focus of the patient's attention. No peripheral nociceptive input.

Afferent nociceptive pathways – ascending spinal tracts

Spinothalamic tract is the most prominent ascending nociceptive pathway. It originates in both nociceptive-specific and wide dynamic range neurons in laminae I and V–VII of the dorsal horn, at which level it crosses the midline and ascends the anterolateral white matter to the thalamus on the contralateral side to the stimulus. As well as nociception, the corticospinal tract conveys information on temperature and crude touch. Electrical stimulation of the spinothalamic tract elicits pain.

Damage to the spinothalamic tract can lead to central pain. The ventroposterolateral thalamus receives input from the spinothalamic tract, and damage to it (Dejerine-Roussy syndrome) leads to spontaneous burning pain and dysaesthesia (abnormal sensation in regions where noxious stimuli are not normally painful).

Spinoreticular tract originates in laminae VII and VIII of the dorsal horn. Some axons form uncrossed projections to the reticular formation and thalamus.

Spinomesencephalic tract originates in laminae V and I and projects to the mesencephalic reticular formation, the periaqueductal grey area and other parts of the midbrain. There are also reciprocal connections to the limbic system, especially the amygdala, via the thalamus.

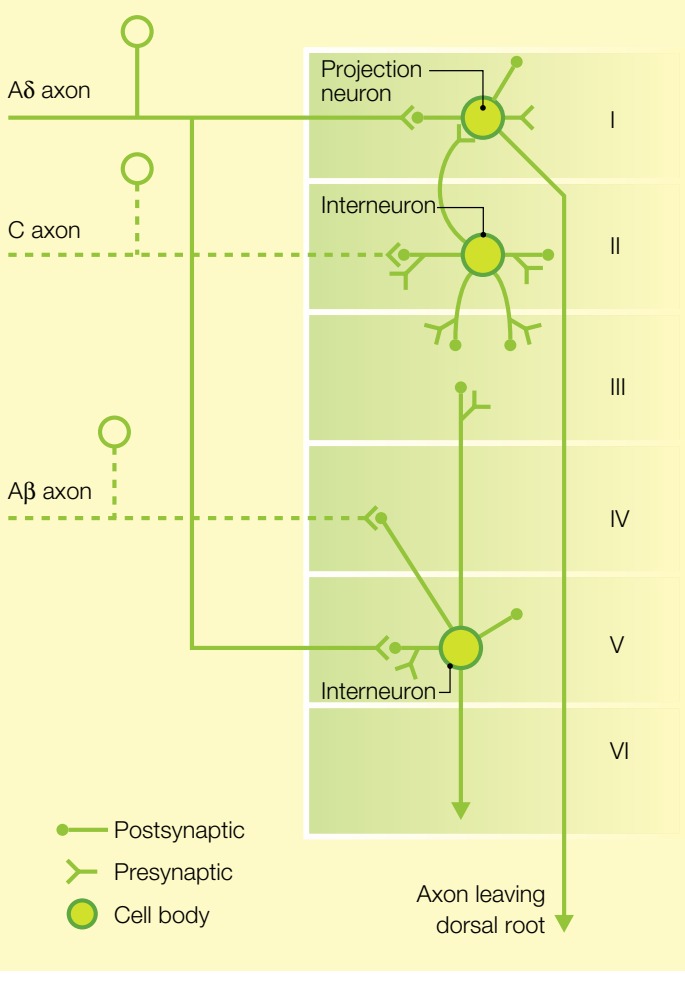
Cervicothalamic tract originates in laminae III and IV of the dorsal horn, projects to the lateral cervical nucleus, crosses the midline and ascends the median lemniscus to the midbrain and thalamus.

Spinohypothalamic tract originates in laminae I, V and VIII and projects to the supraspinal autonomic centres. It is implicated in cardiovascular control.

Dorsal horn

Without anaesthesia, the dorsal horn of the spinal cord is dominated by inhibitory activity (Figure 2). Light anaesthesia can cause disinhibition in the dorsal horn, altering the dynamic ranges of the neurons involved in nociception. Deep anaesthesia reduces the descending, neuromodulatory input into the dorsal horn from higher centres, and can lead to disinhibition of spinal reflexes. 'Industrially' (rather than pharmacologically) deep levels of general anaesthesia in animals lead to spontaneous movement, presumably by elimination of all spinal inhibition, so that reflexes in response to even the slightest noxious stimulus are not adequately damped.

Neurology of the dorsal horn



2

Pain is not experienced in the spinal cord. The spinal cord receives nociceptive input and then gates and relays this on to higher centres where pain is perceived.

There are two types of nociceptor fibre (axon), both of which enter the dorsal horn. Fast Aδ fibres are thinly myelinated and conduct action potentials at 5–30 m/s. They are primarily responsible for the transmission of information regarding thermal and mechanical noxious stimuli. Slow C fibres are unmyelinated, and therefore conduct action potentials in the much slower range of 0.5–2.0 m/s. They are polymodal, transmitting information relating to a wide range of noxious stimuli. The nociceptive fibres bifurcate at the dorsal horn of the spinal cord, with Aδ fibres innervating laminae I and V, and C fibres innervating lamina II (Figure 3). Both Aδ and C fibres initiate the release of glutamate (causing fast synaptic potentials) and neuropeptides (e.g. substance P, causing slow synaptic potentials).

Types of fibres innervating laminae I–VIII

Lamina	Fibres	Significant function
I	Aδ	Nociceptive-specific neurons projecting to higher brain centres Wide dynamic range neurons responding to non-noxious and noxious mechanical stimuli Thermoreception
II	C fibres	Respond to noxious and non-noxious stimuli Interneurons
III	Aβ	Non-noxious stimuli, topographically mapped Thermoreception
IV	Aβ	Non-noxious stimuli, topographically mapped Low threshold mechanoreception Thermoreception
V	Aβ, Aδ, C	Nociceptors, local interneurons, visceral fibres Thermoreception
VI	Aα	Non-noxious proprioceptors (movement detectors)
VII	C	Bilateral polysynaptic nociceptors
VIII	C	Nociceptors

3

There are different populations of nociceptive (and related) neurons with cell bodies in the dorsal root. The laminae contain more than one type of cell, the borders of the laminae are not precise, and the inputs and responses of the neurons are not fixed.

Polymodal nociceptors respond to high intensity heat or cold, mechanical or chemical stimulation. They have slowly conducting (less than 1 m/s) unmyelinated C fibres.

Thermal nociceptors respond to temperatures greater than 45°C and less than 5°C. Mechanical nociceptors respond to heavy pressure on the skin. Both thermal and mechanical nociceptors have myelinated Aδ axons that are narrow in diameter and conduct action potentials at 5–30 m/s.

Free nerve endings in muscle encode noxious stimuli, and terminate in laminae I and V–VI. In the cornea, Aδ and C fibres encode mechanical stimuli, whereas C fibres encode thermal stimuli. In tooth pulp, Aδ fibres encode dentinal noxious stimuli and C fibres respond to external irritants.

Large diameter Aβ fibres are involved in the modulation of the nature of pain, even though the noxious stimuli actually stimulate receptors with C fibres. Temporary anoxia, as a result of prolonged inflation of a blood pressure cuff on the arm, results in the sensation of burning pain to stimuli that would normally be distinguished as individual pinpricks. This is because the Aβ fibres are more metabolically active than C fibres, and fail to conduct action potentials during such anoxia whereas the C fibres continue to function. The loss of Aβ fibres prevents proprioception and touch stimuli from being relayed to the dorsal column, so the perception of pain is distorted.

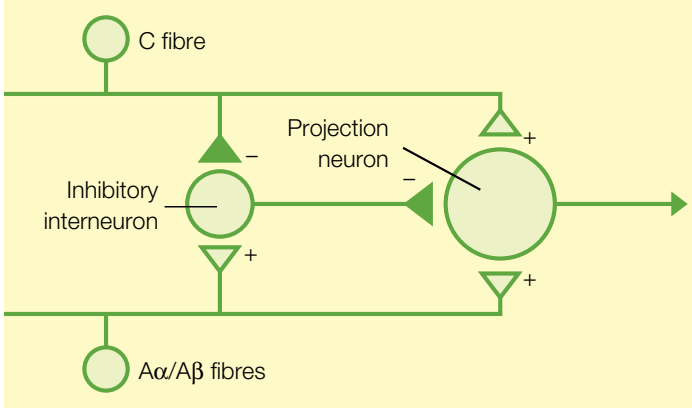
Central mechanisms

There is no central pain centre in the brain. However, functional imaging using positron emission tomography (PET) has demonstrated that emotional responses to a painful stimulus occur only with activation of the anterior cingulate cortex; lesions in the anterior cingulate reduce anxiety caused by pain. Areas S1 and the parietal operculum are important for judging the position and intensity of painful stimuli. The thalamus is vital for relaying information about noxious stimuli to these higher centres.

Neuromodulatory systems

Neuromodulation of the response to noxious stimuli at the level of the dorsal horn of the spinal cord is via descending monoaminergic neurons, originating in the raphe magnus nucleus of the medulla, and noradrenergic neurons, originating in the pons. Other, non-serotonergic interneurons in the medullary reticular formation probably also play a role in the descending neuromodulation of noxious response. The gate control hypothesis explains the modulation of nociception in the spinal cord (Figure 4). Important neurotransmitters in the dorsal horn are L-glutamate, adenosine triphosphate (ATP; causes fast depolarization), substance P (causes slow depolarization) and neurokinin A. Endogenous opiates (dynorphins and enkephalins) are found in the superficial dorsal horn. They may enhance or inhibit nociception; naloxone administered to the superficial layers of the dorsal horn can reduce the response to noxious stimuli, whereas naloxone in deeper layers can enhance the effect of nociceptors.

Modulation of nociception in the spinal cord by the gate control mechanism



The inhibitory interneuron is spontaneously active and would normally inhibit the projection interneuron, which transmits the nociceptive information to central regions that represent it as pain. Stimulation of Aα/Aβ fibres usually encoding the output from proprioceptors during movement or transcutaneous electrical nerve stimulation (TENS) results in excitation of the inhibitory interneuron which then blocks or 'gates' the input of slower nociceptive information from the C fibres

Visceral pain

Noxious visceral stimuli are conducted via both the sympathetic nerves leading to the spinal cord and the parasympathetic vagus nerves leading to the brainstem. The sympathetic nociceptive input ascends via the spinothalamic tract to the posterior thalamus. The parasympathetic nociceptive pathway is via the solitary nucleus of the medulla oblongata and on to the posterior thalamus and anterior cingulate. Functional imaging has shown that angina pectoris activates the hypothalamus, periaqueductal grey, thalamus and left anterior cingulate cortex.

The viscera have silent nociceptors, the activity of which is modulated by inflammation and chemical stimuli. Visceral afferents can continue to conduct noxious stimuli via the vagus nerves even in the presence of epidural or spinal blockade. The vagal nerves give a bilateral route straight into the medulla oblongata of the brainstem from organs such as the heart, stomach and lungs. 80% of vagal neurons are sensory, and most are slowly conducting C fibres. Vagal sensory input is associated with feelings of nausea. In addition, the burning sensation of tracheal intubation or use of a bronchial catheter can be abolished by blocking sensory fibres in the vagus nerve. Most of the sensory fibres of the vagus terminate in the nucleus tractus solitarius, which is rich in peptide neurotransmitters.

Sensitization and hyperexcitability

Sensitization occurs when, after repeated applications of a noxious stimulus, nearby nociceptors also start to transmit. This results from the presence of substances such as histamine, bradykinin and prostaglandins from the injured tissues. Aspirin is an effective analgesic because it blocks the function of the enzyme cyclooxygenase, thereby preventing the synthesis of prostaglandins. Central sensitization occurs in the dorsal horn after severe injury, whereby repeated C-fibre activity releases the excitatory neurotransmitter glutamate. Glutamate opens N-methyl-D-aspartate (NMDA) receptors and causes hyperexcitability in dorsal horn neurons, leading to hyperalgesia. Spontaneous pain and a lowered threshold for pain can both result from this wind-up of sensitivity. Phantom limb pain is an example of central sensitization, especially after amputation under general anaesthesia but with no spinal or local blockade, since the dorsal horn is still active and experiences the full nociceptive input of the amputation, leading to sensitization.

Neuropathic pain

Neuropathic pain is perceived after injury to nervous tissue, and is usually characterized as a burning or electric sensation. There are three specific classifications of pain that many have classified as 'neuropathic'.

Neuritis describes pain resulting from inflammation of a peripheral nerve. Inflammation of a nerve root is termed radiculoneuritis or radiculitis. Inflammation of the spinal cord is myelitis. The inflammation can result from a number of causes, including infection, nerve damage and toxins. Neuritis is usually acute. Treatments generally include rest and cooling of the affected region for the first few hours, followed by heat.

Neuralgia is centrally generated pain referred topographically to the periphery. An example is trigeminal neuralgia, in which repetitive, uncontrolled and abnormal firing of neurons in the trigeminal nucleus results in a referred pain.

Neuropathy: during neuropathy the axon or surrounding myelin sheath is damaged to such an extent that normal nerve conduction is disrupted or prevented. An example is seen in the last stages of shingles, after neuritis, when the sensory nerves have been permanently damaged. Transection of dorsal root nerves to block chronic pain can lead to anaesthesia dolorosa (pain without sensation) due to damage to the nerves. Diabetic neuropathy seldom results in pain, but can do if sensory fibres are damaged, which is more common in juvenile-onset diabetes.

Influence of therapy on nociceptive mechanisms

The gate control theory explains many mechanisms underlying therapeutic analgesia. Stimulation of fast fibres responsible for conveying non-nociceptive information 'close' neurological gates in the dorsal horn. Slow nociceptive afferents open these gates in the absence of non-nociceptive input. Vibration in the painful region activates fast proprioceptors that close the gates, preventing slower nociceptor input from reaching interneurons projecting to the brain.

Electrical stimulation of the brain, especially in the midbrain periaqueductal grey region, can induce profound analgesia. Stimulation in this region specifically reduces pain, while leaving the inputs from other sensory systems intact. This system works by stimulating descending interneurons that inhibit nociceptive neurons directly or via interneurons, in laminae I and V of the dorsal horn. The descending pathway projects from the periaqueductal grey region to the nucleus raphe magnus and other serotonergic nuclei, and then on to the dorsolateral funiculus and the dorsal horn. There are additional descending projections to the spinal cord from noradrenergic nuclei such as the locus ceruleus of the pons, and the nucleus paragigantocellularis.

Transcutaneous electrical nerve stimulation (TENS) has been used successfully as a treatment for pain. It is thought that it stimulates fast fibres that block the nociceptor input from being referred to higher centres.

Opioids

Opioid agents have the same central analgesic effect as electrical stimulation; morphine produces analgesia by activating the same descending pathways, and its effect is antagonized with injections of naloxone into the periaqueductal grey or nucleus raphe magnus. Transection of the descending pathways at the dorsal lateral funiculus also antagonizes stimulation and morphine-induced analgesia.

The three major classes of opiate receptor are μ, δ and κ. μ opiate receptors are found in high concentrations in the periaqueductal grey, the ventral medulla oblongata, and the superficial dorsal horn of the spinal cord. They are also widespread in the central and peripheral nervous system. Three endogenous opiates are known to bind to these receptors: enkephalins (leucine and methionine) bind to μ and δ receptors; dynorphin binds to the κ receptor; β-endorphin is primarily found in neurons of the hypothalamus that innervate the periaqueductal grey and noradrenergic nuclei of the brainstem. In addition to μ, δ and κ receptors, a nociceptin (QFQ/N1–17) receptor has also been identified, and is implicated in nociceptive, behavioural and physiological function.

Symptoms, other than analgesia, associated with the systemic use of opioids, such as constipation or respiratory depression can be explained by the presence of opiate receptors in the gut and medulla oblongata of the brainstem.

Spinal or epidural injection of opioids mimics the action of endogenous opiates and effectively closes the pain 'gates' so that nociceptive stimuli are not relayed via projection neurons to the CNS. Opioids decrease the duration of the action potential of nociceptors by influencing the calcium channels. This reduces the amount of neurotransmitter (e.g. glutamate and substance P) released at the synapses of the nociceptor. Opioids also hyperpolarize dorsal horn neurons by activating K^+ channels; opioids therefore reduce the amplitude of excitatory postsynaptic potentials.

Opioid receptors are also found on peripheral nerve terminals of skin, muscle and joints, but the source of endogenous opiates that target these receptors is unclear. Chromaffin cells of the adrenal medulla may be a source of these opiates, because they migrate to the source of injury during inflammation of tissue.

Spinal cord anatomy and blood supply

The adult spinal cord is about 50 cm long and occupies a volume of about 150 ml. The spinal cord extends to the second lumbar vertebra, below which the lower nerve roots extend. The anterior spinal artery supplies the ventral spinal cord and three spinal arteries supply the dorsal spinal cord. At its most rostral point, the anterior spinal artery is fed by the joining of two branches of the vertebral artery. Distally, segmental arteries of the aorta and iliac arteries feed the anterior and posterior spinal arteries via radicular arteries. The posterior spinal arteries are contiguous. The anterior spinal artery is not contiguous and depends on segmental supply, especially in the upper thoracic region. This anatomy leads to characteristic infarcts due to occlusion of the posterior spinal arteries affecting the territory of the anterior spinal artery. The anterior spinal artery produces sulcal arteries that enter left and right halves of the spinal cord alternately, leading to Brown-Séquard syndrome after infarct with characteristic ipsilateral weakness and contralateral loss of sensation to noxious stimuli and temperature. Damage to the corticospinal tracts alone leads to paraparesis or quadriparesis and loss of sensations of pain and temperature below the site of the lesion. If the dorsal columns are intact, proprioception and sensations of touch are maintained (Figure 5).

Effects of spinal cord section

Indicators of motor level lesions

Root	Major muscles	Reflex
Cervical 3–5	Diaphragm	
Cervical 5	Deltoid, biceps	Biceps
Cervical 7	Triceps, extensors of wrist and fingers	Triceps
Cervical 8	Interossei, abductor fifth finger	
Lumbar 2–4	Quadriceps	Knee jerk
Lumbar 5	Long extensors of great toe, anterior tibia	
Sacral 1	Plantar flexors, gastrocnemius	Ankle jerk

Indicators of sensory level lesions

Root	Sensory area
Cervical 4	Clavicle
Cervical 8	Fifth finger
Thoracic 4	Nipples
Thoracic 10	Umbilicus
Lumbar 1	Inguinal ligament
Lumbar 3	Anterior thigh
Lumbar 5	Big toe
Sacral 1	Lateral foot
Sacral 3–5	Perineum

Complete transection causes immediate trauma with the loss of voluntary movement and feeling below the level of the section. Bladder and bowel control is lost, but may become automatic after time. Normal tendon reflexes are absent as a result of spinal shock, which may recover over several weeks. Clonus (a rapid and repeated contraction of passively stretched muscle) is observed, as well as the Babinski sign, in which a pencil drawn from back to front over the plantar surface of the foot elicits an abnormal movement away from the direction of stimulus.

Partial transection – hemisection of the spinal cord (Brown-Séquard syndrome) causes ipsilateral loss of touch, vibration and positional sense and contralateral loss of noxious stimuli and temperature. Syringomyelia, in which cysts form in the central portion of the spinal cord, first affects nociception and temperature sensitivity, then when the cysts enlarge, touch and position sense are affected.

CSF

The choroid plexus generates about 700 ml of CSF per day. It travels in a predominantly one-way route from the ventricles, around the spinal cord, and into venous sinuses, and this removes metabolites from the CNS. The brain floats in CSF, reducing its weight *in situ* to about 50 g, and acting as a physical shock absorber against impact with the calvarium. The CSF allows peptide hormones to travel from the hypothalamus to other regions in the brain and the CNS. About 150 ml of CSF circulates in the brain and spinal cord.

CSF is usually clear and colourless and does not contain erythrocytes (Figure 6). Increased concentrations of leukocytes or protein make CSF look cloudy, and white cell counts above 4/mm^3 are abnormal. A bloody or yellow appearance (xanthochromia) occurs if the protein content exceeds 150 mg/dl or after a haemorrhage owing to the presence of bilirubin in the CSF. In multiple sclerosis, the γ-globulin content increases as a result of immunoglobin production within the CNS to comprise more than 13% of the total protein of CSF. Protein content greater than 500 mg/dl indicates a compressing lesion blocking the spinal subarachnoid space.

Comparison of typical CSF with serum

Component	CSF	Serum
Water (%)	99	93
Protein (ml/dl)	35	7000
Glucose (mg/dl)	60	90
Osmolarity (mOsm/litre)	295	295
Na^+ (meq/litre)	138	138
K^+ (meq/litre)	2.8	4.5
Ca^{2+} (meq/litre)	2.1	4.8
Mg^{2+} (meq/litre)	0.3	1.7
Cl^- (meq/litre)	119	102
pH	7.33	7.41

Source: Kandel E R, Schwartz J H, Jessell T M, eds. *Principles of Neural Science*. London: Elsevier, 2000.

CSF pressure can be measured by lumbar puncture from the lumbar subarachnoid space between the fourth and fifth lumbar vertebrae. Normal pressure is 65–195 mm H_2O or 5–15 mm Hg.

Senses

Sensory receptors

A typical sensory receptor cell consists of a selectively sensitive transducer and a high gain amplifier, contained within some form of structure to protect the receptor and amplify the stimulus. Sensory receptors are the interface between the environment (both external and internal) and the CNS. All that we see, hear, touch, smell and taste, along with our internal indications of balance and chemical environment, are represented as a result of a translation from energy into graded membrane potentials in sensory receptors.

The simplest receptors are free nerve endings responding to chemical agents. The most complex are involved in vision, where electromagnetic radiation is transduced into chemical electrical energy. In all sensory receptors, the greater the magnitude of an appropriate sensory stimulus, the greater the resultant amplitude of the receptor potential. Large excitatory receptor potentials result in a greater frequency of action potentials.

There are two main types of sensory receptor. Primary receptors generate action potentials within the receptor that propagate along axons into the CNS. An example is a stretch receptor within a muscle spindle. Secondary receptors generate graded receptor potentials that sum by reception of neurotransmitter by an interneuron. This causes some synaptic delay but allows for integration and modulation of the signal. Rods and cones in the retina are examples of secondary receptors.

Sensory receptors filter the environment into separate channels of information that can be perceived. For example, the concept of red, green and blue as individual colours is a perceptual classification of electromagnetic wavelengths. The fact that humans cannot see infra-red or ultra-violet radiation does not stop them from being useful visual wavelengths for other species.

The time taken to translate environmental stimuli from energy into perceived events is neither instantaneous nor consistent for different sensory modalities. The visual evoked potential (VEP) is the averaged electroencephalograph (EEG) response to thousands of visual stimuli. The first major peak of the VEP occurs 100 ms after a flash stimulus, and originates in the primary visual cortex (area V1) at the back of the brain. The primary visual cortex comprises different types of interneurons sensitive to the direction, thickness, width, velocity, colour and binocular disparity of everything seen. This means that everything seen is delayed by at least a tenth of a second from reality. Area V1 is only an early stage of visual processing, because the information from the retina and lateral geniculate nucleus contains raw, largely unprocessed visual information, and the completed cognitive response to a visual event occurs 300 ms after a stimulus. The auditory evoked potential (AEP) is faster than the VEP, indicating that sounds evoke a response in the primary auditory cortex about 40 ms after the stimulus. Resolving this difference in the temporal characteristics of different sensory inputs is a major task for the brain, which has to bind these varied virtual impressions together to make an internal projection of the world. Disorientation at recovery from anaesthesia, and with the use of hallucinogenic agents, can be partly explained by the partial breakdown of binding between these sensory inputs.

Visual system

Humans perceive colour because they have three different receptors in the retina (cones), peaking at 420 nm (blue), 531 nm (green) and 558 nm (red) wavelengths. Cones require more light to function than do rods, which are responsible for encoding light intensity. This explains why colour is not perceived at low light intensities; the colour is still reflected by objects, but is not perceived. Rods also exhibit more neural convergence in the retina, therefore they amplify the effect of available light at the cost of visual acuity, in contrast to the cones. The human retina is about two log units less sensitive to blue light than to red or green. Normal colour vision is trichromatic. About 5% of the male population exhibits congenital deuteranomaly, with an abnormality in the green cone pigment. 1.3% exhibit protanomaly, with abnormal red cone pigment, and 0.001% exhibit tritanomaly (blue cone pigment anomaly).

Increasing depth of anaesthesia progressively disrupts the visual system. It removes the ability of the visual cortex to process complicated visual information, including the texture of an object.

Auditory system

Auditory stimuli are encoded as a result of vibrations of frequency-tuned hair cells in the cochlea. The hair cells are paired and joined by a thin fibre that mechanically opens and closes ion channels in the hair cells as they move. The auditory information is relayed along the cochlear nerve and progressively through brainstem nuclei to the auditory cortices of the brain. Anaesthesia increases the time taken to process auditory information and reduces the magnitude of the AEP. Brainstem responses to auditory stimuli often remain during surgical levels of anaesthesia, meaning that patients can still potentially hear during surgery. Whether the auditory stimuli are perceived appropriately is unknown.

Other receptors

Temperature receptors are the simplest type of receptor in skin, being free nerve endings in the dermis and deeper epidermis. They adapt to stimuli slowly. Thinly myelinated Aδ fibres (1–5 µm in diameter, conducting at 5–30 m/s) encode cooling or pricking noxious stimuli. Unmyelinated C fibres (0.2–2 µm in diameter, conducting at 0.5–2 m/s) encode warming, burning and itching stimuli. If high temperatures damage the free nerve endings, they can release bradykinin, which results in a sticking or jabbing pain.

Mechanoreceptors function by distorting the cell membrane pulling an ion gating protein against an anchoring site within the neuron, such as a more rigid part of the cytoskeleton. The distortion affects the bias of the opening and closing frequency of the ion gate; stretch receptors can be activated or deactivated by distortion, and can be specifically permeable to potassium, calcium, sodium or chloride ions. Receptors such as the carotid sinus or hair cells in the ear can transduce structural distortion using such stretch mechanism. Cell swelling due to changes in osmolarity can also trigger stretch-activated or stretch- inactivated channels.

Osmoreceptor cell bodies are located in the hypothalamus, with axons leading to the pituitary. Osmoreceptors encode changes in the osmolarity of blood, and secrete the hormones oxytocin and vasopressin to modulate plasma osmolarity.

Olfactory receptors initiate a second messenger cascade, that eventually opens cyclic nucleotide-gated ion channels and depolarizes the olfactory cell membrane, and can elicit action potentials when enough channels are opened. ◆

The Pancreas

Garry Tan

Garry Tan is an MRC Clinical Research Fellow and Specialist Registrar in diabetes, endocrinology and metabolism at the Radcliffe Infirmary, Oxford.

The pancreas weighs 70–100 g, yet secretes 1000 g of pancreatic fluid daily. Most cells in the pancreas have an exocrine function, manufacturing digestive enzymes. A small proportion of pancreatic cells (about 1 million) are aggregated into small clusters (tens of cells to several thousand cells) and are scattered throughout the exocrine cells. These aggregations, the islets of Langerhans, contain at least four different cell types (Figure 1) which are densely innervated with autonomic and peptidergic nerves. Despite accounting for only 2% of the mass of the pancreas, the islets receive 10% of the pancreatic blood flow.

Pancreatic islet cell secretion

Cell type	Proportion of islets cells	Peptides secreted	Anatomical distribution
α	25%	Glucagon (GLP-1, GLP-2)	Within islets throughout the pancreas with a preference for pancreatic tail and body
β	60–70%	Insulin, c-peptide (islet amyloid peptide)	Within islets throughout the pancreas
δ	5–15%	Somatostatin 12 and 14	Within islets throughout the pancreas
PP	2%	Pancreatic polypeptide polypeptide (and small amounts of gastrin)	Within islets throughout the pancreas with a preference for posterior portion of the head Also found in acini

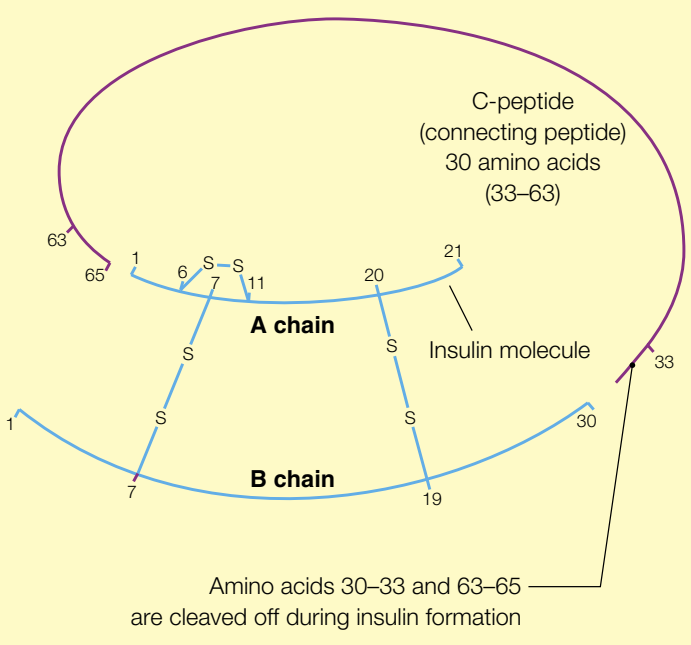
1

Endocrine pancreas

Insulin and c-peptide

Insulin is a polypeptide consisting of two peptide chains, A and B, linked by two disulphide bridges (Figure 2). It is synthesized as preproinsulin, a precursor of insulin. Preproinsulin is cleaved in the endoplasmic reticulum to form proinsulin which is itself cleaved in the Golgi apparatus, to form insulin and c-peptide. These are stored in granules in the β-cell cytoplasm to await secretion. Glucose is one of a number of stimuli that can cause β-cell degranulation and insulin release. In order for glucose to do this, it must first be metabolized; glucose enters the β-cell via the GLUT-2 glucose transporter and is phosphorylated by the enzyme glucokinase (this is the rate-limiting step of islet glucose use). The resulting glucose-6-phosphate undergoes glycolysis to produce ATP. The ATP-sensitive K^+ channels in the cell membrane close, causing membrane depolarization. This causes a calcium influx into the cell as calcium channels open. This leads to granule exocytosis and insulin (and c-peptide) release. Insulin and c-peptide are released into the circulation in equimolar amounts. Insulin circulates as unbound monomers, in contrast to its state before release from the secretory granule, when it forms insulin hexamers around a core of two zinc molecules (pharmaceutical preparations of insulin are based on crystalline zinc insulin).

Insulin



2

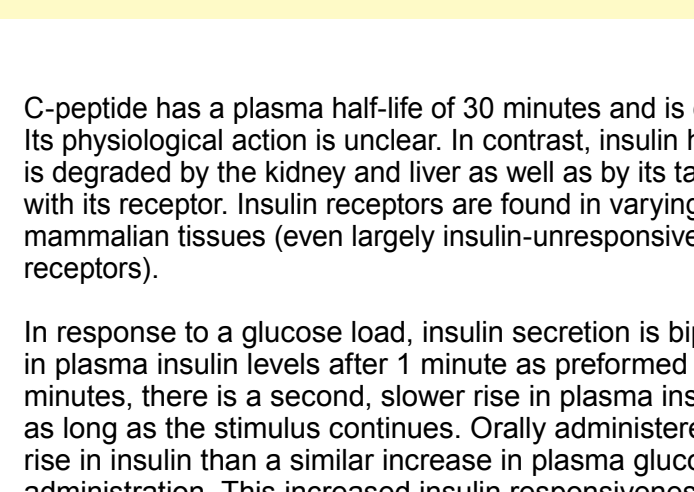
C-peptide has a plasma half-life of 30 minutes and is excreted unchanged by the kidneys. Its physiological action is unclear. In contrast, insulin has a half-life of 4 minutes and is degraded by the kidney and liver as well as by its target cells where it is internalized with its receptor. Insulin receptors are found in varying concentrations on virtually all mammalian tissues (even largely insulin-unresponsive red blood cells possess about 70 receptors).

In response to a glucose load, insulin secretion is biphasic: there is a sharp peak in plasma insulin levels after 1 minute as preformed insulin is released. After 5–10 minutes, there is a second, slower rise in plasma insulin levels which continues for as long as the stimulus continues. Orally administered glucose induces a greater rise in insulin than a similar increase in plasma glucose achieved by intravenous administration. This increased insulin responsiveness is partly due to the production of glucagon-like peptide 1 (GLP-1) and gastric inhibitory peptide (GIP) which also act as insulin secretagogues (stimulators of insulin secretion). Amino acids are insulin secretagogues and act synergistically with glucose. The levels of ketoacids found in fasting can also promote insulin secretion. Factors affecting insulin release are shown in Figure 3.

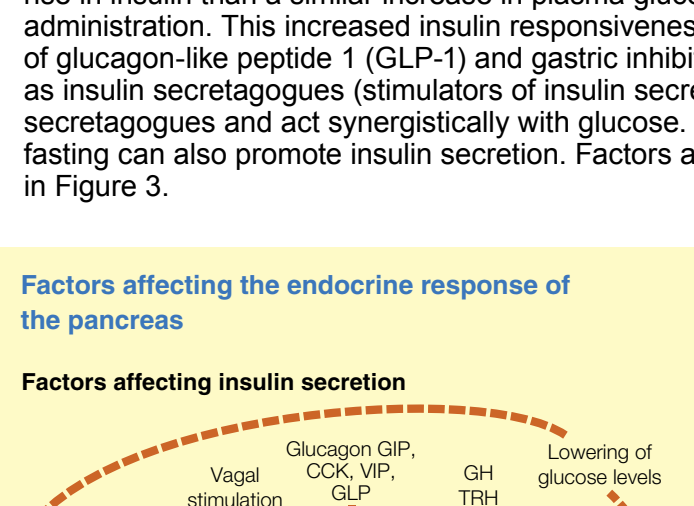
Factors affecting the endocrine response of the pancreas

Factors affecting insulin secretion

Factors affecting glucagon secretion



Factors affecting somatostatin secretion



ACTH, adrenocorticotrophic hormone; CCK, cholecystokinin; GH, growth hormone; GLP-1, glucagon-like peptide 1; GIP, gastrointestinal peptide; NEFA, non-esterified fatty acids; TRH, thyroid releasing hormone; VIP, vasoactive intestinal peptide

3

After binding to its receptor at the cell surface, insulin causes rapid shifts in the fluxes in various metabolic pathways by the activation or deactivation of enzymes at critical steps. It also leads to alterations in gene expression (e.g. inducing glucokinase gene expression) thus reinforcing the metabolic shifts.

Insulin promotes the storage of excess nutrients while inhibiting mobilization of endogenous substrates. It is required for the entry of glucose into most cells, particularly muscle (skeletal and cardiac) cells. The brain and red blood cells are exceptions in which glucose diffuses down a steep concentration gradient into these cells. Insulin also stimulates glycogen formation from glucose in muscle and liver while simultaneously inhibiting glycogen breakdown in the liver. This produces a reduction in the intracellular concentration of glucose in hepatocytes. Glucose diffuses into hepatocytes down this gradient through the GLUT-2 transporter. In contrast, insulin actively enhances glucose uptake into myocytes and adipocytes by inducing GLUT-4 expression (another specialized plasma membrane glucose protein transporter – the only one to be induced by insulin).

In adipose tissue, insulin inhibits mobilization of intracellular triglycerides by uppressing hormone-sensitive lipase activity. Because of this, circulating non-esterified fatty acid (or free fatty acid) levels fall. The resulting fall in their delivery to the liver causes a decrease in their β-oxidation and hence a decrease in the production of ketone bodies.

Other effects of insulin include an anabolic effect on protein metabolism and the promotion of potassium, phosphate and magnesium uptake into muscle cells. The renal tubular reabsorption of potassium, phosphate and sodium is increased. The insulins of different animals differ slightly in their amino acid sequence but have identical biological actions.

Glucagon

Glucagon is a 29 amino acid peptide produced from proglucagon in α-cells. Proglucagon is also synthesized in the gut where it is processed differently to produce GLP-1. The factors affecting glucagon secretion are shown in Figure 3; the stimulating and suppressing factors interact. For example, the suppression of glucagon production by high glucose concentrations is potentiated in the presence of insulin. Despite this, plasma glucagon levels vary less than plasma insulin levels.

Glucagon promotes mobilization rather than storage of fuels, particularly glucose, maintaining normoglycaemia in the presence of an increased glucose demand. Glucagon binds to a hepatic membrane receptor and prompts a cascade of intracellular events involving cAMP as a second messenger, to activate or to deactivate a number of enzyme kinases or phosphatases. The net result is a rapid increase in glucose production from glycogen breakdown, in tandem with a decrease in glycogen synthesis from glucose. Similarly, hepatic gluconeogenesis (e.g. from lactate, pyruvate, amino acids such as alanine) is increased while glycolysis is decreased. Glucagon also diverts incoming non-esterified fatty acids from triglyceride synthesis to β-oxidation, leading to ketogenesis. Hepatic cholesterol synthesis is also suppressed as hepatic hydroxymethylglutaryl CoA reductase is inhibited by glucagon.

Other actions of glucagon include activation of myocardial adenyl cyclase, increasing the cardiac output. It also causes natriuresis by inhibiting renal tubular resorption. In adipose tissue, glucagon also increases hormone-sensitive lipase activity.

Somatostatin
Somatostatin is produced as prosomatostatin which is processed to produce a 14 amino-acid peptide variety of somatostatin (SS14). Prosomatostatin is also produced in intestinal cells but is processed differently to form a 28 amino-acid product (SS28). Within the islets, SS14 is a potent inhibitor of insulin, glucagon and pancreatic polypeptide secretion. SS28 decreases gastric, duodenal and gall bladder motility and gastrointestinal secretions, thus enabling nutrient input to be co-ordinated with substrate disposal.

Islet amyloid peptide
Islet amyloid peptide (amylin) is a 37 amino-acid peptide. It is regulated in a similar fashion to insulin. It accumulates in β cells with age and its accumulation is further increased in type II diabetes mellitus. Its physiological role is unclear.

Pancreatic polypeptide
Pancreatic polypeptide is a 36 amino-acid peptide secreted in response to feeding or hypoglycaemia. It is regulated by the autonomic nervous system. Its physiological role is unclear.

Coordination of insulin and glucagon action
The pancreatic endocrine products act in concert to regulate the metabolism of glucose, non-esterified fatty acids, amino acids and other substrates (Figure 4). As insulin and glucagon usually have antagonistic effects, the direction of substrate fluxes through the metabolic pathways is partly determined by the insulin:glucagon ratio. The usual molar ratio is 2:1, but it changes to 1:2 when mobilization of endogenous substrates is required, such as during fasting or prolonged exercise. The change in the ratio is caused by a simultaneous decrease in insulin secretion and an increase in glucagon secretion, promoting glycogenolysis and gluconeogenesis in the liver and lipolysis in adipose tissue, as well as increasing the flux of non-esterified fatty acids to the liver for β-oxidation.

Effects of insulin and glucagon on metabolism

	Insulin	Glucagon
Liver		
Glycogen synthesis	+	–
Glycogenolysis	–	+
Gluconeogenesis	–	+
Glycolysis	+	–
De novo lipogenesis	+	–
Non-esterified fatty acid oxidation	–	+
Protein catabolism	–	+
Muscle		
Glycogen synthesis	+	
Glycogenolysis	–	
Glucose uptake	+	
Protein synthesis from amino acids	+	
Adipose tissue		
Glucose uptake	+	+
Lipolysis	–	

In the postprandial state, the insulin:glucagon ratio can rise to more than 10:1, primarily because of increased insulin secretion. This ensures increased glucose uptake along with oxidation and storage of glucose as glycogen in muscle and liver. Adipose tissue lipolysis by hormone-sensitive lipase is suppressed; postprandially non-esterified fatty acids are not required.

The endocrine activity of the pancreas is regulated by a variety of factors as well as glucose (Figure 3). For example, while parasympathetic activity stimulates insulin and glucagon secretion, sympathetic activity increases glucagon but decreases insulin secretion. The response of the pancreas depends on the predominating influence. For example, in minor injury, the glucose levels are raised and the insulin levels elevated appropriately. In contrast, in a more serious injury, when there is marked sympathetic activation and the circulating adrenaline levels are elevated, the insulin secretion is not as high as might be expected for that degree of hyperglycaemia.

Exocrine pancreas

The secretory units of the exocrine part of the pancreas are groups of cells, known as acini, surrounding the ends of small ducts. These ducts feed into a centrally located pancreatic duct which drains into the hepatic duct and from there into the duodenum. The acinar cells secrete a fluid rich in digestive enzymes, which can digest proteins, carbohydrates, nucleic acids and fat. In general, these digestive enzymes are secreted as proenzymes. The epithelial cells lining the ducts secrete water and bicarbonate ions. This alkaline pancreatic juice (pH 8) neutralizes the hydrochloric acid from the stomach and provides the optimal conditions for the digestive enzymes to function. The pancreatic juice contains the highly active pancreatic amylase which digests starch and glycogen in the small intestine to di- and tri-saccharides.

Proteins are cleaved to smaller peptides by trypsin and chymotrypsin. Trypsin is the most abundant protease secreted. Carboxypolypeptidase further divides the peptide fragments into their constituent amino acids. Pancreatic proteases are secreted in an inactive form and are activated in the duodenum. Enterokinase, a membrane-bound intestinal enzyme activates trypsinogen to its active form, trypsin. Trypsin activates procarboxypolypeptidase and chymotrypsinogen. To prevent pancreatic autodigestion, the acinar cells also produce ‘trypsin inhibitor’. This prevents activation of trypsinogen in the secretory cells and in the ducts of the pancreas.

Protein and carbohydrate breakdown occur in various parts of the gastrointestinal tract. In contrast, fat digestion occurs only in the small intestine as the pancreas is the only source of intestinal lipase (pancreatic lipase). Pancreatic amylase and lipase are secreted in their active forms.

DNA and RNA are hydrolysed to their nucleotide monomers by pancreatic nucleases.

Pancreatic exocrine secretion is regulated by a number of factors that are part of the response to food of the gastrointestinal tract. Acid from the stomach causes S cells in the duodenal and upper jejunal mucosa to release secretin which causes the secretion of pancreatic fluid and bicarbonate. Secretin causes virtually no pancreatic enzyme secretion.

Stimuli such as long-chain fatty acids and peptides in the duodenum cause the release of cholecystokinin from the I cells of the duodenum and upper jejunal mucosa. Cholecystokinin stimulates the acinar cells of the pancreas to increase digestive enzyme secretion.

Both secretin and cholecystokinin pass from the upper gastrointestinal tract to the pancreas by the blood stream.

Vagal stimulation (and acetylcholine secretion by the enteric nervous system) causes the pancreas to secrete digestive enzymes (though few reach the gastrointestinal tract because vagal stimulation causes the pancreatic fluid secretion to ‘wash’ the enzymes along the pancreatic duct). Vagal stimulation can occur during the cephalic phase or as a result of the presence of food in the stomach.

It is important to emphasize that these stimuli of pancreatic secretion usually occur in concert and exert a multiplicative effect on one another. The response of the pancreas to

Physiology of Ageing

Michael A Horan

Michael A Horan is Professor of Geriatric Medicine at the University of Manchester. His research interests include responses to, and recovery from, injury in the ageing and the genetics of cognitive change.

The processes that underlie the changes of biological ageing affect all tissues, organs and systems to some extent. As a general rule, functions most critical for survival exhibit the least marked changes, whereas systems that are less critical may show marked changes (Figure 1). Ageing processes alone are benign and seldom threaten life. Of more concern are the interactions between ageing changes and co-morbid factors, which may not be immediately apparent. This contribution focuses on the systems of most relevance for a practising anaesthetist.

The newer drugs available for anaesthesia and effective physiological monitoring, make anaesthesia extremely safe for older people, provided they are medically stable at the start of the procedure. Greater threats to homeostasis derive from the nature of the surgical procedure, the abilities of the surgeon and the quality of postoperative care and monitoring.

The World Health Organization classifies those aged 65–75 years as 'young elderly', those aged 75–85 years as old, and those over the age of 85 years as the 'oldest old'. As a rule, the young elderly are physiologically similar to younger age groups and most changes of clinical relevance occur in those aged over 75 years.

Some ageing changes expressed as a percentage of young adult values

Little change

- Body temperature
- Body fluid pH
- Resting heart rate
- Pa_{O_2}

60–70% change

- Maximum heart rate
- V_{O_2} max
- Resting cardiac output
- Renal blood flow
- Urine-concentrating capacity

1

Cardiovascular system

The ECG is a sensitive screening tool for heart disease in older people. Prevalence rates of 5–20% have been reported; the highest rate occurring in the oldest men, and the lowest in the youngest women. Most abnormalities suggest underlying coronary artery disease. Atrial fibrillation is the most common dysrhythmia, and occurs in 1–5% of old people. Hypertension is common in older people, and the prevalence is 20–25% at the age of 70 years. The prevalence of valvular heart disease in the general elderly population is uncertain, but it is the third most common cause of heart failure (after ischaemic heart disease and hypertension).

The ability of the myocardium to generate force does not decline with ageing, though both contraction and relaxation are prolonged by 15–20%. Healthy older people have ejection fractions of 50–75%. The changes in contractility caused by ageing are related to cellular changes in the excitation–contraction coupling mechanism, and may be an adaptation to sustain contractility in the face of an increasing afterload.

Afterload increases modestly with age, in association with a decreasing arterial compliance. Thus, systolic blood pressure and pulse pressure tend to increase with age. Diastolic pressure also tends to increase, but to a lesser extent. The left ventricle reactively hypertrophies to reduce the wall stress imposed by the elevated afterload. Decreased ventricular compliance and impaired diastolic relaxation reduce early diastolic filling (a passive phenomenon) and old people depend on late filling, mainly from atrial contraction. Thus, they tolerate rapid heart rates from any cause poorly, and atrial tachydysrhythmias particularly poorly.

Responsiveness to β-adrenergic stimulation declines with age (as a result of decreased receptor numbers and function), despite age-related increases in circulating catecholamine concentrations. However, responses to α-adrenoreceptor activation are unimpaired. Thus, the ability to increase cardiac output by increasing heart rate is attenuated, and the old become more reliant on the Starling mechanism. Even with relatively mild circulating blood volume reduction, cardiac output can fall precipitously in some older people, and therefore is to be avoided.

Respiratory system

Changes in respiratory function are caused by ageing and external factors. In some populations, overt respiratory diseases are common.

Alveolar surface area is reduced by loss of alveolar septa and disruption of alveolar walls. Static elastic recoil falls, resulting in an increase in lung compliance. However, this is offset by reductions in chest wall compliance and chest mobility and, in some, kyphoscoliosis. Thus, there is no overall change in total lung capacity but there is a fall in respiratory system compliance, which increases the work of breathing. Several studies have shown age-related reductions in peak expiratory flow rate, forced expiratory volume in 1 second and forced vital capacity, even after adjusting for loss of height, reduced muscular effort and the change in lung compliance.

Changes in lung ventilation and perfusion with age show that compensatory mechanisms operate. Closing volume increases with age as a result of the loss of elastic recoil, with reduced lower lobe ventilation. Physiological dead space increases and greater ventilation–perfusion mismatch occurs. This is partly compensated for by increased upper lobe blood flow, but overall, diffusion capacity falls. The Pa_{O_2} is about 9 kPa in those aged 70–80 years.

Reductions in ventilatory drive have been reported, but other age-related changes could explain the fall in ventilation for any given level of ventilatory drive. Even measurements of mouth occlusion pressures (which avoid the limitations of volume measurements) show conflicting results. The precise effects of ageing on ventilatory control, including the regulation of breathing during sleep, have yet to be determined.

Reduced respiratory sensation has been reported in older individuals, which may have clinical implications for the awareness of the severity of asthma attacks. Small studies have reported a reduced ability to detect added elastic and resistive loads, but studies with hypercapnia suggest increased respiratory sensation. As the perception appears stimulus-specific, it suggests that central processing mechanisms are preserved.

Kidney

The reserve capacity of renal function far exceeds the usual demands of young people and the decline in function with ageing adequately meets needs under normal circumstances, though it may be challenged by a variety of stressors or deteriorations in other systems. In the young, the kidneys compensate for all but the most incompetent fluid regimens, but this is not the case in many older people.

The changes observed in the elderly may represent an accumulation of toxic insults as much as the effects of ageing per se. The interactions between changes in multiple systems is well demonstrated in the ageing kidney, which is subject to simultaneous changes in the nervous, cardiovascular and endocrine systems. Also, any disorder modifying renal blood flow (e.g. hypertension, atherosclerosis) will manifest as renal dysfunction.

Both renal plasma flow and glomerular filtration rate (GFR) decline with age in many people. Plasma creatinine is not a reliable indicator of GFR in the old because owing to a fall in muscle mass with age, reduced GFR is often unaccompanied by a rise in plasma creatinine. Acid–base balance is maintained in an unstressed state, but the old have a reduced ability to excrete an acid load, possibly because of defective tubular secretion of ammonium ions.

Concentration of urine in response to water deprivation is impaired in the elderly, possibly because of a reduced number of nephrons to deal with an increased solute load, or the increased perfusion of medullary glomeruli producing medullary washout. The response to water loading is also impaired, but the underlying mechanisms are unclear. Studies with water loading have demonstrated both normal and reduced vasopressin responses, and salt loading has demonstrated normal and exaggerated vasopressin responses. Renal salt conservation on a low salt diet is markedly delayed. The sensation of thirst, despite marked elevations in osmolality, is impaired through uncertain mechanisms.

CNS

The effects of ageing on the CNS are numerous. Major changes include progressive loss of neurons in the grey matter and in major neurotransmitter synthesizing areas. There is modest white matter atrophy and increased CSF volume. The modest reductions in blood flow in the brain seem to be related to reduced metabolic demand rather than to the vasculature per se.

The activities of several neurotransmitter systems are reduced (e.g. adrenergic, noradrenergic, dopaminergic, cholinergic) but not the serotoninergic system. The number, density and binding affinity of cell surface receptors for dopaminergic, β-adrenergic and serotoninergic agonists are also reduced.

Touch and pain thresholds tend to rise with advancing age. However, afferent pain stimuli undergo marked central processing in the spinal cord and thalamus, therefore it should not be assumed that pain perception and the need for analgesia are reduced in the old.

Drug effects: the pharmacokinetics and pharmacodynamics of almost all drugs used in anaesthesia change with ageing, leading to a lower dose requirement, though inter-individual variation is marked. The old are sensitive to drugs with anticholinergic properties, which often explains postoperative delirium. Delayed recovery from anaesthesia is not uncommon with traditional barbiturates and narcotics, probably explained by age-related pharmacokinetic changes. This problem has reduced with the increasing use of agents such as althesin, propofol and desflurane, the kinetics of which are less vulnerable to ageing changes.

Peripheral and autonomic nervous systems

Between young adulthood and the age of 80 years, there is a progressive decline in motor and sensory nerve conduction velocities of about 40%. Conduction velocity in long spinal tracts is well maintained until late middle age but declines rapidly thereafter.

There is also a progressive loss of cell bodies in the spinal cord, which is a major determinant of muscle fibre loss and an increased size of motor units. There are subtle changes at motor end plates as well as an increase in extrajunctional receptors. These extrajunctional cholinergic receptors have a reduced affinity for agonist and respond more slowly after agonist binding. Overall, the dose requirement for competitive non-depolarizing neuromuscular blockers tends to increase with ageing.

The sensitivity of the baroreflex declines rapidly in early adult life, and then more slowly into advancing age. The so-called carotid sinus syndrome (which is common in old age) probably has little to do with true baroreflex sensitivity. The baroreflex is intimately affected by chemoreceptors in the carotid body and in the medulla. Old people do not readily demonstrate tachycardia in response to hypoxaemia, hypercapnia and respiratory acidosis.

Principles of Control Mechanisms

James Waterhouse

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Sciences, Liverpool John Moore's University. He qualified as an animal physiologist and gained his doctorate at the University of Oxford.

Man, like all other living organisms, is involved in a continuous struggle to survive not only the rigours and vicissitudes of the environment, but also the biochemical and physiological consequences of any activities. For example, ambient temperature changes, as does the drying effect of wind speed and humidity; there are changes in the provision of energy for metabolism following eating or fasting; and there are changes in the distribution and amount of blood required by different tissues during exercise – followed by other physiological changes such as temperature, water content and pH.

Enzyme-mediated processes work only within a restricted range of pH, temperature and ion concentration, and it therefore becomes necessary to preserve the internal environment despite the surroundings. This was recognized about 150 years ago by Claude Bernard and, about 70 years ago, Cannon introduced the term 'homeostasis' to describe this principle.

Variation between and within individuals

If any biochemical or physiological variable is measured on several occasions in the same individual, it is found to vary. These changes can arise from differences in the environment and from an individual's recent activities. For these reasons, it is necessary to standardize the conditions before a measurement is taken. For some variables, the previous effects of lifestyle and the environment take a long time to wear off (e.g. the increase in haematocrit that follows training at altitude) while for others, there is a regular and reproducible daily change in value due to the activities of a 'body clock' (e.g. the blood level of cortisol).

When more than one healthy individual is studied inter-individual variations are found. It then becomes important to determine if a particular individual falls within the normal range associated with health. A normal value is one that falls inside a range that encompasses 95%, or some other proportion, of the population.

Even if homeostatic control processes are operating on the variable being controlled, it continues to show changes, but they are within a narrower range than would exist without such control. For example, whether people are asleep or exercising, core body temperature does not normally move outside a range of 35–40°C even though they might be in an environment that is hotter or much cooler than this range. Homeostatic processes therefore limit the range shown by a variable and control its mean value.

Spontaneous corrections of some changes

Many changes that normally occur in the body tend to correct automatically without the need to invoke special control mechanisms. If systems in equilibrium are disturbed, changes occur spontaneously to minimize the disturbance.

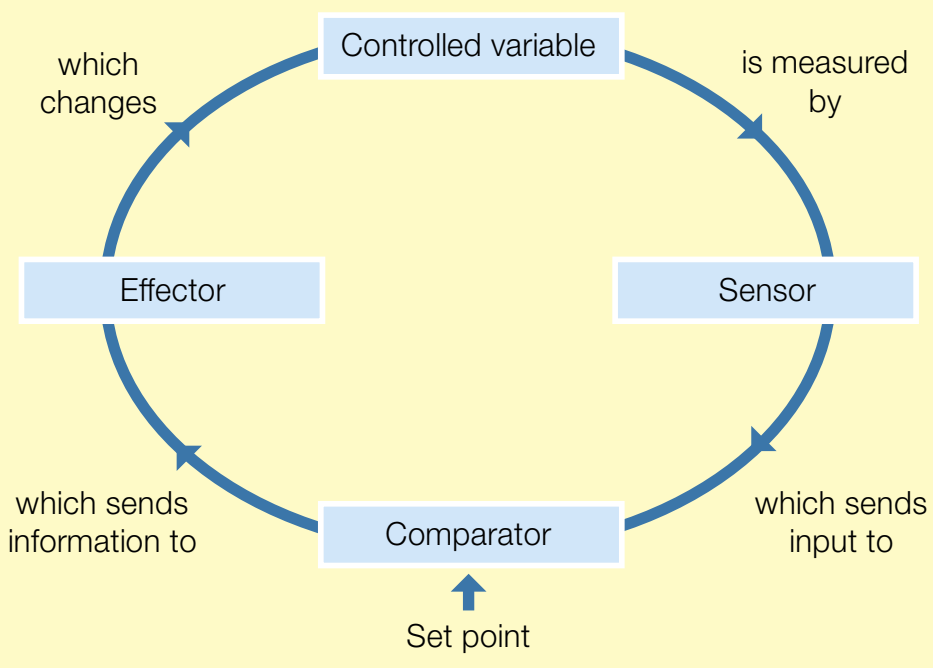
- Consider the delivery of oxygen from the RBC to an active tissue, a process that normally shows a dynamic equilibrium between its different stages. Increased oxygen use by the tissue lowers the concentration of oxygen in the tissue, and this causes oxygen to diffuse more quickly down the increased concentration gradient between the RBC and the tissue; in this way, more oxygen is delivered to the active tissue. Such changes reduce the concentration of oxygen inside the RBC, so upsetting the original equilibrium that existed between free oxygen, reduced haemoglobin and oxyhaemoglobin in the cell; therefore, more oxyhaemoglobin breaks down, so reducing the fall of free oxygen. In such a dynamic system, any initial disturbance results in further changes throughout the system that reduce the initial disturbance.
- Enzymes greatly speed up the rate of attainment of equilibrium in biochemical systems. The kinetics of enzyme activity are such that the rate at which the enzyme-mediated reaction occurs increases if the amount of substrate increases.
- The rate at which sodium is pumped out across the cell membrane is increased if the concentration of sodium ions in the intracellular fluid increases.
- The rate at which a reaction takes place (in order to regain equilibrium) can be considered as a function of the amount of disequilibrium present at that moment. If blood urea rises above normal then more will be filtered by the kidneys and, because urea moves passively, more will be lost in the urine; the greater the rise of blood urea above normal, the greater the rise of urea excretion in the urine above normal.

These examples illustrate that there are widespread mechanisms by which changes away from an equilibrium position can be reversed without the need for special biological reflexes. However, there would be serious problems if these were the only mechanisms involved. One difficulty arises because there would be no control over what the equilibrium would be. On a hot day, for example, the body would equilibrate at a value that was too high for optimal enzyme activity, and on a cold day at too low a value. Also, after a meal, the whole body would equilibrate with glucose levels that were too high, and during fasting the equilibrium value would fall progressively. There is therefore a need for mechanisms that can control a variable at a value determined by physiological and biochemical considerations rather than one influenced by the surrounding environment. The second difficulty with such mechanisms is that, as equilibrium is approached, the response becomes progressively less; deviations from the equilibrium value can be corrected only slowly. Therefore, although the above mechanisms are widespread and important, there must also be mechanisms for controlling the organism independently of the environment and for correcting any errors more quickly. These control mechanisms involve feedback loops.

Feedback loops

The principle of feedback control is widely used in engineering (from which much of the terminology is derived), and is often illustrated by reference to the temperature of a thermostatically controlled water bath. In this system, the temperature of the water in the bath (the controlled variable) is continuously monitored by a thermometer (the sensor), which sends a signal to a comparator (Figure 1). As its name suggests, the comparator compares the signal from the sensor with a pre-set value (the set point). If the signal from the sensor falls below this pre-set value (the temperature of the water has fallen), the comparator sends a signal to switch on a heater (the effector or controller). As a result, the water temperature rises and the original disturbance is corrected. The sequence of events is called a feedback loop, because it is initiated by a change (in water temperature) and results in another change (to the water temperature). There are negative and positive feedback loops.

Feedback loop



Negative feedback loops are the backbone of homeostasis. In negative feedback (Figure 1), the initial disturbance initiates changes that negate the original effect. If the initial disturbance in Figure 1 had been a rise in water temperature, a negative feedback loop would have initiated a cooling process. The action of a negative feedback loop is to stabilize the controlled variable.

Positive feedback produces changes in the same direction as the initial disturbance. This accentuation of the disturbance acts as a further stimulus to change brought about by the loop. The end result is an increasing change that is limited only by the maximum values that can be achieved by the components of the loop, or by the initiation of some opposing mechanism once a threshold has been reached. There are few examples of positive feedback in human physiology, but they are important.

- Oxytocin release is promoted by the pressure of the fetus on the cervix; this hormone promotes uterine contraction thus increasing the stimulus for oxytocin secretion. The end-point is the expulsion of the fetus from the uterus.
- Many gut enzymes are secreted in an inactive form. A small amount of breakdown of this inactive enzyme in the gut produces an active form which, among other actions, promotes breakdown of more of the inactive form into the active one; this process is known as autocatalysis.
- At the onset of inspiration, a group of neurons begin to fire, this promotes activity of the inspiratory muscles and inhibits the firing of expiratory neurons. This activity of the inspiratory neurons also promotes their own firing rate and that of other inspiratory neurons. The result is that, once started, inspiration rapidly takes over from expiration (the same system exists for expiratory neurons and the process of expiration).
- During the rising phase of the nerve action potential, sodium influx across the nerve membrane increases and this causes a depolarization of the cell membrane. In turn, this causes the voltage-gated sodium channels to begin to open, thus increasing sodium influx and a further opening of the gates. This 'explosive' process causes the sodium channels to open quickly – the permeability of the cell membrane to sodium increases over a thousand-fold in under 1 millisecond.

Types of feedback mechanism

In the example of the water bath, the heater was either on or off, with no intermediate state; such systems are described as discontinuous. They are less common in physiological control systems where many processes show continuous or tonic activity.

The above examples of positive feedback can be considered as discontinuous systems, with an action potential, expulsion of the fetus, respiratory neuron activity and enzyme activity not being required all the time, but being brought into action when necessary. When called into action, they must work quickly and effectively (this is where positive feedback is so valuable) and the term 'all-or-none', which is applied to the action potential, could also be applied to the other situations.

Discontinous systems in biology can also show negative feedback, but they seem to be more of an 'emergency' system.

- The clasp-knife reflex is initiated by Golgi tendon organs when the tension in muscles and tendons threatens to become damagingly high. The receptors have a high threshold (they are ineffective in normal movements), but when they do become effective, they inhibit the muscle contraction, so relieving the tension and acting as part of a negative feedback loop.
- Sweating is used when the heat load on the body is too high for it to be controlled by changes in cutaneous vascular tone alone.

Set point

The set point is the value towards which the feedback loop regulates the controlled variable. The set point in a discontinuous negative feedback system is the threshold at which the system is turned on (e.g. the tension in the Golgi tendon organs or the core temperature when sweating starts).

The concept of a set point cannot be applied so easily to a positive feedback system. However, positive feedback mechanisms are initiated when, for example, sodium influx across the nerve membrane is sufficient to cause the voltage-gated sodium channels to begin to open or when the neuro-physiological state that causes inspiratory (or expiratory) neurons to begin to fire is reached.

The set point of a continuous negative feedback system is an important concept, and requires the comparator and set point elements of Figure 1 to be replaced by an integrator. This component of the loop is normally found in the CNS and can be an assemblage of structures. Its role is to integrate the inputs from the various sensors and then to send a signal to the effector systems. Figure 2 shows how the set point can be determined.

The set point exists when the two parts of the feedback loop balance each other. If the value of the controlled variable differs from this set point, then the two arms are not in equilibrium and the feedback loop will initiate changes that continue until this equilibrium is re-established.

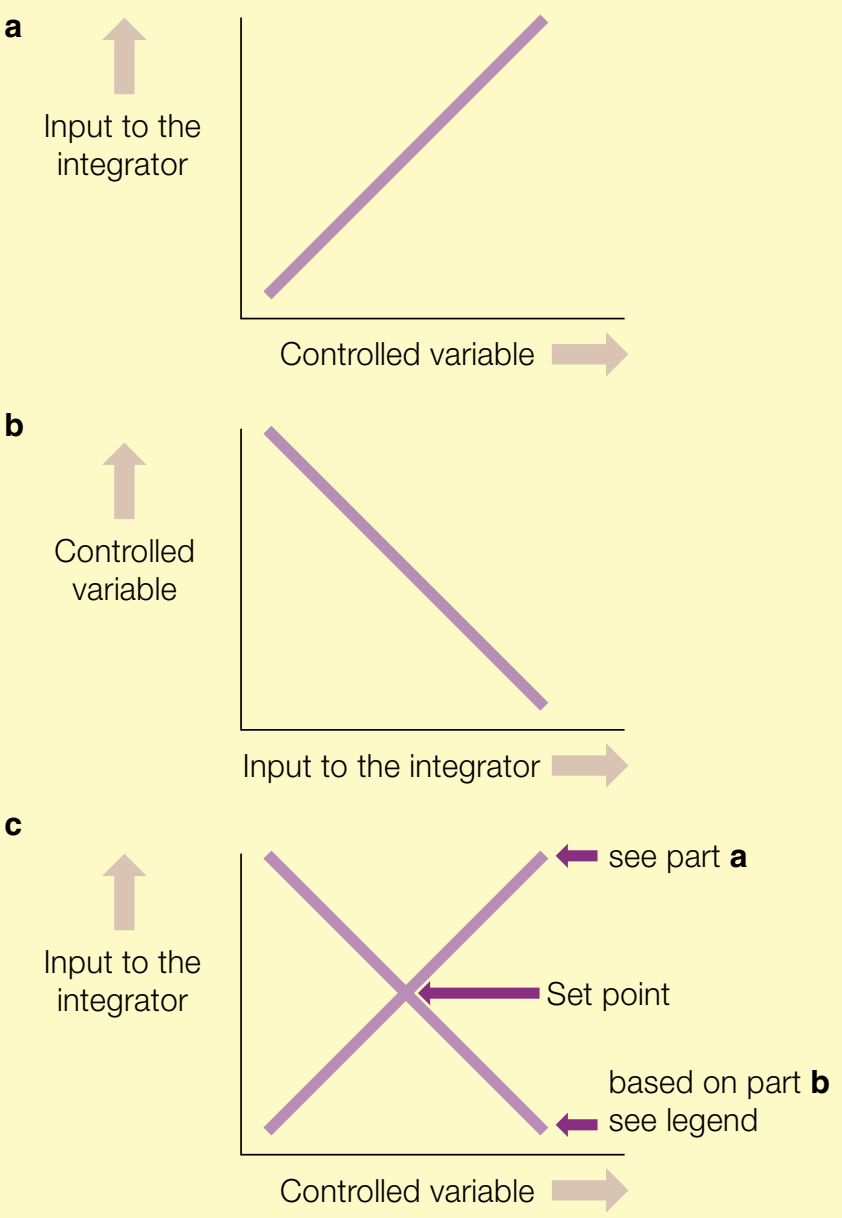
The crossover point (Figure 2) can be altered by changes to the gradient or intercept of either line; biologically, this means by changes in the properties of the sensor, the central integrator and/or the effector mechanisms. It can become (see later) the mechanism by which alterations to the controlled variable are brought about both in health and in physiological disorder.

Oscillation

Even though a variable is controlled by a negative feedback mechanism, its value is not constant, and it oscillates (though this does not mean that it is caused by an oscillator) within a band of values. It is desirable that these deviations from the set point, often referred to as 'errors', should be as small as possible. There are three main causes of oscillation in negative feedback systems.

The 'store' of the variable being controlled: in the control of body water, if the store of water is large, then any inbalance between intake and output will produce only a small proportional change in the overall store, its value will move away from the set point comparatively slowly, and there will be more time to correct the error. By contrast, with a smaller store, the proportional change and the consequent rate of movement of the controlled variable away from the set point will be more rapid, with less time available to correct the error before it becomes life-threatening. This would pose a problem to babies.

Determining the set point



a Part of the feedback loop shows a direct relationship between the value of the controlled variable and the input to the integrator. **b** Because it is a negative feedback loop, the other part of the loop (which starts with the input to the integrator and ends with the changes to the controlled variable produced by the effector systems) shows an inverse relationship. **c** Since the two parts of the loop work are connected and have the same elements (controlled variable and input to the integrator), this can be represented by combining the graphs. The graph of **b** has been reflected and rotated clockwise by 90° before superimposition on **a**. The cross-over point is the set point of the loop

2

Sensitivity of the components of the feedback loop: the feedback loop relies for its operation on a sensor that can measure any change in the controlled variable, and integrator and effector mechanisms that can readily respond. If the sensitivity of any component of the loop were too low, then the error would have to become large before compensatory changes were initiated. Problems can arise in babies (in whom many mechanisms are not fully developed), and in old people (in whom mechanisms are deteriorating).

To increase the sensitivity of the feedback loop to error might seem a good solution, particularly since the initial deviation of a controlled variable from the set point is small; with an increased sensitivity, it might be argued, small errors would be dealt with more rapidly. To an extent this is correct, but too high a sensitivity of a feedback loop can also cause oscillation. The oscillation arises because a small error initiates too large a correction response, and so the error becomes one in the opposite direction; this, in turn, initiates a correction in the opposite direction, which also causes the controlled variable to overshoot, and so on.

Delay in the response to an error can be illustrated by attempts to take a shower. Supposing that the water is too cold, the dial controlling the water temperature is turned towards hot. Because there is a delay between doing this and the warm water coming out of the shower, the dial is turned too far towards hot; eventually the water becomes too hot. There is then a tendency to turn the dial too far towards cold, and after a delay, the water is once again too cold, and the cycle begins again. Some computer games require movements of a joystick to track a moving target; if there is a delay between moving the joystick and producing a movement, it can become difficult to perform the task successfully, because there is a tendency to over-correct any error and initiate oscillation around the target.

Neural feedback loops, such as the stretch reflex in muscles, tend to suffer less from this cause of oscillation, because the delay in the feedback loop is small. In hormonal feedback loops, oscillation due to the slower timing of a response is more likely. This is not only due to the time it takes for the secretion by a gland to build up to a sufficient concentration in the whole of the extracellular fluid, but also because, after a reduction of hormone secretion, it takes time for the hormone that has been released to be removed by metabolism.

Minimizing problems

Many of the above problems are minimized in healthy adults. Some of the mechanisms involved are described below.

Multiple and opposing systems: a variable is seldom controlled by a single feedback loop; instead, there are generally several loops acting in parallel, sometimes in opposite directions and with different time courses. The short-term control of blood pressure is through the interaction of loops involving the sympathetic and parasympathetic nervous systems. They tend to have opposite effects on blood pressure, and also act at several sites (heart, arterioles and venules) and by more than one mechanism (inotropic and chronotropic effects on the heart). The longer-term control of blood pressure involves several hormones that modify salt and water balance. Several hormones are involved in the control of metabolism; between them they promote the metabolism or storage of glucose, or its production from carbohydrate stores or non-carbohydrate sources, and the storage of fatty acid in adipose tissue or its mobilization from this tissue in preparation for its metabolism.

Dynamic sensitivity of sensors: the problem that an error in a feedback loop is initially small can be overcome if the sensor shows dynamic as well as static sensitivity. Dynamic sensitivity is sensitivity to the rate of change of the variable, and it differs from static sensitivity, which measures the actual value of the variable. When an error first arises, even though it is small, the rate at which it is changing need not be small. A sensor with dynamic sensitivity can send a large signal to the integrator as soon as an error appears. Many sensors show dynamic sensitivity, including the baroreceptors and the stretch-receptors in muscles.

Disturbance detectors: so far we have considered sensors that are an integral part of the feedback loop insofar as they are responsible for directly measuring the controlled variable; they are sometimes called ‘error detectors’. However, another type of sensor is found called a ‘disturbance detector’. Even though such a sensor is not a direct part of the feedback loop (and so would not appear in Figure 1), it sends information to the loop, generally to the integrator. Its effect is to give warning of changes that will, in due course, alter the controlled variable.

- A well-known example is in thermoregulation where the error sensors are in the bloodstream (and measure hypothalamic temperature), but the disturbance detectors are in the skin (the cutaneous thermoreceptors). As a result of inputs to the hypothalamus from the disturbance detectors, sweating starts as soon as an individual is placed in a hot environment, and shivering as soon as he is in a cold one.
- Another example is the release of gut hormones that affect metabolism, which occurs soon after eating a meal but before most of the food has been absorbed.

In both the above examples, the disturbance detector enables the feedback loop to initiate changes before the disturbance has produced an ‘error’ in the controlled variable.

- A third example is the sensation of thirst. We feel thirsty because of dehydration and the raised osmotic pressure of the blood acts on osmoreceptors in the hypothalamus. Several effects are produced including the sensation of thirst and secretion of antidiuretic hormone (ADH), which reduces further water loss by the kidneys. After drinking about the amount of water required to correct the osmotic pressure of the blood, the sensation of thirst is abolished, even though the water has not been absorbed and the osmotic pressure of the blood is still raised. The inhibition to drink comes from volume receptors in the stomach and from other inputs originating from the mouth and oesophagus; these can be considered to be acting collectively as a disturbance detector which indicates that, after absorption of the water, the osmotic pressure will have been corrected.

Using feedback mechanisms to produce a controlled change

The set point or equilibrium value of the controlled variable in a negative feedback system can be controlled by altering the properties of its components (Figure 2). One case where this is normally done is in the performance of a controlled movement; the power for the movement comes from the α-motor units, but control comes from a modification of discharge of γ-efferents. The γ-efferents act on the muscle spindles to change their dynamic and static sensitivities. As a result, a new equilibrium point (crossover point in Figure 2) is achieved, and this causes the controlled contraction of the muscle to take up a new length. Similarly, the sensitivity of the chemoreceptors in the carotid body and aortic arch might be changed in exercise, so that ventilation can be increased without marked changes in the partial pressure of carbon dioxide and oxygen in the blood. Also, changes in the sensitivity of the integration component of a feedback loop during sleep, and circadian changes due to the body clock, can both result in changes in the set point of several variables (e.g. blood pressure, core temperature).

Changes in the sensitivity of some sensors can occur. For example, the declining elasticity of blood vessels with ageing, particularly those in the carotid sinus, can result in a decreased distension of this structure caused by the blood ejected at systole. This alters the sensitivity of this component of the feedback loop controlling blood pressure, and might contribute to the increase in blood pressure commonly found with ageing.

Interaction between neural and humoral control mechanisms

Humorally mediated reflexes are slower than, but not inferior to, neurally mediated reflexes; they play different roles. Consider the case of the changes in cardiac output that take place during exercise. Initially, the changes are mediated by neural influences on the heart and the vasculature. However, to maintain a high rate of firing of the sympathetic nervous system would be uneconomical from the viewpoint of the metabolic energy required by the sodium–potassium exchange pumps in the cell membrane of the nerve cells. The secretion of catecholamines by the adrenal medulla, itself brought about by sympathetic discharge, can provide an alternative way of maintaining stimulation of the cardiovascular system; it has the added benefit that, as a blood-borne hormone, it can exert its effects throughout the body. In this way, there can be an increase in blood flow to the vasculature of the skeletal muscles, a decrease in blood flow to the gut and kidneys, and a dilatation of the airways depending on whether the tissue contains mainly α- or β-adrenoreceptors.

Similarly, at the start of a meal, the secretion of saliva needs to be immediate, and is neurally-mediated by the parasympathetic nervous system. As the food passes through the stomach and into the small intestine, the secretory processes (which now do not need to be initiated rapidly but need to be sustained for longer periods) are influenced more by hormonal activation.

In homeostasis, slightly different roles are played by the neurally and humorally mediated reflexes, as can be illustrated by the control of arterial blood pressure. In the short term, it is controlled by the neurally mediated baroreceptor reflexes acting via both branches of the autonomic nervous sytem. In the longer term, it is regulated by the hormonal control of the body’s water balance (by ADH) and sodium content (atrial natriuretic peptide and the renin–angiotensin–aldosterone axis).

It would be wrong to consider that neurally and humorally controlled systems tend to be separate, because of their different time courses; they act in parallel. One example is that of the thyroid gland and thermoregulation. Even though thermoregulation is achieved by a series of neurally mediated feedback loops, they act against a background of basal metabolism controlled by thyroid hormones. In cooler weather, there is an increase in secretions from the thyroid gland and these raise metabolic rate. In this way, it becomes less difficult for the thermoregulatory mechanisms to conserve heat.

This combination of fast-acting, neurally controlled and the slower-acting, hormonally controlled mechanisms requires some point of interaction so that the total response can be integrated. This interaction can be the result of innervation of an endocrine gland by the sympathetic nervous system, as with the islets of Langerhans and the adrenal medulla. In the case of the effects of stress on the release of oxytocin and ADH by the posterior pituitary, it is the fact that this part of the pituitary (the neurohypophysis) is composed of neurons.

However, the interaction between the neural and hormonal systems is most elaborate in hormones that come from the non-neural tissue of the anterior pituitary gland. That there is an interaction is established from the interaction between the thyroid gland and thermoregulation (see above), and from the disruption of the menstrual cycle caused by stress, to give two examples.

There are no neural connections to the anterior pituitary gland, but rather a humoral pathway through which releasing factors can travel from the hypothalamus via a portal system. The control of hormone release that occurs through a feedback loop – between a trophic hormone from the anterior pituitary gland, the endocrine gland and the hormone it secretes, and feedback of this hormone on to the anterior pituitary gland – can be modified by the effects of the releasing factors.

The secretion of these releasing factors is controlled by, among other factors, activity in the CNS. The effect of the releasing factor can be considered to be some form of disturbance detector and/or some mechanism for altering the sensitivity of one component of the feedback loop that exists between the pituitary gland and the target gland; whatever description is applied, there is a neuroendocrine integration that benefits the individual.

Protective Mechanisms of the Body

Peter J Wood

Peter J Wood is Lecturer in Immunology in the School of Biological Sciences, University of Manchester, UK. He obtained a BSc in pharmacology from Liverpool University and a PhD in immunology from London University. His research interests focus on immunological events in insulin dependent diabetes mellitus and in graft rejection.

The body is constantly exposed to environmental microorganisms (pathogens) that have the potential to infect and cause disease. Most pathogens have to enter the body to cause infection though a few (e.g. papilloma viruses, *Vibrio cholerae*) can cause disease without technically entering the body. Even pathogens that do not enter the body must be able to survive on the skin or a mucosal surface.

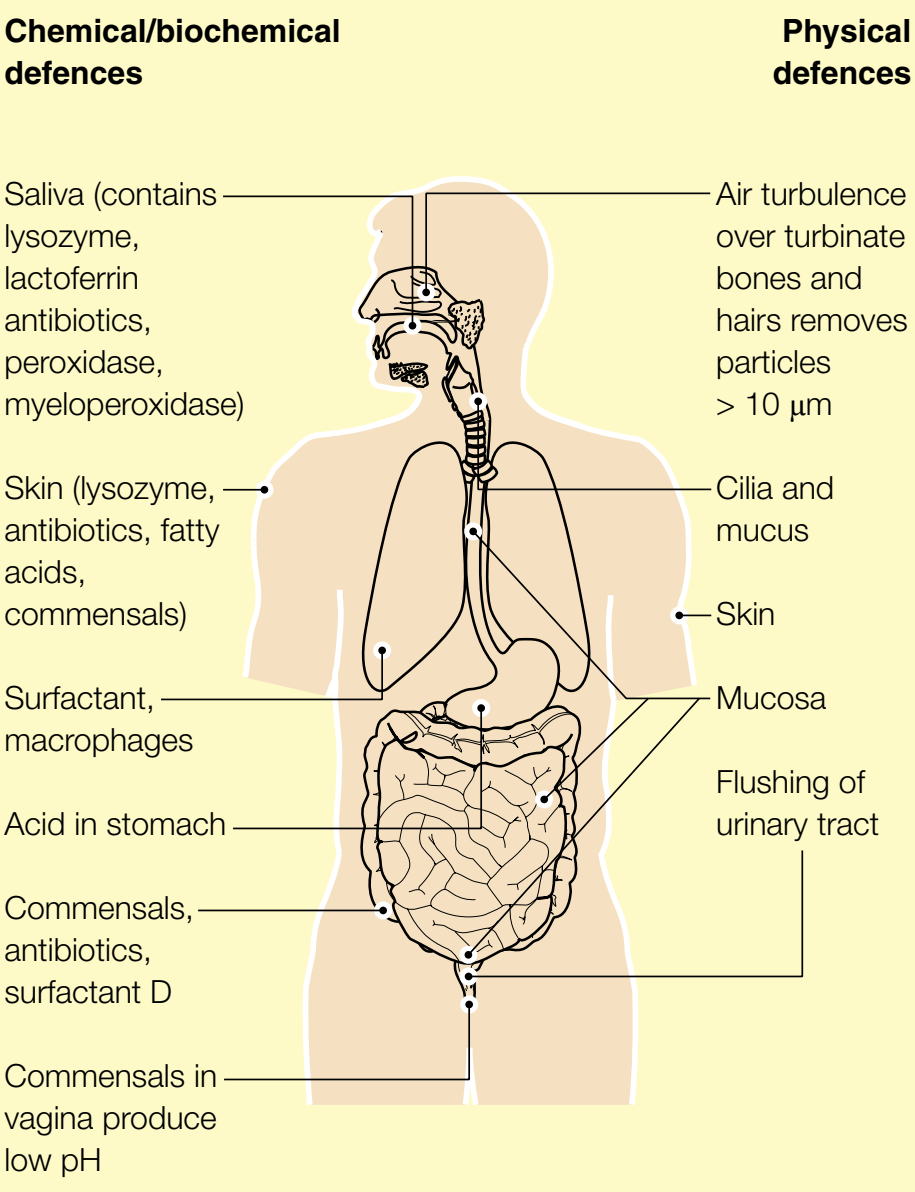
Individuals possess a number of physical, chemical and biochemical defence mechanisms designed to prevent infectious pathogens from gaining entry into the organism (Figure 1). They do this by physically preventing the entry of pathogens into the body, killing pathogens that are on the body surface, or inhibiting the replication of pathogens on the body surface.

Our understanding of protective mechanisms has undergone radical change in the past decade. Far from being primarily a physical barrier with a few fairly unsophisticated chemical and biochemical adjuncts to provide extra protection against bacteria, families of protective molecules are present in mucosal and skin secretions, which provide powerful defences against other types of pathogens, including viruses, fungi, yeast and protozoan and helminth parasites.

The relative importance of the physical, chemical and biochemical defences of the body is difficult to establish but is demonstrated by the following:

- damage to skin leads to increased risk of infection
- overuse of wide-spectrum antibiotics can result in elimination of commensal organisms and increased risk of infection
- use of alkaline douches that neutralize vaginal pH leads to increased susceptibility to infection.

Physical, chemical and biochemical defence mechanisms



1

Physical defence mechanisms

The outer layers of the body that interface with the environment are the skin and the mucosal surfaces of the gastrointestinal, respiratory and genitourinary tracts. Physical defence mechanisms consist of:

- physical barriers (the skin and mucosa)
- cilia (hair-like structures that line the respiratory tract)
- mucus (a viscous high molecular weight secretion).

Skin

The outer layer of the skin consists of dead cell layers containing keratin and lipid. This provides a relatively strong physical barrier compared with mucosal surfaces. Protection is also provided by the constant shedding of dead skin, which carries with it infectious organisms attached to the skin. Commensal organisms on the skin compete with pathogens for environmental niches and therefore limit occupation by pathogens. The most common commensal organisms are bacteria (e.g. *Staphylococcus epidermis*, *Staph. aureus*) and yeast (e.g. *Candida*).

The balance between commensal organisms and surface antimicrobial agents (e.g. lysozyme) is complex. Many commensal organisms are opportunistic pathogens and have the potential to cause disease. The mucosal surfaces and skin hold these potential pathogens in check, but if the balance is upset the commensal organism can cause disease (e.g. *Haemophilus influenzae* causes pneumonia if lung defences are compromised through damage).

Few pathogens can penetrate intact skin; those that can are usually parasites (e.g. schistosomal cercaria). Damage to the skin can allow the entry of pathogens. Mild abrasions may allow the entry of aerobic pathogens (e.g. *Staphylococcus*, *Streptococcus*), while deeper wounds, especially those involving crushing of tissue, provide an anaerobic environment suitable for pathogens such as *Clostridium* spp.

Mucosa

The role of mucosa is more complicated than that of skin because of the specialized nature of different mucosa. To enable it to fulfil its absorptive role much of the intestinal mucosa is a simple stratified epithelium. The respiratory epithelium is exposed to large volumes of potentially contaminated air and the alveoli must enable efficient gaseous exchange. Therefore, mucosa does not provide as strong a physical barrier as skin and is more vulnerable to infection. Many pathogens can enter the body through intact mucosal sites (Figure 2). However, the mucosae provide some physical protection in that the continuous growth and shedding of mucosal cells can remove pathogens in the same way as skin. Like skin, many mucosal surfaces harbour commensals that compete with pathogens for space and nutrients; the most extreme example of this is the intestine where the density of commensal organisms can reach a level of more than 10^{10} organisms per gram of tissue. Some mucosae, such as those of the lower respiratory tract and bladder are normally sterile.

Mucus, secreted by goblet cells, provides a physical trap for pathogens and other particles and contains many substances with antibacterial properties. Mucus consists primarily of mucins, which are macro-molecules of 200–2000 kDa with a peptide backbone and extensive O-linked carbohydrates. As the first stage of infection, most potential pathogens have to bind to mucins through interaction with the carbohydrate component; however, commensal microorganisms compete with pathogens for the mucin carbohydrate binding sites and thus provide protection.

Mucus is continually secreted on to the surface of mucosa, which produces a flow of mucus away from the epithelial surface, carrying microbial and other particles with it. The mucus is further propelled to the opening of the mucosal tract by peristalsis in the intestine or by the beating motion of the cilia in the respiratory tract which propels the mucus towards the throat where it is expelled or swallowed. This so-called respiratory elevator plays an important role in keeping the lower respiratory tract sterile and particle-free. Another specialized physical trap present in the alveoli is provided by pulmonary macrophages, which are able to phagocytose microorganisms and other particles that enter the lower respiratory tract; they may also secrete biochemical defence molecules.

Mucosal sites of entry for pathogens

Pathogen	Disease	Mucosal site of entry
Rhinovirus	Common cold	Nasal epithelium
Influenza virus	Influenza	Upper respiratory tract
Bordatella pertussis	Whooping cough	Lower respiratory tract
Salmonella spp.	Food poisoning	Small intestine
Entamoeba histolytica	Dysentery	Colon
Escherichia coli (some strains)	Urinary infection	Bladder, ureter
Neisseria gonorrhoeae	Gonorrhoea	Vagina, urethra

2

Chemical defence mechanisms

Various chemicals produced in the body kill pathogens or inhibit their growth. Hydrochloric acid in the stomach maintains a pH of 1–2, which is lethal for many bacteria. Sweat and sebaceous secretions contain lactic acid and fatty acids, some produced by commensal bacteria, that provide a pH of 5–6 on the skin and have antibacterial properties. Commensal bacteria in the vagina produce lactic and propionic acid from glycogen secreted by vaginal epithelial cells. The resulting pH of about 5 is acidic enough to inhibit the growth of other bacteria.

Biochemical defence mechanisms

It has been known for many years that secretions of the skin and mucosa contain biochemical agents that have antimicrobial properties. Recently, the discovery of animal and human antibiotic proteins and peptides has increased knowledge about the molecules that provide protection.

Lysozyme, lactoferrin and myeloperoxidase

Lysozyme is a powerful antibacterial agent found in sweat, tears and mucosal secretions. It is able to break down the peptidoglycan component of bacterial cell walls (Figure 3). Because the peptidoglycan component of Gram-positive bacteria is prominent and accessible, they are susceptible to lysozyme. However, in combination with lactoferrin, an iron-binding protein, lysozyme can also kill a number of Gram-negative bacteria. Lactoferrin is also thought to provide antibacterial action by binding iron, which reduces the iron level to below that required for bacterial growth.

Myeloperoxidase is usually found in the granules of neutrophils and macrophages and participates in the killing of phagocytosed microbes. It is also found in lower concentrations in mucosal secretions, where it may have antimicrobial activity. Myeloperoxidase catalyses the production of hypochlorous acid from hydrogen peroxide.

Hypochlorous acid is a strong oxidizing agent capable of killing many microbes. In the presence of chloride, hypochlorous acid can form chlorine, which also has microbicidal properties.

Animal antibiotics

Over 500 animal antibiotic proteins and peptides (peptides are defined as having fewer than 100 amino acids) have been discovered. They can be divided into α- and β-defensins, cathelicidins and peptides derived from other functional proteins. The defensins were originally identified as microbicidal peptides in the granules of neutrophils but they have now been found in secretions of mucosa and skin. Cathelicidins have conserved N-terminal prosequences homologous to cysteine protease inhibitors. They were originally identified as insect antibacterial peptides, but are also present in mucosal secretions. The final type of peptide antibiotic is that derived from other proteins; for instance an antimicrobial peptide derived from the histone H1 has been identified in the ileum.

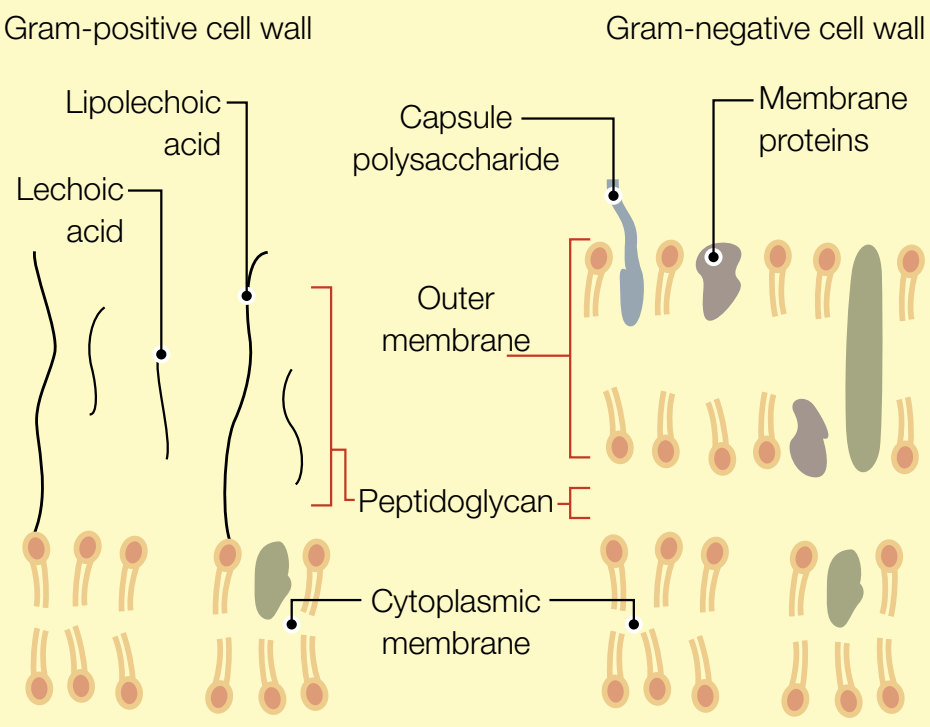
Each individual makes and secretes tens of different peptide antibiotics. The antibiotics have a wide spectrum of antimicrobial activity and are able to kill all types of bacteria, viruses, fungi, yeast and protozoan and helminth parasites.

Originally, it was thought that epithelial leucocytes were the source of mucosal antibiotics but it is now becoming clear that epithelial cells at many sites are capable of synthesizing and secreting these molecules. In the ileum, Paneth cells secrete defensins, cathelicidins, lysozyme and phospholipase A_2, another enzyme that is able to break down the lipid component of bacterial cell walls. Enterocytes secrete the H1 histone-derived peptide antibiotic, and goblet cells secrete mucus. All epithelial cell types in the ileum contribute to the production of antimicrobial factors (Figure 4).

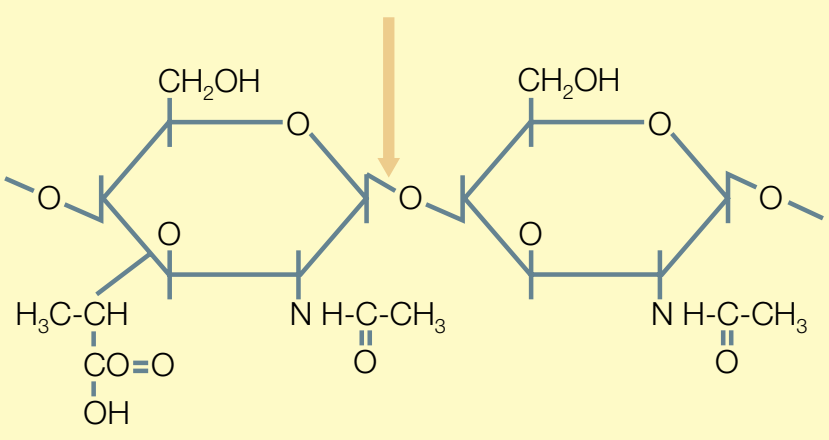
The action of these antibiotics is best understood with respect to the killing of bacteria. Most of the antibiotics are cationic in nature and therefore interact with the anionic components of prokaryotic organisms, fungi or enveloped viruses. The most common mechanism of killing is by insertion of the antibiotic into the bacterial cell membrane leading to loss of ion balance. Other killing mechanisms include disruption of bacterial enzyme metabolism and interference with biosynthetic pathways. One interesting recent observation is that the microbicidal activity of some of these antibiotics is inhibited at the high salt concentrations present in the mucous secretions of individuals with cystic fibrosis and this may contribute to the increased susceptibility to infection seen in these patients.

Action of lysozome

Bacterial cell wall



Basic building block of peptidoglycan



Lysozyme breaks this bond thus breaking down the peptidoglycan layer in the bacterial cell wall

N-acetylmuramic acid N-acetylglucosamine

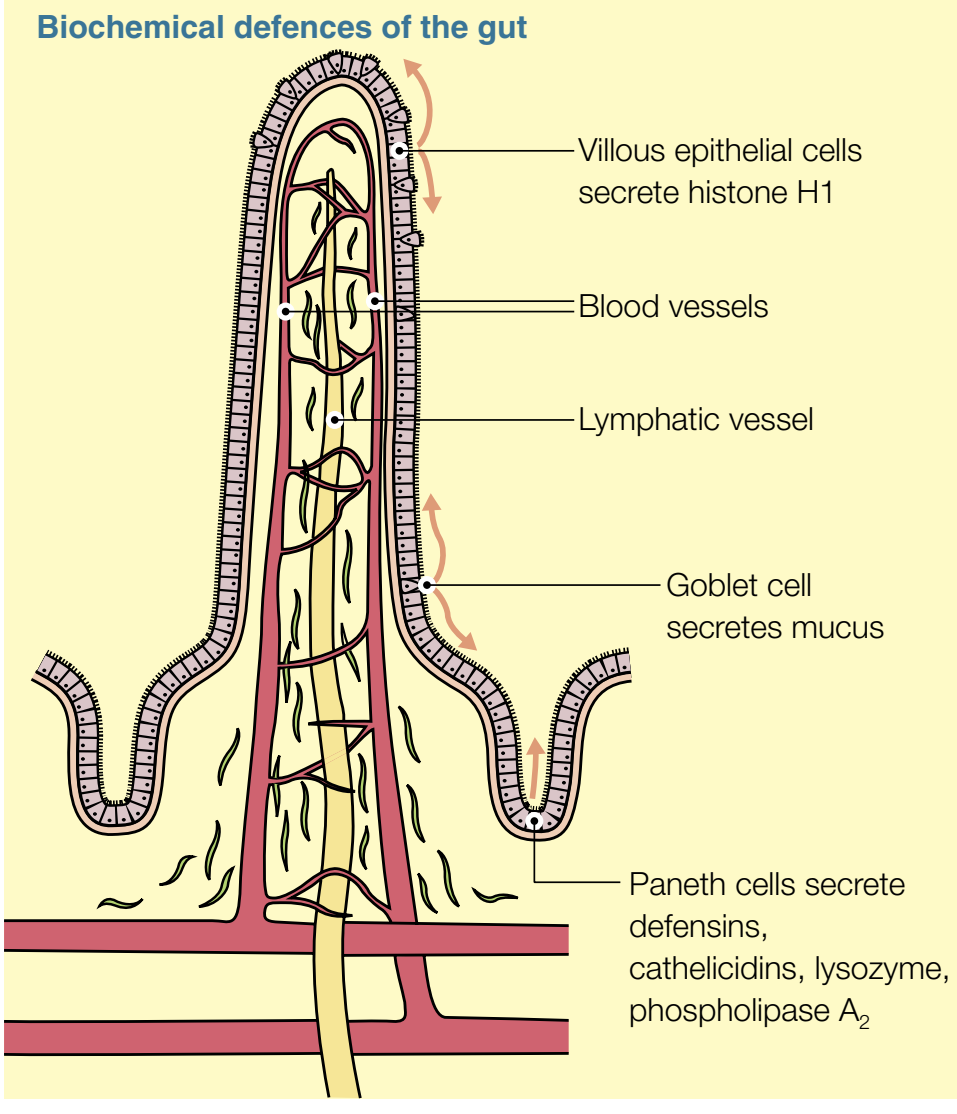
Biochemical defences of the gut



4

Collectins

The collectins provide biochemical protection at mucosal surfaces. They include the serum protein, mannose-binding protein, and the A and D lung surfactants. Collectins are calcium-dependent lectins (C-type lectins) that bind sugar residues on microbial surfaces. They can act as opsonins and promote the phagocytosis of microbes and may also have more direct antimicrobial activity. Although originally identified as lung secretory products, surfactant D has also been found in the gastrointestinal tract.

These biochemical defence molecules are made constitutively and therefore provide pre-existing protection against infection. However, many of them are inducible and their levels increase substantially on exposure to appropriate microorganisms.

Starvation, Exercise, Injury and Obesity

Iain Campbell

Iain Campbell is Reader in Anaesthesia at the University of Manchester and Honorary Consultant Anaesthetist at the University Hospitals of South Manchester. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

Energy is derived from oxidation of the macronutrients, carbohydrate, fat and protein (see **PHYSIOLOGY**). Glucose is an immediate source of energy, fat represents the long-term energy store and protein normally supplies about 10–15% of the body's energy needs. Protein, however, forms the structure of the body and any net loss of protein is accompanied by a deterioration in function. The normal interrelationships between these macromolecules, and their control, mostly by the hormones glucagon and insulin, is described in **PHYSIOLOGY**. This contribution describes the modifications to metabolism that occur in a number of abnormal situations, namely starvation, exercise, trauma and obesity. These conditions represent a stress to the system; trauma and exercise in terms of matching supply to demand; starvation in terms of stretching out limited resources to meet continuing demand; and obesity results from a mismatch of the two. Trauma is also often accompanied by an element of undernutrition because part of the metabolic response is a decline in appetite and food intake.

Starvation

Starvation is an absence or inadequacy of exogenous energy (and protein) intake. It may be partial or complete and the body survives wholly, or in part, on its endogenous stores.

A number of integrated biochemical and physiological changes have evolved in response to starvation. They contribute to a reduction in energy requirements, a preservation of protein (lean tissue) mass and the maintenance of a continuing supply of glucose to those tissues that are obligatory users, mainly the nervous system, but also RBCs and the renal medulla. RBCs and the renal medulla obtain their energy by glycolysis, but the nervous system, initially at least, can obtain energy only from glucose oxidation. Energy expenditure is reduced and protein oxidation diminishes. In normal circumstances, lean body mass is relatively constant, but there is a continuous turnover of protein (synthesis and breakdown to amino acids, some of which are oxidized) as tissues are continually renewed and replaced. In a stable state, nitrogen excretion equals nitrogen (protein) intake, but in starvation intake is absent. Protein oxidation is decreased, but there is an inevitable continuing loss, albeit at a reduced rate, which results in a steady decline in lean tissue mass, and thus in function.

The responses to starvation are behavioural and biochemical. The behavioural response is a decrease in spontaneous activity. Responses to environmental stimuli are diminished; unnecessary movement is eliminated. At the extreme, the organism may respond only if survival is threatened. Some biochemical pathways disappear (glycogenolysis). Minor pathways (gluconeogenesis) achieve major importance, at least transiently, and others that are normally only minimally active (ketogenesis) become extremely important. Temporally, the response to starvation can be described in three phases; glycogenolytic, gluconeogenic and ketogenic (Figure 1).

Phases of starvation

Glycogenolysis
- Stimulated by the decline in insulin and the rise in glucagon
- Liver and muscle glycogen stores exhausted within 24–48 hours

Gluconeogenesis
- Synthesis of glucose from amino acids, glycerol and lactate
- Stimulated by decrease in insulin and rise in glucagon
- Increases over first few days then declines

Ketogenesis
- Tissues (including CNS) adapt, at least in part, to using ketones instead of glucose
- Ketones synthesized from fatty acids by liver
- Stimulated by low insulin

Glycogenolysis
When food intake stops, blood glucose levels decline. Insulin decreases and glucagon rises; it is this reciprocal relationship that normally keeps blood glucose concentrations stable. The stimulus, and the response, is secondary to the change in the glucose levels, but may be partly mediated by the autonomic nervous system (α stimulation inhibits and β stimulation stimulates both insulin and glucagon secretion). Liver glycogen stores are mobilized via glucagon and the activation of liver phosphorylase enzymes. Hepatic glycogen is broken down to glucose-6-phosphate, which is converted to glucose and released into the bloodstream. The liver, which weighs about 1.0–1.5 kg, stores about 50–120 g of glycogen. Muscle is a much larger tissue mass than liver, comprising 40% of body weight or about 25 kg, and holds about 350–400 g of glycogen. This does not, however, contribute to blood glucose directly. Glycolysis occurs, but when the muscles are relatively inactive, the resulting pyruvate is converted to lactate which passes into the circulation and to the liver where, as a gluconeogenic precursor, it is converted to glucose for export into the general circulation. This cycle of glucose to lactate in peripheral tissue, and to glucose in the liver, is known as the Cori cycle.

Gluconeogenesis
Body glycogen stores last only 24 hours (48 hours at most) but the brain requires glucose at a rate of about 100–120 g/day. Initially, this comes from amino acids derived from protein breakdown. The release of amino acids from peripheral tissue is stimulated by the decline in insulin concentration and the concomitant rise in glucagon. Amino acids are converted to glucose by the liver, and to a lesser extent by the kidney. Not all amino acids, however, are glucogenic and 1.75 g of protein has to be broken down to provide 1 g of glucose. If the brain requires 100–120 g of glucose/day and no other adaptation took place, this would result in a daily loss of over 200 g of protein, and a rapid depletion in lean body mass.

Gluconeogenesis increases to a maximum at about 48 hours then decreases over the next 1–2 weeks as keto-adaptation takes place (see below). This may be reflected in a transient rise in urinary nitrogen excretion over days 2–4 until, with full adaptation to starvation, it settles down to about 4–6 g/day. Normal 24-hour urinary nitrogen excretion on a mixed diet is about 11–12 g/day. Gluconeogenesis declines because peripheral tissues adapt to the use of ketones and because of a decrease in metabolic rate (see below). About 50% of the amino acids are released from peripheral tissue as alanine or glutamine. Alanine is the principal gluconeogenic precursor for the liver, and glutamine for the kidney. They are released in larger quantities than occur in peripheral tissue. Alanine is the corresponding amino acid to pyruvate, the principal product of glycolysis, and glutamine the corresponding amino acid to α-ketoglutarate, a constituent of the Krebs', or citric acid cycle. Transamination of these substances (pyruvate and α-ketoglutarate) occurs in peripheral tissues, the amino group being donated by one or other of the branched chain amino acids (valine, leucine and isoleucine), the carbon skeletons of which can then be oxidized. The branched chain amino acids are metabolized only in peripheral tissue; they cannot be used by the liver.

Cortisol is the hormone that normally induces proteolysis, but in starvation, cortisol changes follow no consistent pattern and it seems to have no specific role. The breakdown of protein is due largely to the reduction in the insulin:glucagon ratio and most of it comes from muscle. In the early stages, gluconeogenic amino acids may come from rapidly turning over tissue pools, such as the lining of the gastrointestinal tract, but in the long term, the major protein 'store' is skeletal muscle. It is the largest protein mass in the body and is ultimately the main source of gluconeogenic precursors. This is accompanied by muscle wasting and weakness. Muscle weakness occurs surprisingly early in starvation, but is probably a result more of glycogen depletion than of protein loss.

The other principal gluconeogenic precursor, in addition to lactate and the amino acids, is glycerol. This is a three-carbon alcohol and a major constituent of triglyceride, the form in which most of the fat in the body is stored (see **PHYSIOLOGY**). As the adapatation to starvation takes place, triglyceride is broken down in to its constituents of glycerol and free fatty acids (lipolysis), and the glycerol moiety is transported to the liver where it is converted to glucose. The energy supply for the metabolic activity of the liver comes from fat. The energy for the synthesis of glucose in the liver, from these precursors, is thus derived from the major energy store.

Ketogenesis
Ketogenesis is the final adaptive process that allows the body to function for a prolonged period without food intake. Many of the tissues, including muscle (and the myocardium) adapt to using fatty acids as their energy source. Fatty acids arriving at the liver are normally esterified to triglyceride, a process stimulated by insulin. In the presence of low insulin concentrations, however, fatty acids are converted to ketone bodies (aceto-acetate and β-hydroxybutyrate) and, in many tissues, these substances are oxidized instead of glucose. This includes the brain, which is able to derive two-thirds of its metabolic requirements from ketone oxidation, thus sparing up to 80 g of glucose/day. In the nervous system, there is no alteration (decline) in metabolic demand. Circulating concentrations of ketone bodies increase from their usual level of less than 0.2 mmol/litre up to 6–7 mmol/litre. The glucose requirement of RBCs and the renal medulla remain, but they produce lactate, which is recycled to glucose as described above.

Hormonal changes
Most hormonal changes result from the decline in insulin and the rise in blood glucagon concentrations. This combination has both glycogenolytic and lipolytic effects, which increase free fatty acid concentrations and the rise in glucagon promotes gluconeogenesis. Tri-iodothyronine (T3) levels decrease and there is a rise in reverse T3. This is not only associated with a fall in metabolic rate, but the fall in T3 may have a protein-sparing effect. Sympathetic activity is reduced in starvation. In long-term starvation, difficulties may be experienced with, for example, the control of blood pressure and postural hypotension, as well as with thermoregulation because one of the body's defences against cold stress is sympathetic activation.

Metabolic rate
The metabolic rate decreases in starvation, to some extent out of proportion to the weight loss. In absolute terms, energy expenditure decreases by about 40%. When corrected for the decrease in body weight and expressed per kg body weight or per m^2 of body surface area the figure is nearer 15–20%. There are a number of probable causes; the decrease in sympathetic nervous activity, the decline in T3 and a relatively greater loss of metabolically more active tissue, such as the lining of the gastrointestinal tract and the liver. Although active in terms of gluconeogenic and ketogenic activity, the liver is no longer involved in the daily processes of digestion and assimilation.

Energy value of weight loss
It is a common observation of slimmers that weight loss on a low-energy diet is initially quite rapid and then slows until continuing weight loss is extremely difficult to achieve. Early weight loss is due largely to loss of lean tissue with its high water content and a relatively low energy density of 1000–2000 kcal/kg. As the fast continues and the body adapts to using mostly fat, the energy density of the weight loss increases until, in an established fully adapted fast, it is virtually only adipose tissue being metabolized. The energy density of the weight loss in prolonged starvation is about 7000–8000 kcal/kg.

Duration of starvation
Although there are instances of very obese individuals surviving without food for a year, death normally occurs at 60–70 days. Survival is essentially for as long as the fat stores last. When they run out, the body protein is oxidized for fuel and there is a 'premortal' rise in urinary nitrogen excretion. In practice, when the body has lost about half its muscle, the individual becomes too weak to cough and clear his lungs, and pneumonia ensues.

Exercise

The basal or resting metabolic rate as described in *Anaesthesia and Intensive Care Medicine* **2:3:** 115 is the energy expended in maintaining the processes of life in the resting state. Exercise is part of the body's interaction with its environment (Figure 2). The energy expended during exercise may be up to 20 times the basal metabolic rate and can be quantified in multiples of basal expenditure (MET from metabolic rate). Thus, resting awake and fasted would be 1 MET, sleeping would be 0.9 MET, walking at 5 km/hour 3.5 MET, jogging 10–12 MET and marathon running 18–20 MET.

Exercise can be classified as isometric or isotonic, and as aerobic or anaerobic. In isometric exercise, muscles contract against a resistance, but do not shorten (or lengthen) as opposed to isotonic exercise where muscles shorten (and lengthen) and move joints. In the performance of exercise against a resistance, many forms of 'isotonic' exercise have an isometric element. In aerobic exercise, the supply of oxygen keeps pace with the rate of fuel utilization (e.g. jogging). With anaerobic exercise, the rate of fuel utilization exceeds the oxygen supply; for example a fast sprint or any form of isometric exercise where the strength of the muscle contraction tends to cut off the blood (and oxygen) supply.

The body is about 25% efficient. Thus, in performing external work, 75% of the energy expended is released as heat. Although the energy comes ultimately from the oxidation of carbohydrate, fat and protein, the immediate supply is from the hydrolysis of adenosine triphosphate (ATP). There is enough ATP in skeletal muscle to support a maximal effort for a few seconds but, as this is used up quickly, it requires replenishing. The inorganic phosphate for replenishment comes immediately from phosphocreatine, present in muscle in concentrations about four times that of ATP. The use of these 'phosphagens' (ATP and creatine phosphate) allows time for the longer term mechanisms of energy supply (glycogen breakdown and glycolysis) to come into play. There is an immediate increase in flux through the glycolytic pathway of up to 1000-fold. The substrate driving this process is glucose-6-phosphate, which is released from glycogen stores in the muscle by glycogen phosphorylase, as well as by an increase in the sensitivity of various of the enzymes involved in glycolysis. Glycogen phosphorylase is activated by the increase in sarcoplasmic Ca^{2+} concentrations that occurs with the onset of exercise (driven in turn by the CNS via the motor nerves; Figure 2). Inorganic phosphate, the co-substrate for glycogen phosphorylase, comes from the ATP hydrolysed during muscle contraction and from phosphocreatine. With the onset of exercise the rate of glycolysis exceeds the supply of oxygen until the necessary cardiovascular adjustments take place (i.e. cardiac output increases) and lactate accumulates. Thus, the onset of muscle contraction and the supply of energy substrate are closely interrelated.

Skeletal muscle broadly consists of two types of fibre. Slow twitch or type I oxidative fibres tend to be red, rich in mitochondria and myoglobin and obtain their energy by aerobic mechanisms. Characteristically, they are found in the postural muscles of the back. Fast twitch, type II or glycolytic fibres contract rapidly and obtain their energy supply via anaerobic glycolytic mechanisms. Characteristically, they are found in the small muscles of the hand, though in practice most muscles in the body are made up of roughly equal proportions of fast and slow twitch fibres.

Intensity of exercise relative to the individual's capability is quantified in terms of the maximal oxygen uptake achievable (VO_2max). VO_2max is normally limited by cardiovascular rather than respiratory or metabolic factors. Low intensity exercise (involving a VO_2 at a relatively low percentage of VO_2max) is associated with greater fat oxidation than carbohydrate. As the intensity of the exercise increases, so a greater percentage of the energy expended is obtained from the oxidation of carbohydrate until the so-called 'anaerobic threshold' is reached, usually at about 50–70% of VO_2max. Oxygen delivery can then no longer support energy requirements and lactic acid accumulates. This is evident as an increase in the volume of carbon dioxide relative to the volume of oxygen and thus a rise in the respiratory exchange ratio. The contribution of fat oxidation to energy expenditure at 100% VO_2max does not usually exceed 60%.

Energy supplies come predominantly from muscle glycogen stores, but also from fat stored in muscle. The contribution of circulating substrates (glucose from liver glycogen and free fatty acids from adipose tissue) is relatively small compared with the muscle glycogen and fat stores. Some energy comes from gluconeogenesis, particularly from the recycling of lactate, but this is limited by the visceral (hepatic) vasoconstriction seen as part of the cardiovascular response to exercise (see *Anaesthesia and Intensive Care Medicine* **2:3:** 115). Endurance capacity (i.e. time to exhaustion) is related directly to the size of the muscle glycogen stores.

As an individual gets fitter (i.e. VO_2max increases), the contribution of fat to substrate oxidized at a given VO_2 increases. The fitter individual (with a higher VO_2max) is also better able to tolerate higher levels of lactic acid accumulation than the less fit. The ability to store glycogen and fat in muscle also increases with improving fitness.

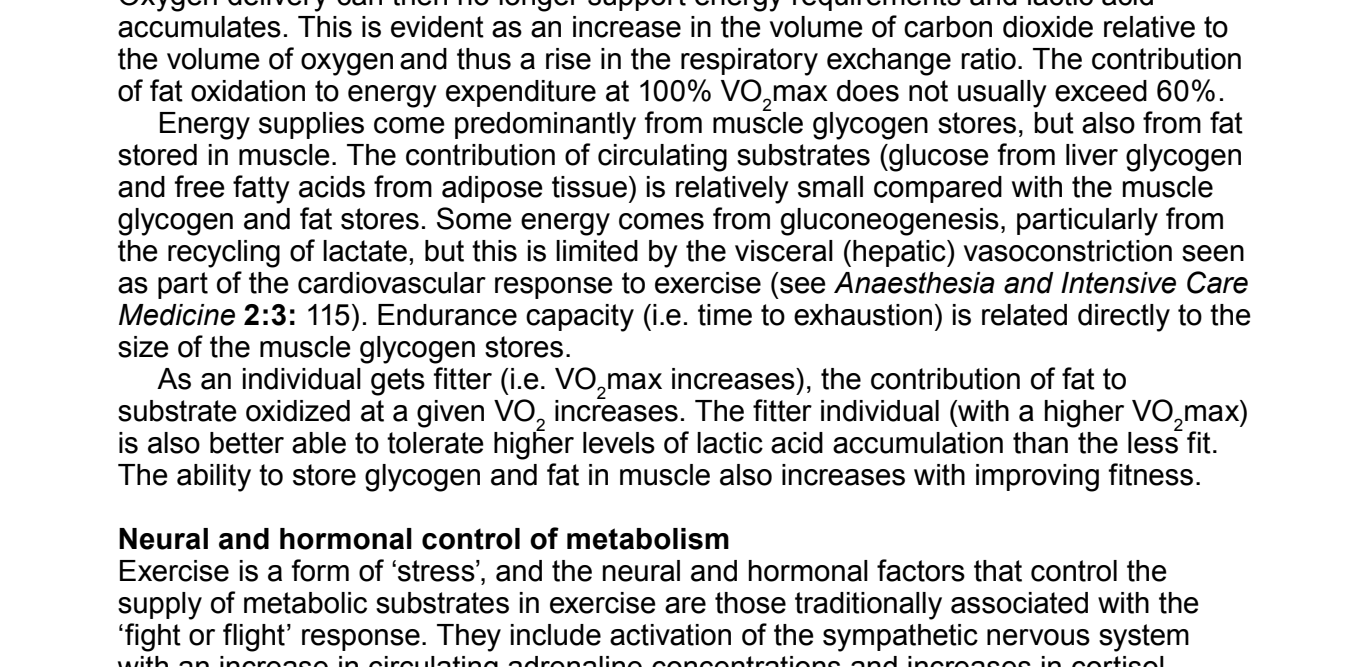
Neural and hormonal control of metabolism

Exercise is a form of 'stress', and the neural and hormonal factors that control the supply of metabolic substrates in exercise are those traditionally associated with the 'fight or flight' response. They include activation of the sympathetic nervous system with an increase in circulating adrenaline concentrations and increases in cortisol and glucagon. As discussed above, skeletal muscle contraction stimulates glycogen breakdown, but sympathetic activation mediated via adrenaline does the same and, with anticipation, may even start before the exercise. Glucose is mobilized from liver glycogen and free fatty acids are released from adipose tissue stores secondary to sympathetically mediated lipolysis. Sympathetic stimulation can either inhibit (α effect) or stimulate (β effect) insulin secretion but, in these circumstances, the inhibitory effect predominates and circulating insulin concentrations fall. There is a reciprocal rise in glucagon. Growth hormone and cortisol are both stimulated, and rise more gradually over the first 30–60 minutes of a bout of exercise.

Sympathetic stimulation also stimulates the cardiovascular system with increases in cardiac output and blood supply to the muscles. There is a fall in pH as lactic acid accumulates and carbon dioxide production increases; these promote vasodilatation and stimulate ventilation. However, the major stimulus to glycogen mobilization in muscle is muscle contraction; the role of the sympathetic system is comparatively minor.

Sympathetic activation stimulates lipolysis, but extreme sympathetic activation also results in vasoconstriction of the blood vessels supplying adipose tissue and this can limit the rise in free fatty acid levels, some of which may remain within the adipose tissue and may become re-esterified. This limits the extent to which fat can be used as a fuel at the highest exercise intensities. Typically, when the exercise stops, free fatty acid concentrations rise as vasodilatation occurs in the fat depots and the fatty acids are flushed into the circulation.

Metabolic features of exercise



2

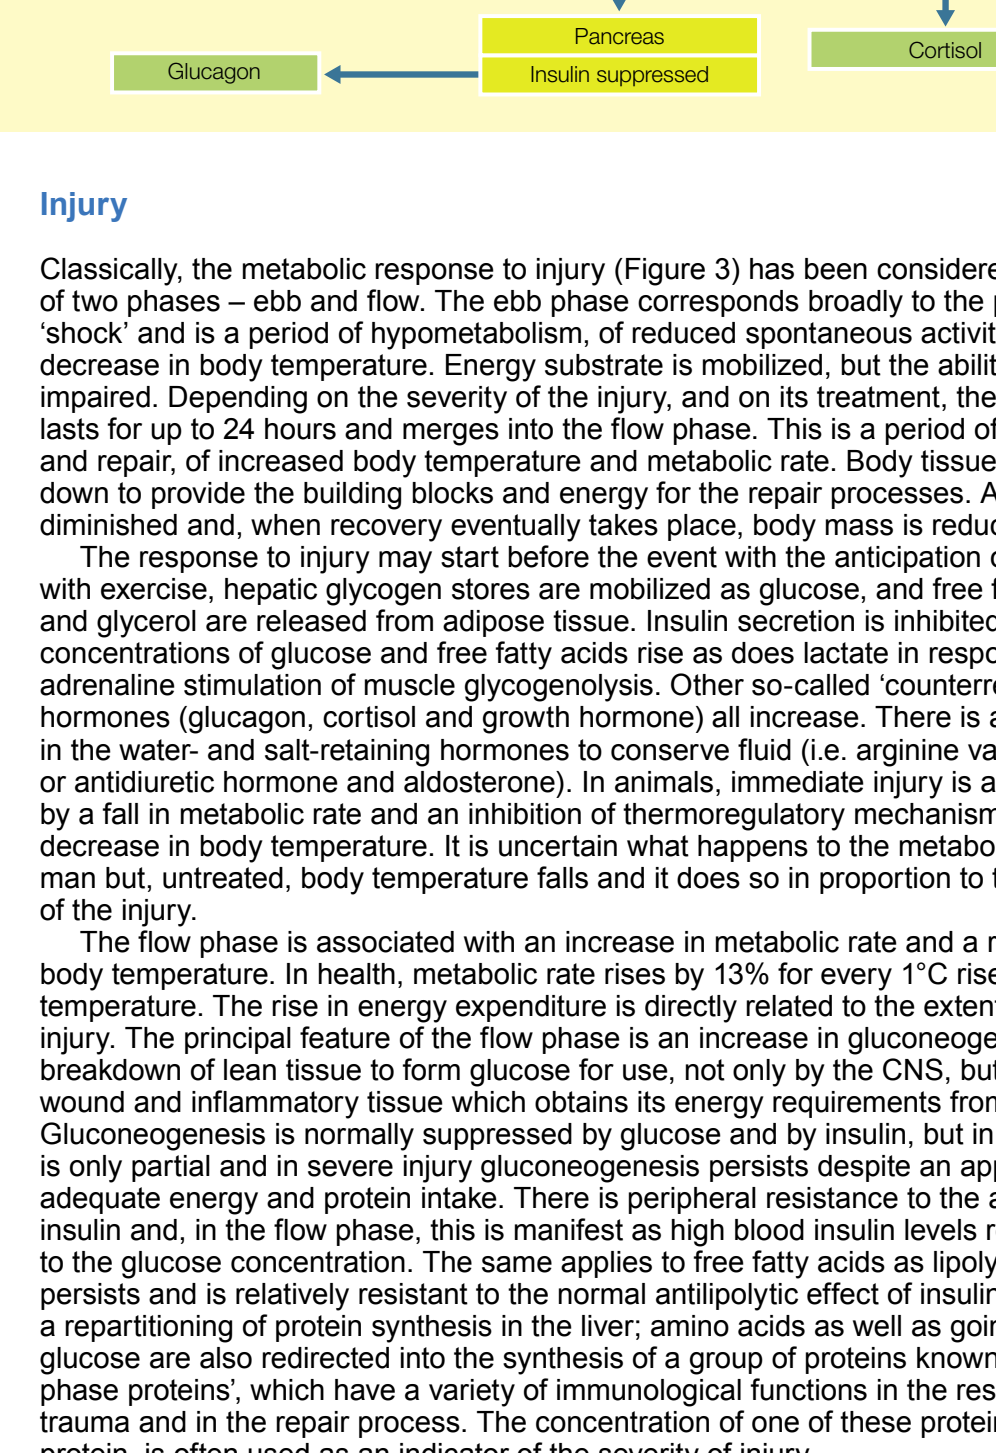
Injury

Classically, the metabolic response to injury (Figure 3) has been considered to consist of two phases – ebb and flow. The ebb phase corresponds broadly to the period of 'shock' and is a period of hypometabolism, of reduced spontaneous activity and a decrease in body temperature. Energy substrate is mobilized, but the ability to use it is impaired. Depending on the severity of the injury, and on its treatment, the ebb phase lasts for up to 24 hours and merges into the flow phase. This is a period of regeneration and repair, of increased body temperature and metabolic rate. Body tissue is broken down to provide the building blocks and energy for the repair processes. Appetite is diminished and, when recovery eventually takes place, body mass is reduced.

The response to injury may start before the event with the anticipation of stress. As with exercise, hepatic glycogen stores are mobilized as glucose, and free fatty acids and glycerol are released from adipose tissue. Insulin secretion is inhibited. Circulating concentrations of glucose and free fatty acids rise as does lactate in response to adrenaline stimulation of muscle glycogenolysis. Other so-called 'counterregulatory' hormones (glucagon, cortisol and growth hormone) all increase. There is also a rise in the water- and salt-retaining hormones to conserve fluid (i.e. arginine vasopressin or antidiuretic hormone and aldosterone). In animals, immediate injury is accompanied by a fall in metabolic rate and an inhibition of thermoregulatory mechanisms with a decrease in body temperature. It is uncertain what happens to the metabolic rate in man but, untreated, body temperature falls and it does so in proportion to the severity of the injury.

The flow phase is associated with an increase in metabolic rate and a rise in body temperature. In health, metabolic rate rises by 13% for every 1°C rise in temperature. The rise in energy expenditure is directly related to the extent of the injury. The principal feature of the flow phase is an increase in gluconeogenesis with breakdown of lean tissue to form glucose for use, not only by the CNS, but also for wound and inflammatory tissue which obtains its energy requirements from glycolysis. Gluconeogenesis is normally suppressed by glucose and by insulin, but in injury this is only partial and in severe injury gluconeogenesis persists despite an apparently adequate energy and protein intake. There is peripheral resistance to the action of insulin and, in the flow phase, this is manifest as high blood insulin levels relative to the glucose concentration. The same applies to free fatty acids as lipolysis also persists and is relatively resistant to the normal antilipolytic effect of insulin. There is a repartitioning of protein synthesis in the liver; amino acids as well as going to form glucose are also redirected into the synthesis of a group of proteins known as 'acute phase proteins', which have a variety of immunological functions in the response to trauma and in the repair process. The concentration of one of these proteins, C-reactive protein, is often used as an indicator of the severity of injury.

Metabolic response to major trauma over 24 hours



3

Obesity

Obesity is the result of a long-term imbalance between energy intake and energy expenditure. The precise mechanisms (i.e. excessive intake or reduced expenditure) have been elusive, because of the problems of making the measurements. A fat gain of 20 kg over 10 years denotes an imbalance of energy intake over expenditure of about 50 kcal/day; techniques to measure this difference between these two parameters do not exist. There are a number of complex techniques for measuring adiposity, none of which are entirely satisfactory, and which are beyond the scope of the present discussion. The simplest measure of excess weight is, however, the body mass index, which is weight divided by height^2 (kg/m^2). The normal range is 18–25, 25–30 is described as overweight, above 30 as obese and above 40 kg/m^2 as morbidly obese. Obesity is associated with an increased incidence of other pathologies, such as hypertension, diabetes, coronary artery disease, cancer and osteoarthritis, as well as respiratory impairment. Obesity is a restrictive respiratory defect and obese individuals are hypoxaemic to a degree proportional to the severity of the obesity.

Opinion as to the cause of the obesity is coming down on the side of a dysregulation of intake rather than expenditure. In hibernating rodents, there is evidence that weight can be controlled by thermogenic mechanisms involving the sympathetic nervous system and brown adipose tissue similar to that seen in response to cold, but this does not appear to apply in man. Increased sympathetic activity increases metabolic rate (i.e. cardiovascular stimulation, glycogenolysis, free fatty acid/triglyceride cycling), but it is not a mechanism for weight control. In the last few years, a peptide hormone called leptin has been identified as being produced by adipose tissue. Circulating levels correlate with adipose tissue mass and it suppresses appetite. It has been suggested that obesity represents a leptin-resistant state, perhaps with reduced levels of leptin transport into the CSF.

The nature of the excess intake is largely fat, which is taken up directly into adipose tissue stores. In man, there is little conversion of excess carbohydrate intake into fat. Carbohydrate does, however, stimulate insulin secretion and this is a potent antilipolytic, suppressing fat mobilization and utilization. Likewise, alcohol significantly suppresses fat oxidation; it is an energy-rich poison (7 kcal/g) that is oxidized preferentially to either fat or carbohydrate.

The characteristic metabolic features of obesity are a propensity to metabolize fat rather than carbohydrate and a degree of insulin resistance that improves with weight loss. The extent to which fat is metabolized relative to carbohydrate is a function of circulating fatty acid concentrations and insulin (stimulated by glucose ingestion), which is antilipolytic. High rates of fat oxidation inhibit pyruvate dehydrogenase and this in turn inhibits glycolysis. This results in a high circulating level of glucose, which stimulates insulin secretion. The obese individual has chronically high fatty acid levels and so is insulin resistant because of this inhibitory effect on carbohydrate metabolism. This results in increased triglyceride synthesis and impaired glucose utilization in peripheral tissue, particularly muscle. This whole scenario predisposes to hypertension, peripheral and coronary vascular disease, and diabetes.

Thyroid and Parathyroid Hormones and Calcium Homeostasis

Adrian Heald

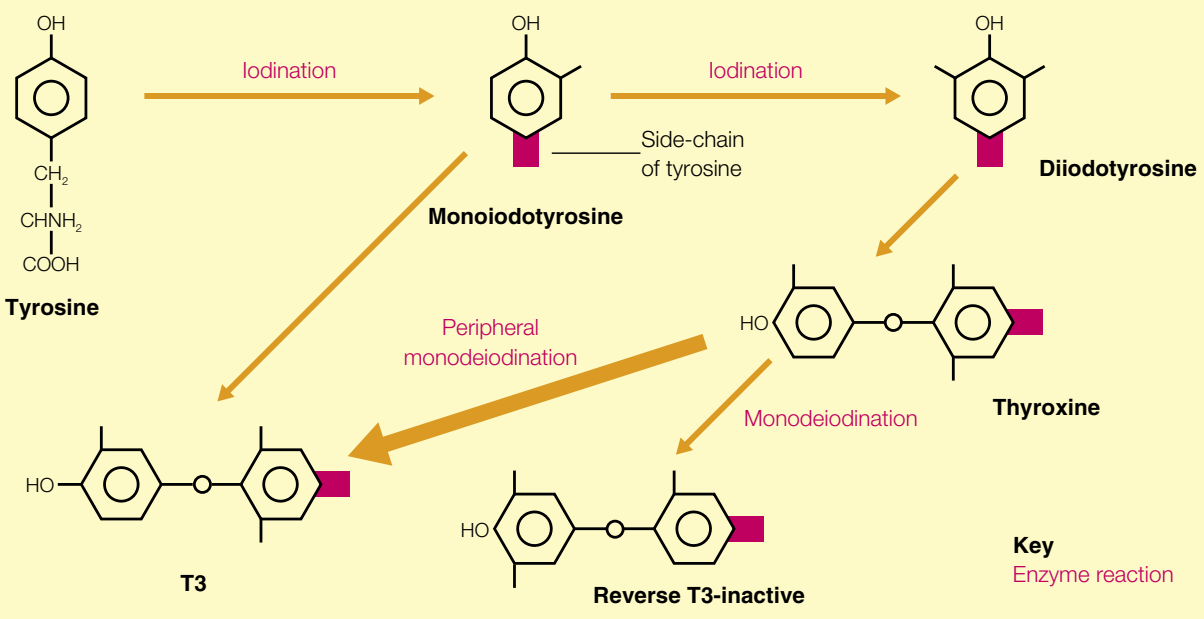
Adrian Heald is Locum Consultant Endocrinologist at Hope Hospital, Salford, UK. He qualified from the University of Oxford and trained in endocrinology in Manchester. His research interests include the IGF system in relation to the epidemiology of diabetes and cardiovascular disease.

Thyroid hormones

Thyroid gland: thyroid hormone synthesis requires iodide. Iodide is oxidized by thyroid peroxidase and stored as iodinated thyroglobulin within the thyroid follicular cell where it is incorporated into tyrosine residues. Thyroglobulin is the main precursor of thyroid hormones. The bioactive iodothyronines are tri-iodothyronine (T3) and thyroxine (T4). Three or four T4 molecules are present per molecule of human thyroglobulin. Thyroglobulin is synthesized in the thyroid follicular cell (Figure 1) and extruded into the follicular luminal colloid where it is stored. Secretion of T4 and T3 (very little T3 is secreted) occurs following proteolytic cleavage of thyroglobulin in the thyroid follicular cell. This process is activated by thyroid stimulating hormone (TSH).

Thyroid hormones in the circulation: various proteins bind T4 and T3 in the circulation but 75% is by thyroxine-binding globulin. About 0.04% of T4 and 0.4% of T3 circulate in the unbound state. The biologically active thyroid hormone is T3. This is produced by peripheral monodeiodination (Figure 1) of T4. Reverse T3 is also produced by monodeiodination of T4. The half-life of T4 is 6.7 days, a reflection of the extent to which T4 is protein bound. Conversely T3 is rapidly cleared from the plasma with a half-life of 0.75 days. Circulating thyroid hormone levels negatively regulate TSH secretion by a classical biofeedback loop on the hypothalamus and pituitary gland.

Thyroid hormone biosynthesis



1

Thyroid hormone action is via a nuclear receptor. Thyroid hormone receptors belong to a family of nuclear receptors that include glucocorticoid, mineralocorticoid, oestrogen and vitamin D receptors. Multiple thyroid hormone receptor isoforms are produced by alternative splicing during trans-cription. The interaction of thyroid hormones with the nuclear receptor stimulates calorigenesis (resulting in increased oxygen consumption), protein synthesis, and carbohydrate and lipid metabolism.

Hyperthyroidism (thyrotoxicosis)
The prevalence of hyperthyroidism is about 20/1000 women and 2/1000 men. Cardinal features are restlessness, heat intolerance, excessive sweating, weight loss despite increased appetite, loose motions and disturbance of the menstrual cycle and may include features of Graves' disease, namely goitre, ophthalmopathy and occasionally pre-tibial myxoedema. Typically circulating T4 and T3 concentrations are raised but occasionally there is elevation of T3 alone (T3 toxicosis).

Graves' disease is the most common cause of hyperthyroidism. The patient is typically female and aged 20–40 years. It is characterized by a diffusely enlarged thyroid gland, ophthal-mopathy and hyperthyroidism. There is a strong familial predisposition. It is associated with several major histocompatibility (HLA) antigens. There is lymphocytic infiltration of the thyroid gland. Pathogenesis is determined by the presence of antibodies (usually of the IgG1 subclass) to the thyroid follicular cell surface membrane TSH receptor.

Toxic multinodular goitre usually occurs in an older individual associated with an existing multinodular goitre. Thyroid gland overactivity is usually less marked than in patients with Graves' disease.

Solitary toxic adenoma is an uncommon cause of hyper-thyroidism. The diagnosis may be confirmed by radionuclide scanning which demonstrates localization of radioisotope to the nodule with suppression of uptake by the surrounding normal thyroid.

Thyroiditis (de Quervain's thyroiditis) is thought to be viral in aetiology and often follows an upper respiratory infection. Presentation is with pain in the thyroid gland, often with fever. Follicular destruction in the thyroid gland leads to leakage of preformed hormone with development of hyperthyroidism. Erythrocyte sedimentation rate (ESR) is high in association with the acute inflammation.

Antithyroid drugs and other treatment: carbimazole and propylthiouracil inhibit oxidation of iodide by H_2O_2 and organification by incorporation into the tyrosine residues of thyroglobulin. Additionally propylthiouracil inhibits the conversion of T4 to T3 in the periphery. Management of thyrotoxicosis is by titration, block or replacement whereby endogenous thyroid hormone secretion is suppressed and the patient maintained on exogenous T4. This regimen is unsuitable in pregnancy because thyroxine does not cross the placenta.

β-blockers (usually propanolol) relieve the peripheral manifestations of hyperthyroidism and are often used in conjunction with antithyroid drugs for symptom relief.

When the patient has been rendered euthyroid, other treatment options are subtotal thyroidectomy and radioactive iodine treatment using the isotope I^{131}. There is a significant long-term consequence of hypothyroidism after treatment with I^{131}. Some patients require more than one dose of radioactive iodine.

Hypothyroidism
Hypothyroidism is usually a result of primary thyroid disease (primary hypothyroidism) rather than reduced TSH secretion from the anterior pituitary gland. Common features include fatigue, lethargy, mental slowness, weight gain, facial puffiness, constipation, delayed relaxation phase of deep tendon reflexes, intolerance of cold, and dry skin. In areas where iodine intake is adequate, the most common cause is autoimmune lymphocytic thyroiditis. This is painless and may occur with enlargement of the thyroid (Hashimoto's disease) or with no goitre (atrophic thyroiditis). Treatment is usually with thyroxine though tri-iodothyronine can be used. In patients with known coronary artery disease, thyroxine must be started at a low dose (25 μg/day) and the dose increased cautiously.

Parathyroid hormones and calcium homeostasis

The concentration of calcium is maintained in a narrow range, varying by less than 5% despite large calcium fluxes across bone, kidney, gut and other tissues. 99% of calcium and 88% of phosphate is found in bone. About 50% of plasma calcium is ionized. The extent to which calcium is protein bound is pH dependent. Alkalosis, induced for example by hyperventilation, results in a decrease in ionized calcium (but no change in total plasma calcium) and symptoms of hypocalcaemia, typically paraesthesiae. The amount of calcium in the extracellular fluid is principally determined by parathormone, calcitriol (1,25-dihydroxyvitamin D_3) and calcitonin.

Parathormone (PTH)
PTH is a single polypeptide chain containing 84 amino acids. Only the first 32–34 amino acids from the amino-terminal end are responsible for biological activity. It is synthesized as a prohormone in the rough endoplasmic reticulum of the chief cells of the parathyroid glands. The major stimulus to secretion is a fall in the plasma ionized calcium concentration. Chronic hypomagnesaemia results in impaired PTH release and consequent hypocalcaemia. Actions of PTH are:

- to increase renal tubular resorption of calcium and decreased tubular resorption of phosphate (causing an increase in plasma calcium and a decrease in plasma phosphate)
- to decrease proximal tubular resorption of bicarbonate (causing an increased excretion of bicarbonate and hyperchloraemic acidosis)
- to stimulate the 1α-hydroxylase enzyme in kidney, responsible for the formation of 1,25-dihydroxyvitamin-D_3 (calcitriol) from 25-hydroxyvitamin-D_3 (calcifidiol)
- to increase the number and activity of osteoclasts causing increased bone resorption
- to decrease proximal tubular resorption of sodium and increased amino-acid excretion.

Calcitonin
Calcitonin is a peptide containing 32 amino acid residues. It is secreted by the parafollicular cells (C-cells) of the parathyroid. The salmon form of calcitonin resembles human calcitonin more than that of other mammals. This has led to therapeutic uses in humans, for example in the treatment of Paget's disease and osteoporosis. Secretion of calcitonin is stimulated by an increase in serum concentration of calcium. Its actions are opposite to those of PTH (e.g. it inhibits osteoclast numbers and activity) it also inhibits the secretion of several gastrointestinal hormones (e.g. gastrin and cholecystokinin).

Vitamin D
Vitamin D_3 (fat soluble) is derived from the diet and from the skin by ultraviolet irradiation of 7-dehydroxycholesterol. Further conversions are in the liver to 25-hydroxyvitamin-D_3 (calcifidiol) which is the main circulating vitamin D metabolite. The concentration of this in serum is highest in late summer and lowest in late winter. Conversions also occur in the kidney (also placenta and decidua) to 1,25-dihydroxyvitamin-D_3 (calcitriol), 24,25-dihydroxyvitamin-D_3 and 25,26-dihydroxyvitamin-D_3. Failure of the process is implicated in the pathogenesis of vitamin D resistance in renal failure. The actions of 1,25-dihydroxyvitamin-D_3 (calcitriol) are to increase the intestinal absorption of calcium and phosphate and to increase the resorption of bone mineral and matrix. Weakness of skeletal muscles, particularly limb girdles, is a feature of vitamin D deficiency.

Hyperparathyroidism
Primary hyperparathyroidism is usually caused by a single parathyroid adenoma of the chief cells of the parathyroid gland. Occasionally it is caused by diffuse hyperplasia or multiple adenomata. Presentation is with symptoms of hypercalcaemia including thirst, fatigue, constipation and renal calculi. Diagnosis is by demonstration of a raised plasma calcium concentration in the face of a normal or raised plasma PTH level. Treatment is by surgical removal of the parathyroid adenoma.

Secondary hyperparathyroidism is caused by prolonged hypocalcaemia, for example in chronic renal failure or
vitamin D deficiency. This results in increased secretion of PTH and hyperplasia of the parathyroid glands. There may be associated osteomalacia. Treatment involves normalization of plasma calcium, often using 1α-hyroxylated derivatives of vitamin D.

Tertiary hyperparathyroidism describes patients with longstanding secondary hyperparathyroidism who develop autonomous parathyroid gland function and hypercalcaemia. The problem is most commonly seen after renal trans-plantation but may occur in patients with longstanding malabsorption or chronic renal failure. Treatment is by parathyroidectomy and appropriate management of the cause.

Pseudohyperparathyroidism involves synthesis of PTH-like substances by tumours, particularly of the lung. Presentation is with biochemical abnormalities similar to those seen in primary hyperparathyroidism.

Hypoparathyroidism
Hypoparathyroidism results in hypocalcaemia and hyper-phosphataemia secondary to defective secretion or action of PTH. It causes paraesthesiae, carpopedal spasm and abdominal cramps, sometimes with irritability and emotional lability or with epilepsy. It most commonly results from parathyroid, thyroid or laryngeal surgery. It has a familial form and a sporadic form associated with autoimmune spectrum disorder and monoliasis.

Pseudohypoparathyroidism results from resistance of one or more target tissues to the actions of PTH. Circulating levels of PTH are high and are suppressed by giving a calcium infusion. There is an association with several somatic abnormalities including short stature, round face and shortening of the metacarpal and metatarsal bones. Resistance to PTH may be partial or complete. There may be other associated endocrine abnormalities, for example TSH deficiency leading to hypo-thyroidism and diabetes mellitus.

In pseudopseudohypoparathyroidism the somatic features of seudohypoparathyroidism are present but plasma concen-trations of calcium and phosphate are normal. PTH levels are usually normal but may be raised. ◆

The Electrocardiogram

Emrys Kirkman

Emrys Kirkman is Senior Lecturer in Physiology at the University of Durham, UK. He has a PhD from Manchester University and has worked at the MRC Trauma Group, Manchester. He also holds an honorary Senior Lectureship in the Academic Division of James Cook University Hospital, Cleveland. His research interests include trauma-induced changes in cardiovascular control mechanisms, the underlying central nervous pathways and the resulting alterations in haemodynamics and oxygen transport.

A large number of cardiac muscle fibres become activated synchronously and generate sufficient electrical disturbance to be recorded at the body's surface: this forms the basis of the electrocardiogram (ECG). An examination of the ECG reveals detail of the pathways along which electrical activity travels in the heart. The ECG does not represent the electrical activity of any single fibre, but the combined activity of all the muscle fibres at any one instant.

Electrical views of the heart

Twelve ECG 'leads' are usually recorded. It is important not to confuse an ECG 'lead' with the 'wires' connected to the electrodes used to make the recording. In ECG terms, 'lead' refers to an electrical view of the heart.

Standard leads: there are six standard leads (I, II, III, VR, VF, VL) which view the heart in the vertical plane (e.g. lead II looks at the left lateral surface of the heart from about the left hip, while VR looks at the heart from the right shoulder). The detail of the other views are given in Figure 1. A further six leads (V_1, V_2, V_3, V_4, V_5, V_6) view the heart in the horizontal plane (Figure 2).

Normal ECG from the standard leads

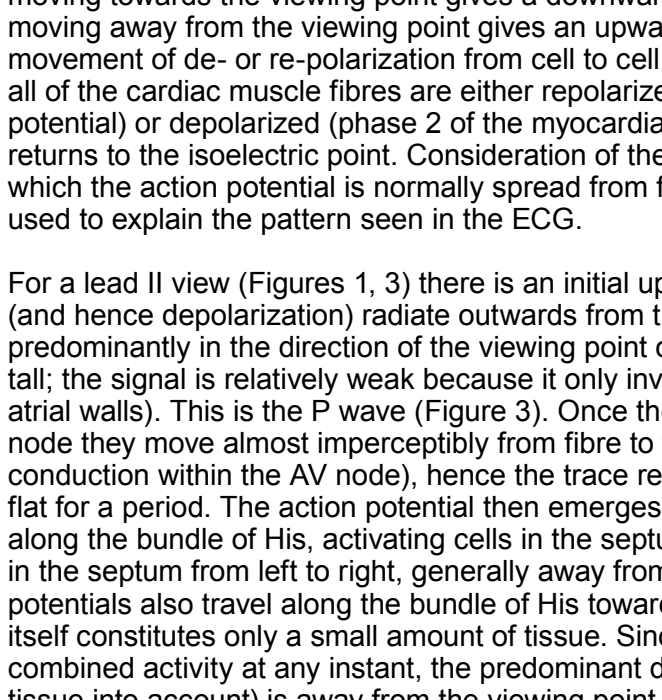
2

The differential amplifiers used to record the ECG are configured such that if a wave of depolarization moves towards the viewing point there is an upward deflection away from an isoelectric starting point. Depolarization moving away from the viewing point gives a downward deflection below the isoelectric point. Conversely, repolarization moving towards the viewing point gives a downward deflection and repolarization moving away from the viewing point gives an upward deflection. When there is no movement of de- or re-polarization from cell to cell with respect to the viewing point (i.e. all of the cardiac muscle fibres are either repolarized (phase 4 of the myocardial action potential) or depolarized (phase 2 of the myocardial action potential)) then the trace returns to the isoelectric point. Consideration of these rules and the pathway along which the action potential is normally spread from fibre to fibre through the heart can be used to explain the pattern seen in the ECG.

For a lead II view (Figures 1, 3) there is an initial upward deflection as action potentials (and hence depolarization) radiate outwards from the SA node across the atria, predominantly in the direction of the viewing point on the left hip. The wave is not very tall; the signal is relatively weak because it only involves a small amount of tissue (thin atrial walls). This is the P wave (Figure 3). Once the action potentials invade the AV node they move almost imperceptibly from fibre to fibre through the AV node (slow conduction within the AV node), hence the trace returns to the isoelectric line and is flat for a period. The action potential then emerges from the AV node and proceeds along the bundle of His, activating cells in the septum. This causes activity to spread in the septum from left to right, generally away from the viewing point. Although action potentials also travel along the bundle of His towards the apex of the heart, the bundle itself constitutes only a small amount of tissue. Since the trace is influenced by the combined activity at any instant, the predominant direction of activity (taking quantity of tissue into account) is away from the viewing point, giving the small downward Q wave. The next major event is the activation of the bulk of the ventricular myocardium, from the endocardial to the epicardial surface: activity in a large amount of tissue moves from cell to cell towards the viewing point. This gives the large upward R wave. Finally, the few muscle fibres at the base of the heart are depolarized giving a small downward S wave. At this point, all the ventricular muscle fibres are depolarized and are on the shoulder (phase 2) of the cardiac muscle action potential (see pages 274 and 277). Thus, there is no wave of depolarization moving with respect to the viewing point, so the trace returns to the isoelectric line. Finally, after 200–300 ms the myocardial fibres repolarize (phase 3 of the myocardial action potential). However, those of the epicardial surface of the heart have a shorter duration action potential (nearer 200 ms) than those of the endocardial surface (nearer 300 ms), so that the wave of repolarization moves away from the viewing point giving a final upward wave, the T wave (Figure 3). Atrial repolarization occurs coincident with ventricular depolarization and, because of the greater amount of tissue involved in the ventricles, the wave produced by the atrial repolarization is lost in the QRS complex. The normal durations of the waves and intervals between them are given in Figure 3. If the viewing point is transferred to the right shoulder (lead VR) then essentially a mirror image is seen (Figure 1) with the bulk of the myocardial depolarization moving away from the viewing points with a predominant large downward wave in the QRS complex.

Waves of a typical lead II ECG showing mean (range) for relevant intervals and durations



Reproduced with permission from Ganong W F. *Review of Medical Physiology*. McGraw-Hill, 2001.

3

In summary, the P wave represents atrial depolarization, the QRS complex in its entirety represents ventricular depolarization and the T wave represents ventricular repolarization.

V_1–V_6: these leads view the heart in the horizontal plane (Figure 2). V_1 andV_2 view the heart from the right and V_5 and V_6 from the left, with V_3 and V_4 in between. Because the septal depolarization arises before ventricular depolarization, and occurs from left to right, initial parts of the ventricular depolarization are shown by an upward deflection in V_1 and V_2 but downward deflections in V_5 and V_6 (Figure 2). Thereafter, the main mass of ventricular tissue is depolarized. However, since there is a much greater mass in the left ventricle, during ventricular depolarization the predominant movement is away from V_1 and V_2 giving a downward deflection and towards V_5 and V_6 giving an upward deflection in these views (Figure 2).

Convention for naming waves: the waves of the ECG are labelled P, Q, R, S and T (with an additional U wave sometimes visible). If the first deflection after a P wave (if it exists) is downward it is called a Q wave. An upward deflection is called an R wave, whether or not it is preceded by a downward wave. A deflection below the isoelectric line after an R wave is called an S wave, whether or not a Q wave has been seen.

Ectopic foci and conduction problems

It is beyond the scope of this article to discuss any ECG abnormalities in detail, but a few examples are given. It should be stressed that a single abnormality in a few leads can be the result of a range of problems, and that the entire picture from all leads and other clinical signs must be integrated.

Ectopic foci can develop in the atria or ventricles. They lead to an abnormal sequence of spread of the action potentials from fibre to fibre through the heart, and hence abnormalities of the ECG.

Atrial ectopic foci can give rise to abnormally shaped P waves (e.g. inverted P waves in lead II). Furthermore, since the focus may be much closer to the AV node, the P–R interval may be abnormally short. However, the spread of the action potentials should be essentially normal from the AV node onwards, and the QRS complex should be normal. Conversely, a ventricular ectopic focus gives rise to an abnormally shaped QRS complex, which is not preceded by a P wave. The shape of the abnormality occurs because of the altered sequence of fibres along which the myocardial action potential travels within the ventricles. The QRS complex is much wider (occurs over a greater period of time) because the spread of the action potentials does not make proper use of the fast conduction system.

In some circumstances, the myocardial action potential is prolonged, which in turn prolongs the QT interval. Long QT syndrome is a recognized condition associated with sudden death and often associated with ventricular arrhythmias and fibrillation. The problem is that during the repolarization of the ventricles the heart is in a critical state, termed the vulnerable period. At this time (which corresponds to the rising phase of the T wave of the ECG) some of the ventricular myocytes have repolarized while others have incompletely repolarized or are still depolarized. Under these circumstances an ectopic beat can establish a re-entry and a circus of action potentials leading to fibrillation.

Conduction problems in the AV node can be indicated by a prolonged P–R interval. If all of the P waves result in a QRS complex this is referred to as a first-degree heart block. In other instances some, but not all, P waves result in a QRS complex: this is second-degree heart block. In more extreme circumstances there is complete block at the AV node and no P wave results in a QRS complex. This is third-degree heart block and in this case ventricular beating is driven by an alternative ventricular pacemaker. In this latter circumstance there may be regular P waves and regular QRS complexes, but they occur at different rates.

Sinus arrhythmia

Examination of the ECG in the normal individual reveals that the heart rate is often not steady at rest: the R–R interval becomes progressively increased during expiration and shortened during inspiration. This rhythmical fluctuation in heart rate in phase with respiration is called sinus arrhythmia. It reflects resting vagal tone to the heart: during inspiration the vagus nerve is inhibited as a consequence of activity in medullary inspiratory neurons and because of inhibition from an afferent pathway originating in pulmonary stretch receptors. On expiration the inhibition is lost and vagal activity increases, leading to a bradycardia. The degree of sinus arrhythmia in part depends on the level of resting vagal tone. If this is high, there is considerable scope for inhibition during inspiration, while if resting vagal activity is low, there is little scope for inhibition during inspiration and sinus arrhythmia is weak or absent. Sinus arrhythmia can therefore be used as a test of vagal activity. It is reduced by anxiety, a decline in cardiovascular fitness and pathological states affecting the vagus nerve, therefore care must be taken when interpreting the results. ◆

Electromechanical Coupling and Regulation of Force of Cardiac Contraction

Emrys Kirkman

Emrys Kirkman is Senior Lecturer in Physiology at the University of Durham, UK. He has a PhD from Manchester University and has worked at the MRC Trauma Group, Manchester. He also holds an honorary Senior Lectureship in the Academic Division of James Cook University Hospital, Cleveland. His research interests include trauma-induced changes in cardiovascular control mechanisms, the underlying central nervous pathways and the resulting alterations in haemodynamics and oxygen transport.

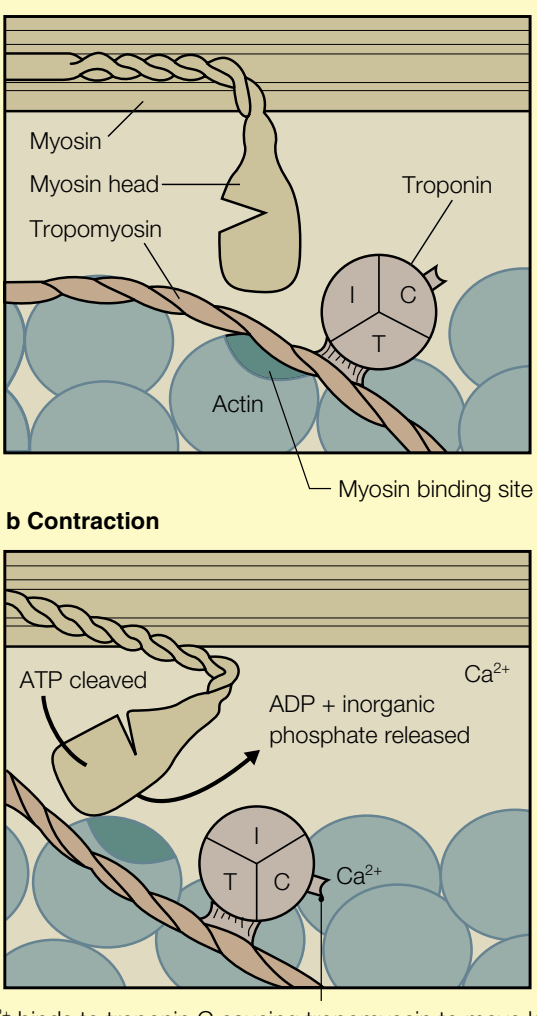
Cardiac muscle fibres, like skeletal muscle fibres, are divided into sarcomeres, the basic unit of contraction. The contractile elements include actin, myosin, tropomyosin and troponin. The myosin molecules are arranged into thick filaments while the actin molecules form the basis of the thin filaments. The troponin and tropomyosin are attached to the thin filaments as in skeletal muscle. In contrast to fast skeletal muscle fibres, which need to produce repetitive mechanical action only for short periods before resting, and hence can accrue an oxygen debt, cardiac muscle fibres need to perform repetitive activity for long periods (a lifetime) without rest. Consequently, cardiac muscle fibres are much more dependent on the utilization of oxygen and have an abundance of mitochondria, with rapid oxidation of substrates and formation of ATP, needed for mechanical contraction.

The myocardium is well supplied with capillaries, and diffusion distances between blood and cardiac muscle fibres are relatively short. In addition, the fibres have a well-defined transverse or T-tubule system. These are deep invaginations of the cell membrane, which connect with longitudinally running axial tubules that constitute an extensive network of 'intracellular' tubules whose lumen is continuous with the interstitium. Thus, the intracellular organelles (e.g. the mitochondria) are positioned close to structures that contain interstitial fluid, with short diffusion distances between the two. This arrangement is prevalent in the force-producing fibres of the ventricles, but less well developed in atrial cells. The T-tubules also come into close approximation with other organelles, such as the sarcoplasmic reticulum, which serves as an important reservoir of the calcium ions needed for part of the contractile process. This system of T-tubules plays an important part in electromechanical coupling, the process by which the action potential in the muscle fibre membrane leads to activation of the actin-myosin contractile mechanism and mechanical shortening.

Molecular mechanisms of contraction

The molecular mechanism of contraction in cardiac muscle is similar to that seen in skeletal muscle. In essence, the thick filaments are made up of myosin molecules, which are long chains grouped together to form the axis of the thick filaments, from which protrude globular heads: two heads for each tail of a myosin molecule. These myosin molecules interdigitate with the thin filaments. Each thick filament is surrounded by six thin filaments in a hexagonal structure, while each thin filament is surrounded by three thick filaments. The thin filaments are made up of two chains of actin molecules, which are twisted round each other to form a long structure with a longitudinal helical groove between the two strands (Figure 1). Positioned along this groove are the rod-shaped tropomyosin molecules, onto which are attached troponin molecules. The part of the troponin molecule attached to tropomyosin is called troponin T. A separate region of troponin (troponin I) also binds to actin.

Arrangement of thick and thin filaments during relaxation and contraction

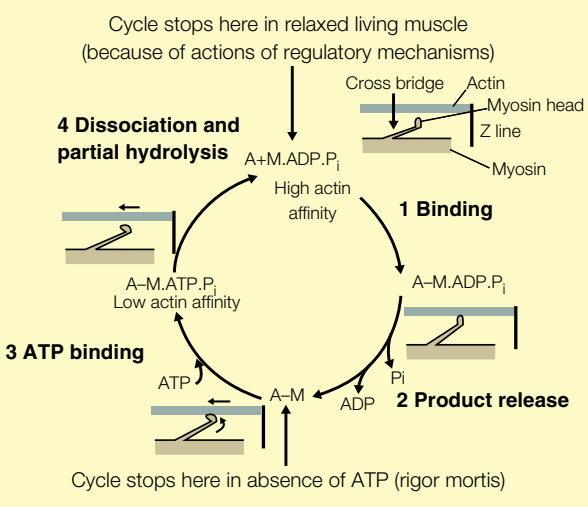


Ca^{2+} binds to troponin C causing tropomyosin to move laterally revealing the myosin binding site on the actin molecule

1

The contractile cycle has four steps (Figure 2). The process is repeated over and over again during contraction. The force of contraction partly depends on the number of myosin heads simultaneously binding and cycling in this way. In the relaxed state, the process does not occur because the sites at which the myosin head binds onto the actin are blocked by tropomyosin (Figure 1). The entire process of contraction is initiated by Ca^{2+} which binds to a region of the troponin molecule (troponin C) weakening the binding of troponin I onto actin and allowing a conformational change, whereby tropomyosin moves laterally and uncovers the myosin binding site on the actin molecule. The elevation of intracellular free Ca^{2+} concentration is initiated by the action potential.

The four steps of muscle contraction



1 An energized myosin head, onto which is bound ADP and phosphate and which has high affinity for a binding site on the actin molecule, binds to the actin molecule
2 Once binding has been achieved, the myosin head releases the ADP and Pi (inorganic phosphate) and energy from a cleaved ATP molecule (origin of the ADP and phosphate). Because of this the myosin head, previously at 90° to the actin molecule, assumes a new conformation at 45° to the actin molecule, pulling the actin over the myosin towards the centre of the sarcomere and shortening the muscle fibre
3 Further ATP is now able to bind to the myosin, reducing its affinity for actin and therefore the myosin head detaches
4 ATP is split to produce ADP and phosphate (still bound to the myosin molecule) again energizing the myosin molecule. The orientation of the head returns to 90 with respect to the actin filaments and the affinity of myosin for actin is increased, leading back to step 1

2

Cardiac action potentials and intracellular Ca^{2+}

The ionic basis of the cardiac action potential is discussed elsewhere.

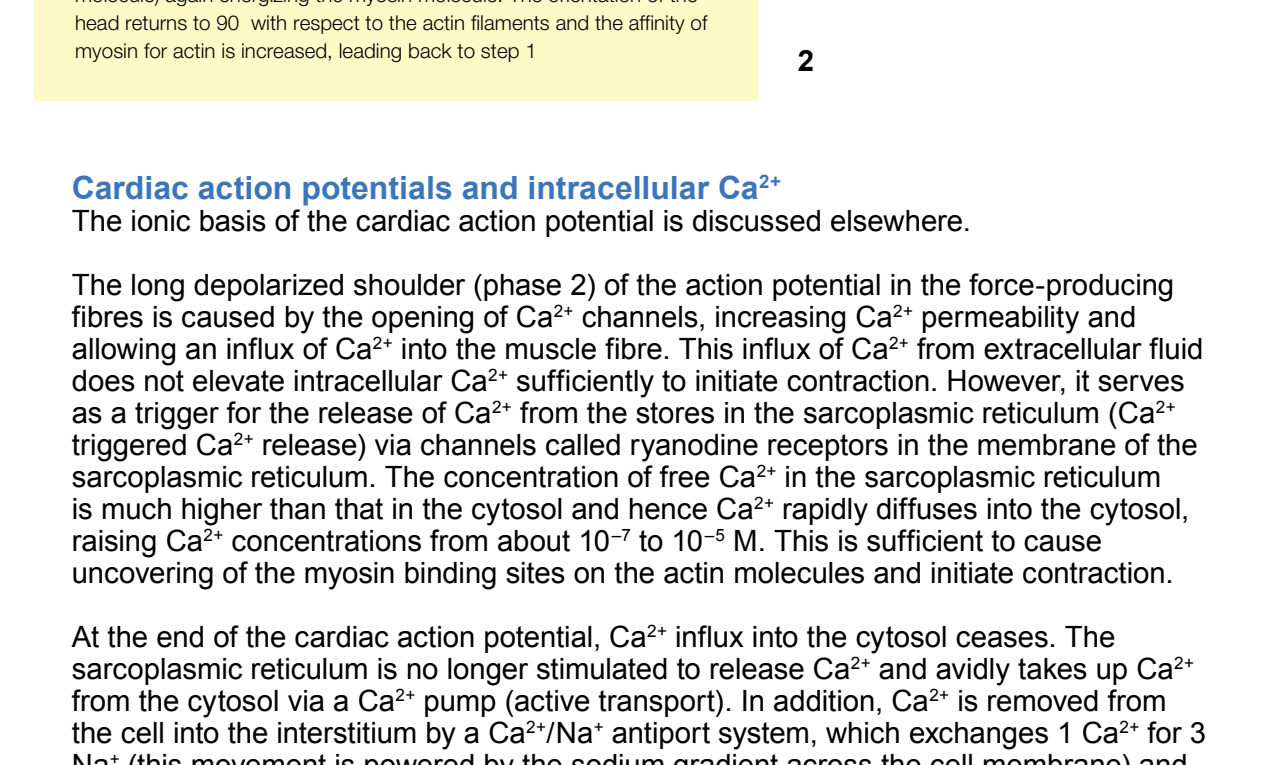
The long depolarized shoulder (phase 2) of the action potential in the force-producing fibres is caused by the opening of Ca^{2+} channels, increasing Ca^{2+} permeability and allowing an influx of Ca^{2+} into the muscle fibre. This influx of Ca^{2+} from extracellular fluid does not elevate intracellular Ca^{2+} sufficiently to initiate contraction. However, it serves as a trigger for the release of Ca^{2+} from the stores in the sarcoplasmic reticulum (Ca^{2+} triggered Ca^{2+} release) via channels called ryanodine receptors in the membrane of the sarcoplasmic reticulum. The concentration of free Ca^{2+} in the sarcoplasmic reticulum is much higher than that in the cytosol and hence Ca^{2+} rapidly diffuses into the cytosol, raising Ca^{2+} concentrations from about 10^{-7} to 10^{-5} M. This is sufficient to cause uncovering of the myosin binding sites on the actin molecules and initiate contraction.

At the end of the cardiac action potential, Ca^{2+} influx into the cytosol ceases. The sarcoplasmic reticulum is no longer stimulated to release Ca^{2+} and avidly takes up Ca^{2+} from the cytosol via a Ca^{2+} pump (active transport). In addition, Ca^{2+} is removed from the cell into the interstitium by a Ca^{2+}/Na^{+} antiport system, which exchanges 1 Ca^{2+} for 3 Na^{+} (this movement is powered by the sodium gradient across the cell membrane) and by active transport of Ca^{2+}. By these means, intracellular (cytosolic) Ca^{2+} concentrations fall rapidly and the myosin binding site on the actin molecule is again blocked by tropomyosin leading to relaxation of the fibre.

Autonomic regulation of force of contraction

Only the sympathetic division of the autonomic nervous system has a significant direct effect on the force of myocardial contraction, because the parasympathetic system provides little innervation of the ventricles. Adrenaline and noradrenaline released from the sympathetic system both activate the G-protein-coupled β_1-adrenoceptors in the cell membrane, which raises the intracellular levels of cAMP. This leads to phosphorylation of the Ca^{2+} L-type channels by a cAMP-dependent protein kinase, which facilitates opening of the channels and leads to influx of Ca^{2+} into the cell (Figure 3). Consequently, a greater number of cross- bridges form and a more forceful contraction occurs. In addition to accelerating contraction, activation of β_1-adrenoceptors also accelerates relaxation. This is because cAMP protein kinase also phosphorylates phospholamban, which enhances Ca^{2+} reuptake into the sarcoplasmic reticulum, and phosphorylates troponin I, which inhibits Ca^{2+} binding to troponin C, thus facilitating relaxation.

Movement of calcium during excitation–contraction coupling in cardiac muscle and the positive inotropic effect of catecholamines



3

Any process that elevates the cytoplasmic concentration of Ca^{2+} increases the force of contraction. Cardiac glycosides achieve this by an indirect mechanism: they reduce the activity of Na^{+}-K^{+} ATPase in the cell membrane (Figure 2). Consequently, intracellular Na^{+} levels rise, leading to a reduction in the transmembrane Na^{+} concentration gradient. This reduces the driving force for Na^{+}-Ca^{2+} exchange and leads to a reduced extrusion of Ca^{2+}. The resulting elevation in intracellular Ca^{2+} increases the force of contraction. ◆

Initiation and Regulation of the Heartbeat

Emrys Kirkman

Emrys Kirkman is Senior Lecturer in Physiology at the University of Durham, UK. He has a PhD from Manchester University and has worked at the MRC Trauma Group, Manchester. He also holds an honorary Senior Lectureship in the Academic Division of James Cook University Hospital, Cleveland. His research interests include trauma-induced changes in cardiovascular control mechanisms, the underlying central nervous pathways and the resulting alterations in haemodynamics and oxygen transport.

The heart has all the components necessary to initiate and maintain a regular heartbeat, without the need for external influence. Thus, a transplanted heart without nervous connection, or a heart completely removed from the body, if adequately perfused with oxygen, beats rhythmically. In the normal intact body, the function of the nervous and humoral regulation is to modulate the activity of the heart, though some aspects of modulation are intrinsic properties of cardiac muscle.

Origin of the heartbeat: pacemaker cells

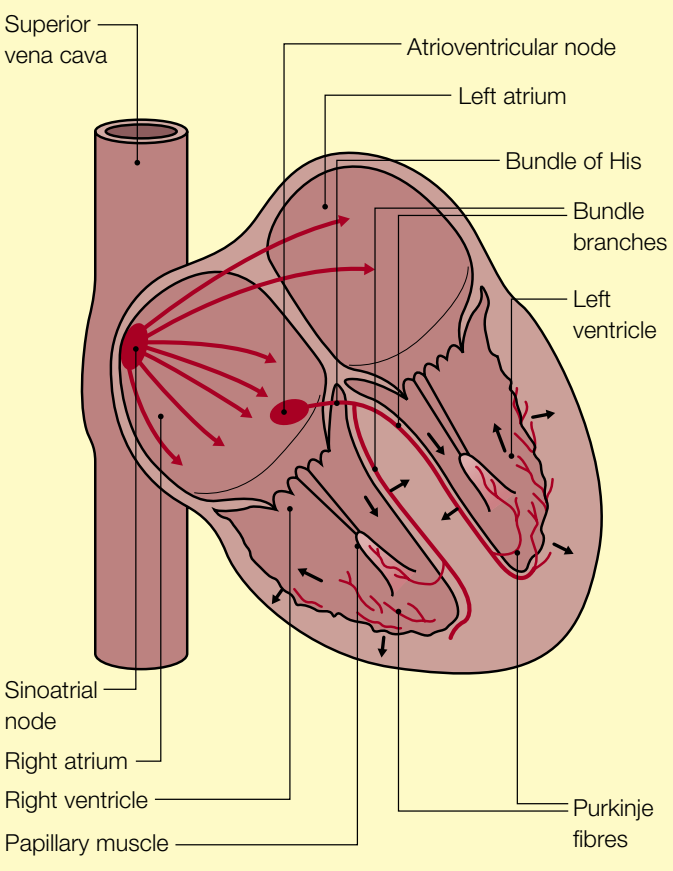
Cardiac muscle fibres can be grouped broadly into three main functional categories:

- pacemakers, which initiate the heartbeat by spontaneously generating action potentials
- conducting fibres, which spread the action potentials throughout the heart in an ordered manner to ensure efficient pumping
- myocardial fibres (most fibres) which produce the force needed to pump blood round the body.

Some of the conducting fibres are also capable of generating action potentials spontaneously, though they do not do so under normal circumstances. The force-producing (myocardial) fibres are normally incapable of spontaneous action potential generation, although under abnormal conditions (e.g. following a period of ischaemia) they may acquire the property and cause problems such as arrhythmias.

The two main groups of pacemaker cells in the heart are found in the sinoatrial (SA) and atrioventricular (AV) nodes (Figure 1). Normally, those of the SA node dominate and the rate and rhythm of the heart is dictated by that of the SA node. However, if the SA node fails, or electrical conduction between the atria and ventricles is blocked, then the AV node pacemaker cells assume control and pace the heart. If the AV node fails, other pacemakers lower in the hierarchy can assume the role of heartbeat generation, though the spread of the heartbeat may be grossly abnormal.

The pacemaker and conduction system



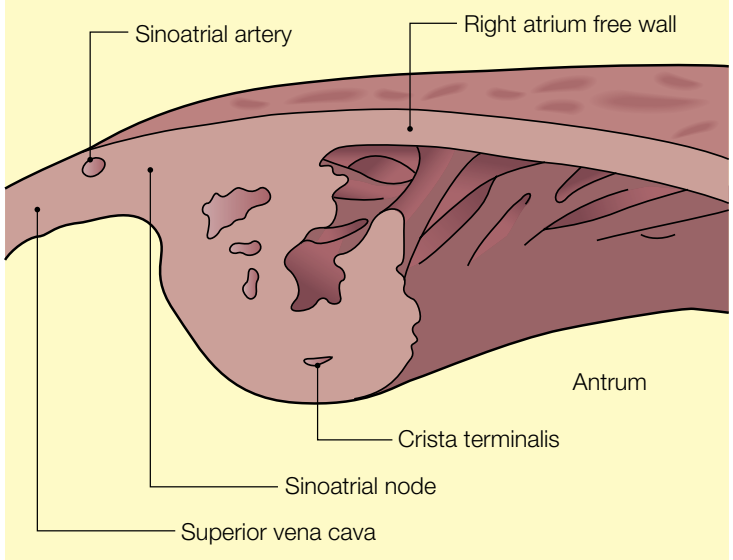
Reproduced with permission from Berne R M, Levy M N. *Principles of Physiology*. Mosby, 2000.

1

In the human heart, the SA node lies in the groove where the superior vena cava joins the right atrium (Figure 2). The SA node contains two histologically distinct fibres types:

- small round cells with few organelles and contractile proteins
- longer elongated cells, which look intermediate between the small round cells and the atrial force-producing cells.

Location of the sinoatrial node



Reproduced with permission from Berne R M, Levy M N. *Principles of Physiology*. Mosby, 2000.

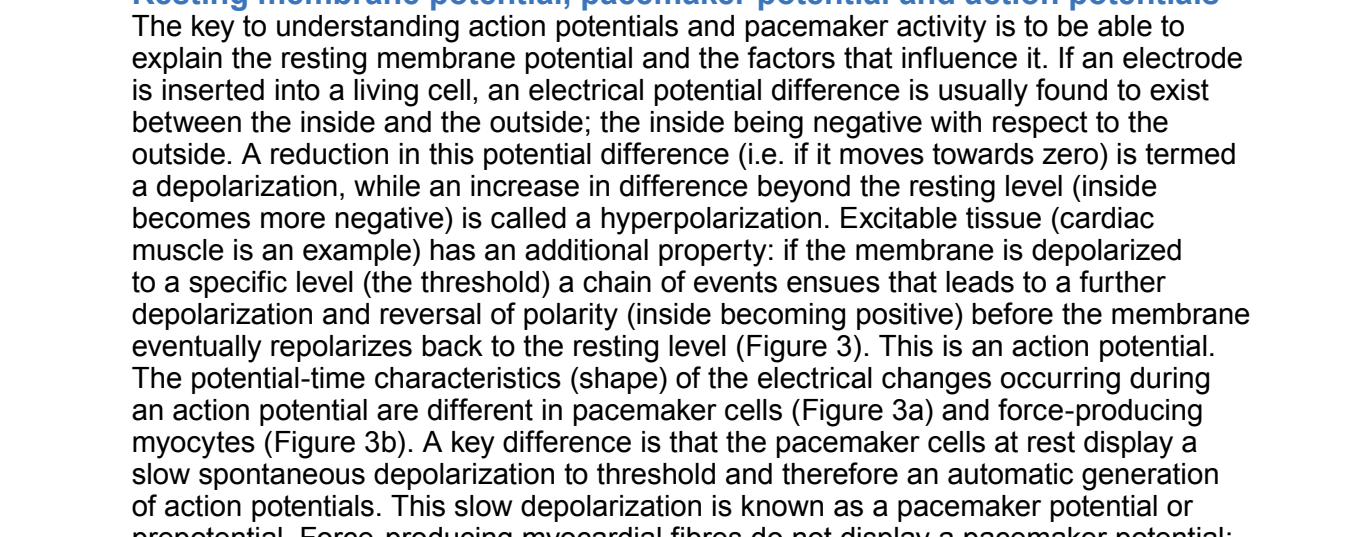
2

The small round cells are thought to be the pacemakers. Detailed mapping of the atrial surface reveals that there are two to three sites of automaticity within 1–2 cm of the SA node. It is suggested that these sites, together with the SA node, act as the normal atrial pacemaker complex. At times, all of the loci may produce action potentials simultaneously, while at other times the primary focus of activity shifts from one group to another, depending on the prevailing level of autonomic activity.

Resting membrane potential, pacemaker potential and action potentials

The key to understanding action potentials and pacemaker activity is to be able to explain the resting membrane potential and the factors that influence it. If an electrode is inserted into a living cell, an electrical potential difference is usually found to exist between the inside and the outside; the inside being negative with respect to the outside. A reduction in this potential difference (i.e. if it moves towards zero) is termed a depolarization, while an increase in difference beyond the resting level (inside becomes more negative) is called a hyperpolarization. Excitable tissue (cardiac muscle is an example) has an additional property: if the membrane is depolarized to a specific level (the threshold) a chain of events ensues that leads to a further depolarization and reversal of polarity (inside becoming positive) before the membrane eventually repolarizes back to the resting level (Figure 3). This is an action potential. The potential-time characteristics (shape) of the electrical changes occurring during an action potential are different in pacemaker cells (Figure 3a) and force-producing myocytes (Figure 3b). A key difference is that the pacemaker cells at rest display a slow spontaneous depolarization to threshold and therefore an automatic generation of action potentials. This slow depolarization is known as a pacemaker potential or prepotential. Force-producing myocardial fibres do not display a pacemaker potential; their resting membrane potential is stable and they require an external stimulus, normally a depolarization from a neighbouring cell, to attain threshold and generate an action potential.

Transmembrane potential changes and currents associated with action potentials



Reproduced with permission from Berne R M, Levy M N. *Principles of Physiology*. Mosby, 2000.

3

Resting membrane potential

The origin of the resting membrane potential is the chemical concentration gradients of ions across the cell membrane and the selective permeability of the membrane to these ions. With regard to pacemaker activity, the two main ions are potassium (K^+) and calcium (Ca^{2+}), together with some contribution from sodium (Na^+). The K^+ concentration is much higher inside the cells, while that of Ca^{2+} and Na^+ is much higher outside (Figure 4). These ions cross the membrane via channels, which display varying degrees of selectivity for particular ions.

K^+ diffuses out of the cell down its concentration gradient. The amount diffusing, as a proportion of the total amount present, is minuscule. However, the movement of the positive ions against a resistance generates a potential difference, with the inside of the cell becoming negative. This electrical gradient opposes the movement of K^+ out of the cell, the negative interior attracting the positive K^+ ions. A state of equilibrium is therefore obtained when the electrical gradient is exactly equal and opposite to the chemical gradient. This is the electrochemical equilibrium, and potential difference attained at this point is referred to as the equilibrium potential for that particular ion. In the case of Ca^{2+} and Na^+ the chemical concentration gradient is such that these diffuse into the cell (Figure 4). Thus, the electrochemical equilibria for these ions has the inside of the cell positive (Figure 4). It is possible to calculate the equilibrium potential for any ion, given the concentrations of the ions on either side of the cell membrane, using the Nernst equation. For a positive ion at equilibrium in an environment at 37°C:

$$E_{ion} = -61.5 \log_{10}([Ion^+]_i/[Ion^+]_o)$$

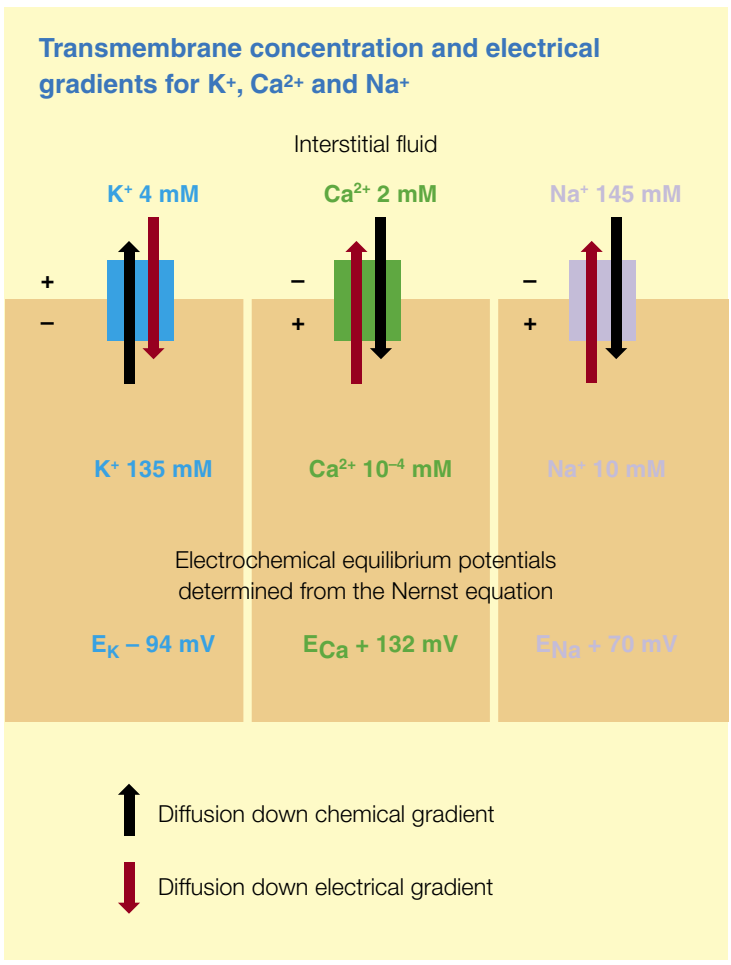
where E_{ion} is equilibrium potential for the ion, $[Ion^+]_i$ is the concentration of the ion inside the cell and $[Ion^+]_o$, is the concentration of the ion outside the cell.

For a typical cardiac muscle fibre cell the equilibrium potential for K^+, Ca^{2+} and Na^+ is shown in Figure 4. Given that each of these ions is attempting to 'drive' the membrane potential to their respective equilibrium potentials, what determines the membrane potential at any given instant? To answer this we must discuss the relative permeability of the membrane to these ions.

Consider an extreme example in which the membrane was permeable only to K^+. Under these circumstances, Ca^{2+} and Na^+ could not diffuse across the membrane and could not influence its electrical potential. Under 'resting' conditions, the membrane potential is closer to E_K (the equilibrium potential for potassium) than it is to E_{Ca} or E_{Na} because the membrane is more permeable to K^+. The resting membrane potential is influenced by the transmembrane chemical concentration difference of a number of ions and the relative permeability of membrane to these ions. This allows us to explain the pacemaker potential and the action potential in the pacemaker cells.

SA node cells: pacemaker and action potentials

The pacemaker and the action potential are brought about by a change in the relative permeability of the membrane to a range of ions, the most important of which are K^+ and Ca^{2+}, with some contribution from Na^+. This change in membrane permeability occurs because a number of membrane channels for these ions are 'gated' (they can be open and functional, or closed and prevent passage of the ion). The state of some ion channels (open or closed) is dictated by the membrane potential (i.e. they are voltage-gated).



4

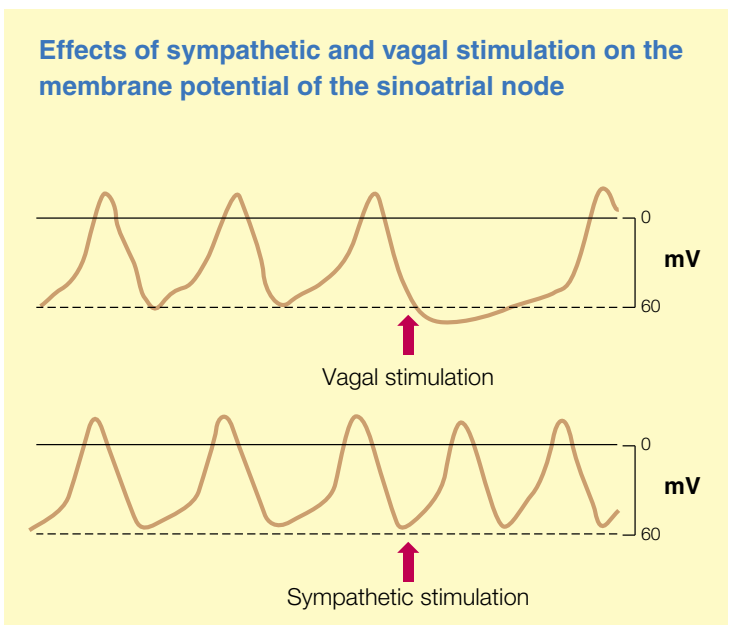
At the start of the prepotential, the permeability to K^+ is high, therefore there is an outward movement of K^+ (producing an outward current called i_K) while the permeability to Ca^{2+} is low. The depolarization that constitutes the pacemaker potential is due to a change in at least three ionic currents:

- an inward current i_f
- an inward calcium current i_{Ca}
- an outward potassium current i_K.

The inward current i_f is mediated mainly by Na^+ entry via specific sodium channels. This inward current became activated (channels opened) during the repolarization phase of the previous action potential, as the membrane potential became more negative than –50 mV. The more negative the membrane potential becomes during the repolarization, the greater the magnitude of this inward current. This inward current serves to depolarize the membrane. The effects of this inward current on membrane potential are opposed by the outward currents due to K^+ (i_K). However, the outward (hyperpolarizing) i_K progressively diminishes and this diminution of a hyperpolarizing current contributes to the depolarization that is the prepotential. As the membrane becomes depolarized beyond about –55 mV, a group of voltage-gated Ca^{2+} channels called T-channels (T for transient because they stay open only for a short while) begin to open, thus increasing membrane permeability to Ca^{2+} and leading to an additional inward current, this time to Ca^{2+} (i_{Ca}), which completes the depolarization to threshold. As threshold is approached, a further group of voltage-gated Ca^{2+} channels called L-channels (L for long-lasting) open, producing a dramatic increase in Ca^{2+} permeability and hence a rapid depolarization, which constitutes the upstroke of the action potential. Then, the L-channels begin to close and the i_K channels open, leading to a repolarization of the cell membrane and the end of the action potential, ready for the whole cycle to begin again. The relationship between the currents of the membrane potential are summarized in Figure 3a.

Autonomic alterations in heart rate

Although nervous impulses are not needed to initiate the heartbeat, activity in the autonomic nervous system can profoundly alter the frequency of action potential formation in the SA node. Vagal stimulation reduces the frequency of spontaneous action potential formation (Figure 5) and induces a bradycardia, while sympathoactivation increases the frequency of action potential formation and gives a tachycardia (Figure 5).



Reproduced with permission from Ganong W F. *Review of Medical Physiology*. McGraw-Hill, 2001.

5

Vagal stimulation causes a hyperpolarization and a reduction in the slope of the pacemaker potential (Figure 5) because acetylcholine released from the vagal nerve terminals activates cholinergic M_2-receptors in the SA node cell membrane. This is an example of a G protein-coupled receptor. Binding of the ligand (acetylcholine) to the M_2-receptor causes the $\beta\gamma$ subunits of the G protein to facilitate opening of a specialized group of K channels in the SA node cell membrane. This increases the permeability to K and causes an inward K current (i_{KACh}) which:

- hyperpolarizes the cell
- counters the decay in K permeability produced by closure of the K channels discussed above and reduces the slope of the prepotential
- in addition, the particular G protein attached to the M_2-receptor leads to a fall in intracellular cAMP which in turn slows the opening of the Ca^{2+} channels, further reducing the slope of the prepotential.

In contrast, noradrenaline and adrenaline both increase the slope of the prepotential (Figure 5) because they activate β_1-adrenoceptors. The β_1-adrenoceptor is another example of a G protein-coupled receptor. However, in this case, the specific G protein coupled to the receptor leads to an increase in intracellular cAMP and facilitates the opening of Ca^{2+} channels.

The right vagus and sympathetic nerves predominantly affect the SA node, and the left predominantly affects the AV node, therefore right-side stimulation has a greater effect on heart rate while left-side stimulation predominantly affects AV conduction. The left vagus slows AV conduction and sympathetic stimulation shortens conduction time and refractoriness. ◆

Mechanical Events and the Pressure–Volume Relationships

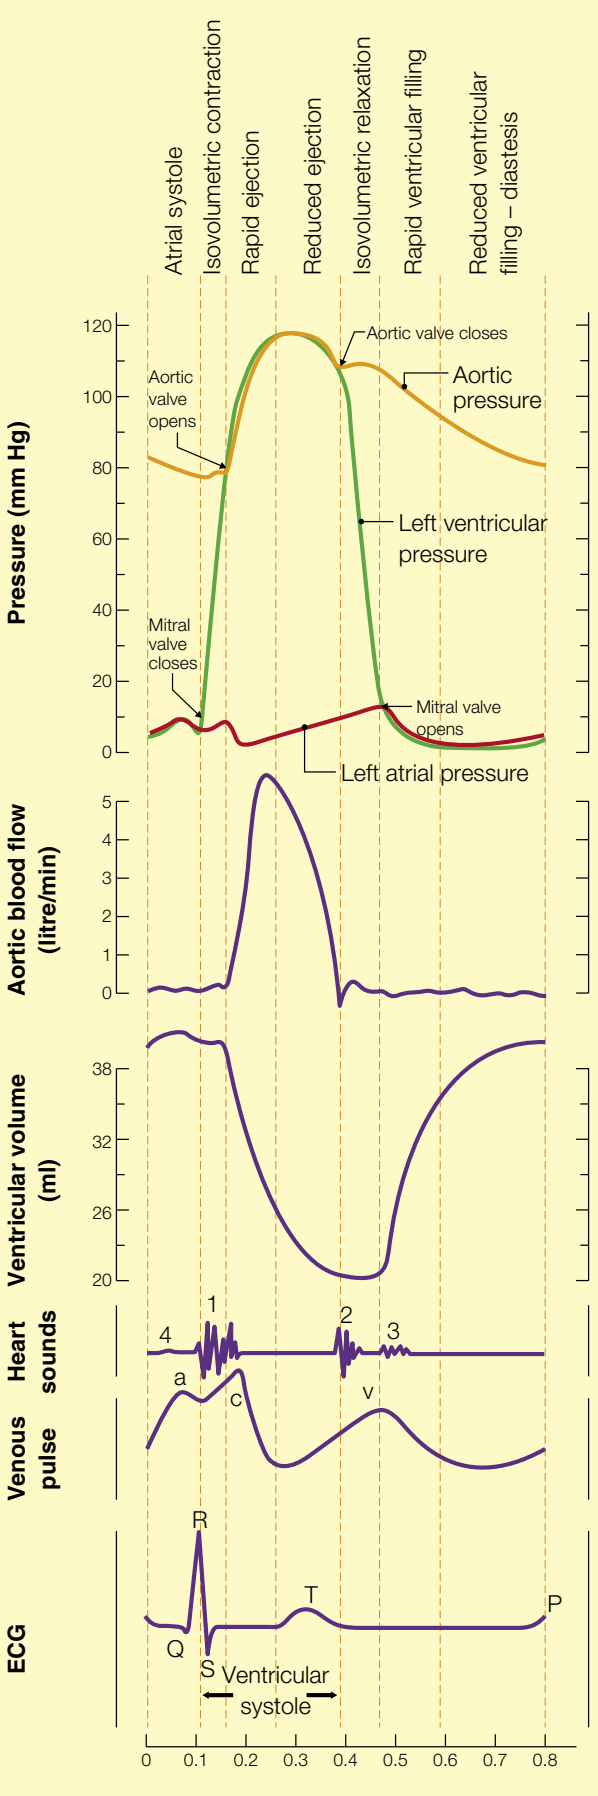
Emrys Kirkman

Emrys Kirkman is Senior Lecturer in Physiology at the University of Durham, UK. He has a PhD from Manchester University and has worked at the MRC Trauma Group, Manchester. He also holds an honorary Senior Lectureship in the Academic Division of James Cook University Hospital, Cleveland. His research interests include trauma-induced changes in cardiovascular control mechanisms, the underlying central nervous pathways and the resulting alterations in haemodynamics and oxygen transport.

The depolarization phases in the cardiac muscle fibres spread throughout the myocardium. In a single fibre, conduction starts just after depolarization and lasts until just after repolarization is complete. The atria contract, completing the filling of the ventricles and thus enhancing their action. In the absence of effective atrial contraction (e.g. atrial fibrillation) cardiac output is decreased on average by 15%.

During diastole, when cardiac muscle is relaxed, blood returns to the heart and passes through the atrioventricular (AV) valves into the ventricles. The semilunar valves, between the ven-tricles and the arteries, are closed as arterial pressure exceeds ventricular pressure (Figure 1). Under normal circumstances, 70% of ventricular filling occurs by late diastole.

Pressure and volume in the left ventricle, systemic artery and veins, heart sounds and ECG



1

Immediately after the P wave of the ECG, the atrial muscle fibres contract giving atrial systole. This helps to push a final amount of blood towards the ventricles. Although there are no valves between the atria and the veins, only small amounts of blood regurgitate into the veins because atrial contraction tends to narrow the orifices between the atria and the superior and inferior venae cavae and the pulmonary veins. In addition, the inertia of blood flowing towards the heart tends to keep the blood within it. The small regurgitation of blood that does occur into the veins gives rise to the 'a' wave of the venous pulse (Figure 1). Thereafter the action potentials sweep through the ventricles (giving rise to the QRS complex) causing ventricular contraction and ventricular systole. During the first phase of ventricular systole, the overall muscle fibre length is not shortened. This is because as the filaments slide, tension is generated in the elastic elements of the walls of the ventricles, which raises pressure in the ventricles above that in the atria. This causes closure of the AV valves (and generation of the first heart sound). However, ventricular pressure is initially below arterial pressure and therefore the semilunar valves remained closed. Thereafter, pressure increases rapidly within the ventricles and, as there is no change in volume, this is termed the isovolumetric phase of ventricular systole (Figure 1). As ventricular pressure continues to rise it eventually exceeds arterial pressure (at about 10.8 kPa (80 mm Hg) in the left and 1.3 kPa (10 mm Hg) in the right ventricle) and blood is ejected rapidly into the arteries so that there is a large and rapid decrease in ventricular volume, accelerating blood flow into the arteries and increasing arterial pressure. This period of rapid ejection accounts for about the first third of ejection time and culminates in the attainment of the peak arterial and ventricular pressures (about 16 kPa (120 mm Hg) and 3.3 kPa (25 mm Hg), respectively in the left ventricle/aorta and right ventricle/pulmonary artery (Figure 1), though there is considerable normal variation between and within individuals. Thereafter, there is a further period of reduced ejection as blood continues to be ejected into the arteries. However, during this phase, blood flow decelerates as potential energy stored in the elastic wall of the arteries reverses the pressure gradient and arterial pressure exceeds ventricular pressure (Figure 1). Despite this reversed pressure gradient, flow continues into the arteries because of its momentum. However, pressure in the arteries falls in this phase because the run-off of blood into the tissues exceeds the amount of blood entering the arteries from the ventricles.

In a normal heart, immediately before ventricular systole, the ventricles contain about 130 ml blood (end-diastolic ventricular volume, EDV). During the entire ventricular ejection phase, about 70–90 ml blood is ejected from each ventricle (stroke volume, SV), leaving about 50 ml of blood in the ventricles (end-systolic ventricular volume, ESV). Ejection fraction (SV/EDV) is thus about 65%. The rapid increase in arterial pressure causes the arteries in some places to impact with the wall of adjacent veins. This, together with a pushing of the tricuspid valves towards the atria in early systole, contributes to the second venous pressure wave of the cardiac cycle: the c wave (Figure 1).

About 50 ms after the end of the myocardial action potential the fibres begin to relax (during and immediately after the T wave of the ECG); this is ventricular diastole. The rapid reduction in ventricular pressure results in it falling quickly below the arterial pressure and the threatened regurgitation of blood from the arteries towards the ventricles causes the semilunar valves to snap shut, giving rise to the second heart sound and the dicrotic notch, evident on the arterial pressure waveform. Pressure within the arteries is now kept higher than ventricular pressure because of the elastic recoil of elements of the arterial wall, which were stretched during systole.

During the first phase of ventricular diastole both semilunar and AV valves are closed. Therefore the rapidly falling pressure is not accompanied by a change in volume and this phase is called isovolumetric relaxation. Thereafter, ventricular pressure falls below atrial pressure and the AV valves open. Initially, blood flow into the ventricles is rapid, giving a sharp rise in intraventricular volume (Figure 1), and a fall in venous pressure (which had previously been increasing as blood was unable to flow from the atria through the closed interventricular valves). This sharp fall in venous pressure produces the third venous pressure pulse of the cardiac cycle: the v wave (Figure 1).

Following the rapid filling phase, blood continues to flow into the ventricles during the remainder of diastole, but now at a reduced rate. This phase is termed diastesis, at the end of which, ventricular filling is about 70% complete before the whole cycle is initiated again by atrial systole immediately after the next P wave of the ECG.

It should be evident from this description that atrial contraction is not essential for ventricular filling, which occurs even in atrial fibrillation. At lower heart rates, atrial contraction is even less important because ventricular filling is essentially complete by the end of diastesis. However, as heart rate increases there is a much more marked reduction in diastolic that in systolic time. Thus, atrial systole becomes increasingly important for ventricular filling during tachycardia.

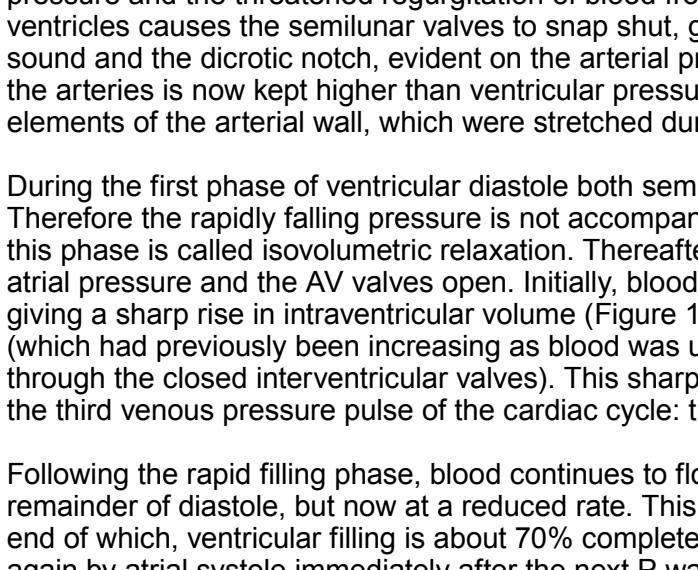
Regulation of cardiac contraction

The two main mechanisms important for regulating the force of cardiac contraction and stroke volume are those that are intrinsic to cardiac muscle and those that are mediated by nervous and hormonal control of the heart.

Intrinsic mechanisms: the Frank–Starling mechanism

A relationship exists between the maximal force a muscle fibre can produce and its length immediately before contraction (preload). This was first described for cardiac muscle by Frank in 1895. He showed that over a limited range of preloads, increasing preload can increase force of contraction. This idea was refined by Starling in a series of studies published in 1914, which showed that an increase in right atrial pressure led to increased force of ventricular contraction and thus stroke volume. This can be represented graphically (Figure 2) as a relationship between end-diastolic volume (which dictates the length of the ventricular muscle fibres just before systole) and an index of cardiac muscle force of contraction: in practice this is taken as either stroke volume or stroke work.

Starling curves and the effects of haemorrhage and exercise



2

Normal cardiac function is represented by a point on the upward slope of this relationship (Figure 2). Thus, if venous return and end-diastolic volume increase (increased preload) the heart responds by producing a more forceful contraction to eject the excess blood. This is an important safety feature, which also matches the output from each side of the heart. Thus, if one side of a heart ejects more blood than the other, there is an increased venous return to the second side and, by the Frank–Starling mechanism, an increase in the output of the second side to match the first.

The Frank–Starling mechanism also helps the heart to respond to changes in afterload (arterial blood pressure or vascular resistance). An increase in the force against which the heart has to pump, leads initially to a reduction in the amount of blood ejected. As a consequence, more blood is left in the heart at the end of systole. When the venous return is added to this, the end-diastolic volume for the next beat is increased and the heart produces a more forceful contraction. Thus, over a few beats, stroke volume can be returned to the original level despite an increase in afterload, albeit at the cost of increased preload.

The mechanisms underlying the Frank–Starling relationship include a variation in the total number of cross-bridges that can be formed. There is an 'optimal' length of muscle fibre at which the maximal number of cross-bridges can be formed, beyond which the number of cross-bridges is reduced. In addition, stretching cardiac muscle increases the sensitivity of the contractile mechanism to Ca^{2+}.

An increase in heart rate can also increase the force of contraction independent of changes in preload. If preload and afterload are maintained constant (experimentally), then an increase in heart rate leads to an increased force of contraction (the Treppe phenomenon). The mechanism underlying this effect is an elevation in intracellular Ca^{2+} concentration for two reasons: there are more depolarizations (action potentials) per unit time (with Ca^{2+} moving in with ejection potential) and there is an increase in the inward Ca^{2+} current per action potential. *In vivo*, this effect is offset by the reduction in diastolic filling time (which accompanies a tachycardia) and, as a consequence, a reduction in preload if the increase in heart rate is sufficiently great.

Extrinsic regulation

The most important extrinsic regulator in normal physiology is the sympathetic nervous system. Activation of cardiac β_1-adrenoceptors by catecholamines increases the myocardial force of contraction. This is achieved by increasing the concentration of cytosolic Ca^{2+} during each beat and results in the Starling curve being displaced upwards and leftwards (Figure 2). This means that for a given filling pressure, cardiac output is increased, and for a decreased filling pressure, cardiac output is maintained. This increase in force of contraction without the need for an increase in resting (end-diastolic) muscle fibre length is termed a positive inotropic effect. Other hormones (e.g. insulin, glucagon) also have positive inotropic effects, though they are not thought to play a part in normal cardiac regulation. Conversely, some agents (e.g. inhalational anaesthetics) have a negative inotropic effect (moving the Starling curve downwards and to the right, Figure 2).

The term inotropic effect is sometimes used interchangeably with the term contractility, which a number of authors take as a 'measure of the performance of the heart at a defined preload and afterload'. Because of the need to eliminate the effects of alterations in preload, afterload and heart rate, measuring inotropic effect in practice is difficult. In an experimental setting, one index of contractility is obtained from the contour of individual ventricular pressure curves. Stimulation of the sympathetic nerves to the heart produces a more forceful contraction, resulting in a rapid rise in pressure, while a depressed heart shows the opposite effect. This can be quantified by measuring the maximum rate of rise of ventricular pressure (dP/dt max) during the beat. Such measurements are difficult to make in practice. Clinically, an indication of inotropic state is taken from the initial velocity of blood flow in the ascending aorta or cardiac ejection fraction. All of these can be influenced by confounding factors (e.g. heart rate) which means that in clinical practice they are only a rough guide.

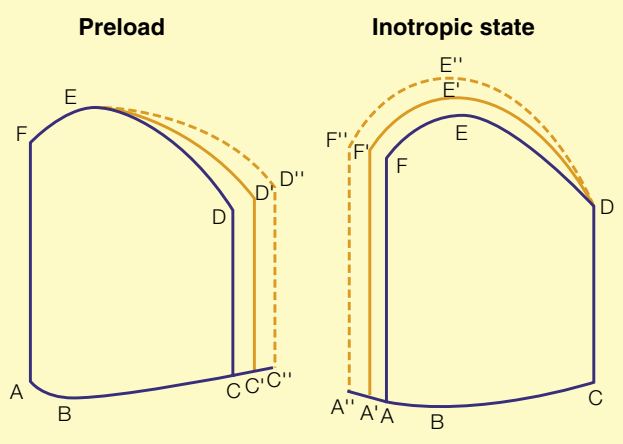
Pressure–volume loops

By directly relating changes in intracardiac pressure to volume, and eliminating the time element, pressure–volume loops can provide additional insight into cardiac function. The effects of altering preload and inotropic state on pressure–volume loops are summarized in Figure 3.

For each pressure–volume loop, A–C represents diastolic filling (ventricular pressure falls despite inflow of blood between A and B because of the progressive relaxation of ventricular muscle). Thereafter C–D represents the phase of isovolumetric contraction (pressure rises but there is no reduction in volume) until the semilunar valves open at D. Ventricular ejection occurs from D to F (D–E represents the period of rapid ejection where the greatest volume of blood is ejected and pressure continues to rise in the ventricle). E–F represents the reduced ejection phase with ventricular pressure falling. The volume of blood ejected between D and F is the stroke volume. After F the pressure in the ventricles falls rapidly and the semilunar valves close as the heart enters diastole. F–A therefore represents isovolumetric relaxation before the AV valves open at A and blood flows once again into the ventricles.

With increasing venous return and preload (Figure 3) end- diastolic volume becomes progressively larger A–C, C' and C'', respectively. However, because of the Frank–Starling mechanism there is a greater stroke volume (D, D' and D''–F, respectively). By contrast, a positive inotropic effect produces a greater force of contraction and hence greater pressure development (E–E'') and emptying of the ventricle (D to F–F'') and reduced residual volume A–A''.

Effects of increases in preload and inotropic state on the pressure–volume relationships of the left ventricle during a complete cardiac cycle



See text for explanation

These pressure–volume loops from successive heart rates can be used to assess the inotropic state of the heart *in vivo* without the need to maintain preload and afterload strictly constant. However, they require a high degree of invasive monitoring and are not applicable to routine clinical practice.

Control of cardiac output

In vivo, many intrinsic and extrinsic factors operate simultaneously. This can be exemplified by considering the response to haemorrhage and exercise.

Haemorrhage

The initial consequences of blood loss is a reduction in venous return and therefore in end-diastolic volume. This, by the Frank–Starling mechanism, leads to a reduction in cardiac stroke volume (Figure 2). Consequently, there is a reduction in arterial pulse pressure, which in turn leads to unloading of the baroreceptors. This causes a reflex increase in sympathetic drive to the heart and an inhibition of vagal efferent activity to the heart. The increased sympathetic drive to the ventricles produces a positive inotropic effect which limits the fall in stroke volume (Figure 2). In addition, the tachycardia resulting from vagal inhibition and sympatho-activation helps to limit the fall in cardiac output (cardiac output = stroke volume x heart rate). However, a severe tachycardia would be counter-productive because it would diminish diastolic filling time and preload, especially when venous return is impaired. This is perhaps one reason why heart rate does not rise to high levels during simple blood loss: as simple haemorrhage becomes severe, a second reflex supersedes the baroreceptor reflex causing a bradycardia, which can paradoxically improve cardiac output because stroke volume may increase as a result of improved diastolic filling.

Exercise

During exercise an initial anticipatory increase in sympathetic drive to the ventricles provides a positive inotropic effect and an increase in stroke volume. This is reinforced once exercise begins as venous return and consequently preload is enhanced because of activity of the skeletal muscle pump. A much larger tachycardia can be tolerated in this instance because venous return is enhanced rather than diminished as is the case during blood loss. ◆

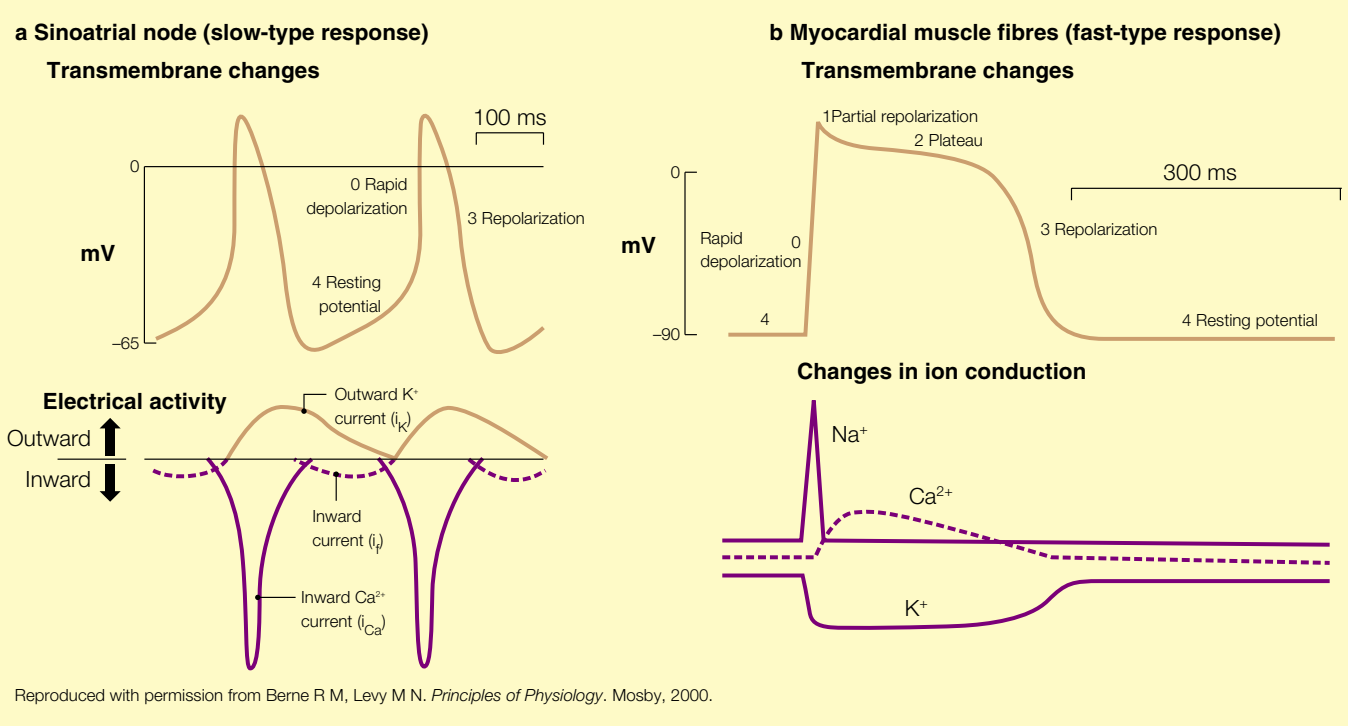
Myocardial Action Potential

Emrys Kirkman

Emrys Kirkman is Senior Lecturer in Physiology at the University of Durham, UK. He has a PhD from Manchester University and has worked at the MRC Trauma Group, Manchester. He also holds an honorary Senior Lectureship in the Academic Division of James Cook University Hospital, Cleveland.

A recording of membrane potential during an action potential in a myocardial (force-producing) fibre shows a different profile from that in the pacemaker cells. The resting membrane potential in myocardial fibres is constant and considerably more negative (Figure 1b). Once the cells have been depolarized to threshold by an external stimulus (normally spread of activity from a neighbouring fibre) the overshoot of the action potential is much steeper than that seen in the pacemaker cells. It is followed by a partial repolarization and a long shoulder (with the inside of the cell positive) before the membrane repolarizes to its resting level (Figure 1b).

Transmembrane potential changes and currents associated with action potentials



1

The rapid upstroke is produced by the opening of voltage-gated fast sodium channels. These channels have two gates called the 'm' or activation and 'h' or inactivation gates. At the resting membrane potential the m gate is closed (the channel does not allow passage of Na^+) and the h gate is open. When the membrane is depolarized towards threshold some of the channels respond by opening the m gate enclosing the h gates. However, the important difference between the m and h gates is that the m gates open rapidly (within 0.1–0.2 ms) while the h gates close relatively slowly (over 1 ms). Thus, for a period, the channels open as the m gates have opened and h gates have not yet closed, thus allowing passage of Na^+. As a consequence, membrane permeability to Na^+ increases. Because the sodium equilibrium potential E_{Na} is markedly positive this depolarizes the membrane further, causing more sodium channels to be opened and generating a positive feedback or regenerative process, giving a very fast depolarization and overshoot of membrane potential. This is short-lived because the h gates close and inactivate the channel. The membrane permeability to Na^+ falls and the fibre begins to repolarize (Figure 1b). In addition, in some myocardial cells, there is a transient increase in K permeability during this phase, which augments this partial repolarization.

Unlike skeletal muscle, and most nerves, the early repolarization described above is only partial because of a slightly delayed increase in permeability to Ca^{2+}. The two main groups of calcium channels important here are both voltage gated and are described in relation to heart rate elsewhere. The T-channels begin to open when the membrane potential has depolarized to about –70 mV and are followed by the L-channels which begin to open when the membrane is depolarized to –10 mV. These allow Ca^{2+} to move down its electrochemical gradient into the cell and thus maintain the depolarized state. The Ca^{2+} channels do not contribute to the upward stroke of the action potential because they take much longer to open than the fast Na channels. However, by the time the fast Na channels have become inactivated these Ca^{2+} channels are open, giving a long shoulder to the myocardial action potential, during which substantial amounts of Ca^{2+} enter the cell (this is important in initiating mechanical contraction). Although the activation of T-channels is short-lived, that of L-channels is long lived, hence the long shoulder of the myocardial action potential. The L-channels can be blocked by a number of calcium channel blocking agents (e.g. verapamil, nifedipine, diltiazem).

During the shoulder of the action potential, the Ca channels begin to close. Towards the end of the shoulder, one group of K channels is activated. They began to open at membrane potentials that prevailed towards the end of the initial upstroke of the myocardial action potential. However, they open slowly and it is not until the end of the shoulder of the action potential that they produce an increase in membrane permeability to K and hasten the process of repolarization (Figure 1). This repolarization causes the closure of the remaining Ca channels (contributing further to the repolarization). The importance of the K current in bringing about repolarization is emphasized by the finding that genetic defects that result in blockade of some of the K channels are associated with delayed repolarization.

During repolarization, increasing numbers of fast Na channels (which were inactivated by closure of the h gates at the end of the initial fast up-stroke of the action potential) begin to reset by closure of the m and opening of the h gates. Although the Na channels are still closed, the importance of this event is that they are returned to the original state ready to be activated during the next action potential.

As a consequence of these changes, the muscle fibre is absolutely refractory (unable to produce a second action potential) while most of the fast Na channels are inactivated and the Ca channels have not completed their cycle. The absolute refractory period is from the start of the upsweep of action potential until halfway through the main repolarization. For a further period, the fibre is relatively refractory (can produce an action potential but only with a stronger than usual stimulus) until the resting membrane potential has been regained. Since the duration of action potential (200–300 ms) is longer (the time required to obtain the peak mechanical event) the cardiac muscle fibre cannot be tetanized. This is an important safety feature, because tetanic contraction would preclude the heart's repeated pumping action.

The numbering of the phases of the membrane potential changes within the action potential are shown diagrammatically elsewhere. Phase 0 is much steeper in the myocardial fibres because it is carried by Na^+ entering through fast-opening Na channels, while it is less steep in the sinoatrial (SA) and atrioventricular (AV) node pacemaker cells, which do not have fast Na channels, and rely on the slower opening Ca channels.

AV node and Purkinje fibres

The mechanisms underlying spontaneous generation of action potential in the AV node are probably similar to those in the SA node. The Purkinje fibres are also capable of producing action potentials spontaneously, though it is thought that Ca is not involved and that the process is determined by the shift in balance between the outward K current (i_K) and the inward current (i_f), mediated by Na^+.

Spread of the heartbeat from the SA node

The action potential from the SA node travels along each muscle fibre, in the same way action potentials travel along nerve fibres, until it comes to a junction with the next muscle cell. The neighbouring force-producing atrial muscle fibre is then depolarized to threshold by local currents flowing via low-electrical resistance gap junctions between cells.

In the heart, muscle cells are joined by intercalated discs, which incorporate gap junctions. They are sites of low electrical resistance and facilitate the movement of local currents between cells. They are made up of conexons, which are hexagonal structures made up of six polypeptide chains surrounding a central channel about 1.6–2.0 nm wide which connect with the cytosol of the adjacent cell. Thus, when one cell is depolarized, giving an action potential, the potential difference between the two cells causes local currents to flow into its neighbour, depolarizing the second cell to threshold and triggering an action potential in it. These gap junctions are predominantly found between cells that are in contact with one another longitudinally, and are sparse between cells that lie side by side. The action potential therefore travels in a direction parallel to the long axis of the muscle fibres and spreads radially over the surface of the right atrium away from the SA node at rate of about 1 m/s (Figure 1).

Tracts of specialized conducting muscle fibres rapidly transmit the action potentials from the SA node to the left atrium. These consist of the anterior interatrial myocardial band and the middle and posterior bands, which consist of a mixture of ordinary myocardial and specialized conducting cells. Although action potentials can spread throughout the atria in this manner, they cannot pass directly from the atria to the ventricles because there are no low electrical resistance pathways between these two structures, except at the AV node. Action potential conduction through the AV node is relatively slow, resulting in a delay before the action potential is passed on to the bundle of His (a group of specialized conducting muscle fibres that rapidly transmit the action potential towards the apex of the heart).

The bundle of His originates in the AV node as a single bundle of muscle fibres running subendocardially for about 1 cm along the interventricular septum. The bundle divides into a right and left branch. The right branch is essentially a continuation of the original bundle while the left, thicker, branch arises at right angles to the original, perforates the interventricular septum and runs down the left subendocardial surface of the septum. The left branch splits again into a thick branch that runs posteriorly and a thinner anterior branch. Finally, all of these branches divide into complex networks of conducting Purkinje fibres, which ramify over the subendocardial surface of both ventricles. The Purkinje fibres have a larger diameter and are able to conduct action potentials faster than any other tissue within the heart (1–4 m/s).

Action potentials from the AV node travel down the bundle of His towards the apex of the heart, generating action potentials in the cells of the interventricular septum. These action potentials sweep from left to right through the septum (Figure 2). In addition, the fibres of the papillary muscles are depolarized to threshold. Once the action potentials reach the Purkinje fibres (via the bundle of His) there is rapid conduction over the entire subendocardial surface of the ventricles. The wave of excitation then spreads at a slower rate (0.3–0.4 m/s) through the thickness of the wall of the ventricles towards the epicardial surface (Figure 2). The apical and central epicardial regions tend to be depolarized first, while the last portions of the ventricles to be excited are the posterior basal epicardial regions (Figure 2).

Fast versus slow response action potentials

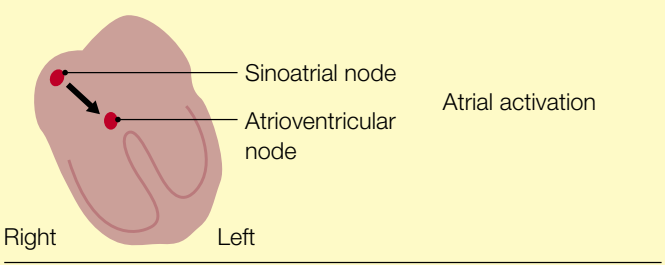
The velocity of transmission of action potentials from fibre to fibre is influenced by the shape (voltage-time profile) of the action potential. Figure 1 shows the two basic shapes of cardiac action potential: the pacemaker-type from the SA and AV nodes and the myocardial type from the other fibres. The former is termed a slow response action potential and the latter is called a fast response. Notable differences in the fast response action potential include a greater resting membrane potential, more rapid depolarization and greater overshoot during the action potential. All of these influence how quickly the action potential is transmitted from one fibre to the next. A greater potential difference between two fibres causes a more rapid depolarization in the next fibre in the chain to threshold and a more rapid transmission. This is why transmission is slow through the AV node, but more rapid elsewhere. Fast response fibres may be converted to slow response after a period of ischaemia, and such changes may predispose to arrhythmias.

The spread of depolarization and action potentials through the heart, starting at the SA node, has a number of important implications. These include effects on other cardiac pacemaker regions and the generation of electrical disturbances, which can be recorded at the body surface as an electrocardiogram.

Hierarchy of cardiac pacemakers

Several regions in the heart have intrinsic pacemaker activity. However, the SA node normally predominates because it has the highest intrinsic rate. Thus, an action potential originating in the SA node is delivered to the other pacemaker cells before they reach the threshold of their own accord. However, if an ectopic focus developed pacemaker activity at a higher rate, the heart rate would be dictated by the fastest pacemaker focus and the pacemaker cells of the SA node would become suppressed by a process known as overdrive suppression. The mechanism underlying this phenomenon is thought to involve the Na^+-K^+ ATPase (sodium–potassium) pump. Although only a relatively small number of Na^+ enter and K^+ leave the cell with each action potential, after repeated action potentials a significant quantity of ions have moved. The Na^+-K^+ ATPase restores the chemical gradients for these ions. Therefore, after the period of stimulation at high frequency the activity of the Na^+-K^+ ATPase is increased. This transports an unequal number of Na^+ and K^+ ions: 3 Na^+ are extruded for every 2 K^+ pumped into the cell. Therefore, there is a net movement of positive charge outwards. Consequently, activity of Na^+-K^+ ATPase tends to hyperpolarize the membrane and make it less likely to depolarize spontaneously to threshold. If the SA node has been driven at a high rate by an ectopic focus it takes some time to regain its own intrinsic rhythm once the ectopic focus ceases activity – this is known as the sinus node recovery time. In the case of sick sinus syndrome, the sinus node recovery time is prolonged and the asystole, because of the delay before the SA node regains its automaticity, can lead to syncope.

Normal spread of electrical activity in the heart



Reproduced with permission from Ganong W F. *Review of Medical Physiology*. McGraw-Hill, 2001.

Ectopic foci

Under normal conditions the heartbeat originates from the SA node and spreads in an ordered sequence to the remainder of the heart. Each cardiac muscle fibre produces only one action potential in response to stimulation by a neighbouring cell. However, it is possible for an alternative area of the heart to develop automaticity because of a change in the properties of the muscle fibres. Recent studies have shown that an important area for the development of ectopic foci leading to atrial fibrillation are the pulmonary veins.

Triggered activity

Triggered activity relates to a spontaneous action potential, or series of action potentials, following a 'normal' action potential. The two forms are early afterdepolarization (EAD) and delayed afterdepolarization (DAD).

EAD occurs predominantly at low resting heart rates and is characterized by an additional depolarization occurring at the end of phase 2 of the myocardial action potential wall or midway through phase 3 (Figure 3a). It is likely that these represent different mechanisms of action. Both cases are thought to involve an activation of Ca^{2+} channels late in the cardiac action potential and are more likely under conditions that prolong the cardiac action potential.

Under normal circumstances, the Ca^{2+} channels are activated early in the action potential and contribute to the plateau (phase 2) of the action potential. They are inactivated at the end of phase 2 and during phase 3. However, if the cardiac action potential is sufficiently prolonged, some of these Ca^{2+} channels can become reset and then re-activated, allowing a further inward Ca^{2+} current, causing a second depolarization of the membrane and additional action potentials. It is thought that the L-type Ca^{2+} channels may be responsible for the EADs that occur towards the end of phase 2, while the T-channels, which can be activated only at membrane potentials significantly below the plateau level, may be responsible for the EAD occurring midway through phase 3.

DAD involves an afterdepolarization during phase 4 of the cardiac action potential (Figure 3b) and is more likely at higher heart rates. As the cardiac muscle fibre is stimulated at increasingly higher rates an afterdepolarization becomes apparent in phase 4. At higher stimulation rates this becomes more pronounced and depolarizes the fibre to threshold, thus producing a spontaneous action potential followed by further afterdepolarization. At even higher stimulation rates, successive spontaneous action potentials produce afterdepolarizations to threshold, giving volleys of spontaneous action potentials and hence a potential ectopic focus in the heart. The mechanisms underlying this phenomenon are thought to involve intracellular Ca^{2+} levels, and the appearance of DAD is a feature of the toxic effects of drugs (e.g. cardiac glycosides, which raise intracellular Ca^{2+} levels). It is thought that the elevated levels of intracellular Ca^{2+} cause the opening of membrane channels, which allow the inward movement of positive ions including Na^{+}. In addition, it is known that the elevated intracellular Ca^{2+} levels stimulate Na^{+}/Ca^{2+} exchange across the cell membrane. This is electrogenic, because 3 Na^{+} enter the cell for every Ca^{2+} expelled, producing a net inward movement of positive charge and a depolarization.

Potential-time profile from a myocardial fibre during an action potential

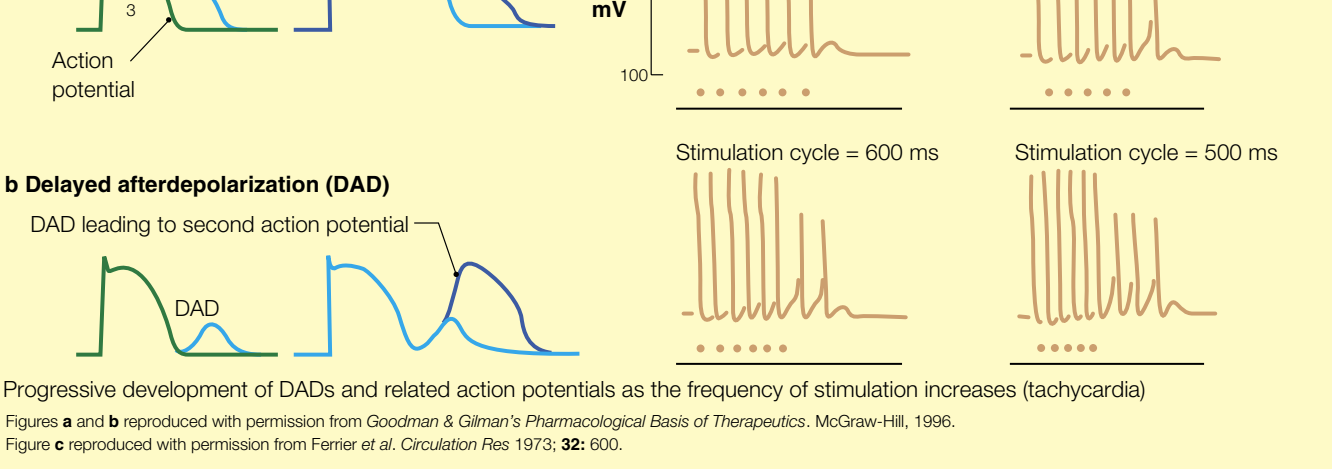
Re-entry

Re-entry is a feature of a series of muscle fibres in contrast to triggered activity which is the property of individual muscle cells. In re-entry, activity generated by single cardiac impulse (SA node depolarization) re-invades part of the heart through which it has previously passed, thereby causing further action potentials. This is termed ordered when the activity traverses a fixed anatomical pathway or random when the pathway is constantly changing. A good example of random re-entry is fibrillation.

Consider a chain of muscle fibres along which the cardiac action potential spreads. In a number of areas in the heart, bundles split into two branches (left and right), and action potentials spread simultaneously through both branches (Figure 4a). When the action potential encounters a connecting branch, the action potential becomes extinguished within it, because the action potentials travelling leftwards from the right branch and rightwards from the left branch encounter fibres that are absolutely refractory (Figure 4a). If a bidirectional conduction block develops in either the left or the right branch then the connecting branch ensures that the action potential is spread to parts of the heart beyond the block (Figure 4b). However, under some circumstances the block can be unidirectional (i.e. the blocked area may not allow passage of action potentials in the normal direction, but allows transmission with difficulty in a retrograde direction). If transmission through this damaged area is also slowed, action potentials may traverse the region and re-invade part of the heart where the cells have gone beyond their refractory period, giving rise to a circus of action potentials that repeatedly traverse the circuit (Figure 4c). The necessary conditions for re-entry therefore include an unidirectional block in one part of the loop and a delay in conduction through this part so that action potentials can re-invade earlier parts of the loop that have gone beyond their refractory period.

The role of unidirectional block in re-entry



Reproduced with permission from Berne R M, Levy M N. *Principles of Physiology*. Mosby, 2000.

Under some circumstances, the conduction is in aberrant anatomical pathways (e.g. the additional conduction fibres between the atria and ventricles responsible for Wolff–Parkinson–White syndrome). In this case, the normal AV nodal pathway constitutes the slow pathway while the abnormal extra fibres constitute the fast pathway. Under other circumstances, conduction through a region of the heart that has been modified because of damage (e.g. ischaemia where groups of fibres have become converted from the fast type to the slow type) slows conduction rates and generates the necessary conditions for re-entry. ◆

Function of the Nephron and the Formation of Urine

John C Atherton

John C Atherton is Senior Lecturer in Physiology at Manchester University. He graduated from Newcastle on Tyne and gained his PhD at Manchester. His research interests focus on renal physiology with particular interest in urinary concentrating mechanisms, renal function in pregnancy and assessment of nephron function.

Every day, about 160–180 litres of plasma are filtered (assuming glomerular filtration rate (GFR) is 120–140 ml/min) at the renal glomerular capillaries and delivered to the proximal tubules (see page 226, Figure 1). The composition of this ultrafiltrate is identical to that of plasma except that it is virtually protein free. If body fluid volume and composition are to be maintained, this fluid must undergo considerable changes in volume and composition by reabsorption and secretion as it passes along the nephron.

Movement of solutes across any membrane can occur by passive or active transport.

Proximal convoluted tubule

Bulk reabsorption of the filtered load occurs at the proximal convoluted tubule. Over 65% of the solutes and water filtered are reabsorbed (Figure 1); the exceptions are urea (about 50%) and Mg^{2+} (about 20%). Na^+-K^+ ATPase in the basolateral membrane maintains a low intracellular Na^+ concentration which provides the driving force for Na^+ movement into the cell across the apical membrane.

Reabsorption (% filtered load) of solutes and water in different parts of the nephron

	Proximal tubule	Loop of Henle	Distal tubule	Collecting duct
Glucose	99–100	0	0	0
Amino acids	99–100	0	0	0
Na^+	65–70	20–25	3–5	3–5
K^+	70–80	10–15	Secretion	20–30
Mg^{2+}	15–20	60–65	3–5	3–5
Ca^{2+}	65–70	20–25	5–8	1–2
Cl^-	65–70	20–25	5–10	3–5
HCO_3^-	75–85	10–15	3–5	0–5
Urea	45–50	Secretion	0	45–50
Water	65–70	15–23	0	5–10

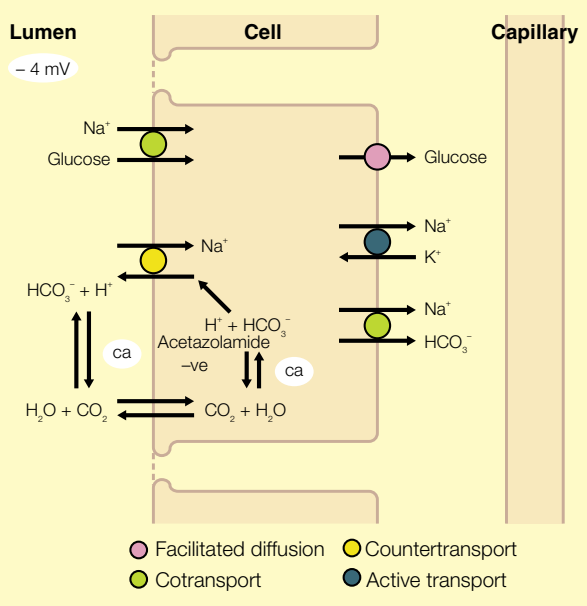
Values are given in percentages. For urea and K^+ the amounts secreted are variable. Urea secretion depends primarily on the medullary interstitial fluid urea concentration and could represent up to 50% of the filtered load.
K^+ secretion is influenced by many factors (see text) and can be equivalent to 20–180% of the filtered load

1

Changes in the tubular fluid to plasma concentration ratios for different solutes along the proximal tubule indicate that there is asymmetry in solute transport. In the early part of the tubule (Figure 2) there is preferential reabsorption of HCO_3^-, PO_4^{2-}, glucose and amino acids, whereas significant Cl^- reabsorption occurs in the second half (Figure 3). The Na^+ concentration ratio does not change along the proximal tubule, therefore there is no asymmetry in Na^+ reabsorption. Reabsorption is by transcellular (66%) and paracellular (33%) pathways.

Early proximal tubule (Figure 2) – Na^+ is reabsorbed on the cotransporters for glucose, amino acids and PO_4^{2-}. The sodium-glucose transporter (SGLT2) is a protein, the amino acid sequence of which is known. Following the combination of two Na^+ ions, the glucose transporter undergoes a conformational change that enhances its affinity for glucose. Reorientation of the transport protein within the apical membrane exposes the glucose and Na^+ binding sites to the cytoplasm, and glucose and Na^+ leave the protein. Passive glucose exit from the cell is facilitated by the presence of glucose transporters (GLUT1 and GLUT2) in the basolateral membrane. Another important entry step for Na^+ across the apical membrane is the Na^+-H^+ countertransporter, which probably accounts for about 60% of transcellular movement. Secreted H^+ combines with filtered HCO_3^-; the CO_2 so formed (carbonic anhydrase is found in the brush border) is in equilibrium with intracellular pCO_2, which is hydrated to form H^+ and HCO_3^-. H^+ is recycled and HCO_3^- leaves the cell via a basolateral Na^+-HCO_3^- cotransporter. The Na^+-H^+ countertransporter can secrete NH_4^+ by replacing the H^+.

Na^+, glucose and HCO_3^- reabsorption across an early proximal tubule cell



Glucose reabsorption is coupled to Na^+ reabsorption across the apical membrane via a SGLT2 transport protein. Glucose moves across the basolateral membrane by facilitated diffusion (GLUT2 transporter). Intracellular hydration of CO_2 is catalysed by carbonic anhydrase (ca), a reaction that is inhibited by diuretics (e.g. acetazolamide)

2

Late proximal tubule – transcellular Na^+ reabsorption is linked to Cl^--anion exchange mechanisms as well as H^+ secretion. The anion countertransport mechanism (Figure 3) is HCO_3^--Cl^- but this can apply to Cl^- and other anions (e.g. hydroxyl, sulphate, formate, oxalate). Secreted H^+ in exchange for Na^+ combines with secreted HCO_3^- to form CO_2 and H_2O. CO_2 diffuses into the cell where it is hydrated and, in the presence of carbonic anhydrase, forms H^+ and HCO_3^-. H^+ and HCO_3^- are recycled; Cl^- (exchanged for HCO_3^-) and Na^+ leave across the basolateral membrane. Cl^- reabsorption in the proximal tubule is not restricted to this mechanism. Preferential HCO_3^- reabsorption in the early part of the tubule leads to an increase in tubular fluid Cl^- concentration (120–140 mmol/litre) providing a concentration gradient sufficient to promote paracellular Cl^- reabsorption against an adverse transepithelial potential difference (4 mV, lumen positive; Figure 3). Water is also reabsorbed through the paracellular route and some Cl^- and Na^+ dissolved in it will be reabsorbed; a process known as solvent drag.

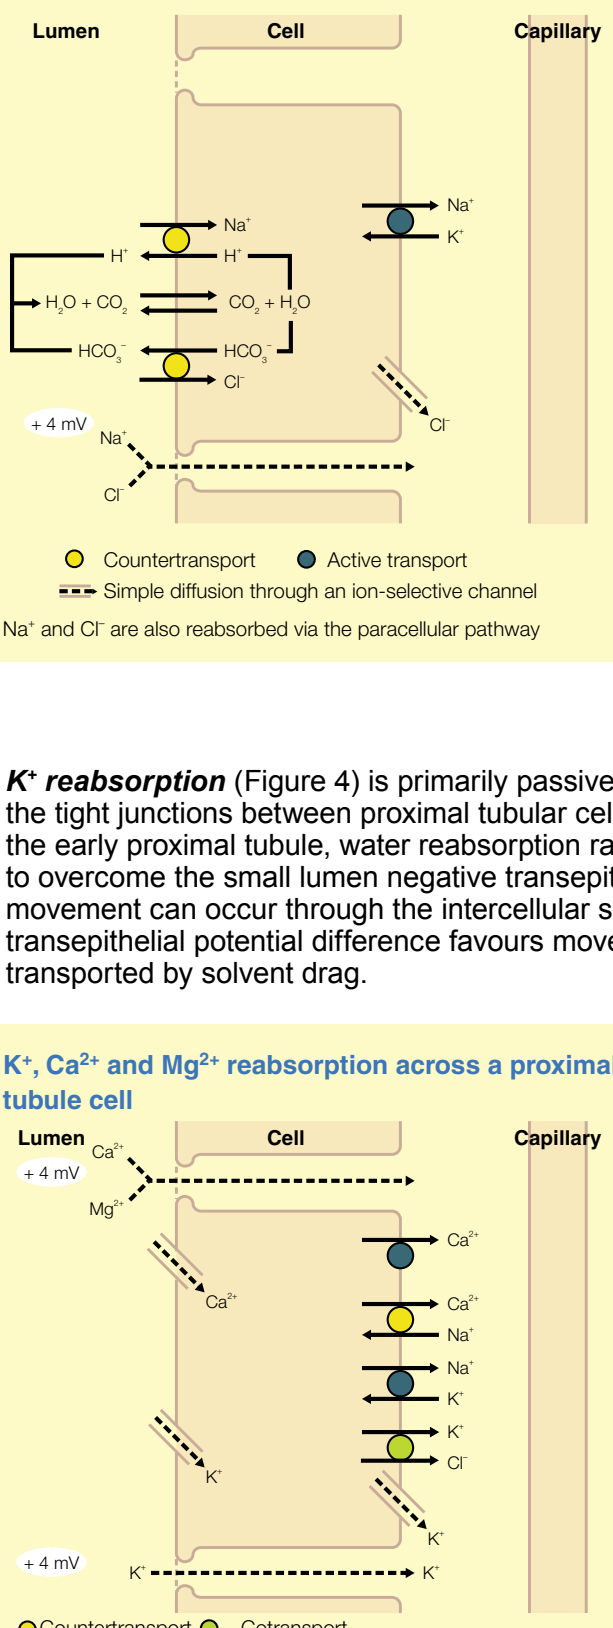
Na^+ and Cl^- reabsorption across a late proximal tubule cell

Na^+ and Cl^- are also reabsorbed via the paracellular pathway

3

K^+ reabsorption (Figure 4) is primarily passive through the paracellular route because the tight junctions between proximal tubular cells are relatively permeable to K^+. In the early proximal tubule, water reabsorption raises the K^+ concentration sufficiently to overcome the small lumen negative transepithelial potential difference, so that movement can occur through the intercellular spaces. In the late proximal tubule, the transepithelial potential difference favours movement through this route. K^+ is also transported by solvent drag.

K^+, Ca^{2+} and Mg^{2+} reabsorption across a proximal tubule cell



Paracellular movement of these cations probably accounts for most reabsorption

4

Ca^{2+} reabsorption occurs through transcellular and paracellular (80%) routes. Reabsorption is by solvent drag along the length of the proximal tubule with a favourable transepithelial potential difference in the second half of the tubule. The transcellular component includes passive entry down a steep electrochemical gradient through Ca^{2+} channels in the apical membrane and exit by a Ca^{2+}-ATPase and/or Ca^{2+}-Na^+ countertransporter.

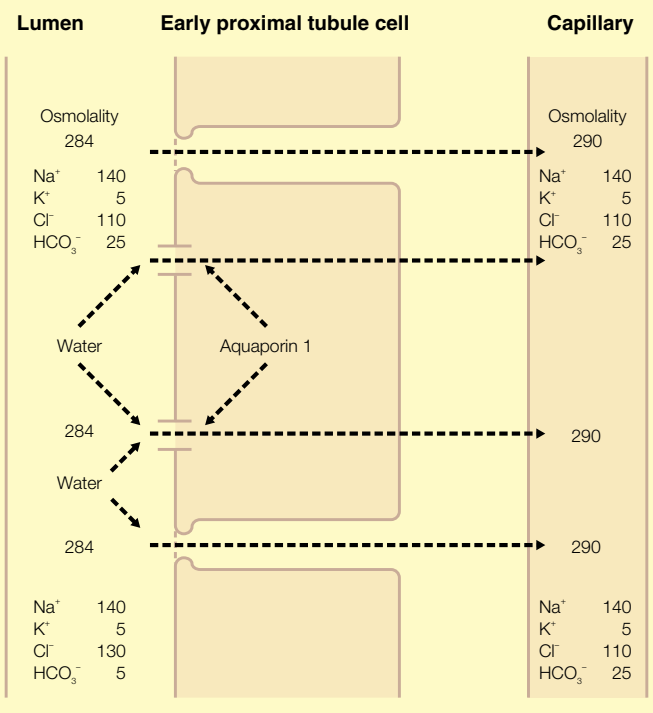
Mg^{2+} reabsorption in the proximal tubule is only 15–20% of the filtered load. Cells have a low permeability to Mg^{2+} and transporters for it have not been isolated in the proximal tubule, therefore paracellular reabsorption in the second half of the tubule probably occurs.

Water reabsorption (Figure 5) is passive and requires an osmotic gradient. Tubular fluid osmolality is about 6 mosmole/kg H_2O lower than that of the surrounding interstitial fluid. This small difference is sufficient (apical and basolateral membranes and tight junctions are highly permeable to water) to account for large amounts of water movement through paracellular and transcellular routes. The effectiveness of the osmotic gradient also depends on the solutes involved. If the difference in osmolality were due solely to the presence of a permeant solute, the gradient would be less effective than if the solute was impermeant (i.e. the composition of the fluid on each side of the membrane is important). The preferential reabsorption of HCO_3^- in the early proximal tubule results in a tubular fluid in the later parts with higher Cl^- and lower HCO_3^- concentrations than interstitial fluid. Since HCO_3^- has a higher reflection coefficient than Cl^-, the effective driving force for water reabsorption is greater in the late proximal tubule. As in other parts of the nephron, transcellular water movement is thought to occur through channel integral proteins (aquaporins). Aquaporin 1 is a 28 kDa protein found in the proximal tubule.

Loop of Henle

The loop of Henle can be divided into three different anatomical components, which exhibit different transport and permeability characteristics (see page 226, Figure 1). The thin descending limb is relatively impermeable to most solutes but has high permeability to water; 15–25% of the filtered fluid is reabsorbed through water channels (aquaporin 1). The thin ascending limb is impermeable to water but is permeable to Na^+. The thick ascending limb is relatively impermeable to water but has a high reabsorptive capacity; about 20–25% of filtered Na^+, Cl^-, K^+ and Ca^{2+} are reabsorbed and about 60% of filtered Mg^{2+}. HCO_3^- escaping reabsorption in the proximal tubules is also reabsorbed by a mechanism similar to that in the proximal tubule.

Transcellular (aquaporin 1) and paracellular water reabsorption in the proximal tubule

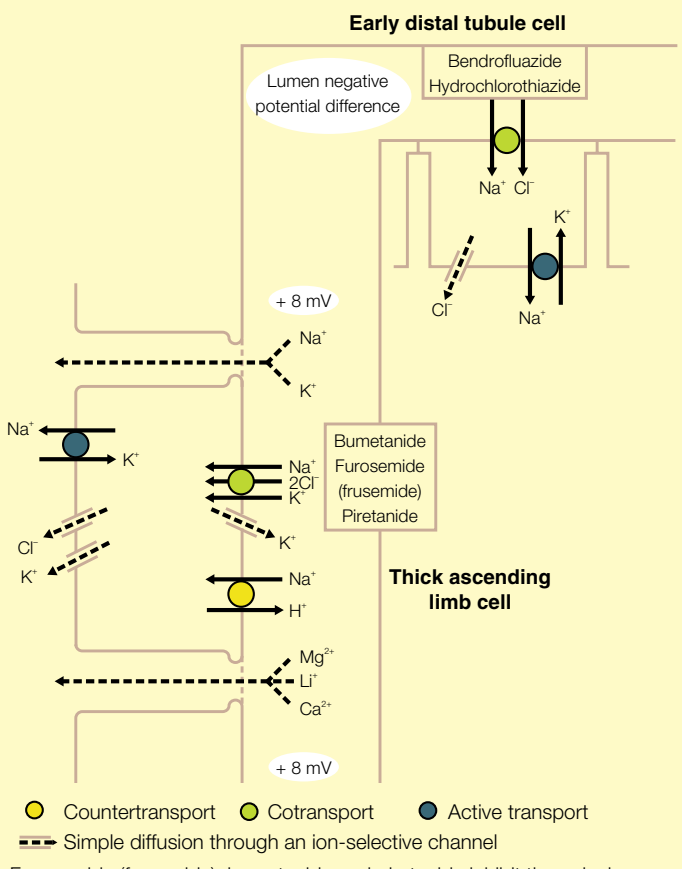


Note the small osmotic gradient across the proximal tubule. Preferential reabsorption of HCO_3^- in early proximal tubule cells results in an increase in the effective osmotic gradient promoting water reabsorption across late proximal tubule cells

5

The primary component of reabsorption is the Na^+-K^+ ATPase in the basolateral membrane (Figure 6). By keeping the intracellular Na^+ concentration low, this maintains a favourable electrochemical gradient for Na^+ entry into the cell across the apical membrane via either a Na^+-H^+ countertransporter (for HCO_3^- reabsorption) or a protein carrier capable of transporting Na^+, K^+ and $2Cl^-$ ions (the Na^+-K^+-$2Cl^-$ cotransporter is quantitatively more important). Exit from the cell across the basolateral membrane of the thick ascending limb is via Na^+-K^+ ATPase for Na^+ and ion-specific channels for K^+ and Cl^-. Some of the K^+ returns to the tubular fluid via apical K^+ channels. The result of these ion movements is the generation of a transepithelial potential difference (about 8 mV lumen positive) that drives reabsorption of many cations through the paracellular pathway. Na^+ movement is transcellular (50%) and paracellular (50%). Most Ca^{2+}, Mg^{2+} and perhaps Li^+ reabsorption occurs via the paracellular route, though some transcellular movement of Ca^{2+} and Mg^{2+} has been suggested. Ca^{2+} transcellular movement is via mechanisms similar to those described for the proximal tubule. Mg^{2+} movement could be via basolateral Mg^{2+} ATPase and Na^+-Mg^{2+} countertransport. NH_4^+ secreted by the proximal tubule can replace K^+ on the triple cotransporter.

Reabsorption of ions across the thick ascending limb of the loop of Henle and early distal tubule



Furosemide (frusemide), bumetanide and piretanide inhibit the apical membrane Na^+:K^+:$2Cl^-$ cotransporter in thick ascending limb cells. Thiazide diuretics (e.g. bendrofluazide, hydrochlorothiazide) inhibit the apical membrane Na^+-Cl^- cotransporters in early distal tubule cells

6

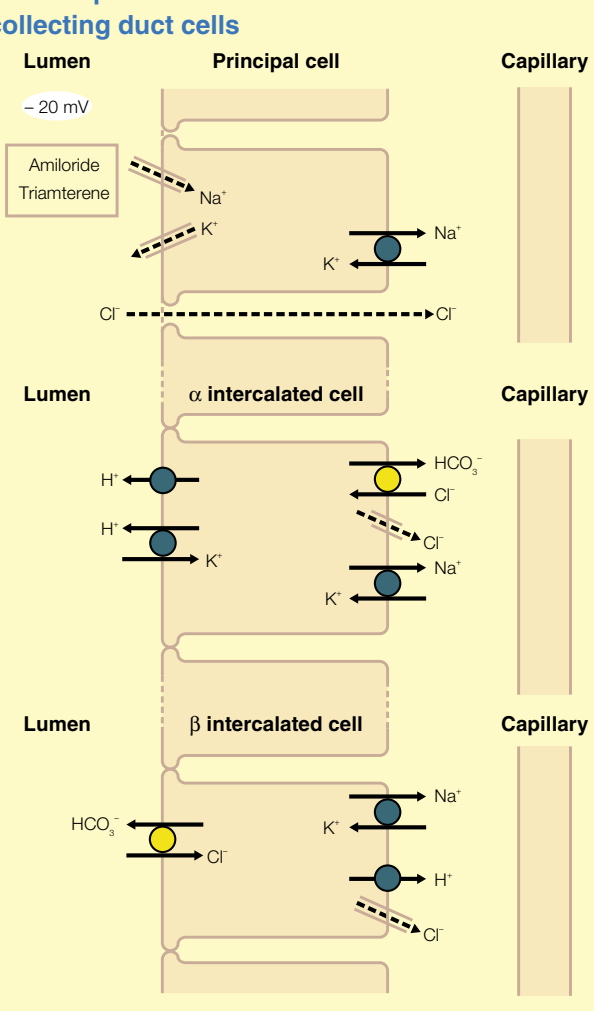
Distal tubule and collecting duct

Transport activity in the final segments of the nephron accounts for 5–10% of the reabsorption of filtered Na^+, Cl^-, Ca^{2+}, Mg^{2+} and water. Urinary excretion of K^+ is normally determined by passive secretion but when dietary K^+ intake is low, active reabsorption occurs. Urinary pH is controlled by H^+ secretion and HCO_3^- reabsorption. The distal tubule is impermeable to water whereas the collecting duct exhibits a variable permeability to water controlled by antidiuretic hormone (ADH).

As in other nephron segments the key transport mechanism is the activity of Na^+-K^+ ATPase in the basolateral membrane of the cells to maintain a low intracellular Na^+ concentration. In cells of the early distal tubule, entry across the apical membrane is via a Na^+-Cl^- cotransporter and exit is via the Na^+-K^+ ATPase and a Cl^- channel (Figure 6). About 60% of the amino acid sequence of the cotransporter is similar to the Na^+-K^+-$2Cl^-$ cotransporter in the thick ascending limb.

Principal cells make up 60% of the cells of the collecting duct. Na^+ movement across apical membranes of principal cells (Figure 7) is by passive diffusion down an electrochemical gradient through Na^+ channels. Na^+ exits the cell via the Na^+-K^+ ATPase in the basolateral membrane. The large transepithelial potential difference (lumen negative) generated by Na^+ movement is probably sufficient to drive Cl^- reabsorption through the paracellular pathway. Passive secretion of K^+ through apical K^+ channels is driven by the steep chemical gradient (maintained by basolateral membrane Na^+-K^+ ATPase) that is sufficient to overcome the adverse transmembrane electrical gradient (cell negative). Water movement is through water channels in the apical (aquaporin 2) and basolateral (aquaporins 3 and 4) membranes.

Reabsorption of ions across cortical and medullary collecting duct cells



Amiloride and triamterene inhibit Na^+ movement through the Na^+ selective channel

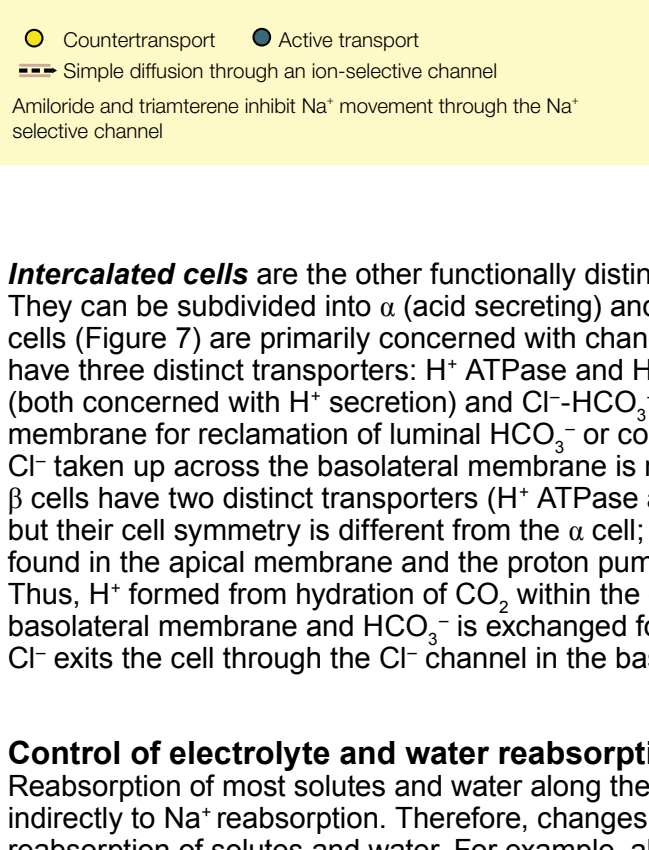
7

Intercalated cells are the other functionally distinct types of cell in the collecting duct. They can be subdivided into α (acid secreting) and β (base secreting) cells. Intercalated cells (Figure 7) are primarily concerned with changes in acid–base status. The α cells have three distinct transporters: H^+ ATPase and H^+-K^+ ATPase in the apical membrane (both concerned with H^+ secretion) and Cl^--HCO_3^- countertransporter in the basolateral membrane for reclamation of luminal HCO_3^- or conservation of newly formed HCO_3^-. Cl^- taken up across the basolateral membrane is recycled through Cl^- channels. The β cells have two distinct transporters (H^+ ATPase and Cl^--HCO_3^- countertransporter) but their cell symmetry is different from the α cell; the anion countertransporter is found in the apical membrane and the proton pump in the basolateral membrane. Thus, H^+ formed from hydration of CO_2 within the cell is actively transported across the basolateral membrane and HCO_3^- is exchanged for Cl^- across the apical membrane. Cl^- exits the cell through the Cl^- channel in the basolateral membrane.

Control of electrolyte and water reabsorption along the nephron

Reabsorption of most solutes and water along the nephron is coupled directly or indirectly to Na^+ reabsorption. Therefore, changes in Na^+ reabsorption cause changes in reabsorption of solutes and water. For example, altered transcellular Na^+ reabsorption in the thick ascending limb modifies paracellular movement of other cations in the same part of the nephron and influences water reabsorption in the descending limb of the loop of Henle and the collecting duct through changes in medullary interstitial fluid osmolality and in the cortical collecting duct through changes in the tubular fluid osmolality. Starling forces also contribute to the control of salt and water movement in leaky transporting epithelia (e.g. proximal tubule). The control mechanisms in different parts of the nephron are summarized in Figure 8.

Reabsorption in different parts of the nephron



8

Proximal tubule – for many years, it was thought that reabsorption at the proximal tubule was load-dependent with a constant fraction of the filtered load being reabsorbed (i.e. glomerular–tubular balance). This simplistic view is incomplete. Na^+ reabsorption is enhanced by angiotensin II and catecholamines released from the renal sympathetic nerve endings (noradrenaline (norepinephrine)) and adrenal medulla (adrenaline (epinephrine)) and reduced by dopamine (released from renal dopaminergic nerves or produced in proximal tubule cells). Parathormone decreases Na^+ reabsorption in the proximal tubule. Reports that atrial natriuretic peptide (ANP) had a direct inhibitory effect on Na^+ reabsorption lack evidence, though the effect could be mediated by inhibition of renin release or an increase in dopamine release.

Thick ascending limb – Na^+ reabsorption in the thick ascending limb is also load-dependent: increasing the load, increases reabsorption. However, other mechanisms affect transcellular and paracellular movement. Renal sympathetic nerve stimulation (catecholamine release) increases reabsorption. Glucagon, parathormone and ADH increase Na^+ reabsorption. The mechanism for this hormonal control, at least for ADH is by basolateral Cl^- channel phosphorylation, increased Cl^- reabsorption and, as a consequence, enhanced activity of the Na^+-K^+-$2Cl^-$ cotransporter. Aldosterone may increase Na^+ reabsorption in the thick ascending limb but the mechanism is unknown. Ca^{2+} reabsorption in the thick ascending limb is controlled by the parathyroid hormones parathormone and calcitonin; parathormone has the greater effect.

Alterations in intratubular flow rate and apical K^+ channel activity affect the lumen positive transepithelial potential difference and therefore paracellular movement. Decreasing flow causes the lumen positive potential difference earlier in the thick ascending limb and decreasing the activity of the K^+ channel (intracellular acidity, NH_4^+, ATP) decreases the lumen positive potential difference.

The distal tubule and collecting duct is where the composition of tubular fluid is finely tuned for the maintenance of body fluid volume and composition. Renal sympathetic nerve activity is involved in Na^+ reabsorption. The Na^+-retaining properties of aldosterone are manifest in the cortical collecting duct; increasing intracellular protein synthesis and insertion of additional transmembrane proteins enhance Na^+ reabsorption and K^+ excretion. There are compelling arguments to consider that the primary physiological action of aldosterone is for K^+ secretion. In conditions of avid salt retention, the natriuretic effects of many distal-acting diuretics are minimal, suggesting that avid salt retention has occurred at sites proximal to the action of the diuretic, and a major stimulus to aldosterone secretion is raised plasma K^+ concentration. Perhaps changes in Na^+ reabsorption are a consequence of aldosterone-induced changes in K^+ secretion.

The natriuretic action of ANP is mediated (as is that of urodilatin) by reducing apical membrane Na^+ permeability in medullary collecting ducts. Urodilatin has a more powerful natriuretic action than ANP, presumably because it gains access to the apical membrane through secretion at the distal tubules rather that at the glomerulus as does ANP, and therefore it is not subject to degradation by proximal tubule brush border endopeptidases. Both ANP and urodilatin inhibit ADH-stimulated water reabsorption in the collecting duct. This might be a direct effect on the transport process or simply reflect inhibition of Na^+ reabsorption reducing the osmotic gradient promoting water movement.

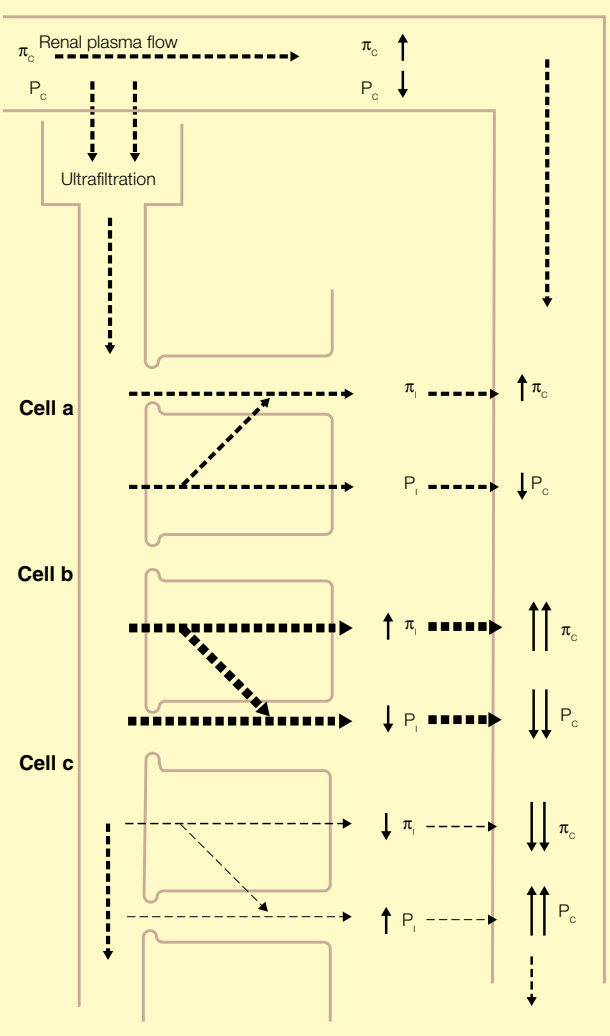
Mechanisms (in addition to aldosterone) that control K^+ secretion include tubular flow rate, Na^+ delivery to more distal nephron sites, ADH and acid–base balance. Excreted K^+ is primarily determined by K^+ secretion in the distal nephron. Increases in either or both tubular flow rate and the amount of Na^+ delivered to Na^+ channels in the principal cells lead to enhanced distal nephron K^+ secretion. Increasing the amount of Na^+ presented to Na^+ channels results in an increase in Na^+ reabsorption, a more lumen negative transepithelial potential difference and, therefore, more K^+ secretion through K^+ channels. Cl^- reabsorption through the paracellular pathway also increases. ADH increases the Na^+ permeability of principal cells, decreases the cell negative apical membrane potential difference and, therefore, favours K^+ secretion. Acidosis and alkalosis, decrease and increase K^+ secretion, respectively, by altering the permeability of the apical membrane to K^+. Alkalosis increases apical membrane permeability thereby enhancing K^+ secretion and excretion; acidosis has the opposite effect. Differences in the response to acidosis depend on whether the acidosis is acute or chronic. Chronic acidosis favours K^+ excretion, presumably because the delivery of fluid from the proximal tubule is increased (proximal tubule Na^+-K^+ ATPase activity is reduced) as are Na^+ load and fluid flow rate to the principal cells, both of which favour K^+ secretion and override the effect of acidosis on K^+ channel permeability.

Calcitonin and calcitriol (a metabolite of vitamin D produced in proximal tubule cells) enhance Ca^{2+} reabsorption at the distal tubules and cortical collecting ducts. These effects appear in-dependent of Na^+ reabsorption because following administration of diuretics (amiloride or bendrofluazide) that reduce Na^+ reabsorption, Ca^{2+} excretion decreases.

Water reabsorption in most nephron segments is a consequence of solute movement and water permeability, the exceptions being the water-impermeable thick ascending limb and distal tubules. Collecting ducts are also impermeable to water except in the presence of ADH, which increases water permeability. This occurs by ADH-induced insertion of water channels in the apical membrane.

Starling forces operating across the peritubular capillaries are important in the control of salt and water reabsorption (Figure 9). The balance of forces operating across the capillary wall influences fluid uptake into the capillary. Uptake of fluid promoted by colloid osmotic pressure (π_c) and interstitial fluid pressure (P_I) is opposed by hydrostatic pressure in the capillaries (P_c) and colloid osmotic pressure in the interstitial fluid (π_I) (Figure 9, cell a). Changes in the uptake of fluid modify reabsorption by increasing or decreasing P_I and hence net fluid movement through the paracellular pathway. For example, assuming RPF is unchanged and GFR increases (i.e. filtration fraction is increased), net fluid uptake into the capillaries is enhanced because P_c decreases and π_c increases (Figure 9, cell b). Back flux into the tubule via the paracellular pathway is reduced. The converse occurs if GFR falls (constant RPF), P_c increases and π_c decreases. The overall effect is reduced uptake into the peritubular capillaries, an increase in P_I and an increase in back flux into the tubule (Figure 9, cell c).

Effect of peritubular Starling forces on transcellular and paracellular reabsorption across the proximal tubule



P_I and P_c are the hydrostatic pressures in the interstitial fluid and peritubular capillary plasma, respectively. π_I and π_c are colloid osmotic pressure in interstitial fluid and peritubular plasma, respectively.

Cell a represents reabsorption when GFR and ECF volume are normal. Cell b represents increased reabsorption when GFR is increased (or reduced ECF volume; see page 241). Cell c represents decreased reabsorption when GFR is reduced (or expanded ECF volume; see page 240)

Diuretics – mechanisms of action

Most diuretics act by inhibition of Na^+ transport at different parts of the nephron, leading to increases in Na^+ and water excretion. Carbonic anhydrase inhibitors (e.g. acetazolamide) reduce Na^+ reabsorption by reducing H^+ secretion and cause modest changes in urine flow. Bumetanide, furosemide (frusemide) and piretanide exert powerful but short lasting natriuretic and diuretic effects by inhibition of the Na^+-K^+-Cl^- cotransporter in the water impermeable thick ascending limb and by binding the concomitant reductions in medullary interstitial fluid osmolality and transtubular osmotic gradient in cortical collecting ducts. Cotransporter inhibition also leads to lowering the lumen positive, transepithelial potentail difference and a reduction in paracellular cation reabsorption. Thiazide diuretic inhibition of Na^+-Cl^- cotransporters in early distal tubules reduces Na^+ reabsorption and the transtubular osmotic gradient in the distal tubule. Some (e.g. bendrofluazide, hydrochlorothiazide) are specific to this cotransporter whereas others (e.g. chlorothiazide) also inhibit carbonic anhydrase activity. The unwanted hypokalaemic effects of many diuretics can be avoided by co-administration of K^+ sparing diuretics (e.g. amiloride and triamterene, which block Na^+ channels in principal cells; and the aldosterone antagonists such as spironolactone). ◆

Micturition

Christopher Fry

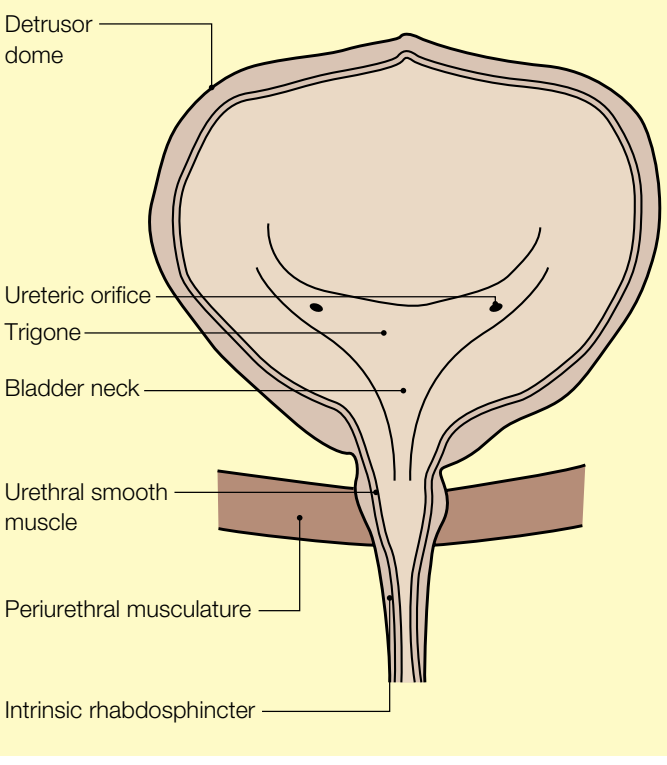
Christopher Fry is Professor of Cell Physiology at the Institute of Urology, University College London. He achieved a PhD in physiology at the University of Leicester and spent time at the University of Bern and St Thomas' Hospital, London. His research interests are in the cellular processes that regulate excitation–contraction coupling in smooth and cardiac muscle.

The bladder has a dual function. For most of the time it is a compliant muscular organ that stores up to 1 litre of urine. It is therefore important that the intravesical pressure is less than that of the upper tract to allow filling. Its second function is to facilitate controlled voiding and for this purpose a sufficient intravesical pressure must be generated to overcome the resistance of the outflow tract.

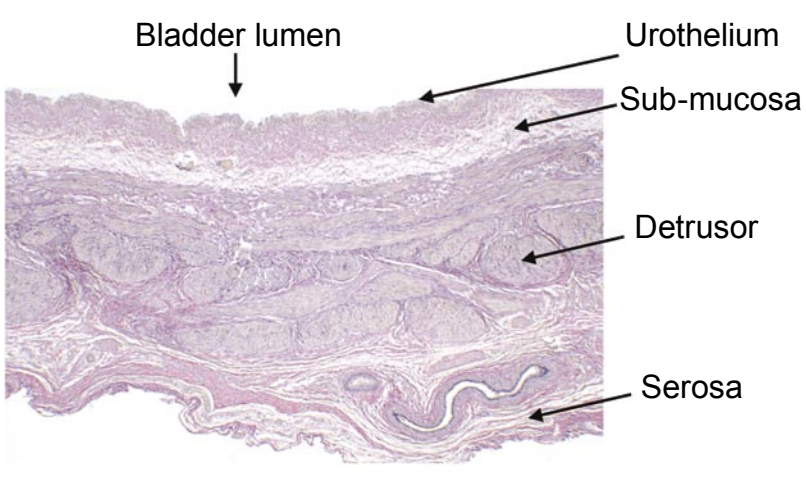
Lower urinary tract

Figure 1 shows the components of the lower urinary tract. Figure 2 shows the three layers of the bladder dome: a trans-itional epithelium facing the lumen with an underlying submucosal layer containing sensory nerves and blood vessels; a detrusor smooth muscle layer; and an adventitial layer. Towards the base of the bladder the ureters open into the lumen and the triangular region thus formed, with the bladder neck as the apex, is the trigone. Towards the bladder neck and urethra the muscle bundles become smaller with more connective tissue. The bladder neck forms a proximal sphincter mechanism, but there is no readily identifiable anatomical structure. In the male, the prostate merges with the neck to form an additional sphincter, mainly to prevent retrograde ejaculation.

Lower urinary tract



1



2 Three-layered structure of the bladder wall.

Further down the urethra is a distinct distal sphincter mechanism consisting of an inner layer of smooth muscle, a layer of skeletal muscle (the intrinsic rhabdosphincter) and a pubo-urethral sling of skeletal muscle especially effective in the male. The intrinsic rhabdosphincter is probably the most important component; it forms a horseshoe-like structure round the urethra, which kinks the tract when it is contracted and reduces flow. The lower urinary tract lies within a number of supporting structures.

Nervous control of the bladder

Efferent innervation: the lower urinary tract receives a dual autonomic innervation; a parasympathetic supply from S2–S4 and a sympathetic supply from T10–L2. Preganglionic parasympathetic fibres run as the nervi erigentes and synapse at ganglia in the pelvic plexus which lie in the adventitia round the bladder base and in the bladder wall. Postganglionic fibres thus act as a motor supply to the bladder and urethra.

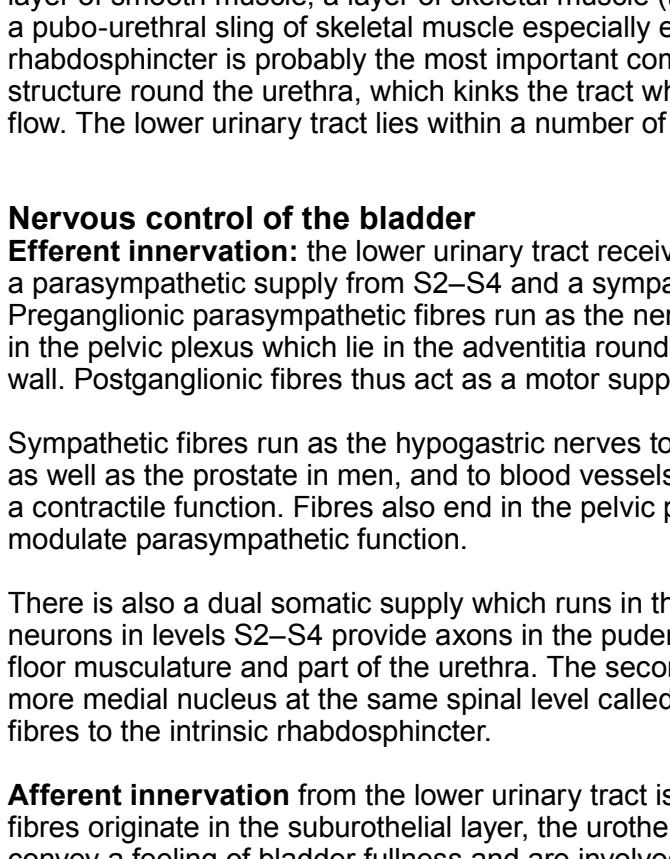
Sympathetic fibres run as the hypogastric nerves to the trigone and bladder base, as well as the prostate in men, and to blood vessels in the bladder, where they effect a contractile function. Fibres also end in the pelvic plexus ganglia where they can modulate parasympathetic function.

There is also a dual somatic supply which runs in the nervi erigentes. Typical motor neurons in levels S2–S4 provide axons in the pudendal nerve to innervate the pelvic floor musculature and part of the urethra. The second component arises from a distinct, more medial nucleus at the same spinal level called Onuf's nucleus. This provides fibres to the intrinsic rhabdosphincter.

Afferent innervation from the lower urinary tract is less well understood. Afferent fibres originate in the suburothelial layer, the urothelium and detrusor layers. They convey a feeling of bladder fullness and are involved in micturition reflexes. The transduction mechanism between bladder filling and afferent excitation was assumed to be mediated by stretch receptors in the suburothelial layer, a hypothesis marred only by the inability to identify such receptors convincingly. More recently, it has been proposed that the urothelium releases chemical mediators such as ATP when stretched, and it is these that initiate afferent activity. The afferent fibres are myelinated (A-δ), but unmyelinated C-fibres are also present, which may respond to more extreme conditions and contribute to pathological reflexes (see below).

Afferent fibres also originate from the trigone and urethral wall and run in the sympathetic hypogastric nerves and pudendal nerves, respectively. They respond to greater degrees of bladder fullness and convey varying levels of urgency to void. Efferent and afferent innervation is shown in Figure 3.

Innervation of the lower urinary tract



3

Micturition and co-ordination of efferent activity

Micturition requires that the lower urinary tract undergoes two co-ordinated processes: reduction of bladder outflow resistance and an increase of bladder vesical pressure. Normal micturition is impossible if these two processes do not occur together. Although afferent and efferent fibres form spinal connections, a simple spinal reflex is insufficient to explain this co-ordinated process and control from higher nervous centres is required.

Most afferent fibres make synaptic connections with ascending fibres that travel in lateral tracts. It is thought that these tracts project to the periaqueductal grey, which controls a region of the rostral pons (the micturition centre). Other fibres travel to areas in the cerebral cortex (the paracentral lobule) that control the pelvic floor musculature and to the medial pre-optic area. The latter projects directly to the pontine micturition centre to co-ordinate different 'pelvic' functions including micturition, defecation and coitus. Fibres that project to the frontal cortex allow social and conscious control over micturition.

The micturition centre is thought to act as a final common pathway and controls the co-ordinated voiding process involving bladder outlet relaxation and detrusor contraction. Descending fibres reduce motor neuron activity to the intrinsic rhabdosphincter by acting on inhibitory sacral interneurons using glycine and γ-aminobutyric acid (GABA) as transmitters. In addition, other fibres to the urethral smooth muscle may be activated to relax this tissue, possibly by the release of a relaxing neurotransmitter (e.g. nitric oxide). Descending fibres also activate parasympathetic fibres that cause the detrusor smooth muscle to contract. This reciprocal innervation theory remains to be proved but represents a reasonable hypothesis.

The role of sympathetic fibres in this process is less clear. In the lower urinary tract, sympathetic innervation is most dense to the trigone and bladder neck and a decrease of activity would relax both these components and assist in the reduction of outlet resistance.

This co-ordinated process of outlet relaxation and detrusor contraction can be seen in Figure 4 which shows the pressures recorded in the urethra and bladder during filling and voiding. During filling, bladder pressure remains fairly constant despite the large increase in volume and there is a small, but definite, rise of urethral pressure. Voiding is characterized by an initial fall of urethral pressure followed almost immediately by a rise of detrusor pressure.

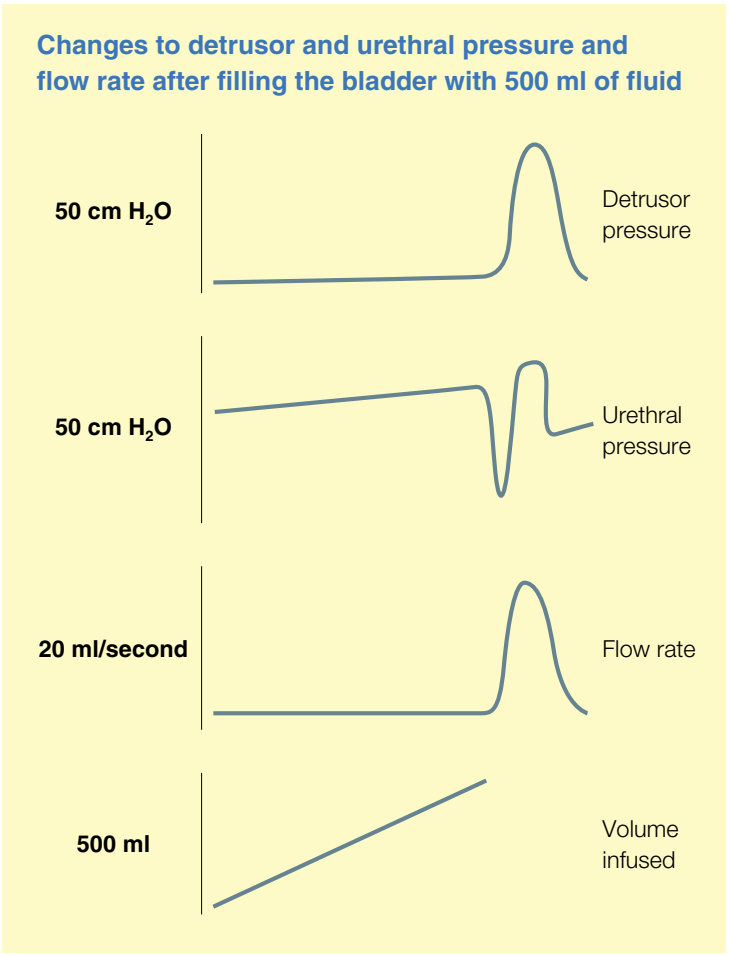
Bladder filling

The tissues that comprise the bladder wall are fairly compliant. They show a remarkable ability to realign themselves when subjected to strain, thus dissipating stress within the tissue (stress relaxation). Whether there is active relaxation of detrusor smooth muscle is more contentious and there is no unequivocal evidence. However, different gating mechanisms may attenuate parasympathetic efferent activity during filling: these include sympathetic inhibition on the pelvic plexuses and a gating of afferent information, such that low threshold activity does not break through to activate a micturition reflex.

The rise of urethral pressure may be a spinal reflex from local afferents that either excite parasympathetic fibres and/or inhibit relaxatory nitrergic efferents.

Smooth muscle function in the lower urinary tract

The end target of efferent nerves is largely the muscular layers in the wall of the urinary tract. In the normally functioning bladder wall, detrusor is under the exclusive control of cholinergic fibres. Parasympathetic fibres release acetylcholine that binds to muscarinic M3 receptors, which elicits a transient rise of intra-cellular calcium via the intermediate generation of the second messenger inositol trisphosphate. In some bladder pathologies (and in most animals, except old-world primates) a second excitatory transmitter, ATP, is involved which increases the intracellular calcium by depolarizing the cell membrane and eliciting calcium influx through calcium channels. The importance of muscarinic receptors in mediating detrusor contraction is the basis of most of the therapeutic control of bladder overactivity.



4

In the trigone and bladder neck, sympathetic activation via α-adrenoreceptor activation plays an important role, alongside muscarinic activation, in regulating contractile activity. This tissue tends to show more spontaneous activity, suggesting that there is more tone in this region of the bladder wall, which may help to preserve a functional proximal sphincter.

Urethral smooth muscle offers a more complex target for efferent fibres as both contractile cholinergic and sympathetic fibres, as well as relaxatory nitrergic fibres have been demonstrated. The balance of efferent activity that maintains urethral tone in filling and relaxation in voiding remains to be elucidated. Nitric oxide relaxes smooth muscle by generating another intracellular second messenger, cyclic GMP, which reduces the proportion of the contractile protein myosin that is in a state to generate contractile force.

Disorders of micturition

Urinary incontinence occurs when bladder intravesical pressure exceeds intraurethral pressure. Thus, incontinence may arise from abnormally high and uncontrolled bladder pressure or abnormally low urethral pressure. The International Continence Society divides the causes into three broad classes: bladder overactivity; bladder underactivity; and underactive sphincter activity. These classifications are not mutually exclusive and patients often exhibit several pathologies.

Bladder overactivity can result from a neurological deficit (hyperreflexia); low bladder compliance or an overactive detrusor activity (idiopathic detrusor instability). Hyperreflexia results from numerous causes that may reduce inhibitory control from the pontine or higher centres or result in the development of abnormal spinal reflexes, a result of disease or injury to the sacral or sub-sacral cord. Attempts have been made to correlate reduced bladder compliance, as observed during urodynamics, with changes in the degree of fibrosis and collagen content and subtype in the bladder wall. A myogenic component to bladder overactivity has been advanced as the cause of idiopathic detrusor instability whereby the detrusor smooth muscle undergoes abnormal and uncontrolled contractions. The causes of such activity remain unclear and are the subject of research.

Bladder underactivity may also cause incontinence particularly in patients with bladder outflow obstruction. There is a retention of urine such that physical intravesical pressures are raised until they are large enough to overcome the increased outflow resistance and result in ‘overflow’ incontinence. This situation may also arise from neuropathies of bladder sensation and from the more infrequent condition of poor detrusor contractility.

Underactive sphincter: in men, sphincter injury following radical (and less commonly transurethral) prostatectomy, radical surgery for pelvic cancer or pelvic trauma commonly results in incontinence. In women, stress incontinence can result from a number of factors that affect smooth and skeletal muscle tone, the pelvic floor musculature and the relative ability of abdominal pressure changes to affect intravesical and intraurethral pressure. ◆

Regulation of Fluid and Electrolyte Balance

John C Atherton

John C Atherton is Senior Lecturer in Physiology at Manchester University. He graduated from Newcastle upon Tyne and gained his PhD at Manchester. His research interests focus on renal physiology with particular interest in urinary concentrating mechanisms, renal function in pregnancy and assessment of nephron function.

The kidneys match renal excretion to intake of water and electrolytes to regulate the osmolality and volume of body fluids. Deficits of water or electrolytes can be compensated for by increases in intake and retention, whereas excesses are compensated for by increases in urinary excretion. It is usually considered that regulation of water excretion determines osmolality, and regulation of electrolyte excretion (principally NaCl) determines fluid volume, however, regulation of water excretion influences fluid volume and osmolality. For example, an increase in osmolality, through excessive sweating or diarrhoea, triggers water retaining and fluid intake mechanisms such as antidiuretic hormone (ADH) release or thirst to return osmolality to normal and restore body fluid volume.

An increase in dietary NaCl that is sufficient to increase plasma osmolality, activates fluid retaining and intake mechanisms and expansion of volume, but the expansion is restricted to the extracellular fluid (ECF) volume. These simple examples show that NaCl, water intake and the regulation of urinary output determine the osmolality and volume of body fluids. The kidneys are the main route for the excretion of salt and water and have an important role in the control of body fluid osmolality and ECF volume.

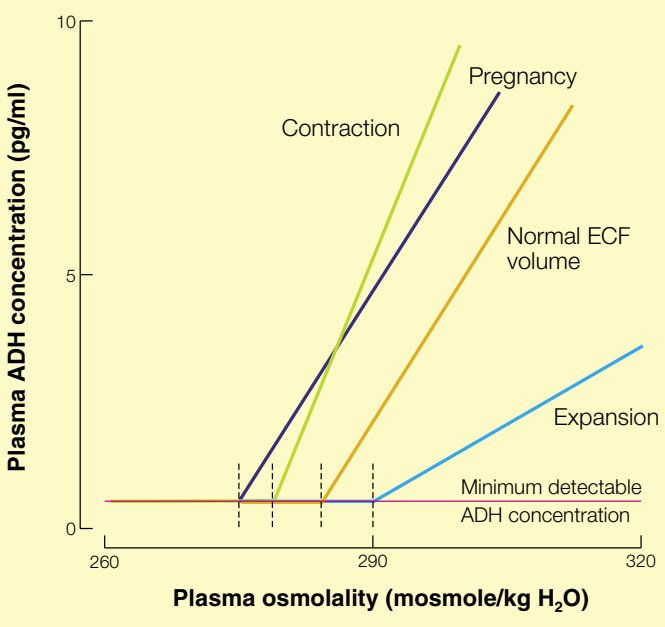
Water balance

Antidiuretic hormone (ADH)

ADH (arginine vasopressin) is a 9-amino acid peptide hormone, synthesized in the magnocellular neurons in the supra-optic and paraventricular nuclei in the anterior hypothalamus, as a 166-amino acid polypeptide. It passes by axoplasmic flow along the hypothalamohypophyseal tract to the posterior pituitary. During its passage along the nerve tract the molecule is cleaved, before storage in secretory granules, as free arginine vasopressin, neurophysin II and glycopeptide.

The main stimuli to ADH secretion are changes in effective plasma osmolality and circulating blood volume. Osmoreceptors in the anterolateral hypothalamus detect changes in effective osmolality to regulate ADH secretion; the set point (osmotic threshold) is 285 mosmole/kg H_2O. Effective osmolality is determined by the extent to which the contributory solute crosses the cell membrane. If cell entry is restricted, the solute (e.g. NaCl) causes cellular dehydration (i.e. it has an effective osmotic effect), whereas solutes (e.g. urea) that readily gain cellular access are less effective in causing cellular dehydration. An increase in effective osmolality of only 1% above the osmotic threshold causes a dramatic and rapid increase in plasma ADH concentration. At plasma osmolality below the osmotic threshold, ADH secretion is minimal (Figure 1).

Effect of ECF volume expansion and contraction on the relationship between plasma osmolality and plasma ADH concentration



The osmotic threshold (---) for antidiuretic hormone (ADH) secretion varies with the state of expansion. In pregnancy the osmotic threshold is reduced by about 10 mosmole/kg H_2O. The osmotic thresholds for the stimulation of thirst are also altered at the different extracellular fluid (ECF) volume expansions (including pregnancy)

1

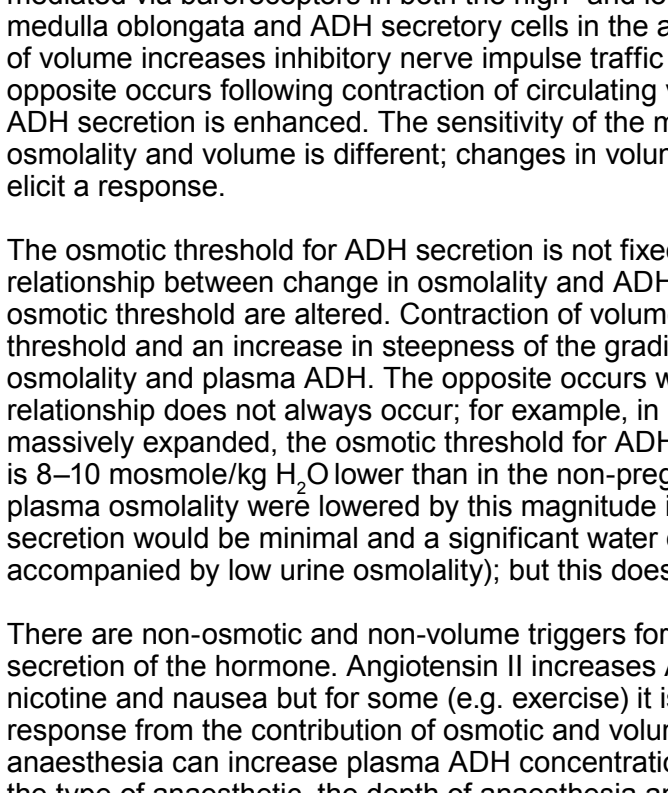
The effects of circulating blood volume and pressure on ADH secretion are reflexly mediated via baroreceptors in both the high- and low-pressure sides of the circulation, medulla oblongata and ADH secretory cells in the anterior hypothalamus. Expansion of volume increases inhibitory nerve impulse traffic and reduces ADH secretion. The opposite occurs following contraction of circulating volume (e.g. haemorrhage) when ADH secretion is enhanced. The sensitivity of the mechanisms for ADH secretion to osmolality and volume is different; changes in volume of about 10% are required to elicit a response.

The osmotic threshold for ADH secretion is not fixed. If ECF volume is altered, the relationship between change in osmolality and ADH secretion (Figure 1) and the osmotic threshold are altered. Contraction of volume is associated with a lower osmotic threshold and an increase in steepness of the gradient for the relationship between osmolality and plasma ADH. The opposite occurs when volume is expanded. This relationship does not always occur; for example, in pregnancy, when ECF volume is massively expanded, the osmotic threshold for ADH secretion (and for thirst sensation) is 8–10 mosmole/kg H_2O lower than in the non-pregnant condition (Figure 1). If plasma osmolality were lowered by this magnitude in the non-pregnant condition, ADH secretion would be minimal and a significant water diuresis manifest (high urine flow accompanied by low urine osmolality); but this does not occur in pregnancy.

There are non-osmotic and non-volume triggers for ADH secretion, but few reduce secretion of the hormone. Angiotensin II increases ADH secretion as does exercise, nicotine and nausea but for some (e.g. exercise) it is difficult to disassociate the response from the contribution of osmotic and volume triggers. Surgery and anaesthesia can increase plasma ADH concentrations; the response is related to the type of anaesthetic, the depth of anaesthesia and the type and extent of surgical intervention. Alcohol inhibits ADH secretion, as does atrial natriuretic peptide (ANP), though this could be ECF volume-mediated.

ADH increases the water permeability of principal cells in the cortical and medullary collecting ducts of the kidney. ADH delivered to the peritubular environment binds to V_2 receptors on the basolateral membrane (Figure 2). This receptor is a member of a family of G-protein-coupled receptor groups (7 membrane- spanning domains) that, once ADH is bound, increases the formation of intracellular cyclic adenosine monophosphate (cAMP) by activation of the enzyme adenylyl cyclase. The increase in cAMP activates another enzyme, phosphokinase A that phosphorylates preformed, inactive water channels (aquaporin 2 channels close to the apical membrane) and this results in their insertion in the apical membrane. Exit of water through the basolateral membrane is facilitated by the presence of aquaporins 3 and 4. When ADH is removed from the receptor, aquaporin 2 water channels resume their original position inside the cell. The rapid insertion of these channels enables rapid and precise changes in the water permeability of the apical membrane of the principal cells and hence corresponding changes in water reabsorption.

Cellular action of antidiuretic hormone (ADH) to increase water reabsorption in a collecting duct principal cell



2

Another action of ADH is to increase urea permeability in medullary collecting ducts but not in late distal tubule or cortical collecting ducts.

The effects of ADH on water and urea reabsorption would be relatively ineffective in the absence of a difference in osmolality or urea concentration across the tubular epithelium favouring their passive movement. That such a gradient exists across cortical collecting ducts for water is a function of the loop of Henle. For urea, establishment of the gradient across medullary collecting ducts depends on the differential effects of the hormone on water and urea permeability in cortical collecting ducts.

Thirst

Changes in ADH secretion are vital to water conservation but are insufficient to maintain water balance. Hypo-osmotic fluid loss (e.g. sweating, diarrhoea) causing dehydration cannot be corrected through increased renal water retention alone. There is always an obligatory water loss to excrete solute (300–400 ml/day) and the kidneys cannot produce water. Thirst centres, located in the anterolateral hypothalamus, respond to changes in plasma osmolality and circulating blood volume. An increase in effective osmolality (e.g. increased NaCl intake) and a decrease in volume (e.g. haemorrhage) elicit the sensation of thirst, but the sensitivity of the mechanism to each stimulus is different. The response to changes in osmolality is initiated by a small (1–2%) increase, whereas a much larger change in circulating volume (8–10%) is required. Changes in volume appear to sensitize the thirst response to changes in osmolality, thus for any given decrease in volume, the thirst response is elicited at lower plasma osmolality (Figure 1).

Angiotensin II exerts a powerful dypsogenic effect via the hypothalamic nuclei; this might be the effective stimulus to thirst in response to changes in circulating blood volume. Blockade of angiotensin II inhibits the response to hypovolaemia, but not completely, suggesting that baroreceptor reflex responses might contribute. Prolactin has also been implicated. Dryness of the pharyngeal mucous membranes elicits the sensation of thirst through nerve reflexes.

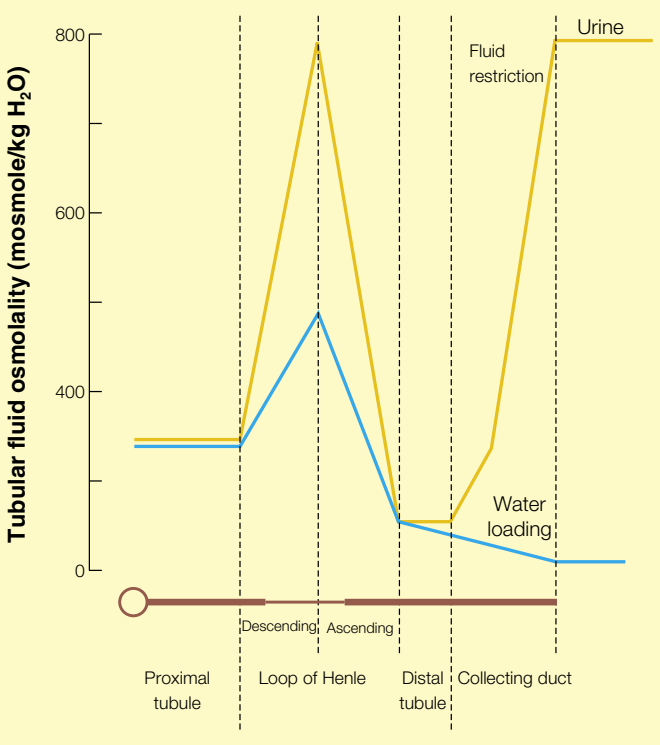
Whatever the stimuli to thirst, corrections in water balance (deficits or excesses) depend on the integrated hypothalamic responses of altered ADH secretion and the sensation of thirst to changes in volume and osmolality of body fluids.

Elaboration of concentrated urine

The osmolality of tubular fluid changes as it moves along the nephron from glomerulus to the terminal part of the collecting duct (Figure 3). Osmolality of fluid leaving the proximal tubule is slightly lower than that of plasma. The descending limb of the loop of Henle is permeable to water, therefore the tubular fluid equilibrates with the increasingly hyperosmotic medullary interstitial fluid such that at the bottom of the loop, deep within the medulla, the osmolality is similar to the maximum osmolality of interstitial tissue fluid at that level in the kidney. As fluid traverses the water-impermeable ascending limb, solute is reabsorbed without water and the tubular fluid becomes increasingly hypo-osmotic to the surrounding interstitial fluid. This occurs along the length of the limb, to such an extent that tubular fluid arriving at the early distal tubule is hypo-osmotic to cortical interstitial fluid. If ADH is present, osmotic equilibration occurs between cortical collecting duct fluid and cortical interstitial fluid. Fluid descends the collecting duct and, if ADH is present, osmotic equilibration occurs with the increasing hyper-osmotic medullary interstitial fluid. Final urine osmolality (maximum 1200–1400 mosmole/kg H_2O) is similar to that of interstitial fluid as tubular fluid leaves the medulla.

This emphasizes another important consequence of the action of ADH on cortical collecting duct water permeability. It reduces the volume flow (ml/min) to medullary collecting ducts, thus avoiding the major dilution of medullary interstitial fluid osmolality that would otherwise occur. Maximum achievable urine osmolality would be reduced. For example, if the glomerular filtration rate (GFR) is 120 ml/min and 85% of the filtrate is reabsorbed before the distal tubule, 18 ml/min fluid with an osmolality about 100 mosmole/kg H_2O would be delivered to the cortical collecting duct. In the presence of ADH, fluid leaving will have equilibrated with cortical interstitial fluid (about 300 mosmole/kg H_2O), thus only 6 ml/min would enter the medullary collecting duct. In the absence of ADH this would increase to 18 ml/min and tubular fluid osmolality would be lower.

Changes in tubular fluid osmolality along the nephron during water restriction and water loading



3

Urine osmolality in humans loaded with water (15–25 ml/kg body weight) to suppress endogenous ADH secretion (water diuresis) can be as low as 30–35 mosmole/kg H_2O. In these conditions, medullary interstitial fluid osmolality is lower and osmotic equilibration across cortical and medullary collecting ducts does not occur (Figure 3). Volume flow to collecting ducts is high and final urine osmolality reflects the hypo-osmolality of fluid leaving the loop of Henle and the extent of electrolyte reabsorption without water in these nephron segments. The absolute (but not fractional) amount of water reabsorbed across collecting ducts is greater in the absence of ADH than when ADH is present. This contributes to the lower medullary interstitial fluid osmolality and would decrease urine flow, but the effect on urine osmolality would not be great because of high volume flow to collecting ducts.

The two reasons why urine with high osmolality can be elaborated are the existence of a hyperosmotic medullary interstitial fluid and the action of ADH on the water permeability of the collecting ducts, which facilitates osmotic equilibration between tubular fluid and the surrounding interstitial fluid.

Countercurrent multiplication mechanism in the loop of Henle

The basic operation of this countercurrent multiplication mechanism is widely known, but some of the fine detail needs to be resolved. It involves two simple steps:

- movement of solute without water out of the ascending limb of the loop of Henle
- flow in opposite directions in ascending and descending limbs of the loop of Henle.

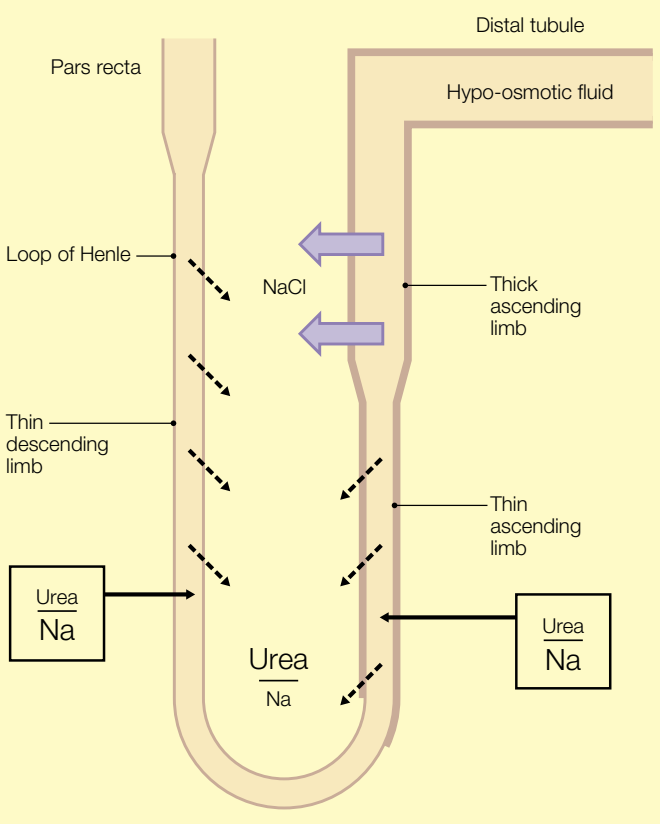
The consequence of the first step is that for any level between the limbs of the loop there is osmotic concentration of fluid in the descending limb (and medullary interstitial fluid) by solute addition to and/or water removal from the descending limb. The second step multiplies this single osmotic effect.

Given that these two steps are operative, it follows that there will be an axial gradient of hyperosmolality within the medulla, with the highest values being at the medullary tip. The steepness of the gradient generated depends on the length of the loop relative to kidney size. In normal antidiuretic conditions, major contributions to this gradient are NaCl (about 45%) and urea (about 45%) with smaller contributions from K^+ and NH_4^+ and their attendant anions. In diuretic conditions, medullary interstitial fluid osmolality is lower but still hyperosmotic. The reduction is a consequence of almost complete dissipation of the urea concentration gradient with smaller contributions from changes in concentrations of NaCl and other electrolytes.

The single osmotic effect in the thick ascending loop of Henle is active reabsorption of Na^+ accompanied by Cl^- but without water into medullary interstitial fluid (Figure 4). If this were the only transport process involved, the osmotic gradient generated would not be continuous from the corticomedullary boundary to the tip of the medulla. The maximum value would be detected at the level of the thick ascending limb and would determine the NaCl concentration at the tip of the medulla by passive transverse movement through the interstitial fluid. The main problem is the failure to demonstrate active Na^+ transport in the thin ascending limb. However, the single osmotic effect in the thin ascending limb may be passive Na^+ movement down a concentration gradient, the magnitude of which is determined by the contribution of urea to the hyperosmotic environment. The greater the contribution of urea, the steeper the gradient favouring passive Na^+ movement, and descending limb fluid being concentrated principally by fluid abstraction rather than solute addition – this limb appears to have limited permeability to Na^+ and urea.

Fluid delivered to the ascending limb has a higher Na^+ concentration than medullary interstitial fluid, thereby facilitating passive Na^+ reabsorption. The single osmotic effect occurs at all levels of the ascending limb, therefore multiplication of this effect generates an increasing Na^+ concentration gradient from the corticomedullary boundary to the tip of the medulla. Although these mechanisms focus on Na^+ movement accompanied by Cl^- as the single osmotic effect, any electrolyte reabsorbed from the ascending limb contributes to the effect of countercurrent multiplication. For example, corticomedullary concentration gradients for K^+ and NH_4^+ are presumably a consequence of their reabsorption by Na^+-K^+-$2Cl^-$ transporters in the thick ascending limb apical membranes and concentration in descending limb fluid.

Components of the countercurrent multiplication system in the loop of Henle



The ratio of urea:Na^+ represents their relative contributions to fluid (tubular and interstitial) fluid osmolality. Fluid in the descending limb is progressively concentrated by passive water abstraction, resulting in the delivery of fluid with a higher Na^+ concentration than in medullary interstitial fluid to the ascending limb

Key: ◂- - - passive water or sodium reabsorption, ⇦ active transport

Countercurrent exchange mechanism in the vasa recta capillaries

The arrangement of the capillaries in tissues other than renal medullary tissue is such that any interstitial fluid hyperosmolality generated would soon be dissipated. In the renal medulla the vasa recta capillaries form parallel hairpin loops that enable them to function as countercurrent exchangers. Since all capillaries are freely permeable to solutes and water, plasma entering the medulla in descending limbs is encountering regions of higher osmolality; osmotic equilibration occurs by water loss and solute addition. This continues along the length of the descending limb so that plasma at the hairpin bend is quite viscous (due to the concentration of proteins) and is at an osmolality similar to the hyperosmotic surroundings. The reverse occurs as plasma moves along the ascending limbs to leave the medulla; water enters from and solutes leave the capillaries to the hypo-osmotic interstitial fluid and plasma protein concentration decreases. The net effect is that water entry into the medullary tissue is restricted by short-circuiting across the bases of vasa recta capillaries from descending to ascending limbs whereas solutes move in the opposite direction and are retained in medullary tissue. It follows that volume flow of plasma decreases down the descending limb and increases up the ascending limb. This lower flow rate in the medulla is essential to allow osmotic exchange. A possible ADH-induced constriction of medullary vessels would reduce vasa recta blood flow and contribute to the efficiency of countercurrent exchange.

If plasma flow rate increases, the time for osmotic exchange reduces, more plasma water enters and more solutes leave the medulla with the results that medullary interstitial fluid osmolality decreases, less water is reabsorbed from the medullary collecting ducts, and less concentrated urine of increased volume is excreted. There is a limit to the effect of decreasing flow on medullary hyperosmolality. If blood flow is reduced to the extent that there is insufficient oxygen delivery to active transport sites, especially in the thick ascending limb, tubular transport is impaired, as is the generation of medullary interstitial fluid hyperosmolality.

Control of Na^+ excretion and ECF volume

Under normal conditions, the kidneys maintain ECF volume relatively constant by matching Na^+ excretion to dietary Na^+ intake. However, if changes in dietary Na^+ intake are not accompanied by changes in Na^+ excretion the osmotic stimulus is altered to increase or decrease water retention with a corresponding increase or decrease in ECF volume. Correction for changes in ECF volume could be effected by changes in Na^+ excretion through changes in the filtered load and/or reabsorption of Na^+.

ECF volume may be compromised by changes in Na^+ balance. If Na^+ excretion increases, an equivalent change in water excretion ensues and ECF volume contracts. Even small changes in Na^+ excretion produce a significant effect. For example, for a small increase in Na^+ excretion from 1% to 4% of the filtered load, the additional Na^+ loss will be about 700 mmole/day (GFR and plasma Na^+ are, respectively, 0.12 litre/min and 140 mmole/litre). If this were iso-osmotic salt loss, an additional 5 litre of ECF volume would be excreted.

ECF volume consists of extravascular and intravascular fluid components.
The circulating intravascular volume component is the important trigger for the compensatory mechanisms because it should reflect volume, pressure and flow within the circulatory system. In health, there is a direct correlation between ECF volume and vascular volume perfusing tissues but there are conditions in which this correlation does not apply. For this reason the effective circulating volume is used to describe the variable that triggers compensatory mechanisms.

Changes in effective circulating volume are detected by volume (stretch) receptors in the low-pressure (atrial and pulmonary receptors) and high-pressure (aortic arch and carotid sinus receptors) sides of the circulation. Low-pressure receptors transmit inhibitory nerve impulses via the vagus nerve to the tractus solitarius nucleus in the medulla oblongata, as do high-pressure receptors via afferent nerve fibres in the vagus and glossopharyngeal nerves. Efferent nerve activity from this nucleus modifies ADH secretion and sympathetic nerve activity. The renal juxtaglomerular apparatus in renal afferent and efferent arterioles is another high-pressure receptor sensing hydrostatic pressure.

Renal control of Na^+ and water reabsorption

Reabsorption of Na^+ and water at different nephron segments is discussed elsewhere.

Renal sympathetic nerve activity mediates its effect in three ways.

- Stimulation of α-adrenergic receptors on vascular smooth muscle of afferent and efferent arterioles to reduce GFR (afferent arteriole constriction appears to be the dominant effect and glomerular hydrostatic pressure is reduced).
- β-adrenergic stimulation of juxtaglomerular cells to stimulate renin secretion.
- α-adrenergic stimulation of Na^+ reabsorption at most nephron segments with the quantitatively important effect on proximal convoluted tubules.

Renin–angiotensin–aldosterone: stimuli to renin secretion include β-adrenergic stimulation of juxtaglomerular cells, reduced perfusion pressure in afferent arterioles and reduction in Na^+ load arriving at macula densa cells in distal convoluted tubules. Renin is a proteolytic enzyme that cleaves angiotensinogen (an α-globulin produced in the liver) to form the decapeptide angiotensin I. Angiotensin I has no known physiological function. However, further cleavage results in the formation of the octapeptide angiotensin II by angiotensin-converting enzyme found on the surface of vascular endothelial cells in pulmonary and renal capillaries.

Angiotensin II has at least five actions important in the regulation of ECF volume:

- as a powerful vasoconstrictor it affects afferent and efferent arterioles to decrease GFR and increases blood pressure through its systemic vascular action
- proximal tubule reabsorption of Na^+ and water is increased
- ADH release is increased with effects on water reabsorption
- thirst sensation is enhanced
- secretion of the mineralocorticosteroid hormone, aldosterone from the zona glomerulosa of the adrenal cortex is increased.

Aldosterone increases Na^+ reabsorption from principal cells in cortical collecting ducts by increasing the synthesis of proteins that increase the number of Na^+ selective protein channels in the apical membrane, increase the number of active Na^+ pumps (Na^+-K^+ ATPase) in the basolateral membrane or increase the available ATP as energy source for the Na^+ pumps.

Atrial natriuretic peptide is a hormone produced in atrial myocytes in response to expansion of circulating volume (increased atrial stretch, increased atrial pressure). Its actions are, in general, opposite to those of the renin–angiotensin–aldosterone axis. They include relaxation of afferent arteriolar smooth muscle to increase GFR and Na^+ reabsorption inhibition, either directly by blocking Na^+ selective channels in apical membranes of inner medullary collecting duct cells, or by decreasing renin secretion and hence the Na^+-retaining actions of angiotensin II and aldosterone.

Challenges to effective circulating volume

Small changes in GFR (e.g. changes in posture or exercise) lead to large changes in filtered load that could cause excessive urinary Na^+ (hence water) loss and a significant contraction of volume. For example, an increase in GFR of only 3% increases the filtered load by over 700 mmole/day, which, if not compensated for, leads to loss of about 5 litres ECF volume. That this does not happen is primarily a direct consequence of glomerulotubular balance and autoregulation of GFR. These compensatory mechanisms maintain the Na^+ load delivered to the nephron distal to the proximal tubule, particularly those sited in the late distal tubule and collecting duct.

Autoregulation of GFR ensures that changes in GFR in the face of changes in perfusion pressure and renal blood flow are of short duration. Glomerular–tubular balance is the balance between the filtered load and proximal tubule reabsorption. A constant fraction (about 70%) of the filtered load is reabsorbed in the face of changes in GFR thereby minimizing changes in the amount delivered to the loop of Henle. The mechanisms responsible focus on changes in Starling forces operating across peritubular capillaries and their effect on reabsorption. If GFR increases and RPF is unchanged (afferent arteriole dilatation, efferent arteriole constriction), filtration fraction increases, as would plasma colloid osmotic pressure (π_C), but peritubular capillary pressure (P_C) decreases. Net fluid uptake into the capillaries is enhanced as filtration fraction increases.

Load dependency of reabsorption in the thick ascending limb and distal tubule also contribute to constancy of Na^+ delivery to the collecting duct. This is necessary to avoid swamping aldosterone-sensitive Na^+-retaining mechanisms in this part of the nephron, thereby avoiding excessive loss of Na^+ and water.

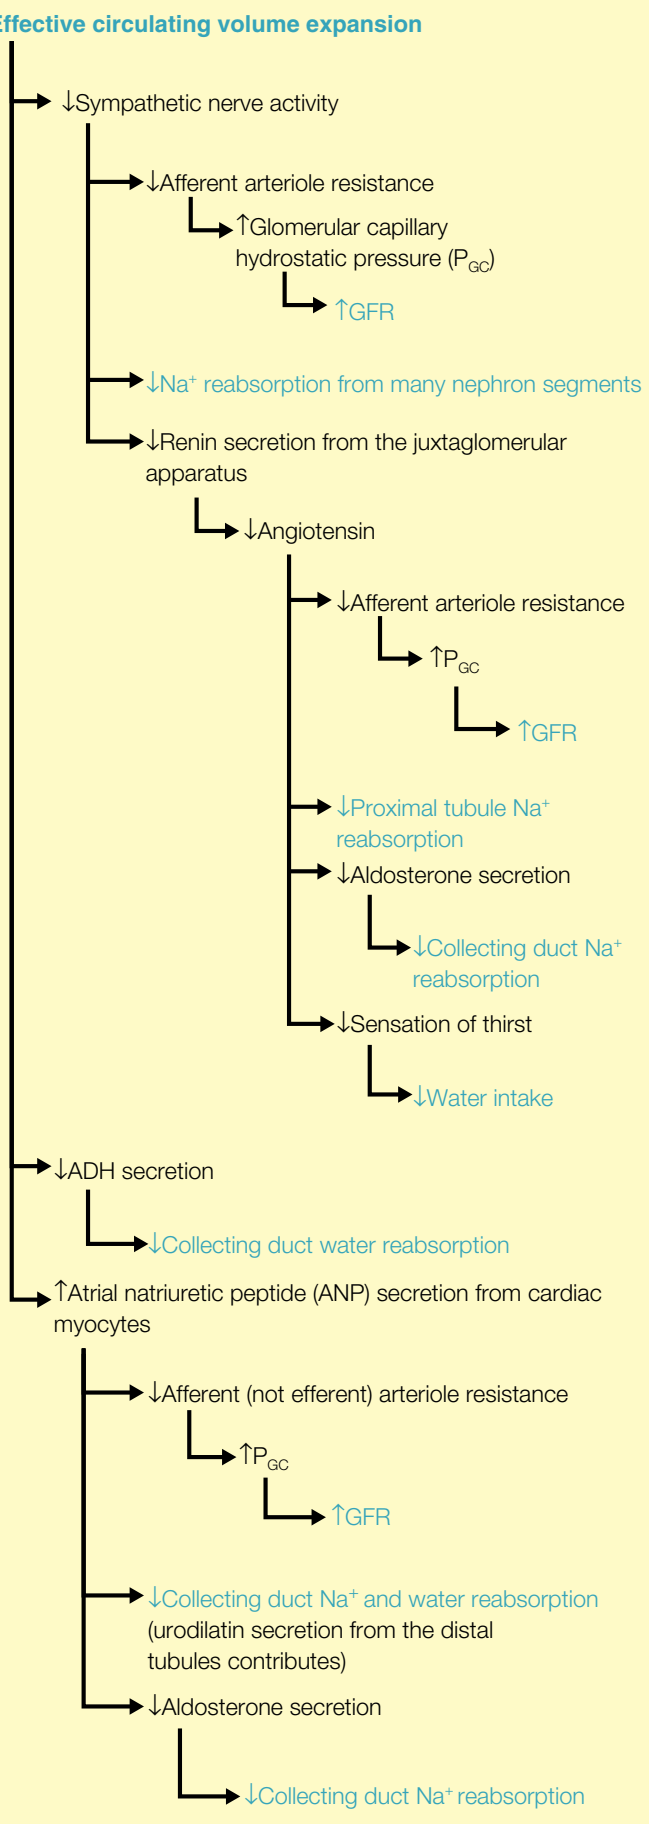
Renal response to ECF volume expansion and contraction

The mechanisms that compensate for changes in ECF volume are illustrated in Figures 5 and 6. In addition to these compensatory mechanisms, volume expansion dilutes plasma proteins and increases hydrostatic pressure in glomerular capillaries. Both contribute to the increase in GFR and to changes in the peritubular capillary environment, which has a direct effect on proximal tubule Na^+ and water reabsorption. Therefore, there is an increase in P_C (due also to a volume expansion-induced increase in venous pressure) and a decrease in π_C with the result that proximal tubule reabsorption is reduced. In contrast, volume contraction is accompanied by decreased hydrostatic pressure in the glomerular capillaries (and decreased venous pressure), which is transmitted to the peritubular capillaries with the effect that fluid uptake from the interstitial fluid (reduction in P_C) is increased and proximal tubule reabsorption is stimulated.

The paradox highlighted here is that volume-induced changes in GFR are accompanied by altered proximal tubular reabsorption that is opposite to changes accompanying spontaneous changes in GFR. Thus, during volume expansion, GFR is increased but proximal tubule reabsorption is decreased; for spontaneous increases in GFR, proximal tubule reabsorption is enhanced. The converse applies to volume contraction. The reasons for these differences are obscure, but it appears that volume expansion or contraction overrides mechanisms responsible for glomerular–tubular balance and autoregulation of GFR.

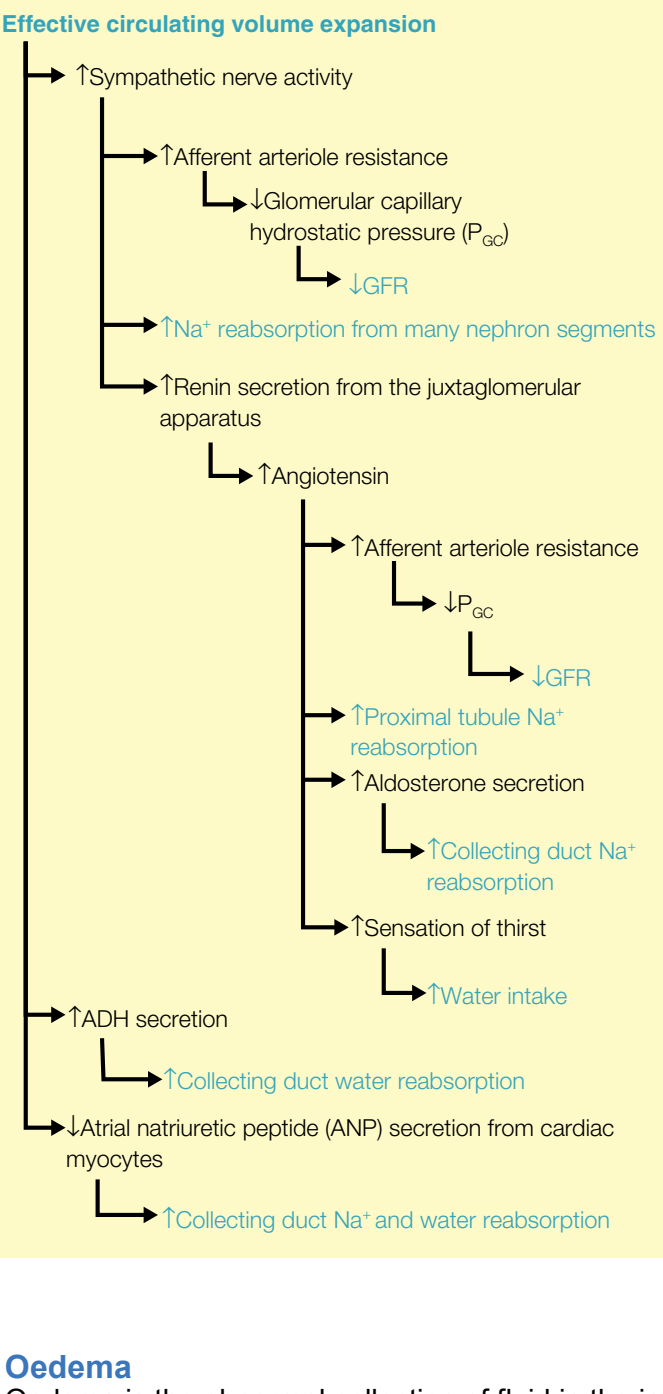
The overall effect of volume expansion is an increase in GFR and filtered load accompanied by reduced Na^+ and water reabsorption from almost all parts of the nephron with the result that fractional Na^+ and water excretion increase and volume is restored to normal. For volume contraction, reductions in GFR and filtered load are associated with enhanced Na^+ and water reabsorption from almost all parts of the nephron to the extent that Na^+ is almost absent from the urine. These changes, plus any associated increases in fluid intake, restore the volume.

Compensatory mechanisms for extracellular fluid (ECF) volume expansion



5

Compensatory mechanisms for extracellular fluid (ECF) volume contraction



6

Oedema

Oedema is the abnormal collection of fluid in the interstitial fluid. Changes in Starling forces operating across capillary walls are responsible. Net movement of fluid = $K_f((P_C - P_I) - (\pi_C - \pi_I))$, where: K_f is the ultrafiltration coefficient; P and π are hydrostatic pressure and colloid osmotic pressure, respectively, in the capillaries (C) and interstitium (I). Any clinical condition that leads to an increase in K_f and/or P_C or a decrease in π_C leads to accumulation of fluid in the interstitial space.

Changes in Starling forces alone are responsible for localized oedema. For example, in deep vein thrombosis increased P_C occurs as a result of restriction of venous outflow. In inflammatory responses, P_C and K_f are increased. Generalized oedema is associated with a more complicated pathogenesis arising from liver malfunction, cardiac insufficiency or abnormal renal function and includes significant contribution from excessive renal Na^+ and water retention as well as changes in Starling forces.

In liver failure and abnormal loss of protein in the urine (nephrotic syndrome) plasma protein concentration declines (decreased π_C) with a continuous loss of fluid to the interstitial space. This loss is self-limiting because as fluid accumulates, an increase in P_I and a decrease in P_C occur to the point where there is no further fluid loss. Total ECF volume does not change, but loss of fluid from the vascular compartment (about 2–3 litres before it is clinically detectable) is such that cardiac output and blood pressure decrease to the point where compensatory changes are initiated in an attempt to restore circulating volume (decreased GFR and increased Na^+ and water retention by the mechanisms described above). This additional renal Na^+ and water retention contributes to the oedema by this positive feedback loop.

Cardiac insufficiency leading to increased venous pressure (hence increased P_C) in either or both the systemic or pulmonary circulation causes systemic or pulmonary oedema. If the cardiac insufficiency is such that cardiac output and blood pressure are reduced, renal compensatory mechanisms are triggered (retention of Na^+ and water). In terms of total ECF volume this is a false signal; total vascular volume might be unchanged but the true signal (effective circulating volume) is reduced. The additional Na^+ and water retention contribute to the oedema, but if untreated, contribute to cardiac insufficiency.

Treatment of generalized oedema can be dietary and/or by prevention of Na^+ and water retention. Reduction in dietary Na^+ limits the amount of Na^+ and water that can be retained and therefore limits the oedema. Diuretic-induced inhibition of Na^+ reabsorptive mechanisms limits retention by increasing Na^+ and water loss. ◆

Renal Blood Flow, Glomerular Filtration and Plasma Clearance

John C Atherton

John C Atherton is Senior Lecturer in Physiology at Manchester University. He graduated from Newcastle upon Tyne and gained his PhD at Manchester. His research interests focus on renal physiology with particular interest in urinary concentrating mechanisms, renal function in pregnancy and assessment of nephron function.

Normal functioning of the kidneys to subserve homeostasis and excretion of metabolic waste products depends on: an adequate blood supply; production of an ultrafiltrate of plasma; and the ability to modify the composition of the filtrate through reabsorption from and secretion into the tubule.

About 25% of cardiac output (> 1 litre/min) is directed to the kidneys, but the distribution is not uniform. Almost 100% supplies the cortex, through the glomerular capillaries and peritubular capillaries that surround the proximal and distal convoluted tubules (Figure 1). Only about 10% enters the medulla, of which less than 3% reaches the inner medulla. Renal plasma flow is 600–650 ml/min of which 100–140 ml/min is filtered (glomerular filtration rate (GFR)) across the glomerular capillary wall into Bowman's space. The magnitude and selectivity of the filtration process is possible because of the arrangement of the capillaries within Bowman's space, the structure of the capillary wall, and the visceral epithelial layer (podocytes) of Bowman's capsule with which it is in intimate contact (Figure 2a).

The three main barriers (Figure 2b) to filtration are: the fenestrated capillary endothelium with pores (diameter 70 nm) that acts as a gross filter preventing the passage of blood cells; the basement membrane consisting of a porous matrix of extracellular proteins; and an epithelial layer with podocytes and foot-like processes (pedicels) that surround the glomerular capillaries. Thin membranous sheets containing pores (4 nm by 14 nm) span the gaps (filtration slits, width 25–60 nm) between the pedicels.

The nephron and its blood supply

Negative charges on the pedicels, basement membrane and endothelial cells are indicated by bars.

The passage of large molecules is limited, but haemoglobin (molecular diameter 6.5 nm) and some small plasma proteins (e.g. albumin; molecular diameter about 7 nm) can pass through the filtration barrier, albeit in small amounts. However, electrostatic charge is as important as the size and shape of the molecule. In general, neutral molecules with a molecular diameter less than 4 nm are freely filtered, but molecules (irrespective of charge) with diameters exceeding 8 nm are not filtered. Between 4 and 8 nm diameter the extent of filtration depends on size and charge. This can be explained by the presence of negatively charged glycoproteins on the filtration barriers (Figure 2b). Thus, for molecules of similar size but opposite charge, cationic molecules pass more readily through the barrier; but negatively charged plasma proteins with molecular diameters less than 8 nm do not pass easily.

Mesangial cells found between capillaries within the glomerular tuft have at least three important functions in the filtration process. They exhibit contractile properties, thereby influencing the surface area over which ultrafiltration occurs. They have a structural role in the glomerular tuft and can secrete extracellular matrix. They are actively phagocytic, preventing accumulation within the extracellular matrix of macromolecules that have escaped through the basement membrane of the capillaries (i.e. they keep the filter clean). They also secrete prostaglandins and cytokines that may enhance the inflammatory response to invasion of the extracellular matrix by immune complexes (the basement membrane surrounds only part of the glomerular capillaries).

Forces involved in ultrafiltration

Forces involved in the formation of an ultrafiltrate of plasma are the Starling forces operating across the glomerular capillary wall (Figure 3). Forces that promote fluid movement out of the glomerular capillary are hydrostatic pressure in the glomerular capillary (P_{GC}) and colloid osmotic pressure in Bowman's space (π_{BS}). The forces that oppose fluid movement from the glomerular capillary are colloid osmotic pressure (π_{GC}) and intrarenal pressure (mainly hydrostatic pressure in Bowman's space (P_{BS})). Thus, net ultrafiltration pressure can be represented as $(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS})$. However, since large protein molecules do not traverse the glomerular capillary wall, π_{BS} can be discounted. Hence, net ultrafiltration pressure and fluid movement out of the capillary (GFR) equal $P_{GC} - (P_{BS} + \pi_{GC})$ and $K_f (P_{GC} - (P_{BS} + \pi_{GC}))$, respectively, where K_f is the ultrafiltration coefficient that takes account of the surface area of the glomerular capillary as well as the permeability per unit of surface area.

At the afferent arteriolar end of the capillary, net ultrafiltration pressure is about 10–15 mm Hg. The ensuing fluid movement without significant protein movement results in a rise in π_{GC}; net ultrafiltration pressure is reduced. Fluid moves out of the capillary until the forces promoting and opposing fluid movement from the capillary are equal. At this point (ultrafiltration pressure equilibrium) fluid movement from the capillary ceases. It is thought that this equilibrium is reached in some species (e.g. rat) but not in others (e.g. humans).

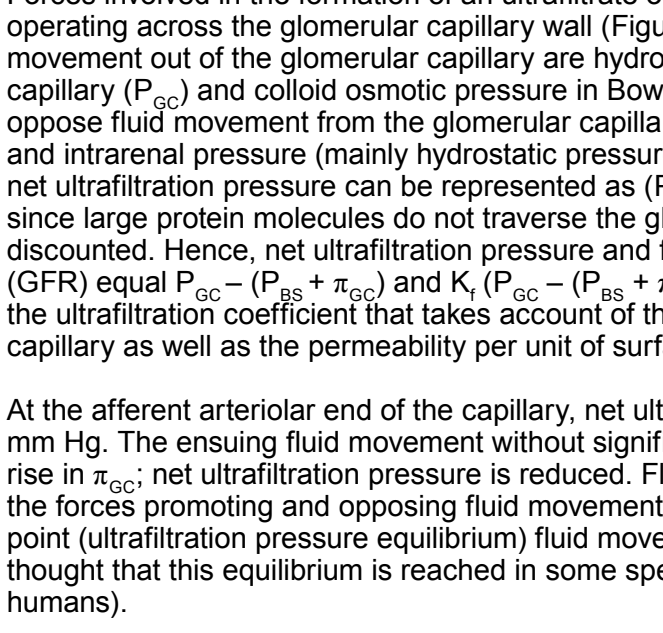
The relationship between these forces operating across a glomerular capillary is different from a systemic capillary. Hydrostatic pressure declines along the length of the systemic capillary and there is no difference between the colloid osmotic pressure at the arterial and venous ends of the capillary. Fluid moves out of the capillary at the arteriolar end into the capillary at the venous end; fluid always moves out of the glomerular capillary. The reason for this difference is primarily because the glomerular capillary is in series with the afferent and efferent arterioles; the balance of vascular resistances is such that only a small decline in hydrostatic pressure occurs along the length of the glomerular capillary.

Factors influencing GFR

Changes in GFR can be mediated by changes in K_f and/or changes in the Starling forces.

Renal plasma flow (RPF) is also an important determinant of GFR. The arrangement of the glomerular capillaries, in series between two sets of arterioles, the resistances of which can be changed independently, means that it is possible to produce changes in GFR that are both in parallel to and divergent from changes in RPF (Figure 4). As flow along the glomerular capillary increases, the difference between P_{GC} and π_{GC} does not decrease at the same rate as at lower flow (Figure 3); the increase in π_{GC} is smaller and therefore net ultrafiltration pressure is greater at all points along the capillary; ultrafiltration pressure disequilibrium at the efferent arteriolar end of the capillary is greater. The opposite changes occur if both afferent and efferent arterioles constrict.

Starling forces and ultrafiltration along a glomerular capillary



P_{GC} and P_{BS}, hydrostatic pressure in glomerular capillary and Bowman's space, respectively; π_{GC}, colloid osmotic pressure on glomerular capillary plasma

3

Effect of changing renal arteriole resistance

Afferent arteriole resistance	Efferent arteriole resistance	Renal plasma flow	Glomerular capillary pressure	Glomerular filtration rate
Decreased	Unchanged	↑	↑	↑
Unchanged	Decreased	↑	↓	↓
Unchanged	Increased	↓	↑	↑
Increased	Unchanged	↓	↓	↓
Decreased	Decreased	↑	↔	↑
Increased	Increased	↓	↔	↓

Changes in sympathetic nerve activity – renal nerves and the adrenal medulla affect afferent and efferent arteriolar resistance by α-adrenoceptor-mediated vasoconstriction, mainly on the afferent arteriole. Moderate stimulation lowers RPF without an equivalent change in GFR, suggesting that vasoconstriction of the efferent arteriole is the predominant effect. More intense stimulation of renal sympathetic nerves (e.g. following severe haemorrhage) dramatically reduces RPF and GFR, suggesting powerful and equivalent changes in resistance in afferent and efferent arterioles.

Angiotensin II – the effects of this vasoconstrictor depend on the plasma concentration; efferent arterioles are more sensitive than afferent arterioles. At low concentrations any reduction in RPF may not be accompanied by an equivalent change in GFR whereas at high concentrations both RPF and GFR are lower.

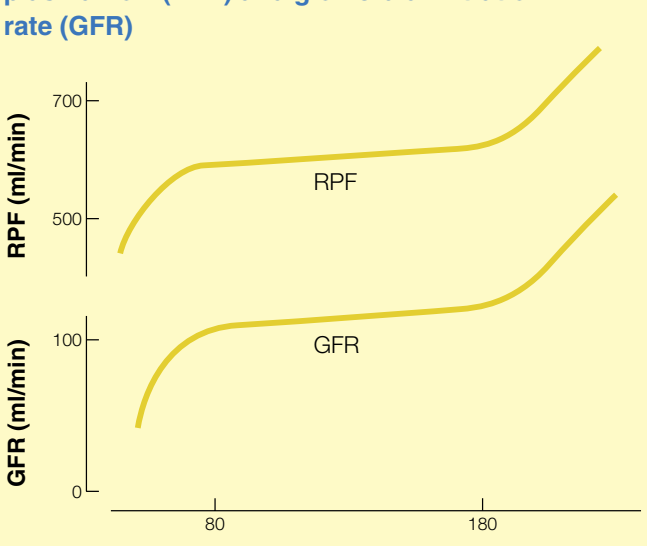
The endothelial cells lining the renal arterioles produce a number of autacoids that have important vasodilator or vasoconstrictor actions. Endothelin has powerful vasoconstrictor effects on the afferent and efferent arterioles, which reduces RPF and GFR. These cells may also have angiotensin-converting enzyme on their cell surface thereby converting angiotensin I, produced systemically or locally, to angiotensin II. Nitric oxide, released from endothelial cells, has significant vasodilator effects causing increases in RPF and GFR. Prostaglandins (PGE_2, PGI_2) produced locally, vasodilate afferent and efferent arterioles to increase RPF (not GFR), but their effects are manifest only during intense sympathetic nerve vasoconstrictor activity. Their primary role is to modulate the powerful vasoconstriction and therefore to protect the kidney from renal ischaemia.

Other hormones are implicated in the control of RPF and GFR in pathophysiological conditions but their role in normal regulation has yet to be defined. Examples are direct vasodilator (dopamine, atrial natriuretic peptide) or vasoconstrictor (adenosine) effects on afferent and/or efferent arterioles or in-direct effects via the release of nitric oxide from the endothelial cells (bradykinin, ATP, histamine).

Mesangial cells may also be involved in the regulation of RPF and GFR; their contractile elements respond to autacoids in a similar way to arteriolar smooth muscle cells. They might influence GFR by controlling flow through glomerular capillaries and by affecting the surface area available for ultrafiltration (an important determinant of K_f).

Autoregulation (Figure 5) – kidneys regulate blood flow by adjusting vascular resistance to changes in perfusion pressure (blood pressure): renal blood flow = perfusion pressure/renal vascular resistance. Within 80–200 mm Hg, increments in blood pressure are not accompanied by significant changes in RPF or GFR. The myogenic feedback mechanism ensures that when blood pressure rises the ensuing stretching of muscle instigates contraction of the muscle and RPF and GFR are relatively constant. The tubuloglomerular feedback mechanism depends on the macula densa sensing tubular flow (or some function of changing flow such as changing sodium load). This sensing mechanism initiates a sequence of events leading to altered afferent arteriolar resistance. If GFR increases, flow past the macula densa increases, the afferent arteriole constricts and RPF and GFR decrease. The converse occurs when GFR declines. This maintains constancy of the filtered load delivered to the reabsorptive sites.

Relationship between renal arterial pressure, renal plasma flow (RPF) and glomerular filtration rate (GFR)



5

Renal clearance measurements

Renal clearance of a solute (C_x) is defined as the volume of plasma passing through the kidneys from which all the solute has been removed and excreted in the urine in unit time. Thus $C_xP_x = U_xV$, where: C_x is clearance of solute x, U_x and P_x are the urinary and plasma concentrations of x; and V is urine flow rate. Hence $C_x = U_xV/P_x$.

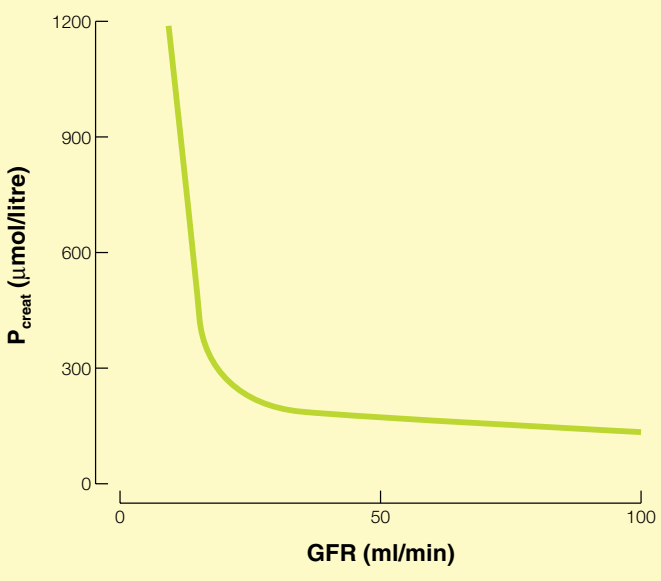
Measuring RPF: to apply this principle to measurement of RPF it is essential to identify a solute that is completely removed from the plasma as it flows through the kidney (i.e. it is filtered and secreted to the extent that the renal venous concentration of the solute is zero) and it is not metabolized in the kidney. The amount delivered to the kidney equals the amount excreted ($RPF.P_x = U_xV$). Such a solute is p-aminohippuric acid (PAH) but it is not endogenous and has to be administered. The kidney excretes this organic acid by ultrafiltration and by a proximal tubular anion secretory mechanism that can actively transport up to a maximum amount per minute (i.e. it can be saturated). When the plasma concentration increases, the amount delivered to the transport sites increases, the transport maximum may be exceeded and renal venous plasma concentration will not be zero. Use of C_{PAH} to measure RPF will not be valid in these circumstances unless both systemic plasma and renal venous PAH concentrations are measured. It is important, therefore, that the secretory transport mechanism is not saturated.

RPF is calculated as $C_{PAH} = U_{PAH}V/P_{PAH}$. However, even at low plasma PAH concentrations, a small amount of PAH escapes secretion because some of the tissues perfused do not possess PAH secretory mechanisms. Measurement of C_{PAH} is referred to as the effective renal plasma flow (ERPF) – plasma flow through renal tissues that effectively remove PAH from the plasma passing through. This assumption underestimates the RPF by about 10%.

Measuring GFR: to apply this principle to measurement of GFR it is essential to identify a solute that is freely filtered and excreted unchanged. Thus, amount filtered = amount excreted ($GFR.P_x = U_xV$). Such a solute is inulin; a polysaccharide of fructose that is not endogenous so has to be administered. GFR is calculated as $C_{inulin} = U_{inulin}V/P_{inulin}$. Inulin has to be administered intravenously over several hours to achieve steady-state plasma concentrations before accurate measurements of GFR can be obtained. For this reason, endogenous plasma creatinine (derived from the muscle protein creatine) and 24-hour urinary creatinine measurements are used instead but they have the disadvantage that some creatinine is secreted by organic cation secretory mechanisms in the proximal tubule. It is usually claimed that this overestimate of GFR is 'balanced' by the error in measuring plasma creatinine that is high owing to the presence of non-specific chromogens. Some data indicate that creatinine clearance can overestimate GFR by 10–30% suggesting that tubular secretion might make a more significant contribution to excreted creatinine.

Plasma creatinine concentration alone is used to assess kidney function in the clinical setting. This might detect significant changes in GFR, but small changes could pass unnoticed. Creatinine production is relatively constant and must equal excreted creatinine if plasma creatinine is to remain constant (i.e. creatinine production = $GFR.P_{creat} = U_{creat}V$). If GFR decreases, a transient decrease in $U_{creat}V$ occurs and P_{creat} increases until equality of production and output is re-established at the lower GFR. Therefore, with a continual chronic reduction in GFR, plasma creatinine concentration increases exponentially (i.e. an initial small reduction in GFR produces only a small increase in plasma creatinine concentration). Only when there is a relatively large reduction in GFR will plasma creatinine increase dramatically (Figure 6).

Hyperbolic relationship between glomerular filtration rate (GFR) and plasma creatinine concentration (P_{creat})



6

Renal clearance is not restricted to measurement of GFR, RPF and filtration fraction (GFR/RPF). Renal clearances of any solute can be measured and, when compared with GFR, its handling by the kidney can be assessed. For example, if the clearance of a solute is less than C_{inulin} there has been net reabsorption of the solute whereas if the clearance is greater than C_{inulin} there has been net secretion.

Proximal and distal nephron function can be estimated using clearances of lithium and free water (C_{H2O}, calculated as $V–C_{osm}$), respectively, but neither is entirely satisfactory. When proximal tubule reabsorption is altered, $C_{lithium}$, a marker of fluid delivery from the proximal tubule, changes in the predicted direction. However, this underestimates fluid delivery because some lithium (12–15%) is reabsorbed in the loop of Henle. C_{H2O} (measured during a maximal water diuresis when ADH secretion is suppressed) is used to estimate Na^+ reabsorption in the water impermeable ascending limb of the loop of Henle and early distal tubule. However, because significant reabsorption of this 'freed water' occurs in the collecting duct even in the absence of ADH, C_{H2O} provides an underestimate of Na^+ absorption. ◆

Role of the Kidney in Acid–Base Balance

John C Atherton

John C Atherton is Senior Lecturer in Physiology at Manchester University. He graduated from Newcastle upon Tyne and gained his PhD at Manchester. His research interests focus on renal physiology with particular interest in urinary concentrating mechanisms, renal function in pregnancy and assessment of nephron function.

The main problem encountered in the homeostatic control of plasma pH within the narrow range 7.38–7.42 is to preserve the alkaline environment in the face of the production of large quantities of volatile acid (15–20 mmol/day as CO_2) and non-volatile acid (about 50 mmol/day) from the metabolism of fats and certain proteins. Defence is achieved through the operation of three basic mechanisms.

- Physicochemical buffering by extracellular and intracellular buffer systems is instantaneous but only limits the fall in pH.
- Respiratory compensation is rapid (minutes) and operates via the control of plasma pCO_2 through changes in alveolar ventilation and subsequent evolution of the volatile acid CO_2. Plasma pH is returned towards the normal values but acid–base status cannot be corrected completely.
- Renal compensation is slower (hours or days) and operates via the control of plasma bicarbonate through changes in the renal secretion of H^+ and the reabsorption and production of bicarbonate. Acid–base status can be corrected completely. This article focuses on these renal mechanisms of controlling acid–base balance.

Reabsorption of filtered HCO_3^- is described elsewhere. The rate of HCO_3^- reabsorption is influenced by glomerular filtration rate (GFR), extracellular fluid (ECF) volume, arterial pCO_2 and a variety of hormones.

Increasing GFR leads to an increase in the filtered load and an increase in total HCO_3^- reabsorption (but not fractional reabsorption). The opposite occurs when GFR is reduced. Glomerulo-tubular balance links filtered load and reabsorption; this protects body buffer stores against spontaneous changes in GFR.

Changes in ECF volume influence HCO_3^- reabsorption in the proximal tubule in the same way as Na^+ reabsorption is affected. ECF volume expansion decreases reabsorption and contraction increases reabsorption. The close linking of HCO_3^- and Na^+ reabsorption via the Na^+-H^+ exchanger in the apical membrane of early proximal tubule cells (accounting for most HCO_3^- reabsorption) provides a mechanism for the association between volume-induced changes in Na^+ and HCO_3^- reabsorption. This also increases the possibility of the involvement of other factors that modify transcellular Na^+ reabsorption (via Na^+-H^+ exchange) in the proximal tubule (and in other nephron segments) in controlling HCO_3^- reabsorption. Thus, altered catecholamines, increased sympathetic nerve activity and angiotensin II, which increase Na^+ reabsorption, and parathormone, dopamine and atrial natriuretic peptide (ANP), which decrease Na^+ reabsorption in the proximal tubule, have corresponding effects on HCO_3^- reabsorption.

pCO_2 – there is an association between chronic changes in pCO_2 and HCO_3^- reabsorption. Raised pCO_2 following prolonged hypoventilation leads to an increase in HCO_3^- reabsorption
in almost all nephron segments, whereas during chronic hyperventilation HCO_3^- reabsorption is reduced. The possible mechanisms responsible include changes in the filtered load and a direct effect on the active pumps for H^+ secretion. During prolonged hypoventilation, plasma HCO_3^- concentration and therefore filtered load increase; HCO_3^- reabsorption increases. Opposite changes (decreased plasma HCO_3^- concentration and HCO_3^- reabsorption) occur in prolonged hyperventilation. Acute changes in pCO_2 are not accompanied by these changes because only small changes in plasma HCO_3^- concentration (hence filtered load) occur. Intracellular acidosis, resulting from chronic increases in pCO_2, increases the steepness of the transmembrane gradient favouring H^+ secretion, and is also thought to cause insertion of more H^+ transport proteins (H^+-ATPase and perhaps H^+-K^+ exchangers) in the apical cell membranes of renal tubular cells, especially intercalated cells in the collecting duct. Both changes favour HCO_3^- reabsorption.

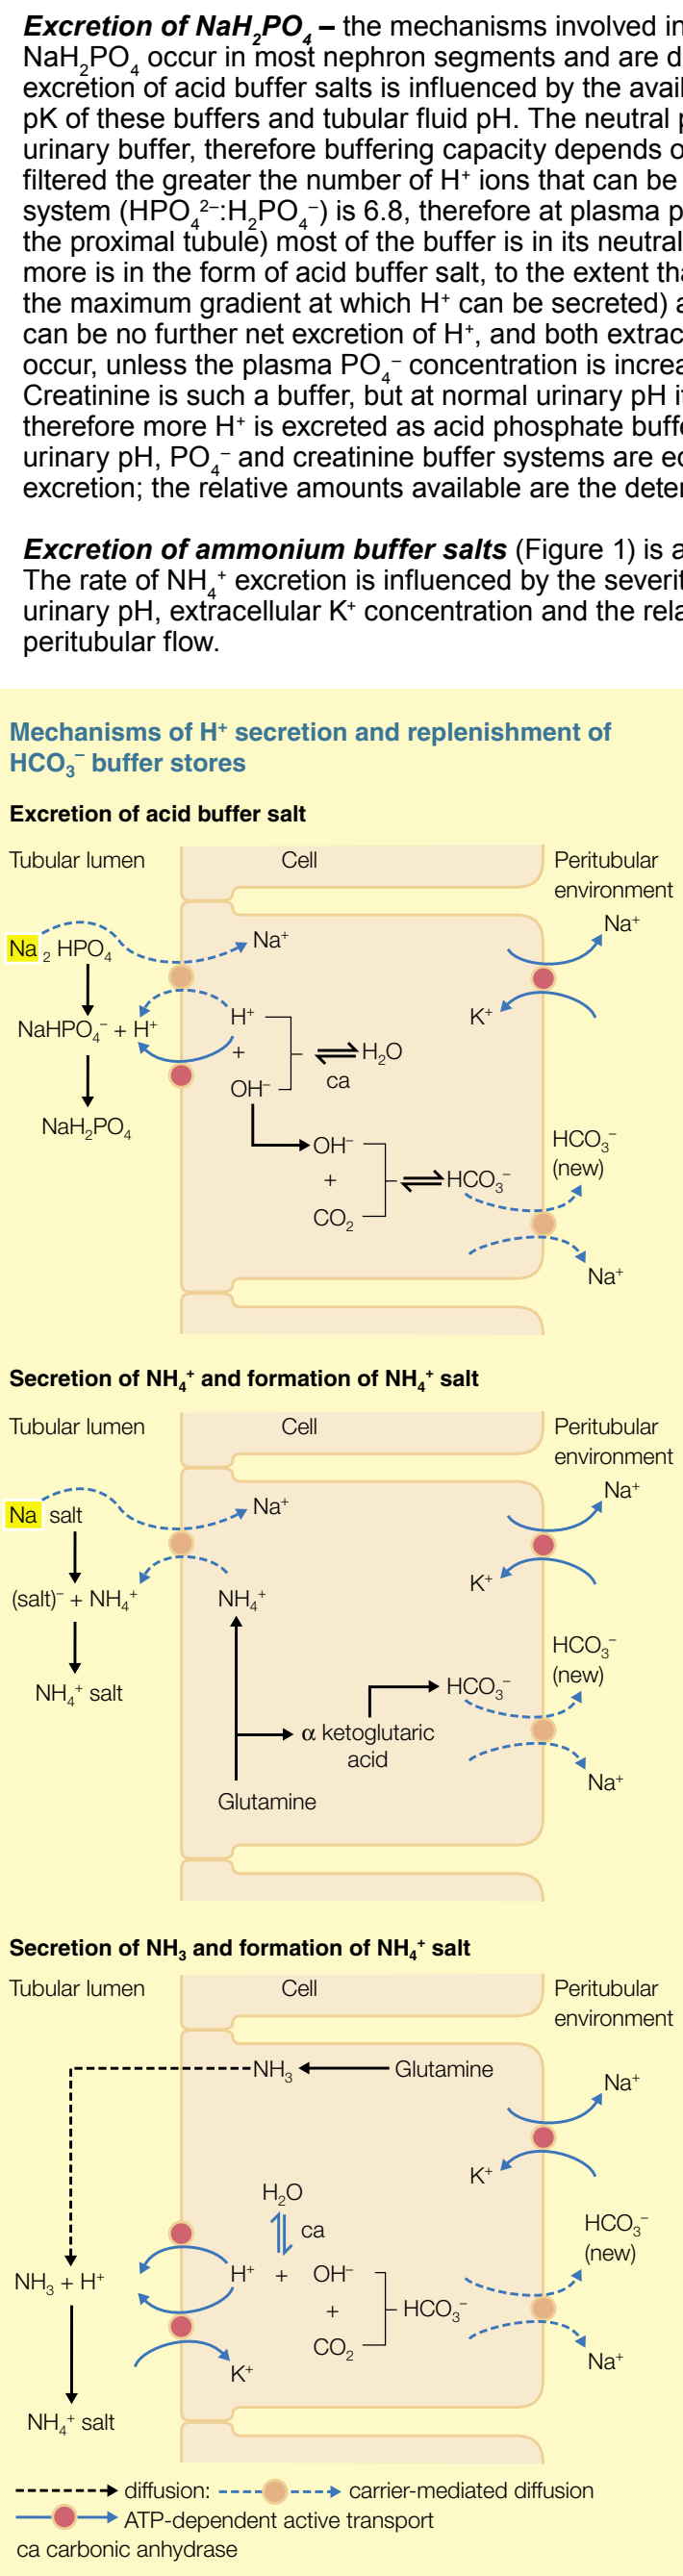
Aldosterone may have a physiological role in HCO_3^- homeostasis. Chronic acidosis raises plasma K^+ concentration and stimulates aldosterone secretion. Aldosterone increases H^+ secretion by collecting duct cells directly and indirectly. The direct effects relate to stimulation of secretion by Na^+-H^+ countertransport in principal cells and by H^+-ATPase in intercalated cells, presumably by increasing the number of protein transporters in the apical membranes. Indirectly, aldosterone increases the negative potential difference in the lumen thereby reducing the electrochemical gradient against which active H^+ secretion occurs.

Production of HCO_3^-: the secretion of H^+ as described above does not lead to net excretion because the CO_2 formed within the tubular lumen is returned to the cell, where more H^+ is formed and then secreted. However, H^+ can be excreted either as neutral ammonium salts (e.g. $(NH_4)_2SO_4$) or as acid buffer salts (NaH_2PO_4). Both these routes for H^+ excretion lead to the formation of one new HCO_3^- for every H^+ secreted.

Excretion of NaH_2PO_4 **–** the mechanisms involved in the formation and excretion of NaH_2PO_4 occur in most nephron segments and are described elsewhere. The rate of excretion of acid buffer salts is influenced by the availability of the urinary buffers, the pK of these buffers and tubular fluid pH. The neutral phosphate buffer salt is the main urinary buffer, therefore buffering capacity depends on its availability; the more that is filtered the greater the number of H^+ ions that can be excreted. The pK of this buffer system (HPO_4^{2-}:$H_2PO_4^-$) is 6.8, therefore at plasma pH (i.e. pH of the fluid as it enters the proximal tubule) most of the buffer is in its neutral form. As tubular fluid pH declines, more is in the form of acid buffer salt, to the extent that at pH 4.4 (minimum urinary pH, the maximum gradient at which H^+ can be secreted) all will be acid buffer salt. There can be no further net excretion of H^+, and both extracellular and intracellular acidosis occur, unless the plasma PO_4^- concentration is increased or other buffers are available. Creatinine is such a buffer, but at normal urinary pH it is less effective (pK = 4.97), therefore more H^+ is excreted as acid phosphate buffer than with creatinine. At minimal urinary pH, PO_4^- and creatinine buffer systems are equally effective for H^+ excretion; the relative amounts available are the determining factor.

Excretion of ammonium buffer salts (Figure 1) is also described in detail elsewhere. The rate of NH_4^+ excretion is influenced by the severity and duration of the acidosis, urinary pH, extracellular K^+ concentration and the relative rates of tubular and peritubular flow.

Mechanisms of H^+ secretion and replenishment of HCO_3^- buffer stores



1

It was reported over 50 years ago that for a given urinary pH, total NH_3 excretion (NH_3+NH_4^+) is higher in prolonged acidosis than in normal acid–base balance. The mechanism appears to be increased NH_4^+ secretion in proximal tubules arising from intracellular pH-induced stimulation of the enzymes involved in the metabolism of glutamine. Stimulation of new enzyme would increase metabolism of glutamine and hence produce more NH_4^+ available for secretion. Chronic alkalosis has the opposite effect.

There is an inverse relationship between urinary pH and total NH_3 excretion; as pH declines, total NH_3 excretion increases. The pK (9.2) of the NH_3:NH_4^+ urinary buffer system is far removed from normal acid urinary pH; total NH_3 is almost exclusively in the NH_4^+ form. Therefore, the relationship between pH and total NH_3 excretion must result from increased NH_3 diffusion into collecting duct lumen with immediate conversion to NH_4^+ at acid pH of luminal fluid. Thus, the gradient favouring passive diffusion of NH_3 into the lumen is maintained and the increase in total NH_3 excretion is a consequence of increased non-ionic diffusion and trapping of the impenetrable ionic form (NH_4^+) in the tubular lumen.

Changes in extracellular K^+ concentration influence NH_4^+ excretion; hyperkalaemia inhibits NH_4^+ excretion; hypokalaemia has the opposite effect. The mechanism responsible is uncertain but may relate to extracellular K^+-induced changes in intracellular pH. Thus, increased exchange of K^+ and H^+ in hyperkalaemia raises intracellular pH, reduces glutamine metabolism and decreases NH_4^+ production and secretion. Hypokalaemia decreases intracellular pH and, therefore, increases NH_4^+ excretion.

NH_3 is lipophilic, therefore any NH_3 produced in renal tubular cells can diffuse into the luminal fluid or peritubular capillary plasma: net movement is determined by relative flow rate and the pH of tubular fluid and plasma. Since the peritubular capillary plasma flow rate is higher (at least five times higher in the cortex) than tubular flow, the more rapid removal in plasma favours movement of NH_3 into the capillary and none appears in the urine. This does not normally occur because of the acid tubular fluid pH, which favours secretion into the tubule. If tubular fluid is more alkaline than peritubular capillary plasma (e.g. following intravenous administration of $NaHCO_3$ in the partial treatment of phenobarbital poisoning or acetylsalicylate overdose) NH_3 formation is reduced and almost all of it moves into the peritubular capillary plasma. Urinary NH_3 excretion is then minimal.◆

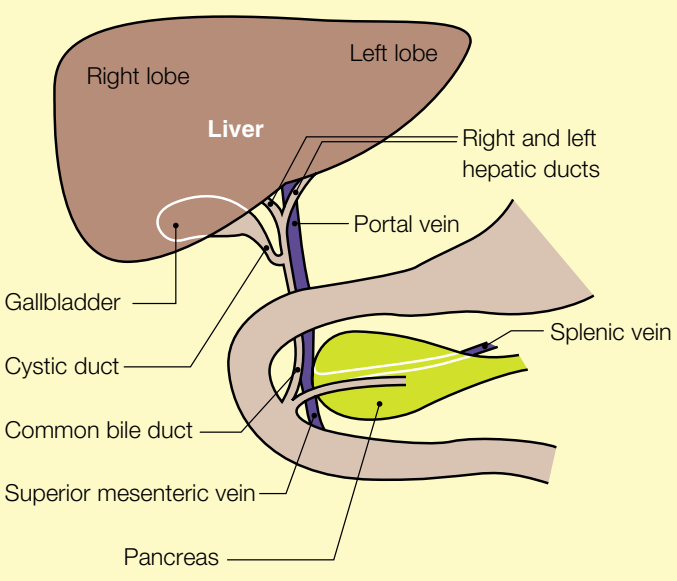
Liver: Functional Anatomy and Blood Supply

Iain Campbell

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds.

The liver is the largest organ in the body. It weighs 1–1.5 kg and lies in the right upper quadrant of the abdomen. It is wedge shaped, occupying almost the whole of the right hypochondrium and the greater part of the epigastrium and extends into the left hypochondrium. The liver is divided into a large right lobe and a much smaller left lobe (Figure 1). On its inferior surface is the porta hepatis, a deep fissure through which the portal vein, the hepatic artery and the hepatic plexus of nerves enter the liver and the right and left hepatic ducts and some lymph vessels emerge. The gallbladder lies on the inferior surface of the right lobe.

Relationships of liver, biliary and portal systems



1

Blood supply
The main blood supply of the liver comes from the portal vein, which gives it a special place in the control of metabolism. The portal vein drains the spleen and the gastrointestinal tract, apart from the distal half of the colon. It thus receives, and processes to varying degrees, almost all the products of digestion and absorption. Total hepatic blood flow at rest is about 1500 ml/minute (i.e. 25–30% of cardiac output). Of this, 70% comes from the portal vein, the remainder from the hepatic artery.

The viscera and liver are supplied by the coeliac, superior mesenteric and inferior mesenteric arteries. The hepatic artery is a branch of the coeliac trunk. Blood flow to the stomach and small intestine (and thus to the liver) doubles after a meal and the increase lasts up to 3 hours. The whole system is capable of extensive autoregulation. Portal venous pressure is about 10 mm Hg and hepatic venous pressure 5 mm Hg. Hepatic arterial pressure is 90 mm Hg but the pressure within the venous sinusoids of the liver is lower than the portal pressure, therefore there is a large pressure drop in the hepatic arterioles. There is a reciprocal relationship between portal venous and hepatic arterial pressures so that when portal blood flow is reduced (e.g. between meals) the hepatic arterioles dilate and total blood flow is maintained. This is thought to be mediated by adenosine. However, portal blood flow is controlled by autoregulation and does not alter when arterial flow changes.

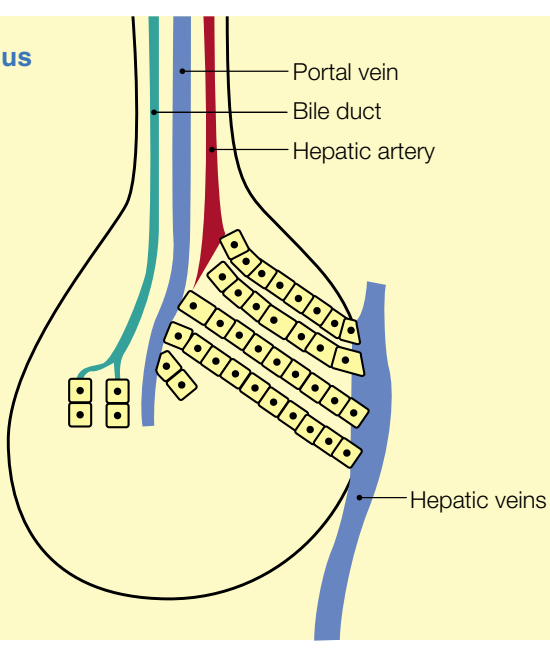
The portal vein is formed from the superior mesenteric and splenic veins in front of the inferior vena cava, behind the neck of the pancreas. It is about 7–8 cm long and enters the liver via the porta hepatis. It differs from other veins in that it has no valves and, in conditions such as cirrhosis, the flow can reverse. The intrahepatic portal vein radicles have smooth muscle in their walls and are innervated by noradrenergic sympathetic nerves, as is the hepatic artery, via the hepatic plexus. There are no vasodilator fibres. At rest, only a portion of the liver is perfused. With rises in venous pressure (e.g. congestive cardiac failure) the sinusoids distend. With diffuse noradrenergic discharge (e.g. hypovolaemic shock, the start of exercise) hepatic arterioles and portal venous radicles constrict and blood flow through the organ is brisk, bypassing most of it. Constriction of the mesenteric arterioles reduces portal inflow. In severe shock, patchy hepatic necrosis may occur. During exercise, constriction of the splanchnic bed, including the liver, effectively increases the circulating blood volume to the exercising muscles by up to 30%.

The pancreatic veins drain into the splenic vein, which joins the portal vein just before it enters the liver. These veins carry the pancreatic hormones, insulin and glucagon, from the endocrine part of the pancreas, therefore they exert their effects first on the liver. The concentrations of these hormones are much higher in the liver than in the systemic circulation, and so liver cells are exposed to higher concentrations than the other body tissues.

The liver is drained by the hepatic veins, which enter the infer-ior vena cava. These emerge from the posterior aspect of the liver and immediately join the inferior vena cava. They have no valves and are invested in fibrous tissue. On dissection they are held open, in contrast to the portal vein which tends to collapse.

Perhaps a more correct way of thinking about the anatomy of the liver is in terms of the acinus as the anatomical unit. There are about 100,000 acini, each composed of hepatocytes, endothelial cells and Küpffer cells arranged like grapes on a vascular stalk (Figure 2) containing terminal branches of portal veins via hepatic arteries and bile ducts. The 'central' vein of the lobule is on the periphery of the acinus.

Liver acinus

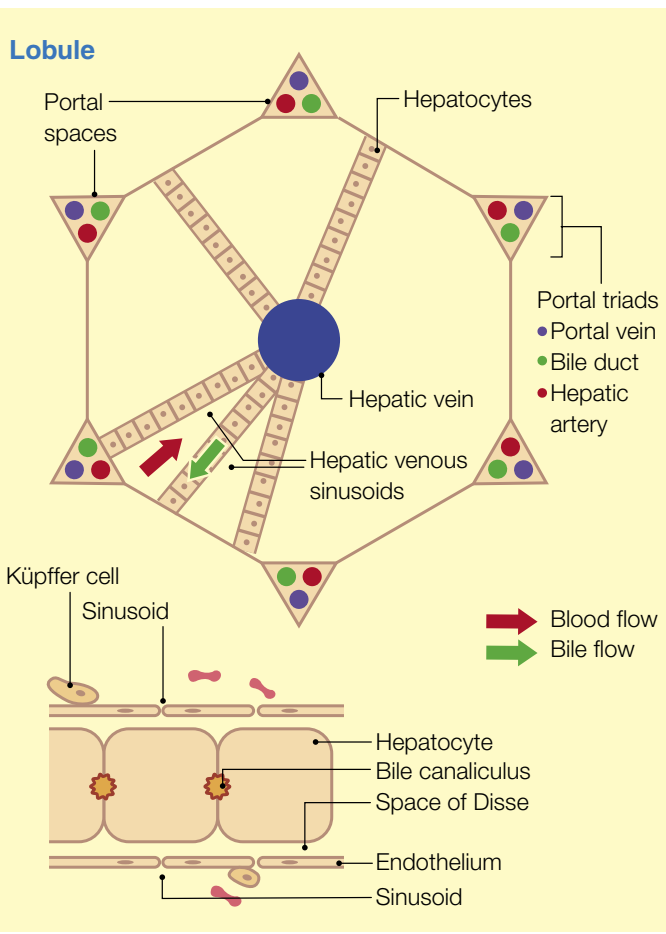


2

Biliary system
Hepatocytes excrete bile into canaliculi that coalesce to form the right and left bile ducts; one from each lobe. They join outside the liver to form the common hepatic duct. The cystic duct drains the gallbladder and unites with the common hepatic duct to form the common bile duct, which enters the duodenum at the duodenal papilla. Bile has several functions including involvement in fat absorption. When food enters the mouth, the sphincter around the duodenal papilla relaxes and when gastric contents enter the duodenum the hormone cholecystokinin, from the intestinal mucosa, causes the gallbladder to contract.

Functional anatomy
For an organ that has such an extensive range of functions, the liver is structurally remarkably homogeneous. 80% is made up of hepatocytes, which are metabolically extremely active. They contain extensive amounts of rough and smooth endoplasmic reticulum, which are involved in protein synthesis and drug metabolism, respectively. The other main cell types are the Küpffer and endothelial cells. The hepatocytes are organized into lobules 1 mm across (Figure 3).

Lobule



3

Each lobule is hexagonal, with a portal space at each corner containing the portal triad, consisting of branches of the portal vein, the hepatic artery and a bile duct. Within the lobule, the hepatocytes are arranged radially in cords. The spaces between the cords constitute the sinusoids filled with blood, which drains from the portal vein and hepatic artery in the periphery of the lobule into the central vein, which drains ultimately into the hepatic veins and the vena cava. The transit time from the portal vein to the central vein is 8–9 seconds.

There is usually only one layer of hepatocytes between two sinusoids so the area of contact between the blood and the hepatocytes is huge. The sinusoid receives blood from both the portal vein and hepatic artery. The space between the endothelial cells and the hepatocytes (the space of Disse) contains the 'extracellular fluid' of the liver, some of which goes to form lymph. This drains via superficial vessels on the surface of the organ and converges on nodes at the porta hepatis or via deep vessels that accompany the hepatic veins.

The sinusoids are lined by endothelial cells that have large gaps between them, facilitating communication between the lumen of the sinusoid and the hepatocytes. Attached to the endothelial cells, also lining the sinusoids, are the Küpffer cells, which are macrophages. They form part of the endothelial system and are found mainly in the periportal region. They constitute 80% of all the resident macrophages in the body. They contain vacuoles and lysosomes and effectively sit astride the portal tract taking up bacteria, particulate matter and endotoxins that enter the portal blood from the gastrointestinal tract. In the fetus, hepatic Küpffer cells produce red cells and, with some diseases that destroy the bone marrow, some red cell production may occur in the liver.

The arrangement of vessels means there is an oxygen gradient within the lobule with cells on the periphery being better oxygenated than those around the central vein. This is reflected in the different metabolic processes that occur in the different areas of the lobule. The better oxygenated areas in the periphery are associated with protein metabolism and the poorer oxygenated areas in the centre with glycolysis and ketone body formation.

Bile secretion
Hepatocytes produce bile and the liver secretes about 500 ml/day, which circulates three times. Bile contains bile salts involved in fat absorption and bile pigments, the products of haemoglobin metabolism, all dissolved in an alkaline electrolyte solution. Cholesterol and alkaline phosphatase are excreted in the bile as are adrenocortical and other steroid hormones as well as a number of drugs. Many are subsequently reabsorbed (the enterohepatic circulation). Bile is excreted by the hepatocytes into bile canaliculi between the hepatocytes. These drain into intralobular bile ducts and coalesce to form the right and left hepatic ducts. While blood in the lobule passes centrally to the central vein, bile moves to the periphery to the bile ducts lying as part of the portal triad in the portal space. ◆

Liver: Metabolic Functions

Iain Campbell

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

The liver plays a major role in the metabolic control of the body (Figure 1).

Bile formation
The liver produces about 500 ml/day of bile, which circulates three times. It is an alkaline electrolyte solution (97% water) containing bile salts and bile pigments. Bile salts are crucial to the digestion and absorption of lipids. Bile pigments are products of haemoglobin breakdown.

Bile salts are sodium and potassium salts of bile acids conjugated to glycine and taurine. The two primary acids are cholic and chenodeoxycholic acid. The two secondary ones (deoxycholic and lithocholic acid) are formed in the colon by bacterial action. The bile salts are amphipathic molecules, which means they have both hydrophilic (–OH, –COOH) and hydrophobic (steroid nucleus) groups. In conjunction with phospholipids (also amphipathic) they form micelles around lipid molecules and transport them to the brush border of the intestine where the lipids are absorbed. 90–95% of bile salts are actively absorbed from the terminal ileum. The absorbed salts return to the liver in the portal vein and are re-excreted in the bile (enterohepatic circulation). The bile salts that enter the colon are converted to salts of the secondary acids of which lithocholate is mainly excreted and deoxycholate is absorbed. The total bile salt pool is about 3.5 g of which 0.2–0.4 g are lost each day in the faeces; the pool recycles about twice per meal (i.e. about 6–8 times/day). Absence of bile is associated with fat malabsorption as is resection of the terminal ileum.

Functions of the liver

Formation and secretion of bile

Macronutrient metabolism
- Carbohydrate
- Fat
- Protein

Inactivation of:
- Drugs
- Toxins
- Steroids and hormones

Plasma protein synthesis
- Albumin
- Clotting factors
- Acute phase proteins
- Binding protein

Immunity
- Küpffer cells

Bile pigments: haemoglobin is broken down by macrophages in the tissues to biliverdin then to bilirubin. The globin part is degraded ultimately to amino acids and the iron complexes with transferrin. Bilirubin is transported, bound to albumin, to the liver where it is conjugated with glucuronic acid in the smooth endoplasmic reticulum to render it soluble. It is then secreted into the bile canaliculi. Some bilirubin glucuronide escapes into the general circulation where it is loosely bound to albumin. Some conjugated bilirubin in the intestine is reabsorbed (enterohepatic circulation) but most is converted by bacterial action in the intestine to urobilinogen, which is eliminated in the faeces as stercobilin, a brown pigment that colours stools. Some urobilinogen is also reabsorbed and excreted by the kidney which oxidizes it to urobilin – a pigment that gives urine its amber colour.

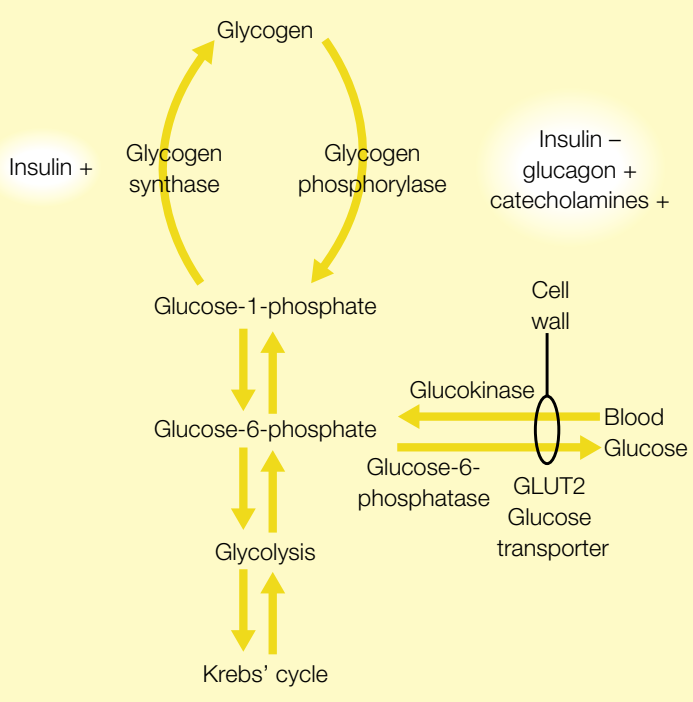
The gallbladder: bile is stored in the gallbladder where it is concentrated by the absorption of water, secondary to the active absorption of sodium. The average water content of gallbladder bile is 89%. Gall bladder contraction is stimulated by cholecystokinin produced by the duodenum in response to entry of fatty acids and amino acids from the stomach.

Glucose is stored in the body as glycogen in liver and muscle. The muscle stores are larger, but muscle lacks glucose-6-phosphatase so muscle glycogen is unable to contribute to blood glucose; only liver glycogen does this and, in the absence of a carbohydrate intake, glycogen stores are exhausted within 24–48 hours. The body normally obtains about 50% of its energy from glucose oxidation therefore in normal circumstances liver glycogen stores have to be replenished continuously.

Glucose is absorbed from the intestine into the portal vein where, after a meal, glucose concentrations can reach 10 mmol/litre. Glucose passes into liver cells via the GLUT2 glucose transporter molecule on the hepatocyte membrane. This transporter is not sensitive to insulin and the rate of entry into the hepatocyte is proportional to the extracellular glucose concentration; it is rapidly phosphorylated by gluco-(hexo-)kinase to glucose-6-phosphate (Figure 2). Glucokinase is increased by insulin. Glucose-6-phosphate may be metabolized to pyruvate via the glycolytic pathway or converted to, and stored as, glycogen. Most of the liver's energy requirements come from amino acid and fatty acid oxidation, therefore most of the glucose taken up by the liver is converted to glycogen.

The system has a high capacity and the liver acts as a glucose sink. Its uptake follows its concentration gradient and this is not insulin dependent. However, insulin is important in glycogen synthesis. Glucose-6-phosphate is converted to glucose-1-phosphate and glycogen is synthesized by the enzyme glycogen synthase, the activity of which is stimulated by insulin and glucose (Figure 2). Liver glycogen acts as a glucose buffer, storing glucose when blood concentrations are high and releasing it when glucose is required in other parts of the body. When blood glucose falls, glucose is released from glycogen through the action of the glycogen phosphorylase. Glucose-6-phosphatase is reformed and glucose released into the circulation via the action of glucose-6-phosphatase. Glycogen phosphorylase is stimulated by glucagon. The catecholamines, adrenaline and noradrenaline, also have a role in glycogenolysis but mostly in stressful situations (e.g. exercise, trauma, shock).

Carbohydrate metabolism



Glycogen is synthesized by glycogen synthase stimulated by insulin. Glycogen is broken down (glycogenolysis) by glycogen phosphorylase under the influence of glucagon, and during stress by catecholamines

Glucagon has a reciprocal relationship with insulin. When blood glucose decreases, insulin falls, glucagon rises and glyco-genolysis occurs. The proximity of the pancreas, with the pancreatic vein draining directly into the portal vein, means that the liver is rapidly exposed to high concentrations of these hormones in response to changes in blood glucose.

The liver is also the main site of gluconeogenesis (the synthesis of glucose from smaller molecules). The major gluconeogenic precursors are lactate, glycerol and the amino acids, principally alanine. The rate of gluconeogenesis is controlled by the rate of substrate supply and hormonal regulation. Release of gluconeogenic precursors from peripheral tissues occurs in situations such as starvation (amino acids from muscle) and severe exercise (lactate from muscle glycogen). The process is similar to glycolysis in reverse with differences in the enzymes involved at three points. The enzymes controlling gluconeogenesis are controlled by the hormones insulin and glucagon and, under stress (exercise, trauma or sepsis), cortisol and the catecholamines. Gluconeogenesis is stimulated by lack of insulin and high levels of glucagon. The relationship between glucagon and insulin is important in starvation, and in trauma and exercise the high cortisol and catecholamine levels provide additional stimuli.

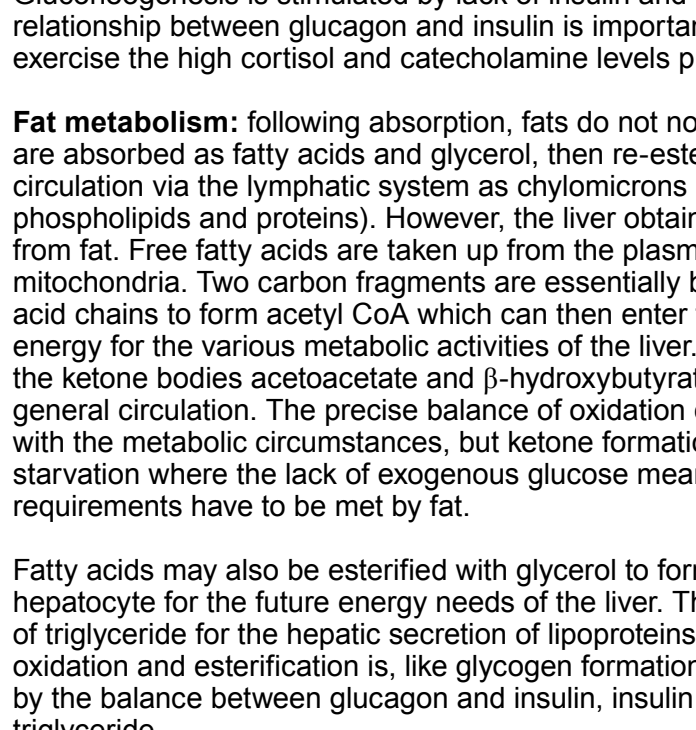
Fat metabolism: following absorption, fats do not normally enter the liver. They are absorbed as fatty acids and glycerol, then re-esterified and transported to the circulation via the lymphatic system as chylomicrons (packages of triglyceride, phospholipids and proteins). However, the liver obtains much of its energy needs from fat. Free fatty acids are taken up from the plasma and undergo β oxidation in the mitochondria. Two carbon fragments are essentially broken off the multicarbon fatty acid chains to form acetyl CoA which can then enter the citric acid cycle to provide energy for the various metabolic activities of the liver. Alternatively they may form the ketone bodies acetoacetate and β-hydroxybutyrate, which are released into the general circulation. The precise balance of oxidation or ketone body formation varies with the metabolic circumstances, but ketone formation is particularly important in starvation where the lack of exogenous glucose means virtually all the body's energy requirements have to be met by fat.

Fatty acids may also be esterified with glycerol to form tri-glyceride, stored in the hepatocyte for the future energy needs of the liver. These stores are also the source of triglyceride for the hepatic secretion of lipoproteins. The balance between fatty acid oxidation and esterification is, like glycogen formation and gluconeogenesis, controlled by the balance between glucagon and insulin, insulin stimulating the formation of triglyceride.

Protein metabolism: proteins are hydrolysed to amino acids and dipeptides for absorption. The intake of protein in a normal Western diet is 70–100 g/day but the body cannot store protein; protein accretion, in the form of muscle, occurs only in response to exercise or drugs such anabolic steroids and β-agonists. Total body protein is normally stable, but this is a dynamic stability with the processes of protein synthesis from, and protein breakdown to, amino acids and amino acid oxidation going on continuously. In this stable state, rates of amino acid oxidation to carbon dioxide, water and urea (also creatinine, ammonia and uric acid) approximate the rates of protein ingestion. The equilibrium is disturbed in starvation, when exogenous protein ceases to be available, and in trauma or sepsis when patterns of hepatic protein synthesis change dramatically (see later). When protein intake is in excess of requirements the excess is metabolized as described above and urea production rates are increased. The liver obtains about half its energy requirement from protein oxidation.

Amino acids are broken down in the liver in two stages (Figure 3). Deamination to the corresponding keto acids (e.g. pyruvate, α-ketoglutarate), which are oxidized, mostly in the citric acid cycle to carbon dioxide and water with the release of energy, occurs. The amine group is metabolized to urea via the urea cycle and the liver is the only site of urea production in the body. An exception is the branch chain amino acids, the metabolism of which occurs mainly in muscle.

Protein metabolism



Inactivation and excretion of toxins, drugs and cholesterol
The liver is a main site for the metabolism of toxic chemicals, many formerly of plant origin but now mostly pharmacological substances. Most drug metabolism occurs in the hepatic smooth endoplasmic reticulum. In general, metabolism involves in-activation of the substance and the creation of a more ionized molecule that allows excretion in the bile or urine. Filtration of a lipid-soluble substance by the kidney would be followed inevitably by reabsorption in the tubule. Making it more polar, stops the reabsorption. This occurs in two phases.

Phase I inactivates the molecule and involves oxidation, reduction or hydrolysis. It is carried out mainly by a nonspecific group of enzymes called the mixed function oxidase or P450 system. They are classified into families and subfamilies by the degree to which they share amino acid sequences. However, the system is not unique to the liver and these enzymes are also found in other tissues. Phase I processes are also carried out by other enzymes (e.g. dehydrogenases, glutathione-S-transferase).

Phase II reactions increase the water solubility of the substance by complexing or conjugating it with other substances such as glucuronide, sulphate, acetyl, methyl or glycine groups. Most reactions occur in the liver but not exclusively so. The smaller molecules are excreted in the urine, larger ones (including those with a steroid nucleus) in the bile.

Steroid hormones are also converted to less active substances in the liver, then conjugated to glucuronide or sulphate and excreted in the bile. Cholesterol is treated similarly and is also excreted in the bile.

Plasma protein synthesis
The plasma proteins consist of albumin, globulin and fibrinogen fractions. The globulin fraction is divided into α, β and γ globulins. Antibodies in the γ globulin fraction are manufactured in the plasma cells. The remainder are synthesized in the liver. Albumin is one of the smallest molecules (molecular weight 69,000). It exerts a plasma osmotic (oncotic) pressure and is important in the maintenance of fluid balance in peripheral tissues but it also binds a number of substances such as barbiturates, penicillin, bilirubin, urobilinogen, hormones (thyroxine) fatty acids and bile salts.

The normal plasma albumin level is 3.5–5 g/100 ml and the total exchangeable albumin pool 4–5 g/kg body weight. 40–45% of total albumin is intravascular and much of the rest is in the skin. 5–10% is degraded each day and hepatic synthesis is 200–400 mg/kg/day. Its production is closely regulated: synthesis is depressed in starvation and increased in the presence of abnormal albumin loss (e.g. in kidney disease). 40% of total plasma proteins are globulin (molecular weight 80,000–150,000). They form part of the lipoprotein complexes that transport lipid molecules and cholesterol between the liver and the tissues. They bind thyroxine, cortisol, vitamin B_{12}, copper and iron. Prothrombin, erythropoietin and angiotensinogen are all globulins.

Following trauma or sepsis, patterns of plasma protein synthesis change with plasma levels and the distribution of proteins between the intravascular and extravascular spaces in what has been termed the acute phase response. Circulating concentrations of albumin, transferrin and prealbumin diminish and fibrinogen (clotting factor), α_2-macroglobulin (protease inhibitor), ceruloplasmin (binds copper) and C-reactive protein (CRP denotes inflammation and tissue damage) all rise. CRP rises the most and is often used as an indicator of the severity of inflammation or tissue damage. Capillaries become ‘leaky’ and there is a redistribution of protein and fluid between the intra- and extravascular spaces.

Küpffer cells
Küpffer cells are tissue macrophages attached to the endothelium in the sinusoids. They are important because they come into contact with almost all the blood draining the gastrointestinal tract, which may contain endotoxins and bacteria. In response to an inflammatory stimulus they produce the cytokines, tumour necrosis factor, interleukin-1 and interleukin-6, which stimulate the liver to produce the acute phase proteins. Loss of integrity of the gastrointestinal tract (e.g. following major trauma or sepsis) may lead to endotoxins and bacteria entering the portal circulation, stimulating the Küpffer cells and causing a systemic inflammatory response. ◆

The Brain: Functional Divisions

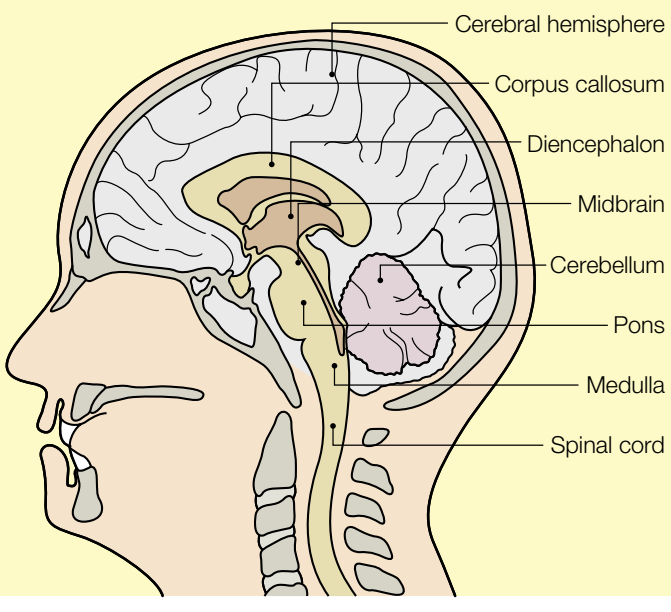
Chris J D Pomfrett

Chris J D Pomfrett is Lecturer in Neurophysiology Applied to Anaesthesia at the University of Manchester, UK. He qualified from Queen Mary College and The Medical College of St Bartholomew's Hospital, London.

Anaesthesia is not the same as natural sleep. The basis of contemporary balanced anaesthesia is the use of the CNS as a target, specific regions of which yield a component of good anaesthesia. Hypnosis (elimination of consciousness) and amnesia are achieved by disrupting the normal function of the cerebral cortex and underlying brain structures. Progressively greater depths of anaesthesia cause progressive reduction in the global metabolic rate of the brain. The adult brain (Figure 1) weighs 1250–1450 g within a volume of 1400 ml. It comprises the:

- telencephalon (cerebral cortex, basal ganglia and olfactory bulbs)
- diencephalon (thalamus, hypothalamus and habenula)
- mesencephalon or midbrain (structures around the cerebral aqueduct, superior and inferior colliculi and the cerebral peduncles)
- metencephalon (pons and cerebellum)
- myelinocephalon (including the medulla oblongata).

The adult brain



1

The most prevalent excitatory neurotransmitter in the brain is glutamate. γ-aminobutyric acid (GABA) receptors are the most important inhibitory receptors in the brain, apart from the brainstem, where glycine is also an important inhibitory neurotransmitter. There are many subtypes of receptor protein. This means that although a specific brain region may have a particular type of receptor, there is no guarantee that the receptor performs in the same manner as a slightly differently configured subtype of the same receptor in another region. For example, the potency of propofol and volatile anaesthesia at $GABA_A$ and glycine receptors is conferred by the protein receptor configuration directed by two amino acids; if those amino acids are substituted, the receptor is no longer sensitive to hypnotic anaesthetic agents

Cerebral cortex

The cerebral cortex comprises millions of neurons. One of the most common is the pyramidal cell. Axons from single pyramidal cells may terminate many centimetres from the cell body, against targets such as other pyramidal cells or, in the case of the corticospinal tract, even spinal interneurons linked to motor neurons.

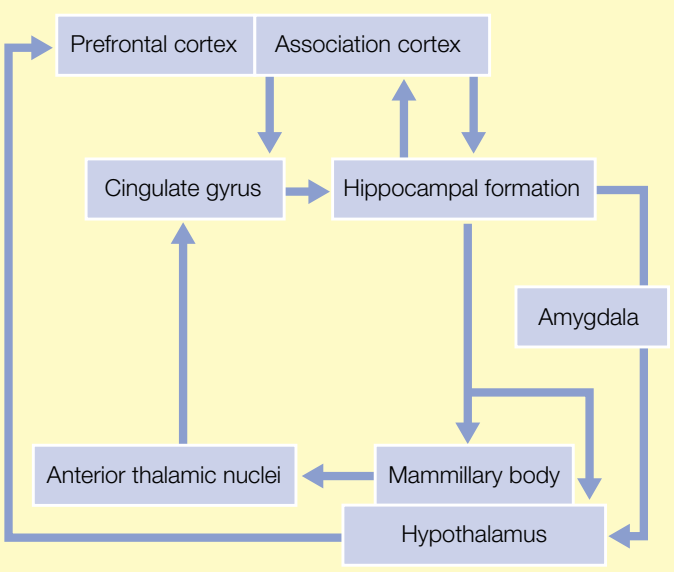
Graded potentials from thousands of pyramidal cells near recording electrodes are the basis for the electroencephalogram (EEG). Single neuron recordings from the sensory regions of the cerebral cortex, such as the primary visual cortex, have been performed since the 1960s and have revealed much about sensory processing. Histology of the cerebral cortex reveals six distinct layers. Layers I–IV receive input from other regions of the cerebral cortex and brain, mainly from the thalamus (layer IV). Layers V and VI house the cell bodies of cortical efferent interneurons. In the most heavily studied region, the primary visual cortex (V1 or Brodmann's area 17), much initial processing is performed by 'simple cells' (i.e. neurons sensitive to visual stimuli such as a line moving at a particular orientation of movement). 'Complex cells' receive input from simple cells along with parallel direct input from the lateral geniculate nucleus, and are selective to movement in a particular direction (not just orientation) and spatial frequency; they are actively inhibited by movement at other orientations. Complex cells are often 'end stopped' (hypercomplex) whereby only stimuli of a specific length, orientation and spatial frequency are encoded into action potentials. Subtle changes in action potential frequency, and hence the sensitivity of these neurons to different characteristics of visual stimuli, have been observed with increasing depths of volatile anaesthesia.

Visual neurons in the primary visual cortex are arranged in columns of similar orientation selectivity. These columns have been directly visualized by the use of voltage-sensitive dyes on the surface of the exposed cerebral cortex. Complex cells are also often sensitive to textured visual stimuli (e.g. wood grain pattern on a desk, or a 'hidden eye' visual illusion), to which simple cells are largely insensitive. Some have suggested that this is evidence for parallel processing of information in the primary visual cortex, rather than a strict hierarchy of function proposed by earlier researchers. It is likely that other sensory regions of the cerebral cortex have a similar organization, and most regions have been topographically mapped to the environmental spatial or frequency position of stimuli.

Limbic system

The limbic system (Figure 2) is responsible for the recall and expression of emotions such as fear, anger, pleasure and contentment. It is a prime target for anaesthesia, because elimination of emotion and the recall of unpleasant events is the basis of adequate hypnosis. Damage to different regions of the limbic system results in a characteristic loss of a component of emotion or memory.

Limbic system



2

The limbic system is also a vital component of consciousness. Consciousness is not located in one particular region of the brain, though localized lesions in the solitary nucleus of the medulla oblongata (brainstem) or the anterior cingulate gyrus (a component of the limbic system) lead to coma. Consciousness appears to be the result of coordinated firing of large assemblages of neurons, whereas subconscious behaviour can be initiated and sustained by groups of relatively few neurons. Fast binding of relevant sensory inputs with large assemblage activity is probably required for the expression of consciousness and components of the limbic system are probably involved. Two types of consciousness (i.e. core consciousness, extended consciousness) have been suggested. Clinical sedation progressively abolishes extended consciousness, and general anaesthesia abolishes core consciousness.

Anterior cingulate gyrus

Ablation of the prefrontal cortex or cingulate gyrus eliminates concern over chronic pain, and pain no longer elicits powerful emotions. Functional imaging studies of the anterior cingulate gyrus have implicated it in the presence of conscious awareness during light sedation. Activity in the left anterior cingulate proportionally decreases with increasing depth of anaesthesia and appears to correlate with the level of hypnosis.

Hypothalamus and thalamus

The hypothalamus and thalamus form the diencephalon. The thalamus is the main relay for ascending information entering the cerebral cortex. The dorsomedial thalamus has to be active during light anaesthesia for explicit recall of events to occur; it is important for the formation of explicit memory and its subsequent retrieval. The dorsomedial thalamus is one example of the thalamic regions, each of which demonstrates varied functionality.

Unconscious regulation of autonomic function is integrated between the autonomic, somatic and endocrine systems by the hypothalamus, the main function of which is to keep internal conditions constant. The hypothalamus is responsible for homeostasis, especially by directing motivation (e.g. temperature, feeding, thirst). Control of core temperature is an important role performed by the hypothalamus, the posterior region of which compares information from relatively warmer neurons on the anterior hypothalamus with cold receptors in the skin. Internal heat is increased by raising the metabolic rate in combination with a decrease in peripheral blood flow in the skin. When core temperature rises, sweating is promoted and dilation of blood vessels in the skin promotes cooling. Anaesthesia disrupts homeostatic control originating from the hypothalamus, and this is a difference between natural sleep and anaesthesia. During natural sleep, the set point of temperature control falls, but it is still under active control by the hypothalamus. Natural sleep is regulated via the hypothalamus, partly by the release of endogenous sleep-promoting hormones.

Hippocampus

The hippocampus is involved in the acquisition of memory from experience, and is important for the recall of spatial position. Functional imaging has suggested that people with enhanced mapping skills have greater activity in the hippocampus. Lesions to specific regions of the hippocampus have resulted in subjects who are unable to recall any events that occurred after the lesion, even though memory of events up to the trauma is secure. Such subjects have proved that long-term memory is not necessary for consciousness, as long as subjects still have a functional working (real-time) memory they exhibit normal consciousness.

Amygdala

The amygdala comprises five nuclei in three groups: the central nucleus; the cortical and medial nuclei; the basal and lateral nuclei. There is extensive connectivity between the amygdala and the telencephalon, diencephalon, midbrain and brainstem (solitary nucleus). The amygdala integrates information from the senses and from within the body (visceral afferents) and associates it with the memory of past experience. Amygdala-driven aversion is particularly profound. Patients with amygdala lesions can see no wrong in people or places that have caused them particular emotional distress in the past. Paradoxically, such behaviour is considered to be mature by many cultures. Recent research suggests that memories mediated by the amygdala are disrupted profoundly during propofol anaesthesia.

Brainstem

The brainstem is the most densely packed region of the brain with vital function. It has little redundancy of function in the event of damage, which is likely, owing to the proximity of the aqueduct of Sylvius (cerebral aqueduct), which is susceptible to occlusion. The brainstem is not bilaterally paired in function, each side has a bias towards differing autonomic function. A specific example of this is the right vagus (X) nerve, which originates in the medulla oblongata and appears to direct chronotropic (beat to beat, as opposed to ionotropic or within beat) heart rate variability. Brainstem and cerebral laterality of autonomic function is a fascinating and clinically important topic that is surprisingly poorly reported in the literature.

Brainstem sensory nuclei are arranged in columns in a similar manner to sensory regions in the posterior horn of the spinal column. The tract of the solitary nucleus (nucleus tractus solitarius) is large and responsible for many crucial functions. The solitary nucleus lies within the visceral sensory column. The special sensory column and vestibular and auditory nuclei of the vestibulocochlear (VIII) nerve receive input from the vestibular organs and the cochlea. Auditory evoked potentials derived from these regions are largely resistant to the effects of hypnotic anaesthesia, their effects being more noted on the auditory cortex. The somatic sensory column receives input from the vagus (X), facial (VII), glossopharyngeal (IX), and trigeminal (V) nerves. The presence of noxious stimuli from the head, face and neck is transmitted through these nerves and via the trigeminal spinal nucleus, as is fine touch, which also uses the main sensory trigeminal nucleus. Vibration and position are encoded by the mesencephalic nucleus of the trigeminal nerve.

Midbrain: the midbrain primarily controls sensory and motor function, particularly the control of eye movement and the coordination of visual and auditory reflexes. The midbrain provides much of the processing necessary to maintain posture, walking, positioning and jumping behaviours. However, the midbrain does not initiate these behaviours. An animal with an intact brainstem, including the midbrain but no higher brain, exhibits righting reflexes (i.e. it can restore its normal posture from an unusual starting point) and normal muscle tone (though visual righting reflexes are eliminated in an animal with no higher brain). Without the midbrain, the righting reflexes disappear and the animal exhibits high muscle tonus (decerebrate rigidity) but can still remain upright because the inputs from labyrinth and neck proprioceptors are still intact.

Pons: the pons is the site of origin for the facial motor cranial nerves and their nuclei (e.g. trigeminal (V) nerve and its nucleus). The frontalis electromyogram (fEMG) has been studied extensively because it declines with increased anaesthetic depth, especially at relatively light levels of anaesthesia; the fEMG reflects activity in the pons. The pons falls within the territory of the medial branch of the basilar artery.

Medulla oblongata: the medulla is a region of the brainstem responsible for autonomic control and falls within the territory of the anterior spinal artery. Damage to the anterior medulla results in 'locked-in' syndrome in which a patient is unable to move or communicate but is otherwise conscious. Damage to the posterior medulla often results in profound coma. Less severe damage is apparent in conditions such as Wallenberg's syndrome, in which localized damage to the nucleus ambiguus causes disruption to motor fibres leading to the glossopharyngeal (IX), vagus (X) and accessory (XI) nerves, affecting muscles in the palate and the larynx, as well as fast control of heart rate.

The nucleus tractus solitarius is predominantly located in the medulla. It is a sensory nucleus, which receives input from many visceral receptors including stretch receptors in the lungs and the carotid sinus. The nucleus tractus solitarius is responsible for integrating the sensory information arriving for the baroreflex; the inferior nucleus tractus solitarius is responsible for encoding sensory information from the heart, lungs, blood vessels and gut. Vagally mediated spontaneous and evoked motor activity in the gut declines during anaesthesia, as does respiratory sinus arrhythmia. The superior nucleus tractus solitarius is also responsible for taste on the anterior 66% of the tongue from the glossopharyngeal (IX) nerve, and taste buds in the pharynx from the vagus (X) nerve. The nucleus tractus solitarius connects to the dorsal vagal motor nucleus and the nucleus ambiguus, both of which innervate the heart and modulate heart rate variability. The dorsal vagal motor nucleus also innervates secretory glands in the pharynx, lungs and gut, along with peripheral ganglia modulating smooth muscle tone in blood vessels, lung and gut.

Cerebellum: the cerebellum comprises 50% of the neurons in the brain, even though it occupies only 10% of the volume. The cerebellum adjusts the output of the major descending systems of the brain, acting as a comparator with information received from the spinal cord, vestibular apparatus and nuclei, medulla, pons, reticular formation and cerebral cortex. Cerebellar efferent pathways project to the brainstem and thalamus to modulate a variety of motor and other functions.

The cerebellum comprises three regions:

- vestibulocerebellum, receiving input from the semicircular canals and otolith organ and encoding the position and movement of the head
- spinocerebellum, regulating body and limb movement
- cerebrocerebellum, evaluating sensory information to evaluate the planning of movement.

The cerebellum is made up of three distinct layers: molecular layer, Purkinje cell layer and granular layer. Purkinje neurons in the cerebellum have large cell bodies and complex dendritic fields, and form many copies of the same basic neural circuit. The Purkinje cells are the only efferent axons leaving the cerebellum. Afferent climbing fibres pass through the granular layer and terminate at the granular layer at dendrites of the Purkinje cells, climbing through the dendritic tree. Afferent mossy fibres end in the granular layer at granule cells. Granule cells produce two collaterals (parallel fibres) in a T shape; collaterals viewed in cross-section explain the dot-like nature of the molecular layer. Climbing fibres synapse directly on the Purkinje neurons, whereas mossy fibres connect to the Purkinje cells via interneurons (granule and basket neurons).

Lesions in the cerebellum result in hypotonia, ataxia and action- or intention-tremor. Lesions in the vestibulocerebellum are characterized by impaired eye movement, difficulty in maintaining balance and irregular movement, which becomes normal when supine.

The spinocerebellum receives pathways from the spinal cord via precerebellar nuclei in the brainstem reticular formation. Different versions of the changing state of the subject and the environment are compared. ◆

Cerebral Blood Flow and Intracranial Pressure

Carl L Gwinnutt
Bhaskar Saha

Carl L Gwinnutt is Consultant Anaesthetist at Hope Hospital, Salford, UK. He qualified from Guy's Hospital, London, and trained in anaesthesia in Birmingham and Manchester. His interests include resuscitation and medical education.

Bhaskar Saha is Specialist Registrar in Anaesthesia. He qualified in medicine in Calcutta, India. He began his training in anaesthesia in India, and is currently based at Hope Hospital, Salford, and works on the North West rotation. His interest is intensive care.

The normal adult skull is a rigid bony structure of fixed volume, containing brain, cerebrospinal fluid (CSF) and blood. An understanding of the interaction between these components is essential for the anaesthetic management of patients with intracranial pathology.

Brain
The brain tissue is the largest component in the skull. It has a mass of about 1400 g and consists of supporting (glial) and neural elements, intracellular and extracellular water. The maintenance of an environment suitable for nerve cell function is achieved by the presence of the blood–brain barrier. This is formed by tight junctions (zona occludens) between the adjacent cerebral capillary endothelial cells, a lack of fenestrations and a region of astrocytes, closely applied to the endothelial cells. It is permeable to oxygen, carbon dioxide and water but not to low molecular weight ions including sodium, potassium and chloride, or plasma proteins. It acts as a semipermeable membrane and the administration of hypotonic solutions increases brain water. Other complex proteins also act to protect the brain against potentially harmful chemicals. The presence of the blood–brain barrier removes the need for lymphatic drainage of the brain. Pathological increases in brain tissue are the result of tumours, increased intracellular water (cytotoxic oedema) or extracellular water (vasogenic oedema).

CSF
There is about 150 ml of CSF in the craniospinal axis, of which about 75 ml is within the skull. It is produced constantly, at a rate of 0.3 ml/minute (500 ml/day), in a process of active secretion by Na^+/K^+-ATPase and carbonic anhydrase. The choroid plexus, situated within the lateral and fourth ventricles, produces about 70% of CSF and the remainder is produced by the non-choroidal surfaces of the ventricles. CSF is reabsorbed into the venous circulation via the arachnoid villi, a loose arrangement of arachnoid cells with large intercellular spaces, situated within the dural walls of the sagittal and sigmoid sinuses and in the dural sinusoids on the dorsal nerve roots. Most CSF (90%) is reabsorbed intracranially. Under normal circumstances, the pressure of CSF is 11 mm Hg and the pressure in the venous sinuses is 6 mm Hg, which results in a 5 mm Hg pressure gradient facilitating absorption across the villi. Increases in the CSF pressure (up to 22 mm Hg) result in an increased rate of reabsorption but do not alter the rate of production.

The CSF has a variety of functions. It helps to ensure a constant supply of glucose and maintains a chemically stable environment, necessary for neurotransmission. It also effectively reduces the mass of the brain to about 50 g, which reduces the inertia of the brain and allows rapid head movement without damage to the delicate neural structures.

Blood
The brain is supplied with blood via the internal carotid and vertebral arteries. Venous drainage is via the cerebral veins, sinuses and internal jugular veins. Under normal conditions (in the absence of any pathology or drugs) there is about 150 ml of blood in the skull, most of which (about 100 ml) is within the venous system. Although cerebral blood volume (CBV) is small, cerebral blood flow (CBF) is relatively high compared with other organs. Normal global CBF is about 50 ml/100 g/minute, grey matter receiving 80 ml/100 g/minute and white matter 20 ml/100 g/minute. This equates to 700 ml/minute or 15% of the cardiac output to an organ that is only 2% of body weight.

Control of CBF
The brain depends on oxidative phosphorylation of glucose to generate adenosine triphosphate (ATP) and as a result is intolerant of hypoxia. Several protective mechanisms control CBF. Blood flow to the neurons of the spinal cord is subject to similar control mechanisms.

Cerebral metabolism
CBF is closely linked to the metabolic activity of the brain to ensure adequate delivery of oxygen and substrates. This is often expressed as the cerebral metabolic rate for oxygen ($CMRO_2$), which under normal conditions is constant at 3.5 ml/100 g/minute. It accounts for 20% of the total body oxygen consumption. At any time, some regions may have relatively increased activity and blood flow, while other areas are less active. As a consequence, global oxygen demand and blood flow remain constant.

Any condition that reduces global metabolic activity will reduce $CMRO_2$ and CBF (e.g. hypothermia). At a brain temperature of 27°C, $CMRO_2$ and CBF are approximately halved. Below 20°C, CBF is approximately 10% of normal, virtually all of which is required to maintain cellular integrity because all neuronal electrical activity ceases at these low temperatures. It is the massive reduction in $CMRO_2$ at low temperatures that allows the brain to tolerate prolonged periods of ischaemia. Conversely, hyperthermia and seizures increase $CMRO_2$ and CBF. Other examples of a metabolically induced reduction in CBF include coma and anaesthesia.

Carbon dioxide and oxygen
The relationship between the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) and CBF is almost linear. At a $PaCO_2$ of 10.6 kPa (80 mm Hg), CBF is approximately doubled. Beyond this, there is no further increase in flow, because the cerebral vessels are maximally vasodilated. Conversely, at a $PaCO_2$ of 2.7 kPa (20 mm Hg) flow is halved and plateaus as a result of maximum vasoconstriction. This is thought to be mediated (indirectly) by changes in the hydrogen ion concentration in the extracellular fluid surrounding the vascular smooth muscle.

The response of the cerebral vasculature to changes in $PaCO_2$ can be used therapeutically in patients with raised intracranial pressure. Hyperventilation causes vasoconstriction, a reduction in CBV and intracranial pressure. However, extreme hypocarbia ($PaCO_2$ < 4 kPa, 30 mm Hg) may be harmful, because the degree of vasoconstriction causes ischaemia.

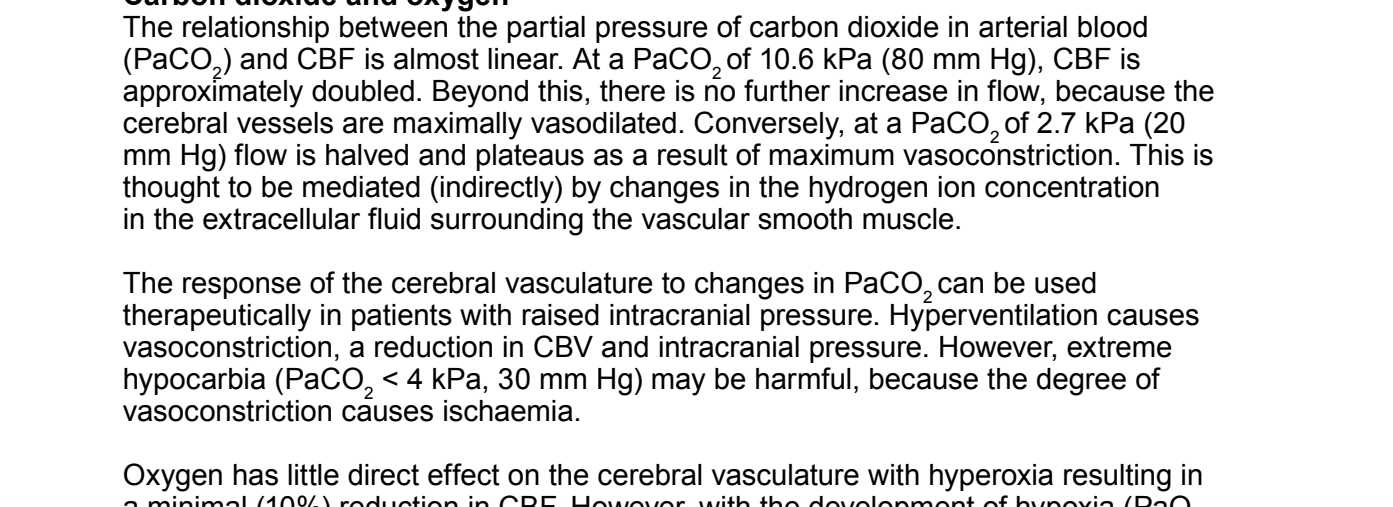
Oxygen has little direct effect on the cerebral vasculature with hyperoxia resulting in a minimal (10%) reduction in CBF. However, with the development of hypoxia (PaO_2 < 6.7 kPa, 50 mm Hg), there is a rapid, progressive increase in CBF secondary to the development of a metabolic acidosis as the total oxygen content of haemoglobin falls.

Autoregulation
Perfusion of the brain depends on the pressure gradient across the vasculature, termed the cerebral perfusion pressure (CPP). This is the difference between the mean arterial pressure (MAP) and venous pressure. However, the latter is difficult to measure and approximates to the more easily measured intracranial pressure (ICP), which is slightly less because the cerebral veins must maintain a higher pressure to remain patent.

$$CPP = MAP–ICP$$

The brain is intolerant of hypo- or hyperperfusion, and therefore requires a constant flow of blood over a range of pressures, this is achieved by autoregulation (Figure 1). This is thought to be a myogenic mechanism whereby pressure changes are sensed and induce either a reflex constriction (increased pressure) or relaxation (low pressure) of the vascular smooth muscle, predominantly in the arterioles. The stimulus to cerebral autoregulation is CPP not MAP. Under normal circumstances (ICP ≤ 10 mm Hg), the two are similar and CBF is held constant over the CPP range 50–150 mm Hg. In the presence of raised intracranial pressure, CPP must be calculated. The lower limit represents the point of maximal vasodilatation and below this flow is described as 'pressure-passive' and depends on the transmural pressure. At the upper limit, there is maximal vasoconstriction and further increases in CPP are accompanied by disruption of the blood–brain barrier, oedema formation and cerebral ischaemia (hypertensive encephalopathy). In patients with chronic untreated hypertension, the autoregulatory curve is shifted to the right to protect against the development of encephalopathy. Autoregulation is easily impaired by head injury, tumours and vasodilatory drugs (e.g. volatile anaesthetics).

Autoregulation



CPP, cerebral perfusion pressure; PaO_2, $PaCO_2$ partial pressure of oxygen/carbon dioxide in arterial blood.

1

Autonomic nervous system
The cerebral vasculature is well innervated by the autonomic nervous system. The sympathetic supply to the extraparenchymal vessels arises from the cervical ganglia and the supply to the parenchymal microvasculature from the locus ceruleus. Their main action is vasoconstriction, which probably serves to protect the brain by shifting the autoregulatory curve to the right in hypertension. The parasympathetic nerves arise from the pterygopalatine and otic ganglia and contribute to cerebral vasodilatation. This is most apparent in conditions such as post-ischaemia reperfusion and hypotension. In addition to these effects it is now thought that initial changes in CBF to meet metabolic demands are initiated via neurogenic mechanisms and then sustained by local chemical factors.

Blood viscosity
Blood viscosity is directly related to the haematocrit. Although reductions in haematocrit improve flow, this will be offset by a reduction in the oxygen-carrying capacity of the blood. The optimum haematocrit at which there is a balance between flow and oxygen capacity is about 30%.

Critical CBF
In normotensive individuals, below the lower limit of autoregulation, CBF mirrors MAP and eventually a reduced flow will cause cerebral ischaemia. At a CPP of about 25 mm Hg, CBF is 20–25 ml/100 g/minute and this is accompanied by slowing of electrical activity on the electroencephalogram. When perfusion pressure reaches 15 mm Hg (CBF 15 ml/100 g/minute), electrical activity ceases and below 10 mm Hg, cellular integrity is lost with a massive efflux of potassium and eventually cell death.

Intracranial pressure
Brain tissue, CSF and blood are incompressible and contained within the skull, a rigid box of fixed volume. It is the relationship between the volumes of brain tissue, CSF and blood that gives rise to the intracranial pressure. In the normal adult, the ICP is 5–13 mm Hg (7–18 cm H_2O), with minor cyclical variations owing to the effects of the arterial pressure waveform and respiration. ICP also varies with posture, coughing, sneezing and straining.

Any increase in the volume of one of the three components within the skull must be compensated for by a decrease in the volume of one or more of the remaining components, otherwise the ICP will increase (this is often referred to as the Munro–Kellie doctrine). Brain tissue is not easily (or safely) displaced, therefore changes in venous blood or CSF volumes initially act as the major buffers against a rise in ICP.

The term compliance is often used to describe this relationship, however, compliance describes the relationship *dV/dP.* Within the skull it is the change in ICP for unit change in volume that is of interest or *dP/dV*, and the term elastance should be used. In the normal brain, with normal elastance, small changes in the volume of one of the contents (e.g. venous blood volume during coughing or straining) do not cause a sustained rise in ICP. However, once the compensation mechanisms have been exhausted or eliminated, for example by the presence of a haematoma or oedema, the ICP rises dramatically.

The traditional method of expressing this relationship has been the 'pressure–volume' curve, which suggests that pathological increases in ICP occur as a result of continuing increase in intracranial volume. However, if we accept that the volume of the skull is fixed, this is clearly inadequate. It is therefore more accurate to regard the relationship as the force required to displace volume from the cranium to accommodate the 'new' volume. As the force generated is difficult to measure it is the resultant pressure (ICP) that is normally measured (force = pressure x area). In fact, the resultant curve (Figure 2) is actually a composite of pressure versus displaced volume curves for venous blood, CSF and arterial blood, each of which is successively more difficult to displace.

2

The relationship between CBF, CBV and ICP

CBV and CBF are independent of each other – a high CBV does not automatically imply a high CBF. Within the autoregulatory range, any increase in CPP induces a reflex vasoconstriction of the cerebral arterioles, reducing CBV. Conversely, any fall in CPP causes vasodilatation, increasing CBV. Any disturbance of ICP is short-lived because the volume of CSF changes in the opposite direction as a result of a change in the rate of absorption. If, however, the CPP falls below the point where no further vasodilatation is possible (i.e. the lower limit of autoregulation), the vascular diameter becomes dependent on the transluminal pressure, CBF follows the mean arterial blood pressure and as the latter falls, the vessels gradually collapse thereby reducing CBF and CBV.

This has important implications in the injured brain, when the autoregulation curve appears to be intact but ICP is increased (e.g. oedema, haematoma). If the CPP is allowed to fall, cerebral vasodilatation occurs increasing CBV and leading to a rise in ICP. This decreases CPP, leading to further vasodilatation, increased CBV and ICP. This process has been termed the ‘vasodilation cascade’. Conversely, if CPP is maintained or increased, it will result in vasoconstriction, reducing CBV and ICP. This increases CPP and induces further vasoconstriction, reducing CBV and ICP. This is termed the ‘vasoconstriction cascade’. For this reason, it is recommended that in the resuscitation phase of head injuries, MAP is maintained above 90 mm Hg or if ICP can be measured, CPP is maintained at 70 mm Hg at least. Paradoxically, if CPP is allowed to fall below the lower limit of autoregulation, passive collapse of the cerebral vessels will reduce CBV and ICP. However, this is achieved at the expense of CBF and oxygenation. ◆

Nerve Cell Function and Synaptic Mechanisms

Chris J D Pomfrett

Chris J D Pomfrett is Lecturer in Neurophysiology Applied to Anaesthesia at the University of Manchester, UK. He qualified from Queen Mary College and the Medical College of St Bartholomew's Hospital, London. He has conducted research into cortical visual processing during anaesthesia and determining the depth of anaesthesia using measurements taken from the brainstem.

There are three broad categories of neurons.

- Sensory receptors translate everything perceived from the external and internal environment into electrical potentials.
- Interneurons communicate between neurons, relaying all the functions of the CNS and processing the information; the human mind is a construct of interneuron activity.
- Motor neurons are the output from the CNS and the method by which we effect change on the environment.

Membrane physiology

All cell membranes, including those of neurons, are made up of an electrically insulating bilipid layer. The neuronal bilipid membrane has the electrical characteristics of a capacitor and can maintain an electrical potential difference across the membrane. The electrical excitability of a neuron is conferred by proteins spanning the membrane which allow the passage of ions. Each neuron has active and passive transport mechanisms to maintain a constant membrane potential across its cell membrane. Sodium and chloride ions are maintained in higher concentration outside the neuron, and potassium and inorganic anions are in higher concentration inside the neuron. The level of the membrane potential determines the excitability of the cell. More hyperpolarized membranes (–75 mV is more hyperpolarized than –50 mV) are less likely to reach the critical threshold necessary to initiate an action potential.

The equilibrium potential (Ex) of any ion is described by the Nernst equation. It is the electrical potential when there is no net flux of an ion across the cell membrane

$$Ex = \frac{RT}{ZF} \cdot \frac{\ln[X]o}{[X]i}$$

where R is the gas constant, T the temperature in degrees Kelvin, Z the valence of the ion, F the Faraday constant, and [X]o and [X]i are the concentrations of the ion outside and inside the neuron.

The equilibrium constant for potassium is typically –75 mV, that for sodium +55 mV and –60 mV for chloride. To maintain the resting potential, passive diffusion is vital to the neuron, but active transport occurs initially to set up the potential and to maintain the potential when the neuron is active. At rest, relatively few sodium channels are open, therefore the conductance to sodium is low. There are many resting potassium channels, and relatively large potassium conductance. The resting membrane potential produces a potassium efflux from the neuron equal to the sodium influx. There is an active Na^+/K^+ pump, consisting of a large membrane-spanning protein, which moves K^+ and Na^+ against their electrochemical gradients. One ATP molecule is used to transport three Na^+ ions out of the neuron and two K^+ ions into the neuron.

Ion channels in the cell membrane are proteins that form ion gates in the otherwise impermeable cell membrane. Voltage-gated channels are opened by changing the membrane potential and allowing specific passage of single types of ion. Voltage-gated channels are found in all electrically excitable regions of a neuron and can be blocked selectively (e.g. tetradotoxin blocks the sodium channel). Ligand-gated channels are found in chemical synapses and open when challenged with a specific neurotransmitter or an analogue (e.g. acetylcholine). The channel opening time can be increased or decreased by neuroactive agents, or the channels can be permanently forced open or shut by toxins.

Propagation of electrical signals

The two methods of propagating electrical signals within a neuron are graded potentials and action potentials. Most postsynaptic and receptor activity is in the form of graded potentials using Ca^{2+}, Na^+ and K^+ channel activity, which, in engineering terms, are analogue signals with information encoded in both the amplitude and decay (time course) of the signal. These potentials travel over a 'tree' of dendrites or fine neuronal processes that vary in anatomical complexity. Some of the most complex dendritic fields are located in the Purkinje cells of the cerebellum. A specialized region of the neuron, known as an integrating segment or axon hillock, adds the graded potentials in the neuron. This trigger zone is sensitive to small changes in membrane potential. If these summed potentials cross the membrane threshold of the integrating segment, an action potential is initiated. The action potential propagates along the axon of the neuron, which in certain interneurons (e.g. those of the corticospinal tract) may be over 1 m long.

Graded potentials

Graded potentials are the summed excitatory postsynaptic potentials (EPSP) and inhibitory postsynaptic potentials (IPSP) of a dendritic tree, which spread electrotonically along the neuron. Different regions of the neuron have different ion channels tailored to their function. The larger the diameter of the neuron, the further the electrotonic spread. For example, the largest diameter axons of the squid are 1 mm and conduct electrotonic potentials further than the dendrites of a mammalian neuron, which can be as small as 1 μm in diameter. This distance is known as the length constant, and typically ranges from 0.1 to 1.0 mm. This means that small graded potentials initiated from a single EPSP or IPSP play no role in the processing of a neuron if they do not summate with other graded potentials within the length constant of the dendrite. This mechanism allows the rejection of much electrical noise from the CNS.

Electrotonic spread of graded potential covers a relatively small area of a neuron, therefore the action potential is required to propagate neuronal conduction of information along a much greater distance than would otherwise be possible. The action potential is an 'all or nothing' (digital), frequency-modulated signal, with the amplitude being any level above a threshold and the information encoded purely in the frequency of successive action potentials. Such encoding is present in even the most primitive nervous systems.

Multiple synaptic connections allow complex and subtle convergence (where many neurons input on a single neuron) and divergence (when one neuron outputs to many neurons). For example, convergence allows a fully dark-adapted subject to perceive single photons of light; divergence allows one action potential in one axon to initiate the contraction of a large muscle.

Action potentials

Action potentials are initiated when summed graded potentials force the membrane potential of the neuron past a threshold of depolarization (e.g. from a resting potential of –75 mV to –50 mV). The time constant of a neuron defines how readily it will integrate successive graded potentials into the initiation of action potentials; a long time constant indicates a greater capability for temporal summation of individual graded potentials into a super-threshold potential. The depolarization opens sodium and sometimes calcium channels, which allow Na^+ (and Ca^{2+}) to flood into the neuron. As the neuron continues to depolarize (e.g. to +50 mV), potassium channels open, and K^+ floods out of the neuron. The sodium channels close, followed by the potassium channels, and the membrane returns to its resting potential. Using these voltage-gated and energy-independent mechanisms, the action potential propagates down the axon, away from the cell body towards terminal dendrites of the neuron. Artificial stimulation of the axon can elicit antidromic conduction of action potentials back up the neuron, towards the cell body. Such antidromic stimulation has been used to determine the presence of electrical synapses, which are bi-directional, as opposed to chemical synapses, which permit signal propagation in only one direction.

Action potentials are well suited to the transmission of fast, processed data over long distances. They are effectively digital, encoding information by frequency modulation. Phasic bursts of action potentials last a few seconds, rapidly decay in frequency and encode transient events. Tonic firing of axons appears as sustained activity lasting for many minutes. Phasotonic activity is seen as an initial burst of action potentials indicating that a change has occurred in the neural system, with a tonic sustained series of action potentials encoding that nothing has changed, but that the stimulus is still there. Adaptation is seen in neural systems as the prolonged stimulus results in increasingly fewer action potentials over time. The long process over which action potentials are transmitted in a neuron is called the axon. The larger the diameter of an axon, the faster its action potentials are propagated. The largest diameter axons are found in invertebrates such as squid and insects. These axons are generally involved in escape or flight reflexes that require fast transmission of action potentials to a large number of motor neurons in relatively simple neuronal networks. The large diameter of these invertebrate axons (greater than 10 μm), means that they are ideal for neurophysiological experimentation. Fine glass capillaries, drawn out to 1 μm tips, are pushed into the axon to measure intracellular potentials. Other advantages are that insect neurons function at room temperature and in the absence of anaesthesia (which must be used in all experiments on vertebrates and cephalopods). Evolution stopped with axon diameters of 1 mm, probably because of the need to produce small, flexible nerves comprising many axons. The classification of axons in terms of diameter, conduction velocity and function is given in Figure 1.

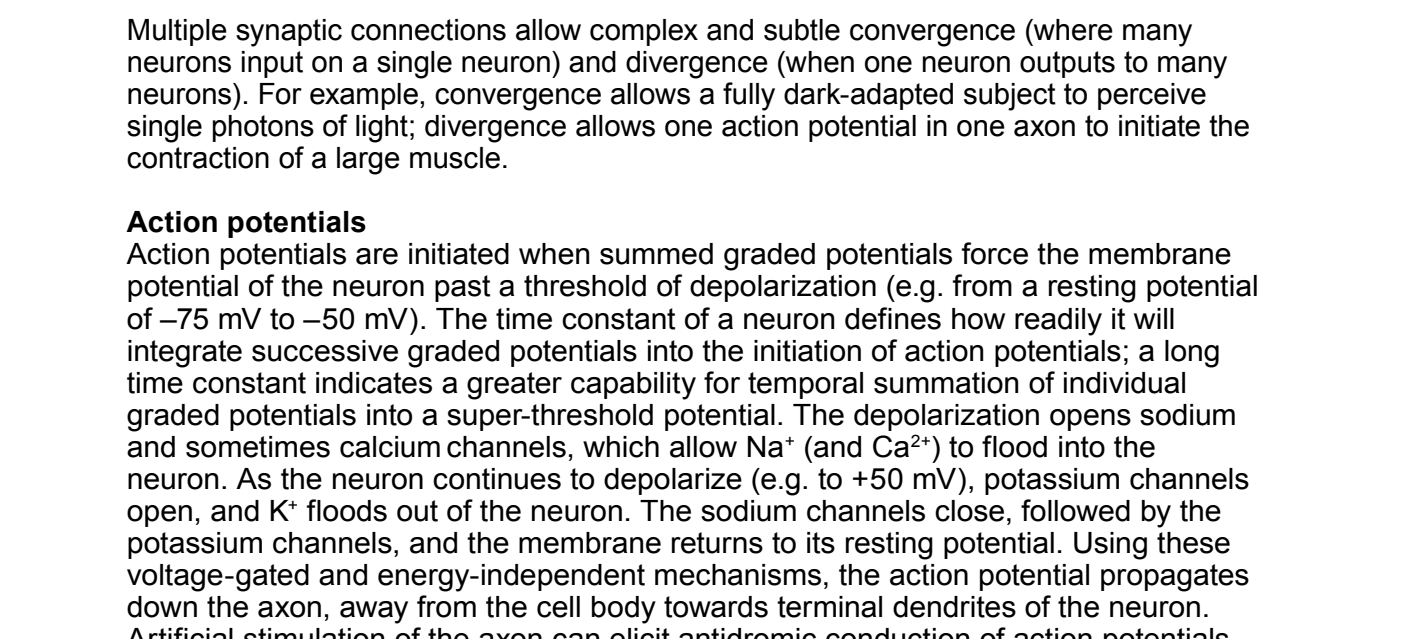
Nerve fibre types and characteristics

Fibre type	Typical function	Average fibre diameter (μm)	Velocity (m/s)
Erlanger/Gasser classification			
Aα	Primary muscle spindle afferents somatic motor	15	100
Aβ	Cutaneous touch and pressure afferents	8	50
Aγ	Motor to muscle spindles	5	20
Aδ	Cutaneous temperature and pressure	3	15
B	Sympathetic preganglionic	3	7
C	Unmyelinated cutaneous pain afferents	0.5	1
Lloyd/Hunt classification (afferent fibres only)			
I	Primary muscle spindle afferents	13	75
II	Cutaneous mechanoreceptors	9	55
III	Deep muscle pressure receptors	3	11
IV	Unmyelinated pain fibres	0.5	1

Conduction velocity

Many lower animal groups have loose myelin sheaths because of the need to insulate the axons electrically and provide a stable chemical environment for them. In more advanced nervous systems, myelin is tightly wrapped around certain axons as the result of Schwann cell development, which allows fast conduction velocities for action potentials with relatively narrow diameter axons. This is called saltatory conduction. Electrotonic potentials are propagated at nodes of Ranvier, which are unmyelinated regions with a high concentration of voltage-gated ionic channels. The internodes are myelinated, and therefore insulated, and promote the passage of electrotonic potentials between nodes (Figure 2). The velocity of action potential conduction falls at the nodes of Ranvier and rises at the internodes. Demyelinating disease makes gaps in the internodes that impair or block the propagation of action potentials. The effects of such demyelination are marked in sensory nerves with parallel pathways of information requiring fast transmission (e.g. the optic nerve).

Typical sensory to motor pathway



Unmyelinated axons have the slowest conduction velocities (e.g. nociceptor C fibres at 0.5 m/s). Intracerebral recordings from animal brains use extracellular electrodes adjacent to cell bodies because the diameter of the axons is so small, and the physical properties of a myelin sheath render intracellular axonal recordings difficult.

Synapses

Electrical synapses

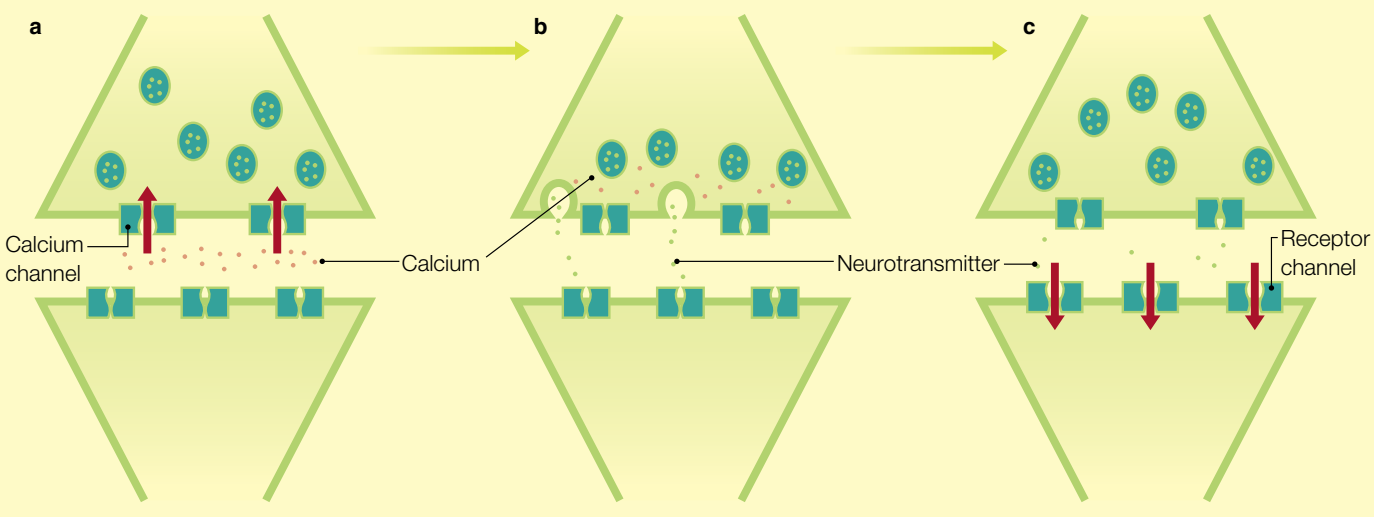
Electrical synapses form a close functionally equal electrical connection between some adjacent neurons, between neurons and glial cells, and between glia. Typically the gap between cell membranes is 2–4 nm. Graded and action potentials travel freely between cells with an electrical synapse, in either direction, and at high speed with no synaptic delay. Gap junctions made up of proteins (connexin) in both the presynaptic and postsynaptic membranes are characteristic of electrical synapses. The connexins can close the gap junctions in conditions of altered pH or high intracellular Ca^{2+} concentration. The flow of metabolites through gap junctions is affected in Charcot–Marie–Tooth disease, in which the connexin protein gene of Schwann cells is mutated, preventing the correct flow of metabolites between cells. The diameter of the junctional area ranges from 0.1 to 10 μm.

Chemical synapses

Protein and lipid synthesis for subsequent exocytosis occurs in endoplasmic reticulum. Proteins and lipids are transported to the Golgi complex and loaded into synaptic vesicles. All enzymes and neuroactive peptides have to be actively transported down the axon to the terminal dendrites. Neurotransmitters are loaded into synaptic vesicles by active transport, and are then physically relocated from a reserve pool to an active pool of vesicles ready for docking with the presynaptic membrane.

Chemical synapses (Figure 3) are excitatory or inhibitory, as defined by the receptor type in the postsynaptic membrane. Excitatory synapses produce EPSPs in the postsynaptic membrane, and inhibitory synapses produce IPSPs. Summed EPSPs cause depolarization of the postsynaptic membrane; IPSPs cause hyperpolarization. Synapses typically release one ‘classical’ neurotransmitter and several neuroactive peptides. Classical excitatory neurotransmitters in the CNS include acetylcholine and glutamate. Classical inhibitory neurotransmitters include acetylcholine, γ-amino butyric acid (GABA) and glycine. Contemporary theories point to the lengthening of opening time for inhibitory $GABA_A$ (higher brain; volatiles, ethanol, barbiturates) and glycine receptors (brainstem; volatiles, ethanol) in the presence of certain anaesthetics.

Typical chemical synapse



a Action potential reaches the presynaptic region, opening Ca^{2+} channels. **b** Ca^{2+} enters the presynaptic region and initiates vesicle fusion with the presynaptic membrane. **c** Neurotransmitters cross the synaptic cleft and initiate receptor channel opening in the postsynaptic membrane. This process takes time; each chemical synapse introduces latency, from 0.3 ms to several ms in a neural reflex

3

Chemical synapses are the principal targets for the action of neuroactive pharmacological agents. A chemical synapse permits the transmission of electrical potentials between neurons in one direction (from the presynaptic to the postsynaptic membrane). Chemical synapses have a synaptic cleft typically 10–40 nm across. Type I chemical synapses have a synaptic cleft of about 30 nm, a large junctional cross-sectional area of 1–2 μm diameter and appear asymmetrical. Type II chemical synapses have a synaptic cleft of about 20 nm, a smaller junctional area and appear symmetrical. Current flow does not cross this cleft. The graded electrical potential or action potential is transduced into a physical release of neurotransmitter(s) from vesicles, which fuse with the presynaptic membrane when calcium channels open on depolarization of the presynaptic region as a result of an incoming action potential. The enlarged presynaptic membrane eventually forms new vesicles by endocytosis, which are recycled by fusion with a specialized membrane compartment (endosome). Binding of the neurotransmitter with ligand- (as opposed to voltage-) gated ion channels then causes an EPSP or IPSP in the postsynaptic membrane. Typically, two molecules of transmitter are required to open an ion channel, so the thousands of transmitter molecules released by each synaptic vesicle can open thousands of postsynaptic receptors. For most agents, general anaesthesia works by potentiating IPSPs, for example inhibitory chloride channels are open for longer in the presence of anaesthetic agents. In contrast to these ionotropic, membrane-bound receptors, neurotransmitters such as noradrenaline (norepinephrine) and serotonin (5-HT) work by altering intracellular metabolism. They are metabotrophic receptors that initiate second messengers such as cAMP and diacylglycerol in the postsynaptic neuron. Iontotropic receptors produce fast synaptic actions lasting a few milliseconds, whereas metabotrophic receptors produce actions lasting for seconds or minutes.

The importance of synaptic protein receptors for the action of anaesthetic agents has been demonstrated by the enhanced action of certain isomers. Examples are the S(+) isomer of ketamine being two to four times more potent than R(–), and the S(+) isomer of isoflurane being 50% more potent than the R(–) isomer.

Acetylcholinesterase, in the synaptic cleft, is responsible for ‘mopping up’ excess neurotransmitter that has not been taken up through the presynaptic membrane by endocytosis. The resulting choline is taken up at axonal terminals by active transport and then used to synthesize acetylcholine with acetyl CoA produced from acetate, also from the synaptic cleft of neuromuscular junctions, or the citric acid cycle.

The location of a synapse on the postsynaptic neuron suggests its purpose. Most excitatory synapses are found on dendrites. Many inhibitory synapses terminate on cell bodies. ◆

Neuromuscular Function and Transmission

Anthony C Wareham

Anthony C Wareham was Senior Lecturer in Physiological Sciences at the University of Manchester until taking early retirement in April 2001.

The initiation of contraction of skeletal muscle fibres requires the stimulus of an action potential from a motor neuron. One motor neuron connects to several muscle fibres to form a motor unit. A motor unit in a large limb muscle may contain 1000 fibres connected to one neuron. In contrast, the motor unit of an extraocular muscle may be composed of less than 10 muscle fibres. This correlates with the fineness of movement required from a muscle. The smallest movement possible is that produced by the simultaneous activation of all fibres in one motor unit.

The axon running to the motor unit is invisible to the naked eye. It may travel as far as 90 cm or more from the spinal cord to its muscle fibres. As it enters a muscle, the axon of the motor neuron divides into fine branches called telodendria, the endings of which each make close approximation with a specialized region of the sarcolemma of one muscle fibre. The specialized region is the motor end-plate, which covers an area of muscle surface of about 3000 μm^2.

The term neuromuscular junction (NMJ) refers to the axon terminal of the motor neuron plus the motor end-plate. In humans, after maturity, only one NMJ occurs per skeletal muscle fibre. During development, multiple NMJs are formed by several different axons on each muscle fibre but all except one are eliminated during maturation. The role of the NMJ is to ensure that a motor neuron action potential results in the generation of a muscle action potential on every fibre in the motor unit, and ultimately leads to contraction of the whole unit. Unlike CNS synapses, the NMJ does not modify signals but is a simple effector system carrying out the demands of the motor output. All of the physiology and pharmacology of the NMJ is directed towards achieving this aim. The role of the NMJ is so important that everything is done to excess, for example excess transmitter is released, there is an excess of postsynaptic receptors and the postsynaptic potential is several times greater than the minimum required to exceed the action potential threshold.

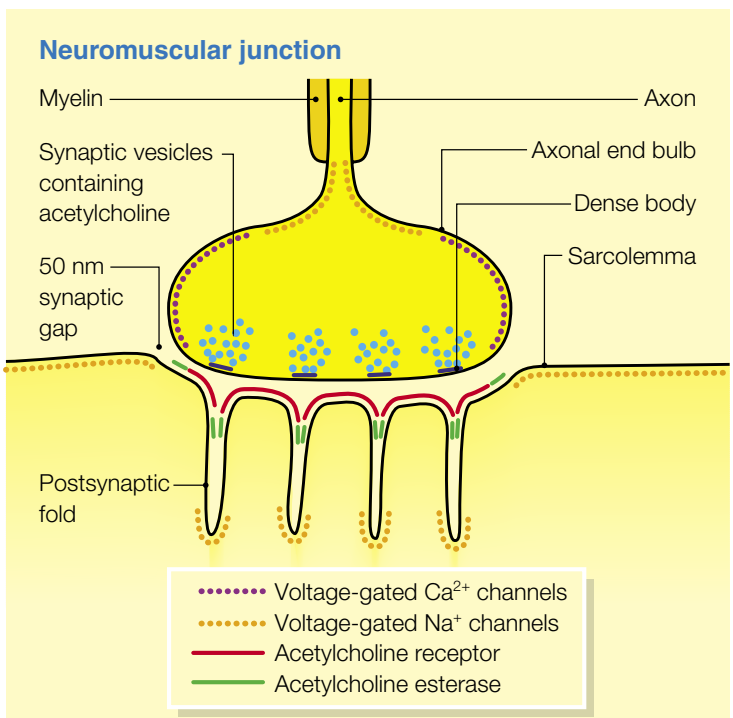
In order for the action potential in the motor axon to activate the muscle fibre by exciting the electrically excitable sarcolemma, several complex steps have to be completed. These include the release of the chemical transmitter acetylcholine (ACh) from the axon terminal by exocytosis, activation by transmitter of nicotinic ACh receptors at the end-plate, generation of an end-plate potential and finally the production of the sarcolemmal action potential. All of these events must be completed rapidly because some skeletal muscle fibres are able to respond to a frequency of motor neuron action potentials greater than 100 Hz for short periods. The process of chemical transmission at the NMJ induces a delay of about 0.5 ms between the time of arrival of an action potential presynaptically and the appearance of a muscle action potential.

Presynaptic transmitter release

The axon ending is typically enlarged and divided at the NMJ to form end bulbs arranged in the end-plate region like the fingers of a hand. The end bulbs contain ACh packaged into membrane vesicles (visible only under the electron microscope) at a high concentration of 5000–10,000 molecules per vesicle. Each end bulb contains thousands of these vesicles, a proportion of which have to release their contents synchronously to activate the end-plate region. This process, called excitation–secretion coupling, requires Ca^{2+}.

At rest, the free Ca^{2+} concentration in presynaptic endings is kept below 10^{-6} M by the low membrane permeability to Ca^{2+}, sequestration of Ca^{2+} by mitochondria and an active Na^+/Ca^{2+} exchange pump in the axolemma. Consequently, at rest, most ACh is kept sealed in the presynaptic vesicles. There is a low level of resting release, thought to represent the random collision of vesicles with the presynaptic membrane leading to exocytosis, manifested as very small postsynaptic depolarizations of about 0.5 mV, termed miniature end-plate potentials. Their function, if any, is unknown but at any one end-plate region they occur at intervals of 1/s or less. The arrival of an action potential at the presynaptic region opens voltage-gated Ca^{2+} channels, which occur at high density in this region of the axolemma. Although the absolute concentrations of Ca^{2+} on either side of the axolemma are low, there is a steep concentration gradient driving the diffusion of Ca^{2+} into the axon terminal because of the low intracellular concentration at rest. It is this subsequent influx of Ca^{2+}, increasing intracellular concentration above 10^{-6} M that is directly responsible for releasing vesicular ACh.

Vesicles are associated with specialized presynaptic areas called dense bodies, which occur opposite postsynaptic clefts and appear to be the sites of transmitter release (Figure 1). The vesicular membrane contains a variety of specialized proteins. One, synaptotagmin, has the ability to combine, in the presence of Ca^{2+}, with others including neurexin and SNAP-25 present in the axolemma of the terminal region. When they combine they form relatively large channels that effectively link the interior of the vesicle with the synaptic cleft between presynaptic and postsynaptic structures. The formation of numerous such channels permits the unloading, by simple diffusion, of ACh from the vesicle into the synaptic cleft. Within 1 ms the depolarizing phase of the presynaptic action potential is over, the Ca^{2+} channels close, Ca^{2+} influx ceases and the free intracellular Ca^{2+} concentration is rapidly returned to below 10^{-6} M. In the absence of Ca^{2+} the now empty vesicles are recycled by a mechanism which is not yet understood. The way in which the vesicles touch and bind to the presynaptic terminal under the influence of Ca^{2+} and are then released to be recycled has been called a 'kiss and run' mechanism. Every evoked response at the neuromuscular junction requires the synchronous release of acetylcholine (ACh) from up to 100 or more vesicles. The process of vesicle recycling and ACh production therefore has to be very active and efficient to keep up with high stimulation rates. In very active NMJs, released ACh feeds back to populations of ligand-gated ACh receptors on the axon terminals and acts via a second messenger system to increase transmitter production in the terminal.



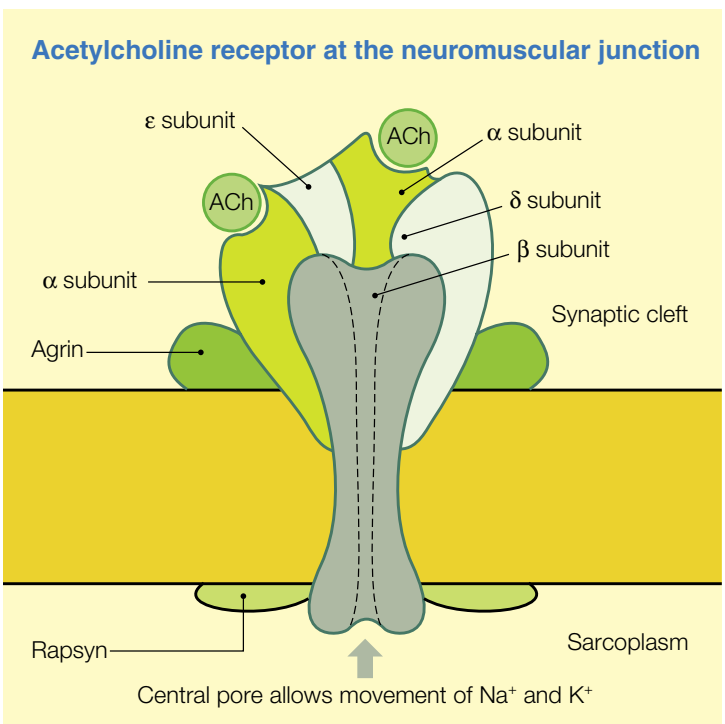
Presynaptic Ca^{2+} concentration is actively maintained below 10^{-6} M at rest. Activation of voltage-gated Ca^{2+} channels by an action potential invading the axonal end bulb increases Ca^{2+} concentration and initiates excitation–secretion coupling to release acetylcholine

1

Postsynaptic transmitter action

The postsynaptic region of the end-plate is separated from the axon by a 50 nm gap. Typically the end-plate region forms a series of folds that increase the contact area significantly (Figure 1). At a typical NMJ, the synaptic area is about 3000–6000 μm^2. This contrasts with about 1 μm^2 of contact at a CNS synapse where subsynaptic folding is absent and underlines the differences in their functions. While the postsynaptic response to most stimuli to a CNS synapse is small and could not reach threshold for an action potential in the absence of summation, the postsynaptic response at the NMJ is always large and is always suprathreshold for a muscle action potential.

The ACh released presynaptically diffuses rapidly across the synaptic cleft. At the crest of each subsynaptic fold there is a high density of nicotinic ACh receptors, which are held in place by two types of protein, agrin and rapsyn (Figure 2). At each NMJ there are about 3 x 10^7 ACh receptors, which equates to 10^4 ACh receptors per μm^2. Each ACh receptor is composed of five protein subunits, two of which, the α units, react with ACh. The ACh receptor at the NMJ, which is blocked by curare, is similar to the nicotinic ACh receptor that occurs widely in the nervous system except that one subunit, the γ unit, is replaced in the NMJ receptor by an ε subunit. The receptor present on fetal muscle fibres does not have this ε subunit, therefore it is considered to occur as part of the maturation process of muscle. The extrajunctional receptors that typically appear all over muscle fibres after denervation, leading to denervation hypersensitivity, do not have the ε subunit either.



When activated by two molecules of acetylcholine (ACh) the receptor acts as an ionopore to allow the passage of monovalent cations. The ε subunit is unique to the junctional receptor

2

The ACh receptor is also an ionopore and when the active sites of both units are each combined with a molecule of ACh the receptor changes its conformation to open a central pore through the receptor, which behaves as a non-specific cation channel (Figure 2). The receptor spans the postsynaptic membrane completely, which allows cations, mainly Na^+ and K^+, to move freely across the membrane. The net result is that the combined inward current flowing through all the activated ACh receptors at the end-plate results in depolarization of the postsynaptic membrane to about –10 mV. ACh is rapidly broken down by the enzyme acetylcholinesterase, located close to the ACh receptors at the crests of the subsynaptic folds (Figure 1). Therefore, the inward current is transient and is followed by repolarization of the end-plate region to the resting state. Unlike voltage-gated Na^+ channels, ACh receptors are not refractory and therefore there is no relative or absolute refractory period to the postsynaptic response. The transient depolarization and repolarization, termed the end-plate potential, is responsible for activating the sarcolemma to produce a muscle action potential.

Activation of the sarcolemma

The end-plate potential is a large depolarization of about 70–80 mV. However, it does not take the membrane potential above 0 mV (i.e. it does not overshoot zero potential as does the action potential). It is also slower than an action potential, lasting 10–15 ms, mainly owing to its slow repolarization. In the case of the end-plate potential, repolarization depends on the chemical breakdown of ACh by acetylcholinesterase to prevent further reactions with ACh receptors and to allow the channels to close. Thus, the properties of an end-plate potential differ in many respects from those of a normal action potential (Figure 3). Nevertheless, because the fast depolarizing phase of the end-plate potential is associated with a relatively intense current it is always strong enough to activate voltage-gated Na^+ channels on the sarcolemma. These Na^+ channels occur in high concentrations at the base of the subsynaptic folds and around the edges of the end-plate region (Figure 1). The end-plate potential activates Na^+ channels in the subsynaptic folds and the combination of the end-plate potential and the depolarization resulting from activated Na^+ subsynaptic channels, is sufficient to overcome the considerable membrane capacitance of the end-plate region and to excite the population of Na^+ channels outside the end plate. Once these Na^+ channels open, an all-or-none action potential is generated and a muscle action potential propagates in all directions from the end-plate across the sarcolemma. This action potential is responsible for activating muscle contraction via the process known as excitation– contraction coupling. ◆

Comparison of the properties of an action potential and an end-plate potential

	Action potential	End-plate potential
Initiation	By depolarization	By acetylcholine
Rising phase	Selective increase in Na^+ permeability	Simultaneous increase in Na^+ and K^+ permeabilities
Falling phase	Selective increase in K^+ permeability	Passive decline in permeabilities due to acetylcholinesterase action
Potential change	Reverses polarity	Does not exceed –10 mV
Additional	Regenerative ascent followed by refractory period	No regenerative action and no refractory period
Pharmacology	Blocked by tetrodotoxin, not influenced by curare	Blocked by curare, not influenced by tetrodotoxin

Neural Reflexes

Chris J D Pomfrett

Chris J D Pomfrett is Lecturer in Neurophysiology Applied to Anaesthesia at the University of Manchester, UK. He qualified from Queen Mary College and The Medical College of St Bartholomew's Hospital, London. He has conducted research into cortical visual processing during anaesthesia and determining the depth of anaesthesia using measurements taken from the brainstem.

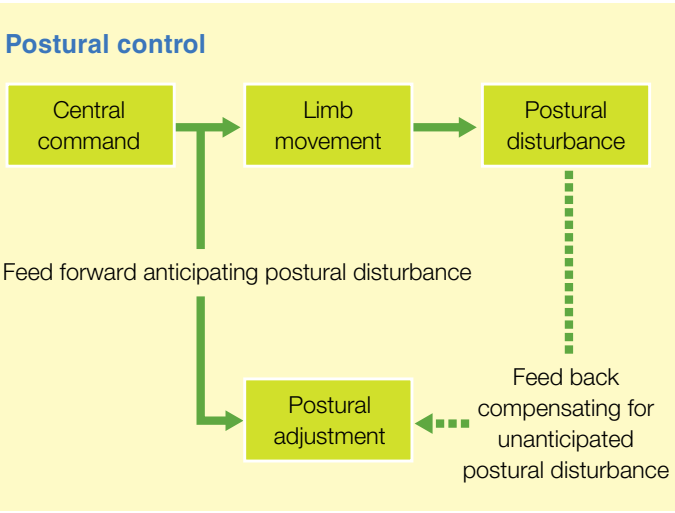
Anaesthesia and sedation are linked closely to neurophysiology. The components of balanced anaesthesia reversibly disrupt natural mechanisms in the CNS.

- Loss of consciousness (hypnosis) and amnesia during general anaesthesia are associated with reductions in the cerebral metabolic rate below thresholds. γ-aminobutyric acid (GABA), glutamate and glycine receptors are involved in the mechanisms of general anaesthesia, whereby anaesthetic agents either potentiate inhibition or antagonize excitation.
- Analgesia is most potently induced by the action of opioid agents on central endogenous opiate receptors.
- Local anaesthetics prevent the propagation of action potentials and disrupt nerve conduction.
- Neuromuscular transmission is disrupted during competitive neuromuscular blockade.

Posture

Posture is the orientation of any body segment relative to the gravitational vector (angular measurement from vertical). It is distinct from balance, which is the specific control of posture in order to prevent falling.

Humans are inherently unstable because they are bipedal and would fall over without an active control system. Control of posture is involuntary and automatic (Figure 1), and is disturbed by neurological deficits such as the reversible pharmacological effects of anaesthetics and ethanol, or the more permanent effects of degenerative disease. Much of this postural control, including righting reflexes, is controlled by the midbrain.



1

The three sensory systems that cooperate to maintain balance and posture are vision (information is almost instantaneous and permits route planning), proprioception (indicating joint and muscle state) and the vestibular system.

Monosynaptic spinal reflexes, particularly those involving proprioceptors, are an important component for the maintenance of posture. In the patellar tendon reflex (see later), afferent sensory input leads to efferent motor response without real-time control from the brain, though descending spinal pathways may modulate the sensitivity of the reflex loop. The afferent sensory fibres from muscle spindles are thick (10–20 μm in diameter) and myelinated, therefore action potential conduction velocities are fast, about 100 m/s. The total reflex time for the intact system is 25–30 ms; much faster than if the sensory and motor cortex of the brain were involved. Specific postural reflexes include:

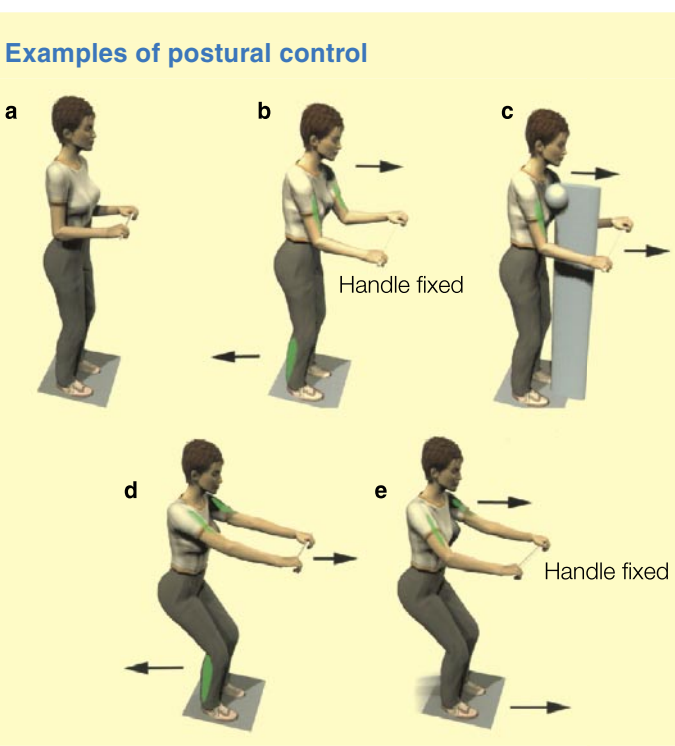
- vision (responsible for reflex and volitional gaze stabilization)
- vestibular-ocular reflex (compensates for head movements)
- cervico-ocular reflex (receptors in the neck take over if the vestibular system is compromised)
- optokinetic or optomotor reflex (detects retinal image slip and permits figure–ground discrimination of objects against a moving background).

Three main types of eye movement are related to the control of posture:

- saccadic movements direct a shift towards targets of interest
- smooth pursuit movements track moving targets
- vergence movements ensure binocular alignment on an object.

The control of posture falls into two broad categories (Figure 2).

- Anticipatory (feed forward). The CNS predicts disturbances and produces programmed responses in order to maintain stability.
- Compensatory (feed back). Movements are evoked by sensory events following loss of balance.



a Volunteer is standing quietly
b Volunteer pulls on a fixed handle. Posture is maintained by the gastrocnemius muscle contracting before the biceps pull the handle
c The handle is pulled while the volunteer's chest is supported. The biceps give a reflex contraction in response to the movement of the handle, but the gastrocnemius remains inactive
d The handle pulls the unsupported, unsuspecting volunteer. The biceps and gastrocnemius contract together to maintain balance
e The foot platform slides forward unexpectedly. The gastrocnemius does not activate, so the volunteer does not fall. The biceps contract, pulling the volunteer forward

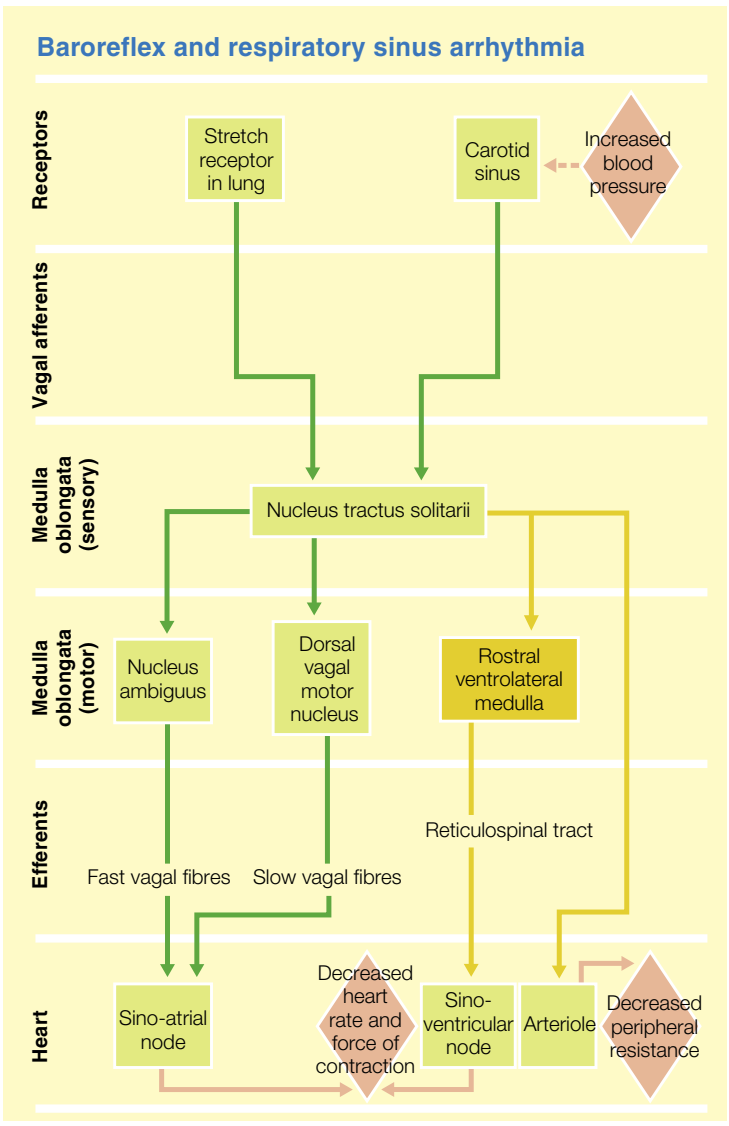
Autonomic nervous system

Sympathetic and parasympathetic systems work in balance to regulate breathing, circulation, body temperature, metabolism, secretion, digestion and the reproductive system involuntarily (Figure 3; see also *Anaesthesia and Intensive Care Medicine* **2:5:** 206). Much work has been done on the rat and care should be taken to ensure that the results are truly indicative of human physiology.

3

Cell bodies of preganglionic sympathetic neurons lie in the thoracic and upper lumbar spinal cord. Axons from these preganglionic neurons leave the spinal cord via the ventral roots and innervate the sympathetic ganglia arranged segmentally on either side of the spinal column. Although the cell bodies are situated in all segments of the spinal cord, anatomically the ganglia extend only as far as the first lumbar segment. Most preganglionic sympathetic axons are myelinated, and about 4 μm in diameter; they conduct action potentials at velocities lower than 20 m/s. The preganglionic fibres use acetylcholine as a neurotransmitter. Axons from the postganglionic neurons innervate effectors of the sympathetic system: the thoracic spinal fibres innervate the head, thorax, abdomen and upper extremities; lumbar spinal fibres innervate the pelvis and lower extremities. Postganglionic fibres may be long because the sympathetic ganglia are usually some distance from the effector target. Most postganglionic sympathetic fibres use noradrenaline as a neurotransmitter at the target. Specific effectors are cardiac muscle, smooth muscle and glands responsible for sweating (cholinergic not noradrenaline), lacrimation, salivation and digestion.

The vagus nerve (X) is an important autonomic sensory and parasympathetic effector pathway connecting the brainstem to visceral organs and the larynx. Therefore, stimulating input from visceral receptors can potentially bypass spinal or epidural blockade during surgery even after an epidural or spinal nerve block via transmission along the vagus nerve, though some visceral sensory fibres enter the spinal column at the dorsal roots. Such autonomic visceral sensory inputs include noxious stimuli, pH and electrolyte concentrations in blood and stomach, inflation of the lungs, intraluminal pressure in the arterial system, and distensions of the bladder, veins and intestine. The vagus nerve is a proven route for infection of the CNS by pseudorabies virus, and may be a route for neuroinvasion by transmissible spongiform encephalopathies (e.g. variant Creutzfeld–Jacob disease). Parasympathetic control of heart rate is via the vagus nerve, and is visible as both low and high frequency components (Figure 4). The low frequency control is most prominent in the baroreflex, driven by slow fibres originating in the dorsal vagal nucleus of the medulla. High frequency parasympathetic slowing of heart rate occurs breath by breath, and gives rise to respiratory sinus arrhythmia, the level of which falls with increasing depth of anaesthesia and is guided by fast fibres originating in the nucleus ambiguus of the medulla.

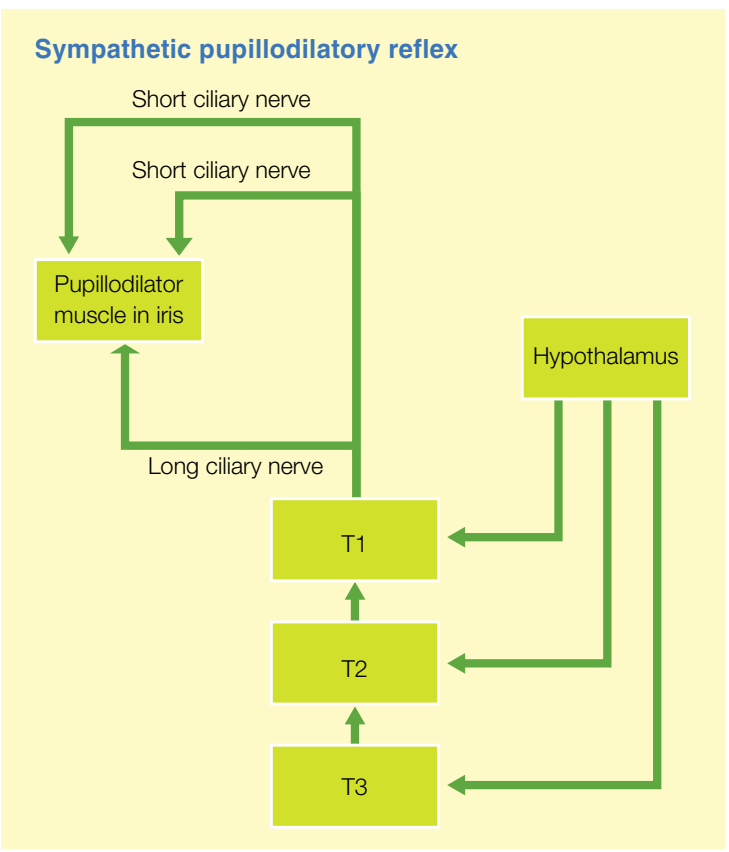


4

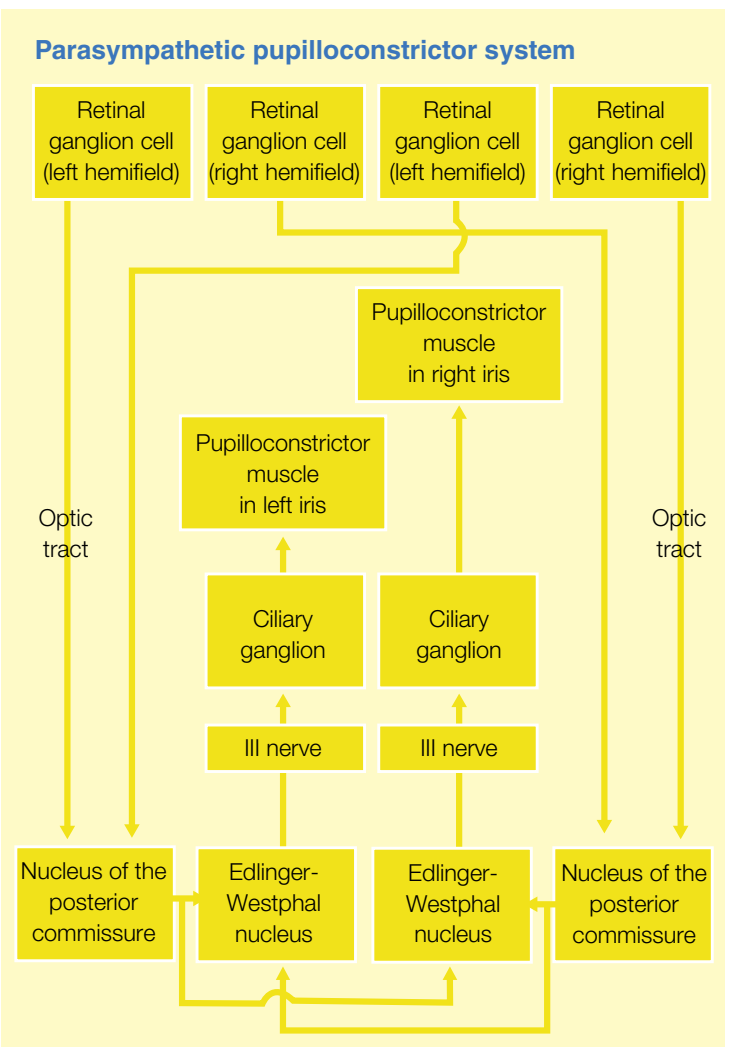
Neurological reflexes

Neurological reflexes are controlled by reflex arcs. They are complete neuronal networks originating at a sensory receptor, travelling through the CNS and ending at a peripheral effector. Reflex arcs are usually capable of functioning in isolation and exhibit standard responses to sensory stimuli. Descending influences from higher centres in the CNS can modulate the sensitivity of reflex arcs. The baroreflex is a typical reflex arc.

Reflex arcs are involved in controlling the pupillary light reflex, which depends on a balance between the sympathetic pupillodilator pathway and the parasympathetic pupillo-constrictor pathway (Figures 5 and 6).



5



6

Retinal ganglion neurons project to pretectal areas preserved for autonomic processing of retinal information via the optic nerve and optic chiasm. Pretectal neurons project to the accessory oculomotor nucleus. Axons from the accessory oculomotor nucleus innervate the optic ganglia via the brainstem and the oculomotor nerve (preganglionic parasympathetic nerve III). Motor neurons originating in the optic ganglia innervate the smooth muscle of the pupillary sphincter. Antagonism of parasympathetic pupilloconstriction with atropine leads to pupil dilation. Increasing concentrations of hypnotic anaesthetics inhibit the light reflex, as do opioids.

Brainstem death is tested by using the pupillary light reflex in conjunction with a number of other cephalic reflexes (i.e. corneal, oculoauditory, oculovestibular, oculocephalic, ciliospinal, snout, pharyngeal, cough and swallowing).

Monosynaptic stretch reflex

Voluntary muscles contain a number of specialized sensory receptors known as muscle spindles. The muscle spindle is an example of a stretch receptor. The frog has a single muscle spindle in each toe, making it a good experimental system because activity recorded in the sciatic nerve as a result of movement of one toe is from just one muscle spindle. In humans, the muscle spindle has intrafusil muscle fibres (15–30 μm in diameter, 4–7 mm long) that are anatomically parallel but separately innervated to the normal extrafusil fibres (50–100 μm in diameter, a few mm to tens of cm in length). Intrafusil muscle fibres are controlled by the gamma motor system, a completely separate neural system from the normal control of extrafusil fibres.

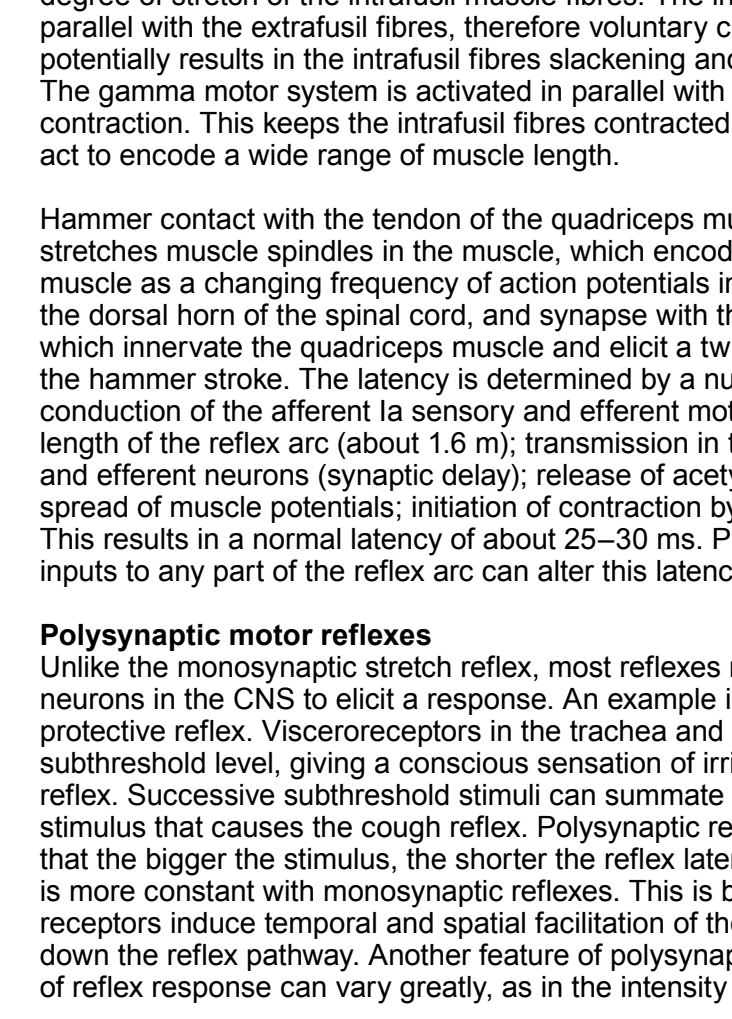
Sensory innervation of the muscle spindle comprises fast, group Ia myelinated afferent neurons wound round the intrafusil muscle fibres (annulospiral ending). The frequency of action potentials propagated in the afferent neurons is proportional to the degree of stretch of the intrafusil muscle fibres. The intrafusil fibres are anatomically in parallel with the extrafusil fibres, therefore voluntary contraction of the extrafusil fibres potentially results in the intrafusil fibres slackening and not communicating stretch. The gamma motor system is activated in parallel with normal, extrafusil muscle fibre contraction. This keeps the intrafusil fibres contracted, so that the muscle spindle can act to encode a wide range of muscle length.

Hammer contact with the tendon of the quadriceps muscle, below the patella, briefly stretches muscle spindles in the muscle, which encode the change in length of the muscle as a changing frequency of action potentials in Ia afferent nerves. These enter the dorsal horn of the spinal cord, and synapse with the cell bodies of motor neurons, which innervate the quadriceps muscle and elicit a twitch with a short latency after the hammer stroke. The latency is determined by a number of factors: the speed of conduction of the afferent Ia sensory and efferent motor fibres (about 100 m/s); the length of the reflex arc (about 1.6 m); transmission in the synapse between afferent and efferent neurons (synaptic delay); release of acetylcholine at the motor end plates; spread of muscle potentials; initiation of contraction by the muscle fibre action potential. This results in a normal latency of about 25–30 ms. Physiological damage or abnormal inputs to any part of the reflex arc can alter this latency or prevent the reflex.

Polysynaptic motor reflexes

Unlike the monosynaptic stretch reflex, most reflexes require the interaction of many neurons in the CNS to elicit a response. An example is the cough reflex, a typical protective reflex. Visceroreceptors in the trachea and bronchi can be stimulated to a subthreshold level, giving a conscious sensation of irritation that does not elicit the reflex. Successive subthreshold stimuli can summate to produce one suprathreshold stimulus that causes the cough reflex. Polysynaptic reflexes often exhibit the effect that the bigger the stimulus, the shorter the reflex latency, whereas the reflex latency is more constant with monosynaptic reflexes. This is because more intensely activated receptors induce temporal and spatial facilitation of their effects on interneurons further down the reflex pathway. Another feature of polysynaptic reflexes is that the magnitude of reflex response can vary greatly, as in the intensity of a cough.

A further example of a polysynaptic reflex is the withdrawal of a limb in response to a noxious stimulus (Figure 7). Flexor muscles ipsilateral to the noxious stimulus are stimulated as ipsilateral extensor muscles are relaxed. At the same time, local interneurons ensure that contralateral extensor muscles are stimulated and contralateral flexors are inhibited. The local interneurons are constantly under the influence of descending interneurons, which can influence the magnitude of this reflex depending on behavioural requirements.



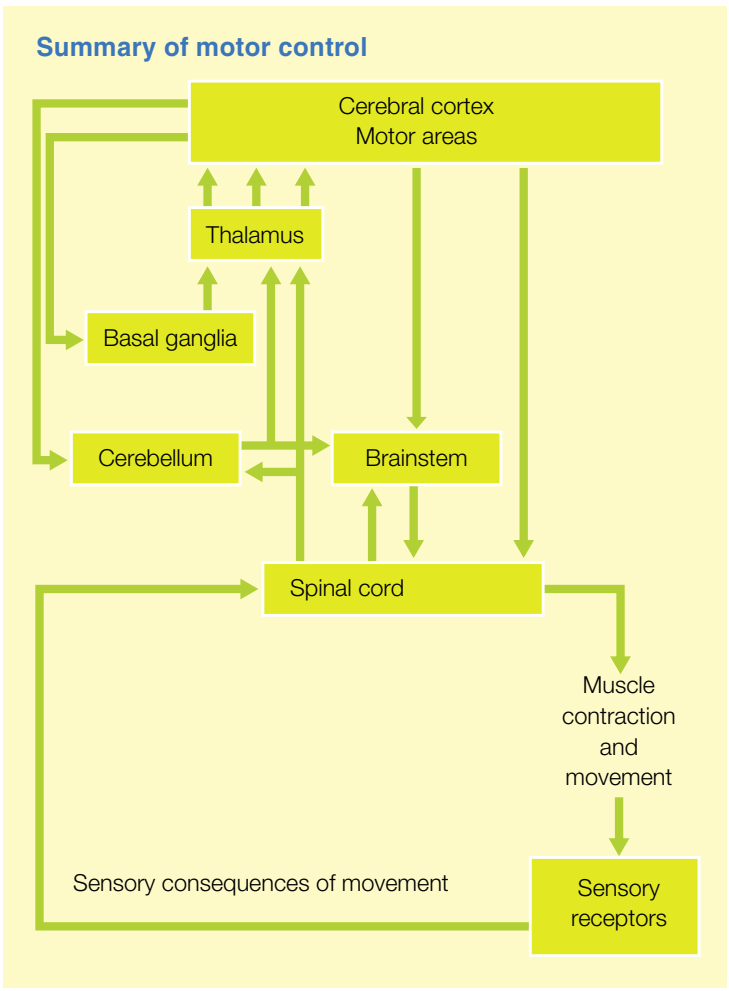
7

As the number of synapses increases, so does the number of potential sites of pharmacological action. Excessively high levels of hypnotic anaesthetic agents in animals increase the amount of simple peripheral motor activity, presumably because of a reduction in descending inhibition, which would otherwise damp these reflexes.

Polysynaptic reflexes also overlap in function. For example, motor neurons involved in the cough reflex may also receive input from interneurons responsible for the timing of normal respiration.

Motor function: spinal and peripheral

Motor function is based on a hierarchical structure (Figure 8). Simple, spinal, monosynaptic motor reflexes are the simplest motor pathways. All motor pathways end with a motor neuron, acting as an interface between the chemical electrical energy of the CNS and the mechanical action of the muscle.



8

Motor cortex and the corticospinal pathway

The motor cortex is topographically (somatotrophically) mapped to different motor structures. The precentral gyrus (primary motor cortex) is characteristically thick (3.5–4.5 mm) and comprises large pyramidal neurons (Betz cells) in layer V. The large pyramidal neurons, along with smaller pyramidal cells in layer III, comprise the corticospinal-tract neurons, with axons running through white matter, through the posterior limb of the internal capsule, and into the basis pontis of the basilar pons of the brainstem. The corticospinal tract descends into the medullary pyramids of the anterior brainstem, hence its alternative name of pyramidal tract. 70–90% of corticospinal axons cross over to the other side of the brainstem at the descussation of the pyramids. The axons of large pyramidal cells have the highest conduction velocities (60–90 m/s) of the corticospinal tract, and yet comprise only 3% (some 30,000 fibres) of all pyramidal cell axons. In the spinal cord, corticospinal neurons synapse on to motor neurons directly or segmental interneurons. Some corticospinal neurons in the adult are over 1 m long.

The corticospinal tract allows direct cortical control of fine movements in the face or distal extremities; these movements are fast and under the direct control of the higher brain. Examples of corticospinal tract control are buttoning a jacket or playing a trumpet. Interruption of the corticospinal tract results in symptoms predominantly on the side contralateral to the injury.

Basal ganglia

The basal ganglia comprise four large, subcortical nuclei participating in the control of movement: the striatum (comprising the caudate nucleus, the putamen and the ventral striatum); globus pallidus (or pallidum); the subthalamic nucleus; and the substantia nigra (comprising pars reticula and pars compacta). Large areas of the cerebral cortex, thalamus and brainstem innervate the striatum. The basal ganglia are responsible for the inhibition of unwanted motor programmes and the facilitation of desired movements. The basal ganglia are also responsible for the control of other functions in addition to voluntary movement, including cognition and oculomotor movement. Four segregated circuits connect the basal ganglia with the cerebral cortex and thalamus: skeletomotor circuit; oculomotor circuit; prefrontal circuit; and limbic circuit.

Lesions in the basal ganglia lead to Parkinson's disease, Huntington's disease, or hemiballismus. Parkinson's disease is a hypokinetic disorder characterized by impaired initiation of movement (akinesia), and reduced magnitude of voluntary movement (bradykinesia), accompanied by muscle rigidity and tremor. The region of damage is the dopaminergic tract connecting the substantia nigra to the striatum, and one treatment is the administration of L-dopa, the precursor of dopamine, which crosses the blood–brain barrier. Another treatment is surgical pallidotomy. Patients with Huntington's disease (a hereditary, hyperkinetic disease) exhibit adverse cognitive and emotional effects, as well as excessive motor activity, with involuntary movements (dyskinesias) and decreased muscle tone (hypotonia). The dyskinesias can be slow and writhing (athetosis), jerky random movements (chorea), violent large movements (ballism) or abnormal postures (dystonia). Damage in Huntington's disease is widespread in the brain, but appears earliest in the striatum and may be caused by excessive glutamate release. In hemiballismus, small strokes cause lesions in the subthalamic nucleus and the symptoms are violent movements of the contralateral limbs.

Rubrospinal and tectospinal pathways

The rubrospinal pathway originates in the midbrain, crosses over in the midbrain, descends in the dorsal labial column and terminates in the dorsal lobe grey matter of the spinal cord. It mediates voluntary control of movements, but excludes fine movement of the fingers, toes and mouth. The tectospinal pathway mediates head and body orientation in response to discrete visual, auditory and tactile stimuli, often originating from the same source. The reticulospinal pathways originate in the brainstem reticular formation and stabilize movement on uneven surfaces. ◆

Functions of the Placenta

Sarah Vause
Daljit K Saroya

Sarah Vause is Consultant in Fetomaternal Medicine at St Mary's Hospital, Manchester, UK. She qualified from Manchester University and trained in obstetrics in Yorkshire and Manchester.

Daljit K Saroya is Consultant Anaesthetist at Stepping Hill Hospital, Stockport, UK. Her interest is obstetric anaesthesia.

The placenta is an interface for the exchange of gases, nutrients and waste products and therefore has respiratory, nutritive and excretory functions. It is also a partial barrier to the transfer of drugs, bacteria and cells between mother and fetus. It is an important site of hormone production and, as an integral part of the fetomaternoplacental unit, has a profound influence on the endocrinology of pregnancy.

Placental blood flow
The fetal and maternal circulations interface in the placenta. The maternal circulation through the intervillous space of the placental bed is almost wholly pressure dependent, with little or no autoregulation. This is unusual because control of blood flow in the arterial tree of most organs depends on vasomotor activity in the arterioles. However, in the pregnant uterus the muscular walls of the spiral arterioles are destroyed by trophoblasts and become passive channels in the uterine circulation.

Blood flow to the uterus is difficult to quantify because the uterus is supplied by a number of arterial channels that anastomose with the ovarian and vaginal blood supplies. Blood flow to the uterus increases throughout pregnancy reaching about 500 ml/minute at term.

The fetal circulation through the placenta is altered by the resistance of the placenta. Usually there is forward flow in the umbilical artery throughout the cardiac cycle of the fetus. However, if placental resistance is increased, for example in pre-eclampsia, flow in the umbilical artery may be absent during diastole. Umbilical artery Doppler measurements are useful in monitoring high-risk pregnancies, because they reflect placental resistance.

Placental transfer
In a healthy human pregnancy the transfer of a substance from mother to fetus depends on:
- maternal uteroplacental blood flow
- fetal umbilical blood flow
- surface area (gross and functional)
- placental metabolism
- concentration in maternal circulation
- concentration in fetal circulation
- mechanism of transfer
- availability of carrier proteins and relative affinities (e.g. fetal haemoglobin).

The materials are transported across the placental membrane by simple diffusion, facilitated diffusion, active transport or pinocytosis. Transfer of a substance may be influenced by its molecular weight, ionization, lipid solubility and protein binding.

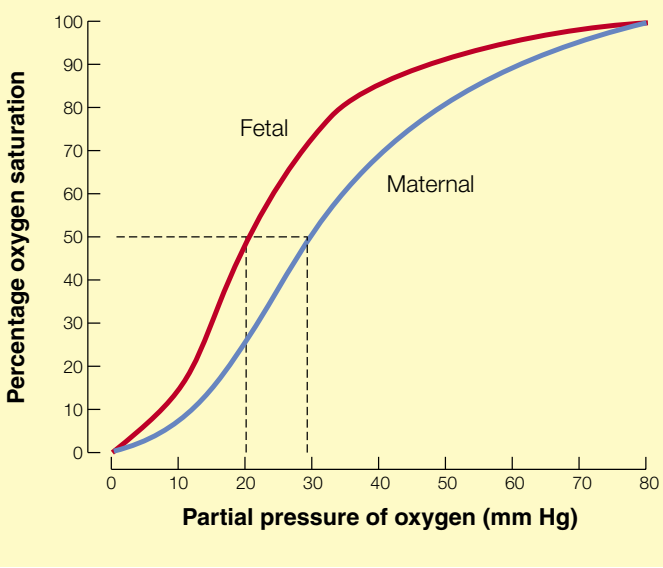
Gases
Respiratory gases cross the placenta by diffusion. The rate and quantity of gas transferred depends on the concentration of each on either side of the placenta, the dissociation curves in both maternal and fetal blood and the supply of blood to each side of the placenta.

Fetal haemoglobin has a greater affinity for oxygen than maternal haemoglobin. The fetal oxygen dissociation curve is shifted to the left of the maternal curve (Figure 1). The partial pressure of oxygen of fetal haemoglobin 50% saturated (P_{50}) is lower (20 mm Hg) than that of maternal haemoglobin (27 mm Hg). This is because the γ chains in fetal haemoglobin bind 2,3-diphosphoglycerate (2,3-DPG) less avidly than the β chains in adult haemoglobin. If the following equation is considered:

$$HbO_2 + 2,3\text{-DPG} = Hb\text{-}2,3\text{-DPG} + O_2$$

it can be seen that in maternal blood, where 2,3-DPG binds to haemoglobin, the equation is tipped to the right and oxygen is liberated. However, in fetal blood where the binding of 2,3-DPG is less, the equation is tipped to the left, and more oxygen is bound to the fetal haemoglobin.

Oxygen–haemoglobin dissociation curves for fetal and maternal haemoglobin

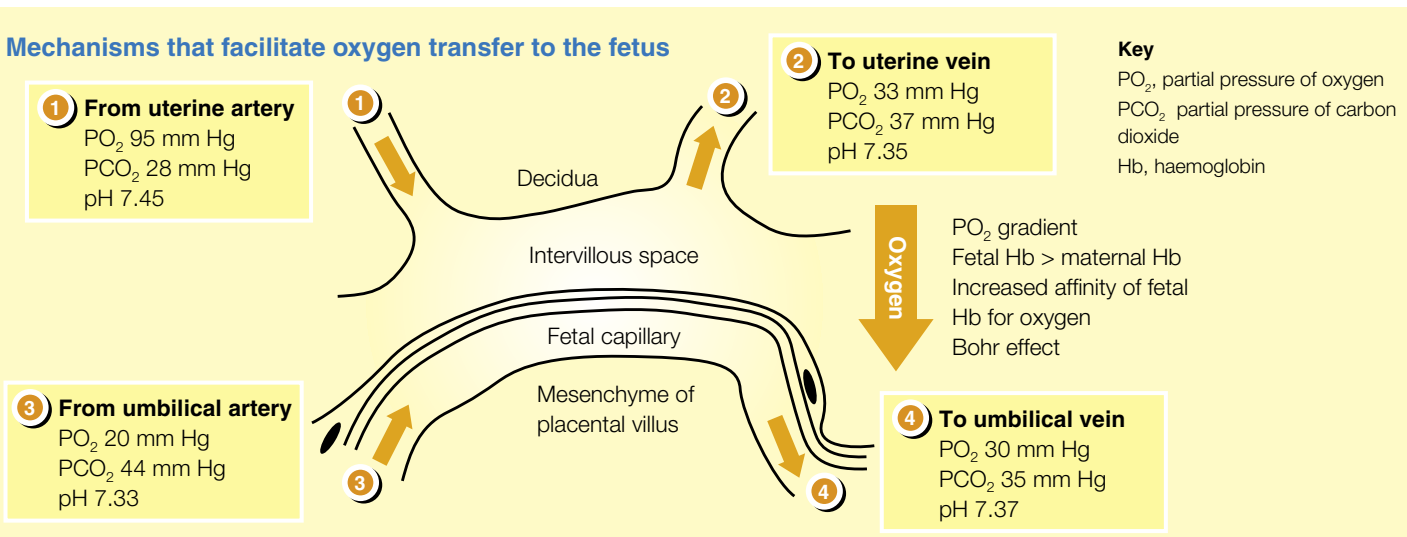


1

The increased haemoglobin concentration (17 g/dl) in the term fetus compared with the maternal haemoglobin concentration also favours oxygen transfer to the fetus. Therefore, at term, the amount of oxygen carried per ml of fetal blood is greater than that of maternal blood.

The decrease in oxygen affinity of haemoglobin when the pH of blood falls is called the Bohr effect. As fetal blood passes through the placenta, carbon dioxide is excreted into the maternal circulation. Consequently, maternal blood becomes more acidic and the oxygen affinity of the maternal haemoglobin decreases. Fetal blood becomes less acidic as it passes through the placenta and its oxygen affinity increases. There is therefore a double Bohr effect in the placenta. Figure 2 shows mechanisms, that facilitate oxygen transfer to the fetus.

Mechanisms that facilitate oxygen transfer to the fetus



2

Carbon dioxide is very soluble and once in the blood soon passes into the red cells. There, about 30% combines with haemo-globin, about 10% is in physical solution, and 60% combines with water to make H_2CO_3 which ionizes almost immediately. The H^+ is buffered by fetal haemoglobin so there is only a slight drop in pH and the fetus is able to carry more carbon dioxide. The HCO_3^- passes out of the red cell. Because of the high haemoglobin content of fetal blood, there are smaller pH changes for any given increase in the partial pressure of carbon dioxide.

Deoxygenated haemoglobin binds more H^+ than oxygenated haemoglobin and forms carbamino compounds more readily, therefore venous blood can carry more carbon dioxide than arterial – the Haldane effect. At the placental surface, maternal blood releases oxygen and so its deoxygenated haemoglobin is free to bind to H^+ and carbon dioxide. At the same time in fetal blood, oxygen binds to the fetal haemoglobin molecule and carbon dioxide is released, facilitating the excretion of carbon dioxide into the maternal circulation. This is a double Haldane effect and occurs in the placenta only because of the relative positions of the fetal and maternal oxygen dissociation curves.

Fetal haemoglobin is a major buffer and in acidosis the oxygen dissociation curve shifts to the right so that for any given partial pressure of oxygen the oxygen saturation falls. This releases oxygen for use in the tissues and makes more fetal deoxyhaemoglobin available for buffering (deoxygenated haemoglobin is a better buffer than oxygenated haemoglobin).

Excretion
Excretion of carbon dioxide is discussed above. Urea and uric acid pass through the placental membrane by simple diffusion and bilirubin is cleared quickly.

Nutrients
Glucose passes through the placenta at a faster rate than might be expected on the basis of simple diffusion alone because there is a carrier system (intramembrane protein carrier molecules) that selectively binds glucose molecules. This facilitated diffusion mechanism can be saturated, but only with extreme hyper-glycaemia. Placental glucose carriers are insulin independent.

Amino acids cross the placenta against a concentration gradient – the concentrations in fetal blood are higher than in maternal blood. An energy-dependent, active-transport mechanism is employed. Transfer of amino acids is limited by the capacity of the placental membrane proteins to transfer amino acids, rather than by placental blood supply. Alcohol and nicotine inhibit placental amino acid transfer.

Essential fatty acids – linoleic and linolenic acids cannot be synthesized by the fetus and must be obtained transplacentally. Lipid transport across the placenta is less in humans than in some other mammals and appears to be non-selective.

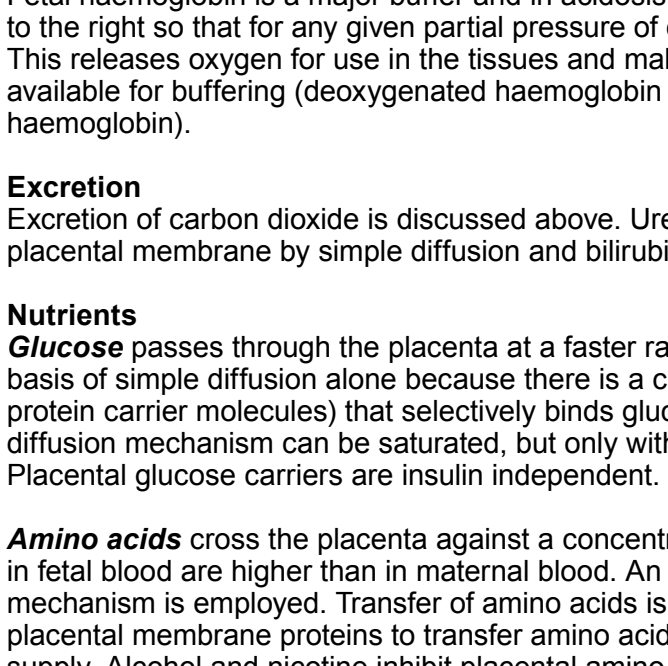
Calcium is transferred across the placenta by active transport against a concentration gradient.

Maternal antibodies such as immunoglobulin G are transferred across the placenta to the fetus by pinocytosis. Immuno-globulins are mainly protective and confer passive immunity to the immunologically immature fetus. However, in some situations transplacental transfer of maternal immunoglobulin can cause problems, for example in haemolytic disease of the newborn.

Drugs
Many drugs cross the placenta; some are beneficial to the fetus (e.g. prophylactic corticosteroids) but others may be teratogenic. A comprehensive review of pharmacokinetics in pregnancy is beyond the scope of this article; those drugs most relevant to the obstetric anaesthetist are discussed.

Anaesthetic agents: non-ionized lipophilic molecules cross the placenta more readily than ionized molecules. The structures of some of these drugs are illustrated in Figure 3.

Structure of some anaesthetic drugs



3

Inhalational anaesthetic agents cross the placenta rapidly even with relatively short induction to delivery times. Nitrous oxide concentrations may reach 80% of that in the mother within 3 minutes and may cause diffusion hypoxia during prolonged delivery.

Induction agents cross the placenta rapidly. Some studies suggest that thiopental (thiopentone) crosses more freely than propofol. Etomidate crosses the placenta less easily because of its lower lipophilicity.

Muscle relaxants are quaternary ammonium salts (fully ionized) and do not cross the placenta readily. Maternal doses of suxamethonium greater than 300 mg are required before the drug can be detected in umbilical venous blood. Fetal neuromuscular blockade can occur if the mother is given repeated high doses of drug or if the fetus has pseudocholinesterase deficiency.

Anticholinergic agents – atropine crosses the placenta easily. Glycopyrrolate does not because of its highly polar structure.

Anticholinesterase agents – neostigmine and edrophonium are quaternary ammonium compounds that are ionized at physiological pH, therefore they do not readily cross the placenta.

Vasopressor agents are often used in regional obstetric anaesthesia. Ephedrine crosses the placenta easily but does not reduce uterine blood flow to a significant degree, unlike metaraminol.

Opioids – morphine crosses the placenta rapidly (fetomaternal ratio 0.92). Fentanyl, and its analogues, cross the placenta less readily because protein binding to albumin is high and this offsets the high lipophilicity.

Corticosteroids may be indicated for the treatment of maternal medical conditions during pregnancy. There are concerns that if large quantities of corticosteroid cross the placenta, fetal adrenal suppression could occur. In practice this does not happen with corticosteroids such as prednisolone because placental 11β dehydrogenase deactivates prednisolone. Under other circumstances it is important that glucocorticoids cross the placenta, for example to promote fetal lung maturity. The maternal:fetal concentrations of predisolone are 10:1 and those of betamethasone are 3:1; therefore betamethasone or dexamethasone should be used.

Anticoagulants: warfarin readily crosses the placenta. If the mother uses warfarin in the first trimester, warfarin embryopathy occurs in 15–25% of fetuses. The risk is reduced if warfarin is discontinued prior to 7 weeks' gestation. Heparin does not cross the placenta and its shorter half-life makes it a more suitable anticoagulant in pregnancy. Self-administered low molecular weight heparin is increasingly being used throughout pregnancy if anticoagulation is required.

Non-steroidal anti-inflammatory drugs may be used in pregnancy for their tocolytic effect. They cross the placenta and reduce fetal renal perfusion, resulting in reduction in liquor volume. There are isolated reports associating their use with premature closure of ductus arteriosus after 32 weeks' gestation.

Captopril is associated with fetal nephrotoxicity and fetal anuria. Its use is contraindicated in pregnancy, particularly in the second and third trimesters.

Anti-epileptics: 33% of infants born to mothers taking phenytoin have minor anomalies and 10% have major anomalies such as cleft lip and palate, hypertelorism, a broad nasal bridge, hypoplasia of distal phalanges and nails, growth deficiency and mental deficiency. Carbamazepine was thought to be relatively safe, but there is an increasing realization that it can be associated with similar abnormalities to phenytoin. Sodium valproate has been associated with a specific valproate syndrome and with an increased risk of neural tube defects (1–2%). Prophylactic folic acid, 5 mg/day, is recommended throughout pregnancy.

Hormone production

Maintenance of pregnancy

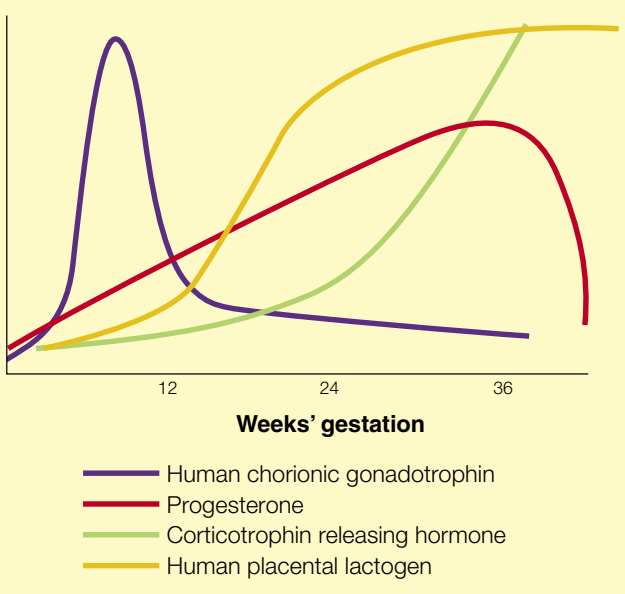
Following ovulation, a progesterone-producing corpus luteum is formed in the ovary. If fertilization does not occur the corpus luteum degenerates, levels of progesterone fall and menstruation occurs. If the egg is fertilized and implantation occurs the syncytiotrophoblast produces human chorionic gonadotrophin (hCG). This enters the maternal blood and maintains the activity of the progesterone-producing corpus luteum in the ovary during the first 7 weeks of pregnancy.

Detection of the β subunit of hCG in maternal urine forms the basis for pregnancy tests. Enough hCG is produced by the syncytiotrophoblast at the end of the second week following fertilization to give a positive pregnancy test. hCG and β-hCG levels peak at 9–11 weeks' gestation.

The placenta also produces oestrogen and progesterone from maternal and fetal precursors. By the sixth week of pregnancy these hormones are being produced in sufficient amounts in the placenta for the corpus luteum to become redundant. hCG secretion declines after 11 weeks' gestation but oestrogen and progesterone secretion increase until parturition.

Progesterone is produced by the placenta at all stages of gestation. Progesterone depends on the presence of oestrogen to exert its biological effects. It maintains uterine quiescence, is thermogenic and increases the respiratory minute volume, thereby reducing the partial pressure of carbon dioxide in the alveoli and the blood. Figure 4 shows how the secretion of placental hormones changes with gestation.

Patterns of change in placental hormones with gestation



4

The maternofetoplacental unit

Some of the progesterone synthesized in the placenta enters the fetal circulation and provides the substrate for the formation of cortisol and corticosterone in the fetal adrenal glands. Pregnenolone, also synthesized in the placenta, is the substrate for formation of dehydroepiandrosterone (DHEA) in the fetal adrenal, and this is subsequently converted to 16-hydroxy-dehydroepiandrosterone in the fetal liver, and then to androstenedione and oestrogens in the placenta. The principal oestrogen formed is oestriol, which enters the maternal blood and is excreted in maternal urine. Maternal urinary oestriol therefore reflects the activity of fetus and placenta, and gave rise to the concept of the maternofetoplacental unit. Previously, maternal urinary oestriols were used as a measure of placental function. However, they have been shown to be of poor predictive value in assessing fetal well-being.

Human placental lactogen (hPL) is a protein hormone, secreted exclusively by the villus trophoblast. It has growth hormone-like effects in both the mother and the fetus. Circulating hPL levels are detected in maternal plasma by about 6 weeks' gestation. It acts as an antagonist to insulin by enhancing insulin resistance in the mother and increasing lipolysis and proteolysis, with the net effect of promoting the transfer of glucose and amino acids to the fetus. Levels of hPL increase linearly throughout gestation to peak at the 30th week. It disappears rapidly after delivery of the placenta.

Onset of parturition

The mechanism that initiates the onset of labour remains obscure. One of the many theories is that placental corticotrophin releasing hormone (CRH) may play an important role in the timing of its onset. CRH is synthesized in the syncytiotrophoblast and secreted into the maternal circulation. It rises steadily to 35 weeks and then increases markedly to term (Figure 4). CRH activity in both maternal and fetal circulations is modulated by CRH binding protein. This is synthesized in the liver, placenta and brain and its circulating levels are in excess of those of CRH, such that most of the circulating CRH is bound. However, towards term when the levels of CRH are rising those of the binding protein are declining, resulting in increasing free levels of circulating CRH. CRH enhances the release of placental adrenocorticotrophin (ACTH) and increases the production of prostaglandins by the trophoblast and fetal membranes. The prostaglandins further increase CRH production, resulting in a feed forward loop and a further increase in prostaglandin release. Once labour begins, it appears to be a self-perpetuating process involving many factors, including prostaglandins and oxytocin.

Endocrinology of pregnancy

Carbohydrate metabolism and diabetes

Insulin resistance develops in pregnancy, though the aetiology remains uncertain. The effect is likely to be mediated by the increased production of one or more of the hormones associated with pregnancy, possibly hPL or free cortisol. Women with pancreatic β cell insufficiency before pregnancy are unable to increase their insulin secretion adequately and tend to be hyperglycaemic in pregnancy.

The plasma glucose concentration of the fetus closely follows that of the mother. Insulin appears in the fetal circulation from 10 weeks' gestation. Insulin does not cross the placenta, therefore it has been postulated that in pregnancies complicated by diabetes, fetal hyperglycaemia resulting from maternal hyperglycaemia stimulates fetal pancreatic β cell hypertrophy, resulting in release of insulin. Fetal hyperinsulinaemia then leads to macrosomia and the subsequent complications of a traumatic delivery, neonatal hypoglycaemia, increased erythropoiesis and reduced surfactant production.

Conversely, in non-diabetic women with growth-restricted fetuses the fetus may have fewer pancreatic β cells. In later life these adults may have increased insulin resistance.

If a woman with diabetes needs treatment with prophylactic corticosteroids to enhance fetal lung maturity, insulin requirement may increase. It may also increase in labour. Insulin requirements reduce rapidly in the post-natal period. If an insulin infusion is used it needs to be reduced or stopped immediately after delivery, otherwise hypoglycaemia might result.

Thyroid

In pregnancy, the increased maternal glomerular filtration rate causes an increased loss of iodine in the urine, a reduction in serum iodide and increased size and vascularity of the thyroid gland. hCG produced in the first trimester has thyroid-stimulating properties. Total triiodothyronine (T3) and thyroxine (T4) are increased. Oestrogens also increase thyroid-binding globulin levels. Therefore free T3 and T4 are usually unchanged. In view of the alteration in thyroid-binding globulin it is important to measure TSH and free T3 or free T4 levels, when assessing thyroid function in pregnancy. Very little maternal TSH, T3 or T4 crosses the placenta. However, iodine is actively transferred by the placenta and fetal thyroid function begins at 10 weeks' gestation. ◆

Kamran Abbas is Specialist Registrar at the Manchester Royal Infirmary, UK. He qualified from the University of Manchester in 1993 and trained in general practice before moving to anaesthesia. His research interests include biophysiological changes in exercise and the interpretation of pulse oximetry.

Suna D Monaghan is Consultant Anaesthetist at the Central Manchester and Manchester Children's University Hospitals NHS Trust. She qualified in medicine from Cambridge University and trained in anaesthesia in Warwick and Manchester. Her specialist interests are obstetric anaesthesia and management of the difficult airway.

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

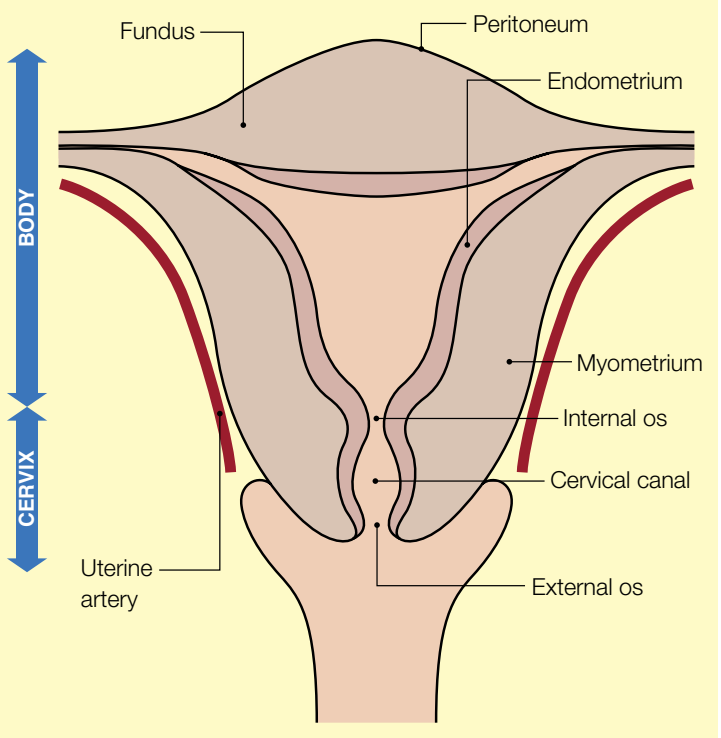
The role of the uterus is to nurture the fetus until parturition. Functionally it consists of a lower cervix (which acts at different times as a passageway, a barrier and a reservoir) and an upper body in which the fetus develops.

Anatomy

The superior part of the uterus is called the fundus; on either side of this the uterus communicates with the Fallopian tubes at the cornua (Figure 1). It is connected to and supported at its lower end by a number of ligaments connected to the bladder, the rectum and the walls of the pelvis. Some of these are peritoneal folds, others consist of unstriped muscle and fibrous tissue. The two broad ligaments pass from the margins of the uterus to the lateral wall of the pelvis. In 80% of women the uterus tilts up towards the abdominal wall, in 20% it is retroverted, tilting back into the pelvis.

The uterus has three layers (serosa, myometrium and endometrium). The serosa is formed by peritoneum. The muscular coat or myometrium is the middle layer and is composed of smooth muscle with areolar tissue, blood and lymph vessels and nerves. It is arranged in three distinct layers and the muscle fibres hypertrophy in pregnancy. The muscle of the uterus is not an anatomical syncytium like the heart, but in late pregnancy it forms a functional syncytium by the electrical coupling of the branching bundles of cells at gap junctions which greatly increase in number towards term. The formation of gap junctions is stimulated by the rise in the oestrogen/progesterone ratio (see later). The cervix is a more collagenous structure with a muscle content of only 10–15%. This gives it the capacity to undergo profound tissue remodelling during pregnancy and labour and to return to its former state after parturition. The endometrium or inner layer of the uterus is lined by columnar epithelium. It contains many tube-like glands that open into the uterine cavity and secrete mucus.

Anatomy of the uterus



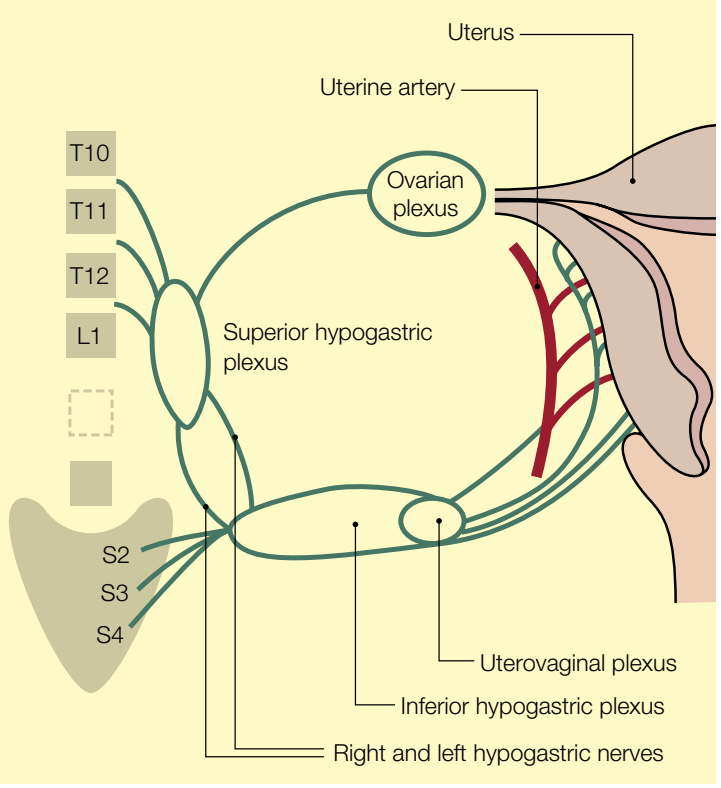
1

The uterus is supplied by the uterine branch of the internal iliac artery; it anastomoses with the ovarian artery (a branch of the aorta) and inferiorly with vessels of the upper vagina. The arteries supplying the uterus are remarkable for their tortuous course within the substance of the organ. The lymphatic drainage from the body of the uterus goes to the pelvic nodes, but lymph from the upper part drains to the para-aortic nodes. Occasionally, infection or malignancy may spread to the inguinal nodes.

Nerve supply

The nerve supply to the uterus is via autonomic pathways (Figure 2): the body is supplied predominantly by sympathetic fibres from T10–L1, the cervix by parasympathetic pathways from the sacral outflow S2–4. The sympathetic nerves pass via the superior hypogastric plexus; this is formed from the union of branches from the aortic plexus and the third and fourth splanchnic nerves and lies in front of the abdominal aorta. It gives off branches to the ovarian plexus, then divides below into the right and left hypogastric nerves. These lie in the extraperitoneal connective tissue before passing into the pelvis where they are joined by parasympathetic fibres from the pelvic splanchnic nerves and a few fibres from the sacral sympathetic ganglia to form the inferior hypogastric plexus which lies on the front of the sacrum. Branches from this plexus are distributed to the pelvic viscera either directly or accompanying the branches of the internal iliac artery.

Nerve supply to the uterus



2

The uterine nerves come from the inferior hypogastric plexus, predominantly from the part that lies in the base of the broad ligament of the uterus and is known as the uterovaginal plexus. They pass directly to the uterus and upwards with the uterine artery in the broad ligament. They communicate with branches of the tubal nerve and nerves of the ovarian plexus. Branches of the uterine nerves ramify in the myometrium and endometrium, most of them accompanying blood vessels. Some nerves from the uterovaginal plexus pass to the uterine cervix. The ovarian plexus is formed from branches of the renal and aortic plexuses. It accompanies the ovarian artery and is distributed to the ovary and Fallopian tube.

Motor function: while sympathetic activation normally produces uterine contraction and vasoconstriction, and parasympathetic activity produces uterine inhibition and vasodilatation, these actions, particularly in pregnancy and parturition, are complicated by the hormonal control of uterine function (see later).

Sensory function: pain fibres from the body of the uterus pass centrally to T10–L1 in the sympathetic nerves via the superior hypogastric plexus and the lumbar splanchnic nerves. Afferent pain fibres from the cervix pass via the parasympathetic nerves S2–4.

Physiology

Myometrial contractility

Growth and activity of the uterus is largely under hormonal control. In broad terms, oestrogen stimulates myometrial activity, the muscle becomes more active and excitable and action potentials in the individual fibres more frequent. An 'oestrogen primed' uterus is also more sensitive to oxytocin. Progesterone on the other hand depresses the excitability of the uterine musculature, decreasing spontaneous electrical activity and sensitivity to oxytocin. During the normal menstrual cycle, circulating oestrogens are at their highest immediately before ovulation, increasing the motility of the uterine tubes and thus potentially aiding conception. Progesterone is secreted by the ovary in the second half of the menstrual cycle and, by depressing uterine activity, potentially aids implantation. Uterine contractions during menstruation are stimulated by prostaglandin.

In pregnancy, the uterus increases from 30–60 g to 750–1000 g owing to hyperplasia and hypertrophy of the myometrium, largely under the influence of oestrogens. Muscle cell size increases from 50 to 500 μm, glycogen is laid down and there is an increase in ATP. Muscle contraction is induced by intracellular liberation of calcium from intracellular stores and from extracellular fluid. Spontaneous depolarizing pacemakers occur and if these exceed a critical threshold a sharp increase in intracellular calcium is seen and a contraction follows. Contractility can therefore be modulated by changing pacemaker potentials and the threshold for contraction. Prostaglandins enhance the liberation of intracellular calcium and oxytocin lowers the excitation threshold for contraction.

Cervical 'ripening'

In order for the fetus to be expelled the collagenous nature of the cervix changes or 'ripens.' There is a reduction in collagen and an increase in glycosaminoglycans (mucopolysaccharides). These are complex carbohydrates with a high amino sugar content. They have a high water content and occupy space, cushioning and lubricating. There is an influx of inflammatory cells and proinflammatory cytokines rise, the inducible form of nitric oxide synthase (iNOS) rises as does nitric oxide output. The pharmacological inhibition of iNOS prevents ripening. Prostaglandins also affect cervical ripening; both PGE_2 and $PGF_{2\alpha}$ increase the compliance of the cervix when given intravaginally or intracervically.

Parturition

During pregnancy, prostaglandin synthesis is inhibited, but at parturition this inhibition is lifted and prostglandins are synthesized and released, principally by the endometrium, but also by the myometrium, cervix, placenta and fetal membranes. This occurs because of alterations in the stability of membranes binding phospholipase A2 and the consequent production of arachidonic acid. Oestrogens promote phospholipase A2 production and progesterone inhibits it. Thus a rise in the oestrogen:progesterone ratio results in an increase in prostaglandin synthesis and release. Oestrogen also increases the number of myometrial oxytocin receptors and oxytocin stimulates the release of prostaglandin directly. A rising oestrogen:progesterone ratio is also responsible for induction of iNOS activity. Release of oxytocin from the posterior pituitary is produced by tactile stimuli from the reproductive tract. In addition to myometrial contraction it contributes to cervical softening in interactions with oestrogen/progesterone, prostaglandins and possibly nitric oxide. This is known as the Ferguson reflex and is facilitated by a high oestrogen:progesterone ratio.

In animals, the pattern of change and the role of these various 'hormones' are well described. A decrease in progesterone is brought about by regression of the corpus luteum, which produces progesterone. Luteal regression is induced by $PGF_{2\alpha}$ produced by the placenta, which in turn is dependent on an increased output of glucocorticoids produced by the fetal adrenal cortex. Fetal corticosteroids also induce oestrogen release by the fetal adrenal cortex and these enhance the placental production of $PGF_{2\alpha}$. Thus the oestrogen:progesterone ratio is increased, the 'block' on the myometrium is removed and the myometrial contractions commence, reinforced by oxytocin release induced by the Ferguson reflex. In some animals the main site of progesterone production is the placenta.

The precise mechanisms surrounding the induction of parturition in the human are less certain. Maternal progesterone does not generally fall at parturition but the fetal adrenal gland stimulates placental oestrogen synthesis via secretion of androgen precursors from a specialized zone of the fetal adrenal cortex, which regresses soon after birth. They form the major substrates for oestrogen synthesis by the placenta. In humans the onset of labour does not appear to be critically dependent on any consistent alterations in oestrogen synthesis, though this does not rule out the possibility of alterations in binding or local tissue concentrations. Likewise elevations in circulating $PGF_{2\alpha}$ concentrations have not been consistently described in humans in advance of labour though they do rise in amniotic fluid and increase as labour progresses. Myometrial oxytocin receptors increase, even in the absence of changes in the oestrogen: progesterone ratio.

Pharmacology

A number of drugs affect uterine function, directly and indirectly. Some are used in the management of labour (sympathomimetics, prostaglandins), others have effects that are usually regarded as undesirable (inhalational anaesthetic agents). Prostaglandins are used to induce abortion and are administered intravaginally. α-sympathomimetics (e.g. ergotamine, ergometrine) produce smooth muscle contraction. They cause the uterus to contract and are used in the control of uterine bleeding, both post-partum and following incomplete abortions. Syntocinon is a synthetic oxytocin. On the other hand, the β_2-sympthomimetics (terbutaline, salbutamol) produce smooth muscle relaxation and are used to delay the onset of labour. Inhalational anaesthetic agents depress smooth muscle contraction and given at concentrations in excess of 1 MAC can result in uterine haemorrhage. At less than 0.5 MAC they probably have little effect. The use of spinal-epidural local anaesthetics and/or opiates, or opiates administered systemically can affect the progress of labour, but have no direct effect on the uterine musculature. ◆

Applied Respiratory Physiology

Iain Campbell
James Waterhouse

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Science at Liverpool John Moores University. He qualified as an animal physiologist from Oxford University and gained his DPhil there. His research interests are circadian rhythms, with particular reference to jet lag and assessing the clock-driven components of measured circadian rhythms.

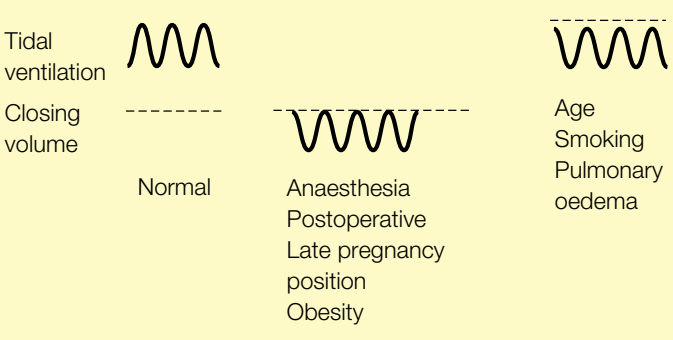
The respiratory system adapts in response to a number of physiological stimuli. This article briefly describes the effects of ageing, obesity, exercise, pregnancy, smoking, general anaesthesia and surgery on respiratory function. Adaptation to the chronic hypoxia of high altitude and to increased pressures (diving) are described elsewhere.

Functional residual capacity and closing capacity

Functional residual capacity (FRC) is the volume of air in the lungs at the end of a quiet tidal ventilation. It is the reservoir from which oxygen is replenished and via which carbon dioxide is eliminated and is one of the main influences on oxygenation. At rest, tidal volume is about 0.5 litre and FRC is 3 litres, therefore with each breath about 15% of the FRC is exchanged with the atmosphere. A decrease in FRC means a decrease in alveolar volumes, a decrease in ventilation–perfusion (V_A:Q) ratio and a worsening of the partial pressure of oxygen in the alveoli at the lung bases where the alveoli are the smallest and in arterial blood (PaO_2). The situation is made worse by small airway closure.

Small airways in the fit young healthy individual in the upright position normally start to close at 10% of vital capacity (i.e. above residual volume, but significantly below FRC). In these circumstances, small airway closure is not usually a factor in oxygenation. Airway closure affects oxygenation when closing capacity exceeds FRC; small airways start to close during normal tidal ventilation and gas becomes trapped distal to the collapsed airway. This is seen either when FRC is reduced or closing capacity elevated (Figure 1).

Functional residual capacity (FRC) and closing volume



Relative positions of closing volume and normal tidal ventilation (FRC) and their alteration under a variety of circumstances

1

Position: FRC is reduced in the supine position when the abdominal contents tend to push the diaphragm into the chest. The same occurs to a lesser extent when sitting.

Obesity is effectively a restrictive pulmonary defect and FRC is reduced. There is an inverse relationship between body size and PaO_2. In more severe cases (e.g. obesity with hypoventilation syndrome) severe hypoxaemia may develop accompanied by raised pulmonary artery pressures, oedema, congestive cardiac failure and carbon dioxide retention, but the more usual blood gas changes associated with obesity are mild hypoxaemia with a normal or slightly reduced partial pressure of carbon dioxide ($PaCO_2$).

Abdominal surgery: after open upper abdominal surgery the FRC decreases by 30% because of pain and spasm of the abdominal muscles and diaphragmatic splinting, and PaO_2 is reduced by about 20 mm Hg on the day after the operation. FRC is also reduced after lower abdominal surgery and the reduction in PaO_2 is about 10 mm Hg. A decrease in FRC and PaO_2 is also seen following laparoscopic surgery but to a lesser degree. PaO_2 returns towards normal values over the ensuing month as FRC recovers. $PaCO_2$ does not normally change unless opiate administration has produced hypoventilation.

Ageing: closing capacity increases as the lung ages and small airways narrow with the loss of supporting elastic tissue. Forced expiratory volume in 1 second (FEV_1) declines steadily from the age of about 30 years. With the decrease in FRC on lying down, closing volume impinges on normal tidal ventilation in the mid-forties and when sitting in the early sixties. The rise in closing volume results in a steady decline in PaO_2 of about 0.5 mm Hg/year. PaO_2 in the twenties is typically about 95 mm Hg and in the sixties about 80 mm Hg but with a wide spread of individual values. Most studies indicate that FRC does not change with age.

Chest disease: small airways close with the decrease in lung volume seen in restrictive chest disease (e.g. chronic bronchitis) and hypoxaemia can be severe. Small airways narrow with obstructive chest disease but FRC tends to increase and severe hypoxaemia is not often a major problem. Improvement in PaO_2 with small airway closure can sometimes be obtained with continuous positive airways pressure or positive end-expiratory pressure. With acute respiratory disease this may work best when applied before the alveoli distal to the closed airway have collapsed. Breathless patients can often be seen breathing out against pursed lips, thus applying their own positive pressure to expiration.

Smoking

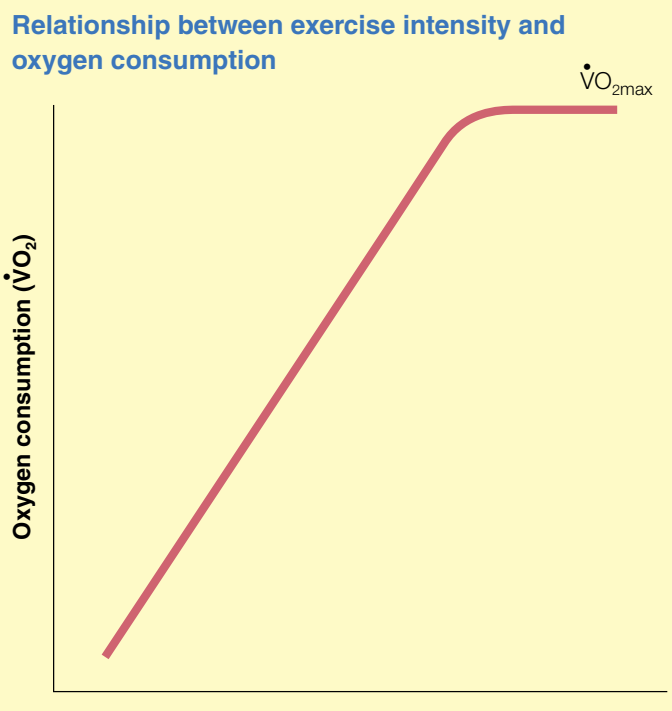
Smoking affects many aspects of respiratory function. Airway reflexes are more sensitive in smokers and inhaled histamine has an enhanced effect in producing more airway narrowing than it does in non-smokers. Smokers are also more sensitive to the irritant effects of inhalational anaesthetic agents. Mucus production is increased and the ciliary activity of the bronchial mucosa is impaired. Airway diameter is narrower due to bronchoconstriction and increased mucus production. This results in airway closure and disturbed ventilation–perfusion relationships. Airway narrowing is also reflected in a decrease in FEV_1. Dead space as a percentage of tidal volume (V_D/V_T) is increased and there is evidence of damage to the barrier function of the alveolar capillary membrane.

Exercise

Oxygen consumption

Oxygen consumption increases with exercise in proportion to its intensity. The respiratory and cardiovascular systems respond to meet the demand. As the intensity of exercise increases, oxygen consumption (VO_2) rises to a maximum; further increases in running speed, or power output on a cycle ergometer do not produce any further increase in VO_2 (Figure 2). This maximum VO_2 (VO_{2max}) is a measure of cardiorespiratory or aerobic fitness and is normally limited by cardiovascular function, specifically the maximum heart rate that an individual can achieve. Maximum heart rate normally declines with age, as does $VO_{2\,max}$.

Relationship between exercise intensity and oxygen consumption



Exercise intensity increases with for example speed of running or power output on a cycle ergometer. At $\dot{V}O_{2max}$ oxygen consumption does not rise with increasing exercise intensity

2

Resting VO_2 is about 250 ml/minute. VO_2 walking briskly is about 1 litre/minute and running at 12 km/hour about 3 litres/minute. VO_{2max} of a fit healthy 70 kg adult is about 3 litres/minute (42 ml/kg), of an athlete about 5 litres (70 ml/kg) and in elite athletes figures of 6 litres (85 ml/kg) have been recorded. VO_{2max} declines to about 2 litres at 70 years and may be reduced by inactivity by 50% of that expected. It can be increased by regular exercise, but most of the adaptations are cardiovascular, such as increased myocardial size and stroke volume and capillary proliferation in peripheral tissues. An improvement in cardiorespiratory fitness means that any task of a given exercise intensity takes place at a lower percentage of VO_{2max}. This puts less strain on the oxygen delivery systems (respiratory, cardiovascular and metabolic).

Respiratory reserves are larger than cardiovascular reserves. With exercise, oxygen extraction from the alveoli increases slightly and there is a decrease in mixed expired oxygen concentrations, but there is a much more marked extraction of oxygen from blood, and mixed venous PO_2 declines markedly. At rest, mixed venous blood is 70% saturated, but with severe exercise this may drop to 20%. This occurs over the steep part of the haemoglobin–oxygen dissociation curve so a large volume of oxygen is given up for a relatively small decrease in PO_2. Temperature is elevated and pH decreased so the dissociation curve moves to the right which assists unloading of oxygen in the periphery (*Anaesthesia and Intensive Care Medicine* **3:9:** 342).

Ventilation

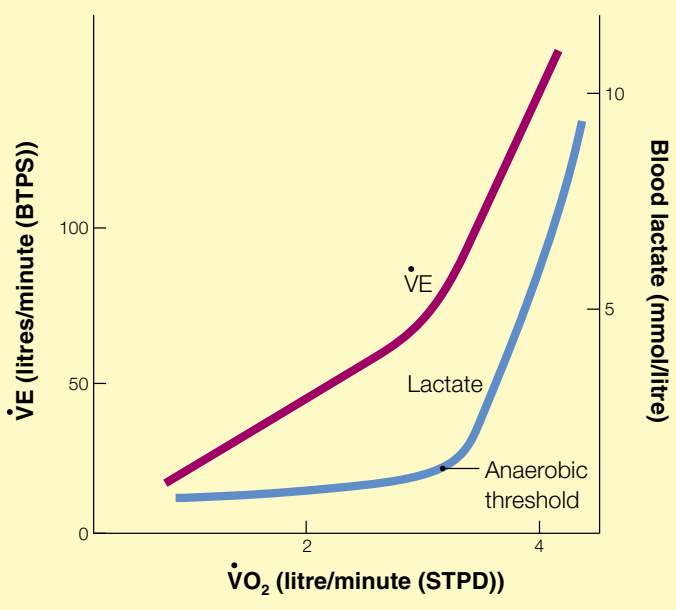
Maximum breathing capacity is about 200 litres/minute and cardiac output in severe exercise about 25 litres/minute. At VO_{2max} individuals are usually breathing at about 60% of their maximum breathing capacity (120 litres/minute), thus ventilation rises about 15-fold compared with a fivefold increase in cardiac output. Oxygen delivery mechanisms are able to keep pace with oxygen demand up to about 60% of VO_{2max}. At higher intensities, energy requirements are increasingly met by anaerobic mechanisms. Rates of muscle glycogenolysis and glycolysis exceed the rate at which pyruvate can enter the citric acid cycle and lactic acid accumulates at a rate proportional to the severity of the exercise. It diffuses from muscle into the general circulation and affects both the metabolic and respiratory responses. The exercise intensity (expressed as a percentage of VO_{2max}, the relative intensity) at which lactate accumulation starts is known as the anaerobic threshold.

Lactic acid is stronger than carbonic acid and therefore lactate accumulation due to anaerobic metabolism is associated with an increased loss of carbon dioxide, relative to oxygen consumption, in the expired air. Therefore the respiratory exchange ratio (R) rises (Figure 3). In severe exercise, lactate concentrations rise progressively; levels of 11–12 mmol/litre are seen and in elite athletes lactate may be as high as 20 mmol/litre. The R value may rise to 1.1 or 1.2. Lactate accumulation is one of the factors that limit sustained heavy exercise. Fit individuals produce less lactate than unfit ones but can also tolerate higher lactate concentrations.

Minute volume is normally well matched to exercise intensity and oxygen consumption. The oxygen equivalent of ventilation is the amount of ventilation per unit of oxygen consumed and is in the range 20–30 litres ventilation/litre of oxygen. It is remarkably constant up to the anaerobic threshold, but above that ventilation rises disproportionately because of the excess carbon dioxide production. At VO_{2max} about 80% of the oxygen consumed is used by exercising muscles. The percentage of VO_2 used by the respiratory muscles at rest is about 1–2%. This rises to 5% with moderate exercise and to 10% with severe exercise.

Ventilation rises immediately with the onset of exercise and like cardiac output may even occur before the exercise starts. The control of ventilation during exercise is not entirely understood, but it seems to be remarkably efficient. Chemoreceptors become more sensitive to hypoxia, possibly through local stagnant hypoxia mediated via the sympathetic nerves to the chemoreceptors. Blood gases do not normally change much from the resting state. Chemoreceptor activity does not account for much of the increase in ventilation. Large disturbances in blood gases occur on the venous side but no chemoreceptors have been found in the venous side of the vasculature and it is thought that afferents arising from the exercising muscles and joints may play a major role in stimulating ventilation as well as CNS activation due to stress or excitement.

Relationship between oxygen consumption ($\dot{V}O_2$) and pulmonary ventilation ($\dot{V}E$) at increasing intensities of exercise



$\dot{V}E$ starts to increase at the anaerobic threshold where significant amounts of lactate start to accumulate. Carbon dioxide production increases to compensate for lactic acidosis and this results in increased $\dot{V}E$

BTPS, body temperature, ambient pressure and saturated with water vapour; STPD, standard temperature and pressure dry

3

With severe sustained exercise the oxygen consumption may continue to rise despite the intensity of the exercise, such as speed of running or power output on a cycle ergometer, remaining the same. This is known as the 'slow component' of oxygen consumption. Why it occurs is unknown. Oxygen consumption declines when exercise ceases, but it does so gradually as the oxygen debt is paid off (i.e. accumulated lactate is oxidized and other energy stores such as high energy phosphates are replenished). As lactate is removed, carbonic acid levels are replenished and the respiratory exchange ratio may fall to as low as 0.5.

Diffusion

The diffusing capacity of the lung is well able to cope with exercise. The pulmonary capillaries expand (distension) and unperfused capillaries open up (recruitment) particularly in the underperfused upper part of the lung and the volume of blood in the pulmonary capillaries increases. Pulmonary arterial and venous pressures rise and the amount of V_A/Q mismatch diminishes because of the more uniform blood distribution. Diffusing capacity as a consequence increases about fivefold. Blood gases are thus normally unaffected by exercise; PaO_2 is usually normal and $PaCO_2$ may be reduced slightly by hyperventilation. There are problems with oxygenation during exercise at altitude, when the driving pressure of oxygen across the alveolar capillary membrane is diminished, and oxygen in the alveoli may not have equilibrated by the time the blood leaves the capillary.

Anaesthesia (Figure 4)

Respiratory control: inhalational anaesthetic agents affect responsiveness to both carbon dioxide and to hypoxia. The effect on carbon dioxide responsiveness is predictable, with a dose-dependent depression of the ventilation response curve. Inhalational anaesthetic agents also depress the hypoxic ventilatory response in doses as low as 0.1 minimum alveolar concentration, but the response is more variable than the response to carbon dioxide. Much of the variation can be ascribed to methodological differences in the studies reported, dependent on whether $PaCO_2$ was maintained constant or had been allowed to change. Hyperventilation induced by hypoxia results in hypocarbia and this can depress the response to the hypoxia. Attenuation of the hypoxic ventilatory response is important in individuals dependent on their hypoxic drive, such as those in chronic respiratory failure or at altitude or, potentially, in the early postoperative period.

Changes in respiratory function associated with general anaesthesia

- Depression of hypoxic and hypercarbic responses and hypoventilation
- Upper airway obstruction
- Decrease in functional residual capacity
- Atelectasis
- Impairment of gas exchange
  - Increased dead space
  - Increased venous admixture

4

Respiratory muscles: anaesthetic agents relax the muscles of the pharynx and depress the muscles of ventilation. In the supine position, the soft palate falls back and occludes the nasopharynx; the tongue tends to do the same but does not occlude the pharynx completely. Activity of the intercostal muscles is depressed leading to decreased thoracic excursions, but phasic activity of the diaphragm is maintained. This can result in paradoxical ventilation with diaphragmatic contraction causing expansion of the abdomen and lower ribcage, while the upper ribcage is drawn in owing to the decreased intrapleural pressure and the lack of support from the ribcage respiratory muscles. General anaesthesia can cause phasic activity of the abdominal muscles in expiration, not normally seen in the conscious individual. The reason is unknown and it does not appear to have any useful function.

FRC falls during anaesthesia by about 15–20% with or without muscle relaxants. It occurs within a few minutes of induction but does not fall beyond that and recovers within hours of the end of anaesthesia. The cause is uncertain but it has been suggested that the diaphragm, particularly the dependent posterior part moves cephalad and decreases lung volume. Blood shifts into the pulmonary circulation from the periphery and this may decrease thoracic lung volume.

Atelectasis: alveoli tend to collapse under anaesthesia, most commonly in the dependent lung regions (i.e. posteriorly and close to the diaphragm). The fall in FRC decreases alveolar volume and may cause airway trapping, reducing V_A/Q ratios and rendering alveoli liable to collapse. This is worse if the patient breathes highly soluble gases such as nitrous oxide or 100% oxygen. Even a few minutes breathing pure oxygen predisposes to the condition; the alveoli fill with oxygen but mixed venous PO_2 alters relatively little because of the nature of the haemoglobin-dissociation curve. There is thus a huge gradient between alveolus and blood, and absorption takes place rapidly. A 'skeleton' of relatively insoluble nitrogen delays the process.

Gas exchange is impaired. Alveolar dead space increases and there are increases in shunt and in V_A/Q mismatch. The reason for the increase in alveolar dead space is unknown. Venous admixture in the healthy individual normally amounts to about 1–2% of cardiac output. Under general anaesthesia this increases to 10%. About half of this is due to atelectasis, the remainder to a deterioration in ventilation–perfusion relationships with the increase in alveolar dead space already referred to and the redistribution of perfusion to areas of poor ventilation. This deterioration in venous admixture with general anaesthesia appears to worsen with age. Inhalational anaesthetics inhibit hypoxic pulmonary vasoconstriction and this also contributes to the deterioration in gas exchange.

Preoxygenation

Preoperative oxygenation is performed routinely if the patient is to be paralysed and difficulties are anticipated in securing the airway, or in the presence of a full stomach. Inhaling 100% oxygen washes nitrogen out of the lungs. Classically, the time to complete denitrogenation is 7 minutes, but this is an exponential function and is about 80% complete after only 1 minute. The store of oxygen in the functional residual capacity increases over this period from about 0.5 litres to about 2 litres. A similar increase in stores of oxygen in the FRC can be produced by two or three vital capacity breaths. This degree of preoxygenation supports about 3 minutes of apnoea time before arterial saturation drops to 90%. 3 minutes' preoxygenation significantly increases the oxygen stores in other body tissues, and apnoea times in excess of 5 minutes are observed before saturation drops to 90%.

Pregnancy and the fetus

Pregnancy

Fluid balance changes in pregnancy, with fluid retention caused by oestrogen and an increase in cardiac output. Oxygen consumption rises in proportion to the increase in body weight. Minute volume rises by 40% owing to an increase in tidal volume; $PaCO_2$ drops to 30 mm Hg and PaO_2 rises by 5–10 mm Hg. This is attributed to an increase in progesterone levels which rise sixfold during pregnancy and is associated with an increased sensitivity of the central chemoreceptors to carbon dioxide and an increase in steepness of the ventilation/$PaCO_2$ curve (*Anaesthesia and Intensive Care Medicine* **3:9:** 345). Sensitivity to hypoxia is also increased. These changes facilitate gas exchange for the fetus. The increase in ventilation is seen at the start of the second trimester.

In the third trimester the enlarging uterus interferes with the mechanics of ventilation. The diaphragm is pushed cephalad and FRC is reduced by about 25–30%. This effectively reduces the largest store of oxygen in the body and renders the pregnant woman susceptible to hypoxia. Despite this, arterial oxygen saturation is normal; the potential problems arise perioperatively during intubation.

Fetal respiration

The lungs are present in the fetus in a functional state from about 24–26 weeks of pregnancy. At birth only about 15% of the alveoli are present and development continues up to about 2 years. Fetal lung contains liquid secreted by alveolar cells maintained at a positive pressure relative to the amniotic fluid. This maintains the lungs in a partially expanded state. Breathing movements are present from the second trimester.

Fetal circulation

The fetal circulation is different from that of the adult. Blood enters the inferior vena cava from the umbilical vein via the sinus venosus in the liver where it is joined by the portal vein. Umbilical vein blood has a partial pressure of oxygen (PO_2) of 30 mm Hg and is depressed to about 25 mm Hg by blood from the portal vein, but fetal haemoglobin has a dissociation curve to the left of adult haemoglobin and therefore for a given PO_2 is better saturated (80% in the umbilical vein). Only about 10–15% of the blood entering the right side of the heart goes to the lungs. The rest passes to the left side of the heart via the foramen ovale or traverses the right side of the heart to the pulmonary artery and enters the aorta, via the ductus arteriosus, beyond the origin of the carotid arteries. Inferior vena caval blood is the best oxygenated (about 67%) and passes predominantly via the foramen ovale to the brain. Blood returning to the right atrium from the brain goes via the pulmonary artery and the ductus arteriosus to the aorta to supply the lower part of the body. The PO_2 of blood in the aorta is about 20–25 mm Hg (about 60% saturated) and the PCO_2 about 40–45 mm Hg. Blood returns to the placenta via two umbilical arteries that arise from the iliac vessels.

Neonatal respiration

Normal infants take their first breath within 20 seconds of birth and regular breathing is established within 90 seconds. Chest compression during delivery followed by recoil of the ribcage contribute to drawing air into the lungs but major stimuli are probably the cooling of the skin and the nonspecific mechanical stimulation of being born. As air enters the lungs, large surface tension forces have to be overcome and with the first breath intrapleural pressures fall to atmospheric (A) – 40 cm H_2O. FRC is achieved in a few moments but it may be several days before the whole lung is ventilated evenly.

There are massive changes in pressure in the two circulations. Pulmonary circulatory pressure falls partly as a result of chest expansion and partly because of changes in blood gases, possibly mediated by nitric oxide. There is an increase in resistance of the systemic circulation; left atrial pressure rises as a result of which the foramen ovale closes. The ductus arteriosus closes within a few minutes of birth in response to the increased PO_2; prostaglandins are also involved. ◆

Barometric Pressure: Extremes and Challenges

Karl New
Damian M Bailey
Iain Campbell

Karl New is a Postgraduate Research Physiologist undertaking a PhD programme at the University of Glamorgan, South Wales, UK. His research is centred on exercise and hypoxic physiology looking at the roles of oxygen-free radicals, nitric oxide and further metabolic aspects of eposure to hypoxic environments.

Damian M Bailey is Reader in Physiology at the University of Glamorgan, South Wales, UK. He was previously employed as Senior Research Physiologist at the British Olympic Medical Centre, Harrow, UK. His current research interests include the pathophysiology of high altitude related illness and the role of oxygen-free radicals in cellular oxygen sensing.

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

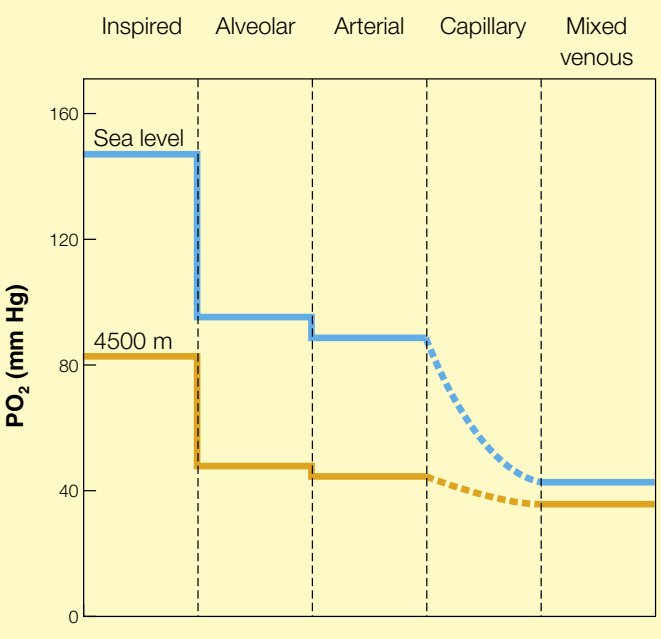
Oxygen sustains life in physiologically controlled amounts, yet is fatal in excess. Exposure to high altitude and ocean depths provide extremes of barometric pressure and oxygen availability.

Low pressures – high altitude

The decrease in barometric pressure with altitude means that there is less atmosphere pressing down on us. The concentration of oxygen in atmospheric air at 20.9% is independent of altitude, so the inspired pressure (P_IO_2) is a function of barometric pressure only and is given by the equation: $P_IO_2 = 0.209$ (barometric pressure – saturated water vapour pressure at body temperature (47 mm Hg)).

The decrease in P_IO_2 produces a decrease in the flux of O_2 to the tissues (Figure 1), due to a lowered partial pressure of O_2 in alveolar gas (P_AO_2). The movement of gases relies on a concentration gradient from high to low pressure. The partial pressures of O_2 and CO_2 determine the driving force of the gas. At altitude, this flux is diminished because of the decreased number of molecules per unit volume. The opposite is true when breathing compressed air under water.

Oxygen cascade at sea level and at 4500 m



Note reductions in the inspired alveolar gradient due to hyperventilation, alveolar–arterial PO_2 difference due to improved gas transfer and arterial–venous PO_2 difference due to increased capillary density in peripheral tissue

1

Hypoxia – the symptoms vary depending on altitude. Impairment in night vision occurs at about 1500 m; tingling in the mouth and fingers at 4000–5000 m. On acute exposure to a barometric pressure equivalent to the height of Mount Everest, consciousness is lost after 2 minutes. Exposure to the barometric pressure on the summit of Mount Everest is not fatal to the successful climber because he acclimatizes over the gradual ascent. Maximal oxygen consumption (VO_{2max}) is diminished at altitude. Deterioration occurs at about 1500 m, reducing by 5% for each increase of 500 m above sea level; this rate becomes more profound at higher altitudes. A healthy climber on the summit of Mount Everest has a VO_{2max} as low as 15 ml/kg/minute, similar to that of a congestive heart failure patient at sea level.

Respiratory system

Oxygen uptake within the pulmonary capillary – in the healthy lung, the first limitation at altitude is the reduced diffusive (partial) pressure of O_2. At sea level, at rest, and with moderate exercise, oxygenation in the pulmonary capillary occurs rapidly. It takes place in two stages: diffusion through the blood–gas barrier (capillary membrane, plasma and intracellular); and reaction with haemoglobin (Hb). At sea level, blood arrives in the lung with a PO_2 of 40 mm Hg, this rises rapidly to equilibrate with P_AO_2 when it has traversed only one-third of the capillary. There is a negligible PO_2 difference between alveolar gas and end-capillary blood. This indicates no diffusion limitation. On the summit of Mount Everest, where P_AO_2 is 35 mm Hg, blood enters the lung with a PO_2 of 21 mm Hg. The PO_2 rises slowly along the pulmonary capillary, reaching a value of 28 mm Hg. There is thus a large PO_2 difference (7 mm Hg) between alveolar gas and end-capillary blood, which increases with exercise.

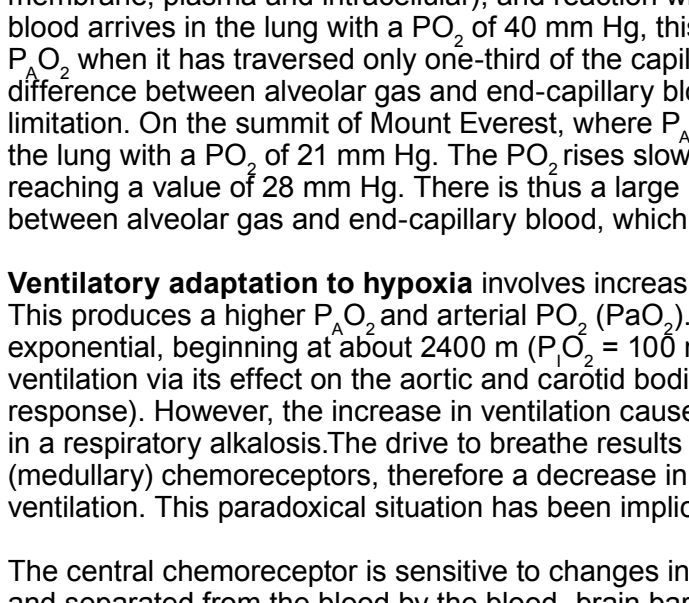
Ventilatory adaptation to hypoxia involves increasing the minute ventilation. This produces a higher P_AO_2 and arterial PO_2 (PaO_2). The increase in ventilation is exponential, beginning at about 2400 m (P_IO_2 = 100 mm Hg). Hypoxia stimulates ventilation via its effect on the aortic and carotid bodies (the hypoxic ventilatory response). However, the increase in ventilation causes $PaCO_2$ to decrease, resulting in a respiratory alkalosis.The drive to breathe results from PCO_2 acting on the central (medullary) chemoreceptors, therefore a decrease in PCO_2 leads to a reduction in ventilation. This paradoxical situation has been implicated in acute mountain sickness.

The central chemoreceptor is sensitive to changes in PCO_2 and pH. It is bathed in CSF and separated from the blood by the blood–brain barrier, which is impermeable to H^+. The H^+ concentration is determined from the buffering of CO_2, which passes freely into the CSF, by bicarbonate. This relationship is defined by the Henderson–Hasselbalch equation.

During the first days at altitude, blood and CSF bicarbonate decrease through increased excretion of bicarbonate by the kidney, or active transport of bicarbonate from the CSF. The decrease gradually restores pH towards normal, resulting in ventilation steadily increasing over the first few days at altitude. The second form of respiratory acclimatization is an increase in the sensitivity of the respiratory centre to PCO_2. Higher ventilation is thus achievable in the face of lower PCO_2 values.

Hb oxygen affinity*:* in the range of PO_2 normally encountered, the binding and unloading of oxygen to Hb usually occurs over relatively flat portions of the oxyhaemoglobin dissociation curve (Figure 2). Thus, at a PO_2 of 50 mm Hg (at about 4300 m) Hb maintains a saturation of about 85%. However, O_2 delivery and gas exchange over the steep part of the curve predispose to diffusion limitation. Also, the polycythaemia of high altitude increases blood oxygen concentration per unit change in PO_2. Increasing Hb affinity for oxygen by moving the curve to the left increases the loading of O_2 in the pulmonary capillary under conditions of diffusion limitation at high altitude, but decreases unloading of O_2 in the systemic capillaries to the working tissues. At altitude, the low $PaCO_2$ moves the curve to the left. An increase in 2,3-diphosphoglycerate, a by-product of the glycolytic pathway under hypoxic conditions, tends to move it back to the right, but the effect of the respiratory alkalosis predominates.

Relative positions of the haemoglobin and myoglobin dissociation curves



2

Cardiovascular response

Heart rate – acute exposure to altitude causes an increase in resting and sub-maximal heart rate. Acclimatization to high altitude generally leads to a return in resting heart rate to sea-level values but maximal heart rate is reduced. Theories include an adaptation that spares myocardial workload under hypoxaemic conditions and a relationship between circulating catecholamines and down-regulation of myocardial β-adrenergic receptors.

Stroke volume is reduced after a few weeks' acclimatization at altitude and for a given pulmonary filling pressure oxygen breathing does not rectify the decrement.

Cardiac output during acute hypoxia is increased at rest and during sub-maximal exercise compared with normoxia. In well-acclimatized lowlanders, cardiac output returns to its sea level–work intensity relationship. Increasing cardiac output at high altitude has no effect on VO_{2max} perhaps because of diffusion limitation in the lung and systemic tissues. The return of cardiac output to near sea-level values may be attributed to the polycythaemia associated with altitude acclimatization as the increase in the oxygen-carrying capacity of the blood may be adequate to sustain cellular O_2 needs.

Systemic and pulmonary arterial blood pressure do not change up to altitudes of 4600 m. However, acute hypoxia results in pulmonary hypertension due to an increase in pulmonary vascular resistance. Pulmonary hypertension persists and is also present in high-altitude natives. O_2 breathing relieves the pulmonary hypertension caused by acute exposure but does not alter the pulmonary hypertension found in acclimatized subjects or highlanders. The resting pulmonary artery pressures increase considerably during exercise at altitude. Pulmonary vasoconstriction directs blood away from hypoxic regions of the lung and improves ventilation–perfusion inequalities. Pulmonary hypertension results in right ventricular hypertrophy in acclimatized lowlanders and high-altitude natives.

Haematology – red cell mass increases with altitude, maintaining O_2 content at sea-level values (20 ml of O_2/100 ml of blood) up to about 5300 m. This increased carrying capacity acts as a countermeasure to the decreased SaO_2. The initial increase in packed cell volume and Hb is due to a reduction in plasma volume not an increase in the number of circulating red cells. Hypoxia causes the release of erythropoietin from the kidneys and liver, which stimulates the bone marrow and increases the red cell mass over days to weeks. After several weeks, plasma volume increases but remains slightly below that at sea level. Blood volume increases.

Passage of oxygen into the cell – oxygen diffuses from the Hb molecule to the capillary wall. Diffusion distances in tissues are typically higher than at the blood–gas membrane in pulmonary capillaries. During exercise, when an increased flux of oxygen is required, additional capillaries open, reducing the diffusion distance and increasing the surface area of the capillaries. Once in the cell, oxygen transport is aided by facilitated diffusion via myoglobin. Myoglobin has similar properties to Hb, though it has a hyperbolic curve (Figure 2) with a very low P_{50} of about 5 mm Hg compared with 27 mm Hg for Hb. This assists in the release of oxygen at the low partial pressures found in the cells. The PO_2 around the mitochondria is very low.

Skeletal muscle

Capillary–fibre interface – capillary density in the tissues increases with exposure to high altitude but whether this is a true increase or a relative decrease in fibre size is uncertain.

Myoglobin concentration and mitochondria – hypoxia increases myoglobin concentration. Adaptation to moderate altitude (4500 m) increases mitochondrial number but over 6000 m, mitochondria decrease.

Biochemical pathways – at the mitochondria, oxygen is used to generate adenosine triphosphate by the electron transport chain on the inner mitochondrial membrane and the Krebs' cycle in the cytosol of the mitochondria. Anaerobic glycolysis provides a valuable source of energy in anoxic conditions. Exercise training and exposure to moderate altitude (4500 m) increase key enzymes in the two aerobic pathways whereas exposure to higher altitudes causes a decrease.

Other adaptations
The authors' laboratory has investigated further adaptations at high altitude. A mass action effect has been explained for the exercise-induced oxidative stress, whereby an increase in flux of O_2 through the mitochondria produces the superoxide radical. Paradoxically, when exposed to intermittent hypoxia, free-radical generation increases independently of the exercise undertaken. During a prolonged stay at high altitude, these radicals may contribute to the pathogenesis of high-altitude illness. The prophylactic benefits of antioxidant supplement-ation against acute mountain sickness add further support to these findings.

Acute mountain sickness (AMS): benign symptoms, including frontal headaches, lassitude, insomnia, emesis, fatigue, irritability, occasional photophobia and peripheral oedema, normally subside within 4–5 days but may develop into the life-threatening malignant forms of high-altitude pul-monary (o)edema (HAPE) and high-altitude cerebral (o)edema (HACE). The mechanisms of AMS are unknown. It is a self-limiting condition seen after rapid ascent to altitude. Once the symptoms have subsided they do not recur at that altitude. Its pathogenesis is complex, the prominent aspects are the rate of ascent and the elevation reached, but with wide individual variations.

The hypoxic ventilatory response has been implicated in AMS. Increased vascular permeability may precipitate subclinical pulmonary oedema, which exacerbates arterial hypoxaemia. Fluid balance and water retention are also critical. Individuals prone to AMS usually respond to altitude exposure with an antidiuresis, which would expand plasma and extracellular volume. The symptoms are thought to be the result of cerebral oedema and raised intracranial pressure. Damage to muscle membranes associated with free radicals is also implicated.

A controlled slow rate of ascent to high altitude reduces AMS. Above 3000 m, each night should not be spent higher than 300 m above the last with a rest day every 2–3 days. Acetazolamide, which functions as a respiratory stimulant by inhibiting carbonic anhydrase, and effectively producing a metabolic acidosis, or offsets the respiratory alkalosis, is effective. Increased ventilation improves arterial hypoxaemia. Nutritional supplementation with antioxidants may also be useful.

HAPE is a potentially lethal form of AMS. It presents at a wide range of altitudes from 2000 to 7000 m. The patient shows signs of AMS that develop into tachycardia, tachypnoea, crackles at the lung bases and a dry cough that becomes productive. A more pronounced pulmonary pressor response is a constitutional risk factor and susceptibility has a genetic basis in the variation of the angiotensin-converting enzyme gene. Patients with HAPE have a high pulmonary artery pressure (about 100 mm Hg) and normal wedge pressures. Other factors proposed include uneven pulmonary vasoconstriction and perfusion, stress failure of pulmonary capillaries, venular constriction, arterial leakage, multiple pulmonary emboli, increased vascular permeability and inflammation.

HACE is a severe malignant form of AMS which progresses to ataxia, hallucinations, coma and eventually death. Blood counts and biochemistry are usually normal. The relative proportions of the brain to the cranial cavity may be critical in the disease process as is the vascular integrity of the blood–brain barrier.

High pressures

While nobody lives permanently under water, SCUBA (self- contained underwater breathing apparatus) diving is a popular activity and professional divers may live under high environmental pressures for several weeks. Civil engineers building tunnels may also work in pressurized chambers. The two basic physiological problems are the effect of pressure and its effect on gas solubilities.

Pressure
Under water, pressure increases by 1 atmosphere for every 10 m of depth (at a depth of 30 m a diver is exposed to 4 atmospheres). The body is composed largely of incompressible solids and water. However, gas is present in the lungs, the gastrointestinal tract, the sinuses and inner ear. Gases follow Boyle's law: at constant temperature, volume (V) is proportional to 1/pressure (P) or PV is a constant, so for an increase in pressure of 1 atmosphere (10 m depth) the volume of a fixed mass of gas halves. For an individual to breathe under water, gases have to be supplied at the ambient pressure at depth. In an individual breathing via a snorkel, the work of breathing is increased because the water pressure compresses the chest. To expand the lungs against this restriction the work of the respiratory (inspiratory) muscles has to increase. The greatest pressure the respiratory muscles can generate is about 90 cm H_2O. When water pressure exceeds this (at a depth of 1.2 m) inspiration from the surface is impossible. In practice, divers breath from a pressurized source, either compressed air from cylinders carried on their back, via a demand valve, or air is supplied via hoses from the surface at a pressure equal to that at which the diver is working. In these circumstances, transthoracic pressure (i.e. the difference between intra-alveolar and water pressure at depth) is normal. In a breath-holding dive from the surface, the lung volumes are compressed with the increasing pressure, then re-expand to their original volume on ascent. If the diver goes so deep that the water pressure exceeds the intrathoracic pressure the lungs are damaged, developing congestion, oedema and haemorrhage.

It is important when breathing under pressure that the diver breathes normally on ascent (i.e. he continues to exhale). Gas expands and if exhalation does not occur (i.e. he holds his breath) alveoli rupture with the development of a pneumothorax, mediastinal and tissue emphysema (barotrauma). Provided the mass of gas in the gastrointestinal tract remains constant the volume shrinks on descent and re-expands to its former volume on ascent. There are some relatively inaccessible gas spaces in the inner ear and the sinuses. These have to equilibrate with the increased pressure on descent via the Eustachian tube. If these structures cannot equilibrate (e.g. due to mucosal swelling), capillaries may rupture or the tympanic membrane may burst. With increasing pressure, gas density rises and the work of breathing goes up. Airflow may become turbulent and the work of breathing increases further. The increased density also slows intra-alveolar diffusion, and gas exchange is impaired. Maximum ventilatory volume and VO_{2max} diminish, the latter due to respiratory causes.

Cardiovascular responses – normally there is a hydrostatic pressure gradient in the upright individual with fluid pooling in the lower half of the body. However, when submerged, the surrounding pressure forces about 500 ml of blood centrally, raising right atrial pressure and cardiac output. There is an improvement in ventilation–perfusion relationships and the pressure receptors in the cardiovascular system detect the increased volume. This promotes a diuresis mediated via a decrease in antidiuretic hormone and increased atrial natriuretic peptide. Immersion in cold water, specifically exposure of the face to cold water, also induces the 'diving reflex'. The heart rate falls and peripheral vasoconstriction occurs.

High pressures and gas solubility
Although the tissues are compressible compared with gas volumes, lipids are more compressible than water, and this disturbs membrane function. The result is the high-pressure neurological syndrome. Symptoms include tremor, decreased manual dexterity, loss of attention and nausea. It is seen at depths over 200 m and is worse when the rate of descent is rapid. The symptoms may be lessened by adding nitrogen to the helium/oxygen mixtures normally breathed at these depths.

Nitrogen narcosis occurs when breathing compressed air at depths over 30 m. The symptoms resemble alcohol intoxication and include euphoria, irrational behaviour, reduced manual dexterity and mental function. They are marked at depths below 50 m. Below 90 m, the diver approaches unconsciousness. The cause is thought to be an effect on cell membranes producing narcosis, similar to that seen with anaesthetic gases.

Oxygen toxicity – oxygen is toxic under pressure. 100% oxygen at atmospheric pressure is toxic when breathed for over 9–10 hours. It affects the CNS and lungs. Neurons become hyperexcitable causing convulsions, vertigo, paraesthesia, twitching and nausea. In the lungs, pulmonary oedema and intra-alveolar haemorrhages occur due to disruption of endothelial and epithelial cells. The onset is hastened by increasing depth and is due to the high PO_2 itself, so occurs with compressed air. At a P_IO_2 of 1500 mm Hg, symptoms occur after 5 hours. Below 50 m divers usually breathe a mixture of helium and oxygen. Helium is less soluble than nitrogen so problems of nitrogen narcosis are avoided, but because of oxygen toxicity, the percentage of oxygen in the mixture is decreased the deeper the diver goes, in order to keep the P_IO_2 below 300 mm Hg. At 300 m the oxygen content of the mixture is 1.26%. Helium is less dense that nitrogen and the work of breathing is decreased.

Decompression – when gases are breathed under pressure they dissolve in body fluids. Breathing air at sea level, the body contains about 1 litre of nitrogen. When breathing compressed air, this increases by a further 1 litre for every 10 m increase in depth. Equilibration takes 6–8 hours and depends on the depth, and thus the amount of nitrogen dissolved, and on the vascularity of the tissues supplied. When ascent is too rapid, bubbles of dissolved gas appear in the tissues and circulation. The problem lies with the inert gases nitrogen and helium; helium has 40% of the solubility of nitrogen. Oxygen is used by the tissues and CO_2 is not a problem because there is none in the inspired air. Signs and symptoms may appear up to 48 hours after the dive. They include joint pains due to bubbles in the relatively poorly perfused joint and bone tissues, dyspnoea and cough due to bubbles trapped in the lungs and a combination of motor and sensory deficits due to bubbles in vessels supplying the spinal cord. Avascular bone necrosis may be a long-term problem.

Decompression sickness is avoided by slow ascent, the precise rate depending on the depth and duration of the dive, and controlled in accordance with published tables. This may be done in a pressurized chamber and if the individual is at depth for a prolonged period 'saturation' techniques may be used where he lives under pressure for several weeks. 'Saturation' means the gases dissolved in the body equilibrate fully with those of the environment. He then requires several days to de-compress. The likelihood of decompression sickness is less when breathing helium. It is increased if the diver immediately exposes himself to hypobaric pressures (i.e. goes to altitude or flies).

Other problems
Under water, the diver is effectively weightless so greater effort is required to perform manual tasks (and VO_{2max} is reduced). Cold may be a physiological stress because the thermal conductivity of water is greater than air. Helium is a better conductor than nitrogen. Deep-sea divers usually need heating in their diving suits. ◆

Fluid Balance and Non-respiratory Functions of the Lung

Iain Campbell
James Waterhouse

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Science at Liverpool John Moores University. He qualified as an animal physiologist from Oxford University and gained his DPhil there. His research interests are circadian rhythms, with particular reference to jet lag and assessing the clock-driven components of measured circadian rhythms.

Fluid balance

The factors affecting fluid balance in the lung are similar to those governing fluid balance in peripheral tissues. There is a balance between the oncotic (colloid osmotic) pressures and the hydrostatic pressures in the capillaries and in the interstitial tissues. Forces pushing fluid out of the pulmonary capillaries are the hydrostatic pressure in the capillary minus the hydrostatic pressure in the interstitium. The pressures pulling fluid into the pulmonary capillary are the oncotic pressure of the blood minus the oncotic pressure of the interstitium.

The oncotic pressure in the blood is 28 mm Hg; the oncotic pressure of the interstitial fluid in the lung is unknown, but the oncotic pressure of lung lymph is 20 mm Hg. Particular features of the pulmonary circulation are that the hydrostatic pressure at the base of the lung is higher than at the apex. Although the hydrostatic pressure of the interstitium is uncertain, some measurements have shown it to be below atmospheric.

The net pressure is thought to be outwards and normally there is a net lung lymph flow of about 20 ml/minute. Lymphatics flow in the perivascular and peribronchial tissues. In the early stages of pulmonary oedema, as a result of fluid overload, left ventricular failure or increased permeability of the pulmonary capillary membrane, these peribronchial and perivascular tissues become engorged (interstitial oedema). When the drainage capacity of the interstitium is exceeded, fluid passes into the alveoli. If an alveolus floods completely, oxygenation ceases.

Non-respiratory lung functions

The lung functions primarily as an organ of gas exchange. It is the sole recipient of the output of the right ventricle and has a huge area of delicate epithelium and pulmonary endothelium potentially exposed to the atmosphere. Endothelium, including pulmonary endothelium, is extremely active metabolically. In addition to its primary function the pulmonary circulation acts as a reservoir, a filter and a site of metabolism for endogenous and exogenous substances.

Reservoir

The pulmonary circulation is able to act as a reservoir because of its distensibility. It can accommodate the large shifts in blood volume that occur during the day, for example the increase in venous return when an individual lies down or undertakes dynamic exercise. One of the main factors governing cardiac output is venous return and ventricular filling pressures; the ability of the pulmonary circulation to accommodate varying volumes of blood means it can act as a reservoir and allows fine adjustment of left ventricular filling.

Filter

The pulmonary circulation receives the entire blood volume on average once a minute and is therefore well placed to act as a filter for particulate matter in the systemic venous return. Without this filter the systemic circulation would be at risk of embolization, particularly the cerebral and coronary circulations.

Pulmonary capillaries are about 7 μm in diameter, though particles much larger than this (e.g. air and fat emboli) have been known to gain access to the systemic circulation via the pulmonary vessels. 25% of the population have a patent foramen ovale which is normally kept closed by the higher pressures on the left side of the heart. Circumstances that raise right-sided pressures (e.g. a Valsalva manoeuvre) can open it. There may also be arteriovenous shunts in the lung.

Because of its huge area, the pulmonary circulation is well adapted to coping with microemboli, but a large venous embolus that blocks a significant proportion of the circulation has an adverse effect on ventilation–perfusion relationships. Microemboli, blocking significant numbers of pulmonary capillaries, may also cause neutrophil activation with increases in endothelial permeability and alveolar oedema. The lung has proteolytic, fibrinolytic and anti-coagulant systems (e.g. plasmin activator, thromboplastin, heparin) to clear its vessels of thromboemboli, and it may also have a role in overall blood coagulability.

Inhaled substances: the alveolar capillary membrane is thin and leaves the lung open to a number of airborne hazards such as inhaled irritants, chemicals and infective agents. Particles of 5 μm and above impact on the mucous membrane of the airways, in the nose and large airways, but particles of 1 μm and below can penetrate to the alveoli. Particles impacting on the bronchial mucosa are swept into the pharynx by the flow of mucus. Neutrophils and macrophages deal with infecting organisms in the bronchial tree and these cells can also move to the pulmonary capillaries. Activation of neutrophils involves release of proteases, particularly elastase and trypsin, which may cause lung damage. Proteases are normally conjugated by α_1-antitrypsin in plasma, but those in whom α_1-antitrypsin is deficient are vulnerable to lung damage and the development of emphysema.

Metabolic functions

Two important substances synthesized in lung and bronchial tissue are phospholipids, which form components of surfactant and are secreted by type II alveolar epithelial cells, and the mucopolysaccharides of bronchial mucus.

Metabolism of toxic substances follows a two-stage pattern similar to that seen in the liver. Oxidation, mostly by P450 mono-oxygenase and to a lesser extent by a flavin-based mono-oxygenase, is followed by conjugation to glucuronide or glutathione. The lung is one of the main extrahepatic sites of cytochrome P450 oxidation.

Despite an apparent paucity of organelles, the cells of the pulmonary endothelium are active. A number of substances are removed or inactivated during passage through the lungs. 30% of noradrenaline (but not adrenaline) is removed by pulmonary endothelium. Catecholamines in all tissues are metabolized by monoamine oxidase and catecholamine-O-methyl-transferase, but in the pulmonary vasculature it appears to be the uptake site for noradrenaline that makes it different from adrenaline. Dopamine is not metabolized. About 98% of 5-hydroxy-tryptamine (5-HT) is removed by the pulmonary circulation as is acetylcholine, though its half-life in the circulation is about 2 seconds. Histamine is not affected. Angiotensin I is the major peptide hormone affected by passage through the lungs where it is converted to angiotensin II by angiotensin-converting enzyme (ACE) bound to the surface of the endothelium. Other substances removed by the lung are bradykinin (also by ACE) and atrial natriuretic peptide.

Various arachidonic acid metabolites are synthesized and released by lung tissue. Some ($PG_{E2\alpha}$, $PG_{F2\alpha}$) are metabolized in the lung whereas others (PG_{A2}, PG_{I2}) pass unchanged. Some drugs (particularly basic and lipophilic ones) are taken up by the pulmonary circulation where they may act as a reservoir to be released later. Acid drugs bind to plasma proteins. Some chemicals (e.g. paraquat, nitrofurantoin, bleomycin, amiodarone) accumulate in the lung and are toxic.

The lung releases a variety of inflammatory mediators on exposure to inhaled allergens, notably histamine, endothelin and arachidonic acid derivatives that have undesirable effects on the rest of the body (e.g. hypotension, rashes). It also produces nitric oxide, but this is probably important only in the local control of blood flow and the regulation of perfusion in relation to ventilation. ◆

Measurement of Respiratory Function
Part 1: Ventilation

Iain Campbell
James Waterhouse

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Science at Liverpool John Moores University. He qualified as an animal physiologist from Oxford University and gained his DPhil there. His research interests are circadian rhythms, with particular reference to jet lag and assessing the clock-driven components of measured circadian rhythms.

The mechanics of getting oxygen into the bloodstream and removing carbon dioxide from it is brought about by a combination of the movement of air in and out of the lung (ventilation) and the ability to transfer oxygen and carbon dioxide in and out of the bloodstream via the alveoli (perfusion). A typical value for alveolar ventilation with the individual at rest is about 4–5 litres/minute and pulmonary blood flow (cardiac output) is about 5 litres/minute, thus the ratio of ventilation ($\dot{V}$) to perfusion ($\dot{Q}$) is about 0.8: 1. Minute ventilation, calculated from tidal volume (500 ml) and respiratory frequency (15 breaths/minute) is about 7.5 litres, anatomical dead space is 150 ml and alveolar gas volume (functional residual capacity: FRC) is 3 litres. The volume of blood in the pulmonary capillaries is only about 70 ml.

Gas transfer may be limited by the time the blood spends in the capillary. When blood is diverted from other parts of the lung (e.g. following a large pulmonary embolus) the time taken for the blood to traverse the capillaries that are still open is reduced and gas transfer may be incomplete. With exercise at altitude, the lower atmospheric partial pressure of oxygen results in a decrease in the driving pressure of oxygen across the capillary membrane, and equilibration may be incomplete, worsening the hypoxaemia.

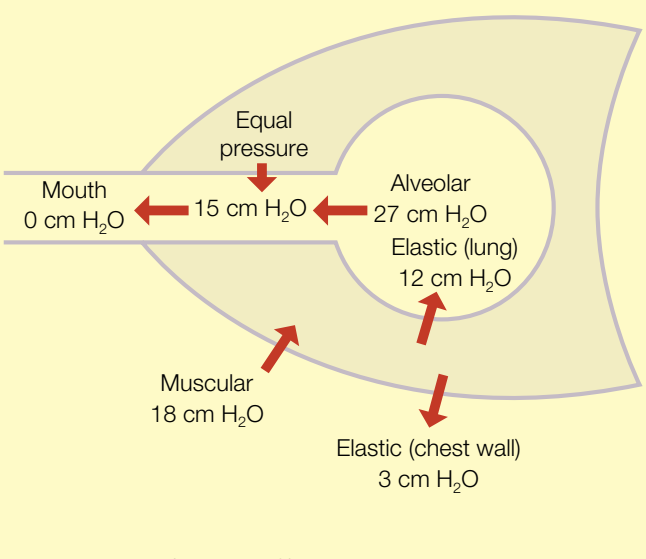
Equilibration between the alveolus and the blood is normally limited by perfusion. However, it may be limited if the resistance to gas transfer is increased by diffusion, for example in chronic chest diseases with thickening of the alveolar capillary membrane or if fluid is present. In health, diffusion reserves are huge and, with a normal alveolar-capillary membrane, disturbances in gas transfer are mainly caused by alterations in the matching of perfusion to ventilation.

Lung volumes

Airflow in and out of the lung is dependent on the generation of pressure differences between the alveoli and the atmosphere. Air flow is a mixture of laminar and turbulent flow, the latter occurring particularly at airway junctions. At high rates of flow, the amount of turbulence increases and resistance rises disproportionately.

Quiet expiration to FRC is a passive process driven by elastic forces in the lung, while the inspiratory muscles gradually relax. At FRC, intrapleural pressures are negative, but in the upright individual there is a difference between the top (atmospheric pressure (A) – 8 cm H_2O) and the base (A – 2 cm H_2O) of the lung, as a result of which, alveoli at the base of the lung (in the upright position) are relatively compressed and smaller (less full with gases) than those at the top. During expiration to residual volume the intrapleural (intrathoracic) pressure becomes positive and compresses alveoli and airways. Alveolar pressure is thus made up of the intrapleural (intrathoracic) pressure plus the elastic recoil pressure of the lung (Figure 1). Pressure at the mouth is atmospheric, therefore there is a point along the airway from alveoli to the mouth where the intraluminal pressure equals the surrounding intrathoracic pressure – the so-called 'equal pressure point'.

Respiratory pressures during a forced expiration



Muscular effort (18 cm H_2O) produces a positive intrathoracic (intrapleural) pressure equal to the effort (18 cm H_2O) minus the elastic recoil of the chest wall (3 cm H_2O) of 15 cm H_2O. The pressure gradient down the airway ranges from the intra-alveolar pressure (27 cm H_2O) to zero at the mouth. Intra-alveolar pressure (27 cm H_2O) is made up of the elastic recoil of the lung (12 cm H_2O) plus the positive intrathoracic pressure (15 cm H_2O) therefore a point must exist along the airway where airway equals intrathoracic pressure. Any further increase in pressure compresses the airways at and below the equal pressure point and does not increase the rate of airflow which is thus determined only by the elastic recoil of the lung (12 cm H_2O) and so is independent of muscular effort

1

Towards the mouth from this equal pressure point mainly comprises the large, relatively rigid, airways and towards the alveoli, the smaller airways, which are less well supported and less rigid. Any increase in muscular effort tends to compress these small airways at or on the alveolar side of the equal pressure point. The alveolar pressure is thus a combination of elastic recoil of the lung plus the raised intrathoracic pressure, but this raised intrathoracic pressure is also compressing the airways at the equal pressure point, therefore the expiratory flow rate is determined by the elastic recoil of the lung only and is independent of muscular effort (Figure 1). When the rise in intrathoracic pressure completely blocks off the airways, the alveoli cease to empty and gas trapping occurs. In a healthy young adult, breathing quietly down to residual volume in the upright position, this is seen at about 10% of vital capacity.

Other factors that predispose to premature small airway closure and air trapping are those that cause a reduction in calibre of the smaller airways (e.g. smooth muscle contraction, mucosal swelling, secretions), a loss of supporting tissues and elasticity (emphysema, age), increased intrathoracic pressure (obesity), or decreased elastic recoil of the lung. This occurs first at the lung bases because of the higher intrapleural (intrathoracic) pressure. With a forced expiratory manoeuvre and high intrathoracic pressure, airway closure occurs at a higher lung volume.

Tests of ventilation

Ventilation is normally assessed from measurement of static lung volumes and various indices of expiration, namely forced expiratory volume (FEV), forced expiratory volume in 1 second (FEV_1), peak expiratory flow rate (PEFR) and flow–volume curves.

Static lung volumes

Static lung volumes are traditionally measured using a conventional bell-type spirometer or a dry rolling seal-type spirometer, which is essentially a piston in a cylinder with a pliant seal between the two which is free to move as the piston moves in and out. The volumes obtained are compared with published tables of normal values for age, height, weight and gender. All measurements can be read directly from the spirometer trace except for FRC (and residual volume) which is measured with helium dilution, or using a whole body plethysmograph or calculated from nitrogen washout.

FRC is the oxygen reservoir from which gas exchange takes place and which is replenished by tidal ventilation. It is affected by a number of conditions (e.g. obesity, pregnancy, abdominal surgery) and such changes affect oxygenation mechanisms, particularly via the relationship between FRC and small airway closure. FRC cannot be read off the spirometer trace and is most commonly measured using helium dilution because helium is easily analysed and virtually insoluble in the tissues.

The spirometer is filled with a mixture of a known concentration of helium (C_1) and oxygen-enriched air. The volume (V_1) of the spirometer is known. The individual, wearing a nose clip, breathes into the spirometer via a mouthpiece. The mouthpiece is initially open to room air. At the end of a normal quiet expiration (i.e. at FRC:V_2) the individual is switched into the spirometer circuit and continues to breath quietly via the circuit. Carbon dioxide is absorbed and oxygen added as necessary to maintain the end-tidal position. The helium equilibrates between the spirometer and the lung and its concentration in the circuitry is observed to fall to a final concentration C_2. Thus:

$$C_1 V_1 = C_2(V_1 + V_2)$$

$$\text{from which } V_2(\text{FRC}) = V_1 \times \frac{C_1 - C_2}{C_2}$$

The individual normally takes a couple of quiet vital capacity breaths to facilitate mixing. The whole process takes 5–10 minutes depending on the type and degree of lung pathology (poorly ventilated alveoli take longer to equilibrate).

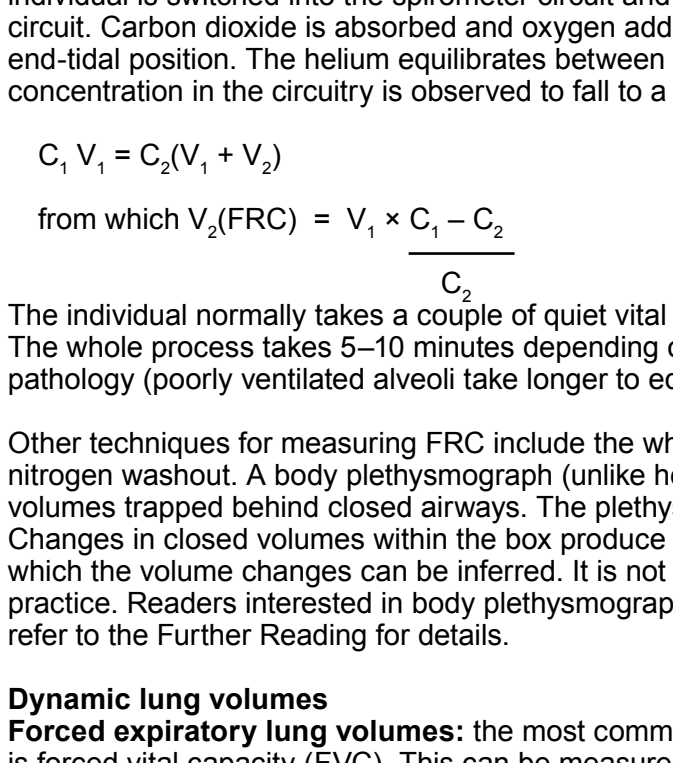
Other techniques for measuring FRC include the whole body plethysmograph and nitrogen washout. A body plethysmograph (unlike helium dilution) measures gas volumes trapped behind closed airways. The plethysmograph is a closed airtight box. Changes in closed volumes within the box produce changes in box pressures from which the volume changes can be inferred. It is not in common use in anaesthetic practice. Readers interested in body plethysmography and nitrogen washout should refer to the Further Reading for details.

Dynamic lung volumes

Forced expiratory lung volumes: the most common measurement of ventilation is forced vital capacity (FVC). This can be measured using a wedge spirometer (or Vitalograph) which is easily transported to the bedside. A typical FVC trace is shown in Figure 2. The individual takes a maximal inspiration then breathes out as far and as forcibly as possible. FVC and FEV_1 are derived from the tracing. The ratio FEV_1: FVC (x 100) gives a measure of airways obstruction; its normal value is 75–80%. FVC is slightly less than VC (measured with a slow quiet expiration) because of airway trapping. It is affected by diseases of the thoracic cage (e.g. kyphosis, acute injury), of the respiratory muscles (e.g. poliomyelitis), of the pleural cavity (e.g. pneumothorax) or by decreased compliance (e.g. chronic bronchitis, fibrosis, obesity). It is also affected by obstructive conditions (e.g. asthma). The ratio FEV_1:FVC gives more information about obstruction than either of the two measurements alone.

The point of greatest resistance in the normal respiratory tract is in the medium-size bronchi, about the fourth or fifth generation, just beyond the origin of the bronchopulmonary segments. With a forced expiratory manoeuvre, the intrathoracic pressure rises and compresses the alveoli, causing the small airways to be compressed as well. In the latter part of such a manoeuvre, the point of greatest resistance is the small airways. Other measurements of flow that can be derived from the FVC curve are PEFR (by taking a tangent to the steepest part, normally the start of the curve) and mid-expiratory flow rate ($FEV_{25–75}$: by measuring the slope of a line drawn between the two points on the curve at 25% and 75% of FVC).

Forced expiratory lung volume measured by wedge spirometry

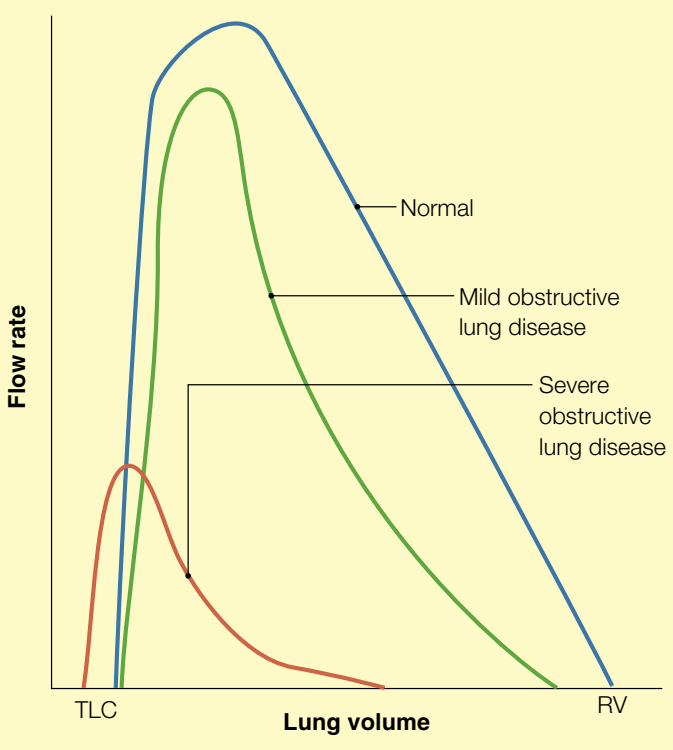


The graph shows the derivation of forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1) and the line from which peak expiratory flow rate (PEFR) can be determined

2

Flow volume loops: the above measurements are more an index of large or medium airway function. Small airways are studied specifically using the flow volume loop, an example of which is shown in Figure 3. The individual carries out an FVC manoeuvre; flow rate is measured and plotted against lung volume. The peak of the curve denotes peak flow; beyond that point, airway compression occurs and increased muscular effort does not increase the expiratory flow rate. With worsening disease of the small airways the flow rate declines earlier in expiration to give a typical scooped out appearance (Figure 3). With obstructive disease, vital capacity may be decreased and residual volume increased (i.e. the patient breathes at a higher lung volume because of the obstruction to expiration).

Flow volume loops



Note the scooped out appearance of the obstructive curves and the limitation of peak flow with severe obstructive lung disease
RV, residual volume; TLC, total lung capacity

3

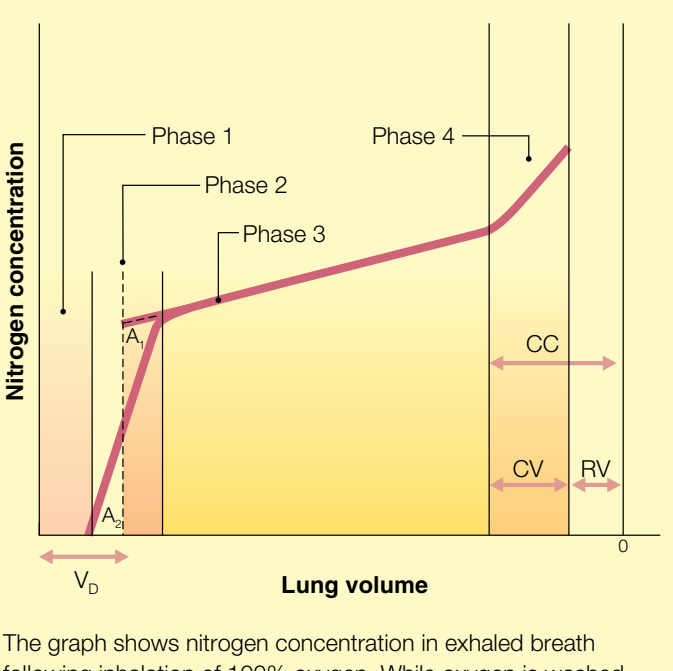
Modern spirometers are often electronic, integrating flow signals from various types of flowmeter to derive volumes such as FVC, FEV_1, $FEV_{25–75}$. All of the parameters discussed above can be derived electronically from a single forced expiration. Lightweight portable instruments are available, but have to be calibrated and, though more convenient than the traditional ones, are not as robust nor as accurate.

It is conventional to present respiratory volumes at body temperature and pressure saturated (BTPS). All of the measurements are made under ambient conditions, therefore volumes are corrected for temperature, including the difference in saturated vapour pressures at ambient and body temperatures.

Assessment of uneven ventilation
Two tests give a ready assessment of uneven ventilation. The single breath nitrogen test is a research tool, but is much loved by examiners and has other applications in terms of measuring the volume at which small airways start to close. The single breath carbon dioxide washout curve is used in everyday anaesthetic practice.

The single breath nitrogen test: the individual takes in a single vital capacity inspiration of pure oxygen then exhales to residual volume and the concentration of nitrogen at the mouth is monitored. A typical tracing is shown in Figure 4. Four phases are recognized.
- Phase 1: pure oxygen is exhaled from the upper airways and the nitrogen concentration is zero.
- Phase 2: there is a rapid rise in nitrogen concentration as the anatomical dead space is washed out with alveolar gas.
- Phase 3 is known as the alveolar plateau. With uneven ventilation the nitrogen concentration rises steadily. The slope is a measure of the unevenness of ventilation.
- Phase 4: towards the end of phase 3 there is a sharp rise in nitrogen concentration. This signals the onset of small airway closure at the base of the lung.

Single breath nitrogen test



The graph shows nitrogen concentration in exhaled breath following inhalation of 100% oxygen. While oxygen is washed out of the upper airway (phase 1) nitrogen concentration rises (phase 2) to alveolar plateau (phase 3). Closing volume (CV) is the transition from phase 3 to phase 4. Steepness of phase 3 denotes unevenness of ventilation. RV, residual volume; CC, closing capacity; V_D anatomical dead space

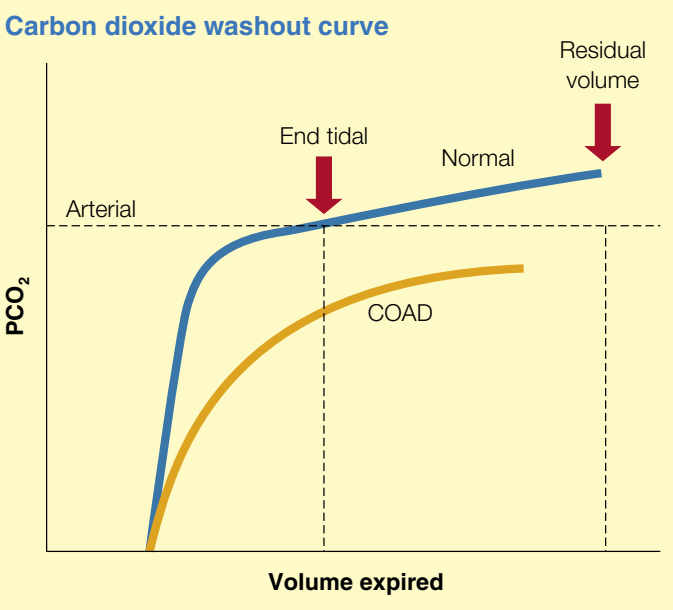
4

Alveoli fill and empty at different rates. When the individual breathes in 100% oxygen the nitrogen present in the airways essentially acts as a tracer. During inspiration, the alveoli at the base of the lung open last and expand the most. During expiration, the 'fast' or better-ventilated alveoli empty first; they contain more oxygen with lower nitrogen concentrations than the 'slower' ones, resulting in an increase in nitrogen concentration during expiration. The steeper the slope the more uneven the ventilation.

The inflection from phase 3 to phase 4 occurs because at residual volume, alveoli at the base of the lung are smaller and expand more than those at the top. Towards residual volume, the (small) airways to some of them are closed, because the intrathoracic (pleural) pressure exceeds the airway pressure. With a vital capacity inspiration the alveoli at the base of the lung, which are closed at residual volume, expand far more than those at the top, so when breathing in 100% oxygen, the nitrogen in the alveoli at the base is more diluted by oxygen than in those at the apex. During expiration, upper and lower zones tend to empty together, producing the alveolar plateau, but as soon as the airways at the base start to close, the higher nitrogen concentrations in alveoli in the upper zones, which are still emptying, produce the abrupt rise in nitrogen concentration.

Carbon dioxide washout curve: expired carbon dioxide concentrations are monitored routinely during anaesthesia. Figure 5 shows a typical carbon dioxide concentration curve during a slow quiet expiration to residual volume in a normal individual and in a patient with airway obstruction and uneven ventilation. Also indicated are the normal end-tidal points, the expired partial pressure of carbon dioxide (PCO_2) at residual volume and the partial pressure of carbon dioxide in arterial blood ($PaCO_2$). The slope of the curve is analogous to the slope of the nitrogen washout curve following a vital capacity inspiration of 100% oxygen. End-tidal PCO_2 at the end of a normal quiet tidal expiration approximates closely to $PaCO_2$ and in clinical practice can be used as an indicator of $PaCO_2$. If the individual breathes slowly and steadily to residual volume, $PaCO_2$ rises further and tends to venous PCO_2. The slope of the tracing is an indication of abnormalities in ventilation (and perfusion), the steeper the slope the more uneven the ventilation in relation to alveolar perfusion. The lower curve in Figure 5 shows the type of curve seen in individuals with obstructive airways disease. It is also similar to that seen during a forced expir-atory manoeuvre; airway trapping occurs at relatively high lung volumes, the alveolar slope is steeper and there is a significant difference between end-tidal (end expiratory) PCO_2 and $PaCO_2$. ◆

Carbon dioxide washout curve



Expired partial pressure of carbon dioxide (PCO_2) breathing quietly from normal inspiration to residual volume. End-tidal PCO_2 approximates to the partial pressure of carbon dioxide in arterial blood ($PaCO_2$). The steepness of the alveolar plateau gives an index of unevenness of ventilation. PCO_2 at residual volume is higher than $PaCO_2$. The lower trace shows that in chronic obstructive airways disease (COAD) end-tidal PCO_2 does not approximate to $PaCO_2$

Measurement of Respiratory Function
Part 2: Gas Exchange

Iain Campbell
James Waterhouse

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Science at Liverpool John Moores University. He qualified as an animal physiologist from Oxford University and gained his DPhil there. His research interests are circadian rhythms, with particular reference to jet lag and assessing the clock-driven components of measured circadian rhythms.

Blood normally spends about 0.75 seconds in the alveolar capillary. Equilibration of carbon dioxide occurs in about 0.25 seconds and of oxygen in about 0.4 seconds. Therefore, equilibrium occurs rapidly and is normally complete when the blood has traversed only about half the capillary. Within the pulmonary capillary there is thus a large reserve for gas transfer. Although pulmonary blood flow may rise fivefold with exercise, gas transfer (at sea level) is still normally complete. The pulmonary circulation has a large reserve. With increases in cardiac output, pulmonary capillaries have the capacity to expand (distension) and capillaries that are closed at rest or have no blood in them, open up (recruitment).

The carbon monoxide transfer test is used in chest medicine as a noninvasive method of quantifying gas transfer. Carbon monoxide is more soluble in blood than carbon dioxide or oxygen. When it is present in inspired air, equilibrium is not reached by the time the blood has perfused the alveoli. No appreciable loss of diffusion gradient develops in the alveolus and the gas continues to move rapidly into the bloodstream, therefore its uptake is normally independent of blood flow, and thus limited by diffusion. Its rapid uptake from the alveolus makes it a sensitive test of gas transfer. It is considered principally as an index of diffusion, but probably is also affected by ventilation–perfusion abnormalities. The carbon monoxide transfer test is not widely used in anaesthetic practice.

Measurement of ventilation ($\dot{V}_A$) and perfusion ($\dot{Q}$) involves the inhalation or injection of radioactive isotopes, respectively. These methods are in common use in chest medicine to assess localized abnormalities. Multiple gas elimination is a research technique that allows ventilation–perfusion abnormalities to be quantified precisely. It involves injection of tracer gases of varying solubilities and allows distribution curves to be plotted for pulmonary blood flow and ventilation in relation to $\dot{V}_A$:$\dot{Q}$ ratios. Such techniques are not in routine use in anaesthetic practice and are beyond the scope of this article, which focuses on the common clinical techniques used to measure ventilation and gas exchange, and the derivation of parameters that can be calculated from them.

Blood gases

The ultimate test of how well ventilation is matched to perfusion is the measurement of blood gases. Inadequate ventilation (hypoventilation) is always accompanied by a raised partial pressure of carbon dioxide in arterial blood ($PaCO_2$). Mismatch of ventilation to perfusion results in hypoxaemia. $PaCO_2$ does not rise with ventilation–perfusion abnormalities unless ventilation is inadequate, because of depression of the respiratory centre (e.g. opiates) or pathology of the ventilatory apparatus (e.g. muscle paralysis, crush injury of the chest).

$PaCO_2$ is a function of CO_2 production ($\dot{V}CO_2$) and alveolar ventilation ($\dot{V}_A$) and is given by the relationship:

$$PaCO_2 = \dot{V}CO_2/\dot{V}_A \times K$$

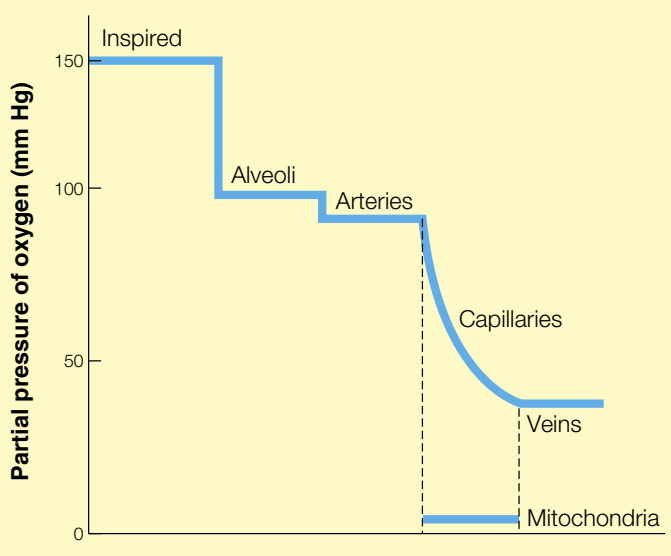
where K is a constant.

Thus, halving $\dot{V}_A$ results in doubling $PaCO_2$.

The oxygen cascade

Figure 1 illustrates how the partial pressure of oxygen (PO_2) falls as gas is moved from the inspired air to the tissues. Inspired air is humidified in the upper airways and gas exchange with the alveoli is a function of ventilation. From the alveoli, oxygen moves into the arteries. The difference between PO_2 in the alveoli (P_AO_2) and in the arteries (PaO_2) is a function of ventilation–perfusion relationships and, in some chest diseases, diffusion across the alveolar capillary membrane. From the arteries, gas exchange with the peripheral tissues occurs in the capillaries. O_2 and CO_2 diffuse through the tissues. Most oxygen is used, and most CO_2 produced, in the mitochondria where PO_2 is very low (1–4 mm Hg).

Oxygen cascade



1

Inspired PO_2 (P_IO_2) is calculated from barometric ressure (760 mm Hg at sea level) and the proportion of O_2 in inspired air (F_IO_2 – for atmospheric air 20.9%) allowing for humidification of the inspired air; the saturated vapour pressure of water at 37°C is 47 mm Hg. Thus:

$$P_I O_2 = (760 - 47) \times 20.9/100 = 149 \text{ mm Hg}$$

The decrease in PO_2 from the inspired air to the alveolar air is due to dilution by the CO_2 in the alveoli, but the body produces less CO_2 than it uses O_2. The ratio of CO_2 produced to O_2 consumed is given by the respiratory quotient or respiratory exchange ratio (R). This is normally 0.7–1. It is seldom measured and a value of 0.8 is normally assumed. Based on this, P_AO_2 can be calculated from the simplified form of the alveolar air equation:

$$P_AO_2 = P_IO_2 - P_ACO_2/R$$

P_ACO_2 can be taken as end-tidal CO_2, though it is more usual to use $PaCO_2$. In terms of the figures quoted above:

$$P_AO_2 = 149 - 40/0.8 = 99 \text{ mm Hg}$$

P_AO_2 can be influenced by raising or lowering the F_IO_2 or by changing ventilation, which changes $PaCO_2$ and thus alters the P_AO_2 in line with the alveolar air equation. O_2 uptake from the alveoli may also have an effect, particularly in patients with respiratory impairment and a raised oxygen consumption caused by shivering, pain, anxiety or fever.

The difference between P_AO_2 and PaO_2 (the alveolar–arterial oxygen difference or gradient) is due mainly to ventilation–perfusion mismatch, specifically alveoli overperfused relative to their ventilation (i.e. $\dot{V}_A$:$\dot{Q}$ < 0.8) ranging from alveoli with a $\dot{V}_A$:$\dot{Q}$ ratio only slightly less than 0.8 to alveoli that are perfused and not ventilated at all (i.e. $\dot{V}_A$:$\dot{Q}$ = 0; atelectasis, lobar collapse, pneumonia). In health (in the upright position), the alveoli with $\dot{V}_A$:$\dot{Q}$ ratios less than 0.8 occur in the lower part of the lung. There is a gradation of $\dot{V}_A$:$\dot{Q}$ ratios from about 3.3 at the top (overventilated and underperfused) to 0.63 at the base (underventilated and overperfused). This distribution of $\dot{V}_A$:$\dot{Q}$ ratios leads to a spread of P_AO_2 values, with those at the top of the lung being high (about 130 mm Hg) and those at the base being low (about 80 mm Hg). With such a spread of P_AO_2 values how can one justify using a single figure? The figure given by the alveolar air equation is conventionally taken to be an average value for P_AO_2 over the whole lung. However, the figure is heavily weighted by basal alveoli which is where most of the ventilation (and perfusion) takes place. It is also known as the ideal P_AO_2.

The principal factor affecting ventilation and perfusion in the lung is gravity in relation to the weight of the lung and the low pressures in the pulmonary circulation. All of the above arguments about the distribution of ventilation and perfusion have applied to the conscious individual in the upright position. When the individual lies down gravity still applies, so the areas of high $\dot{V}_A$:$\dot{Q}$ ratios move to the anterior aspect of the chest and of low $\dot{V}_A$:$\dot{Q}$ to the posterior. Airway closure then takes place posteriorly rather than at the base.

Measurement of gas exchange

The causes of hypoxaemia are broadly classified as impairment of diffusion (abnormalities of the pulmonary capillary membrane, pulmonary embolus, exercise at altitude), ventilation–perfusion abnormalities (specifically overperfusion of underventilated alveoli) and 'shunt', the most extreme form of ventilation–perfusion mismatch ($\dot{V}_A$:$\dot{Q}$ = 0). In normal circumstances, most arterial hypoxaemia is due to ventilation–perfusion mismatch.

Alveolar–arterial difference

The difference between P_AO_2 and PaO_2 can be used as an indicator of ventilation–perfusion mismatch. In the young healthy individual, the alveolar–arterial difference is less than 10 mm Hg, but it increases with age and with any condition that impairs gas exchange. It exists because of the shape of the haemoglobin dissociation curve. Consider three alveoli of equal size and equal perfusion in the upper, mid and lower zones with PO_2 of 120, 80 and 40 mm Hg (i.e. in an individual with some ventilation–perfusion mismatch; Figure 2). The average P_AO_2 is 80 mm Hg. The blood leaving these three alveoli has partial pressures corresponding to the P_AO_2, but there is little difference in the oxygen content between the 120 and 80 mm Hg alveoli because they both lie on the flat part of the oxygen–haemoglobin dissociation curve and the blood from them will be 98% and 95% saturated, respectively. However, the blood leaving the 40 mm Hg alveolus lies on the steeper part of the dissociation curve and its saturation is only 75%. Assuming equal blood flow through each of the three alveoli gives an overall arterial saturation of 89%, corresponding to a PaO_2 of 57 mm Hg and an alveolar–arterial difference of 23 mm Hg. In other words, the relative overventilation of the 80 and 120 mm Hg alveoli has little effect on arterial saturation and does not compensate for the underventilation of the 40 mm Hg alveolus which, because of its position on the curve, has a very marked effect. This is even greater in practice because blood flow through the base of the lung is normally much greater than through the apex.

Shunt

True shunt refers to blood that enters the arterial system without passing through ventilated lung such as occurs with pneumonia, (consolidation) or pulmonary collapse. There is a small amount of shunt in the normal lung; blood supplying the bronchi (bronchial arteries) drains into the pulmonary veins and a small amount of coronary venous blood drains directly into the cavity of the left ventricle through the Thebesian veins. The addition of this desaturated blood depresses PaO_2. The same occurs in individuals with a defect between the right and left sides of the heart. In clinical practice, true shunt is mainly seen in pneumonia with inflammatory consolidation of the alveoli or with the alveolar flooding of pulmonary oedema.

If all hypoxaemia were caused by true shunt it would be possible to quantify the shunt from measurements and calculation of the oxygen content of arterial and mixed venous blood and a knowledge of P_AO_2. Figure 3 shows a shunt with a proportion of the cardiac output ($\dot{Q}t$) passing through ventilated lung ($\dot{Q}c$) and a proportion through the shunt ($\dot{Q}s$):

$$\dot{Q}t = \dot{Q}c + \dot{Q}s$$

Oxygen content (C) for each component can be calculated from the haemoglobin concentration and the PO_2 of each component, such as mixed venous blood (CvO_2), arterial blood (CaO_2) and end pulmonary capillary blood ($Cc'O_2$) the pressure of which is assumed to equal P_AO_2.

Thus:

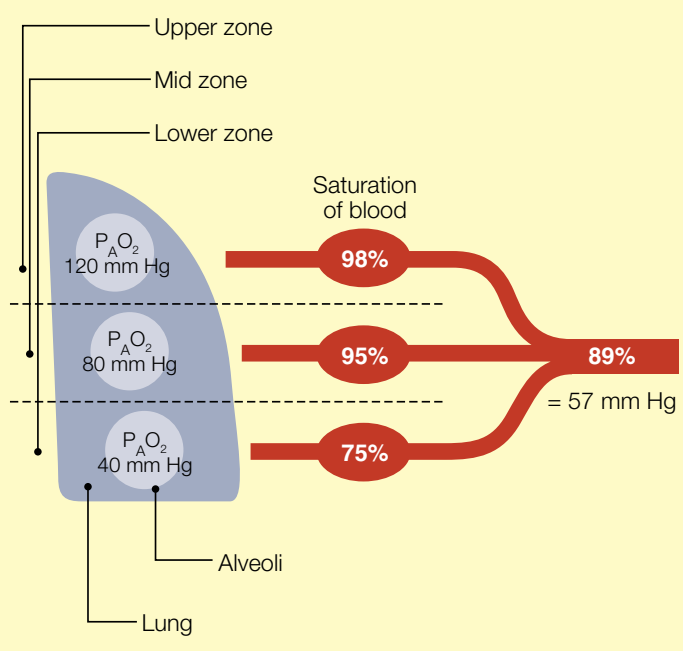
$$\dot{Q}t \times CaO_2 = \dot{Q}c \times Cc'O_2 + \dot{Q}s \times CvO_2$$

Rearranging

$$\frac{\dot{Q}s}{\dot{Q}t} = \frac{Cc'O_2 - CaO_2}{Cc'O_2 - CvO_2}$$

gives shunt as a percentage of cardiac output. Calculation of CvO_2 necessitates the measurement of mixed venous oxygen pressure using a pulmonary artery catheter. This also allows the measurement of cardiac output and a figure for shunt could be obtained in terms of volume/minute.

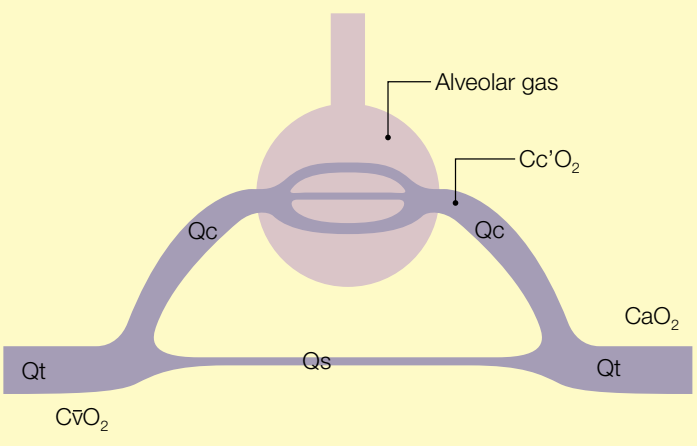
Origin of the alveolar–arterial gradient



Mean partial pressure of oxygen in alveoli (P_AO_2) is 80 mm Hg
Alveolar–arterial gradient = 80 – 57 = 23 mm Hg

2

Shunt



Degree of venous admixture can be quantified by assuming that it is all due to true shunt and calculating the amount of shunt that would be required to produce that degree of hypoxaemia. End pulmonary capillary oxygen content ($Cc'O_2$) is calculated assuming $Cc'PO_2$ to be the same as partial pressure of oxygen in alveoli (P_AO_2)
Qt, cardiac output; Qc, blood flow through ventilated lung; Qs, shunt.
Partial pressure of oxygen in arterial blood (CaO_2) and mixed venous blood $C\bar{v}O_2$

3

Ventilation–perfusion mismatch

Hypoxaemia is seldom caused by true shunt; much of it arises from ventilation–perfusion mismatch. To measure this requires the sophisticated laboratory-based techniques referred to earlier, which are not readily available. A method of quantifying impairment of oxygenation in clinical practice is to assume that all the hypoxaemia, including ventilation–perfusion mismatch is caused by true shunt and to calculate the amount of shunt that would be required to produce that degree of hypoxaemia. The lung is considered to consist of:

- alveoli that are ventilated but not perfused (dead space)
- alveoli that are perfused but not ventilated (shunt)
- alveoli that are perfused and ideally ventilated (i.e. blood leaving these alveoli (end pulmonary capillary blood) has the same PO_2 as ideal alveolar air).

In terms of ventilation–perfusion mismatch, the overperfused underventilated alveoli at the base of the lung contribute to ‘shunt’ and hypoxaemia. This is often referred to as venous admixture. Similarly the overventilated underperfused alveoli at the top of the lung contribute to ‘dead space’.

A feature of hypoxaemia caused by true shunt is that increasing the F_IO_2 makes little difference to the severity of the hypoxaemia whereas hypoxaemia caused by ventilation–perfusion mismatch can be abolished by increasing the inspired concentration of oxygen.

Dead space is gas that takes part in ventilation but not in gas exchange. It is made up of anatomical dead space and alveolar dead space; both of which constitute physiological dead space. Physiological and anatomical dead space can both be measured and alveolar dead space can therefore be calculated.

Anatomical dead space is measured using Fowler’s technique. This is a research tool not commonly used in clinical practice. The method is based on the nitrogen washout curve. Following a single inspiration of 100% O_2 expired N_2 is monitored at the mouth as described previously but is plotted against expired volume. In phase 2 of the curve a vertical line is dropped such that area A_1 is equal to area A_2. The anatomical dead space is the volume expired up to the vertical line.

Physiological dead space can be measured in clinical practice and is calculated from the Bohr equation:

$$\frac{V_D}{V_T} = \frac{PaCO_2 - P_ECO_2}{PaCO_2}$$

Where V_D is physiological dead space, V_T is tidal volume, and P_ECO_2, the partial pressure of mixed expired CO_2, is calculated from barometric pressure and the fractional concentration of CO_2 in the mixed expired air.

Mixed expired air is a mixture of all the air breathed out over a period and includes both the anatomical dead space and the alveolar gas. It is collected either into a spirometer or reservoir (Douglas) bag for analysis or passed through a mixing box and sampled. The important feature is that it includes all the dead space air and all the air that has taken part in gas exchange. Mixed expired CO_2 concentration is usually about 2–4% CO_2 depending on the amount of dead space. It must be distinguished from end-tidal CO_2 which normally reflects $PaCO_2$ and is about 5–5.5% CO_2. Rearranging the Bohr equation:

$$V_D = V_T \frac{PaCO_2 - P_ECO_2}{PaCO_2}$$

The calculation of V_D thus entails measuring V_T, $PaCO_2$ and P_ECO_2 all at the same time. This can be done by collecting expired air over a timed period and measuring its volume, its CO_2 content and $PaCO_2$ during the period of collection. V_T can be calculated from the timed expired volume and the respiratory rate. It is important to maintain a steady state throughout; in a conscious individual this can be difficult when a mouthpiece and the sampling of arterial blood both tend to induce hyperventilation. With an intubated unconscious patient undergoing mechanical ventilation it is relatively easy and some ventilators calculate physiological dead space automatically using end-tidal CO_2 as an approximation of $PaCO_2$. As discussed earlier, in the diseased lung this can cause problems because the assumption that end-tidal CO_2 approximates arterial CO_2 may not be valid.

Alveolar–arterial gradients and mixed expired PCO_2: in practice, shunt can be measured only with a pulmonary artery line in place, but the alveolar–arterial PO_2 difference in breathing air is a reasonable reflection of the extent of ventilation–perfusion mismatch. At a high F_IO_2 the relationship is more complex. From the Bohr equation it is self-evident that the mixed expired CO_2 concentration has an inverse relationship with the size of the dead space. ◆

Respiration: Control of Ventilation

James Waterhouse
Iain Campbell

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Science at Liverpool John Moores University.

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University.

The control of ventilation involves control of:
- the rhythmical process of inspiration and expiration
- the overall rate of ventilation and gaseous exchange with the environment.

Animal experiments show that the respiratory centres are in the pons and medulla, and the vagi are also involved. Figure 1 shows the breathing patterns after sectioning the brainstem at different levels, with the vagi remaining intact or sectioned.
- The basic inspiratory–expiratory cycle originates from the medulla, but it is irregular in tidal volume and frequency.
- A 'smoothing' of the respiratory cycle takes place in the pons. If the medulla and pons are intact, then respiration is normal, though voluntary influences, needed for speech and singing, are impossible.
- Making a section above (rostral to) the medulla but below (caudal to) the nuclei parabrachialis (the pneumotaxic centre), causes inspiration to be prolonged; if the vagi are also sectioned, then apneusis develops – expiratory gasps for air from a position of exaggerated inspiration. Inspiration is normally inhibited by the pneumotaxic centre and the vagi.

Inspiratory–expiratory cycle
Neurons in the medulla and pons discharge mainly during the inspiratory or expiratory phase of the respiratory cycle; they are often referred to as 'inspiratory' or 'expiratory' neurons, respectively. There are also neurons that fire during the inspiration–expiration and expiration–inspiration transitions known as 'switching' neurons. The inspiratory neurons are most common in the dorsal medulla, the expiratory neurons in the ventral medulla, and the 'switching' neurons in the pons, but there is overlap between the sites.

The inspiratory and expiratory neurons send efferent impulses to the intercostal muscles and diaphragm, and the inspiratory neurons in particular receive inputs from the vagi and chemoreceptor areas (see below).

The origin of the respiratory rhythm is not known in detail, but the following account covers the main principles. The respiratory cycle consists of coordinated phases of inspiration and expiration, and smooth transitions between the two.

Inspiration causes the inspiratory cells to fire in unison, and the expiratory cells to be quiescent. This is achieved by the inspiratory cells exciting their inspiratory agonists and inhibiting their expiratory antagonists. Lung volume increases.

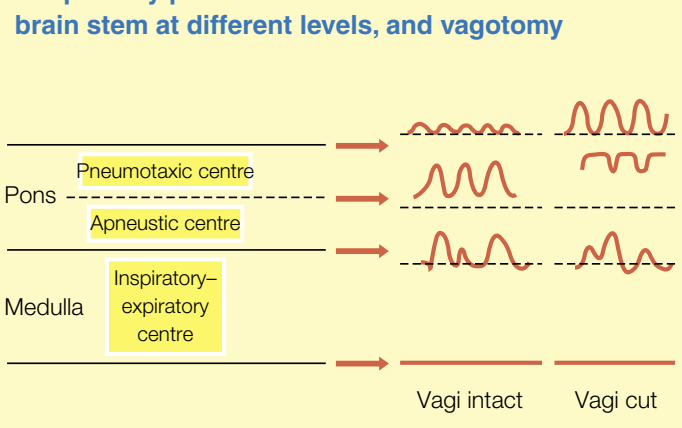
Inspiration is terminated by several simultaneous influences. First, the excitability of the inspiratory cells falls (fatigue); second, the excitability of the quiescent expiratory cells rises; third, inhibitory inputs from stretch receptors in the bronchial tree of the expanding lungs (the Hering–Breuer reflex) travel to the inspiratory neurons via the vagi; fourth, inhibitory inputs reach the inspiratory cells from the pneumotaxic centre. This combination reaches a point when activity of the inspiratory neurons begins to decline. At this point, the expiratory neurons are released from their inhibition, and the system switches to the expiratory mode.

Expiration takes place, often passively (see above), using the force of lung recoil. However, this does not negate the need for expiratory neurons. They are required firstly for rapid or deep expirations when expiratory muscle effort is necessary and secondly to reset the gamma-loops of the muscle spindle-extrafusal fibre system of the respiratory muscles, so that they do not oppose being stretched during expiration. Like inspiratory neurons, expiratory neurons also show self-re-excitation of their agonist neurons and inhibition of antagonistic neurons. The lungs decrease in volume.

Expiration is terminated when the declining excitability of the expiratory neurons, the increasing excitability of the quiescent inspiratory neurons, and the falls of inhibitory impulses to the inspiratory neurons from the vagi and the pneumotaxic centre, all combine to switch the system back to the inspiratory mode. The cycle then starts again.

The vagi and the control of respiratory work
The vagi play an important role in terminating inspiration and thus in determining the tidal volume (Figure 1). The system is set so that the combination of frequency and depth of breathing at rest minimizes the work to be performed.

Respiratory patterns associated with sections of the brain stem at different levels, and vagotomy



The horizontal dashed lines indicate normal functional residual capacity.

1

Achieving total alveolar ventilation of 4 litres/minute (required at rest) can be by an infinite combination of frequencies and depths of breaths. A low frequency of ventilation, such as 4/minute, requires 1000 ml of air to be taken into the alveoli with each breath. Since about 150 ml of each breath is dead space, the tidal volume required is 1150 ml, about 13% of which is wasted. The rate of air flow required (1150 ml in 7.5 s of inspiration) is about 150 ml/s. The main problem is the large amount of work required to be done against recoil forces.

Decreasing the size of each breath and increasing the frequency of ventilation requires less work to be performed against recoil forces. However, this change increases the effect of resistance. A high frequency of ventilation such as 25/minute, requires 160 ml of air to be taken into the alveoli with each breath. For a tidal volume of 310 ml, about 48% would be wasted. The rate of airflow required (310 ml in 1.2 s of inspiration) is 258 ml/s. This more rapid airflow requires an increase in the work done against pulmonary resistance forces. The problem is exacerbated because there are more breaths per minute and an increased risk of turbulence in the airways. When air flow becomes turbulent rather than laminar, the pressure gradient required to move the air is increased.

The total work done per minute equals the sum of work done against compliance and resistance forces. As the above analysis indicates, breaths that are too large or too rapid increase the respiratory effort required and the amount of work wasted. There is an intermediate frequency and depth of ventilation that requires a minimum of effort, and the natural frequency and depth – determined in part by the Hering–Breuer reflex acting via the vagi – are close to this.

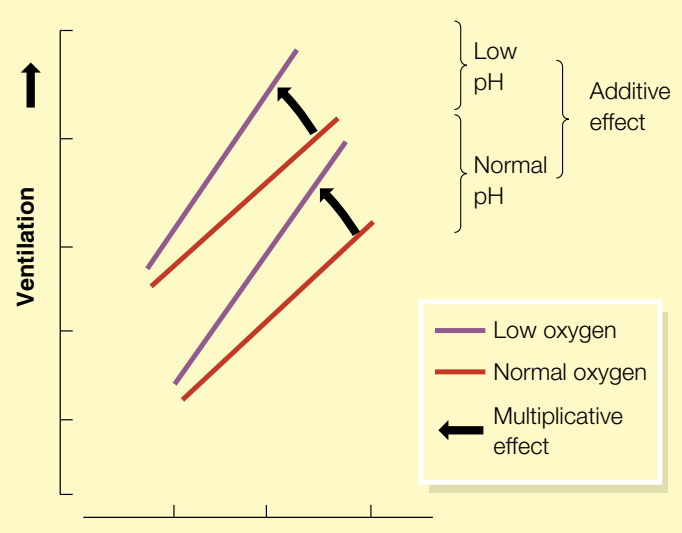
Whole body chemoreceptor reflexes

The basic respiratory cycle must be able to change in depth and frequency in order to keep oxygen and carbon dioxide levels normal, and to be able to deal with changes in metabolic demand (exercise), the partial pressure of ambient oxygen (altitude), and acid–base balance. Marked deviations from normal values lead to a deterioration in the body's performance and even to death. Under normal circumstances (breathing atmospheric air at sea level), increasing the respiratory minute volume replenishes the alveolar air with atmospheric air that is higher in oxygen (about 150 mm Hg) and lower in carbon dioxide (< 1 mm Hg). Since the blood is in equilibrium with the alveolar air, this raises the partial pressure of oxygen in the blood and lowers that of carbon dioxide. This does not significantly affect the amount of oxygen carried in the blood because the haemoglobin is already saturated, but it increases the amount of carbon dioxide blown off and decreases the amount of carbon dioxide carried in the blood. Moreover, since carbon dioxde is in equilibrium with carbonic acid, the pH of the blood rises.

Control of the respiratory gases in the blood is achieved by chemoreceptor reflexes. Considering the responses of the whole body, the most powerful stimulus to ventilation is asphyxia – the simultaneous presence of high carbon dioxide (and low pH) and low oxygen. This is the natural consequence of the respiration falling below that required to maintain normal values of the gases in blood.

The effects of changing only one or two of the variables have been investigated experimentally (Figure 2). A rise of carbon dioxide in the body (hypercapnia), oxygen and pH being unchanged, is also a strong stimulus to ventilation, but not as strong as asphyxia. If the pH is lowered at the same time as carbon dioxide is raised, it exerts an independent (additive) effect. By contrast, if oxygen is lowered (hypoxia) in the presence of hypercapnia, then there is an interaction between the two stimuli (multiplicative effect), the hypoxia sensitizing the body to the hypercapnia.

Relationship between ventilation and partial pressure of carbon dioxide



Effects due to simultaneous changes in oxygen (multiplicative) and pH (additive) are also shown.

2

The body's response to hypoxia is weak until it approaches dangerous levels (about 40 mm Hg). This appears to be partly because any increase in ventilation that hypoxia might produce also reduces respiratory drive by lowering carbon dioxide levels and raising the pH. If the levels of carbon dioxide and acid are kept at normal values during hypoxia, then the hypoxic response is greater, but is still comparatively weak until oxygen tensions have fallen below about 50 mm Hg.

Chemoreceptors
The sensory limb of the chemoreflexes are the peripheral and central chemoreceptors. The peripheral chemoreceptors (aortic and carotid bodies) are wholly responsible for the reflex responses to hypoxia, but are also sensitive to hypercapnia and to lowered pH. The central chemoreceptors (found on the floor of the fourth ventricle) are not sensitive to hypoxia, but are sensitive to the pH of the CSF.

Carotid bodies
Of the peripheral chemoreceptors, the carotid bodies have been studied more than the aortic bodies. The carotid bodies consist of round glomus cells surrounded by flattened sustentacular cells, and the sensory nerves abut the glomus cells. Hypoxia causes the nerves to increase their rate of firing, the release of dopamine probably being involved, but the link between hypoxia and transmitter release is not understood. What is known is that anaemic hypoxia (due to a decreased amount of haemoglobin in the erythrocytes) is not a stimulus – the glomus cells monitor the blood plasma rather than the erythrocytes. The fact that the glomus cells are influenced by the oxygen supplied by the blood plasma rather than the oxygenated haemoglobin is less surprising when it is appreciated that, relative to its size, the carotid body receives the greatest blood flow of any organ in the body.

The carotid body receives a sympathetic innervation. It is believed that, at the onset of exercise, an increase in sympathetic outflow constricts the blood vessels and this reduces the blood flow through the carotid body. This constriction produces a local stagnant hypoxia, and this contributes to the immediate increase in ventilation.

How the carotid bodies respond to hypercapnia and increased acidity is unknown, though individual glomus cells appear to respond to all three stimuli. This gave rise in the 1930s to the unitary hypothesis, by which all stimuli acted by a common pathway, intracellular acidity. (For hypoxia, this is postulated to be *via* glycolysis and the production of lactic acid.) This hypothesis cannot be tested until simultaneous recordings have been made of intracellular acidity, oxygen and carbon dioxide from the same glomus cell and activity in the nerve arising from it.

Central chemoreceptors
The central chemoreceptors comprise large neurons in the medulla, and are distinct from the respiratory centres described above. They monitor the CSF, particularly its pH. Owing to the blood–brain barrier, hydrogen ions from the blood cannot pass freely into the CSF, but changes in the partial pressure of carbon dioxide in the blood are reflected rapidly because there is no blood–brain barrier to this gas (nor to oxygen). The buffering capacity of the CSF is low; it contains no proteins. Accordingly, small changes in the partial pressure of carbon dioxide produce large changes in pH, and it is these changes that stimulate the chemoreceptors.

Integrating the receptor responses and the whole-body chemoreflexes
How the responses of the chemoreceptor areas are integrated into the whole-body responses is unknown. It appears that the central chemoreceptors guard the CSF against changes in pH, and this protection extends to brain tissue, which is in equilibrium with the CSF. This stability of the brain tissue pH is vital if changes in excitability of the neurons (influenced by the level of free calcium which is, in turn, controlled by pH) are to be avoided.

Oxygen levels are unimportant until they deviate markedly from normal. This is because there is a plateau at the top of the oxygen dissociation curve and small falls in the partial pressure of oxygen at the lungs are without effect; blood leaving the lung continues to be saturated. It is only when the blood leaving the lung is no longer fully saturated with oxygen that its role as a transporter of this gas becomes compromised. This loss of saturation is not marked until the partial pressure of oxygen in blood has fallen below about
50 mm Hg, and this is the point at which the hypoxic drive begins to increase markedly. Considered in this way, the lack of sensitivity of the body to hypoxia is apparent rather than real, and this aspect of the chemoreceptor reflexes is suited to the needs of the body. ◆

Respiration: Gas Transfer

James Waterhouse
Iain Campbell

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Science at Liverpool John Moores University.

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University.

Diffusion of gases across the alveoli
In the pulmonary circulation, gases move down the concentration gradient between the alveoli and the blood by diffusion. The rate of diffusion of a gas (D) between sites 1 and 2, is given by Fick's law of diffusion, which states that:

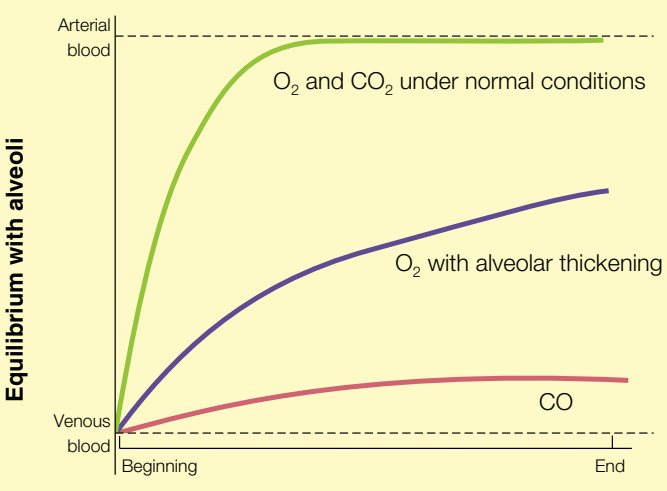
$$D = K \times (PP_1 - PP_2) \times \text{Area/Path length}$$

where: PP_1 is the partial pressure of the gas at site 1; PP_2 is the partial pressure of the gas at site 2; Area is the surface area across which diffusion can take place; Path length is the distance between sites 1 and 2; and K is a constant (the diffusion coefficient). K is directly proportional to the solubility of the gas, and inversely proportional to the square root of its molecular weight.

The thin alveolar walls and dense pulmonary capillary network ensure that the path length and area are conducive to diffusion. The continual replenishment of the air in the alveoli maintains the gradients of partial pressure of oxygen (down into the blood) and carbon dioxide (down out of the blood). In health, the processes of diffusion in the lung are so effective that equilibrium for oxygen has been achieved well within the time (less than 1 s) that the blood is in the pulmonary capillaries. This also applies to carbon dioxide, even though the partial pressure gradient (about 8 mm Hg) is small and it is a larger molecule, because it is very soluble.

The rates at which oxygen is removed from the alveoli, and carbon dioxide is delivered to them, are limited by pulmonary blood flow (Figure 1). For this reason, the excretion of carbon dioxide or the uptake of oxygen can be used to measure the cardiac output (or, more pedantically, the pulmonary blood flow). For the same reason, pulmonary diffusion capacity (a measure of the maximum rate at which a gas can diffuse across the lungs between the alveoli and the blood) cannot be measured using these gases.

Rates at which gases in the pulmonary blood equilibrate with alveolar air during passage through the capillaries



1

By contrast, when carbon monoxide is breathed into the alveoli, the capacity of the blood for this gas is so great that the blood and alveoli have not equilibrated by the time the blood leaves the pulmonary capillaries (Figure 1). The uptake of this gas is not flow-limited, but diffusion-limited; its rate of uptake therefore can be used to assess pulmonary diffusion capacity, but not cardiac output.

A perfusion gradient down the lungs
Just as there is a gradient of ventilation from the apical to the basal alveoli, there is also a gradient of their perfusion by pulmonary blood. This gradient is in the same direction as that of ventilation (more perfusion at the base than the apex), and it arises because of the effects of gravity on the pulmonary circuit.

The peak pressure of the pulmonary circuit is about 25 cm H_2O during systole. Low capillary pressures reduce the loss of fluids into the surrounding tissue and alveoli, which is beneficial, because fluid accumulation would decrease diffusion by increasing the path length. The low pressures in the pulmonary circuit are achieved despite having to carry the whole of the cardiac output. This requires the resistance of the circuit to be low, which means that, compared with the systemic circuit, there is far less smooth muscle in the pulmonary arterioles. Because of this, the pulmonary arterioles do not damp the cardiac pulse and the vasculature is much more affected by transmural pressure changes caused by gravity and posture.

Any point, x, in a column of fluid has a pressure, P_x, that differs from the pressure, P_f, at some fixed point, f, by an amount given by the equation:

$$P_x = P_f \pm h.\rho.g$$

where: h is the vertical distance between the two points (it is + $h.\rho.g$ if x is below f, and – $h.\rho.g$ if x is above f); ρ is the density of the fluid; g is the acceleration due to gravity.

This can be used to calculate the extra changes in blood pressure in blood vessels that arise because the site under consideration is above or below the heart. If the pressure is measured in cm H_2O, then, since the density of blood is about that of water, the pressure changes can be calculated simply. For example, when an individual is standing up, the blood pressure in the retinal artery is about 25 cm H_2O lower than when lying down. This is because the eyes are about 25 cm above the heart when standing, but about level with the heart when lying down. Similarly, the pressure inside the arterioles and veins in the feet when standing is raised by about 100 cm H_2O, because these vessels are 100 cm below the heart. Note that all vessels in a circulation are affected equally, so the force driving blood through the capillaries is not changed. However, whereas the raised pressure in the veins of the feet causes them to become distended, and causes the opening of more blood vessels (recruitment), this does not occur with the arterioles. This is because the veins contain little smooth muscle, and so cannot resist the distending force, whereas the arterioles contain much smooth muscle, which contracts automatically when distended by the increased pressure inside the vessel.

The pulmonary circuit behaves more like systemic veins because it contains less smooth muscle. The distension caused reduces the resistance to blood flow provided by the arterioles. Thus, even though the arteriovenous pressure difference is unchanged, the resistance of the system is decreased. As a result, the pulmonary blood flow increases from the apical to the basal alveoli in an upright individual. Recruitment of blood vessels adds to this effect.

In practice, the position is more complicated for two reasons. The first concerns the pressures in the surrounding tissues (including the alveoli). The lungs in an upright individual can be divided into three zones, each covering about one-third of the lung. In the basal zone, both arterial and venous blood pressures are greater than those in the surrounding tissue throughout the respiratory cycle, and so the above description (of the effects of hydrostatic forces on the amount of distension of the arterioles) applies directly. Blood flows are highest in this zone of the lung. In the middle zone, even though the arterial pressure is always greater than the pressure in the surrounding tissues, the venous pressures are lower. In these circumstances, blood flow is determined by vessel resistance and the difference between arterial and tissue pressure. Blood flows here are lower than in the basal zone. In the apical zone, there is no blood flow during diastole, the fall in pressure due to the height of the apex of the lung being greater than the blood pressure at this time. During systole, however, the blood pressure is raised sufficiently for the system to act like the middle zone. Blood flows are lowest in this zone. Nevertheless, in spite of these differences between the three zones, the pressure relationships change in such a way that there is also, within each of them, an increase in blood flow from the top to the bottom of the zone.

The second complication arises because as the lungs are expanded, so too are all the blood vessels and bronchioles. This reduces the resistance of both sets of vessels, but it is most evident at the base of the lung, owing to the proximity of the diaphragm and its role in promoting inspiration.

In summary, in the upright individual there is a gradient of blood flow past the alveoli from the apex (where it is lowest) to the base of the lung (where it is highest).

Ventilation–perfusion balance
Blood flow past the alveoli (perfusion) and airflow into them (ventilation) increase from the apex to the base of the lungs, and both are caused in part by gravity. (For this reason, the gradients are in the reverse direction if the subject is inverted, and disappear in a zero-gravity environment.) However, the causes of these two gradients are not identical, and their sizes are unequal. The gradient of perfusion is greater than that of ventilation. Accordingly, there is a gradient in the ventilation–perfusion ratio, which decreases from the apex to the base of the lung. The alveoli at the apex are over-ventilated for the (very small) amount of perfusion that they receive, while those at the base of the lung are under-ventilated, the larger amount of ventilation being less than the much increased perfusion.

Such ventilation–perfusion imbalances threaten to decrease the efficiency with which gas exchange takes place in the lung. Further, there is wasted work because the respiratory muscles over-ventilate the apical alveoli, and the heart over-perfuses the basal alveoli. In practice, these inefficiencies are minimized by local reflexes that act to balance perfusion and ventilation.

At the lung apex, the over-ventilation results in a fall of carbon dioxide levels in the bronchiolar tree. This causes broncho-constriction, tending to direct airflow away from the over-ventilated/under-perfused regions at the lung apex. At the base of the lung, the excessive perfusion results in an increased uptake of oxygen from the alveoli and a tendency for hypoxaemia (a low tension of oxygen in the blood) to develop. However, the pulmonary arterioles show a remarkable property that is the opposite of that shown by systemic arterioles. In systemic arterioles, hypoxaemia leads to vasodilatation, therefore an exercising tissue gets more blood, and a balance exists between the metabolic need and local perfusion of the tissue. In pulmonary arterioles, hypoxaemia has the opposite effect, causing vasoconstriction. This property, though not fully understood, is vital when the relationship between alveolar ventilation and perfusion is considered, because it means that blood tends to be directed away from the over-perfused/under-ventilated regions at the base of the lung. The stimulus to hypoxic vasoconstriction comes mainly from the low partial pressure of oxygen in the alveolus and also in the mixed venous blood (pulmonary artery). In the presence of chronic hypoxia (high altitude and some forms of lung disease) pulmonary artery pressure rises due to pulmonary vasoconstriction.

Transport of gases by the blood

Oxygen
Oxygen is carried in the erythrocytes, bound reversibly to haemoglobin. Haemoglobin is a complex molecule consisting of four subunits, each containing a molecule of ferrous iron, a tetrapyrrole ring and a protein chain. The reaction involves four molecules of oxygen and one of haemoglobin; it is one of oxygenation, reduced haemoglobin being converted to oxy-haemoglobin.

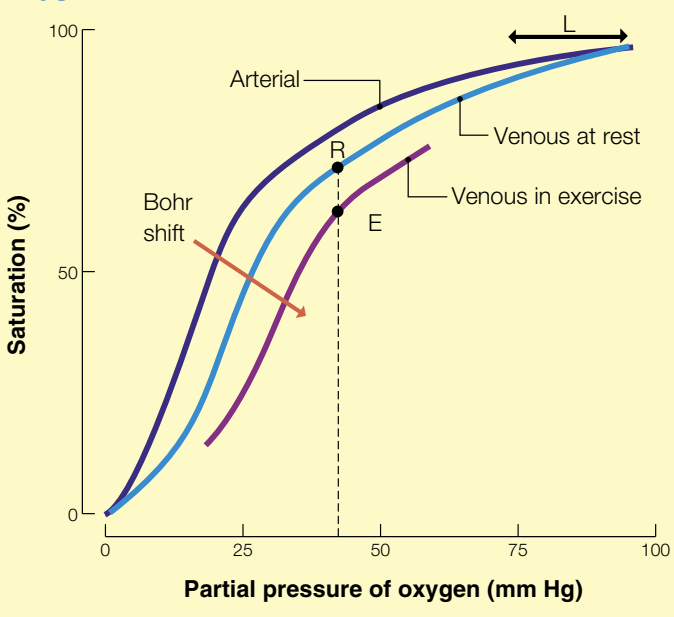
At the lungs, where the partial pressure of oxygen is high, the reaction can be represented as:

$$Hb_4 + 4O_2 \text{ Æ } Hb_4O_8 + \text{heat} + H^+$$

At the tissues, where the partial pressure of oxygen is low, the opposite reaction takes place. In health, the haemoglobin is saturated during its passage through the lungs, and the amount of oxygen carried is about 200 ml/litre of blood.

The relationship between the partial pressure of oxygen (expressed as mm Hg partial pressure of oxygen) and the amount of oxygen bound to haemoglobin is complex because the binding properties of haemoglobin depend on several factors including pH, the amount of carbon dioxide, temperature, and the amount of 2,3-diphosphoglyceric acid (2,3-DPG). In practice, therefore, it is conventional to describe the relationship under two conditions, those found in arterial and venous blood. Also, as is shown in Figure 2, it is often the case that the ordinate is percentage saturation of haemoglobin rather than amount of oxygen carried. Several aspects of the oxygen dissociation curves are important physiologically.

Oxygen dissociation curve



L, line representing the situation in the lungs; R, the situation in the tissues at rest. See text for explanation.

2

The curves show a plateau region – the molecule is almost saturated with oxygen at partial pressures as low as 75 mm Hg. This is important because oxygen is being lost from the alveoli (and the partial pressure of oxygen in them is falling) all the time between the end of one inspiration and the beginning of the next (about 2–3 s). The plateau means that blood leaving the lungs (a point somewhere on the line L in Figure 2) continues in health to be saturated with oxygen during the time when alveolar oxygen is not being replenished. It also means that whereas breathing 100% oxygen leads to huge increases in the partial pressure of oxygen in arterial blood (> 600 mm Hg) the rise in oxygen content is small, and the rise in PVO_2 produced by breathing 100% oxygen is also small.

The curves show a steep portion – this arises because the affinities for oxygen of the subunits of reduced haemoglobin increase as oxygen binds to the other subunits. (The affinity of haemoglobin is determined by the partial pressure of oxygen which produces 50% saturation of the molecule. The lower this value, the greater the affinity.) The steepness begins when the percentage saturation of haemoglobin falls below about 70%. Since this value is that found in venous blood in subjects at rest (point R, Figure 2), it means that the steep part of the curve is not used at rest but acts as a reserve for use during exercise. The steepness means that further unloading of oxygen can take place with only a small further change in the partial pressure of oxygen.

Bohr shift – the curve can be shifted towards the right by several circumstances. This is illustrated by a comparison of the arterial and venous curves. It can be predicted from the equation above and an application of Le Chetalier's principle. The oxygenation of haemoglobin releases heat and hydrogen ions, therefore increased acidity (carbonic acid and 2,3-DPG) and temperature promote unloading of oxygen from oxyhaemoglobin. This is particularly the case with exercising tissues, when the curve is shifted even further to the right by the rises in lactate and temperature. The curve is also shifted to the right by increases in the amount of carbon dioxide carried by the blood (the Haldane effect). This is partly because the carbon dioxide is carried as carbonic acid in the blood, partly because some of the carbon dioxide is carried attached to the protein chains as carbamino compounds (a process that promotes the release of further hydrogen ions from the globin molecules), and possibly also because of the steric effects of carbon dioxide molecules on the oxygen-carrying power of the haemoglobin molecule. Whatever their causes, these shifts mean that extra oxygen can be unloaded with no further fall in the partial pressure of oxygen (compare points R and E in Figure 2).

Partial pressure of oxygen – the properties of the haemoglobin molecule ensure that the fall in this pressure is minimal. This is important because the oxygen is being carried in the blood and it is required in the tissues. Oxygen passes to the tissues by diffusion, and this requires a concentration gradient (see Fick's law of diffusion, above). Keeping the partial pressure of oxygen as high as possible ensures that the gradient is maintained. The factors that aid this phenomenon (raised acid, temperature and carbon dioxide) are produced by exercising tissues, and they also promote vasodilatation of the arterioles of the systemic circulation. The effect of this is to increase blood flow (and oxygen delivery to the tissues) and to cause the opening of capillaries by recruitment. This aids diffusion by increasing the area over which it can take place and by decreasing the path length.

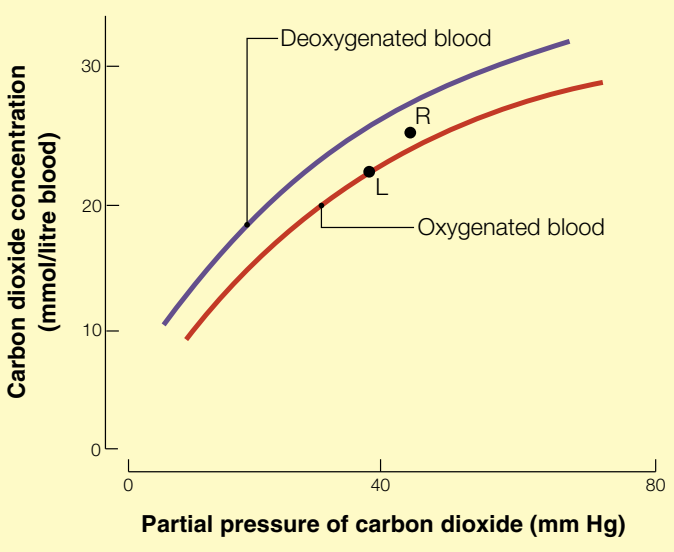
Anaemia – in a patient suffering from anaemia there is no change in the oxygen dissociation curve shown in Figure 2, because anaemia (by itself) does not affect the interaction between oxygen and the reduced amount of haemoglobin. However, if the ordinate were the amount of oxygen carried, then the plateau value would fall below the normal value of 200 ml/litre of blood by an amount that indicated the severity of the anaemia.

Carbon dioxide

About 10% of the carbon dioxide that is picked up from the tissues is dissolved in the plasma (carbon dioxide is 20 times more soluble in plasma than is oxygen). The rest is carried, directly, or indirectly, by haemoglobin. About 10% of the carbon dioxide is carried as carbamino-haemoglobin. In this reaction, the carbon dioxide molecule combines with an amino ($-NH_2$) residue from the globin molecule, a $NH.COO^-$ (carbamino) residue being formed and a hydrogen ion released. Most carbon dioxide is carried in the plasma as bicarbonate. This is achieved by the combination of carbon dioxide with water, a process catalysed by the enzyme carbonic anhydrase found in the cell membranes of erythrocytes. The carbonic acid splits up spontaneously into hydrogen and bicarbonate ions, the bicarbonate ions passing out of the erythrocyte into the plasma in exchange for chloride ions (the Hamburger shift). A further role of haemoglobin is to buffer the hydrogen ions, produced from the formation of carbonic acid or carbamino-haemoglobin.

The carbon dioxide dissociation curve (Figure 3) shows the relationship between the partial pressure of carbon dioxide and the amount that is carried in the blood (about 50 ml/100 ml of blood). It is almost linear, therefore reducing the partial pressure of carbon dioxide in the alveoli by 10% (by hyperventilation) reduces the amount of carbon dioxide carried in the blood by the same amount, the carbon dioxide being expired into the atmosphere. Figure 3 also shows that reduced (deoxygenated) haemoglobin can carry more carbon dioxide than the oxygenated form (the Haldane effect). This means that the entry of carbon dioxide into the blood from the tissues aids the unloading of oxygen. The reverse situation holds at the lungs.

Carbon dioxide dissociation curve



L, point representing the situation in the lungs
R, the situation in the tissues at rest.

3

Given the concentrations of bicarbonate ions and carbonic acid in the blood, the pH of the blood can be deduced from the Henderson–Hasselbalch equation:

$$pH = 6.1 + \log_{10}\{[HCO_3^-]/[H_2CO_3]\}$$

Normally, the concentrations of bicarbonate ions and carbonic acid are 24 and 1.2 mmol/litre, respectively. This gives a normal pH of 7.4. Since the carbonic acid is in equilibrium with carbon dioxide, it can be seen that ventilation and the pH balance of the body are interrelated. In metabolic acidosis, when there is an increase in the amount of acid in the body at the expense of the concentrations of the buffer reserve, bicarbonate levels fall and carbonic acid levels rise. Increased ventilation can remove the excess carbonic acid by driving off carbon dioxide. Also, hyperventilation raises the pH of the blood by lowering the levels of carbon dioxide and carbonic acid, and this influences the chemoreceptor reflexes. ◆

Iain Campbell

James Waterhouse is Senior Lecturer at the Research Institute of Sport and Exercise Sciences, Liverpool John Moores University. He qualified as an animal physiologist at the University of Oxford and gained his DPhil there. His research interests are circadian rhythms in humans, with particular reference to jetlag and assessing the clock- driven component of a measured circadian rhythm.

Iain Campbell is Consultant Anaesthetist at the University Hospital of South Manchester NHS Trust and Visiting Professor at Liverpool John Moores University. He qualified from Guy's Hospital Medical School, London, and trained in anaesthesia in Zimbabwe, Southend, Montreal and Leeds. His research interests include the metabolic aspects of critical illness and exercise.

SI units are not routinely used in respiratory physiology and we have chosen to follow convention in these articles. For comparison 1 atmosphere = 100 kPa = 760 mm Hg = 1000 cm H_2O

The primary function of the lungs is to deliver oxygen to the blood and to remove carbon dioxide from it. This exchange of gases takes place across an intricately folded respiratory exchange surface, consisting of the alveoli surrounded by capillaries from the pulmonary circuit. Gaseous exchange is passive, by diffusion, and the process continues only so long as the partial pressure of oxygen in the alveoli is greater than that in blood, and the partial pressure of carbon dioxide in the alveoli is lower than that in blood. Therefore, the air in the alveoli must be continually replenished by atmospheric air that is high in oxygen (about 20 kPa) and low in carbon dioxide (< 0.1 kPa). This is achieved by alternate inspiratory and expiratory movements of the lungs.

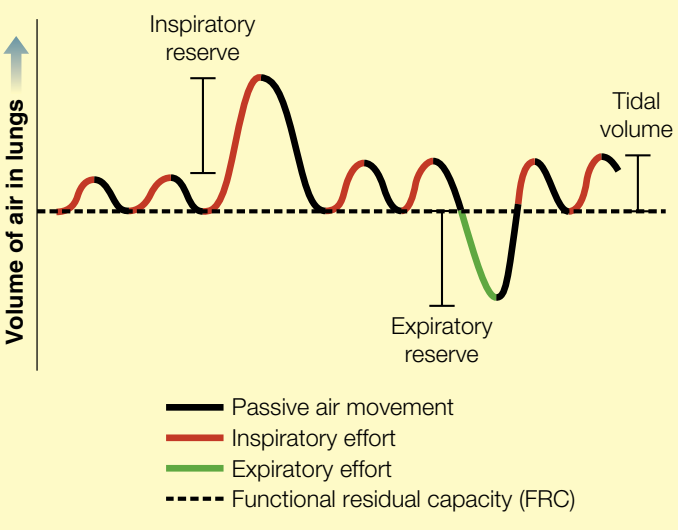
Respiratory movements

Inspiration is caused by sucking air into the alveoli. During inspiration, the alveolar pressure is made subatmospheric, so air flows into the alveoli down a pressure gradient. This decrease in alveolar pressure is caused by an increase in lung volume brought about by two factors. The first is a contraction of the external intercostal muscles, as a result of which the ribs are moved upwards and outwards, thus increasing the cross-sectional area of the chest. The second is activity in the phrenic nerve which results in contraction of the diaphragm which moves downwards. The lungs follow this increase in volume of the thoracic cavity because they are attached to the inner surface of the chest wall and the upper surface of the diaphragm by the two pleural membranes. These membranes slide over one another, allowing the lungs to unfold and to expand. They also provide protection for the delicate respiratory exchange surface.

Lung volumes

Figure 1 shows a spirometer trace from a healthy seated individual breathing at first normally (the tidal volume) and then producing a maximal voluntary inspiration and, after a few more normal breaths, a maximal voluntary expiration. At all times, the airway was open. The trace shows when inspiratory or expiratory muscle effort is required, and when the volume of air in the lungs changes passively without muscle effort. It shows that muscle effort is required to change the volume of air in the lungs away from functional residual capacity (FRC). Conversely, if the volume of air in the lungs differs from FRC then relaxation of the muscles causes air flow, so that FRC is approached. At FRC, there is no air flow even though the airways are open; that is, alveolar pressure is atmospheric.

Relationship between volume of air in the lungs and whether air movement is passive or requires muscle effort

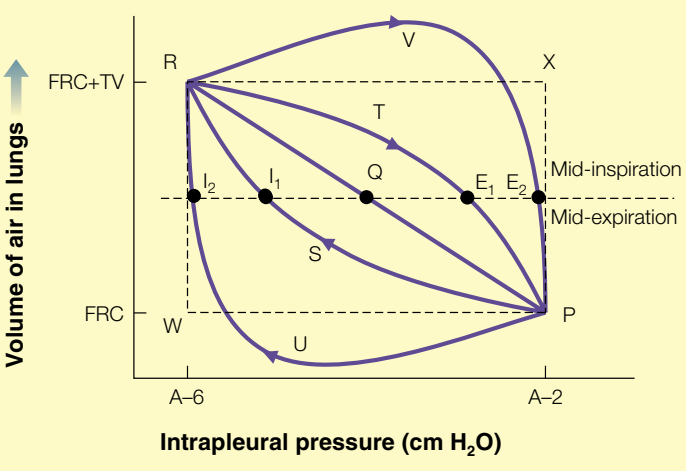


FRC is an equilibrium position for the recoil forces in the chest wall. If the pleural membranes were to be separated, the lungs would recoil inwards and tend to collapse, and the chest wall would recoil outwards. When the pleural membranes join these two structures together, the two recoil forces oppose one another; at FRC, they are equal in size. To change the volume of air in the lungs away from this equilibrium position requires muscle effort. After inspiration, the expanded lungs recoil inwards with a greater force and the chest wall recoils outwards with a lesser one, therefore the system is no longer in equilibrium. The moment that muscle effort ceases, this disequilibrium causes air to leave the lungs, forced out because the recoil of the lungs inwards is greater than the recoil of the chest wall outwards. This expulsion of air ends when FRC has been attained again.

Intra-pleural pressure

From the above, it can be understood that the two pleural membranes are being pulled in opposite directions by the recoil forces, and this suggests that the intrapleural pressure is low. Intrapleural pressure can be measured using an intra-oesophageal balloon, provided the individual is not swallowing and the oesophagus is passive and not showing any muscular activity. Figure 2 shows the intrapulmonary pressures during a normal inspiration (PQR), with the individual starting at P (FRC) and ending the inspiration at R (FRC + tidal volume, TV). To produce this trace, the airway would have to be open, with the breath being held at the end of the inspiration by muscular effort. Intrapleural pressure starts at A – 2 cm H_2O; where A is atmospheric pressure, and falls to A – 6 cm H_2O.

Relationship between intrapleural pressure and volume of air in the lungs during a single breath



A, atmospheric pressure; FRC, functional residual capacity; TV, tidal volume. For explanation see text.

At FRC, the pressure difference across the lungs – with the pressure in the intrapleural space lower – causes an outward force on the lungs that balances their inward recoil. This gradient is 2 cm H_2O; since the intra-alveolar pressure is A, the intrapleural pressure is A – 2 cm H_2O. At FRC, the pressure difference across the chest wall – with the pressure immediately inside it in the intrapleural space lower – is also 2 cm H_2O, since the pressure outside the chest wall is A. This causes an inwards force that balances the outward recoil of the chest wall.

At point R, the expanded lungs recoil inwards with a greater force. To prevent their movement (the breath is being held), a greater pressure difference across them is required, with the intrapleural pressure lower than alveolar pressure. This gradient is 6 cm H_2O and, since alveolar pressure is A (the airway is open and there is no air flow), the intrapleural pressure becomes A – 6 cm H_2O. This means that, at point R, the pressure drop across the chest wall is also 6 cm H_2O (the pressure outside the chest wall remaining atmospheric). However, the chest wall is nearer to its equilibrium position and therefore a pressure drop of 1 cm H_2O (pressure inside the chest wall in the intrapleural space being lower) would balance its recoil force outwards. That is, the chest wall is not in equilibrium. This is exactly why inspiratory muscle effort is required to maintain this position at the end of inspiration – it imposes a force that balances this disequilibrium.

There are two other ways in which the volume of air in the lungs could be held at FRC + tidal volume. First, the mouth could be closed and then no muscle effort would be required. In this circumstance, the inward recoil of the lungs would be greater than the outward recoil of the chest wall, and this would cause the alveolar and mouth pressures to rise to A + 5 cm H_2O; it would also decrease venous return slightly (a very mild Valsalva manoeuvre). Second, if the airway were open to the atmosphere and the pressure outside the chest wall were decreased to A – 5 cm H_2O, inspiration would occur without the need for muscle effort. This is how inspiration is achieved during negative pressure artificial ventilation.

Origin of the recoil forces

The recoil of the chest wall is due to the elastic properties of the muscles, tendons and joints. The recoil of the lungs is more complex. In part, it is due to the presence of elastic fibres in the lungs, but it is also due to surface tension forces.

Surface tension forces arise at an air–water interface (the alveoli are lined with fluid), because the attraction between molecules of water is stronger than that between air and water molecules. The effect of this is for the air–water interface to become as small as possible. (It is for this reason that bubbles are spherical, because a sphere has the smallest surface area for a given volume.) The tendency for surface tension to decrease the area of an air–water interface results in the alveolus becoming smaller, and this contributes to the recoil force of the lungs. This is a function of the surface tension of the liquid lining the alveoli. The relationship between pressure in a bubble (P) or alveolus, and the size of the bubble (radius r) is given by the law of Laplace: $P = 2T/r$ where T is the surface tension of the liquid. It follows from this, that if the lung is filled with saline rather than air, its volume can be increased more easily, because the recoil force is due only to the elastic fibres, there being no air–water interface.

Pulmonary surfactant

Surface tension forces can be decreased by substances called surfactants (washing-up liquid is a common example). Type II pneumocytes produce a pulmonary surfactant. These cells are not thin like the type I alveolar cells, but more spherical in shape, and have lamellate inclusions that are the source of the surfactant. They continuously secrete the surfactant onto the alveolar surface.

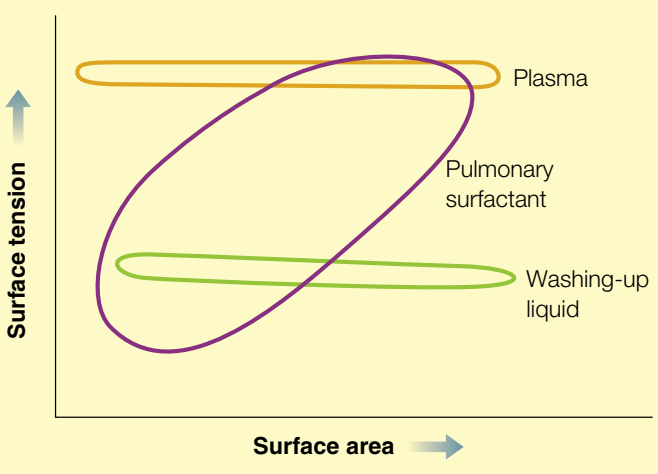
Chemically, pulmonary surfactant is complex, but one of its constituents is dipalmitoyl choline. Like other surfactants, it is an amphipathic molecule, one end being charged and hydrophilic, and the other lipophilic, consisting of a long chain of hydrocarbon residues. The hydrophilic parts of the molecules insert themselves into the surface of the water layer and form a boundary layer. The lipophilic parts interact with each other, as a result of which the cause of the surface tension – the increased attraction of molecules in the aqueous phase – is reduced.

Pulmonary surfactant is produced under the influence of cortisol, and its production starts in the fetus towards the end of a normal pregnancy. For premature babies, therefore, production might be low, which gives rise to difficulty in breathing (due to the extra forces required to overcome the surface tension forces) leading to 'respiratory distress of the newborn'.

Pulmonary surfactant also stabilizes the alveoli of the lungs. The millions of alveoli in the lung tend to be similar in size, but those at the apex of the lung in an upright individual are larger than those towards the base (see below).

In terms of Laplace's law the intra-alveolar pressure in the smaller alveoli (r is less) tends to be greater than that in the larger ones. This implies that the system is unstable; with the smaller alveoli tending to collapse at the expense of the larger ones. Such damage to the lungs does not occur because of the second property of pulmonary surfactant (Figure 3). Unlike washing-up liquid, in which the surface tension-reducing effect is independent of the area of the air–water interface, the surface tension-reducing effect of pulmonary surfactant increases as the surface area of the interface decreases. (This is possibly because the amount of interaction between the molecules increases as the molecules are squeezed together.) Whatever the reason, as r decreases, so does the value of 2T; that is, the pressure excesses inside the alveoli (2T/r) become independent of alveolar size.

Relationship between surface area and surface tension



3

Air flow and pulmonary resistance

In Figure 2 the line PR joins the two points during a single inspiration when there is no movement of air or the lungs and chest wall system – the beginning and end of the inspiration. It is called the compliance line, and is a measure of the distensibility of the lungs. Since the normal tidal volume is about 400 ml, and the pressure change required to produce it is about 4 cm H_2O, the compliance of the lung at these volumes (also known as 'static' compliance) is about 100 ml/cm H_2O.

It would be expected that, during inspiration, the intrapleural pressure would move along the line PQR, and that it would follow the line RQP during expiration. In practice, this would be the case only if inspiration and expiration were extremely slow; during a normal inspiration, the trace follows one curve (PSR), and, during expiration, another (RTP). The pressure changes follow a loop which illustrates hysteresis. The width of the hysteresis loop is determined by the speed of air movement and by the degree of constriction of the airways. Thus, both when the breath is of a normal size, but inspiration and expiration are both quicker, and when the breath is of a normal size and speed, but the airways are constricted, the loop is wider (PUR during inspiration, and RVP during expiration).

Considering the moment when the breath is midway between its start and end (the horizontal line) and air flow is taking place, it can be seen that the intrapleural pressure is more negative during inspiration and less negative during expiration. Moreover, the deviations of the observed trace from point Q on the compliance line are greater if the breath is being taken faster or the airways are constricted. This is illustrated by comparing points Q, I_1 and I_2 for changes during inspiration, and Q, E_1 and E_2 for changes during expiration.

These deviations from the compliance line represent the extra pressure gradient across the lung (extra force) involved in changing the volume of the lung and moving air through the airways. They reflect the resistance of the system, also known as 'dynamic' compliance. By analogy with an ohmic resistor, the resistance, R, can be defined as R = pressure gradient/flow. This can be re-arranged to give pressure gradient = resistance x flow. This equation explains why the loop widens if the breath is taken more quickly (flow is higher) or the airways are constricted (resistance is greater).

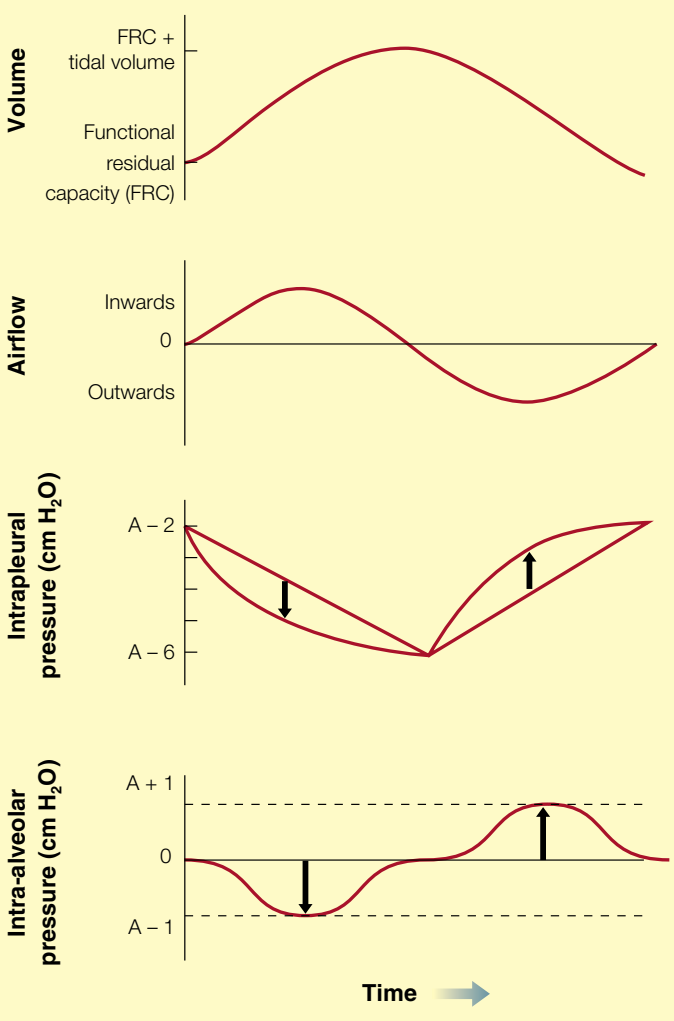
Figure 2 indicates that the extra pressure required during the normal breath at the mid-point of a normal inspiration, point I_1, was 1.0 cm H_2O. (The compliance line predicted an intra-pleural pressure of A – 4 cm H_2O, but the observed value was A – 5 cm H_2O.) Given that the air flow at this moment was 0.5 litre/s, then the total pulmonary resistance was 2 cm H_2O/litre/s.

Total pulmonary resistance can be divided into airway resistance (the resistance of the airways to the flow of air through them) and lung tissue resistance (the resistance of the lung tissue elements to being distorted). Normally, airway resistance accounts for 80% of total pulmonary resistance. This means that the pressure gradient required to suck air into the alveoli from the mouth – to overcome airway resistance – is about 0.8 cm H_2O (80% of the difference between points Q and I_1 in Figure 2). Since the mouth is at atmospheric pressure, intra-alveolar pressure becomes subatmospheric by 0.8 cm H_2O at this moment. It becomes supra-atmospheric by this amount during the mid-point of a normal expiration (80% of the difference between points Q and E_1).

At point I_1, when the intrapleural pressure is A – 5 cm H_2O and the intra-alveolar pressure is A – 0.8 cm H_2O, the pressure gradient across the lungs is 4.2 cm H_2O. Since the pressure gradient required to overcome the compliance of the lungs (given by point Q on the compliance line) is 4 cm H_2O, this leaves 0.2 cm H_2O as the pressure required to overcome lung tissue resistance.

The time courses of the volume, flow and pressure changes in the alveoli and the intrapleural space during the course of a normal breath are summarized in Figure 4.

Volume and pressure changes during a normal breath



Note that at mid-inspiration (downward arrows), intrapleural pressure is 1 cm H_2O below the compliance line, and intra-alveolar pressure is 80% of this. The opposite holds during expiration (upward arrows).

A, atmospheric pressure

4

Work done in breathing

As indicated in Figure 1, when muscle effort is required during breathing, work is being done. The amount of work entailed is calculated as follows:

Work done = Force x Distance
Work done = Force/Area x (Distance x Area)
Work done = Pressure x Volume

This last equation means that the areas contained by different components of the pressure–volume curves in Figure 2 can be used to calculate the amount of work done. (Area within a curve equals length x breadth; if the axes are pressure and volume, then, from the above equation, this becomes work done.)

- The work done against elastic recoil during inspiration is the area of the triangle PWR.
- The work done against total pulmonary resistance during a normal inspiration is the area of the secant PSRQP.
- The total work done during a single inspiration is the sum of these two areas.

During expiration, the work done against total pulmonary resistance is the area RTPQR, but the area of the triangle RXP is the amount of work released by the recoil of the lungs. Since the triangle is larger in area than the secant, expiration is passive. This difference between the two areas, the work released during an expiration, can be used for talking or singing, for example.

In the case of a more rapid breath, or one against a higher airway resistance (with the same compliance line, PR, but a wider loop, PURVP), the calculation is performed in the same way. It shows that the work done against total pulmonary resistance during inspiration is greater than before, though the work done against elastic recoil is unchanged. Note, however, that the work that has to be performed to overcome total pulmonary resistance during expiration is now greater than the work released by lung recoil (the area RVPQR is greater than the area RXP). This means that expiration is also an active process.

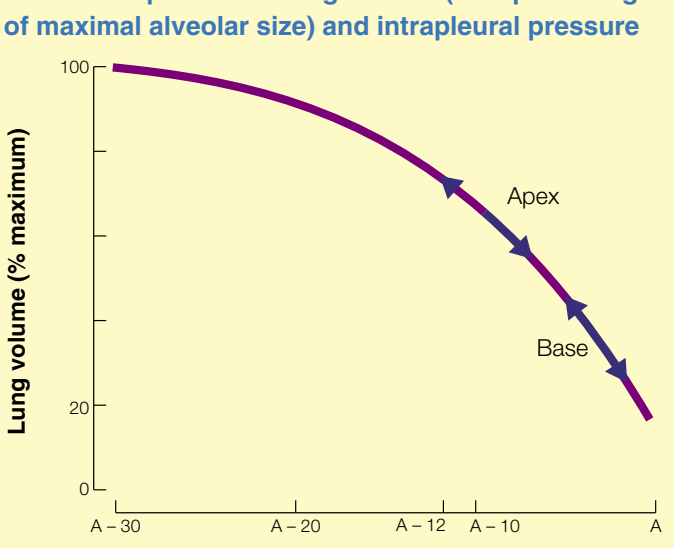
Ventilation gradient down the lungs

The apical alveoli are more distended than those at the base of an upright individual.

Figure 2 indicates that the intrapleural pressure is A – 2 cm H_2O at FRC. In fact, this is correct only towards the base of the lung. Nearer the apex, the pressure is more negative. The system acts as though the lung were a fluid with a density 0.2 times that of water. Therefore, at the lung apex, about 30 cm above the lung base in an upright individual, the intrapleural pressure is 6 cm H_2O less than at the base (A – 8 rather than A – 2 cm H_2O). This explains why the apical alveoli are more distended than those at the base of the lung.

Figure 2 also indicates that the relationship between lung volume and pressure gradient across the lungs, the compliance, is linear (the line PR). This is essentially true for breaths of a normal size, but, if volume changes from maximal voluntary inspiration to maximal voluntary expiration are considered, then compliance is found to be less with larger lung volumes (Figure 5).

Relationship between lung volume (as a percentage of maximal alveolar size) and intrapleural pressure



A, atmospheric pressure

5

Putting these two facts together, it can be seen that, during an inspiration of normal size starting at FRC, whereas the intra-pleural pressure falls by 4 cm H_2O (see Figure 2) at all levels of the lung, the different levels of the lung are described by different parts of the compliance curve. Therefore (see Figure 5), the fall in intrapleural pressure of 4 cm H_2O associated with the inspiration causes the alveoli at the lung apex (A – 8 to A – 12 cm H_2O) to expand less than those at its base (A – 2 to A – 6 cm H_2O; Figure 5). That is, the alveoli at the apex are more distended at FRC than are those at the base of the lung, but they inflate less for any given fall in intrapleural pressure. ◆

Regional Anaesthesia: Choice of Agents, Additives, Systemic Effects and Toxicity

Carol A Chong

Nicholas M Denny

Carol A Chong is Specialist Registrar on the East Anglian Anaesthetic Training Rotation. She qualified from the University of Queensland, Brisbane, Australia, and has also trained in Lancaster, Australia and Malaysia. She is currently Pain Fellow at St Bartholomew's Hospital, London.

Nicholas M Denny is Consultant Anaesthetist and Lead Clinician in the Department of Anaesthesia, Queen Elizabeth Hospital, King's Lynn, Norfolk. He qualified from St Thomas' Hospital, London, and spent a year at the University of Illinois Hospital, in Chicago. He lectures, nationally and internationally, on regional anaesthesia including the RCA Fellowship Revision Courses.

Local anaesthetics reversibly block nerve impulses and are the mainstays of regional anaesthesia. Local anaesthetics can be divided into two main groups, esters (e.g. cocaine, procaine, chloroprocaine, tetracaine (amethocaine)) and the more commonly used amides (e.g. lidocaine (lignocaine), prilocaine, bupivacaine) and the new drugs, ropivacaine and L-bupivacaine, which are single enantiomers.

The onset, potency and duration of action of each agent are determined by the physical properties of the drug, in particular its pK_a, lipid solubility, protein binding and its intrinsic vasodilator activity (Figure 1).

pK_a – the pK_a of a chemical compound represents the pH at which its ionized form and non-ionized forms are in equilibrium. The pK_a of a local anaesthetic determines its speed of onset of action because only the uncharged form is lipid soluble and is able to diffuse quickly across the myelin layers of nerve fibres. Local anaesthetics are weak bases but are injected in acidic solutions as hydrochloric salts. The tertiary amine (hydrophobic or water insoluble) becomes quaternary and is thus soluble in water and suitable for injection. At physiological pH, the proportion of the drug that dissociates into a free base (which is lipid soluble) is determined by its pK_a. This un-ionized portion passes through the lipid cell membrane to the inner axon where re-ionization takes place. It is the re-ionized portion of the local anaesthetic that blocks sodium channels. The closer the pK_a of the drug is to physiological pH (7.4) the greater the amount of free base or un-ionized drug that will be present and the faster the onset of block. The higher the pK_a, less un-ionized drug is available and the slower the onset of block. For example, at pH 7.4, lidocaine (lignocaine) (pK_a 7.7) is 35% un-ionized and bupivacaine (pK_a 8.4) is 12–13% un-ionized, therefore lidocaine (lignocaine) has a faster onset of action than bupivacaine in equipotent doses.

Lipid solubility determines a local anaesthetic's potency. Potency is defined as the minimum amount of a drug required to produce a given effect. In simple terms, a local anaesthetic that is more lipid soluble will have more of its molecules penetrate the nerves; therefore less drug is required to give the same blockade.

Protein binding – the duration of action of each local anaesthetic depends on its degree of protein binding. The sites of action for local anaesthetics are sodium channels, which are protein molecules, therefore highly bound drugs have a long duration of action. However, the intrinsic vascular effects of the drug may also influence its duration of action as well as the total dose given.

Local vascular effects – all local anaesthetics are vasodilators, except for cocaine, ropivacaine and L-bupivacaine, which are vasoconstrictors. The degree of vasodilatation influences the toxicity and potency of local anaesthetics because a higher degree of vasodilatation causes more systemic absorption of the drug, particularly in vascular sites and thus less drug is available for neural blockade.

Differential block – ropivacaine is said to produce more selective blockade for sensory fibres when used in lower concentrations than bupivacaine. It has lower lipid solubility and a similar high pK_a and this reduces its affinity and penetration of the myelin sheath. Therefore, blockade of C fibres is greater than that of larger myelinated A fibres.

Physical properties of local anaesthetics

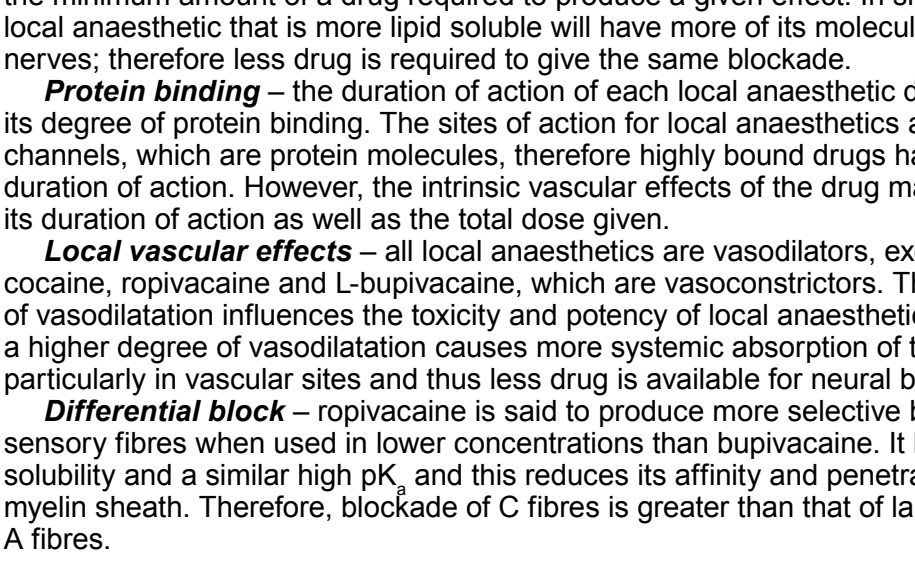
Drug	pK_a	Relative lipid solubility	Plasma protein bound (%)	Onset of action	Duration of action
Procaine	8.9	1	6	Slow	Short
Lidocaine (lignocaine)	7.7	200	65	Fast	Moderate
Prilocaine	7.8	50	55	Fast	Moderate
Bupivacaine	8.1	1000	95	Moderate	Long
Ropivacaine	8.1	400	94	Moderate	Long
L-bupivacaine	8.1	1000	95	Moderate	Long

Systemic effects and toxicity

The two potentially lethal complications of local anaesthetic systemic toxicity are CNS and cardiovascular system collapse, which are nearly always the result of rapidly rising plasma drug concentration caused by inadvertent intravascular injection. Other forms of local anaesthetic toxicity include neural toxicity, methaemoglobinaemias and allergic reactions.

Early signs of systemic effects should be sought. Mild symptoms, such as numbness of the tongue or light-headedness should alert the anaesthetist to more ominous problems (Figure 2).

Development of toxic effects with rising plasma concentrations of lidocaine (lignocaine)



Adapted from: Cousins M J, Bridenbaugh P O. *Neural Blockade in Clinical Anesthesia and Management of Pain.* 3rd ed. Philadelphia: Lippincott-Raven. 1998. With permission from the publisher

CNS toxicity: local anaesthetic toxicity causes CNS excitation before coma because of selective neural blockade. Inhibitory pathways in the cerebral cortex are inhibited first by local anaesthetics, allowing the excitatory pathways to become unchecked. Increased cortical activity may result in convulsions.

Cardiovascular system: initially there is increased blood pressure and tachycardia from CNS excitation. This is followed by:

- decreased cardiac output (negative inotropy)
- vasodilatation and profound hypotension
- prolonged QRS and PR intervals therefore arrhythmias
- ventricular arrhythmias with bupivacaine
- cardiac arrest.

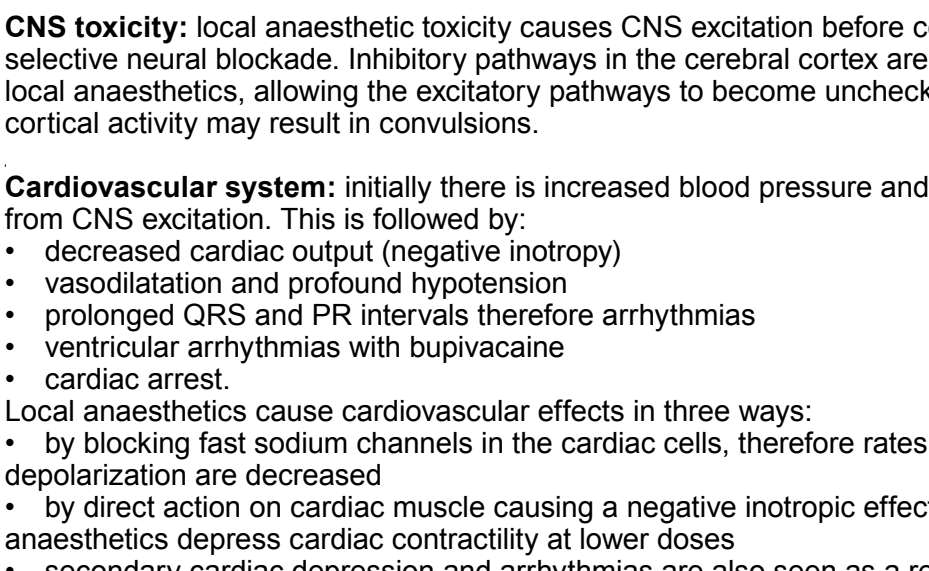
Local anaesthetics cause cardiovascular effects in three ways:

- by blocking fast sodium channels in the cardiac cells, therefore rates of depolarization are decreased
- by direct action on cardiac muscle causing a negative inotropic effect: potent local anaesthetics depress cardiac contractility at lower doses
- secondary cardiac depression and arrhythmias are also seen as a result of direct effects on brainstem cardiovascular centres.

Cardiovascular collapse to CNS ratio (CC/CNS) is the ratio of the dose of drug that will cause cardiovascular collapse and CNS toxicity. The ratio for lidocaine (lignocaine) is much higher (7.1) than that for bupivacaine (3.7), which means a proportionately much higher dose of lidocaine (lignocaine) is needed to cause cardiovascular toxicity than to produce symptoms of CNS toxicity. It is desirable to have a high ratio so that the anaesthetist is alerted by CNS symptoms before cardiovascular collapse occurs. With bupivacaine, cardiovascular collapse has been reported without previous signs of CNS toxicity.

Bupivacaine induces arrhythmias that are refractory to treatment because its inhibition of sodium channels is prolonged. Bupivacaine dissociates from myocardial sodium channels slowly, particularly at physiological heart rates and therefore tends to accumulate. Lidocaine (lignocaine) disassociates in one diastole time and tends not to accumulate (Figure 3). Diastole time is the period of myocardial relaxation and is dependent on heart rate. The time constant for dissociation of lidocaine from the cardiac sodium channel is much briefer than the R:R interval enabling drug dissociation from the channel during diastole. Bupivacaine also blocks slow calcium channels and potassium channels. It is 16 times more likely than lidocaine (lignocaine) to induce ventricular arrhythmias. Bupivacaine is a racemic mixture with the R isomer being more toxic; hence L-bupivacaine and S-ropivacaine are marketed as safer options. There are reports suggesting that resuscitation from cardiac arrhythmias induced by L-bupivacaine and S-ropivacaine is less prolonged and more successful than those induced by racemic bupivacaine.

Time constants for dissociation of local anaesthetics



Adapted from: Arlock P. Actions of Three Local Anaesthetics: Lidocaine, Bupivacaine and Ropivacaine on Guinea Pig Papillary Muscle Sodium Channels. *Pharmacol Toxicol* 1988; **63(2):** 96–104. With permission from the publisher.

Neural toxicity: local anaesthetics at clinically used concentrations are unlikely to cause direct neural toxicity. There has been some concern with spinal lidocaine (lignocaine) following reports of cauda equina syndrome with intrathecal microcatheters (32 G) and 5% lidocaine (lignocaine) with dextrose. These fine-bore catheters allow extremely slow injections to be made, preventing the drug from mixing and being diluted by CSF, allowing it to pool undiluted around the nerves of the cauda equina and exposing them to high concentrations of lidocaine (lignocaine). This is not to be confused with the controversial transient radicular irritation syndrome in which patients complain of transient buttock pain, which responds to simple analgesics.

Methaemoglobinaemia most commonly follows prilocaine exposure but has also been reported with lidocaine (lignocaine), tetracaine (amethocaine) and benzocaine. Prilocaine is converted by hepatocytes to O-toluidine, which oxidizes haemoglobin to methaemoglobin. Pulse oximetry may be helpful in detecting this by showing a saturation of about 85%. Methaemoglobinaemia is treated with intravenous methylene blue, 1 mg/kg.

Allergic reactions to the more commonly used amide local anaesthetics are uncommon. There have been reports of anaphylaxis to the para-amino-benzoic acid (PABA) moiety ester local anaesthetics.

Management

Prevention of local anaesthetic toxicity involves the avoidance of intravascular injection. This is done by careful needle placement, aspirating before injecting and not giving the whole dose at once, but in several smaller doses as separate injections. Close verbal contact should be maintained with the patient so that any symptoms may alert the anaesthetist to problems. If symptoms of toxicity occur, injection should be stopped immediately.

Safe doses of local anaesthetic, as recommended in the British National Formulary are useful as a guide, but consideration should be given to the site of injection, additives, drug, patient, absorption and metabolism (Figure 4). Factors that affect the systemic absorption of a local anaesthetic include:

- dose injected into tissues
- blood supply to site of injection
- use of vasoconstrictors (e.g. adrenaline (epinephrine) 1:200,000 decreases absorption by one-third), but only local anaesthetics with intrinsic vasodilatory properties have systemic uptake decreased by addition of vasoconstrictors; the uptake of ropivacaine is not influenced by vasoconstrictors because ropivacaine itself has vasoconstricting properties
- characteristics of the local anaesthetic. Different systemic absorption of local anaesthetics also occurs at different sites. The descending order of uptake is intercostal, caudal, epidural, brachial plexus, sciatic, femoral (Figure 5).

Treatment involves management of the airway, breathing and circulation. Seizures should be controlled with benzodiazepines or sodium thiopentone. Early management of the airway, venti-lation and control of seizures reduces mortality (Figure 6).

Treatment of systemic toxicity

• Airway	Secure if necessary, give oxygen
• Breathing	Ventilation, get patient to take deep breaths, provide oxygenation
• Circulation	Inotropic support, cardiopulmonary resuscitation if necessary, bretylium for arrhythmias
• Seizures	Treat with diazepam, thiopental (thiopentone)
• Correct	Acidosis, electrolyte imbalances

6

Choice of agents and additives

Neuroaxial blockade

The most commonly used local anaesthetics for neuroaxial blockade are bupivacaine and lidocaine (lignocaine). More recently, levobupivacaine and ropivacaine have also been used. The factors that affect the duration and spread of intrathecal blockade are the type and total dose of local anaesthetic, its specific gravity relative to CSF and the additives used (Figure 7).

Studies evaluating the use of ropivacaine for intrathecal use have found it to be half as potent as bupivacaine, but it does not have a product licence. Many substances have been used intrathecally or epidurally as additives or sole agents; the most popular remain opioids and vasoconstrictors. Many of these additives have also been used in the management of chronic pain conditions. Some substances that have been used by the neuroaxial route are:

- bicarbonate
- clonidine
- cholinergic drugs (e.g. neostigmine)
- N-methyl-D-aspartate (NMDA) antagonists (e.g. ketamine)
- other pharmacological agents (e.g. somatostatin, calcitonin, adenosine, baclofen).

Duration of local anaesthetic solutions in spinal anaesthesia

Agent	Concentration (%)	Volume (ml)	Baricity	Total dose (mg)	Duration (minutes)	Duration with adrenaline (epinephrine) 0.2 mg
Bupivacaine	0.5	2–4	Isobaric	10–20	140–200	90–240
	0.5		2–4	Hyperbaric	10–20	120–180 90–180
	0.25		2–5	Isobaric	5–12.5	120–180 90–240
2% Lidocaine	2.0		2–4	Isobaric	40–80	100–140 90–180
(lignocaine)	5.0		1–2	Hyperbaric	50–100	30–60 30–60

7

Vasoconstrictors: adrenaline (epinephrine) is the most common vasoconstrictor added to local anaesthetic solutions for intrathecal anaesthesia. Adrenaline (epinephrine), 5 µg/ml, is used for epidurals and is said to have no β-mimetic side-effects. Phenylephrine has also been used. Vasoconstrictors are thought to increase the intensity and duration of the block by two mechanisms. Firstly, vasoconstriction of epidural vessels has been shown to reduce systemic uptake and more of the drug becomes available to the nerves. Secondly, vasoconstrictors may exert a direct antinociceptive effect by acting on α_1- and α_2-receptors, thus modulating dorsal horn action. This has been shown to have a dose-dependent analgesic effect. However, vasoconstrictors do not prolong spinal anaesthesia to the same degree with all local anaesthetic agents. Lidocaine (lignocaine) and prilocaine benefit the most because they have intrinsic vasodilatory properties.

Bicarbonate: alkalinization of local anaesthetic solutions (which are weak bases in an acidic solution), increase the un-ionized component, allowing faster penetration of nerves and therefore theoretically a quicker onset of block after epidural administration. The literature is controversial, with some studies unable to demonstrate a difference when bicarbonate is added to 0.5% bupivacaine or 2% lidocaine (lignocaine) for epidurals; however, other studies have demonstrated this technique to be effective. There is a risk of precipitation with bicarbonate and solutions with concentrations ranging from 1 to 8.4% have been used.

Clonidine has been shown to prolong neuroaxial blockade and extends the duration of postoperative analgesia beyond the period of anaesthesia. Clonidine has two mechanisms of action. It is an agonist at the α_2-receptors by activating a negative-feedback mechanism; it decreases the release of catecholamines thus modulating nociceptive input at the dorsal horn. It also has cholinergic effects by increasing the amount of acetylcholine available centrally. Oral premedication with clonidine also prolongs intrathecal anaesthesia. However, administration of clonidine via the neuroaxial route produces better analgesia than systemic administration and at lower doses. Clonidine, 150 µg, is commonly used for epidural administration; problems include hypotension, bradycardia and sedation.

Opioids: opioid receptors are found in the dorsal horn as well as in the brainstem. Binding of opioid receptors causes the nerve membranes to become hyperpolarized, decreasing nerve transmission. Substance P and glutamate release are also inhibited. Many different types of opioids have been used in neuroaxial blockade. Their onset and duration of action depends on their physicochemical properties. For example, morphine, which has relatively low lipid solubility, has a delayed onset but prolonged duration of action of up to 24 hours. Fentanyl is more lipid soluble than morphine and therefore produces quicker onset of analgesia, but has a shorter duration of action. The properties of diamorphine lie in between. Only 4% of epidural-administered morphine reaches the CSF. Most of the morphine is taken up by the epidural fat where it is absorbed rapidly by the vertebral venous plexus.

Animal experiments suggest that opioids and local anaesthetic may have a synergistic effect. The addition of opioids allows more dilute solutions of local anaesthetic to be used for both epidural and intrathecal blockade.

Respiratory depression seen with neuroaxial opioids occurs because of rostral spread of the opioids to the brainstem. This is more likely with the less lipid-soluble agents. The common side-effects of opioids such as pruritus, urinary retention and vomiting are also associated with its rostral migration to the brainstem. Opioids and α_2-adrenergic agonists have an additive effect when administered by the neuroaxial route.

Cholinergic drugs: the cholinergic nerves play a role in central pain mechanisms. Drugs that increase the amount of acetylcholine available centrally (e.g. clonidine, neostigmine) have been shown to produce analgesia. However, intrathecal neostigmine, 25–100 µg, is associated with a high incidence of nausea and vomiting and should not be used intrathecally. Neostigmine should not be administered epidurally because rapid systemic uptake occurs.

NMDA antagonists: the NMDA receptor is activated by glutamate, an excitatory neurotransmitter that plays a key role in central transmission of pain signals. Ketamine blocks the open calcium channel on the NMDA receptor complex. Ketamine, 0.7 mg/kg, has been used intrathecally but is often associated with a high incidence (up to 30%) of psychomimetic effects. This dose produces inadequate analgesia (though sufficient motor blockade) and therefore should not be used as the sole anaesthetic agent. There have been some concerns about the neurotoxicity of intrathecal ketamine but this could be due to the preservatives in commercial preparations. There have been reports of ketamine, 1 mg/kg, being used caudally as a sole analgesic, producing surgical and postoperative analgesia equivalent to that of bupivacaine.

Peripheral nerve blockade

The choice of agent for peripheral nerve blockade depends on the site, the nature of the operation and whether the purpose of the block is primarily for anaesthesia or postoperative analgesia or both.

Generally, agents such as lidocaine (lignocaine) and prilocaine, with a faster onset time, are best used in anaesthetic blocks for short operations in which prolonged postoperative analgesia is not required. Long-acting local anaesthetics, such as bupivacaine, L-bupivacaine and ropivacaine are best suited for painful procedures requiring prolonged analgesia. In the arm, bupivacaine and ropivacaine have a duration of action of about 12 hours. In the leg, bupivacaine acts for 24 hours and ropivacaine lasts for about 15 hours.

In the arm, where neither bupivacaine nor ropivacaine last for more than 12–14 hours, catheter techniques have been used to provide a longer period of analgesia. Ropivacaine has been shown to have quicker onset and better quality anaesthesia when used for axillary blocks compared with bupivacaine.

Various agents have been used to enhance peripheral nerve blockade:

- vasoconstrictors (e.g. adrenaline (epinephrine), felypressin)
- pH modifers (e.g. bicarbonate)
- opioids (e.g. tramadol, fentanyl)
- enzymes (e.g. hyaluronic acid)
- others (e.g. neostigmine, clonidine, ketamine).

Adrenaline (epinephrine) and felypressin: owing to the intrinsic vasodilator properties of local anaesthetics (with the exception of ropivacaine and L-bupivacaine, which are vasoconstrictors in low concentration), vasoconstrictors decrease vascular uptake and thus allow more anaesthetic molecules to reach the nerve membrane in vascular sites. They improve the depth and duration of anaesthesia in the order lidocaine (lignocaine), prilocaine, bupivacaine, L-bupivacaine and ropivacaine.

Adrenaline (epinephrine), 5 μg/ml, is commonly used. Lidocaine (lignocaine), and prilocaine have been shown to benefit greatly from addition of adrenaline (epinephrine) for peripheral nerve blocks. However, prilocaine and bupivacaine are not markedly enhanced for epidural blockade when vasoconstrictors are added.

Felypressin, 0.03 IU/ml, is added to prilocaine for eye blocks. It is a synthetic octapeptide that is chemically related to vasopressin.

Bicarbonate: the onset and duration of peripheral nerve blocks may be improved by the addition of sodium bicarbonate. Sodium bicarbonate increases the pH of the local anaesthetic solution and thus more un-ionized drug is available for diffusion into the nerve sheath. This technique is useful in brachial plexus blockade. 1 ml of 1% sodium bicarbonate for each 20 ml of local anaesthetic solution has been shown to alkalinize a range of local anaesthetics without risk of precipitation. However, ropivacaine precipitates at a pH of 6.0 and is unsuitable for alkalinization.

Clonidine: in a recent review of adjuncts to local anaesthesia in brachial plexus blockade, clonidine, up to 150 μg, was shown to enhance the duration and quality of the block. However, trials using a control group of patients receiving clonidine systemically are yet to be done. Clonidine may enhance analgesia via a direct effect on nociceptor α_2-receptors. Alternatively, it may reduce vascular uptake of local anaesthetic via effects on vascular adrenergic receptors.

Neostigmine: studies using neostigmine, up to 500 μg, as an adjunct to peripheral nerve blockade have not been convincing. This acetylcholinesterase inhibitor potentiates endogenous acetylcholine. Activation of acetylcholine receptors is thought to contribute to an endogenous form of analgesia and the administration of systemic neostigmine has been shown to display a dose-dependent analgesic effect. Muscarinic receptors have also been found on peripheral nerves.

Opioids: opioid receptors have been found on peripheral nerves and it seems logical to add opioids to local anaesthetic solutions for peripheral nerve blockade. However, there is insufficient evidence to recommend the use of opioid analgesia in peripheral nerve blockade. Studies involving the addition of fentanyl, tramadol, morphine and alfentanil have been performed but results are unconvincing. Adverse effects of opioid administration are not avoided by using them in peripheral nerve blockade.

Hyaluronidase: this enzyme is used in combination with local anaesthetics for eye blocks. It is said to increase the speed of onset and quality of block by enhancing penetration through fascial planes. It is manufactured as a powder for reconstitution and the dose for ophthalmology is 15 IU/ml.

Regional Anaesthesia: Physiology and Pharmacology

Michael J Hudspith

Michael J Hudspith is Consultant in Anaesthesia and Pain Relief at the Norfolk and Norwich Hospital, UK. He qualified from King's College Hospital, London, after an intercalated PhD in neuropharmacology. He trained in anaesthesia and pain management in East Anglia and Sydney, Australia.

The role of the nociceptive sensory system is to alert the individual to potential or actual tissue damage arising from internal pathology or external injury. Although pain may have evolved to serve a protective function, it is clear that pain and associated physiological consequences create significant morbidity and even mortality following trauma or surgery. Regional anaesthesia aims to alleviate or prevent this morbidity and to minimize mortality by selective blockade of afferent sensory input from the periphery to the CNS.

The practice of regional anaesthesia necessitates a sound grasp of three-dimensional anatomy in order that the practitioner may safely place a needle and appropriately access central or peripheral nervous system targets. Once a route of administration of drug towards neural tissue is established it is paramount that an appropriate agent, in an appropriate dose, is administered and that the consequences of such administration are understood. A precise knowledge of the applied physiology and pharmacology of neurotransmission is therefore required to determine the appropriate choice of anaesthetic or analgesic drug. The consequences of the interruption or modulation of both afferent and efferent transmission must clearly be appreciated.

Nociception and pain perception

The nociceptive system requires a means of transducing physical, thermal or chemical stimuli into neurally encoded information that may be relayed via nociceptive pathways to appropriate integrative higher centres. It is at such spinal and higher centres that nociceptive sensory information activates autonomic and endocrine-mediated stress responses and ultimately achieves conscious perception as 'pain'. It is essential to appreciate that the nervous system is not a hard-wired 'Cartesian' network of neurons, rather it functions with a dynamic balance between excitatory and inhibitory inputs; each synapse having the potential to exhibit plasticity over a variety of time scales.

Ion channels, neurotransmitters, receptors and second messenger systems of the neurons comprising pain transduction and perception represent potential targets for the manipulation of nociceptive information and the production of analgesia. Where molecular mechanisms are specific to nociceptive transmission the potential exists for selective analgesia with a minimum of side-effects. As yet, there are relatively few molecular targets that have absolute localization to the nociceptive system. Of those targets with apparent nociceptive specificity few have clinically available drugs to target them.

Regional anaesthetic techniques enable physical and anatomical localization of nociceptive pathways such that systemic side-effects can be minimized while analgesia is optimized. Most regional anaesthetic techniques involve the reversible blockade of axonal conduction by 'classical' local anaesthetic drugs. Central nerve blocks, and to a lesser degree plexus and peripheral nerve blocks, may also be supplemented by a range of analgesic and adjunctive agents.

Neurophysiology

The diffusely ramifying unmyelinated terminals of Aδ and C fibres provide the initial transduction mechanism for mechanical, thermal and chemical noxious insult. The resultant action potentials evoked in unmyelinated C fibres and myelinated Aδ fibres propagate to the dorsal horn of the spinal cord where they synapse with both spinal interneurons and projection neurons (Figure 1): however, it must also be appreciated that retrograde action potential transmission may evoke local 'axon reflex' mediated peripheral release of neuropeptides contributing to inflammation and peripheral sensitization following injury. C fibres synapse primarily in the ipsilateral lamina II of the spinal cord dorsal horn, whereas Aδ fibres synapse in both laminae I and V. Projection neurons form the spinothalamic, spinoreticular and other ascending tracts that relay nociceptive information via thalamic nuclei to cortical centres of pain representation. Sensory discriminative components are relayed primarily via the lateral thalamic nuclei to somatosensory cortical areas SI and SII, while medial thalamic nuclei projecting to the anterior cingulate and prefrontal cortex mediate the affective-motivational components.

Sensory neuron-specific receptors and ion channels

Key:
ASICs, acid-sensing ion channels; B2, bradykinin receptor; DRASIC, dorsal root acid-sensing ion channel; EP2, prostaglandin E_2 receptor; P2X3, purinergil receptor; VR-1, vanniloid receptor; P75 and Trk-A, nerve growth factor receptors; I/II, III/IV, Rexed's laminae.

1

$$E_m = \pm 61 \log \frac{C_{Na^+_i} P_{Na^+} + C_{K^+_i} P_{K^+} + C_{Cl^-_o} P_{Cl^-}}{C_{Na^+_o} P_{Na^+} + C_{K^+_o} P_{K^+} + C_{Cl^-_i} P_{Cl^-}}$$

where: C = concentration, P = permeability, o = extracellular concentration of ions, i = intracellular concentration of ions.

However, K^+ is the major contributor to the resting E_m which is more simply approximated by the Nernst equation:

$$E_m = \pm 61 \log \frac{[K^+]_i}{[K^+]_o}$$

Neural conduction

Aδ and C fibres at rest have a transmembrane potential of about –70 mV with the intracellular aspect of the phospholipid neuronal plasma membrane negative with respect to the extracellular membrane. The neuronal plasma membrane, selectively permeable to K^+ permits their outward diffusion from an internal concentration of about 140 mmol/litre toward the extracellular fluid (about 4 mmol/litre) with a relative loss of intracellular cations and the development of negative intracellular potential. A corresponding tendency for extra-cellular Na^+ (about 140 mmol/litre) to diffuse inwards towards the intracellular fluid (12–15 mmol/litre) is prevented by selective impermeability of the neuronal membrane. Differential permeability of the membrane and ATP-dependent Na^+/K^+ pumps maintains the distribution of ions across the neuronal plasma membrane. The resultant resting membrane potential (E_m) represents the equilibrium state between the concentration and electrochemical gradients of cations and ions across the membrane (Gibbs–Donnan equilibrium). It is formally described by the Goldmann equation in which sodium, potassium and chloride are the major contributory ions:

However, K^+ is the major contributor to the resting E_m which is more simply approximated by the Nernst equation:

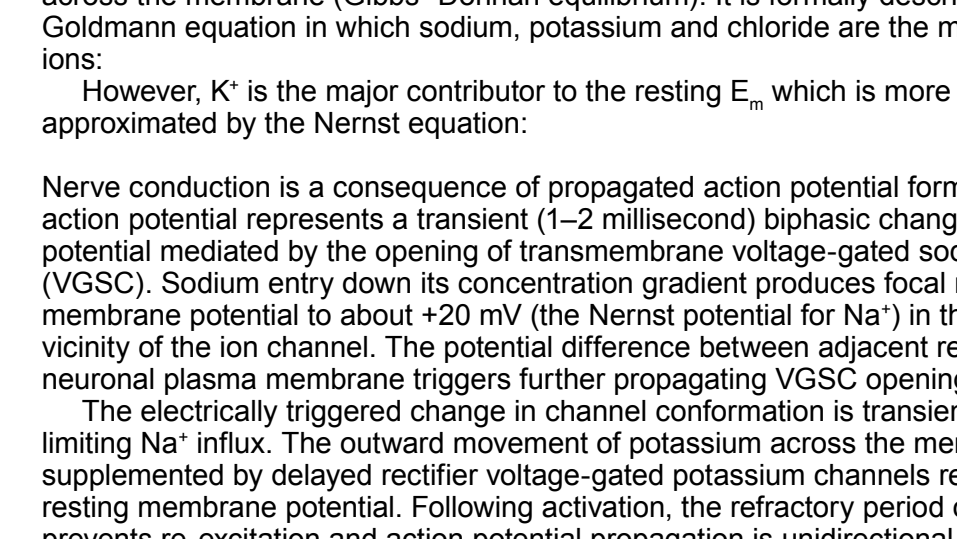
Nerve conduction is a consequence of propagated action potential formation. The action potential represents a transient (1–2 millisecond) biphasic change in membrane potential mediated by the opening of transmembrane voltage-gated sodium channels (VGSC). Sodium entry down its concentration gradient produces focal reversal of the membrane potential to about +20 mV (the Nernst potential for Na^+) in the immediate vicinity of the ion channel. The potential difference between adjacent regions of neuronal plasma membrane triggers further propagating VGSC opening.

The electrically triggered change in channel conformation is transient, thereby limiting Na^+ influx. The outward movement of potassium across the membrane supplemented by delayed rectifier voltage-gated potassium channels restores the resting membrane potential. Following activation, the refractory period of the VGSC prevents re-excitation and action potential propagation is unidirectional under normal circumstances.

Sodium channels: the neuronal VGSC is not a single entity but encompasses a large multigene family. All VGSC comprise a large membrane spanning a polypeptide β-subunit of 260 kDa with smaller regulatory β_1 and β_2 subunits. Most VGSC have a low threshold for activation (about –55 mV), rapid inactivation kinetics and nanomolar sensitivity for tetrodotoxin. There is now clear evidence for populations of novel tetrodotoxin-resistant sodium channels that are selectively expressed in small diameter nociceptive neurons (e.g. SNS/PN3 channel)

Sodium channel blockade – classical local anaesthetics are aromatic amino-esters (procaine) or amino-amides (lidocaine (lignocaine), bupivacaine) that bind selectively to the gating mechanisms of VGSC located at the intracellular region of the transmembrane channel. The drugs are weak bases existing in equilibrium between charged (membrane-impermeant) and uncharged (membrane-permeable) moieties dependent on tissue pH and drug pK_a (the pH at which the ionized and non-ionized forms of a chemical compound are in equilibrium). VGSC blockade occurs in a use-dependent manner (i.e. local anaesthetics block the channel preferentially in its 'open state') once they have accessed the neuronal intracellular compartment (Figure 2).

Local anaesthetic equilibrium and binding to sodium channel



2

Currently available local anaesthetic drugs appear to block all VGSC subtypes. The relative selectivity of bupivacaine and ropivacaine for nociceptive transmission reflects primarily pharmacokinetic aspects of penetration of myelinated and unmyelinated fibres in mixed nerves. Subtype selective sodium-channel blockers aimed at selectively targeting the SNS/PN3 channel are under development and may provide the potential for pharmacodynamically specific blockade of nociceptive transmission without motor or proprioceptive dysfunction.

With peripheral nerve and plexus techniques, blockade of axonal VGSC is unequivocally the mechanism of action of local anaesthetics. Likewise, epidural local anaesthesia initially represents segmental blockade of VGSC in nerve roots within the dural sleeve. Epidurally administered local anaesthetic diffuses through arachnoid villi with resultant high CSF concentrations of drug. Therefore, both epidural and, more significantly, subarachnoid local anaesthesia has a direct effect on the outer regions of the spinal cord where although VGSC effects predominate, anaesthesia will also encompass more subtle effects on synaptic mechanisms, which may involve potassium channel and calcium channel modulation.

Peripheral nociceptor

Transduction of injurious mechanical, thermal and chemical stimuli into Aδ and C fibre action potentials occurs at the peripheral axon terminal of the primary afferent nociceptor, the cell body of which resides in the dorsal root ganglion. Peripheral nociceptor transduction represents the selective activation of thermal, chemical or mechanically gated ion channels and is amplified following injury by the release of chemical mediators of inflammation. These include ATP, bradykinin, prostanoids, histamine, 5-HT, adenosine, catecholamines, potassium and hydrogen ions with the development of peripheral sensitization. Furthermore, inflammation results in increased local levels of nerve growth factor (NGF) and resultant unmasking of 'silent nociceptors', thereby enhancing the number of functional nociceptors and amplifying pain transduction.

The molecular structure and activation of mechanoreceptors are poorly understood; however, the recently cloned VR-1 vanniloid receptor is a thermally activated non-selective cation channel for thermal nociception. The VR-1 receptor selectively binds and is ultimately inactivated by capsaicin (hence chilli peppers produce the sensation of heat). Similarly the dorsal root acid-sensing ion channel may mediate hydrogen ion associated nociception. These receptors provide theoretical targets of analgesic action such as the delayed inactivation of VR-1 expressing C fibres by topical capsaicin in osteoarthritic and neuropathic pain. However, it is the modulation of nociceptor VGSC activation and attenuation of action potential generation that forms the basis of current regional anaesthetic action.

Peripheral opioid actions

In situ hybridization and immunohistochemical studies of opioid binding demonstrate the synthesis and expression of OP1 (δ), OP2 (κ) and OP3 (μ) receptors (see below) in the dorsal root ganglion; these receptors are transported peripherally via axonal transport and a similar population of receptors exist on terminals of Aδ and C nociceptive fibres. In common with spinal and supra-spinal opioid receptors, the binding of opioid agonists results in potassium-channel mediated neuronal hyperpolarization, attenuation of Ca^{2+} entry through voltage-gated calcium channels and reduced cAMP availability with resultant reduction in nociceptor activity.

Experimental peripheral opioid-mediated antinociception is enhanced under conditions of inflammation where the axonal transport of opioid receptors from the dorsal root ganglion and peripheral expression of opioid receptors is increased. Clinical studies have demonstrated significant peripheral opioid analgesia after intra-articular administration. However, a systematic review of data from opioid supplementation of local anaesthetic brachial plexus blocks suggests lack of efficacy.

The α_2-agonist clonidine has been demonstrated to potentiate local anaesthetic brachial plexus block. However, clonidine alone fails to produce analgesia at this site, suggesting that potentiation of analgesia may reflect altered vascular reuptake of local anaesthetic as much as a direct peripheral α_2-receptor-mediated analgesia within major nerve plexuses.

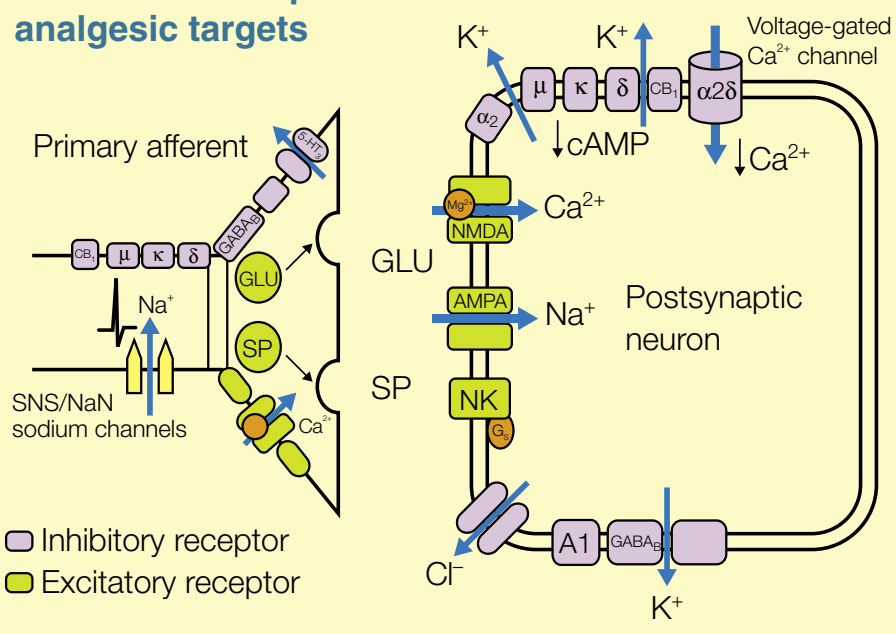
Dorsal horn

Epidural and intrathecal administration of opioids and other adjunctive drugs has a clear pharmacodynamic effect within the dorsal horn of the spinal cord. Aδ and C fibre nociceptors project to the superficial and deeper laminae of the dorsal horn where they synapse with both interneurons and projection neurons. Nociceptive afferent fibres co-release the excitatory amino-acid transmitter glutamate with neurokinins (predominantly substance P), calcitonin gene-related peptide (CGRP) and other peptide transmitters. At this locus, initial excitatory transmission is initiated by α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptor activation, sodium ion entry and fast depolarization of postsynaptic neurons supplemented by potassium channel inactivation through neurokinin NK1 receptor activation. Depolarization of sufficient duration and magnitude to remove magnesium ion block of the N-methyl-D-aspartate (NMDA) receptor channel results in the entry of calcium ions, amplification of nociceptive transmission and initiation of central sensitization at both presynaptic and postsynaptic sites, which may be further supplemented by metabotropic glutamate receptor activation.

Excitatory transmission within the dorsal horn is under complex inhibitory tone mediated in part by γ-aminobutyric acid (GABA), glycine, catecholaminergic and opioid systems. Critically, dorsal horn mechanisms of neural transmission exhibit remarkable plasticity as illustrated in Figure 3.

The dorsal horn therefore provides a multiplicity of potential analgesic targets: only a few of which are exploited by analgesics in clinical use. Receptor classification and localization within the dorsal horn has recently been reviewed, and it is appropriate to consider briefly the role of certain of these as analgesic targets within the spinal cord dorsal horn.

Potential nociceptor afferent and dorsal horn analgesic targets



Key: AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate; CB_1, CB_1 cannabinoid receptor; GABA, γ-aminobutyric acid; GLU, glutamate; NMDA, N-methyl-D-aspartate; NK, neurokinin; SP substance P

Inhibitory targets

Opioid receptors: within the spinal cord, OP3 (μ), OP2 (κ) and OP1 (δ) opioid receptors are localized primarily within laminae I–II (and possibly deeper laminae) of the dorsal horn. Dorsal rhizotomy results in a variable loss (40–70%) of receptor expression within the superficial dorsal horn indicating a predominant localization on presynaptic terminals of primary afferent nociceptors. In consequence, pain following de-afferentation (neuropathic pain such as phantom limb or brachial plexus avulsion) may be opioid resistant.

Opioid receptors mediate spinal analgesia by presynaptic inhibition of nociceptive transmitter release from Aδ and C fibres together with attenuation of postsynaptic depolarization via inhibition of voltage-gated calcium channels, activation of potassium channels and a reduction of cAMP. Neuraxial administration of opioids alone provides significant analgesia from a spinal site of action. However, mechanically triggered incident pain is often poorly controlled without co-administration of local anaesthetic. There is clear evidence of synergy between neuraxially administered local anaesthetic and opioid which is likely to reflect both nerve root attenuation of afferent action potential transmission to the dorsal horn and opioid inhibition of Aδ and C fibre transmitter release within the dorsal horn. This synergy provides the basis of most postoperative epidural analgesic regimens in which the co-administration of opioid and local anaesthetic enables high-quality analgesia with minimal motor deficit, minimal sedation and low risk of respiratory depression from supraspinal opioid receptor activation.

α_2 receptors: spinally administered α_2-agonists attenuate nociceptive transmission within the dorsal horn and produce analgesia. Binding sites for α_2-ligands are concentrated in laminae I–II of the dorsal horn, though there is dispute as to their relative presynaptic and postsynaptic distribution. Activation of α_2-receptors triggers an inwardly rectifying potassium conductance thereby hyperpolarizing both dorsal horn neurons and dorsal horn nociceptive neurons. α_2-mediated inhibition of N-type calcium channels has been shown to reduce dorsal horn glutamate and substance P (SP) release.

Alone, clonidine (and the more selective α_2-ligand dexemedetomidine) produce spinally mediated analgesia, though efficacy is limited by hypotension and supraspinally mediated sedation. While multiple α_2-receptor subtypes exist, and most data suggest that analgesia is mediated by spinal α_{2A}-receptors, the same subtype appears to subserve locus coeruleus-mediated sedation and spinal/medullary mediated hypotension. Co-administration of α_2-agonist with local anaesthetic and opioid provides the basis for synergistic analgesia.

Recent data indicate that (at least in neuropathic pain) α_2-mediated analgesia involves spinal muscarinic and cholinergic receptor activation with nitric oxide, suggesting that α_2-receptors may be primarily located on spinal cholinergic interneurons.

Cholinergic mechanisms: spinal cholinergic mechanisms may play a key integrative role in both spinally mediated α_2-adrenergic and supraspinal opioid analgesia. Spinal administration of cholinergic agonists or potentiation of endogenous acetylcholine release within the dorsal horn of the spinal cord by cholinesterase inhibition produces both experimental antinociception and clinical analgesia. Cholinergic spinal analgesia involves primarily muscarinic (and to a lesser extent nicotinic) receptors mediating antinociception via nitric oxide synthesis and release. Studies of pre-clinical or clinical use of intrathecal neostigmine have demonstrated effective analgesia at the expense of severe nausea.

Excitatory targets

NMDA receptors: the established role of the NMDA receptor in the initiation of central sensitization together with their anatomical localization to presynaptic and postsynaptic nociceptor synapses within the dorsal horn presents an attractive target and has generated a vast literature in multiple models of inflammatory and neuropathic pain. Many clinical studies have demonstrated analgesia after epidural administration of ketamine and much of this effect may be presumed to be a consequence of NMDA channel blockade. However, in a number of these studies, dose requirements were similar to those producing analgesia by the intravenous route, suggesting that supraspinal effects may be important. Recent clinical studies have demonstrated benefit in combining ketamine with local anaesthetic/opioid epidural infusion. Caudal epidural administration of ketamine in neonatal and paediatric surgery provides effective analgesia and potentiates local anaesthetic analgesia.

Systemic considerations of regional anaesthesia

Local anaesthetic drugs are non-selective blockers of VGSC. Consequently, inadvertent intravascular administration or excessive absorption of local anaesthetics results in direct toxic effects on myocardial (cardiotoxicity) and CNS neuronal (CNS toxicity) sodium channels. The mechanisms and management of these reactions are described on page 89.

While it is possible to achieve relative selectivity of sensory and motor blockade with low concentrations of bupivacaine and ropivacaine which reflects relative sparing of sodium channel blockade of Aα fibres (see page 88) it is clear that the small myelinated B fibres of preganglionic sympathetic efferents (hence white rami communicantes) and unmyelinated post-ganglionic sympathetic efferents (grey rami communicantes) are exquisitely sensitive to local anaesthetic blockade. Consequently, epidural or spinal local anaesthesia affecting the T1–L2 segments results in inevitable sympathetic blockade, manifest as vasodilatation and loss of reflex tachycardia if the cardiac fibres exiting at T4 are blocked. The risk of hypotension must be appreciated and its management is discussed on page 87. The sympathetic chains may also be selectively blocked in the cervical (stellate ganglion block), thoracic or lumbar paravertebral regions, and it must also be appreciated that brachial plexus or lumbar plexus anaesthesia will also produce sympathetic blockade; single limb sympatholysis is seldom associated with significant cardiovascular compromise.

Regional Anaesthesia: Recognition and Management of Adverse Effects

Jonathan Francis

Jonathan Francis is Consultant in Anaesthesia and Pain Management at Cheltenham General Hospital, UK. He qualified from Southampton University and trained in anaesthesia and pain management in East Anglia and London, UK.

The reversible inhibition of nerve conduction has long been of interest to physicians as a means of providing analgesia and anaesthesia. Mechanical methods (cold and pressure) were superseded when cocaine, the first local anaesthetic, was identified. Safer amide local anaesthetics and improved equipment technology have increased the use of spinal, epidural (neuroaxial) and regional anaesthesia. Neuroaxial and regional techniques permit optimal peroperative analgesia and improve postoperative recovery (Figure 1).

Benefits of spinal, epidural and regional anaesthesia

Cardiovascular
- Inhibits neuroendocrine response
- Reduces plasma catecholamines
- Reduces cardiovascular stress
- Improves organ perfusion
- Reduces intraoperative blood loss
- Reduces postoperative thromboembolic complications

Respiratory
- Maintains functional residual capacity
- Maintains peak expiratory flow rate
- Maintains ability to cough
- Reduces tendency to basal airway collapse

Gastrointestinal
- Maintains splanchnic perfusion
- Enhances gastrointestinal motility

Sympathetic inhibition
- Improves blood flow locally to potentially ischaemic areas (e.g. peripheral vascular disease and free flap surgery)

1

Management of neuroaxial and regional anaesthesia

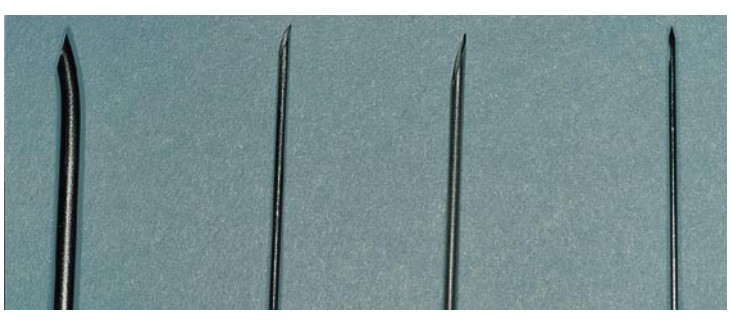
Preoperative preparation
Patients having neuroaxial and regional anaesthesia should be prepared as for a general anaesthetic. Physiological disturbances should be investigated and treated. Pre-existing neurological deficits and haemostatic disturbances should be identified. When obtaining informed consent from the patient, the procedure and any common or potentially serious risks should be explained.

Patient refusal is an absolute contraindication to neuroaxial and regional techniques. Psychiatric or psychological disturbance, haemostatic disturbances and local sepsis are often considered contraindications and the benefits and risks have to be determined for the individual. Similarly, pre-existing neurological deficit, low cardiac output states, previous spinal surgery or serious spinal pathology and systemic sepsis necessitate careful consideration before undertaking regional anaesthesia. For procedures in which loss of consciousness is a potential complication, the patient should observe the same fasting rules that would apply to general anaesthesia.

Perioperative management
Neuroaxial and regional procedures should be carried out in an environment staffed and equipped to deal with common and serious adverse effects. Intravenous access and basic monitoring should be observed, and full resuscitation facilities should be available immediately.

Procedures carried out after the induction of anaesthesia may enable greater patient acceptability, but this introduces a potentially greater risk of nerve or spinal cord injury, particularly when considering the use of thoracic epidural analgesia in abdominal surgery. It may be safer to carry out procedures before the induction of anaesthesia in a cooperative and informed patient.

Needle type: a variety of needles has been designed to allow the safe and accurate placement of drugs around neural structures (Figure 2). In general, the smallest needle possible should be used to carry out a procedure. The insertion of catheters through needles requires larger gauge needles (e.g. 16 G Touhy epidural needle). Long-bevel needles (a bevel cut at 12° ± 2°) tend to cut tissues and carry an increased risk of traumatizing nerves. Short-bevel needles (cut between 18° and 45°) part tissues and reduce the likelihood of nerve injury. They also allow greater operator feel and are more commonly used in regional anaesthetic techniques. Pencil-point needles with a side hole to prevent intraneural injection have been developed for intrathecal anaesthesia. Such needles are said to part the dural fibres and are less likely to cause post-dural puncture headache (PDPH).



2 Needles commonly used in neuroaxial and regional anaesthesia.
Left to right: 16 G Touhy needle, 22 G short-bevel regional block needle, 21 G long-bevel hypodermic needle, 25 G pencil-point spinal needle.

Needle position: the following techniques allow the operator to assess whether the needle is in the correct position.
- A potential space may be identified by a ‘loss of resistance' using saline or air. Saline is gaining popularity because it is sterile and has a more distinct loss of resistance end-point.
- The feeling of a ‘click’ or ‘pop’ can be used to identify correct needle placement. When appropriate, this end-point is more easily felt with a short-bevel needle.
- The presence of paraesthesia in the distribution of the target nerve is indicative of close proximity between needle and nerve. There is no clinical evidence to suggest that this is associated with nerve injury, though it remains a possibility.
- Nerve stimulators use low-power electrical stimulation at a frequency of 1–2 Hz to electrolocate peripheral nerves with a motor component. The observed motor twitch is related to current strength. A motor twitch at 0.5 mA is consistent with needle placement within 2 mm of the nerve. The use of sheathed (insulated) needles allows the needle tip to be the sole current source and improves the accuracy of needle placement.

Drugs: local anaesthetic drugs form the mainstay of neuroaxial and regional anaesthesia. Other drugs (e.g. opioids) have been shown to act centrally and peripherally and can be used to complement local anaesthetics. Ester agents (cocaine, procaine, tetracaine (amethocaine)) have been superseded by the amides (lidocaine (lignocaine), prilocaine, bupivacaine, ropivacaine) because they do not hydrolyse readily, penetrate tissues more easily and are less likely to produce allergic-type reactions.

Local anaesthetics exist in isomeric forms and toxic effects may be isomer specific. Ropivacaine and levobupivacaine are isomerically selective and may be less toxic. Vasopressors (e.g. adrenaline (epinephrine)) can be added to local anaesthetics to prolong their action and reduce systemic absorption and subsequent toxicity, allowing the administration of larger doses. Vasopressors are contraindicated around end arteries.

Administration – the injection of drugs should be smooth, painless and easy; a painful and difficult injection suggests intraneural injection. Regular aspiration protects against inadvertent intravascular injection. A test dose can help to identify incorrect needle or catheter placement, particularly in the epidural space. Controversy surrounds the ideal test dose, but 2 ml of 2% lidocaine (lignocaine) with 1:200,000 adrenaline (epinephrine) allows detection of intrathecal or intravascular placement.

The volume of injectate varies according to the anatomical site and the desired effect. Brachial plexus blocks require a large volume (0.5 ml/kg) to occupy the fascial sheath. Epidural drug volume depends on the desired dermatomal block and the level of catheter placement. When drugs are injected into the intrathecal space, small volumes of drugs circulate within the CSF and can produce profound and widespread anaesthesia. The height of the block depends on the drug dose, the posture of the patient, the spinal level of injection and the relative baricity of the drug compared with CSF.

Post-procedure care
The operating theatre is a hostile and intimidating place for the patient, every step of the procedure should therefore be explained to make them feel confident and comfortable. The developing block should be assessed by dermatomal distribution using pinprick or cold sensitivity. Anaesthesia of deep structures is also required but is more difficult to assess. Demonstration of the sensory block can be used to reassure patients. They should be informed that not all sensation will be lost and some feeling should be expected. If significant motor weakness occurs, care should be taken of the affected limb and patients should be encouraged to mobilize only when significant motor function has returned.

During the recovery period, the likelihood of adverse events should always be borne in mind and any suspicious symptoms or signs should be investigated (e.g. shortness of breath following a supraclavicular brachial plexus block may indicate pneumothorax).

Recognition and management of adverse effects

Complications can be minimized by careful patient assessment, planning and induction of the block and by monitoring the patient during and after the procedure.

Adverse effects of neuroaxial and regional anaesthesia (Figure 3)
Allergic reactions to local anaesthetics are usually the result of vasopressors or preservatives. Although uncommon, anaphylactic and anaphylactoid drug reactions can be severe. They present with skin reactions (skin wheals, flares, rashes), breathing difficulties (wheeze, breathlessness, bronchospasm) and cardiovascular collapse (hypotension, tachycardia, arrhythmias, cardiac arrest). Early clinical recognition allows treatment with basic life support, oxygen administration and the intravenous administration of adrenaline (epinephrine), bolus of 50–100 µg, fluid, 20 ml/kg, hydrocortisone, 100–300 mg, and chlorphenamine (chlorpheniramine), 10–20 mg.

Adverse effects of neuroaxial and regional aesthesia

Systemic adverse effects
- Adverse drug reaction (e.g. allergic hypersensitivity)
- Local anaesthetic toxicity (e.g. drug overdose, intravenous injection)
- Vasovagal faint

Local adverse effects
- Neurological injury (e.g. direct trauma, ischaemia, abscess, drug toxicity)
- Block failure
- Damage to surrounding structures (e.g. pneumothorax)
- Sepsis
- Haematoma formation

3

Local anaesthetic toxicity is determined by the rate of plasma concentration rise, peak plasma level and individual drug characteristics. The rise in plasma concentration depends on the rate of injection and regional blood flow. Peripheral subcutaneous tissue has a poor blood supply and drug absorption is slow. The epidural space, paravertebral space and oropharynx have a generous blood flow and rapid absorption is more likely to produce dangerously high plasma drug levels. Intravenous injection leads to a rapid rise in plasma concentration. Intra-arterial injection, particularly into the cerebral vessels, leads to a high intracerebral drug concentration and CNS toxicity.

Signs and symptoms of local anaesthetic toxicity range from light-headedness, periorbital paraesthesia and slurred speech, to tinnitus and muscle twitching. At higher plasma concentrations, loss of consciousness and coma occur before the development of myocardial depression, cardiac arrhythmias and ventricular arrest. Bupivacaine can cause malignant ventricular arrhythmias without warning. Intravenous bretylium, 5 mg/kg, is the anti-arrhythmic of choice.

Maintaining verbal contact with the patient allows early detection of toxic symptoms. In the event of local anaesthetic toxicity, the injection should be stopped. Hypoxia and acidosis exacerbate local anaesthetic toxicity and should be prevented. Basic life support and oxygen administration are essential. Convulsions should be treated with intravenous benzodiazepines.

Vasovagal faint is a common complication of regional anaesthesia. The profound vagal response is usually self-limiting and venous return should be enhanced by a supine posture. Anticholinergic drugs such as atropine, 1 mg, are effective.

Adverse effects of spinal and epidural anaesthesia (Figure 4)
Post-dural puncture headache: needle puncture of the dura mater (either deliberate, as in the case of spinal anaesthesia, or accidental, as a complication of epidural anaesthesia) can produce a prolonged headache. Headaches are more common in the young and when the dura is punctured by large-bore cutting needles (e.g. Touhy needle). The conservative treatment of PDPH includes bed rest, hydration and simple analgesics. Intravenous caffeine, 300–500 mg, epidural saline infusions, sumatriptan and adrenocorticotrophic hormone have all been tried with varying degrees of success. An epidural blood patch relieves PDPH in 85–90% of patients within 24 hours.

Adverse effects of spinal and epidural anaesthesia

- General adverse effects
- Post-dural puncture headache
- Nausea and vomiting
- High block/ total spinal
- Hypotension
- Pruritus
- Inadequate block/ block failure
- Prolonged block
- Backache
- Neuronal injury

Hypotension: local anaesthetic drugs administered by the intrathecal and epidural routes rapidly penetrate small-diameter, unmyelinated sympathetic fibres, producing a sympathetic block. The resulting peripheral vasodilatation and loss of reflex tachycardia with blocks extending above T4 produce hypotension. Hypotension is more profound and of quicker onset following spinal anaesthesia, and is proportional to the height of the block. Hypovolaemia and low cardiac output states (aortic stenosis and left ventricular failure) can produce catastrophic hypotension and circulatory collapse. Correction to normovolaemia, vigilant assessment of block progression and liberal use of vasopressors (ephedrine or methoxamine) limits troublesome hypotension. The practice of fluid pre-loading patients is controversial; colloid solutions seem to be more effective than crystalloid solutions in reducing hypotension.

Total spinal: inadvertent intrathecal injection of a large dose of local anaesthetic results in rapid ascension of motor and sensory blockade. Phrenic nerve (C3–5) involvement produces apnoea, and intracranial spread results in loss of consciousness, fixed dilated pupils and profound hypotension. This is usually the result of intrathecal administration of an epidural dose, therefore careful assessment of epidural catheter position by aspiration guards against it. Excessive drug delivery can occur in short, elderly or pregnant patients. Regular assessment of block progression allows early identification. Basic airway maintenance should be followed by tracheal intubation and lung ventilation. Cardiovascular support with intravenous fluids and vasopressors are needed until the block regresses.

Backache: the chance of prolonged backache following neuroaxial anaesthesia is a common concern of patients. Epidural analgesia during labour can be associated with backache for up to 6 months. Backache is also common during normal pregnancy and labour. Complicated or prolonged labour is more likely to require epidural anaesthesia, and this may be a confounding factor. Epidural analgesia may mask an uncomfortable patient position and result in ‘acute back strain’. A careful technique, posture awareness and avoidance of dense motor blockade should reduce the chance of backache, but patients should be warned of the possibility.

Haematoma formation following peripheral nerve blockade is usually of little consequence, but in the spinal canal it can be disastrous. Spontaneous epidural haematoma formation is associated with haemostatic disturbances, anticoagulant and antiplatelet therapy. Haemostatic abnormalities are a relative contraindication to neuroaxial and regional procedures, including the removal of an epidural catheter.

Warfarin should be stopped several days before any procedure. Heparin allows short-term control if anticoagulation is essential (e.g. prosthetic heart valve). International normalized ratio and activated partial thromboplastin time ratio should be less than 1.5 at the time of surgery. Procedures should be delayed for 2 hours following the administration of subcutaneous heparin, and for 12 hours following low molecular weight heparins. Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit platelet function, and prolong bleeding time for up to 10 days. There are few reports of haematoma formation following NSAID use, but care should be exercised when other coagulation abnormalities exist. Antithrombotic agents (e.g. streptokinase) actively lyse clot and prevent clot formation, and are an absolute contraindication to neuroaxial and regional anaesthesia.

An unexplained increase in spinal pain or prolonged neurological block is suspicious and should be investigated rapidly. Epidural haematomas should be surgically evacuated at the earliest opportunity if neurological function is to be preserved.

Clinical Assessment of Renal Problems

Helen Paynter
Tom Pickett

Helen Paynter is Staff Grade Nephrologist at the Gloucestershire Royal Hospital, Gloucester, UK. She qualified from Bristol University.

Tom Pickett is Consultant Physician at the Gloucestershire Royal Hospital, Gloucester, UK. He qualified from Cambridge University and University College, London, and trained in general medicine and nephrology in London and Stevenage, Hertfordshire, UK. His interests include district general hospital nephrology and acute medicine.

Renal impairment, whether acute or chronic, affects many organs, and presents a challenge for the anaesthetist.

Renal impairment reduces the body's ability to autoregulate fluid status, electrolytes and pH. For example, a patient with renal failure is less able to tolerate the potassium release that follows succinylcholine administration.

Many drugs (e.g. opiates, muscle relaxants) or their metabolites, are renally excreted, and therefore their pharmacokinetics are modified in renal failure.

It is also important to identify patients with renal dysfunction before surgery so that their postoperative management can be planned effectively. Such patients are more likely to require a period on an intensive care or high-dependency unit postoperatively.

Questions to be addressed

The anaesthetist assessing a patient preoperatively should address the following questions.

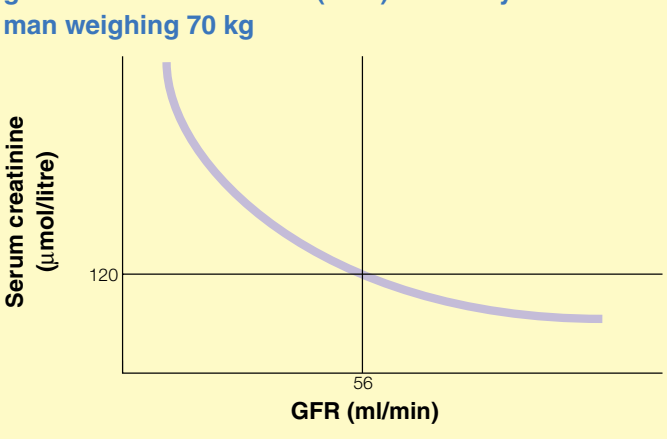
Is the renal function normal?

A normal serum creatinine level is commonly assumed to represent normal renal function. However, the serum creatinine concentration depends not only on creatinine clearance by the kidneys, but also on muscle mass, and to a lesser extent on dietary meat intake. Therefore, patients with low muscle bulk may have a misleadingly normal serum creatinine despite significantly impaired renal function. This is most commonly seen in the elderly, the malnourished and in women. As Figure 1 shows, the relationship between serum creatinine and glomerular filtration rate (GFR) is far from linear, and a rise in creatinine outside the normal range indicates significant loss of glomerular filtration. If time allows, a paired assay of serum and a 24-hour urine collection permits a calculation of creatinine clearance, which is a useful guide to GFR. Alternatively, if the patient's weight is known, the Cockcroft–Gault equation can be applied to the serum creatinine to estimate GFR:

$$\text{GFR (ml/min)} = \frac{1.2 \times [140 - \text{Age (years)}] \times \text{Weight (kg)} \times 0.85 \text{ (if female)}}{\text{Plasma creatinine } (\mu\text{mol/litre})}$$

Therefore, a 60-year-old man weighing 70 kg with a serum creatinine at the upper end of normal (120 μmol/litre) has an estimated GFR of 56 ml/min. This formula applies only in a steady state and not when the serum creatinine is rapidly changing due to acute renal failure.

Relationship between serum creatinine and the glomerular filtration rate (GFR) for a 60-year-old man weighing 70 kg



1

Is renal impairment acute or chronic?

Chronic renal failure is often associated with co-morbidity such as hypertension, left ventricular hypertrophy or ischaemic heart disease.

Patients with acute renal failure are generally less stable in terms of electrolyte and fluid control. They are likely to have co-morbidity in association with the aetiology of their renal dysfunction, particularly if they have sepsis or trauma.

It is important to assess the chronicity of renal impairment. This may be determined reliably only if old notes or test results are available, for example from the general practitioner. However, a careful history and examination may provide clues, as may some basic investigations.

Are there issues requiring urgent treatment?

It is vital that the life-threatening complications of renal dysfunction are detected early, so that appropriate treatment can be provided. The most common are hyperkalaemia, fluid overload resulting in respiratory embarrassment, and uraemic pericarditis. It is also imperative that easily reversible causes of acute renal failure (e.g. hypovolaemia, renal outflow obstruction, sepsis) are diagnosed and treated.

Is renal replacement necessary?

In a patient with severe renal impairment, anaesthesia and surgery often precipitate the need for renal replacement. It is therefore important to decide whether dialysis should be instigated before surgery, or planned for afterwards. This may require discussion with the local renal team.

Haemodialysis patients should be dialysed less than 24 hours before surgery. If they are acutely ill and likely to be catabolic, more recent haemodialysis may be required.

What is the underlying diagnosis?

The underlying diagnosis is valuable because it helps to anticipate problems associated with co-morbidity. For example, a 40-year-old man with end-stage renal failure due to diabetes mellitus is at considerably greater operative risk than an equivalent patient whose renal failure is due to polycystic kidney disease. An accurate diagnosis is also important because acute renal failure is reversible in some circumstances.

History

Clinical assessment should begin with the history.

Does the patient have pre-existing renal disease? Many renal patients are well informed about their condition, to the extent that they can cite their latest biochemical and haematological results. Is the patient undergoing any renal replacement therapy such as haemodialysis (and, in the acute setting, haemofiltration, and haemodiafiltration), peritoneal dialysis or renal transplantation? In the case of renal transplantation, it is important to determine which immunosuppressive treatment the patient is taking, and to consider drug interactions in the subsequent management.

The family history can provide useful clues about aetiology, and sometimes about chronicity. The most common familial causes of renal impairment in adults are autosomal dominant polycystic disease, and reflux nephropathy, which has the same pattern of inheritance.

It is important to enquire about a previous diagnosis of hypertension, which often arises with renal disease, and previous vascular events or symptoms such as claudication.

Though common in men, nocturia may indicate obstructive uropathy or loss of urinary concentrating ability due to chronic renal failure. Oliguria may be part of the stress response of normal kidneys and non-oliguric acute renal failure is well recognized. Nevertheless, oliguria makes fluid management more difficult and may give important diagnostic clues (Figure 2).

Case history

Mrs X, a 67-year-old woman saw her general practitioner 10 days ago with gout, for which she was prescribed indomethacin. 5 days later, she suffered an acute myocardial infarction, with a 36-hour period of hypotension. She now has acute renal failure. She is able to provide a clear history that her oliguria began before her cardiac event. This makes a diagnosis of drug-related interstitial nephritis likely with the possibility of superimposed acute tubular necrosis

2

A detailed, accurate drug history is imperative for diagnostic and management considerations (Figure 3). It must include the use of over-the-counter drugs, particularly self-medication with analgesic agents. Use of herbal preparations may also be relevant (e.g. St John's wort reduces plasma theophylline levels). Acute renal failure in hospitals is often associated with the combined use of diuretics, angiotensin-converting enzyme inhibitors or non-steroidal anti-inflammatory drugs, including topical preparations. An accurate drug history reduces the risk of causing dangerous drug interactions, such as the potentiation of ciclosporin by diltiazem.

Drugs commonly implicated in acute renal failure

Functional reduction in glomerular filtration
- Angiotensin-converting enzyme inhibitors
- Angiotensin II blockers
- Non-steroidal anti-inflammatory drugs (NSAIDs)

Glomerulopathy
- Gold salts
- D-penicillamine
- NSAIDs
- Mesalazine

Acute tubular necrosis
- Aminoglycosides
- Sulphonamides
- Aciclovir
- Foscarnet
- NSAIDs
- Cisplatin

Interstitial nephritis
- β-lactam antibiotics
- NSAIDs

3

Special situations should be considered when taking the history of a patient with acute renal failure, because of the profound metabolic disturbances that may ensue. These patients are likely to require early, aggressive dialysis.
- Care should be taken to elicit any risk factors for rhabdomyolysis. Trauma should be evident, but status epilepticus, prolonged stasis (as in the case of an elderly patient who has fallen at home and sustained a hip fracture), and even vigorous exercise in a patient with a metabolic myopathy, may not be apparent unless the appropriate questions are asked.
- Tumour lysis syndrome, in which administration of chemotherapeutic drugs causes massive cell lysis, may result in rapidly fatal hyperkalaemia, hyperphosphataemia and hyperuricaemia.
- In certain poisoning situations, early dialysis is useful in reducing the toxin levels. In particular, a history of lithium, aspirin or ethylene glycol poisoning should be sought.

Examination

The aim of examination is to determine the presence of complications of renal impairment, to elicit any aetiological clues and to assess the patient's co-morbidity.

Urgent assessment of the patient's airway, oxygenation and circulation takes priority over history taking. Subsequently, signs that might indicate an urgent need for renal replacement must be sought. These include encephalopathy (confusion, metabolic flap), pulmonary oedema and pericardial rub. Remember it takes time to organize dialysis, especially if transfer of the patient to another unit or hospital may be involved.

A careful assessment of fluid status is mandatory. Signs of volume depletion are a low jugular venous pressure, hypotension (a postural drop is a sensitive marker of early hypovolaemia), tachycardia and peripheral shutdown. Occasionally it may be useful to give a therapeutic trial of fluid. The aim is to increase the intravascular volume, by giving a relatively small volume (usually 250 ml) of intravenous fluid rapidly, before inter-compartmental equilibration can occur. If there is no clinical deterioration after 5 minutes, the trial may be repeated. Fluid overload may manifest in a raised jugular venous pressure, hypertension, peripheral and pulmonary oedema, and a gallop rhythm.

A careful examination of the cardiovascular system should include assessment of all the pulses. Vascular disease is a common cause of chronic and acute renal impairment in at-risk patients, and is important for prognosis. Complications of long-standing hypertension (chronic hypertensive retinopathy, left ventricular hypertrophy) may be evident.

It is easy to miss a palpably distended bladder unless it is sought.

Signs of chronicity may be found, but are often absent. Leuconychia or brown nail arcs may suggest chronic disease. Uraemic pigmentation is often seen in patients who have reached end-stage renal failure without previous medical attention.

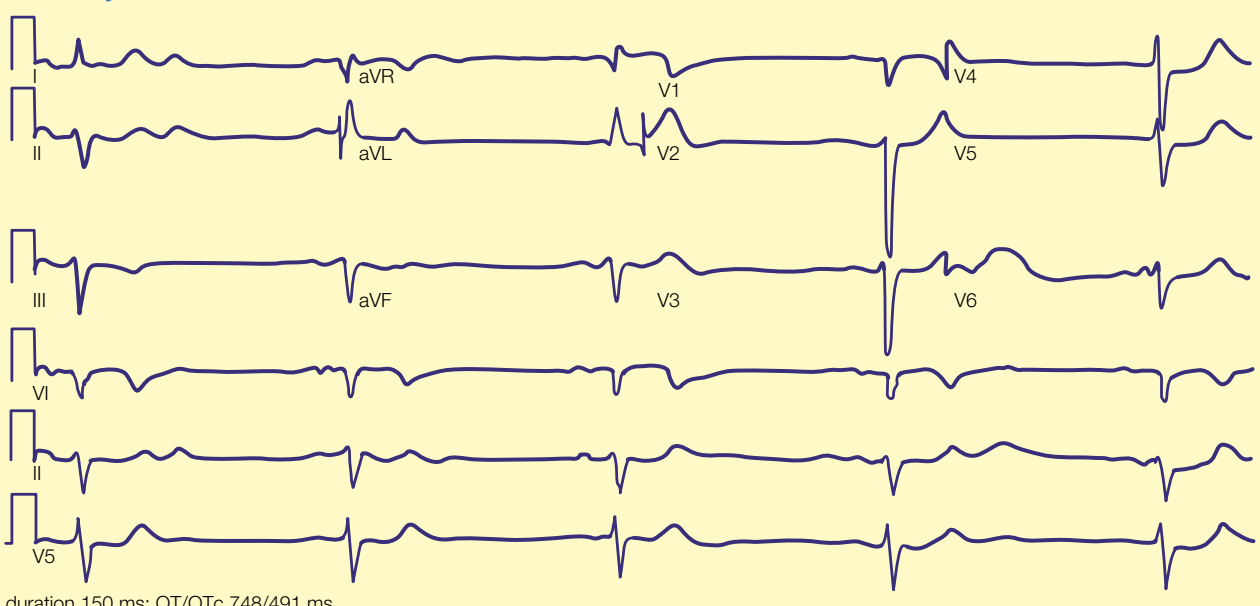
Investigations

One of the most useful, and under-rated, investigations in renal practice, is dipstick urinalysis. This should be performed on a urethral rather that a catheter specimen of urine, to make interpretation of haematuria more reliable. Heavy proteinuria makes glomerular disease more likely than prerenal or obstructive failure. Urine that is strongly positive for blood, but contains no red cells on microscopy, may indicate myoglobinuria or haemoglobinuria seen in rhabdomyolysis or haemolysis, respectively. Red cell casts on microscopy indicate glomerular disease.

A full blood count and clotting profile are important to assess the degree of anaemia, and to diagnose disseminated intravascular coagulation or microangiopathy. It is important not to overlook disturbances of calcium and phosphate metabolism often associated with acute or chronic renal failure.

An electrocardiogram is mandatory. It allows assessment of left ventricular wall thickness, and permits diagnosis of life-threatening hyperkalaemia (Figure 4).

ECG of a patient with a serum potassium of 7.8, showing bradycardia and broadened QRS complexes, peaked T waves may also be seen



QRS duration 150 ms; QT/QTc 748/491 ms.

In many circumstances, urgent renal imaging is appropriate. Hydronephrosis suggests obstruction, a potentially reversible cause of acute renal failure. Bilaterally small kidneys strongly suggest chronic and irreversible disease. The most useful investigations in this situation are a plain radiograph of the kidneys, ureter and bladder (KUB) to look for calculi, accompanied by a renal and bladder ultrasound. An intravenous pyelogram is unlikely to be diagnostically useful in the presence of significant renal impairment, because the damaged kidneys are unable to concentrate the dye sufficiently for adequate visualization of the urinary tract. If a CT scan of the abdomen has been performed for other reasons it may provide useful diagnostic information about the kidneys.

Special investigations

In unexplained renal failure, special investigations assist diagnosis. Immunological tests (complement, antinuclear, antineutrophil cytoplasmic and antiglomerular basement membrane antibodies) and serum and urine electrophoresis are often helpful. Ultimately, the diagnosis is made only by renal biopsy. ◆

Salt and water regulation

The perioperative management of a patient's fluid and electrolyte balance requires a basic understanding of the physiology of salt and water regulation. Water constitutes 50–70% of body fluids; two-thirds (28 litres) is in the intracellular compartment and one-third (14 litres) in the extracellular compartment. The extracellular fluid (ECF) is divided between the interstitial space (75%, 10.5 litres) and the intravascular space (25%, 3.5 litres).

Osmoregulation (water balance): the distribution of water between the fluid compartments is determined by hydrostatic pressure and osmotic pressure (osmolarity (mosmole/litre) or osmolality (mosmole/kg)).

Plasma osmolality = 2 × [Na] + [Glucose] + [Urea]

Differences between measured and calculated osmolality suggest the presence of osmolytes not routinely measured, such as mannitol and methanol, the latter being particularly important to consider in the unconscious patient in the emergency department. Plasma osmolality is determined almost entirely by water balance. Increases in osmolality are detected in the hypothalamus and result in the stimulation of the thirst drive (increased water intake) and release of antidiuretic hormone (ADH or vasopressin) from the posterior pituitary gland. ADH reduces water loss by acting on receptors in the collecting ducts of the kidneys to increase the number of water channels (aquaporin) on the collecting duct cells. By this and other intra-renal mechanisms (active sodium transport, counter-current exchange and low medullary blood flow) the kidney is able to produce urine as concentrated as 1200 mosmole/kg H_2O.

Volume regulation (sodium balance): extracellular volume is regulated by the renin–angiotensin–aldosterone system and atrial natriuretic peptide through their effects on sodium excretion. Renin is released from the juxtaglomerular apparatus in response to reduced plasma volume, renal ischaemia and sympathetic drive and converts angiotensinogen to angiotensin I. Angiotensin converting enzyme converts this to angiotensin II with resulting increased vascular tone, tubular sodium re-absorption and thirst. Angiotensin II also stimulates the secretion of aldosterone from the adrenal cortex. Aldosterone causes the tubules to retain sodium in exchange for potassium and hydrogen ions, which are lost.

The clinical approach

The stages to managing a patient's fluid and electrolyte status are:

- assess the patient's normal maintenance (background) fluid and electrolyte requirement
- correct pre-existing fluid and electrolyte deficits
- replace fluid and electrolyte losses during and following surgery
- adjust the type and quantity of fluids according to the patient's response and the presence of co-existing disease (e.g. cardio-pulmonary, renal disease).

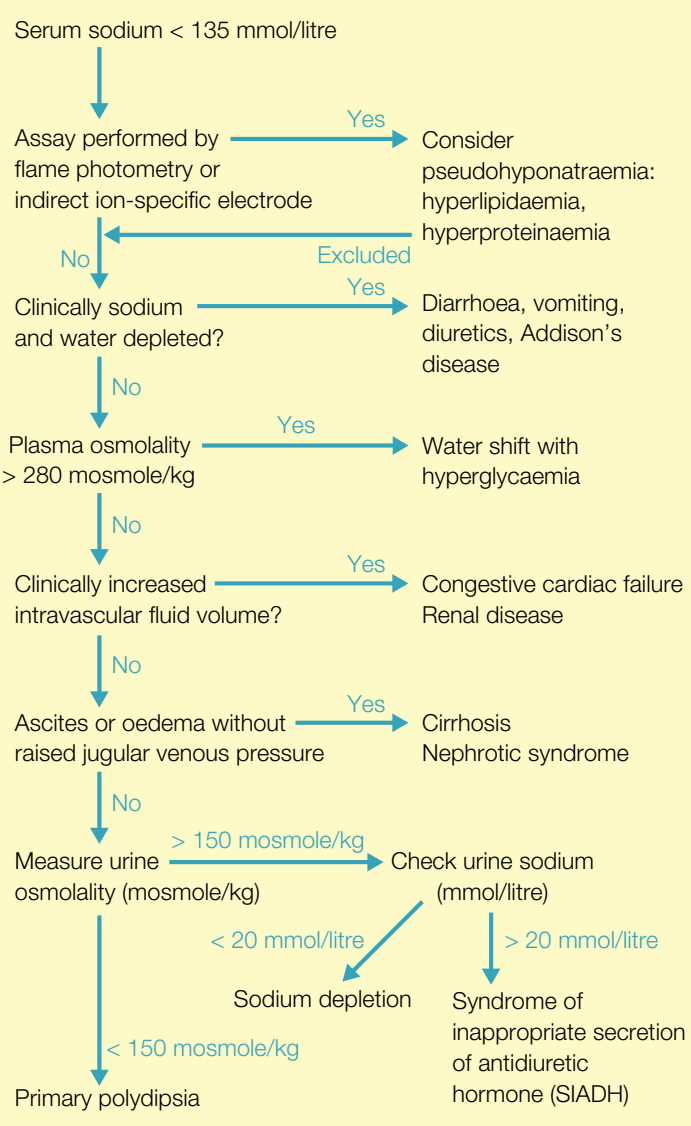
In all but the simplest of cases, the patient's response must be evaluated frequently and the replacement regimen adjusted accordingly. Changes in heart rate, blood pressure, capillary refill, skin turgor, urine output and jugular venous or central venous pressure must be interpreted alongside the results of laboratory data. In particular cases, it is helpful to quantify specific fluid losses by analysing the electrolyte content of nasogastric, diarrhoea or stoma losses. Although urine output is a useful gauge of central perfusion pressure and renal perfusion postoperatively, renal blood flow is regulated by opposing neurohormonal factors. Surgical stress tips the balance of these systems in favour of renal vasoconstriction and salt and water retention, and a degree of oliguria, irrespective of volume status, may last for days after surgery.

Specific electrolyte disturbances

Hyponatraemia

Hyponatraemia is a serum sodium level below 135 mmol/litre. Its cause can be established by combining measurements of serum osmolality, urine osmolality and serum creatinine with a clinical assessment of the patient's fluid status (Figure 1). Most UK laboratories use an indirect ion electrode method to measure sodium, therefore pseudohyponatraemia must be excluded by measuring osmolality or by measuring sodium using a blood gas analyser (a direct ion electrode method).

Evaluating hyponatraemia



1

The main symptoms of hyponatraemia (headache, nausea and vomiting, confusion, seizures and coma) and the side-effect of treatment (central pontine myelinosis) make the CNS of primary importance in hyponatraemia management. After 6–12 hours of hyponatraemia, an adaptive process in the brain reduces the number of osmotically active organic compounds in the brain cells. This minimizes the transcellular shift of water that would otherwise cause cerebral oedema and is complete by 72 hours. Consequently, rapid correction is appropriate when hyponatraemia is known to have developed acutely, but if there is any doubt about the duration of hyponatraemia the rate of correction of plasma or serum sodium must not exceed 1–2 mmol/litre/hour or 12–20 mmol/litre/24 hours. Patients with liver disease are particularly at risk.

The general management of hyponatraemia is as follows.

- Exclude a removable underlying cause.
- If ECF volume is reduced give isotonic saline.
- If ECF volume is normal or expanded, sodium is greater than 120 mmol/litre and the patient is asymptomatic, restrict fluid; if sodium is less than 120 mmol/litre or the patient is symptomatic, give isotonic saline or hypertonic saline; use loop diuretics, if necessary, to control ECF volume.

Although formulae help inform decisions about sodium replacement, they are often inaccurate, do not consider continuing losses, and must be used in conjunction with frequent laboratory assessment.

Na requirement (mmol) =
Total body water × Desired change in serum sodium

Hypernatraemia

Hypernatraemia (serum sodium greater that 145 mmol/litre) always indicates insufficient water in the body in relation to its solute content. Hypernatraemia in hospitals is most commonly caused by insufficient water intake, increased water loss and excess salt intake (intravenous or nasogastric). It develops if the patient is unable to perceive or communicate their thirst or is unable to retain ingested fluid (Figure 2).

Causes of hypernatraemia

Insufficient water intake

- No water available (e.g. lost at sea or on land)
- Inability to signal thirst to others
  - Infants
  - Intubated patients
  - Expressive dysphagia
  - Confusional states
  - Coma
- Unable to retain ingested water (e.g. vomiting)
- Hypodipsia

Increased water loss

- With sodium losses
  - Osmotic diuresis
  - Sweating
  - Diarrhoea/emesis
- Without sodium losses
  - Insensible (e.g. fever, hyperventilation (altitude))
  - Diabetes insipidus (e.g. central, nephrogenic)

Excess solute intake

- Accidental
- Deliberate: hypertonic or excess isotonic NaCl
- Iatrogenic: hypertonic $NaHCO_3$

2

Diabetes insipidus is associated with inappropriately dilute urine and may be caused by a reduction in ADH secretion (central diabetes insipidus) or a lack of responsiveness of the kidney to ADH (nephrogenic). It is diagnosed by a urinary osmolality less than 400 mosmole/kg H_2O. The causes of central diabetes insipidus include head injury, neurosurgery and CNS infections and tumours. Ethanol transiently blocks ADH release. Nephrogenic diabetes insipidus may be familial (ADH receptor and aquaporin-CD defects), drug related (e.g. lithium, demeclocycline), secondary to electrolyte disturbances (hypokalaemia, hypercalcaemia) or be associated with renal disease (e.g. polycystic kidney disease, myeloma).

The initial symptom of hypernatraemia is thirst. As serum sodium rises, patients develop nausea, confusion, coma and seizures. To protect the brain cells from injury, idiogenic osmoles are produced to reduce the shift of water out of the cells during hypernatraemia, but their metabolism takes time and too rapid correction of serum sodium risks cerebral oedema.

Management of the hypernatraemic patient begins with repletion of the intravascular volume with either colloid or isotonic saline. Once this has been achieved, correction of the total body water deficit begins. Although the extent of the water deficit can be estimated, continuing fluid losses must also be considered.

Water deficit (litres) =
{(serum sodium/140) – 1} × Total body water

About 30–50% of the water deficit should be replaced in the first 24 hours and the remainder replaced over the following 48–96 hours.

Hypokalaemia

Potassium is the major intracellular cation. Intracellular potassium levels are about 150 mmol/litre compared with 3.4–4.6 mmol/litre in plasma; this gradient is maintained by the Na/K pump. Acidosis decreases potassium uptake by cells and insulin and catecholamines activate the pump and drive potassium into cells. 90% of potassium is excreted in the urine (largely regulated by aldosterone) and the remainder in the stool.

Hypokalaemia may be the result of a shift of potassium into cells or a deficiency of intracellular potassium (Figure 3). Hypokalaemia increases the intracellular:extracellular potassium ratio causing hyperpolarization of cell membranes with neuromuscular, renal and endocrine sequelae. As well as the characteristic flattened T waves, depressed ST segments and U waves seen on the ECG, hypokalaemia enhances digitalis toxicity and can induce life-threatening ventricular dysrhythmias. Magnesium depletion can cause hypokalaemia, and when magnesium and potassium deficiencies coexist, correction of serum potassium is achieved only if magnesium stores are also replenished.

Causes of potassium depletion

Extrarenal
(Urine K < 20 mmol/day)
- Inadequate intake
- Copious perspiration
- Gastrointestinal losses
  - Diarrhoea
  - Laxative abuse
  - Villous adenoma

Renal
(Urine K > 20 mmol/day)
- Renal tubular acidosis
- Diabetic ketoacidosis
- Chloride depletion
  - Emesis/gastric suction
  - Diuretics
- Disorders of tubular function
  - Bartter's syndrome[1]
  - Gitelman's syndrome[2]
  - Liddle's syndrome[3]
- Mineralocorticoid excess
- Glucocorticoid excess
- Magnesium depletion
- Antibiotic therapy
- Leukaemia

[1]An inherited condition associated with normotension and hypokalaemic alkalosis. The primary defect may be defective chloride reabsorption or increased potassium tubular secretion

[2]Similar to Bartter's syndrome but associated with hypercalciuria

[3]A rare autosomal dominant condition that mimics a state of mineralocorticoid excess. Amiloride and triamterene, but not spironolactone, correct the hypokalaemia and hypertension

Potassium management depends on the underlying cause of the disorder. When a deficit exists, replacement should be achieved by oral supplementation or using potassium-sparing diuretics (e.g. amiloride). When intravenous replacement is necessary for life-threatening hypokalaemia (paralysis, ventricular dysrhythmias, digitalis toxicity) infusion rates of potassium 10–40 mmol/hour may be given, but only in the coronary care or critical care setting.

Hyperkalaemia

Hyperkalaemia may result from a shift of potassium from the intra- to the extracellular compartment or from the retention of potassium in the body (Figure 4). Defective urinary excretion of potassium has three main causes: an inadequate number of functioning nephrons; hypoaldosteronism; and defective tubular secretion of potassium. Although hyperkalaemia can cause paralysis, acidosis and hypotension, the primary concern is the increased risk of cardiac dysrhythmias heralded by characteristic changes on the ECG (flattening of P waves, widening of the QRS complexes, tenting of the T waves).

Aetiology of hyperkalaemia

Spurious
- Ischaemic venesection
- Haemolysis
- Abnormal erythrocytes
- Thrombocytosis
- Leucocytosis

Redistribution
- Acidosis
- Insulin deficiency
- β-adrenergic blockade
- Drugs
  - Arginine HCl
  - Succinylchloride
  - Digitalis toxicity
- Hyperkalaemic periodic paralysis
- Exercise
- Malignant hyperthermia

Renal
- Renal failure (severe)
- Aldosterone deficiency
- Addison's disease
- Enzymatic defects
- Hyporeninaemic hypoaldosteronism[1]
- Drugs
  - Prostaglandin synthase inhibitors
  - NSAIDs
  - Angiotensin-converting inhibitors
  - Heparin
  - Ciclosporin (cyclosporin)
  - Potassium-sparing drugs
- Tubular dysfunction
  - Acquired disorders
  - Pseudohypoaldosteronism

[1] Type IV renal tubular acidosis

Treatment of hyperkalaemia is indicated when serum potassium exceeds 6.5 mmol/litre, ECG changes are present or if the condition is likely to worsen rapidly. Management is initially aimed at minimizing the risk of cardiac toxicity with calcium preparations, then at shifting the potassium back into the cells (insulin/dextrose, sodium bicarbonate and β-agonists). It is then important to remove the cause of the hyperkalaemia and eliminate the excess potassium from the body with a cation exchange resin. In those with resistant hyperkalaemia, haemodialysis and peritoneal dialysis may be required. ◆

Laboratory Tests of Renal Function

Joanna Bayley
Ian Crabb

Joanna Bayley is a Trainee in Accident and Emergency Medicine in Bristol. She qualified from Bristol University and trained in London, Australia and the South-West of England.

Ian Crabb is Consultant in Anaesthesia and Intensive Care, Gloucestershire Royal Hospital, UK. He qualified from Charing Cross Hospital Medical School, London. He trained in anaesthesia and intensive care medicine in London and Australia. His main areas of interest are the ventilatory management of acute respiratory distress syndrome, and the role of renal support therapy in sepsis.

The kidney's main function is to maintain normal composition of the extracellular fluid, which it does by producing urine. The kidneys of a healthy adult receive about 25% of the resting cardiac output (about 1300 ml/min). This large blood supply is channelled into the glomeruli, each of which filters blood into the Bowman's capsule of an individual nephron. There are about 1 million nephrons in each human kidney, which drain via the renal tubules into the renal pelvis and subsequently into the ureter.

The glomeruli filter 170–200 litres of protein-free ultrafiltrate fluid every 24 hours (50–60 times the normal plasma volume). However, up to 99% of the water is reabsorbed within the renal tubular network, resulting in a normal daily urine output of about 1500 ml, though this varies depending on changes in plasma volume or osmolality. The filtrate initially has the same crystalloid composition as plasma, but ion exchange and transport occur within the tubular system, which results in the composition of the fluid varying, depending on the needs of the body.

Normally, glucose is completely reabsorbed by the renal tubules and only minute quantities of protein appear in the urine. The breakdown products of protein metabolism, especially urea and creatinine, are almost exclusively excreted in the urine. The urine is the main route of elimination for water-soluble drugs and their metabolites, and the presence of oxidase enzyme systems in renal cells allows some drug metabolism to occur. The kidney also has endocrine functions and is an important site for the production of kinins and prostaglandins.

Assessment of renal function

The composition of blood and urine may reflect renal dysfunction and systemic disorders. Clinical evaluation of renal function should include an assessment of:

- concentration of non-protein nitrogen compounds in blood and urine
- glomerular filtration function
- secretory capacity of the renal tubules
- tubular ability to reabsorb water and electrolytes, as measured by urine concentrating ability.

No single test of renal function should be used or considered in isolation. All test results should be interpreted with reference to the patient's clinical history and examination.

Glomerular filtration rate (GFR)

The GFR is a measure of the clearance of substances from the bloodstream into the glomeruli, expressed in ml/min. It is related to the number of functioning nephrons. Most methods of measuring GFR involve the kidney's ability to clear marker substances. Depending on the substance, the renal clearance may be achieved by glomerular filtration, tubular secretion or a combination. In clinical practice, it is the volume of plasma cleared solely by glomerular filtration that is relevant.

If a substance is freely filtered by glomerular filtration, but is neither secreted nor absorbed by the renal tubules, then its plasma clearance represents the GFR. Plasma clearance of a substance may be calculated using the formula:

$$C_s = \frac{U_s \times V}{P_s}$$

where: C_s is clearance of the substance (ml/min); U_s is urinary concentration of the substance; V is urine flow rate (ml/minute); and P_s is plasma concentration of the substance. GFR is potentially the most useful marker of renal function, but accurate assessment is difficult in practice.

A number of exogenous substances are accurate markers of GFR, including inulin (the gold standard) and iohexol. The disadvantage of using exogenous markers is that they have to be administered by intravenous bolus, usually followed by an in-fusion to maintain steady-state plasma levels. During the infusion, accurately timed urine collections are obtained, making these tests labour-intensive and costly, and therefore usually restricted to use as research tools.

GFR may also be estimated using endogenous markers such as creatinine, urea and low molecular weight proteins (e.g. cystatin C).
Advantages of using endogenous markers are that they do not need to be injected and only a single blood test is required for the estimation.

Creatinine and creatinine clearance: creatinine is derived from creatine and creatine phosphate. Its production and renal excretion is constant and proportional to muscle mass. It is freely filtered by the glomerulus, but small amounts are also secreted by the proximal tubule. Thus, the GFR is overestimated by 5–10% in healthy individuals, but as renal function deteriorates, the contribution of secreted creatinine to overall clearance becomes more important. In addition, drugs such as cimetidine, trimethoprim and some cephalosporins interfere with the tubular secretion of creatinine thus increasing serum levels and decreasing clearance, without affecting GFR.

Despite these limitations, creatinine clearance is the simplest and most widely used method of assessing renal function. Nevertheless, it is important that urine should be correctly and accurately collected over 24 hours. The urine should be refrigerated during this period to avoid bacterial overgrowth and conversion of creatinine to creatine. A blood sample may be taken from the patient at any time during the collection period for plasma creatinine analysis.

The first and easiest test used in the assessment of renal function is usually measurement of plasma creatinine concentration. There is a wide range of normal values, reflecting the variation in muscle mass between individuals. Plasma creatinine levels are affected by a number of factors, including high-protein meals and concomitant administration of some drugs (see above). Therefore extrapolation of measured plasma creatinine levels to an estimate of GFR is difficult. Various formulae exist, the most widely accepted is that of Cockcroft and Gault:

Creatinine clearance in men =
(140 – Age) × Weight / (Plasma creatinine × 72)

Creatinine clearance in women =
(140 – Age) × Weight / (Plasma creatinine × 85)

Although incorporating the variables of age, gender and weight, these formulae have their limitations. For example, creatinine clearance is overestimated in patients who are obese or oedematous. As a rule of thumb, however, for every doubling of the plasma creatinine concentration, the GFR decreases by 50%.

Urea is the breakdown product of normal protein metabolism. In renal failure, urea is retained and its serum concentration rises. Dehydration also results in raised urea levels, but this does not necessarily reflect significant renal damage. Other factors influencing serum urea levels are shown in Figure 1. These variables can affect serum urea, therefore its measurement as an index of renal function has largely been supplanted by plasma creatinine estimation.

Factors influencing serum urea levels

Production
Increased by
- High protein diet
- Increased protein breakdown (e.g. infection, trauma, surgery)
- Glucocorticoid therapy
- Gastrointestinal bleeding
- Drugs (e.g. tetracyclines)
- Cancer

Decreased by
- Low protein diet
- Reduced catabolism (e.g. old age, hypothyroidism)
- Hepatic failure

Elimination
Increased by
- Raised glomerular filtration rate (e.g. pregnancy)

Decreased by
- Reduced renal blood flow (e.g. hypotension, dehydration)
- Glomerular disease
- Urinary obstruction

1

Plasma electrolytes: urine output and composition influence the plasma concentrations of sodium, potassium, bicarbonate and chloride. Thus, changes in plasma levels of these electrolytes may be indicators of renal function. However, the kidney also influences water balance and this must be taken into account when interpreting electrolyte results. For example, water overload is the most common cause of a low plasma sodium level in intensive care patients. On the other hand, sodium and bicarbonate retention may occur in severe illness, resulting in a low plasma chloride concentration.

Renal failure interferes with potassium excretion, resulting in hyperkalaemia. Hydrogen ion excretion is impaired, which may manifest as a low plasma bicarbonate and metabolic acidaemia.

Assessment of glomerular permeability

Healthy glomeruli largely prevent plasma proteins from entering the urine. Much of the protein that does cross the glomerulus is reabsorbed by the renal tubules, and as a result less than 150 mg/day protein is excreted via the kidneys. About 60% is derived from plasma proteins, the rest originates from the kidneys and lower urinary tract.

Urine dipsticks are the simplest and most common method of measuring urinary proteins. Urine dipsticks are sensitive to albumin and other negatively charged proteins, but are relatively insensitive to positively charged molecules, such as immunoglobulin light chains. A standard dipstick does not detect urinary proteins at a concentration less than 100–200 mg/litre (200 mg/day assuming daily urinary output of 2 litres).

Alternatives to dipstick testing involve analysis of collected urine. Overnight samples, first morning void, second morning void, random samples and spot samples have all been used. In these cases, the protein:creatinine ratio is used to correct for dilution effects. In the presence of stable renal function, a protein: creatinine ratio greater than 3.5 (mg/mg) indicates nephrotic-range proteinuria (defined as urine protein excretion over 3.5 g/day). However, the gold standard for quantifying proteinuria is the measurement of a 24-hour urine collection.

Interpretation of proteinuria should always be made with reference to renal function. As renal function deteriorates, less protein is available for filtration, and urinary protein loss falls. In the same way, low serum albumin levels result in reduced urinary albumin loss.

Assessment of tubular concentrating ability

Measurements of urine osmolality or specific gravity are used to assess the kidney's ability to conserve water by estimating the number of active particles in the urine.

Osmolality is considered a more useful measure of the kidney's concentrating ability than specific gravity because it measures the number of particles in the urine and is not greatly influenced by the presence of larger molecules (e.g. urea, glucose, proteins). The urine osmolality in normal subjects can vary from 50 to 1200 mosmole/kg depending on fluid intake, with a 'normal range' of 300–900 mosmole/kg.

The concentrating ability of the kidneys is usually assessed by an overnight fluid deprivation test and measurement of the osmolality of the first morning urine sample. A value over 850 mosmole/kg represents normal concentrating ability. In individuals with an absolute deficiency of antidiuretic hormone (ADH), or with an abnormal renal response to ADH (nephrogenic diabetes insipidus), urine osmolality seldom exceeds 300 mosmole/kg.

Specific gravity: urine specific gravity is a measure of the weight or density of dissolved particles in the urine relative to the density of water. Usually there is a close relationship between specific gravity and osmolality. However, the presence of large molecules, or of glucose or protein, upsets this relationship. For example, significant amounts of glucose in the urine (e.g. in diabetic nephropathy) increase urine density, though tubular concentrating ability may be preserved. Nevertheless, it is easy to drop a hydrometer into a urine specimen and determine its specific gravity, and this is sometimes used as a rapid assessment of urine concentration. The specific gravity of the plasma ultrafiltrate is 1.010, but the normal range for urine specific gravity is 1.003–1.035. However, the value may fall to 1.001 in patients with diabetes insipidus, and may be as high as 1.040–1.050 in patients who are excreting radiographic contrast medium.

Renal tubular acidosis (RTA) is an uncommon group of conditions that produce a metabolic acidosis in the presence of a normal anion gap. The acidosis results from renal tubular dysfunction such that chloride and hydrogen ions are retained at the expense of sodium and bicarbonate. These conditions are also referred to as hyperchloraemic acidoses. Ammonium chloride loading or fractional bicarbonate excretion tests are used in the investigation of RTA. The ammonium chloride loading test is performed to assess distal tubular RTA; the patient is given ammonium chloride, 100 mg/kg, and the urine pH measured hourly over 8 hours. In normal subjects, the urinary pH falls below 5.5 in at least one sample, whereas in cases of RTA, the pH seldom falls below 6.5. Fractional bicarbonate excretion is used in the assessment of proximal tubular RTA. Bicarbonate and creatinine concentrations are measured in urine and plasma and the fractional bicarbonate excretion is then calculated from the ratio of urine and plasma creatinine levels. In subjects with proximal RTA, the fractional bicarbonate excretion is high at 10–15%.

Urinalysis

Examination of the urine is an important step in the assessment of diseases of the urinary tract. Ideally a clean-catch midstream sample is used. Its appearance (colour, odour, turbidity) should be assessed, its specific gravity and pH determined, and it should be analysed with standard urinary dipsticks for the presence of blood, proteins, sugar and infection.

Appearance – the urine may appear darker than the usual straw colour, indicating a more concentrated urine or the presence of other pigments. For example, haemoglobin and myoglobin turn the urine a pink–brown colour. If the urine appears turbid, it may indicate the presence of infection or fat. Foaming of the urine on shaking suggests proteinuria.

Specific gravity and pH – the specific gravity provides an indication of the concentration of the urine. Urinary pH measurement is useful in patients with RTA or a history of renal stones.

Blood – the presence of red blood cells (RBCs) or free haemoglobin indicates renal or bladder disease. However, not all dipsticks can distinguish between intact erythrocytes and free haemoglobin. Therefore, any urine sample testing positive for blood should be examined microscopically for the presence of RBCs (more common than haemoglobinuria or myoglobinuria).

Proteins – standard dipsticks can detect urinary proteins at a minimum concentration of 150 mg/litre. The sticks are sensitive to albumin, but relatively insensitive to globulins or Bence-Jones proteins. If proteinuria is detected, a 24-hour urine sample should be collected and analysed for urinary protein excretion. The normal range depends on the laboratory method used, and may vary between laboratories. Most adults excrete 60–100 mg protein/day, but up to 200 mg is acceptable (300 mg/day in adolescents). The presence of proteinuria should always prompt further investigation, though postural proteinuria is accepted as a normal variant unlikely to progress to renal failure.

Microalbuminuria describes the excretion of 40–150 mg albumin/24 hours (i.e. above normal range, but below the level normally detectable by dipsticks). Microalbuminuria is an early indicator of diabetic nephropathy and it may also be a predictor of the development of nephropathy in other diseases (e.g. systemic lupus erythematosus). Kits are available to test urine samples for microalbuminuria.

Glucose – diabetes is the most common cause of glycosuria and patients who test positive for urinary glucose must be screened for the disease. However, glycosuria may also be found during pregnancy or as a result of renal tubular dysfunction.

Bacteriuria – detection of urinary nitrite indicates the presence of bacteria that degrade urinary nitrates. Leucocyte esterase in the urine indicates the presence of neutrophils. Used together, these tests are strongly suggestive of urinary tract infection if both are positive.

Microscopy – examination of the sediment from a spun sample of fresh urine normally shows the presence of a few RBCs, white blood cells (WBCs), renal cells, casts and possibly fat particles. However, an unspun, clean-catch sample is more suitable when examining for the presence of cells. More than 10 WBCs/ml^3 is abnormal in fresh urine, and indicates an inflammatory reaction within the urinary tract. Usually this represents a urinary tract infection, but sterile pyuria may be found in patients taking antibiotics or within 14 days of treatment. One or more RBCs/ml^3 of fresh unspun urine is abnormal and results in a positive dipstick test.

Casts are cylindrical bodies formed within the renal tubules and are composed mainly of renal glycoproteins. Their presence almost always indicates renal disease. They are described as hyaline, granular or cellular in appearance, depending on the material trapped inside the cast at the time of formation.

The presence of bacteria in the sediment of a clean-catch mid-stream specimen of urine is highly suggestive of infection. ◆

Renal Failure and its Treatment

Daniela Tonucci
Alastair McCrirrick

Daniela Tonucci is Specialist Registrar in Anaesthesia at Gloucestershire Royal Hospital, Gloucester, UK. She qualified from Bristol University Medical School, and has worked in paediatrics and anaesthesia in the South-West Region.

Alastair McCrirrick is Consultant in Anaesthesia and Intensive Care at Gloucestershire Royal Hospital, Gloucester, UK. He qualified from Southampton University and joined the Royal Air Force. He completed his anaesthetic training in Bristol and the South-West Region. He now specializes in intensive care and anaesthesia for major bowel and vascular surgery. His particular interests include anaesthesia for carotid endarterectomy.

In the UK, the annual incidence of end-stage renal failure is about 78/1,000,000 population. Many patients with acute renal failure present for anaesthesia or critical care. There are many aetiologies for renal failure, but the final pathways of loss of glomerular and tubular function are usually the same.

Acute renal failure defines an abrupt decrease in renal function sufficient to result in retention of nitrogenous waste. This accumulation leads to a range of disturbances, such as metabolic acidosis, hyperkalaemia, fluid balance problems and effects on other organs. It is associated with significant morbidity and mortality.

Chronic renal failure is usually characterized by a slow, but progressive, deterioration in measured renal function. Symptoms and signs tend to occur only when more than 60% of the total nephron mass is lost. Dialysis is not normally required until fewer than 10% of the nephrons are functioning.

Acute renal failure

Acute renal failure is a recent reversible or potentially reversible deterioration in renal function. It is a presenting feature in 1% of patients admitted to hospital and affects 2–5% of patients during their hospital stay. It is a major cause of death during acute illness especially in the ICU.

Causes

The causes of acute renal failure are generally multifactorial but are classified as prerenal, renal or postrenal (Figure 1). Prerenal and postrenal causes should be excluded as soon as possible because they are treatable but precipitate intrinsic renal disease if left uncorrected.

Causes of acute renal failure

Prerenal
Total body water depletion
- Haemorrhage
- Gastrointestinal losses
- Renal loss
- Skin loss

Volume redistribution
- Third spacing of fluid – isotonic transfer of fluid from the extracellular fluid to a non-functional interstitial compartment (e.g. pancreatitis, ascites)
- Increased vascular capacity (e.g. sepsis, anaphylaxis)

Decreased cardiac output
- Left-sided heart failure
- Right-sided heart failure
- Valvular heart disease
- Pericarditis, tamponade

Renal
Glomerular
- Primary (post-streptococcal, rapidly progressive glomerulonephritis)
- Secondary (systemic lupus erythematosus, vasculitis, endocarditis)

Tubulointerstitial
- Ischaemic (acute tubular necrosis)
- Nephrotoxin (aminoglycoside, radiocontrast)
- Allergic interstitial nephritis (drug induced)
- Interstitial nephritis (immune complex, non drug induced)
- Metabolic toxin (uric acid, calcium)
- Heavy metal (cis-platinum)

Vascular
- Atheroembolic
- Small vessel disease (scleroderma, malignant hypertension, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura)

Postrenal
- Obstruction in the urinary collection system

1

Prerenal causes result from renal hypoperfusion, usually from decreased intravascular volume. The decrease in renal blood flow leads to a fall in glomerular filtration rate (GFR). The kidney retains water and sodium to compensate, causing oliguria, and produces concentrated urine with a progressive inability to excrete nitrogenous waste. If left uncorrected, the reduction in renal blood flow damages the renal tubules and acute tubular necrosis develops. When this occurs, the kidney loses its ability to produce concentrated urine and the small volume of highly concentrated urine that was being produced becomes increasingly dilute.

Renal causes: intrinsic parenchymal renal disease is classified according to the site of injury (Figure 1). Glomerular disease is thought to be immunologically mediated and results in disrupted glomerular filtration. Continuing inflammation leads to glomerulus destruction.

Interstitial nephritis accounts for less than 10% of acute renal failure. It is a complex collection of inflammatory diseases. Drugs are the most common cause.

Acute tubular necrosis (ATN) accounts for 85% of renal causes of acute renal failure and 75% of all cases of acute renal failure. It is essential to differentiate between ATN and prerenal causes for correct management (Figure 2). The most common causes of ATN are renal hypoperfusion or ischaemia, chemical toxicity, trauma or sepsis. Nephrotoxins include analgesics (e.g. aspirin, non-steroidal anti-inflammatory drugs (NSAIDs)), aminoglycosides, immunosuppressive agents, contrast media and heavy metals. The thick ascending limb of the loop of Henle is particularly predisposed to injury because it is situated in the medulla, which receives only a small proportion of the total renal blood flow (in order that the concentration osmolality gradient is maintained). The active ion pumps in the loop of Henle are high oxygen consumers and the area is vulnerable to ischaemia.

Differentiating causes of acute renal failure

Test	Prerenal causes	Acute tubular necrosis
Urinalysis	Normal	Granular cell casts
Urine osmolality (mosmole/kg)	> 500	< 350
Urine sodium (mmol/litre)	10–20	> 20
Urine urea (mmol/litre)	> 250	< 150
Fractional sodium excretion	< 1%	> 1%

2

The tubular response to injury is not aetiology specific. The result is a rapid decline in renal function, which may require dialysis or haemofiltration. The two histological changes that can occur are:
- tubular necrosis with sloughing of the epithelial cells
- occlusion of the lumina by casts and cellular debris.

Other factors involved, in addition to the tubular obstruction, include backleak of filtrate across the tubular epithelia and a reduction in glomerular filtration. Histological changes may be patchy and appear mild compared with the severity of the resulting renal dysfunction.

Postrenal causes are always associated with obstruction (mechanical or functional) in the urinary collection system. Examples include bladder tumour, prostatic hypertrophy and ureteric stones. Ultrasound examination detects most cases.

Diagnosis

Diagnosis relies on a good history and examination, as well as laboratory tests and imaging.

History and examination indicate the likely cause of the renal failure. It is also important to review previous notes. The history should cover:
- nausea, vomiting or diarrhoea
- bleeding
- heart failure
- previous renal insufficiency
- oedema, hypertension or change in urine colour
- rashes
- what medications are being or have been taken?
- prolonged episodes of hypotension
- any radiocontrast dye?
- stones or other urinary obstruction
- nephrotoxic drugs (e.g. NSAIDs).

In a critical care setting, oliguria may be the first indicator of imminent renal failure. Physical examination is useful for assessing the volume status of the patient. Concentrated urine suggests prerenal renal failure. Signs of systemic disease should also be sought.

Urinalysis: laboratory tests begin with urinalysis (Figure 3). Protein +3 or 4 on dipstick testing suggests intrinsic renal disease with glomerular damage. Prerenal, ATN or postrenal causes of renal failure produce less protein in the urine. Microscopy can be used to examine the sediment from a centrifuged urine sample. Casts are formed from urinary Tamm-Horsfall protein, produced by tubular epithelial cells and reflect the content of the tubule.
- Hyaline casts are devoid of content, and are seen with dehydration, after exercise or associated with glomerular proteinuria.
- Red cell casts indicate glomerular haematuria (e.g. glomerulonephritis).
- White cell casts imply inflammation in the renal parenchyma (e.g. interstitial nephritis).
- Granular casts are composed of cellular remnants and debris.
- Fatty casts are usually associated with heavy proteinuria and nephritic syndrome.

In patients with prerenal and postrenal acute renal failure, the sediment usually lacks casts, cells or debris.

Results of urine analysis

	Urinary sediment	Proteinuria	Specific gravity
Prerenal	Generally benign sediment, few hyaline or granular casts	Trace	Increased
Intrarenal			
• Acute glomerulonephritis	RBCs with casts, WBCs with casts, granular casts, fatty casts	++++	Increased
• Acute tubular necrosis	Renal tubular cells and casts, course granular and pigmented granular casts	++	1.010–1.012
• Acute interstitial nephritis	RBCs, WBCs, WBC casts, renal tubular cells	++	1.010–1.012
Postrenal	Benign sediment	Trace	Increased early

3

Urine osmolality: the kidney can concentrate urine to a maximum osmolality of 1400 mosmole/kg. Dilute urine may have an osmolality as low as 30–60 mosmole/kg. The ability to produce concentrated urine depends on having intact, functioniong tubules. If there is tubular damage (e.g. ATN) the urine is relatively dilute, typically 300–350 mosmole/kg.

Urine sodium concentration: urinary sodium excretion reflects the ability of the nephron to retain filtered sodium (Figure 4). When the GFR is reduced, the tubule avidly reabsorbs sodium and water and sodium clearance is low. If the tubule is damaged, a high concentration of sodium passes into the urine. The fractional excretion of sodium (FENa) is the percentage of filtered sodium excreted in the urine:

$$\text{FENa} = \frac{\text{Urine sodium}}{\text{Urine creatinine}} \times \frac{\text{Plasma creatinine}}{\text{Plasma sodium}} \times 100$$

In prerenal failure and acute glomerulonephritis, when tubular function is retained, FENa is less than 1%. In disease processes affecting the tubule it is usually greater than 2%. Assessment of FENa can be misleading because some causes of ATN (e.g. dye-induced, rhabdomyolysis, haemolysis) may have a low FENa and patients with prerenal acute renal failure taking diuretics may have a high FENa.

Urine and serum diagnostic indices

	Prerenal	Renal	Postrenal
Urine sodium (mEq/litre)	< 20	> 20	> 20
Urine chloride (mEq/litre)	< 20	> 20	< 20
Fractional excretion of sodium	< 1%	> 2%	> 2%
Urine osmolality (mosmole/kg)	> 500	< 350	< 350
Urine/serum creatinine (mmol/litre)	> 40	< 20	< 20
Urine/serum urea (mmol/litre)	> 8	< 3	< 3

4

Serum creatinine and urea levels: creatinine is produced from the breakdown of muscle mass. The serum creatinine concentration is a function of the amount of creatinine entering blood from the muscles, its volume of distribution and rate of excretion. The first two factors are usually constant, therefore changes in serum creatinine are usually caused by changes in its rate of excretion.

Creatinine rises by 1–2 mg/dl/day in acute renal failure. Serum urea also rises but is a less reliable indicator of renal function because there are other causes of elevated urea (e.g. increased protein intake, gastrointestinal bleeding, enhanced catabolism). Other biochemical abnormalities in acute renal failure include metabolic acidosis, hyperkalaemia, hypermagnesaemia, hyperphosphataemia and hypocalcaemia.

Radiology: an intravenous pyelogram gives a good anatomical picture of the kidney, but no assessment of function. Ultrasound is highly portable and has no associated morbidity. Both investigations may identify or exclude obstruction to the renal tract and provide information about kidney size.

Prevention

Acute renal failure can often be prevented by attempting to maintain normal fluid balance, blood pressure and blood volume in patients at risk. These include patients who have undergone major surgery, burns or haemorrhage especially if they have some pre-existing renal impairment. If acute renal failure becomes established, accurate diagnosis is essential. Renal rescue therapy may avoid the onset of renal failure. Many cases of renal failure have a prerenal element and therefore renal blood flow and oxygen delivery must be optimized. Untreated prerenal failure precipitates ATN.

Maintenance of oxygen delivery – the first steps in preventing and treating prerenal failure are to exclude or treat hypoxia and optimize the circulating blood volume. This may require monitoring the right or left atrial pressure or other ways of assessing volume status. Low cardiac output states associated with normovolaemia may require inotrope therapy. Severe anaemia may impair renal oxygen delivery despite adequate renal perfusion.

Autoregulation – under normal circumstances, autoregulation determines that renal blood flow remains fairly constant over a range of mean arterial pressures. In disease states, autoregulation may be impaired and the renal perfusion pressure becomes more critical. Vasoconstrictors (e.g. noradrenaline) may increase urine output by increasing perfusion pressure. Noradrenaline also increases efferent arteriolar resistance more than on the afferent side, thus increasing the filtration fraction.

Furosemide (frusemide) infusion inhibits sodium reabsorption in the thick ascending loop of Henle by decreasing the activity of the Na^+-K^+-$2Cl^-$ cotransporter. It also stimulates vasodilator prostaglandins thereby increasing afferent arteriolar flow. However, there is little evidence that it prevents renal failure and it may increase the volume of urine produced with little or no effect on the failing kidney's ability to remove waste products. Increasing urine volume may decrease the need for haemofiltration or dialysis as a result of fluid overload.

Dopamine infusion increases the fractional sodium excretion and urine output, but not creatinine clearance. Its primary effect was thought to be an increase in renal blood flow mediated by dopamine receptors. However, it probably increases urine production by increasing cardiac output and therefore renal blood flow by its actions as an inotrope. In patients already receiving inotrope therapy it has no effect on renal blood flow. It has not been demonstrated to prevent the onset of acute renal failure. Side-effects include nausea, gastric stasis, inhibition of anterior pituitary hormones and depression of hypoxic drive.

Mannitol is thought to decrease tubular swelling, though there is little evidence. It is advocated by some in high-risk surgery (e.g. open heart surgery). Recent evidence suggests it may potentiate acute renal failure associated with radiocontrast administration.

Avoidance of nephrotoxins – nephrotoxic drugs (e.g. aminoglycosides, NSAIDs) should be avoided in all patients at increased risk of acute renal failure. This may include the elderly, those with pre-existing renal dysfunction and patients with circulatory impairment or hypotension.

Treatment

Renal blood flow and oxygen delivery should be optimized (see above) in all patients with acute renal failure, especially if the initial cause had a prerenal component. If there was an element of congestive cardiac failure, diuretics may be useful because they decrease afterload and so may increase renal perfusion. In liver failure, diuretics (e.g. spironolactone) or paracentesis may have a role.

There is no specific treatment for ATN, the most common renal cause of acute renal failure. All drugs with any degree of nephrotoxicity should be stopped. Nutritional and circulatory status should be optimized and sepsis treated. In some situations, oliguric ATN can be converted into non-oliguric ATN with diuretic therapy, which may have advantages regarding fluid balance and the requirement for dialysis or haemofiltration. There is little evidence that diuretic therapy influences long-term outcome despite non-oliguric ARF having a better outcome than oliguric renal failure.

Acute glomerulonephritis may respond to immunosuppressant drugs and/or plasmapheresis. In acute interstitial nephritis, removal of the offending allergen and treatment with corticosteroids may improve the outcome.

In postrenal failure, the obstruction to the flow of urine must be relieved. Treatment depends on the level of obstruction and varies from urinary catheter to percutaneous nephrostomy. There is often a secondary element of infection.

Renal replacement therapy

Renal replacement therapy may be required if conservative treatment fails. The three choices are peritoneal dialysis, intermittent haemodialysis and continuous haemofiltration/haemodiafiltration. Absolute indications for dialysis include:

- life-threatening hypoxia caused by fluid overload
- life-threatening systemic acidosis
- hyperkalaemia
- lethal drug overdoses that are better cleared by dialysis (e.g. lithium, theophylline)
- uraemia causing confusion, coma or pericarditis.

Relative indications for dialysis include:

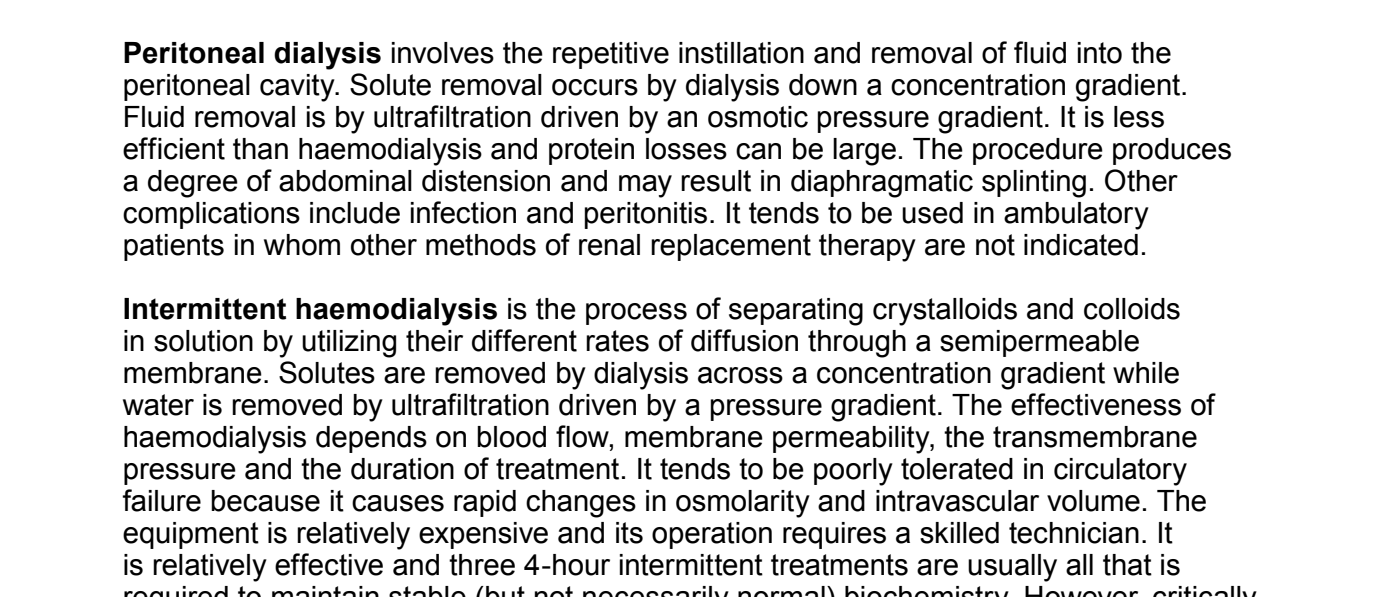
- blood urea nitrogen over 100 mg/dl
- platelet dysfunction causing bleeding
- fluid overload.

Peritoneal dialysis involves the repetitive instillation and removal of fluid into the peritoneal cavity. Solute removal occurs by dialysis down a concentration gradient. Fluid removal is by ultrafiltration driven by an osmotic pressure gradient. It is less efficient than haemodialysis and protein losses can be large. The procedure produces a degree of abdominal distension and may result in diaphragmatic splinting. Other complications include infection and peritonitis. It tends to be used in ambulatory patients in whom other methods of renal replacement therapy are not indicated.

Intermittent haemodialysis is the process of separating crystalloids and colloids in solution by utilizing their different rates of diffusion through a semipermeable membrane. Solutes are removed by dialysis across a concentration gradient while water is removed by ultrafiltration driven by a pressure gradient. The effectiveness of haemodialysis depends on blood flow, membrane permeability, the transmembrane pressure and the duration of treatment. It tends to be poorly tolerated in circulatory failure because it causes rapid changes in osmolarity and intravascular volume. The equipment is relatively expensive and its operation requires a skilled technician. It is relatively effective and three 4-hour intermittent treatments are usually all that is required to maintain stable (but not necessarily normal) biochemistry. However, critically ill patients may develop arrhythmias, increased intracranial pressure (ICP) and/or haemodynamic instability during intermittent therapies. This may be related to the significant extracorporeal blood volume or rapid fluid, electrolyte, or osmolality shifts during a 2–4-hour intermittent therapy.

Continuous renal replacement therapies have many advantages over intermittent therapies. The slow and continuous fluid and solute removal during continuous renal replacement therapy results in less haemodynamic instability and less acute changes in ICP. The basis of this treatment is haemofiltration, a convective clearance method to which haemodialysis may be added to improve the efficiency with which waste products are cleared. Blood may be taken from the arterial side and returned to the venous side (CAVH, continuous arterio-venous haemofiltration) using arterial pressure as the driving force for haemofiltration. Modern equipment tends to employ continuous veno-venous haemodialysis or diafiltration in which electric pumps remove blood from and return it to the venous circulation. Venous access is obtained in a large central vein using a cannula with two lumens (Figure 5).

Continuous venovenous haemodiafiltration circuit



5

Whichever method is used, blood is taken to an extracorporeal circuit and the removal of solutes occurs by ultrafiltration. Fluid volume is replaced as required with a balanced electrolyte solution. Haemofiltration is effective at removing fluid but less so at removing waste solutes. Urea clearance is proportional to the filtration rate and blood flow. Dialysate can be passed countercurrent to blood flow to add a degree of dialysis and improve the efficiency of solute removal. With haemodiafiltration, urea removal is improved and its clearance becomes proportional to dialysate flow rate but independent of blood flow.

Possible problems

Anticoagulation – anticoagulants are required to prevent blood clotting in the filter and extracorporeal circuit. Heparin, low molecular weight heparin or epoprostenol are commonly used.

Dialysate solutions – acetate has now been replaced by lactate as the buffering agent used most commonly in dialysate solutions. They can both accumulate in patients with liver dysfunction, when their metabolism to bicarbonate is impaired. Under these circumstances, metabolic acidosis may worsen. The ideal buffering agent is bicarbonate, but it is unstable in solution and therefore more difficult to prepare.

Nutrition – ensuring adequate nutrition can be a problem, because amino acids are lost across filters. Patients require nitrogen and essential amino acids, preferably via the enteral route.

Drug clearance – the drug dose may require adjustment at the beginning of renal replacement therapy. Some drugs are cleared effectively by dialysis and haemofiltration depending on their molecular size, degree of protein binding and membrane adherence. Other drugs (e.g. ACE inhibitors) are not cleared at all.

ICU: there are no guidelines to indicate when supportive dialysis or haemofiltration should begin for patients with acute renal failure in the ICU. In most patients, the onset of acute renal failure represents a part of multi-organ dysfunction. Acute renal failure in the ICU is most commonly associated with ATN and therefore is potentially reversible, but the overall pathology is often overwhelming. Decisions regarding the commencement of renal replacement therapy must therefore take into account the whole picture and an experienced clinician must assess the likelihood of a successful outcome. Renal replacement therapy can complicate treatment, because of the potential hazards of dialysis catheter placement and the use of anticoagulants. However, by providing a mechanism for the easy removal of fluid it can solve fluid balance problems and 'create room' for enteral or parenteral nutrition.

Chronic renal failure

Symptoms and signs

Chronic renal failure is irreversible and may follow an episode of acute renal failure. It may result from any major cause of renal dysfunction, though the most common causes are glomerulonephritis and diabetic nephropathy. The progress of chronic renal disease is often slow, with symptoms and signs occurring only when more than 60% of the nephron mass is lost. As the disease progresses, anaemia and uraemia develop. Uraemia initially presents with malaise, lethargy and decreased mental acuity. Patients may experience nocturia as they lose their ability to produce concentrated urine. Plasma creatinine and urea concentrations rise in a non-linear way as GFR diminishes. To begin with, this rise is minimal, but once GFR is below 6 ml/min, the rise is rapid with systemic uraemia.

Neuromuscular symptoms of uraemia include twitching, peripheral and autonomic neuropathies, confusion, convulsions and ultimately coma. Anorexia, nausea, vomiting and diarrhoea are also common. Malnutrition leads to muscle wasting. Gastrointestinal ulceration and bleeding occur later in the disease process. 80% of patients develop hypertension due to increased renin–angiotensin activity, sodium and water retention and secondary hyperaldosteronism. Cardiomyopathy, ischaemic or hypertensive, and congestive cardiac failure occur leading to generalized oedema. Pericarditis can develop secondary to uraemia.

The skin is thin with poor healing. It may become pigmented and the patient may develop pruritus. Renal osteodystrophy and hyperparathyroidism, as well as osteomalacia, can occur. Normochromic, normocytic anaemia develops as a result of decreased erythropoietin production, shortened RBC survival and marrow depression. Hyperkalaemia and a chronic moderate metabolic acidosis usually signify end-stage renal failure.

Prognosis and treatment

Prognosis and treatment depend on the cause of the renal failure. Good control of blood glucose and arterial blood pressure reduces the rate of deterioration in GFR.

Diet – careful diet control is needed. Dietary protein must be reduced and calorie intake increased. Vitamins are necessary because of dietary restrictions. Dietary phosphorus is given to delay secondary hyperparathyroidism in early renal failure, but in later disease, phosphate-binding calcium salts are needed to achieve lower serum phosphate. Hypertriglyceridaemia is common and requires dietary control, because fibric acid derivatives can cause rhabdomyolysis.

Fluid and electrolyte balance – water intake is restricted if serum sodium is not in the normal range. Sodium is not restricted unless there is oedema or hypertension or congestive cardiac failure when diuretics can also be used.

Anaemia – erythropoietin and iron can be given.

Dialysis or transplantation is given if conventional therapy fails, or the underlying disease process is untreatable.

Anaesthesia

Effects on renal function

All general anaesthetic agents depress renal function. The type of procedure being undertaken, the duration of surgery, and the preoperative fluid status affect how much function is reduced. The changes to renal function are normally transient and resolve completely postoperatively.

Direct effects – toxicity may arise from volatiles as a result of alteration in renal concentrating capacity induced by fluoride ions. The link between halogenated anaesthetics and nephro-toxicity was established in 1970 and is related to free fluoride ions at a plasma concentration of 50 μmol/litre. It produces high output renal failure, which resolves after 10–20 days. Enflurane and sevoflurane may reach nephrotoxic levels but are eliminated so rapidly that the total amount of fluoride exposure is low.

Indirect effects – all anaesthetics reduce GFR and intraoperative urine flow. This is secondary to regional and systemic haemodynamic changes, alterations in the renin–angiotensin–aldosterone axis, and antidiuretic hormone release.

Anaesthesia in renal failure

The preoperative assessment should look for cardiovascular complications of renal disease, fluid and electrolyte balance and acid–base derangements. Autonomic neuropathy is associated with an increased risk of gastric aspiration and should be sought. Anaemia of renal failure seldom requires preoperative transfusion. Preoperative dialysis may be needed. Careful fluid balance is needed intraoperatively, with avoidance of potassium-containing fluids. A regional technique may be suitable.

Influence of renal disease on anaesthetic drugs

Changes in the pharmacokinetics of drugs in patients with renal failure result from changes in drug protein binding, altered drug elimination and altered cellular hepatic metabolism.

Intravenous anaesthetic agents: most anaesthetic agents are metabolized in the liver and excreted renally, and are considered safe in renal failure. Often the initial dose is decreased by 25–50% and the response noted as a guide to further treatment. Uraemia alters hepatic metabolism, increasing mixed function oxidase activity, therefore most drug metabolism is normal or increased in renal failure. Uraemia causes decreased plasma protein binding and CNS depression, therefore drugs causing further CNS depression should be avoided. Thiopental (thiopentone) causes prolonged anaesthesia in renal failure owing to the depressant effect of uraemia and decreased protein binding, leaving more unbound thiopental (thiopentone) available for effect. Propofol is safe, though dose reduction is advised because of the profound hypotension that can occur in renal failure patients. Etomidate may be a good alternative.

Opioids can be used; fentanyl is safe and has no active metabolites, but morphine does and should be avoided. Suxamethonium is safe if there is no hyperkalaemia or peripheral neuropathy. The rise in potassium is the same in renal failure as in normal renal function (0.5 mEq/litre).

Non-depolarizing muscle relaxants should be used carefully (Figure 6). Atracurium is a good choice because it is not eliminated renally. Its duration of action is the same in renal failure as in normal renal function. Pancuronium should be avoided and vecuronium used with care.

The dependence of non-depolarizing muscle relaxants on renal excretion for elimination

Elimination	Drug
60–90%	Pancuronium
25–60%	Tubocurarine
< 25%	Vecuronium, atracurium, suxamethonium, mivacurium

6

Inhalational agents: some volatile agents are degraded to renally excreted metabolites, which may have toxic effects. However, they do not rely on kidney function for reversal and so are considered safer in renal failure than intravenous agents.

Isoflurane has low peak fluoride levels and is safe, desflurane has no renal toxicity and halothane is not metabolized to fluoride. Enflurane and sevoflurane have the highest fluoride levels. Sevoflurane also degrades in soda lime to form compound A, which is nephrotoxic in rats. There is no evidence to support this in humans, and sevoflurane and enflurane are safe in renal failure.

Others: antihypertensives must be carefully titrated, because blood pressure can be labile in renal failure. Esmolol and labetalol are metabolized extrarenally and are safe to use. Sodium nitroprusside has a toxic metabolite, thiocyanate, which can accumulate in renal failure. Vasopressors may cause a decrease in renal perfusion. ◆

Statistics

Ian Kestin

Ian Kestin is Consultant Anaesthetist at the Western Infirmary, Glasgow. He trained in anaesthesia in Southampton, Bristol and the USA. His interests include education in anaesthesia and mathematical applications in medicine.

Statistics are the tools used to describe and analyse numbers. The complete data set from a study may comprise many thousands of observations and it is impractical to give the full results in a published paper. Descriptive statistics are used to summarize this numerical information.

Types of data

There are three main types of data obtained in a research project and the type determines the methods used to describe and analyse the data.

Categorical (nominal) data: each of the subjects in the study is allocated to one of two or more mutually exclusive categories such as gender (male, female), blood group (A, B, AB, O), or social class. The categories have no ranking or numerical relationship to each other.

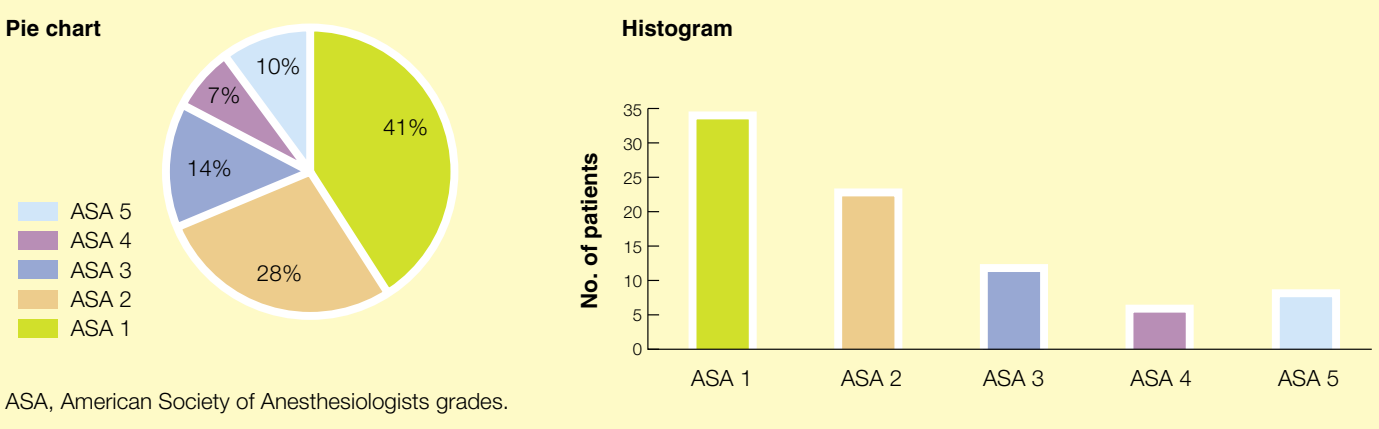
Ordinal data (ordered categories or ranked data): each of the subjects in the study is allocated to one of several mutually exclusive categories, and these categories have an intrinsic ranking or ordering. Examples are grades of oedema (mild, moderate, severe), or ASA scores (1–5). The categories may be numbered, but the numbering defines only the ordering of the categories, and does not 'scale' the relative magnitude of one category to another. For example, patients with head injuries are allocated using the Glasgow Coma Score (GCS) to one of 13 possible categories denoted by a whole number between 3 and 15. A patient with a GCS of 4 is worse than a patient with a GCS of 8, but is not 'twice as bad', whereas a patient with a weight of 80 kg is exactly twice as heavy as one with a weight of 40 kg. Misusing ordinal data by treating the numbers as if real measurements had been made is a common mistake.

Numerical data describe the actual numerical properties of the subjects. The measurements can be discrete or continuously variable. Discrete numerical data can take only certain values, usually integers (e.g. number of children, hospital deaths per year); continuously variable data can theoretically take any numerical value, but usually within a certain range (e.g. heart rate, weight).

Descriptive statistics

Descriptive statistics are required to summarize large data sets. Categorical data are easily described by histograms or pie charts; a visual illustration of the data clearly shows the frequency of the categories (Figure 1).

Two methods of illustrating the frequency distribution of categorical or ordinal data



ASA, American Society of Anesthesiologists grades.

1

Two essential properties describe ordinal or numerical data:

- the central location – where the bulk of the observations lie
- the variability – how closely the observations are clustered about the central location.

The central location of a series of observations is usually described using the mean, median or mode (Figure 2). Misuse of the mean is a common error, which properly should be used only with continuously variable numerical data. For ordinal data the median or mode must be used (e.g. it is wrong to quote a mean GCS of 7.5).

Common measures of central location

Measure of central location	Type of data	Definition
Mean	Continuously variable	Sum of all observations/number of observations
Median	Ordinal and numerical	The observation with half the observations above and half below (i.e. 50th percentile)
Mode	Ordinal and numerical	The most commonly occurring observation

2

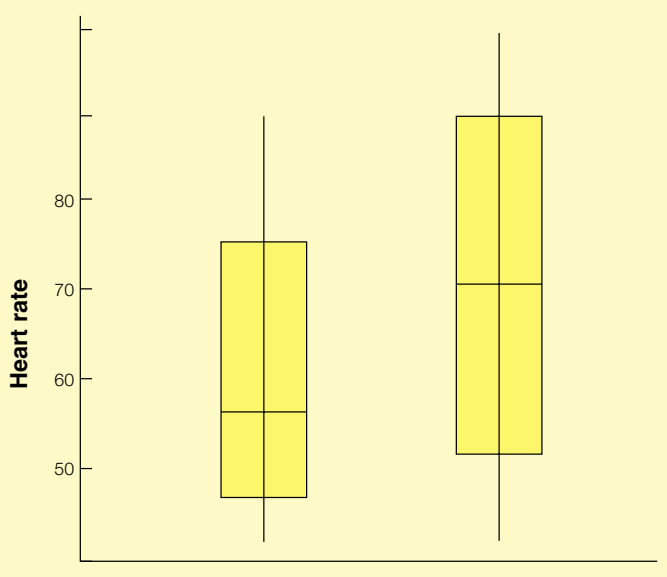
The variability can be described by the range, percentiles or the standard deviation.

The range gives the maximum and minimum values of the observations and is useful if there is some particular interest in the maximum or minimum response (e.g. the lowest respiratory rate recorded would be of clinical importance in patients given opiates). However, the range can give a misleading impression of the variability if there are single extreme results in the data.

A percentile is that observation which is greater than the appropriate percent of all the observations in the data set, so the 10th percentile is the observation that is greater than 10% of all the observations, the median is the 50th percentile, and the 90th percentile is the observation that is greater than 90% of the observations. Commonly used percentiles are the interquartile range (the 25th to 75th percentile), and the 2.5th to 97.5th percentile (containing 95% of the observations). Percentiles can be used for any type of data.

The standard deviation is applicable only to data that are continuously variable and normally distributed (see later). A common graphical way of summarizing information is the 'box and whisker' plot (Figure 3).

Box and whisker plot of heart rate after two different drugs



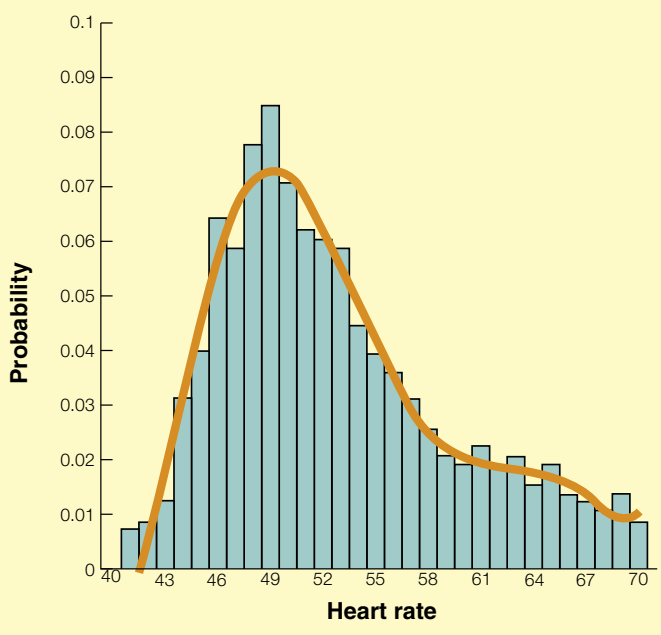
The horizontal line shows the median, the 'box' shows percentiles, commonly the 2.5th to 97.5th, and the vertical line shows the range of the sample data

3

Frequency distribution curves

A graph showing the probability of obtaining any particular observation is called a frequency distribution (Figure 4).

Frequency distribution

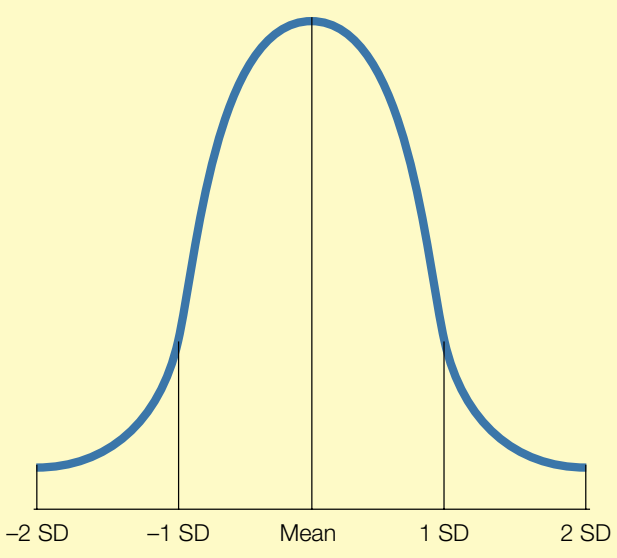


The heart rates of patients after an intravenous opiate have been measured. The probability of obtaining any given heart rate is shown by the histogram. As more patients are studied, the histogram can be replaced by a continuous curve

4

Normal distribution is a specific frequency distribution pattern that is common in biological data for which many statistical tests have been designed (e.g. t-test, analysis of variance). The central location can be described by the mean (which is the same as the mode and median), and the variability is described by the standard deviation. Multiples of the standard deviation about the mean always contain the same proportion of the observations (Figure 5). Not all symmetrical frequency distributions are normal (Figure 6).

Characteristics of a normal distribution



Calculation of sample parameters

Sample mean = $\Sigma_{x/n}$

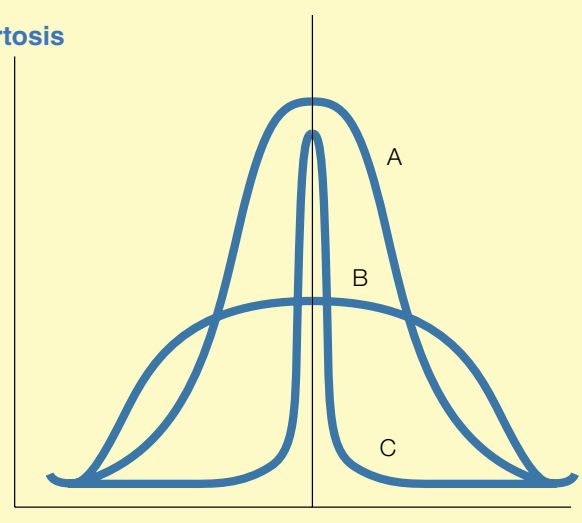
Sample standard deviation = $\sqrt{\frac{\Sigma(x - \bar{x})^2}{n - 1}}$

Mean ± 1 SD 67% of observations
Mean ± 2 SD 95% of observations
Mean ± 3 SD 99% of observations

SD, standard deviation

5

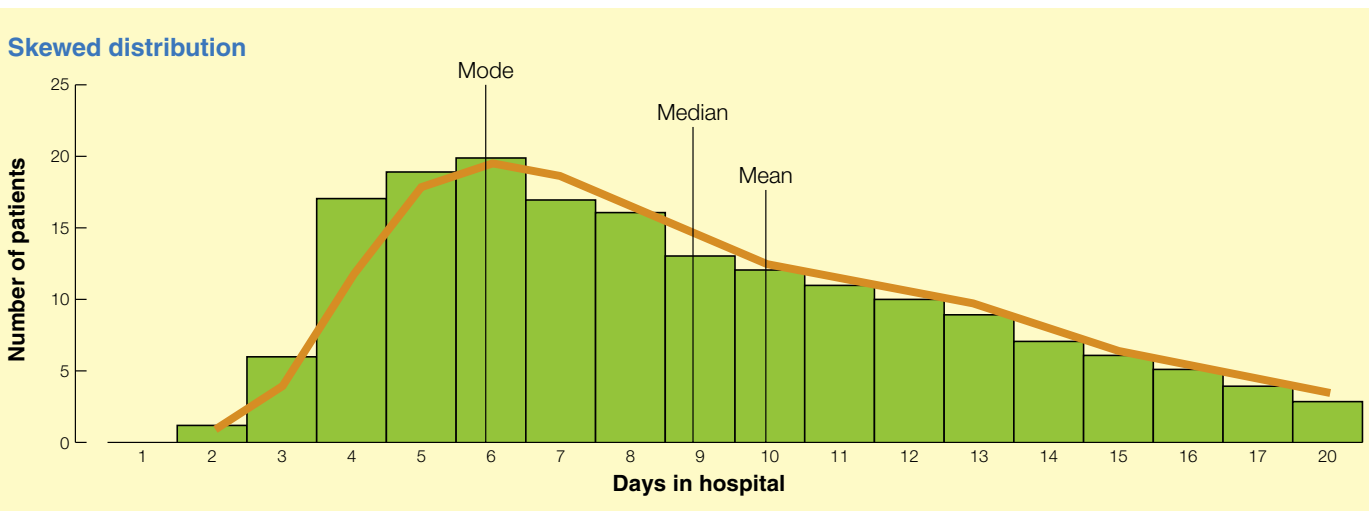
Kurtosis



Not all symmetrical frequency distributions are normal; the curve may be flatter or more peaked than the normal distribution. Plot A is a normal distribution. Plots B and C show symmetrical distributions that have a broader (platykurtic) or more narrow (leptokurtic) distribution than the normal distribution. A bimodal distribution is an extreme example of a platykurtic distribution

Skewed distributions are a common pattern in biological data, when the frequency distribution curve is not symmetrical (Figure 7). The frequency of hospital stay after an operation is commonly skewed most patients have similar lengths of stay, but some have complications and stay longer. This is an example of positively skewed data; negatively skewed data would be the reverse pattern and are less common. The mean, median and mode are all different for skewed data. If the single largest observation in the sample is increased, the mean increases, but the median and mode are unchanged; thus the median or mode are better indicators of the central location of a skewed distribution. As a rough estimate, if the standard deviation of a sample is more than half the mean, then the data are probably skewed.

Skewed distribution



Length of stay in hospital after surgery is an example of a positively skewed distribution. The mode is 6 days, the median is 9 days, and the mean is 10 days

Skewed data can often be mathematically transformed to conform to a normal distribution. Taking logarithms of a sample that is positively skewed usually produces a data set that is approximately normally distributed, and then techniques designed for the normal distribution can be used on the transformed data. The alternative is to use statistical tests designed for any data. If the data are transformed, care must be taken when reversing transformations back to the original units – confidence intervals can be reverse transformed, but not the standard deviation (the confidence limits will not be symmetrical about the mean). There are methods of testing if data conform to a normal distribution (e.g. the Shapiro-Wilk W test), and these ought to be carried out before using statistics designed for the normal distribution. Statistical techniques that use assumptions about the underlying distribution of the data (nearly always a normal distribution) are called parametric statistics. Techniques to describe and analyse data that make no assumptions about the underlying distribution of the sample or population data are called non-parametric statistics, and can be used on any type of data. Most of these tests are called rank sum tests; all the sample data are sorted in order and assigned a ‘rank’, and then the significance test compares the ranks of the data from different groups.

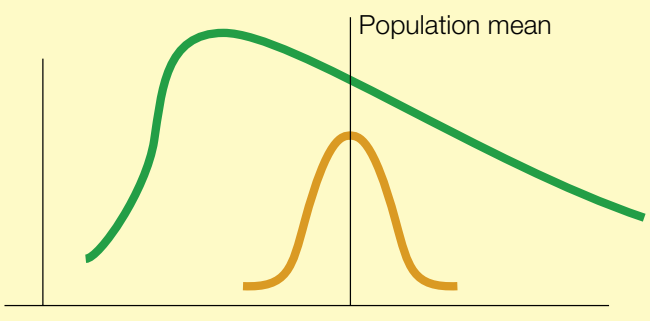
In practice, parametric statistics are reasonably reliable if used for continuously variable data that are not normally distributed provided the deviation is not too extreme. Parametric statistics should never be used for ordinal data, but non-parametric statistics can be used for all data, including the normal distribution. When the data are normally distributed, it is better to use the parametric tests specifically designed for the normal distribution.

Inferential statistics

Inferential statistics are used to infer properties about a wider population of subjects beyond those studied. These inferences are always made with some uncertainty because it is never known how representative the sample is. This uncertainty is measured by probabilities that measure the degree of confidence of the conclusions about the wider population.

The central limit theorem is the basis of much inferential statistics. This states that if several samples are taken from a population, then the means of these samples are distributed normally around the true population mean. The standard deviation of this normal distribution of the sample means is called the standard error of the mean (SEM). This is true even if the variable is not distributed normally in the population, provided that the samples are sufficiently large (Figure 8).

Central limit theorem



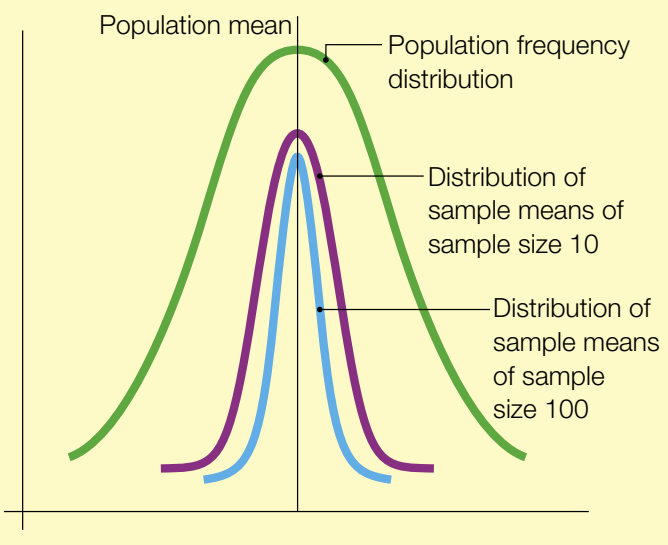
Frequency distribution of population

Distribution of means of samples size n from population. The SD of this distribution is the SEM. As n increases, the SEM decreases

The mean of samples taken from the population is distributed normally about the population mean.
SD, standard deviation; SEM, standard error of the mean

If the variable is distributed normally within the population (unlike Figure 8, where the population data are positively skewed), then we can further obtain an estimate of the SEM from the sample standard deviations (Figure 9).

Relationship of sample size and SEM



Standard error of the mean (SEM) = $s/\sqrt{n}$, where s is the standard deviation of the sample and n is the number of subjects in the sample

Using the properties of the normal distribution, an estimate of the true population mean can then be obtained from the sample mean. We can be 95% confident that the true population mean lies within the range

$$\bar{x} \pm (2 \times SEM)$$

where x is the sample mean. This range is called the 95% confidence interval for the true population mean. If we had 100 different samples, we could obtain 100 different estimates of this range; in about 95 of these, the true population mean would be within this range and in about 5 it would not lie within this range. In practice, we usually have only one sample, and we do not know if this is one of the 5% of occasions when the true population mean is outside the calculated range.

As n increases, the SEM decreases, and the 95% confidence intervals for the true population mean are narrower. Intuitively, large samples are more representative of the whole population, and the sample means of large samples are more closely clustered about the true population mean than those of small samples.

We have therefore used our sample and the central limit theorem to infer properties about the unknown parent population from which the sample was obtained. This introduces the concepts of assumptions (the assumptions that allow us to use the central limit theorem), of probabilities (the true population mean is 95% probable to lie within the calculated range) and of inferential errors (we make conclusions based on probability not certainty). Our application of statistics may be completely correct, but our conclusions can still be wrong!

Hypothesis testing

One of the main uses of statistics in medicine is to decide if the data from a clinical trial represent a real difference between treatments or could have arisen by chance – this is hypothesis testing.

For example, a clinical trial has been completed and the heart rates have been recorded in two groups of patients treated with drugs A and B. Our samples are drawn from two hypothetical populations; population A, all patients (similar to those in the study given drug A) who are or could be taking drug A, and population B, all patients (similar to those in the study given drug B) who are or could be taking drug B. We do not know how representative our samples are of these two populations. All statistical tests calculate a probability or confidence limits that the sample results could have been obtained if populations A and B did not differ. The logical stages in hypothesis testing are as follows.

- Form a null hypothesis. This states that the frequency distribution of heart rates in population A is the same as that in population B. The alternative hypothesis is that populations A and B have different frequency distributions.
- Choose the appropriate statistical test. In this case, we have continuously variable data that are usually normally distributed, so we can use a t-test.
- Obtain the *p* value. The statistical test uses the actual heart rates of our samples to calculate the probability (the *p* value) that we could have obtained our sample data if the null hypothesis were true (i.e. if the samples had been obtained randomly from a single population).
- Accept or reject the null hypothesis. Conventionally, a probability of 0.05 (5%) is chosen as the cut-off for the *p* value as sufficiently unlikely that we can reject the null hypothesis. This value is called the level of statistical significance, and can be chosen at a lower value (e.g. 0.01 or 1%) if we wish to make our conclusions less likely to be wrong. A higher value than 0.05 is seldom used. If *p* is less than 0.05, we conclude drugs A and B have different effects on the heart rate. If *p* is greater than 0.05, then there is a reasonable probability that we could have obtained these results because populations A and B are the same, and we conclude that drugs A and B do not have different effects. Both of these conclusions may be wrong. This pattern of reasoning is common to all clinical trials using inferential statistical tests for hypothesis testing for differences between groups in the study (Figure 10).

Choice of statistical test

The choice of statistical test is determined by the type of data and the number of groups; the most common statistical tests used in medical research are listed in Figure 11. In some studies, each subject in one group is uniquely paired with one in the other group(s). For example, if a variable is measured in the same individual before and after an intervention, then these two observations are related and the data are said to be paired (even if there are more than two groups). There are appropriate statistical tests that should be used for this type of data.

Logical steps in hypothesis testing and possible errors.

Form the null hypothesis

Choose a statistical test
Possible error: incorrect test chosen (e.g. one that is not applicable to this type of data)

Obtain a *p* value

Reject the null hypothesis if $p < 0.05$
Possible errors
- By definition, this decision will be incorrect on 5% of occasions (a Type I error)
- Poor study design. Samples show a real difference, but this is caused by bias – either because of poor study design or by chance, the samples differing in some important confounding factor, known or unknown

Accept the null hypothesis if $p > 0.05$, and conclude the treatments do not have different effects
Possible errors: there is a real difference in the treatments, but the study has failed to demonstrate this difference. This is a Type II error, and is more common than a Type I error. The most common cause of a Type II error is insufficient numbers of patients in the study

10

Multiple significance testing
If there are three or more groups in a study, it is tempting to test all the possible paired combinations to determine the differences between the various treatments (i.e. A versus B, B versus C, A versus C, etc). If all these combinations are tested with a statistical significance level of 5%, the risk of finding spurious differences by chance (a Type I error) increases considerably. The correct procedure is to use the appropriate statistical test for three or more groups (Figure 11). If we reject the null hypothesis, we conclude that there are differences between the three or more treatments used in the study, but we do not know which treatments differ.

Choice of statistical test is determined by the type of data and the number of groups

Type of data	Two groups	More than two groups
Categorical data (e.g. blood group)	Contingency tables	Contingency tables
Ordinal data (e.g. Glasgow Coma Scores)	Unpaired – Mann–Whitney test Paired – Wilcoxon rank sum test	Unpaired – Kruskall–Wallis test Paired – Friedman's test
Continuously variable data normally distributed (e.g. weight)	Unpaired – t-test Paired – paired t-test	Unpaired – Analysis of variance (ANOVA) Paired – paired ANOVA
Continuously variable data, not normally distributed (e.g. duration of hospital stay)	As for ordinal data, or transform the data to a normal distribution	As for ordinal data, or transform transform the data to a normal distribution

11

There are two ways round this problem. Special multiple comparison techniques (e.g. Scheffe F test, Duncan's test) can be used to determine the differences between the groups that limit the overall risk of a Type I error to 5%. Alternatively, a Bonferroni technique can be used. A decision is made on how many paired comparisons between groups are required, and each of the chosen paired comparisons is tested with a lower level of statistical significance (usually 0.05 divided by the number of comparisons). This works well if there are fewer than five comparisons, but above this, the technique becomes very conservative, and differences between groups do not achieve statistical significance even when the differences are large.

Contingency tables
Contingency tables are used to analyse categorical data. Usually the rows of the table are the different groups and the columns are the different categories to which the patients are allocated. Each cell in a table is the number of subjects from that group that have been allocated to that category (Figure 12).

A 2 × 2 contingency table

	Nausea and vomiting	No nausea and vomiting
Morphine	14	9
Ketorolac	3	17

The table compares the numbers of patients with nausea and vomiting after two different analgesic drugs

12

Contingency tables can be used for any number of groups and any number of observations about the groups for example, a study of the Glasgow Coma Scores of patients in 10 cities would be a 10 x 13 contingency table (10 cities, 13 possible GCS scores). There are problems with using large contingency tables; in the above example, only one city may be different and the other nine similar; the analysis may not detect this single difference. The logical process of hypothesis testing is exactly as before (i.e. a null hypothesis and an alternative hypothesis are formulated and a *p* value is obtained from the sample data). The test commonly used for contingency tables is called the chi-squared (χ^2) test. The number of expected patients if the null hypothesis were true is calculated for each cell and the difference between the observed and expected data in each cell is used to obtain the *p* value.

The following conditions must be observed when using contingency tables.
- The entries in each cell of the table must be the actual number of patients, not percentages.
- The χ^2 test calculates only an approximate *p* value and can be quite inaccurate with small samples; Fisher's exact test is a better choice.
- There are particular problems in 2 x 2 tables with small sample sizes. If the total in the table is less than 50, a modification of the χ^2 , called Yates' continuity correction should be used.

Repeated measurements
Many studies in anaesthesia involve making a series of observations over time on a single subject (e.g. the heart rate and blood pressure are measured in each patient for some time after administering a drug). This violates one of the assumptions of statistical tests that all the observations are independent of the others. This is clearly not the case in this experiment; if the heart rate is high at one measurement, then it is more likely to be high at subsequent measurements. This type of study can also generate enormous amounts of data, and multiple statistical comparisons are often made searching for statistical differences, increasing the risk of Type I errors. There are two methods of analysing this type of data.
- The simpler method is to use a 'summary measure' for the observations; the changes with time that have been measured in each patient are summarized in a single value used for the analysis. For example, if the systolic blood pressure and heart rate after induction of anaesthesia have been recorded, then examples of suitable summary measures for each patient could be the lowest systolic arterial pressure, the highest heart rate, the time to lowest blood pressure or the mean heart rate. The summary measures chosen depend on which clinical factors are most important. Summary measures can usually be analysed using simple methods.
- The alternative method is to use statistical tests designed for these data, such as analysis of variance for repeated measures. ◆

Statistics: Part 2

Ian Kestin

Ian Kestin is Consultant Anaesthetist at the Western Infirmary, Glasgow. He trained in anaesthesia in Southampton, Bristol and the USA. His interests include education in anaesthesia and mathematical applications in medicine.

Correlation and regression techniques are used to measure the relationships between two or more variables. For example, do they rise and fall together, are they inversely related (i.e. one decreases while the other increases), is the association linear, or is there no relationship at all?

- Correlation measures the degree of relationship between two independent variables.
- Regression mathematically expresses the dependence of one dependent variable on another independent variable. Regression is used to predict the dependent variable from the independent variable.

The common statistical techniques for correlation and regression measure linear relationships, but non-linear relationships can also be expressed mathematically.

Linear regression is expressed by the equation of a straight line

$$y = mx + c$$

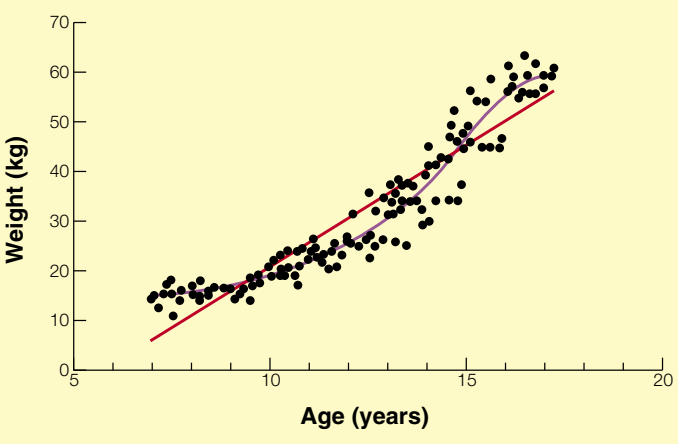
where: y is the dependent variable, x is the independent variable, m is the slope of the line and c is the intercept on the y axis.

Statistical programmes calculate m and c, the statistical significance of this linear relationship, and confidence limits for the true population values for m and c, provided certain assumptions are met:

- the possible values for y in the population for any given value of x should be normally distributed
- the variability of this normal distribution for y should be the same for all values of x
- the relationship is linear.

These assumptions can be tested mathematically, but it is usually sufficient to check the scattergram visually for any obvious deviations. If there is no scattergram, the reader cannot check if linear analysis is appropriate (Figure 1).

Non-linear regression



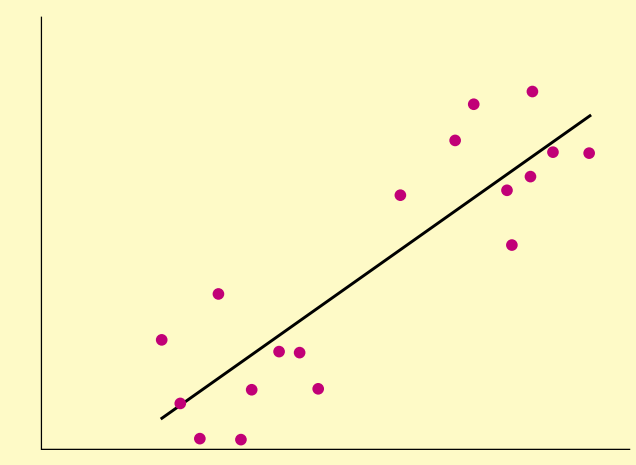
The ages and weights of 130 boys have been plotted and show a non-linear relationship because of the growth increase at puberty. A computer program would derive a highly statistically significant linear regression, though the relationship is better described as sigmoid. Accepting a linear regression equation just because it is statistically significant would miss important information in the data

1

Correlation

Correlation measures the degree of linear association of two independent variables. A common mistake is to assume that if two variables are correlated there must be a causal relationship. It is important to inspect the scattergram before using computer programs to obtain a correlation coefficient (Figure 2).

Errors in correlation



A statistically significant linear correlation in the whole sample can be calculated, but the data actually have a bimodal pattern, and within each subgroup there is no correlation of the two variables

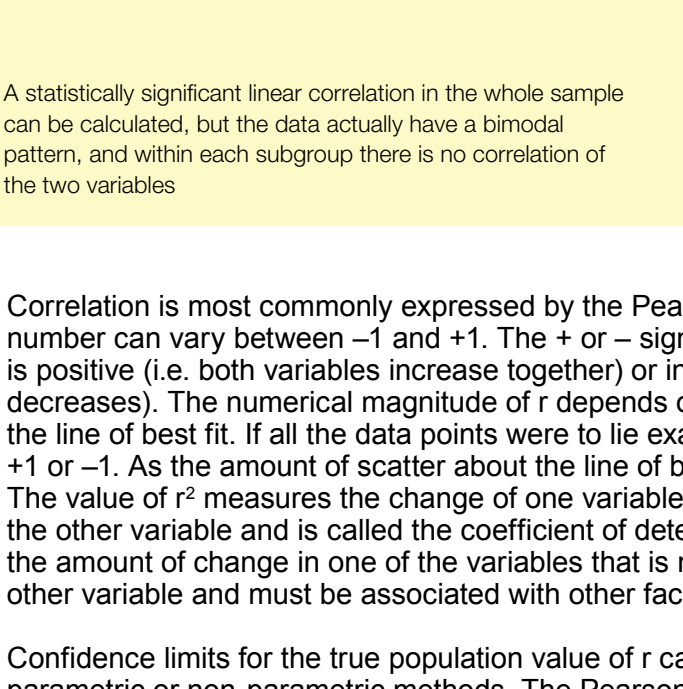
2

Correlation is most commonly expressed by the Pearson correlation coefficient, r. This number can vary between –1 and +1. The + or – sign conveys whether the relationship is positive (i.e. both variables increase together) or inverse (one increases as the other decreases). The numerical magnitude of r depends on the scatter of the points about the line of best fit. If all the data points were to lie exactly on a straight line, then r = +1 or –1. As the amount of scatter about the line of best fit increases, r approaches 0. The value of r^2 measures the change of one variable that is associated with change in the other variable and is called the coefficient of determination. The value of $(1–r^2)$ is the amount of change in one of the variables that is not associated with changes in the other variable and must be associated with other factors.

Confidence limits for the true population value of r can be calculated using either parametric or non-parametric methods. The Pearson correlation coefficient can be used for data that are continuously variable and approximately normally distributed in the population. If this assumption is incorrect then the alternative non-parametric method, the Spearman rank correlation coefficient, should be used. The two advantages of the Spearman non-parametric technique are that the strength of non-linear associations and the association between ordered categories can be measured.

Method comparison studies: any new method of measurement needs to be compared with the standard techniques. This is done by measuring the variable using the standard and new technique, and statistically analysing the paired measurements. The correlation coefficient has commonly been used for this purpose, but this is incorrect. If a new method is being compared with a standard method, and there is a constant bias to the new method compared with the standard, then the linear correlation coefficient will be +1 because there is perfect correlation, but complete disagreement, between the two measurements. The correct statistical technique to use is the Bland–Altman plot (Figure 3).

The Bland–Altman technique for a method comparison study



A new non-invasive method of measuring the arterial blood pressure (NIBP) is being calibrated using simultaneous intra-arterial measurements. The Bland–Altman plot has the systolic pressure measured invasively (IBP) as the x axis and the difference between the two measurements (NIBP–IBP) as the y axis. The mean difference (NIBP–IBP) is the bias, and the 95% confidence interval for the difference is the precision or limits of agreement for the two methods

3

Multiple regression analysis

The dependent variable can be expressed mathematically as a combination of any number of independent variables, either linearly or non-linearly, and this technique is 'multiple regression'. Logistic regression allows us to extend regression techniques to dependent or independent variables with categorical states (e.g. smokers/non-smokers, survived/dead).

It is common, especially in epidemiological studies, to find many possible factors associated with the prevalence of a disease. Some of these are independent causative risks and some are associated through other common factors. In the 1980s, smoking was found to be strongly associated with cervical cancer and proposed as a causative agent along with many other possibilities, including parity and alcohol consumption. It is now generally accepted that cervical cancer is commonly caused by a sexually transmitted virus, and these other correlated factors are more commonly present in women likely to acquire the virus. Stepwise logistic regression is a technique that mathematically includes those factors independently associated with the condition and removes from the equation those factors associated through some other common feature.

Meta-analysis and systematic reviews

Meta-analysis is a statistical technique used to combine the data from several studies of the same topic to reach a single conclusion. It is particularly useful if different studies report conflicting or equivocal results. There are various mathematical techniques for combining the data from different studies, and there is no single correct method. Like all statistical methods, accurate results are obtained only if the data and methods are used correctly. There have been some serious errors; for example, several studies in the 1980s demonstrated that intravenous magnesium reduced mortality after acute myocardial infarction, and a meta-analysis confirmed an important reduction in mortality. Subsequently, a large, single-centre study showed no beneficial effect of magnesium. A re-examination of the meta-analysis suggested a strong publication bias. Small studies showing a positive beneficial effect of magnesium had been published in journals, but small studies that showed no effect had not been published, probably because they had been rejected by the editors for insufficient power. The meta-analysis therefore included a biased selection of all the clinical trials of magnesium that were done and the conclusion was incorrect. To help avoid this problem in the future, a central register of all clinical trials has been suggested. This will enable reviewers to locate all the trials on a subject, published or not.

In a systematic review, the methods used to find all the published papers on the topic, the criteria used to assess the quality of the papers, and the techniques for combining and analysing the data, are all decided in advance and reported in detail in the published paper. Readers ought to be able to repeat the methods used by the authors with the same results. The two principal problems of conventional reviews are failure to find all the papers published on a topic (especially those in a foreign language) and bias in the reviewers. Some conventional reviews and editorials can be little more than disguised polemics.

Statistics and clinical trials

The general principles of clinical trials are described elsewhere. As well as describing and analysing the data obtained, statistical techniques have other uses in clinical trials.

Power analysis

An essential part of the design of any clinical trial is to reduce the risk of a Type II error as low as possible. A power analysis is a statistical technique to estimate the number of patients required to reduce the risk of a Type II error to an acceptable value. The calculations in a power analysis depend on the type of data (i.e. categorical, ordinal or continuously variable). The risk of a Type II error is called the β error; it should be 20% or less, and the power of the study is defined as $(1-\beta)$. For example, if β has been chosen to be 10%, the power of the study is 90%; with this number of patients, the study has a 90% probability of demonstrating any treatment difference if such a difference exists. The main determinants of the number of patients required in a study are:

- the magnitude of the difference between the treatment and control groups and the variability of the data (this information is usually unknown and is usually the purpose for doing the study, but estimates can be obtained from pilot studies, previously published work, or chosen by the investigators as the minimum difference of clinical importance to detect)
- the values chosen for α and β.

Large numbers of patients are needed if the difference between the treatment and control groups is small and the data are scattered widely about the poulation means.

Presentation of results

Confidence intervals are generally better than *p* values for reporting the results of clinical trials; both contain the same mathematical information, but confidence intervals better illustrate the conclusions and implications of the analysis. For example, if the 95% confidence interval for the difference between the treatment and control group includes zero, then the reader immediately knows the treatment may be ineffective or even harmful. Confidence intervals are particularly useful to indicate the true possible incidence of uncommon complications or side-effects after a trial in which there were few adverse events. Many authors report there were no complications in their study and recommend their technique as safe, without giving a thought to what the true incidence could be (Figure 4).

Upper 95% incidence for the true population incidence of a complication after a trial with n patients

Number of complications reported in a study of n patients	Upper 95% confidence limit for the true incidence of the complication in the population
0	3/n
1	5/n
2	7/n
3	9/n
4	10/n

If nothing goes wrong in a study of 50 patients, then the 95% confidence limit for the true incidence of adverse events is 6%, usually an unacceptable incidence of serious complications of a new technique or drug. A technique could not be recommended as safe from a small trial such as this

4

Number needed to treat (NNT) is the reciprocal of the absolute risk reduction of a treatment. It is a useful statistic for reporting clinical trials, combining both statistical and clinical information (Figure 5).

Incidence of stroke after 5 years in treated and untreated hypertensive patients

	Untreated hypertension; absolute risk of stroke	Treated hypertension; absolute risk of stroke	Relative risk	Relative risk reduction	NNT
Mild hypertension	0.015	0.009	0.6	0.4	167
Moderate hypertension	0.2	0.12	0.6	0.4	13

The number needed to treat (NNT) is the number of patients necessary to treat to prevent one stroke in that group. In both treated groups the incidence of stroke is reduced to 60% of that in the control group, but the baseline incidence of stroke in the patients with mild hypertension is much less. Because so many fewer patients with mild hypertension suffer strokes, many more must be treated unnecessarily to prevent one stroke than patients with moderate hypertension. In these patients, the cost and side-effects of treatment would be relatively more important

5

Design of clinical trials

Statistical techniques have been used to demonstrate the effects of bias in clinical trials. There have been four meta-analyses comparing those studies with adequate techniques to ensure the investigators were unaware of the treatment allocation (i.e. adequate 'blinding') with studies of the same topic in which the investigators probably could have discovered the treatment of the patients. All reported that there was an obvious exaggeration of the benefits of treatment in studies in which the investigators were inadequately blinded. The effects were similar but less marked if the trials had inadequate randomization of the subjects or if the patients were aware of the treatment allocation (*BMJ* 2001; **323:** 42–6). ◆

Caudal Block

Sanjeeva Gupta
Nanda Kumar

Sanjeeva Gupta is Consultant in Anaesthesia and Pain Management at the Bradford Royal Infirmary, UK.

Nanda Kumar is Specialist Registrar at the Aberdeen Royal Infirmary, UK.

The sacral hiatus, through which the caudal block is performed, is formed by the non-fusion of the 5th sacral vertebral arch and is covered by the sacrococcygeal membrane. In infants and young children, the sacral hiatus and the adjacent cornua are easily palpable because of the absence of the sacral pad of fat that usually develops at puberty. In adults, considerable anatomical variation exists, resulting in differences in size and shape of the hiatus that may make caudal block difficult. The sacral canal contains the dural and arachnoid sac, sacral nerves, blood vessels, lymphatics and areolar fat. The dural and arachnoid sac usually terminates at the level of S2 in adults but may extend to the level of S3 or S4 in infants.

Indications: caudal block is ideal for children because it is technically easier to perform than other approaches to the CNS. Single-shot caudal blockade can be used to provide analgesia for most outpatient surgical procedures below the level of the umbilicus, including surgery involving lower extremities, hip, pelvis, urogenital and perianal regions. In children, continuous caudal blockade has been used successfully for surgery to the upper abdomen and sites below the umbilicus. Excellent postoperative analgesia is obtained by infusing low-dose opioid, in combination with low concentrations of local anaesthetic.

The single-shot approach is most often used in adults for injection of a mixture of steroid and local anaesthetic to treat chronic pain conditions, particularly if the patient has had lumbar spine surgery. The caudal approach to the epidural space can offer a virtually straight course to the lumbar epidural space and for this reason it is commonly used to perform spinal endoscopy or to thread an epidural neuroplasty catheter to the desired lumbar level in patients with chronic low back pain with or without radiculopathy.

Technique: asepsis must be maintained throughout the procedure. With the patient in the lateral or prone position, the sacral hiatus is identified between the two sacral cornua. A line joining the sacral hiatus to the posterior superior iliac spines forms an equilateral triangle with its apex at the sacral hiatus. If difficulty is encountered in adults, lateral radiographic screening can be helpful.

After infiltration of local anaesthetic, the caudal epidural space is entered using a 23 or 21 G needle. The needle must be placed in the midline and inserted at an angle of about 60° to the coronal plane, perpendicular to the other planes. The bevel of the needle should face anteriorly, allowing it to slide along the anterior sacral wall without piercing it. As the needle is advanced, a distinct loss of resistance is felt when the sacrococcygeal membrane is pierced. The needle is then lowered to an angle of about 20° (Figure 1) to ensure that all the bevel of the needle is in the caudal space. The advancement along the canal should be no more than necessary (the shortest distance to the dural sac is 19–34 mm in adults and less in infants). After negative aspiration for blood and CSF the local anaesthetic solution is injected slowly. If a Touhy needle is used, the bevel of the needle should face posteriorly before attempting to pass the epidural catheter.

The volume, dose and concentration of the local anaesthetic determine the quality, duration and extent of the block. Bupivacaine is the most commonly used agent but ropivacaine is being increasingly used because it is has a better toxicity profile with less motor blockade. The usual concentration is 0.25% bupivacaine or 0.2% ropivacaine. In children, 0.5 ml/kg of either drug results in an adequate sacral block; 1 ml/kg is used to block the lower thoracic nerves and 1.25 ml/kg to reach the mid-thoracic region. The total dose of bupivacaine or ropivacaine should not exceed 2 mg/kg. Additives such as opioids, clonidine and preservative-free ketamine prolong the duration of caudal anaesthesia. Several studies have shown that clonidine, 1–2 µg/kg, or preservative-free ketamine, 0.5 mg/kg, added to 0.25% bupivacaine or 0.2% ropivacaine can prolong analgesia two- or threefold. Clonidine can cause sedation, bradycardia and hypotension and is best avoided in day case procedures. The use of caudal opioids should be reserved for major surgery, when patients will be nursed in high-dependency units.

Potential complications of caudal block are infection, intravenous injection, intraosseous injection, dural puncture and venous air embolism.

Needle position for caudal block

A change of alignment is needed to advance the needle smoothly along the sacral canal without piercing the sacral vertebral body

Extradural Anatomy and Anaesthetic Techniques

Alice Gaynor
Adrian J England

Alice Gaynor is Consultant in Pain Management at the East Surrey Hospital, Redhill. She qualified from Charing Cross Hospital, and trained in pain management at King's College Hospital. Her research interests are the anatomy of the epidural space and its implications in regional techniques for pain management. She is lead clinician for the Acute Pain Service.

Adrian J England is Consultant Anaesthetist and Honorary Senior Lecturer at the Royal Free Hospital, London, UK. He has a primary interest in obstetric anaesthesia and co-ordinates the haematology section of the UK register of High Risk Obstetric Anaesthesia.

Regional blockade for pain relief during labour was first reported in 1900 by Kreis, using subarachnoid cocaine. Shortly afterwards, caudal anaesthesia became popular for surgery and in 1909 caudal extradural analgesia for labour was introduced. Sicard and Forestier described the loss of resistance technique for lumbar extradural needle insertion in 1921. This approach has a greater application for anaesthesia than the caudal route, though it was not popular for several years.

In the early 1940s, ureteric silk catheters were introduced into the caudal extradural space through a needle and by the mid-1940s, Tuohy had introduced the curved bevel needle to aid catheter insertion. By 1949, Tuohy's catheter technique had been modified for lumbar extradural blockade and extradural infusions were introduced in the 1950s. Extradural blockade for pain relief during labour started to increase in popularity in the 1950s and 1960s, particularly with the introduction of bupivacaine, a longer-acting local anaesthetic, and lately with the addition of opiates. Currently, in the UK, extradural analgesia is requested by about 30% of parturient women and is often used for postoperative analgesia.

Methods of investigation
Until the 1980s, extradural anatomy was largely described from post mortem findings and contrast-enhanced radiographs. Now epiduroscopy and superfine fibreoscopy allow direct visualization of the extradural space and spinaloscopy allows visualization of the subarachnoid space. CT and MRI allow investigation of anatomy without distortion from instrumentation, and the cryomicrotome differentiates finer details.

Extradural region and surrounding structures

Boundaries and shape: the extradural space extends from the foramen magnum, at the base of the skull, to the tough sacrococcygeal membrane covering the sacral hiatus. It lies between the dural sac and the vertebral canal in the cervical, thoracic and lumbar regions. In adults the dural sac terminates opposite the middle third of the second sacral vertebra and below this extends the extradural space.

In a neutral, supine position, the spinal column forms a thoracic kyphosis, with T8 as the most posterior aspect (not T4 as previously postulated) and a lumbar lordosis, with L4 the most anterior vertebra. This gives the extradural space an S shape when viewed in sagittal section (Figure 1).

The vertebral canal is widest in the lumbar and cervical regions, narrowing in the thorax. Its diameter ranges from 16 mm (sagittal) by 30 mm (coronal) in the lower lumbar and upper cervical regions to 14 mm by 16 mm in the mid-thoracic region giving it the contour of an elongated, flattened hourglass.

In the cervical and thoracic spine, the vertebral canal is oval, giving the extradural space a crescent shape, but in the lumbar region the vertebral canal is triangular and the extradural space deepens into the posterior sulcus.

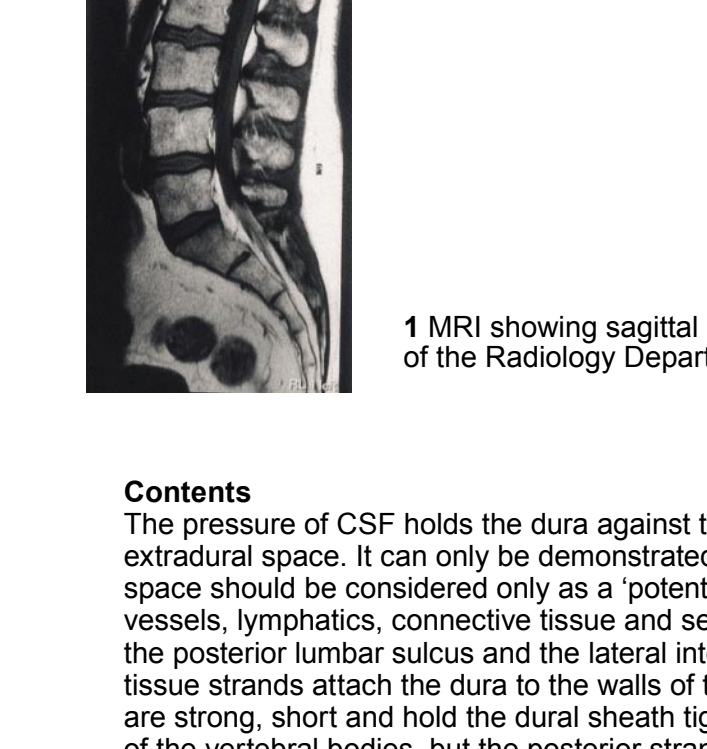
There is a marked variation in sacral canal anatomy between individuals. The sacrococcygeal membrane is absent in about 10% of adults; the distance from the upper limit of the sacrococcygeal membrane to the dura ranges from 34 mm to over 80 mm; and the volume of the caudal space ranges from under 10 ml to over 25 ml.

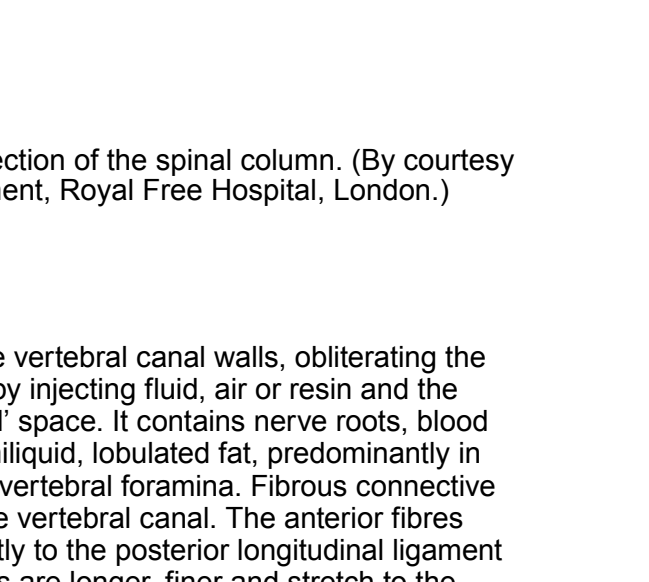
1 MRI showing sagittal section of the spinal column. (By courtesy of the Radiology Department, Royal Free Hospital, London.)

Contents
The pressure of CSF holds the dura against the vertebral canal walls, obliterating the extradural space. It can only be demonstrated by injecting fluid, air or resin and the space should be considered only as a 'potential' space. It contains nerve roots, blood vessels, lymphatics, connective tissue and semiliquid, lobulated fat, predominantly in the posterior lumbar sulcus and the lateral intervertebral foramina. Fibrous connective tissue strands attach the dura to the walls of the vertebral canal. The anterior fibres are strong, short and hold the dural sheath tightly to the posterior longitudinal ligament of the vertebral bodies, but the posterior strands are longer, finer and stretch to the laminae. Controversy surrounds the potential width of the posterior extradural region. Estimates vary with measurement technique,position, and changes in arterial, venous, CSF, abdominal and thoracic pressures. The distance between the ligamenta flava and the dura in the lumbar region varies from less than 2 mm to 8 mm and in the thoracic and cervical regions the 'potential' extradural space is even smaller.

Plica mediana dorsalis: the presence of a physical barrier such as a dorsomedian connective tissue band attaching the dura to the posterior vertebral laminae, or a fold of dura, have been postulated. These would provide a plausible explanation for the development of the unilateral blockade that is sometimes observed during extradural analgesia. Some human epiduroscopy studies have visualized a structure, but there is a wide variation in its reported appearance, ranging from a few strands of connective tissue to a complete membrane. A unilateral filling defect following injection of contrast into the extradural space has also been demonstrated using CT. However, this evidence for a barrier remains controversial. These invasive techniques require cannulation of the extradural space, which could distort its anatomy, or may induce changes within the space, therefore these findings may represent an artefact. Other epiduroscopy studies have not reported the membrane. Investigations that do not require instrumentation of the extradural space, such as unenhanced CT or MRI, and anatomical studies (Figure 2) using the cryomicrotome have failed to demonstrate it. Also, inadvertent segmental or unilateral analgesia following extradural blockade is usually correctable by resiting the catheter. If a structural barrier was present then subsequent catheters should also cause segmental or unilateral blockade. Alternative explanations include extradural fat in the posterior sulcus causing an occasional filling defect, but not causing a complete structural barrier. Unilateral or segmental extradural blockade could be caused by the migration of the extradural catheter to the anterolateral extradural space with unilateral spread of local anaesthetic.

Transverse section of the second lumbar interspace





Photograph and line drawing showing a transverse section through the second lumbar interspace, revealing the cauda equina within the dural sac and posterior and anterolateral deposits of fat within the extradural space. Note the deep posterior sulcus between the ligamenta flava, with no evidence of a posterior fold of dura mater or midline fibrous band. The posterior longitudinal ligament with the longitudinal veins of the internal venous plexus are clearly defined, lying anterolaterally. (By courtesy of Dr J Salisbury, Department of Histopathology, King's College Hospital, London.)

Anterior, lateral and posterior borders: the posterior longitudinal ligament forms the anterior relation of the extradural space throughout its length. This extends across the posterior surface of the vertebral bodies and contains longitudinal fibres adherent to the posterior aspect of each vertebral disc and to the adjacent margins of the vertebral bodies. The laminae of the vertebral arches within the ligamenta flava make up the posterior border of the vertebral canal, with the vertebral pedicles and intervertebral foramina lying laterally.

Ligamenta flava: these two fibro-elastic bands lie anterior to the vertebral laminae and posterolateral to the extradural space. The midline sulcus between them forms the apex of the extradural space. They are thin in the cervical region, becoming progressively thicker towards the lumbar region where they measure between 12 mm and 22 mm wide and between 2 mm and 5 mm thick and their medial margins oppose at less than 90°.

They contain vertically running fibres that stretch from the lower half of the anterior surface of the laminae above to the posterior surface of the upper margin of the laminae below and extend laterally to the intervertebral foramina where they join the capsule of the articular facet joint. In the midline they are generally separated by fat and a few small veins, but may be fused in some areas.

Interspinous ligaments run obliquely between the spinous processes of adjacent vertebrae. Anteriorly, they splay out from the sagittal plane and merge with the posterior fibres of the ligamenta flava at the vertex of the midline sulcus. Posteriorly they are continuous with the tough supraspinous ligament. In the cervical region they fuse with the supraspinous ligament to form the strong and thick ligamentum nuchae, which extends from the spine of the seventh cervical vertebra to the occipital protuberance.

Dural sheath is a continuous cylinder of fibrous tissue of varying thickness, marking the internal border of the extradural space. It is lined by the thin arachnoid mater and contains CSF, the spinal cord and the nerve roots before they leave the spinal canal. It bulges slightly at the lower cervical and lower thoracic regions and runs inside the vertebral canal from the foramen magnum to the lower border of the second sacral vertebra. When viewed by MRI the dural sheath appears attached to the posterior longitudinal ligament at the level of the intervertebral disc anteriorly but to the periostium of the lamina posteriorly. This creates a 'saw tooth' appearance to the posterior extradural fat when viewed in a sagittal plane (Figure 1).

The adult spinal cord ends, as the conus medullaris, at the lower border of the first lumbar vertebra. Below this the nerve roots form the cauda equina. In adults, the dural sac terminates opposite the middle third of the second sacral vertebra.

Between the dura and arachnoid mater lies another potential space, the subdural space. This extends a short distance down the nerve roots and contains a thin film of serous fluid, which may communicate with lymph and venous channels.

Spinal nerve roots lie inside the dural sheath and pass through the anterolateral extradural space. Anterior and posterior spinal nerve roots cross the subarachnoid space and perforate the dura independently. Invested by a dural cuff, the two roots unite at the intervertebral foramen forming the spinal nerve root.

In the cervical and thoracic regions the nerve roots follow a short lateral course in the spinal canal, but in the lumbar region they form the cauda equina and run vertically, tightly packed inside the dura, before leaving the spinal cord through the appropriate intervertebral foramina.

Venous and arterial systems: the internal venous plexus drains the vertebrae, spinal cord and meninges. It is a system of valveless longitudinal veins mostly in the anterolateral part of the extradural space. These vessels divide to allow the passage of the nerve roots and form segmental veins which connect with the systemic circulation through the lateral sacral veins in the pelvis; lumbar veins in the abdomen; azygous and intercostal veins in the thorax and vertebral veins to the cerebral sinuses in the cervical region.

In late pregnancy, the gravid uterus compresses the abdominal aorta and almost completely occludes the inferior vena cava when supine, even with a lateral tilt. This leads to an engorged extradural venous plexus, which displaces the dura from the posterior border of the vertebral bodies. The dural sac becomes compressed anteriorly, but the posterior extradural space is not affected.

Segmental arteries, arising directly from the aorta and vertebral arteries, supply medullary feeder branches, which pass through the intervertebral foramina at each level and supply the spinal cord through locally perforating radial arterioles. There is a marked variation in arterial supply within the spinal cord. Generally, three arterial trunks extend the length of the spinal cord, a midline anterior spinal artery lying in the anterior median fissure and two smaller, paired, posterior spinal arteries. The segmental arteries also supply the spinal nerve roots by dividing into small anterior and posterior radicular arteries that travel with the nerve roots and sometimes anastomose with the large anterior spinal artery or the smaller posterior spinal arteries. Often the artery of Adamkiewicz, a single large anterior radicular artery that usually arises from one of the lower left intercostal or upper lumbar arteries, is present. This provides the main blood supply to the lower section of the anterior spinal artery, and is responsible for the blood supply to the lower spinal cord.

Extradural blockade

Extradural cannulation is normally achieved with the spine flexed because this widens the gap between the vertebral laminae, allowing easier passage of a Tuohy needle. The lateral position causes a scoliosis, which distorts the midline anatomy. A sitting position prevents this deformity, but substantially raises hydrostatic pressure within the CSF, potentially increasing the risk of inadvertent dural puncture.

Lumbar approach: the triangular shape of the posterior extradural space in the lumbar region renders this the most suitable site for extradural cannulation. At this level, regional blockade can provide analgesia across the lower thoracic, lumbar and upper sacral dermatomes and is suitable for procedures involving the lower limbs and lower abdomen.

The shortest distance from the skin to the posterior extradural midline sulcus in the lumbar region is at the L3/4 interspace and is usually 4 to 5 cm). This is the safest recommended level to attempt epidural or subarachnoid needle insertion. Historically, Tuffier's line, running between the iliac crests, was believed to be at L4, but cadaveric and radiographic studies show wide variations. Misidentification of vertebral level may result in cord damage if the conus terminates below the instrumented space.

The distance between the posteromedial border of the ligamentum flavum and the dura at the L3/4 interspace varies from less than 2 mm to 8 mm. If a needle-through-needle technique is used for combined subarachnoid/extradural blockade using a midline approach a spinal needle extending 10 mm beyond the tip of the Tuohy needle will usually penetrate the dura.

Caudal approach: for regional blockade the caudal extradural space is approached through the tough sacrococcygeal ligament covering the sacral hiatus. It is popular for sacral and perineal anaesthesia, though volumes of local anaesthetic solution in excess of 20 ml are usually necessary for an adequate block in adults. Recent MRI has shown the shortest distance from the sacrococcygeal membrane to the dura is 34 mm, therefore a 25-mm-long 23 G needle can be safely used without risk of dural puncture.

Thoracic and cervical approach: the thin, crescent shape of the extradural space and the proximity of the spinal cord to the ligamentum flavum increase the risk of spinal cord trauma with instrumentation at these levels. This risk may be reduced by adopting a paramedian approach. Thoracic extradural blockade may provide useful analgesia following upper abdominal or thoracic surgery and the cervical extradural space may be cannulated for the treatment of chronic pain.

Midline and paramedian approaches: to facilitate instrumentation of the extradural space, the spine is flexed to open the spaces between the vertebrae. With the midline approach, the needle is inserted between two spinous processes and advanced in a slightly cephalad direction, between the two ligamenta flava. With the paramedian approach, the needle is inserted at right angles to the skin, 1–1.5 cm lateral to the spinous process and advanced perpendicularly to the lamina then redirected cephalad and medially towards the midline sulcus, stepping off the lamina before passing through the ligamentum flavum. The end-point is identified using a loss of resistance technique. The advantages of the paramedian approach are listed in Figure 3.

Advantages of the paramedian approach

- It is easier to teach
- Vertebral flexion need not be so marked for instrumentation
- Catheter insertion is easier
- The catheter is more likely to run cephalad
- The catheter is less likely to coil in the anterolateral space
- Nerve root irritation by the catheter is less likely
- Fewer inadvertent dural punctures
- Fewer inadvertent bloody taps
- Fewer segmental or unilateral blocks
- It is the approach of choice for thoracic extradural cannulation

Insertion of a Chest Tube to Drain Pneumothorax

Eric Lim
Peter Goldstraw

Eric Lim is Specialist Registrar in Cardiothoracic Surgery at Papworth Hospital, Cambridge, UK. He qualified from Sheffield and trained in London and Cambridge. He is undertaking thoracic surgical training with Mr Peter Goldstraw at the Royal Brompton Hospital, London.

Peter Goldstraw is the Head of Thoracic Surgery at the Royal Brompton Hospuital, London. He is Chairman of the International Staging Committee on Lung Cancer and the National Specialist Advisory Committee in Cardiothoracic Surgery.

Intercostal chest tube drainage with an underwater seal is a simple and effective method of eliminating air from the pleural space. It is undertaken as an elective or urgent procedure. Emergency chest drainage for tension pneumothorax is undertaken using a wide-bore cannula in the second intercostal space (mid-clavicular line) of the affected side. Knowing when and how to place an intercostal chest drain safely is a valuable skill for all doctors.

When to insert a chest drain

Not all pneumothoraces require chest tube drainage. The average rate of absorption of air in the pleural space occurs at about 1%/day. Expectant management is a reasonable option for patients who are not compromised, with a small and non-progressive spontaneous pneumothorax. Chest drain insertion is required for patients with moderate to large spontaneous pneumo-thoraces and pneumothoraces associated with trauma.

Patients with a history of multiple pneumothoraces or who have undergone previous thoracic surgery may have adhesions. As a result, areas of lung can adhere to the chest wall. Under these circumstances, chest drain insertion by an inexperienced person may lead to inadvertent lung perforation. If difficulty is anticipated, expert advice or assistance should be sought.

Preparation and positioning

All the necessary equipment should be available before scrubbing up (Figure 1). To alleviate the patient's anxiety, it is helpful to explain the procedure, benefits and risks. The patient is then positioned lying, shoulder elevated and undressed to the waist with the arm abducted at 90° (Figure 2). The arm may be held behind the head, but this often results in a slow downwards drift as the patient becomes tired or experiences pain. Absorbent pads are placed under the patient to prevention soiling of the clothes or bed.

Equipment required for chest drain insertion

- Sterile gown and gloves
- Antiseptic solution
- Sterile gallipot for antiseptic solution
- Sponge-holding forceps
- Swabs
- Sterile disposable drape
- 10 ml syringe
- 21G needle
- l0 ml 1% lidocaine (lignocaine)
- Scalpel with a No. 11 blade
- Roberts clamp
- Chest drain (the standard size is 28F)
- No. 2 silk stitch on a hand-held needle
- Drain bottle (primed with saline)
- Sterile connecting tubing

Opinions vary on the ideal size for a chest tube. It is influenced by the size and build of the patient. Its aim is to drain air. The flow in a chest tube is governed by the Fanning equation that relates turbulent flow to the fifth power of the radius of the tube. If the flow in the tube is not sufficient to drain the air leak, then the lung will not expand fully. Therefore, the largest tube that can fit comfortably within the intercostal space should be used

1

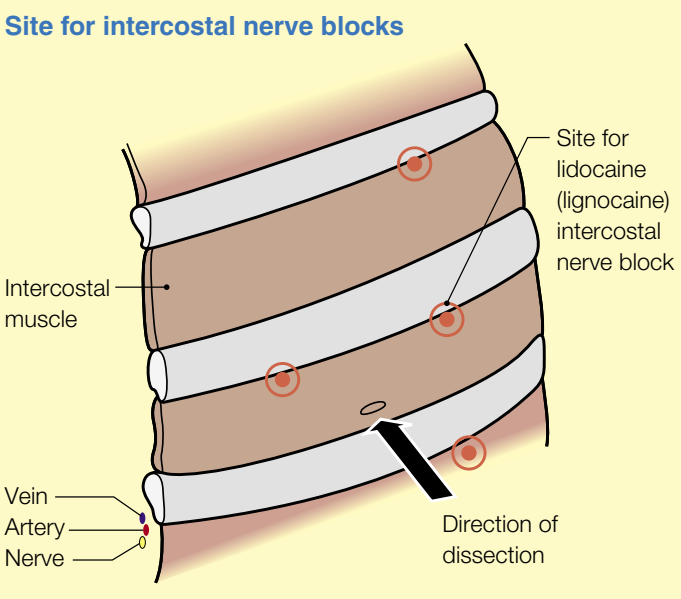
2 Position for chest drain insertion.

How to insert a chest drain

The position of the skin incision depends on which intercostal space the chest drain is introduced through. The triangle (or more correctly quadrangle) of safety is bounded posteriorly by the posterior axillary line, anteriorly by the lateral border of pectoralis major and overlies the 3rd to 5th intercostal spaces. Usually the 4th intercostal space is chosen, just anterior to the midaxillary line.

The surgical field is prepared with a generous coat of antiseptic solution and the intended spot marked by palpation; the antiseptic leaves an imprint as it dries. A small hole is cut in the centre of a sterile paper drape which is applied to the chest wall, such that the antiseptic imprint lies within the centre of the hole. About 1–2 ml of 1% lidocaine (lignocaine) is then injected to create a transverse wheal to demarcate the length and position of the skin incision. The tip of the scalpel blade is used to make a skin incision large enough to admit the operator's index finger comfortably. Blunt dissection can proceed painlessly through the subcutaneous fat up to deep fascia without the need for lidocaine (lignocaine). Once the deep fascia is reached, the intercostal space becomes distinctive. Further lidocaine (lignocaine), 8 ml, is used to create a field block by injecting multiple intercostal nerves. The needle is advanced to identify the rib immediately superior to the chosen intercostal space and 'walked' down the rib until soft tissue is felt. The needle is then angled 45° upwards and the syringe aspirated to ensure that the tip does not lie within the vessels of the neurovascular bundle before injecting 1% lidocaine (lignocaine), 2–3 ml. Using the same method, a further 2 ml is injected in the targeted intercostal space to block the intercostal nerve anteriorly and also in the intercostal nerve of the space above and below the targeted intercostal space (Figure 3).

Site for intercostal nerve blocks



3

When the intercostal block is effective, the Roberts clamp (a heavy duty, serrated large artery forceps) is used with gentle but firm pressure to spread the intercostal muscles apart. Dissection occurs superiorly, starting at the inferior aspect of the targeted intercostal space (to avoid the neurovascular bundle). The Roberts clamp should enter the pleural cavity easily once the deep fascia and muscle layer has been negotiated; a gush of air is normally audible at this point. The jaw of the Roberts clamp is opened to dilate the puncture site, followed by the index finger to dilate a tract into the pleural space. This is an important step. The tip of the finger detects any adherent lung tissue. If all is well, the tract is dilated in the process to admit a 28F chest drain comfortably. If this manoeuvre is not performed satisfactorily, it can become difficult to find the tract for the chest drain because the tissues retract to seal the path made by the Roberts clamp.

Once satisfied that no lung tissue is adherent to the chest wall, a 28F drain is introduced into the pleural space without a trocar. To direct the drain to an apical or basal position, thoracic surgeons may leave the trocar engaged in the drain but with its sharp tip usually more than 2.5 cm (1") away from the tip of the chest tube to facilitate the initial direction of the chest tube. The drain and trocar can then be angled upwards within the thorax to achieve an apical position or directed posteroinferiorly to achieve a basal position. Once the first 5 cm (2") of the drain are directed within the thoracic cavity, the trocar is withdrawn. The drain is advanced continuously until a change in resistance is felt as the tip abuts the pleural apex or base of the diaphragm. Occasionally, pain is experienced in the neck and shoulder as the tip of the drain impinges on the apex. Withdrawal of the drain by 2.5 cm (1") ensures a perfectly apical position and alleviation of pain. At this point, make a mental note of the distance marker at skin level.

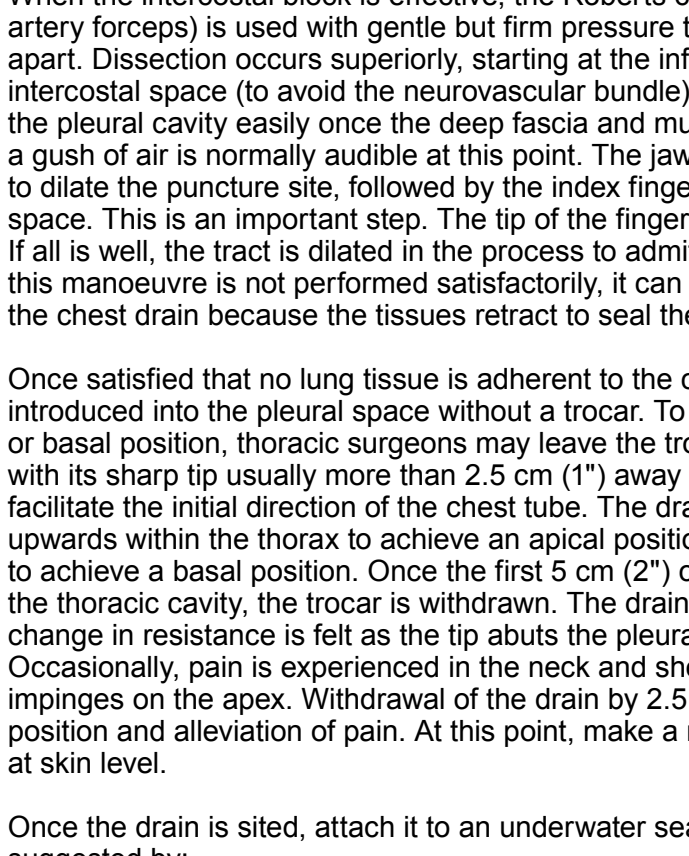
Once the drain is sited, attach it to an underwater seal. Entry into the thoracic cavity is suggested by:

- fogging of the tube
- a respiratory swing
- bubbling on coughing.

The drain is then sutured with a No. 2 silk suture as a horizontal mattress suture, with a double throw to secure the initial tie (Figure 4). Check that the distance marker on the skin has not changed before tying a knot around the tubing to secure the chest drain. It is important to ensure that the tension on the knot is sufficient to indent the chest tube to ensure that the drain does not displace. This suture also acts as a purse string to secure the wound after chest drain removal. It is standard practice to obtain a chest radiograph following chest drain insertion to:

- ensure that the drain lies within the thoracic cavity
- evaluate the position of the drain
- ensure that the lung re-expands
- screen for complications (such as a new effusion from intra-thoracic bleeding).

Securing the chest drain



4

Complications

Perforation of the lung is a potential complication of chest tube insertion. It usually occurs when a chest drain is forcibly inserted with the trocar fully engaged, such that the point sticks out from the tube. Warning signs are bleeding and a brisk air leak. Laceration to the intercostal artery can result in impressive haemorrhage. If this occurs, fluid resuscitation and clamping of the drain to tamponade the bleeding is warranted. Both these complications require consultation with a thoracic surgeon and usually necessitate surgical exploration. ◆

Intravenous Regional Anaesthesia

Corinna M Matt

Corinna M Matt is Specialist Registrar in Anaesthesia at the Luton and Dunstable Hospital, UK. She qualified from Justus-Liebig University, Giessen, Germany, and trained in England at the James Paget Hospital, the Norfolk and Norwich Hospital, and Addenbrooke's Hospital, Cambridge. Her interests include regional anaesthesia and acute pain.

Intravenous regional anaesthesia (IVRA) was first described by August Bier in 1908. He observed that when local anaesthetic was injected between two tourniquets into a limb, a rapid onset of analgesia occurred in the area between the tourniquets and a slower onset occurred beyond the distal tourniquet. The technique did not become popular until the 1960s when it was reintroduced by Holmes.

Today, the technique is slightly modified, using either a single or a double tourniquet at one site and injecting local anaesthetic as distal as possible to the cuff. The double tourniquet is used to increase safety and to reduce tourniquet pain in the awake patient, but there is potential for confusion and accidental deflation of the wrong cuff, which may lead to toxic systemic levels of local anaesthetic.

IVRA is technically staightforward and does not require specific anatomical knowledge. Published series report successful anaesthesia in 96–100% of patients with a low incidence of side-effects. It is a reliable, simple and safe method of providing anaesthesia for minor surgical procedures to the extremities if it is administered by experienced clinicians. The advantages and disadvantages of IVRA are listed in Figure 1.

Advantages and disadvantages of intravenous regional anaesthesia

Advantages

- Speed of onset and rapid recovery
- Reliability (in the absence of local infection and with adequate equipment)
- Muscle relaxation
- Technical simplicity

Disadvantages and complications

- Poor postoperative analgesia
- Limited time of surgical anaesthesia (< 90 minutes)
- Difficulty in providing a bloodless field
- The potential of systemic local anaesthetic toxicity
- Nerve damage secondary to direct compression by the tourniquet
- Compartment syndrome and loss of limb (very rare)

1

Mechanisms of action: local anaesthetic diffuses into the small veins surrounding the nerves and then into the vasa nervorum and capillary plexus of the nerves, leading to a core to mantle (centripetal) conduction block in the nerves involved. Local anaesthetic then diffuses into the small nerves in the skin, blocking their conduction. The tourniquet produces ischaemia which contributes to the analgesic action of the local anaesthetic by blocking nerve conduction and motor endplate function. 20 minutes after tourniquet application there will be analgesia to pinprick without the additional injection of local anaesthetic. However, the speed of onset and the density of anaesthesia are greater with injection of local anaesthetic.

Indications: IVRA is used for surgical interventions on the hand, forearm or elbow, which will not exceed 1 hour. These include manipulation of forearm fractures, excision of wrist ganglia and palmar fasciotomy. IVRA is particularly useful for tendon grafting because it enables the surgeon to observe movement and tension of the grafted tendon (after deflating the tourniquet) before closing the wound (continued anaesthesia with a wrist block). IVRA can also be used for surgery on the foot, ankle or lower leg, for example for removing plates, screws and foreign bodies. Surgery on the elbow or knee is poorly tolerated using IVRA.

Contraindications are mainly related to tourniquet use. Absolute contraindications include sickle cell disease, Raynaud's disease and scleroderma, allergy to local anaesthetics and patient refusal. Relative contraindications include severe hypertensive or peripheral vascular disease, local infection, and skeletal muscle disorders or Paget's disease (local anaesthetic may spread to the systemic circulation via venous channels in bone).

Procedure

Before the procedure the patient should be:

- starved for 6 hours
- monitored closely (standard monitoring applied)
- placed on a tipping trolley
- have consented after explanation of the procedure.

The equipment required for IVRA includes:

- pneumatic tourniquet, a pressure gauge, checked for leak before the procedure
- Esmarch bandage or Rhys-Davis exsanguinator
- local anaesthetic solution
- resuscitation equipment and drugs.

IVRA of the arm: a 22 G cannula is placed intravenously as distal as possible in the arm to be anaesthetized. Venous access is established in the opposite arm to allow administration of fluids or drugs if necessary. The double tourniquet (two tourniquets each 6 cm wide or a single one 14 cm wide) is applied on the arm with generous layers of padding, ensuring that no wrinkles are formed and the tourniquet edges do not touch the skin.

The arm is exsanguinated either by using the Esmarch bandage or a Rhys-Davis exsanguinator. If this is impossible, exsanguination can be achieved by elevating the arm for 2–3 minutes while compressing the axillary artery. The distal tourniquet is inflated to at least 100 mm Hg higher than the patient's systolic blood pressure (250–300 mm Hg). The proximal tourniquet is inflated to the same pressure. After ensuring inflation, the distal cuff is deflated.

Before injecting local anaesthetic it must be confirmed that no radial pulse is palpable. The local anaesthetic is then injected slowly. A standard volume for injection into the upper limb is 40 ml, which can be increased to 50 ml in a fit, large adult. If the injection is too rapid the venous pressure may exceed the tourniquet pressure and the local anaesthetic solution may escape into the systemic circulation.

Surgical anaesthesia is usually achieved within 15 minutes. The distal tourniquet, which overlies part of the anaesthetized arm, can then be inflated and the proximal one deflated to relieve tourniquet pain.

The cuff should not be deflated until 20 minutes after local anaesthetic injection because systemic toxic doses of local anaesthetic may occur. It is thought that after 20 minutes, 30% of the injected drug is fixed within the tissues and is unavailable for immediate release into the systemic circulation. Cuff deflation should be performed in cycles with deflation/inflation times of less than 10 seconds until the patient no longer exhibits signs of systemic toxicity (e.g. tingling of the lips, tinnitus, drowsiness). Severe signs of systemic toxicity include bradycardia, hypotension, ECG abnormalities, fitting and loss of consciousness. Maximum blood levels of local anaesthesia occur within 10 minutes of cuff deflation. Therefore, the patient should be monitored closely for 30 minutes following tourniquet release. With lidocaine (lignocaine), 2.5–3 mg/kg, and cuff deflation after 10 minutes, blood levels have been reported to be less than 2 μg/ml.

If severe CNS intoxication occurs, baseline resuscitation guidelines should be followed. Emergency drugs (e.g. thiopental (thiopentone), propofol) must be readily available and 100% oxygen should be administered.

IVRA of the leg: the basic technique is the same as for the arm but the dose and volume of local anaesthetic has to be doubled for IVRA of the leg, which is associated with an increased potential for local anaesthetic toxicity. The tourniquet pressure must be higher in the leg (350–400 mm Hg), to occlude blood flow in the femoral artery. This may increase the occurrence of tourniquet pain. Tourniquets may be applied to the thigh (two tourniquets about 9 cm wide) or one at the calf (below the head of the fibula) and one at the thigh. The latter is for safety in case of distal cuff failure and is not usually inflated.

Choice of drugs

Many local anaesthetic drugs, with or without additives, have been used for IVRA, but it is commonly felt that 0.5% prilocaine, 3–6 mg/kg, is the drug of choice because it has less systemic toxicity and is partially taken up in the lungs before reaching the systemic circulation. The usual dose is 40 ml (200 mg) without adrenaline (epinephrine). However, the manufacturers have ceased production of 0.5% prilocaine. 1% prilocaine remains available and is licensed for IVRA, though its stability is not guaranteed if diluted. In the USA, prilocaine is unavailable and 0.5% lidocaine (lignocaine), 3 mg/kg, is used. If IVRA is applied to the leg a larger volume must be injected (up to 100 ml). Prilocaine can be used undiluted (maximum recommended dose is 400 mg in adults) but lidocaine (lignocaine) is commonly diluted to lower concentrations (e.g. 0.2% to 0.25%).

Prilocaine can cause methaemoglobinaemia (up to 6% of haemoglobin) but this is usually clinically insignificant.

Other local anaesthetic agents have been used but are not superior regarding analgesia or onset time of block. Severe toxic reactions and death have been observed with bupivacaine and its use is contraindicated. In one study, 0.2% ropivacaine was intraoperatively as effective as 0.5% prilocaine but postoperative analgesia was prolonged; no side-effects were reported.

Additives to local anaesthetics have not been consistently shown to have an effect during IVRA but may increase the length of postoperative analgesia, probably because of a systemic effect following tourniquet release. The reported enhancement of IVRA with pethidine, 1 mg/kg, may reflect intrinsic local anaesthetic activity of the drug.

Experiments with the addition of muscle relaxants produced marked muscle relaxation but did not augment analgesia.

Ketamine alone appears to provide good sensory analgesia but some patients lost consciousness and exhibited the typical features of ketamine anaesthesia after tourniquet release.

Many other drugs have been studied, but only the addition of clonidine, 150 μg, an α_2-agonist, or the non-steroidal anti-inflammatory drugs ketorolac, 20 mg, and tenoxicam, 20 mg, to the local anaesthetic solution appeared to be effective in prolonging postoperative analgesia and relieving tourniquet pain. Guanethidine and calcium-channel blockers have been evaluated only in the context of chronic pain management.

Local Anaesthesia for Awake Tracheal Intubation

Nick Woodall

Nick Woodall is Consultant Anaesthetist at the Norfolk and Norwich Hospital, UK. He qualified from Liverpool University and trained in Anaesthesia in London, the North West, and the USA. His clinical and research interests centre around airway problems and training.

Intubation under local anaesthetic is widely recognized as a cornerstone in the management of the difficult airway. However, the variety of local anaesthetic techniques available leads to confusion and often gives the impression that intubation under local anaesthesia is difficult. This article attempts to clarify the situation. Readers are referred to more detailed texts for a discussion of the indications for awake intubation.

Preparation
Patients require psychological preparation, this is best provided by an explanation of the indication for intubation under local anaesthesia and a description of what they should expect. Premedication or sedation is useful for anxious patients. Patient co-operation is essential, over-sedation is a dangerous substitute for adequate local anaesthesia.

If nasotracheal intubation or fibre-optic endoscopy is planned, topical nasal vasoconstrictors (e.g. xylometazoline spray, cocaine) reduce bleeding. Systemic pre-treatment with anticholinergic agents reduces secretions and increases the intensity, speed of onset and duration of topical local anaesthesia. Glycopyrrolate, 5 µg/kg, can be given 10–15 minutes before administration of local anaesthetic at a time when oxygen and routine monitoring is being attached.

Anaesthesia of the upper airway

Topical anaesthesia of the upper airway is required whatever method is used to provide anaesthesia of the pharynx, larynx and trachea.

Nasal anaesthesia
Cocaine as a 4% solution, 80 mg (2 ml), is a commonly used topical local anaesthetic for the nasal mucosa because it is also a vasoconstrictor. However, toxic side-effects and myocardial ischaemia have been reported following small doses. The maximum recommended dose of cocaine is 1.5 mg/kg.5% lidocaine (lignocaine) combined with phenylephrine as co-phenylcaine is an alternative. If this is unavailable, 4% lidocaine (lignocaine), 80 mg (2 ml), applied to the nasal mucosa as a spray or on cotton-wool tipped swabs produces satisfactory analgesia of reasonable duration.

Oral analgesia
4% lidocaine (lignocaine) spray, 80 mg (2 ml), is suitable for oral analgesia. The patient should swirl the solution around the mouth and then gargle with it. The gag reflex may be initiated by stretch receptors in the tissues of the oropharynx or by mucosal stimulation, therefore complete abolition is difficult with surface anaesthesia alone. However, additional 10% lidocaine (lignocaine) spray, 100 mg, directed into the posterior oropharynx at the back of the tongue to the left, right and in the midline usually provides satisfactory conditions for fibreoptic endoscopy or laryngeal mask insertion. 10% lidocaine (lignocaine) stings when applied to mucous membranes, therefore a dilute local anaesthetic solution should be applied first.

Anaesthesia of the lower airway

Following anaesthesia of the mouth, topical anaesthesia of the lower airway may be used alone or supplemented with nerve blockade.

Topical anaesthesia
Nebulization is a simple method of producing airway anaesthesia. However, nebulization is time consuming and the resultant airway anaesthesia often requires supplementation. This technique may be useful to obtund airway reflexes before another form of local anaesthesia if coughing needs to be avoided or minimized. Concentrated local anaesthetic solutions are needed in high doses because only about 15% of a nebulized drug reaches the airway. 10% lidocaine (lignocaine), 6 mg/kg, is effective and peak plasma lidocaine (lignocaine) concentrations have been found to be less than one-fifth of the level regarded as toxic (5 mg/litre) following nebulization of this dose.

Transendoscopic administration: anaesthesia of the pharynx, larynx and trachea may be produced by the direct application of local anaesthesia under vision using a fibrescope. Trans-bronchoscopic administration provides a straightforward and reliable method of producing airway anaesthesia, which avoids many of the complications or contraindications associated with injections. Though the doses of lidocaine (lignocaine) given by this route tend to be high, a total dose of up to 9 mg/kg appears to be safe when given by the transbronchoscopic route. Much of the local anaesthetic swallowed is metabolized in the liver before it reaches the systemic circulation, but lower doses must be used in the presence of severe liver disease.

Following topical anaesthesia of the mouth or nose the endoscope is advanced into either orifice until the posterior aspect of the tongue or the epiglottis can be seen (protection for the endoscope is essential to prevent damage by the teeth if the oral route is chosen). From a distance, local anaesthetic is sprayed on to the back of the tongue. If the epiglottis is not seen, the endoscope is advanced further until it is visible overlying the glottis. The epiglottis and glottis are sprayed in turn until the vocal cords cease reacting to local anaesthetic administration. The endoscope is then advanced closer to the larynx and additional local anaesthetic is delivered through the vocal cords to the lower airway until coughing ceases. When this has been achieved, the passage of an endoscope into the trachea is usually well tolerated.

Heavy contamination of the airway with blood, sputum or vomit may obscure the view rendering the spray-as-you-go method difficult.

Translaryngeal or transtracheal administration produces satisfactory conditions for fibreoptic, retrograde or blind intubation techniques when combined with topical upper airway anaesthesia. Local anaesthetic injected into the airway through the cricothyroid membrane or between the tracheal rings precipitates a brief but intense bout of coughing, dispersing local anaesthetic throughout the airway and producing anaesthesia of the trachea and a significant degree of anaesthesia of the laryngeal inlet and epiglottis.

The cricothyroid membrane is most easily located and recognized. Infiltration of the skin and subcutaneous tissues with local anaesthetic containing a vasoconstrictor provides analgesia and reduces bleeding at the puncture site. A cannula or needle is then inserted through the anaesthetized area into the airway. During insertion this should be directed backwards and slightly caudad to avoid vocal cord trauma. Entry into the airway is confirmed by aspiration of air via the needle.4% lidocaine (lignocaine), 80–160 mg (4 ml), is then rapidly injected and the needle removed. Injection at end inspiration results in the rapid upward spread of lidocaine (lignocaine), whereas injection at end expiration produces more effective anaesthesia of the lower airway.

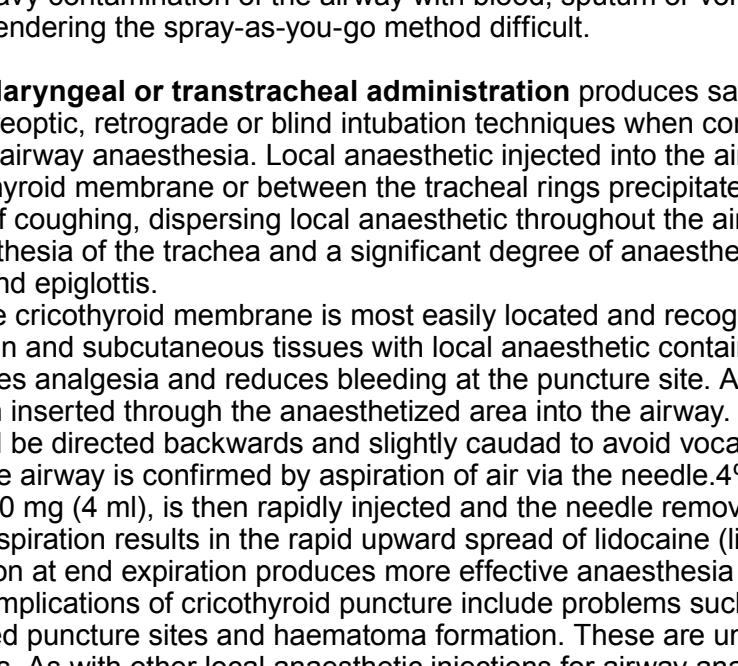
Complications of cricothyroid puncture include problems such as broken needles, infected puncture sites and haematoma formation. These are uncommon and seldom serious. As with other local anaesthetic injections for airway anaesthesia, local infection or the presence of a coagulopathy may contraindicate its use.

Nerve block
Nerve blocks produce intense analgesia of part of the airway, they require small volumes of local anaesthetic and induce little coughing. However, they are often difficult to perform on patients with airway problems owing to limited mouth opening or restricted neck movement.

Glossopharyngeal nerve block: the glossopharyngeal nerve supplies sensation to the posterior third of the tongue, the anterior surface of the epiglottis, the lateral pharyngeal wall and the inferior surface of the soft palate. It passes behind the anterior pillar of the tonsillar fossa to send branches to the tongue and pharynx. Bilateral glossopharyngeal nerve block combined with topical oropharyngeal anaesthetic may abolish the gag reflex permitting direct laryngoscopy. This intensity of analgesia is seldom required for fibreoptic intubation unless it is necessary to pass a double-lumen tube under local anaesthesia.

To perform a glossopharyngeal nerve block, the tongue is displaced medially with a laryngoscope blade or a spatula (Figure 1). Surface analgesia is provided by the topical application of lidocaine (lignocaine), following which a 20 G spinal needle is inserted to a depth of 5 mm into the base of the anterior pillar of the tonsil, at the level of the skin reflection on to the tongue. Following aspiration, 2% lidocaine (lignocaine), 40 mg (2 ml), is injected slowly.

Site of glossopharyngeal nerve block



1

Superior laryngeal nerve block: the superior laryngeal branch of the vagus nerve supplies sensation to the undersurface of the epiglottis and the larynx above the level of the vocal cords. It can readily be blocked as it passes anteromedially between the greater horn of the hyoid bone and the superior cornua of the thyroid cartilage as it passes medially along the thyrohyoid membrane which it pierces to provide sensation to the larynx (Figure 2).

The hyoid bone is found directly above the thyroid cartilage where it can be rocked between the thumb and index finger of one hand. The lateralmost part of the hyoid bone, the greater horn, lies extremely close to the carotid artery. The superior laryngeal nerve may be blocked by ‘walking’ a 25 G needle inferiorly off the greater horn and injecting 2% lidocaine (lignocaine), 2 ml subcutaneously, superficial to the thyrohyoid membrane following negative aspiration of blood.

Superior laryngeal nerve block and cricothyroid puncture

Lower Limb Nerve Blocks

Paul J G Hutchings

Paul J G Hutchings is Consultant Anaesthetist at the Norfolk and Norwich Hospital, Norwich, UK. He qualified from Guy's Hospital, London, and trained in anaesthesia in the Royal Navy, Sheffield and Birmingham, UK. His special interests include anaesthesia for maxillofacial surgery and orthopaedic surgery with an emphasis on major joint replacement in the lower limb.

Lower limb blocks have been perceived to be difficult to learn. In fact they are easy to perform; the nerves are large and simple to locate, there are fewer absolute contraindications than for central neuroaxial block and the rate of complications is low. Clinical experience rapidly increases success rates and successful outcomes will reinforce the impetus for their widespread use.

Patients and their anaesthetists want to avoid severe postoperative pain. In the case of surgery for hip and knee replacement, the debate on how to reduce postoperative pain usually revolves around the merits of central regional blocks versus general anaesthesia. Many surgeons comment on the increased requirement for urinary catheterization and a perceived delay in the throughput on a list if regional blocks are performed. An insensate limb (including the non-operated limb) is also at risk of pressure area trauma. Anaesthetists may withhold regional blocks for fear of central neurological damage, post-dural puncture headache or if anticoagulant drugs have been given for prophylaxis of deep venous thrombosis or thromboembolism.

The obvious solution is to carry out the local anaesthetic block on the affected limb only. Historical methods, necessitating a search for paraesthesiae and deposition of large volumes of dilute local anaesthetic with patchy effectiveness have largely been abandoned with the widespread availability of specifically designed low-power nerve stimulators. The large nerves supplying the lower limb are straightforward to locate. A relatively low volume of high-concentration local anaesthetic deposited in this way may produce effective analgesia for up to 72 hours. The patient retains the use of the unblocked limb to move around the bed or for early mobilization as opposed to being 'tethered' to the bed by a patient-controlled analgesia system or an epidural infusion, and urinary catheterization is avoided in many patients.

For surgery below the knee, especially in younger patients, it is unnecessary to produce a dense surgical block of both lower extremities with spinal or epidural anaesthesia when perhaps only the hallux is being operated on. In the foot and ankle, the nerves are superficial and blocks are simple to perform even without a nerve stimulator.

Nerve-blocking techniques are an ideal supplement to light general anaesthesia and can also be used as 'rescue' from failed epidural anaesthesia, for preoperative analgesia or for treatment of patients in recovery, when either the surgical procedure is more extensive than expected or the pain experienced by the patient is unexpectedly severe.

Patients are becoming better informed and more critical in the discussion of the choice of anaesthetic technique. Some patients reject epidural or spinal anaesthesia outright but will accept a peripheral nerve block. The popularity of nerve-blocking techniques is growing and increasingly patients will have experienced successful nerve blocks before and ask for them again.

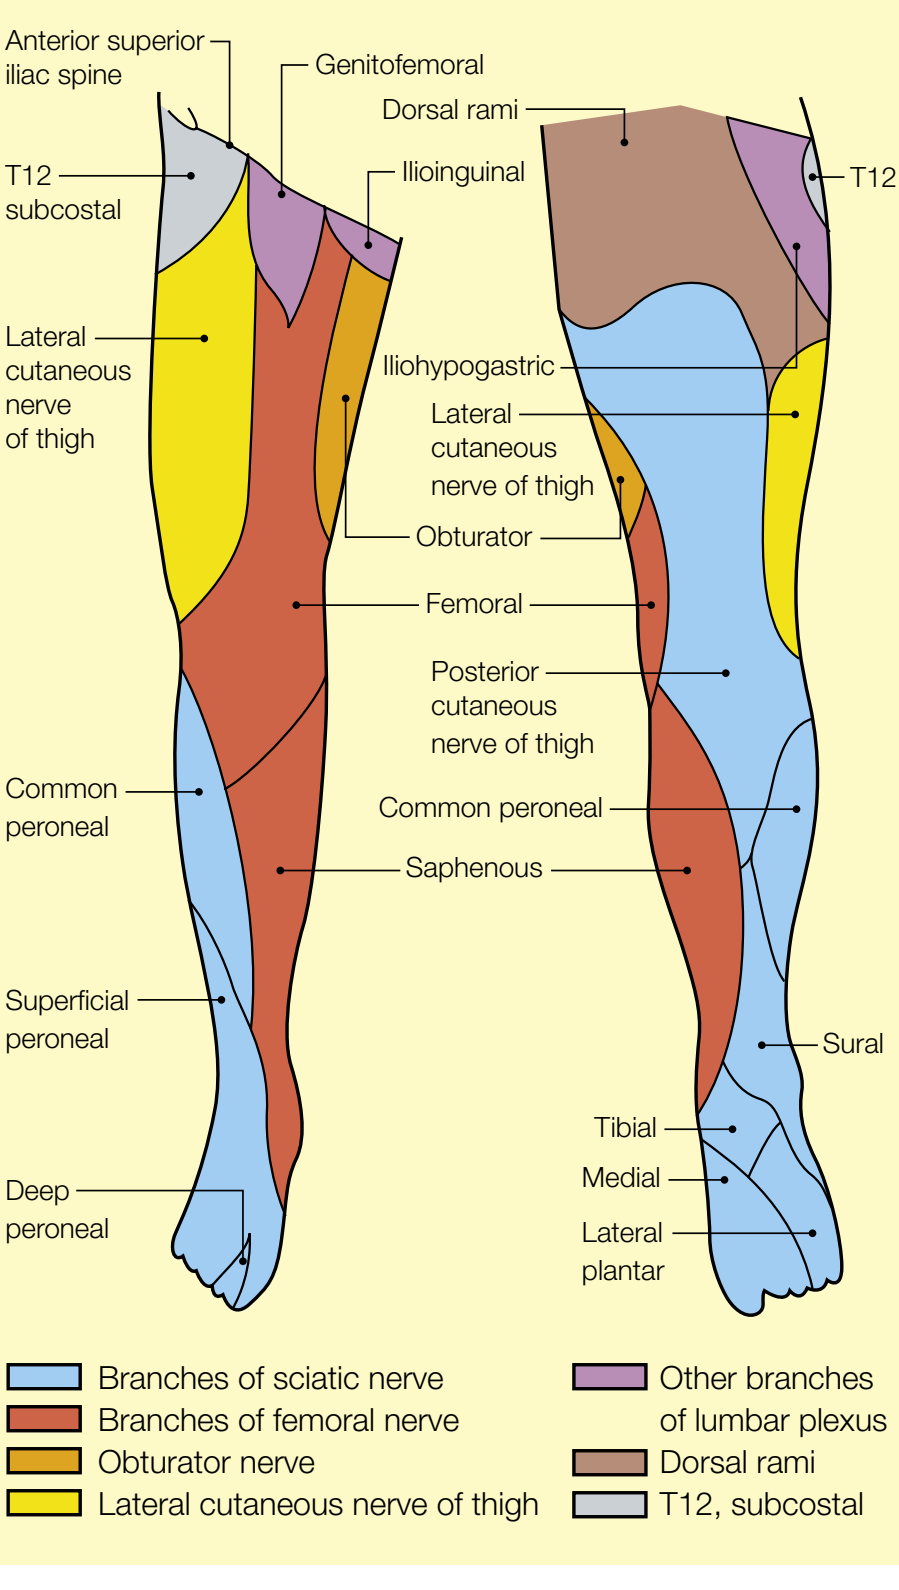
General requirements

It is always important to check with the surgeon exactly what the proposed surgery entails. The site of the main surgical procedure might be blocked but the tourniquet pain or a requirement for bone graft may lie outside the blocked area. A light general anaesthetic might cover this eventuality but it should be checked.

Anatomy

When hip surgery is included, the innervation of the lower limb involves dermatomes T12–S5 (Figure 1). The T12 ventral ramus, the subcostal nerve, travels obliquely downwards until its terminal portion supplies the area of the greater trochanter. The anterior primary rami of lumbar roots 1 to 4 form nerves in a lumbar plexus, which then pass through the body of the psoas muscle. In sequence, from superior to inferior, the nerves are iliohypogastric, ilioinguinal, genitofemoral, lateral cutaneous of thigh, obturator and femoral. The femoral branch of the genitofemoral supplies a small patch of skin on the upper thigh over the femoral triangle, which is compressed by a high thigh tourniquet. The sacral plexus receives the anterior primary rami of sacral nerve roots 1 to 5 and contributions from lumbar roots 4 and 5 as the lumbosacral trunk (separate and medial to the lumbar plexus). The sciatic nerve is formed from these roots and from its origin two distinct bundles may be seen. The tibial nerve is the larger of the two and runs down via the popliteal fossa to the posterior aspect of the medial malleolus where it divides into the medial and lateral plantar nerves. The common peroneal nerve, is about half the size of the tibial nerve, and runs lateral to the tibial nerve through the popliteal fossa round the head of the fibula to terminate as deep and superficial peroneal nerves. The two trunks forming the sciatic nerve constitute the largest nerve in the body (about 20 mm).

Sensory innervation of the lower limb



1

Specific clinical indications

Hip surgery

Joint replacement: the main sensory innervation of the hip is from the lumbar plexus, but the subcostal nerve T12, should also be covered by infiltrating along the iliac crest with 10–15 ml of relatively dilute local anaesthetic (e.g. 0.25% bupivacaine).

Lumbar plexus block offers a proximal block of most of the major nerves (femoral, obturator and lateral cutaneous nerve of thigh) that supply the hip region. The plexus is deep-seated, adjacent to vascular structures and close to epidural and intrathecal spaces; therefore, though complications are unusual, a high index of suspicion should be maintained. A 100–150 mm stimulator needle is introduced 30–40 mm from the midline and advanced perpendicular to the skin in all planes. The caudal edge of the transverse process is level with the cephalad edge of the spinous process of the same vertebra. The L3 transverse process is the easiest to use because it is the longest and thinnest of the lumbar transverse processes, allowing the block to be performed as far away from the epidural and intrathecal spaces as possible, and with a reasonable space between it and the adjacent transverse processes. When the transverse process is contacted the needle is 'walked off' usually above the process and advanced a few more millimetres until a pulse-synchronous muscle twitch is obtained in the thigh. This occurs on average at 90 mm from the skin surface.

Large volumes of local anaesthetic, 30–50 ml, are needed for a complete block, but they are associated with an increased risk of epidural and intrathecal spread. To avoid this risk, lower-volume block can be used as a supplement to a light general anaesthetic or to extend analgesia following a spinal anaesthetic.

Sciatic nerve block – the hip joint receives an articular branch from the sciatic nerve, but blocking it increases the risk of pressure area damage to the heels. The therapeutic block may also be confused with surgical trauma caused to the nerve at operation and less drug can be used for the lumbar plexus block.

Fractured neck of femur: the block required does not have to be as proximal as for hip replacement surgery. The procedure can sometimes be performed as a percutaneous procedure and is of relatively short duration. An injection adjacent to the femoral artery can spread up under the inguinal ligament and block the nerves of the lumbar plexus; femoral, obturator and lateral cutaneous nerve of thigh. The block is often referred to as the 3-in-1 block. In clinical use, large volumes (35–50 ml) are required to block the higher portions of the plexus reliably, but in combination with sedation or supplementary analgesia even lower-volume techniques offer a viable alternative to spinal anaesthesia. Individual nerve block may also be used or the 'missing components' of the 3-in-1 block can be added.

Femoral nerve block – the technique to block the femoral nerve, and with larger volumes to produce the 3-in-1 block, is to introduce the block needle 10 mm lateral to the femoral artery, a sufficient distance below the inguinal ligament to allow a 45° angle of approach to the nerve. In heavily built or obese patients it may be easier to approach from 20–30 mm below the ligament to allow this 45° slope, but the nerve should not be blocked too low because it commonly divides at a high level. It usually lies at a shallower depth than the artery, but it is variably placed, sometimes even behind it, and the nerve stimulator is more or less essential for a successful surgical block.

Fascia iliaca compartment block of femoral, obturator and lateral cutaneous nerve of thigh by an injection below the fascia iliaca at the junction of the lateral one-third and medial two-thirds of the inguinal ligament is easy to perform in children because their tissue planes are much looser. A double 'pop' is felt, as first the fascia lata and then the fascia iliaca are penetrated. The situation in adults is less clear, but because the fascia is attached to the capsule of the hip joint this might improve the chance of local spread to the area of surgery.

Lateral cutaneous nerve of thigh – missed block of the lateral cutaneous nerve of thigh is common and can be corrected by direct block 20 mm below the anterior superior iliac spine with a push through the fascia lata with a distinct 'pop'. The nerve is blocked with 10–15 ml of solution and no subcutaneous swelling should be seen. Alternatively, the nerve may be blocked in the canal under the inguinal ligament with injection made just above it, with a double 'pop' through fascia lata and iliaca as for fascia iliaca compartment block.

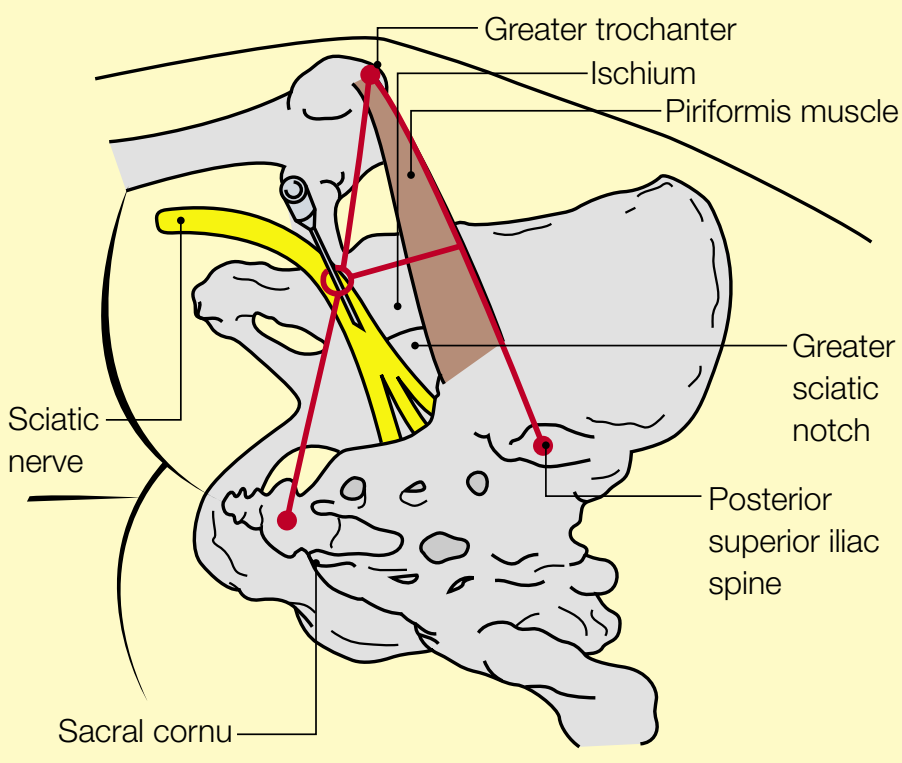
Obturator nerve block is easy to perform, contrary to some textbook descriptions. The heel of the leg to be blocked is put on to the opposite lower leg or knee and a needle introduced above the most prominent adductor muscle tendon directed slightly upwards, backwards and at about 10–15° lateral to the sagittal plane until a pulse-synchronous muscle twitch is obtained in the adductor muscles. The needle can be walked off the inferior pubic ramus into the obturator canal if bone is contacted. Block of T12 fibres should also be performed as described above.

Knee surgery

Femoral, sciatic and obturator nerve block is required for complete surgical block of the knee. Individual nerve blocks are probably a better choice than a 3-in-1 block because the placement of relatively small quantities of concentrated local anaesthetic gives a long period of anaesthesia, for example up to 72 hours with 0.75% bupivacaine on the femoral or sciatic nerves, or 12 hours with lidocaine (lignocaine) or prilocaine. The technique may therefore be contraindicated in day surgery. Surgical techniques are improving and arthroscopic-assisted anterior cruciate ligament repair or unicompartmental replacement of the medial tibial and femoral surfaces only do not justify long-duration block and may prevent discharge within 24 hours, which is usual for these techniques in fit patients.

Sciatic nerve block – the sciatic nerve is large and relatively easy to locate. The two simplest and most logical approaches are the classical 'Labat' method performed in the lateral position and the supine 'Raj' technique carried out with the patient's leg flexed to 90° at the hip and knee. The lateral approach is less easy to landmark and the anterior approach requires a 150 mm approach to a structure that is as little as 30 mm under the skin posteriorly. The insertion point for the needle for the 'Labat' sciatic notch method is a hand's breadth below the midpoint of a line between the posterior superior iliac spine and the greater trochanter, whereas in the supine method it is halfway between the greater trochanter and the ischial tuberosity (Figure 2).

Landmark anatomy for somatic blockade



Adapted from: Bridenbaugh P O, Wedel D J. The Lower Extremity: Somatic Blockade. In: Cousins M J, Bridenbaugh P O eds. *Neural Blockade.* Philadelphia: Lippincott-Raven, 1998.

Alternative techniques include intra-articular local anaesthetic with or without an opiate or local infiltration, however, they require a tourniquet, which precludes their use as sole anaesthetics. Intravenous regional anaesthesia is theoretically possible but not often performed owing to the high volumes required, the lack of analgesia after tourniquet release, and tourniquet discomfort in the conscious patient.

Foot and ankle surgery

Blocks may be carried out proximally (as described above), at knee level, at the ankle or by metatarsal or digital block. The lower leg and foot receive the terminal branch of the femoral nerve, the saphenous nerve, which closely follows the long saphenous vein, and the two main branches of the sciatic nerve, the common peroneal and tibial nerves. Block of these nerves at knee level is a good choice for major foot and ankle surgery.

Saphenous block at the knee is achieved by infiltrating along the inner aspect of the knee from tibial tubercle to the medial border of the tibia; 5–8 ml of local anaesthetic is sufficient. The saphenous vein is a good landmark, if it is visible, because the nerve lies just medial to it.

Sciatic nerve (common peroneal and tibial nerve) block at the knee is carried out in the popliteal fossa. The direct posterior approach is probably the most straightforward; the needle passes through subcutaneous tissues and fat only before the nerve is located at a depth of 20–30 mm. The patient either lies prone or an assistant holds the leg up vertically to allow access for a nerve-stimulating needle. The sciatic nerve, or its two branches if it has already divided, are lateral to the popliteal artery in the upper part of the popliteal fossa. Both branches of the nerve should be located and blocked with 5–10 ml of local anaesthetic. The pulse-synchronous muscle twitch found with the tibial nerve portion is plantar flexion of foot and hallux and that of common peroneal stimulation is eversion and dorsiflexion of the foot.

Ankle block: to anaesthetize the foot completely, five nerves (saphenous, sural, tibial, deep and superficial peroneal) must be blocked. However, surgery is often limited to part of the foot only and therefore it is uncommon to have to block all five nerves. The nerves may be blocked at any point in their course according to surgical requirement and general convenience. The technique is simple to perform and there are few complications. Three nerves are relatively superficial and a subcutaneous infiltration from just behind the lateral malleolus, across the anterior aspect of the ankle, to the saphenous vein in front of the medial malleolus blocks them all.

The saphenous nerve is usually blocked at the level of the medial malleolus, superficially and around the saphenous vein. The territory supplied by this nerve is a strip along the medial border of the foot and the medial side of the arch of the sole.

The sural nerve is blocked as it runs behind the lateral malleolus and its territory is a strip along the lateral border of the foot as far as the little toe.

The superficial peroneal nerve supplies the dorsum of the foot except for the cleft between the first and second toes (deep peroneal).

The deep peroneal and tibial nerves can be blocked close to arteries, the dorsalis pedis on the dorsum of the foot and the tibial artery behind the medial malleolus, respectively. The tibial nerve is blocked halfway between the point of the malleolus and the heel. The disadvantage of blocking at these points is that there is limited space available to deposit local anaesthetic, and so the block is of limited duration. It may also be risky to compromise the arterial supply to the foot in patients in whom peripheral arterial disease may have been the indication for surgery such as debridement or amputation of ischaemic toes and ulcers.

A mid-tarsal block is an alternative block for the tibial nerve. In addition to the subcutaneous infiltration for blocks of saphenous, sural and superficial peroneal nerves, 5–10 ml of local anaesthetic is deposited just distal to the retinaculum below the medial malleolus. At this point, the tibial nerve will already have divided into the medial and lateral plantar nerves and the space is much less restricted than the area around the tibial artery, therefore pressure on or trauma to the arterial supply is unlikely. The deep peroneal nerve can be blocked at mid-tibia to avoid injection on the dorsum of the foot. The needle is inserted about 60 mm above the skin crease at the ankle and 10 mm lateral to the sharp anterior edge of the tibia. The needle is advanced until the tibia is contacted, then 3–5 ml local anaesthetic is injected after withdrawing sufficiently to avoid subperiosteal placement.

Metatarsal and digital block can be performed in a manner analogous to hand blocks. They are all that may be required for minor toe surgery (e.g. nail bed ablation). The advantage of the metatarsal block in this circumstance is that it is still applicable even if surgery extends proximal to the area covered by digital nerve block or if the area to be operated on is infected. These blocks are best avoided in patients with digital ischaemia: in particular, no adrenaline (epinephrine) preparation must be used.

Refinements and developments

Although it is possible to produce extended analgesia from 'single-shot' blocks, the total volume of anaesthetic required may be high, though complications of local anaesthetic toxicity are uncommon in clinical practice. An elegant solution is to place a catheter next to the nerve or into the nerve plexus. Equipment is available so that the standard nerve stimulator can be used for nerve location and once the pulse-synchronous muscle twitch end-point is reached a catheter can be passed via the cannula pre-positioned over the stimulator needle. The initial blocking dose can then be given in divided doses and further doses can be given for postoperative analgesia or a local anaesthetic infusion delivered.

Better systems are being developed, so that the catheter can deliver the nerve location current. Another development is an insulated Tuohy-type needle which avoids the intermediate step of placing a cannula to pass the catheter and potentially increases accuracy.

Local anaesthetic drugs that have reduced toxicity in overdose (e.g. ropivacaine, L-bupivacaine, both of medium to long duration of action) have recently become available. Their place in peripheral nerve block is not yet clear, because most of the early investigations have focused on obstetric epidural analgesia, but the potential to use relatively larger doses for the major nerve blocks offers a significant advantage over standard bupivacaine. Ropivacaine also offers the possibility of separating motor and sensory effect so that extended analgesia may be possible with minimal motor block.

Tests of Pulmonary Function

Sheena Hubble
Peter Macnaughton

Sheena Hubble is an Advanced Trainee in Intensive Care Medicine at Derriford Hospital, Plymouth, UK. She qualified from Bristol University and has trained in anaesthesia and intensive care medicine in the South-West of England.

Peter Macnaughton is Consultant in Intensive Care Medicine and Anaesthesia at Derriford Hospital, Plymouth, UK. He qualified from Westminster Medical School, London, and trained in anaesthesia and intensive care in London, Bristol, and Sydney, Australia. His research interests are in acute lung injury and applied respiratory physiology.

Pulmonary function tests provide objective measurements that are essential tools in the investigation of respiratory disease. They are used to screen for and define respiratory impairment, to quantify its severity, and to monitor the course of disease and its response to treatment. They may also be used as part of preoperative assessment and risk stratification. Simple tests, such as spirometry and peak expiratory flow rate, may be performed readily at the bedside. More complex tests of pulmonary gas exchange, such as carbon monoxide transfer factor and flow volume loops, require the facilities of a lung function laboratory.

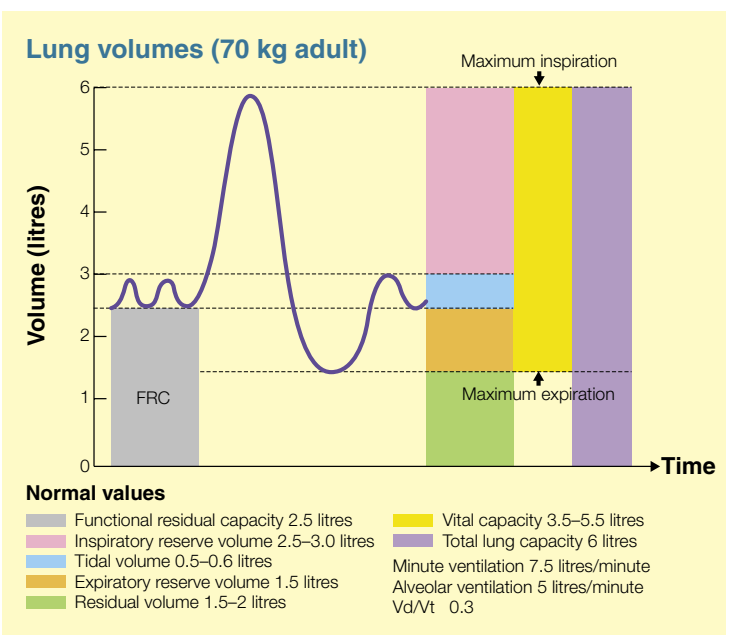
Normal values depend on the patient's height, age, gender and ethnic group. Population studies of healthy never-smoking subjects have produced reference equations for predicting the mean normal values for an individual. The patient's test result may be compared with the mean reference value and predicted range, which includes 90% of the population, or expressed as a percentage of the population's mean reference value (percent predicted). Pulmonary function tests should not be interpreted in isolation and should be considered in the context of all relevant clinical information.

Standards in interpretation of lung-function tests: most tests of pulmonary function require patient cooperation, therefore test quality is an important factor in interpreting results. Variability is greater than with most other clinical tests because of the inconsistency of patients' efforts; about 5% of ambulant patients are unable to cooperate. The European and American Thoracic Societies have published standards to minimize variability in the performance and interpretation of these tests.

Measurements are made in the erect or sitting posture and it is conventional to present respiratory volumes at body temperature and pressure saturated (BTPS). As measurements are made under conditions of ambient temperature and pressure, saturated with water vapour (ATPS), a correction is required to convert the measured volume into the volume occupied at 37°C (BTPS).This results in approximately a 10% increase in volume.

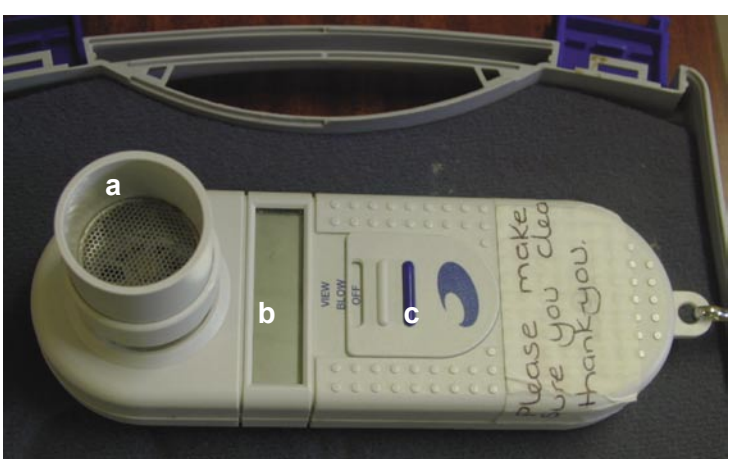
Spirometric tests

Spirometers measure expired lung volume (Figure 1). Dry bellows spirometers such as the vitalograph (Figure 2) are convenient for bedside use. They are designed to record a single vital capacity expiration using a bellows attached to a pen and a recording chart that plots expired volume against time. Electronic spirometers (Figure 3) are increasingly used, which incorporate a handheld pneumotachograph and are lightweight and portable. In intubated patients an estimate of vital capacity may be obtained with the moving plane respirometer (Figure 4). Whatever device is used, it should be calibrated regularly against a standard volume to ensure accurate measurements.



1

2 Vitalograph. **a** Mouthpiece, **b** spirometer trace.



3 Hand-held electronic spirometer. **a** Mouthpiece, **b** display, **c** reset button.

4 Wright's respirometer. Large outside scale measures in 0.1-litre divisions. Small inner scale measures in 1-litre divisions.

Residual volume cannot be exhaled, therefore spirometers measure only vital capacity and its subdivisions. Measurement of residual volume, total lung capacity and functional residual capacity can be undertaken only with techniques such as helium dilution or body plethysmography.

In standard spirometric evaluation, the subject takes a maximal inspiration followed by a forced expiration for as long as possible into the spirometer. When using the dry bellows spirometer it is important to ensure that expiration continues until all air has been expired from the lungs and not to stop when the record chart stops moving after 5 seconds. This is particularly important in patients with severe airflow limitation who may have a prolonged expiration time. Figure 5 shows the typical expiratory spirometry obtained in normal, obstructive and restrictive lung disease.

Vital capacity (VC) and forced vital capacity (FVC)

VC is the maximum volume of air expelled from a starting point of maximum inspiration to residual volume. It is termed FVC when obtained from a maximum effort expiration and slow VC following a normal effort expiration. In the normal subject, slow VC equals FVC, but in airways obstruction, slow VC is consistently larger than FVC, owing to airway collapse reducing forced expiration.

VC or FVC may be reduced by:

- reduced lung compliance (e.g. lung fibrosis)
- chest deformity (kyphoscoliosis)
- muscle weakness (myopathy, Guillain–Barré, high spinal cord injury)
- airways obstruction (in chronic obstructive pulmonary disease (COPD) air trapping occurs, causing increased residual volume and reduced VC).

A reduced VC, which falls by more than 10% when the patient is supine suggests diaphragmatic weakness. A VC greater than 10–15 ml/kg is required to sustain spontaneous ventilation and can be a useful bedside measurement to indicate the need for ventilatory support or to predict successful weaning from ventilation. In the ICU, VC measurements are of greatest use in patients with neuromuscular disease (e.g. Guillain–Barré syndrome). Measurement of VC depends on technique and effort, which limits its use in most patients with acute respiratory failure because they are dyspnoeic and unable to comply.

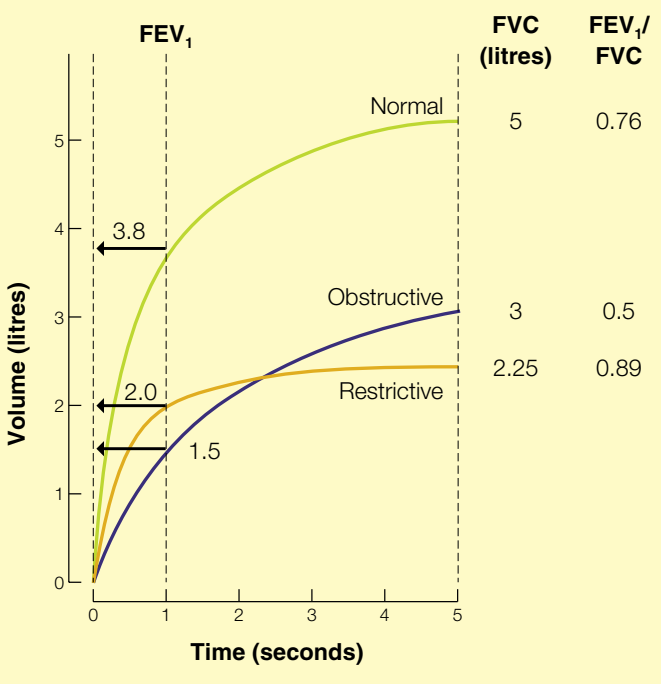
Forced expiratory volume in 1 second (FEV_1)

FEV_1 is the volume of air expelled in the first second of forced maximal expiration after a full inspiration. FEV_1 is reduced by obstruction of the airways, loss of lung recoil and, rarely, by severe weakness of the respiratory muscles. FEV_1 is a more reproducible measurement than FVC, particularly in airflow obstruction, and is used to quantify intrathoracic airway obstruction and assess response to bronchodilators. In COPD, FEV_1 grades the severity of disease and is an important predictor of prognosis. However, FEV_1 is not particularly sensitive in detecting early or mild obstruction and there is poor correlation between FEV_1 and dyspnoea in COPD. A reduced FEV_1 may also reflect a reduction in total lung capacity (TLC), which occurs in restrictive lung disease (e.g. pulmonary fibrosis) or following pneumonectomy.

FEV_1: FVC ratio

In normal subjects during a forced expiratory manoeuvre, at least 75% of the air is expelled in the first second. In patients with obstructive lung disease, the FEV_1 falls proportionally more than the FVC, therefore the ratio of FEV_1:FVC falls. In restrictive lung disease, the FEV_1 and FVC are reduced in the same proportion and the FEV_1:FVC ratio remains normal or even raised, reflecting accelerated lung emptying (Figure 5).

Spirometry in normal, obstructive and restrictive lung disease



FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity

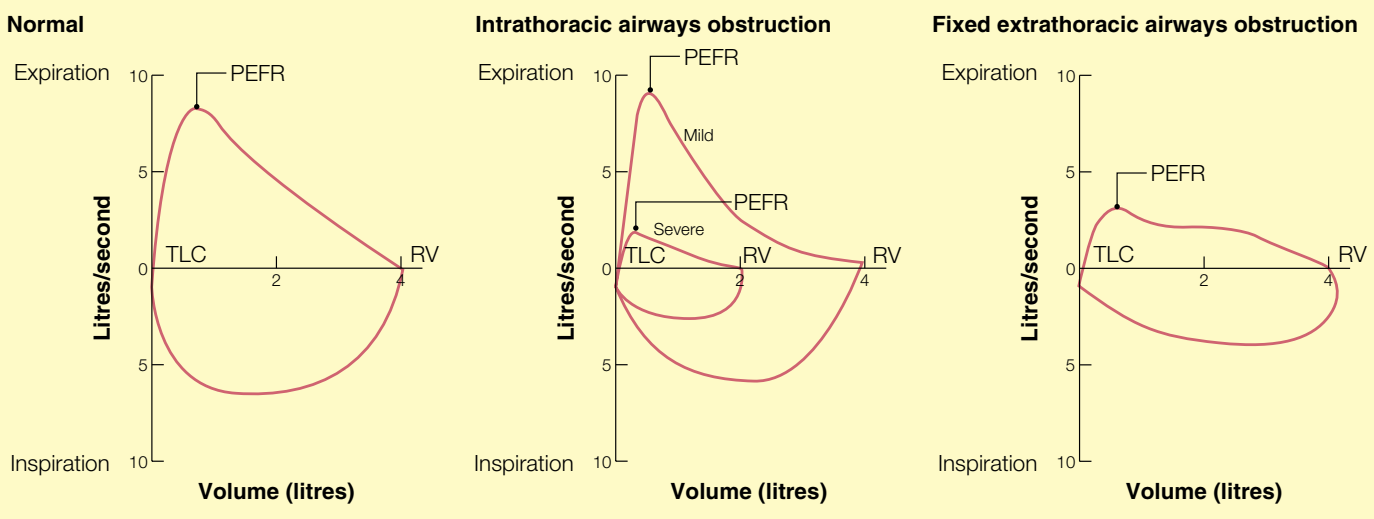
Tests of maximum flow

During a forced expiration at any lung volume, increasing effort at first increases flow but a plateau is reached at most lung volumes when expiratory flow cannot be increased regardless of effort. Above a critical level, the increased alveolar pressure resulting from increased effort is exactly counterbalanced by compression of large intrathoracic airways, limiting further increase in flow. Thus, expiratory flow measurements are not dependent on maximum effort apart from the peak expiratory flow. The maximum expiratory flow rate that can be achieved is reduced as lung volume drops, producing the characteristic expiratory flow volume curve (Figure 6). The highest expiratory flow rate is achieved at TLC and is termed the peak expiratory flow rate (PEFR). In contrast, maximum inspiratory flow is proportional to the negative pleural pressure generated and is effort dependent.

Flow volume loops



PEFR, peak expiratory flow rate; TLC, total lung capacity; RV, residual volume.

In patients with severe airway obstruction, expiratory flow cannot be increased with any effort, even at rest (expiratory flow limitation) and during exercise, end expiratory volume increases (dynamic hyperinflation). Peak expiratory flow occurs at full lung inflation and in normal subjects the maximum value obtained is effort dependent because flow limitation does not occur.

In the lung function laboratory, expiratory (and inspiratory) flow measurements are made with a rapid-response pneumotachograph. This measures flow from the small pressure drop that occurs across a fixed resistance using a sensitive pressure transducer.

Flow volume loop

The flow volume curve is obtained by asking the subject to inhale to TLC, then producing a forced maximum effort expiration to residual volume followed immediately by a maximum effort inspiration back to TLC. Flow is plotted against lung volume between TLC and residual volume to produce the characteristic flow volume loop (Figure 6). The maximum expiratory flow rate at various lung volumes, including 75%, 50% and 25% VC, is commonly reported. The maximum mid-expiratory flow (MMEF) is the flow recorded during the middle half of forced expiration (between 75% VC and 25% VC) and is a sensitive indicator of obstruction in the smaller peripheral airways. Flow volume loops are commonly used to supplement spirometry because they provide additional information. In particular, distinctive patterns represent the presence of intra- or extra-thoracic obstruction (Figure 6). The expiratory flow volume curve is abnormal in patients with mild obstructive airways disease even when measurements such as FEV_1 are within normal limits.

Peak expiratory flow rate (PEFR)

At the bedside, PEFR may be measured with a simple hand-held device. Wright's peak flow meter is a constant pressure, variable orifice device, able to measure peak flow rates up to 1000 litres/min. A fixed baffle in the meter directs exhaled air to strike a moveable vane. The vane reaches its furthest excursion according to the PEFR and is held there by a ratchet. A simpler, cheaper version consists of a cylindrical tube, and a piston, which is blown along its length proportionate to the peak flow. Subjects are asked to take a full inspiration to TLC then to blow out forcefully into the peak flow meter, which is held horizontally. The lips must make a tight seal round the mouthpiece and the best of three attempts is recorded. In normal subjects, the value of PEFR depends on effort and the calibre of the large central airways. In airway disease, PEFR is reduced by obstruction in small or large airways. Although PEFR is used for monitoring the course of asthma, reduction in PEFR is not specific to airway obstruction. Restrictive lung disease and respiratory muscle weakness may be associated with a reduction in PEFR, and a diagnosis of airways obstruction has to be confirmed with spirometry.

Transfer factor for carbon monoxide (TLCO)

The efficiency of gas exchange by the lungs can be assessed from the uptake of inhaled carbon monoxide (CO), which is limited by the rate of diffusion from alveolar space into the erythrocyte. CO has a high affinity for haemoglobin, such that the blood in the alveolar capillary never becomes saturated with CO and the capillary CO tension can be assumed to be zero. This simplifies the calculation of diffusing capacity for CO, which is expressed as the quantity of CO taken up per unit of time per unit of partial pressure of CO. Originally termed the diffusing capacity (CO diffusion in the lungs: DLCO), it has been realized that in addition to the molecular diffusion of CO across the alveolar capillary barrier, the chemical combination of CO with haemoglobin is a rate-limiting step (this explains why TLCO changes with haemoglobin). Therefore, the term transfer factor (CO transfer in the lung: TLCO) was introduced and is used interchangeably with DLCO.

TLCO is estimated by inhaling a known quantity of CO and measuring the change in CO concentration over a measured time. This is typically undertaken during a 10-second breath-hold at TLC or during a period of re-breathing. An insoluble gas, such as helium, is also inhaled and the lung volume to which the inhaled CO is diluted is measured from the change in concentration of the insoluble gas. This volume is termed the alveolar volume (VA). The coefficient of gas transfer or specific gas transfer (KCO) is the TLCO expressed per unit of alveolar volume (KCO = TLCO/VA). DLCO is reported in North America and expressed in ml/min/mm Hg. In Europe, the term TLCO is used with the units mmol/min/kPa.

TLCO measurement is influenced by the alveolar oxygen tension (PAO_2) because of the competition between oxygen and CO for haemoglobin binding sites. Measurements are usually made with an FiO_2 (fraction of oxygen in inspired air) of 18% and variations in PAO_2 between subjects can be ignored. Changes in haemoglobin concentration have a significant influence, with a 4% fall of TLCO per 1 g drop in haemoglobin. Values obtained in the pulmonary function laboratory may be corrected to a reference haemoglobin of 14.5 g/dl with a standard equation.

When interpreting the TLCO, the following fundamental relationship should be considered:

Gas exchange capacity (TLCO) =
Alveolar volume (VA) x Efficiency (KCO)

TLCO may be reduced from a reduction in alveolar volume, a reduction in the efficiency of gas exchange or a combination. A low KCO is characteristic of emphysema, interstitial lung disease (fibrosis) and pulmonary vascular disease. Pulmonary hypertension and pulmonary embolism are associated with reduced KCO with a preserved VA. The increase in alveolar volume associated with emphysema results in a marked reduction in KCO. In extrapulmonary restriction (e.g. chest wall disease), TLCO is slightly reduced while KCO is increased owing to the reduction in VA but reflecting the normal underlying lung. In asthma, TLCO may be slightly elevated, while alveolar haemorrhage is associated with marked elevations in TLCO owing to the presence of extravascular haemoglobin which binds CO. TLCO measurements are also used in assessing a patient's predicted tolerance of lung resection, with a predicted value over 50% being desirable. Following pneumonectomy, the TLCO falls according to the amount of lung resected, while KCO is preserved or increased.

Typical changes in lung-function tests

Condition	VC	FEV_1	FEV_1/VC	TLCO	KCO	Notes
Asthma	→	↓	↓	→	↑	FEV_1 increased after bronchodilator
Emphysema	↓	↓↓	↓↓	↓	↓↓	Increased VA results in marked decrease in KCO
Pulmonary fibrosis	↓	↓	↑ or →	↓↓	↓	VA reduced SaO_2 may fall on exercise due to diffusion limitation
Chest wall restriction	↓	↓	→	↓	↑	VA reduced but KCO increased as underlying lung normal
Respiratory muscle disease	↓	↓	→	↓	↑	10% fall in VC from erect to supine posture suggests diaphragm weakness
Alveolar haemorrhage	↓	↓	→	↑	↑↑	Increased KCO returns to normal after 48 hours

FEV_1, forced expiratory volume in 1 second; KCO, gas transfer coefficient; SaO_2, oxygen saturation in arterial blood; TLCO, transfer factor for carbon monoxide;
VA, alveolar volume; VC, vital capacity

Patterns of lung-function tests in respiratory disease

When diagnosing a patient with respiratory symptoms, the results of the range of pulmonary function tests need to be considered. Figure 7 (above) summarizes the typical changes that occur to the standard lung-function tests in a number of common conditions.◆

Principles of Intravenous Drug Administration

Johan F Coetzee

Johan F Coetzee is Associate Professor of Anaesthesiology at the University of Stellenbosch and Tygerberg Hospital, South Africa. He is Director of the Bureau for Biomedical Engineering of the University of Stellenbosch.

Circulating drugs are removed by distribution to peripheral tissues and by excretion and metabolism. Thus, bolus doses exert transient effects and repeated doses are required for continuous effects. However, repetitive boluses produce peaks and troughs in blood concentration and therefore varying effects. The most efficient method of maintaining a desired drug effect is by continuous infusion to achieve constant blood concentrations.

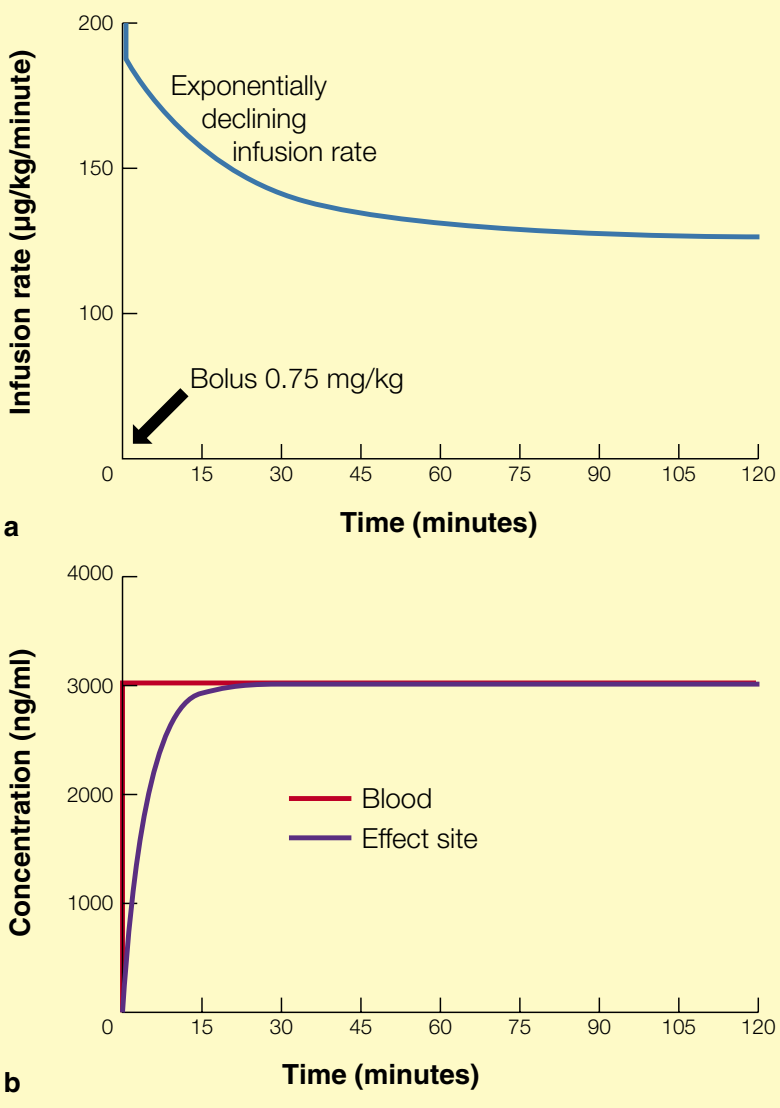
Achieving steady-state drug concentrations in blood

The behaviour of drugs subject to first-order kinetics can be represented by multicompartmental models, typically comprising a central compartment that receives and excretes drug, and from which distribution occurs into one or two large peripheral compartments. In 1968, Kruger-Theimer indicated how pharmacokinetic models can be used to design efficient dosage regimens. This Bolus, Elimination, Transfer (BET) regimen, comprises three components (Figure 1).

- Administer a **B**olus dose calculated to fill the central (blood) compartment.
- Admininster a constant-rate infusion equal to the **E**limination rate.
- Simultaneously, administer an infusion that compensates for **T**ransfer to the peripheral tissues. This infusion is initially rapid and declines asymptotically towards the elimination rate as the tissues absorb drug. Mathematical details can be obtained from textbooks on pharmacokinetics.

A simplified approach to approximate the exponentially declining infusion is by a series of manually stepped-down constant infusions. This is exemplified by the ‘10, 8 and 6’ dose regimen for propofol (Figure 2).

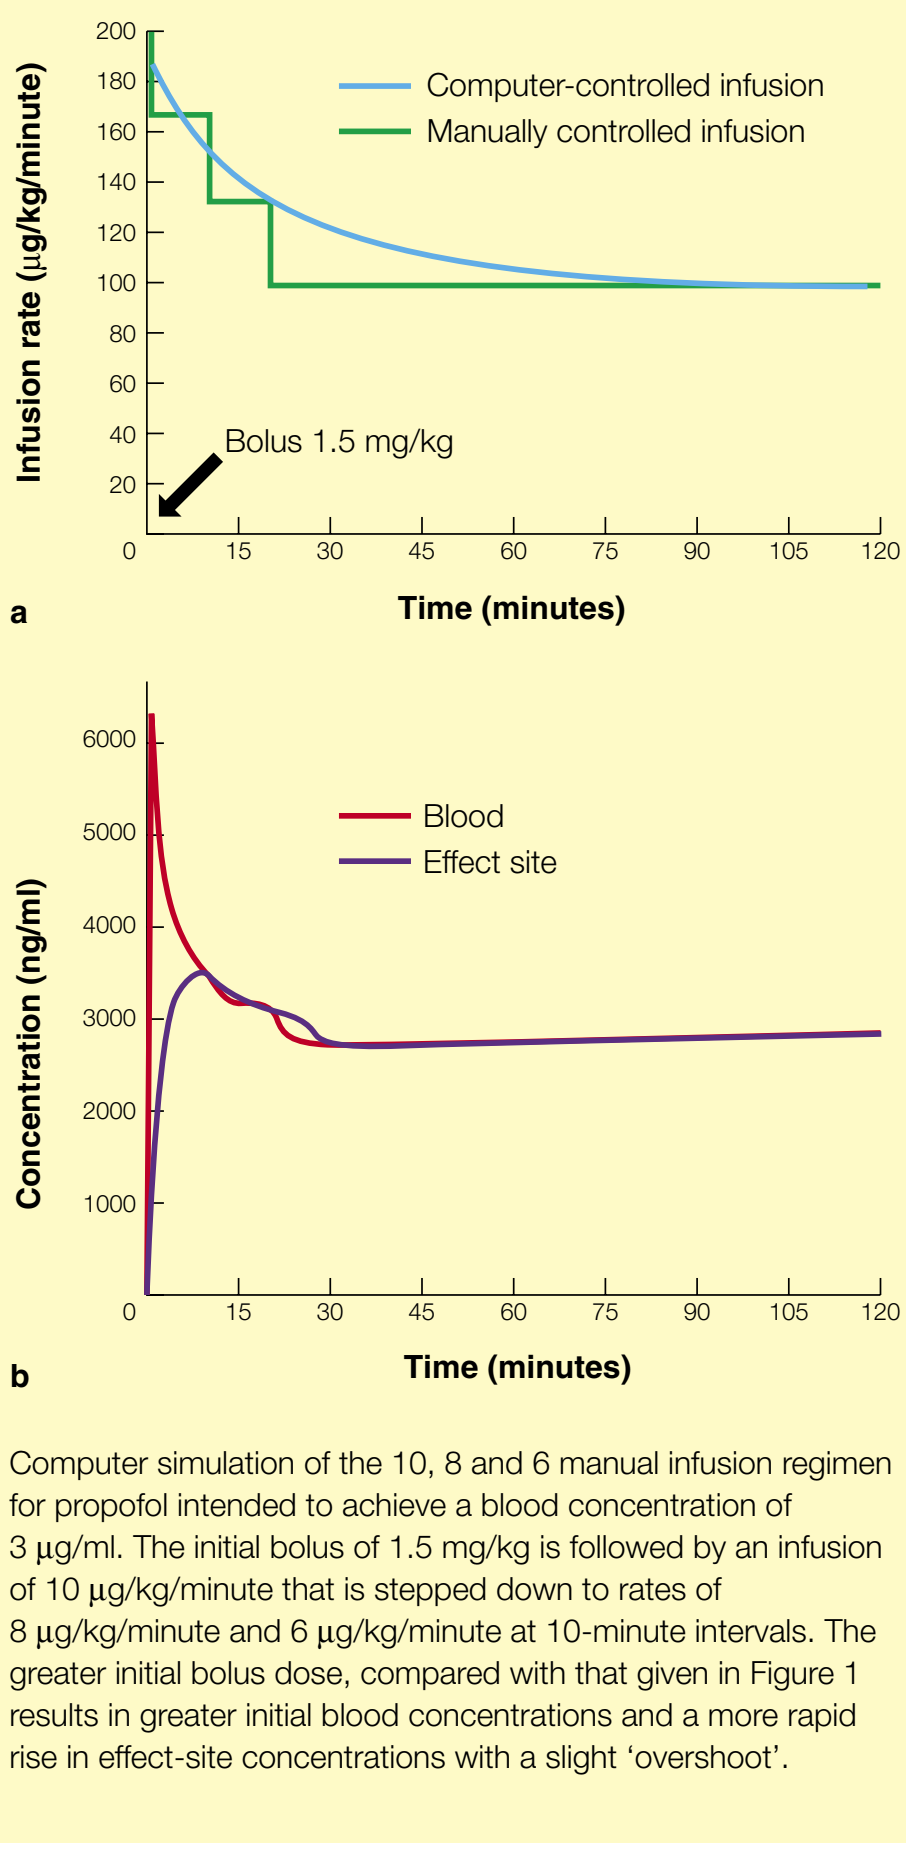
Achieving a constant blood concentration of propofol using a BET regimen



Computer simulation of propofol administered by a **B**olus, **E**limination and **T**ransfer (BET) dose regimen to achieve and maintain a constant blood concentration of 3 µg/ml.
a Administration of a bolus dose at time zero, calculated to establish the initial targeted concentration. This is followed by an infusion, which is initially rapid and then declines asymptotically to the maintenance rate. **b** The theoretical blood and effect-site concentrations. Note how the effect-site concentrations lag behind those in the blood. It is possible to achieve a more rapid rise in effect-site concentrations towards the targeted concentration at the cost of greater blood concentrations and therefore a greater likelihood of side-effects.

1

The 10, 8 and 6 manual infusion regimens



Computer simulation of the 10, 8 and 6 manual infusion regimen for propofol intended to achieve a blood concentration of 3 µg/ml. The initial bolus of 1.5 mg/kg is followed by an infusion of 10 µg/kg/minute that is stepped down to rates of 8 µg/kg/minute and 6 µg/kg/minute at 10-minute intervals. The greater initial bolus dose, compared with that given in Figure 1 results in greater initial blood concentrations and a more rapid rise in effect-site concentrations with a slight ‘overshoot’.

2

Target-controlled infusions (TCI) by computer
Using a pharmacokinetic model, a computer performs a simulation, continuously calculating the ‘patient’s’ expected drug concentration and administers the BET infusion, adjusting the pump speed, typically at 10-second intervals. By specifying an appropriate target concentration, the anaesthetist uses the device in a similar fashion to a vaporizer. There are differences between predicted and actual concentrations, but these are not of great consequence, provided the true concentrations are within the drug’s therapeutic window, within which the clinician may adjust the targeted concentrations, according to patient response. Measured/predicted errors of about 30% are clinically acceptable. These devices simplify intravenous drug administration by relieving the clinician of tedious calculations and by eliminating errors. Furthermore, computer-assisted TCI allow more accurate dosing, maintenance of stable drug concentrations (and therefore stable effects) and ability to make proportional changes (Figure 3). In order to use TCI, clinicians need to associate blood drug concentrations with expected effects; this is a familiar exercise for anaesthetists who relate alveolar anaesthetic partial pressures of inhaled anaesthetics to drug effect. Similarly, the concept of minimum effective plasma concentration (EC_{50}) is identical to that of minimal alveolar concentration for inhaled agents. Target-concentration guidelines for different intravenous drugs and drug combinations are available from standard textbooks. It must be borne in mind, however, that as with inhaled anaesthetics, no one targeted concentration will suit all patients. Patient pharmacokinetics and pharmacodynamics are influenced by age, cardiac output, coexisting disease, smoking, concurrent drug administration, body temperature and intensity of noxious stimulation. These factors must be considered when choosing target concentrations, and dose should be titrated according to clinical signs.

Advantages of BET dose regimens

- Rapid achievement of desired blood concentrations
- Avoidance of high peak concentrations that occur with a manually delivered bolus and therefore a reduced risk of side-effects
- More accurate dosing and therefore:
  - better haemodynamic control
  - reduced drug consumption
  - more rapid recovery
  - less postoperative depression
- Ability to maintain stable concentrations and therefore stable effects
- Ability to make proportional changes
- Use is similar to that of a vaporizer. Titrate to effect

Added advantages of computer-assisted BET infusions
- Elimination of calculation errors
- Compensation for any interruption to the infusion
- Easy to assess the relationship between drug concentration and effect
- Display of effect-site concentrations
- Prediction of time to recovery (context-sensitive decrement time)
- Possibility of targeting the effect site (analogous to targeting end-tidal partial pressures of volatile anaesthetics)

3

The *Diprifusor* (AstraZeneca, Macclesfield, UK) is a TCI device dedicated to propofol administration. It is anticipated that commercially available TCI technology will expand to include other drugs such as opioids and other hypnotics. TCI can be applied to any drug that exhibits first-order kinetics and should be applicable to those with narrow therapeutic indices, for example certain antibiotics, cytostatics and, anti-epileptics. Various computer programs may be downloaded from the Internet (e.g. http://pkpd.icon.palo-alto.med.va.gov/) and several TCI pumps (e.g. STELPUMP, STANPUMP and RUGLOOP from the Universities of Stellenbosch, Stanford and Ghent, respectively); others are screen-based simulators (PK-SIM). These programs provide useful educational and research tools that enable clinicians to experiment with dose regimens and to represent the expected results graphically, thereby developing familiarity with intravenous drug administration and encouraging dosing according to pharmacokinetic and pharmacodynamic principles.

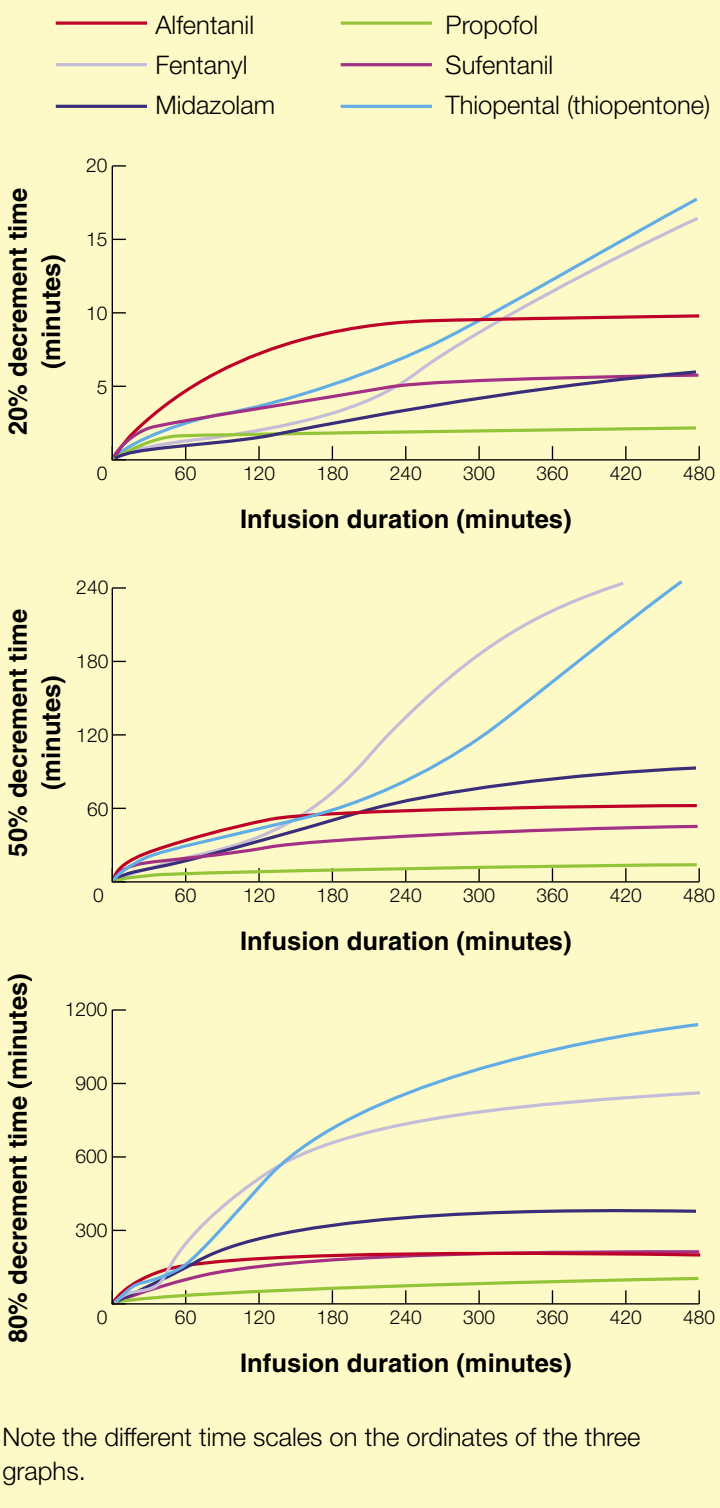
Furthermore, pharmacokinetic simulations can be used to develop manually adjusted BET infusion regimens that approximate the continuously changing infusions provided by computer control. Nomograms for devising manually adjusted infusion regimens are available in the literature.

Recovery after intravenous infusions

Prolonged infusions can lead to prolonged recovery times. A method for quantifying this phenomenon is to calculate the times required for blood concentrations to decrease by a fixed fraction after maintaining constant concentrations for various infusion durations. These are termed 'context-sensitive' decrement times ('context sensitive' referring to the infusion duration) (Figure 4). Note that propofol and sufentanil have context-sensitive 'half-times' (50% decrement times) that increase gradually with infusion duration. In contrast, the context-sensitive half-times of thiopental (thiopentone), fentanyl and midazolam are markedly dependent on infusion duration and become inordinately prolonged after infusions that last longer than 1 hour. Clinically, 50% concentration decrements of propofol and the three opioids often represent recovery from moderate clinical effects, however, there are also circumstances in which a 20% or an 80% plasma-concentration decrease is required for recovery. In Figure 4, conservative dosing, achieving blood concentrations that require only 20% decrements for recovery, leads to rapid recovery times, even after prolonged infusions. In contrast, when large concentration decrements are required for recovery (80%), context-sensitive recovery times show steep increases even after brief infusions.

Figure 4 illustrates that sufentanil is a good choice for opioid administration by infusion, having short, predictable context-sensitive half-times. The new opioid, remifentanil is rapidly hydrolysed by tissue esterases so that the 50% and 80% context-sensitive decrement times are 3 and 12 minutes, regardless of infusion duration because there is virtually no accumulation of drug in peripheral compartments. The protracted decrement times of fentanyl may be used to provide postoperative analgesia by administering infusions during prolonged surgery, attaining concentrations at which moderate analgesia is achieved without excessive respiratory depression (2–3 ng/ml).

Computer simulations of the context-sensitive decrement times of various hypnotics and opioids



Note the different time scales on the ordinates of the three graphs.

4

The rate at which drug concentration decreases after an infusion, is determined by the rate at which it is irreversibly removed from the body, as well as the rate of redistribution to peripheral tissues. Recovery after an infusion therefore has little relevance to the elimination half-life of a drug because the elimination half-life does not take redistribution into account. For example, propofol and sufentanil have long elimination half-lives but short context-sensitive half-times. Note that context-sensitive decrement times are not represented by a single number: they are a continuum of time values that are a function of infusion duration and can be represented by a graph. Considering that decrement times depend on the concentrations achieved as well as the dose history, it is often difficult for clinicians to anticipate patients' time to recovery. A useful feature of TCI is continuous calculation and display of expected times to recovery, should the infusion be stopped, assisting the clinician to ascertain when to reduce or terminate the infusion. A hydraulic model has been used to explain context-sensitive recovery times, in which the heights of fluid levels in interconnecting cylinders represent drug concentrations in various compartments. This analogy is identical to the model used by Mapleson to represent the uptake and elimination of inhaled anaesthetics.

Relationship between drug concentration and effect

Most drugs exert their effects at a distant site and the circulation transports drug molecules to their site of action. Whereas steady-state blood concentrations correlate with drug effects, when blood concentration is changing, or has recently changed, there is a time-lag between changing blood concentrations and changing effects. This phenomenon is illustrated in Figures 1 and 2. Limited space precludes a detailed discussion of the relationships between blood and effect-site concentrations; the time-related hysteresis between dose and effect is described in the further reading.

Spinal Anaesthesia

William Harrop-Griffiths

William Harrop-Griffiths is Consultant Anaesthetist at St Mary's Hospital, Paddington. His interests include regional and vascular anaesthesia.

There are few, if any, techniques in anaesthesia that can match the effectiveness, elegance, economy, simplicity and safety of spinal anaesthesia. Its popularity has waxed and waned since its inception in 1898 but its use in anaesthesia and analgesia is likely to increase.

Anatomy
The spinal cord terminates at about the level of the first lumbar vertebra (L1) in the adult human. However, it is important to note that there is variation and that the end of the cord is below L1 in about 40% of patients. Beyond its termination, nerves continue to their exit points from the vertebral canal as a sheaf of nerves called the cauda equina (see page 108). The spinal cord and cauda equina are bathed in CSF contained by the arachnoid mater, a gossamer-thin membrane closely applied to the inside of a more substantial layer called the dura mater. The subarachnoid space ends at the level of the second sacral vertebra (S2).

The spinal anaesthetist aims to place drugs in the CSF so that they can act on the cauda equina and spinal cord. Spinal anaesthesia at the thoracic, and even cervical, level is recorded, but its use is not standard practice. Access to the subarachnoid space is usually attempted below the L1 level to avoid direct mechanical damage to the spinal cord by the spinal needle. It is thought that the nerve roots comprising the cauda equina are difficult to skewer with a needle. It has been suggested that the L3/4 interspace is the “highest that all good anaesthetists should aim for spinal insertion”.

Technique
The patient should receive a full explanation of the risks and benefits of the technique. Ideally, the patient should be treated in an environment that contains trained assistance for the anaesthetist, full resuscitation equipment and the facilities necessary for the performance of a general anaesthetic. Secure intravenous access should be gained. The patient should be placed in a position that increases the palpable spaces between the spinous processes. Usually, this is achieved by the patient flexing his or her spine in the lateral or sitting position.

The technique should be aseptic. Local anaesthetic should be injected subcutaneously and through the interspinous ligament into the space between the spinous processes. A spinal needle, usually at least 9 cm in length, is inserted in the midline and passed, often with a slightly cephalad angulation, until the characteristic feeling of the passage of the needle through the ligamentum flavum and dura mater is felt. The trochar of the needle is removed and a free flow of CSF is awaited before injection. It is common, though not mandatory, to aspirate CSF into the syringe at the beginning and end of the injection to confirm that the entire dose of drug is delivered into the CSF. The needle is then withdrawn.

A paramedian or lateral approach (i.e. using an entry point lateral to the midline) may be used if there are difficulties in accessing the subarachnoid space by the midline approach.

Recent modifications to include the passage of an epidural catheter at the same time as spinal injection (combined spinal-epidural) may involve the placement of a Tuohy or other epidural needle in the epidural space and the subsequent passage of a spinal needle through the epidural needle. A longer spinal needle is needed for this technique so that it emerges about 1 cm beyond the end of the epidural needle. Alternatively, purpose-designed epidural needles with separate channels or orifices may be used to facilitate this technique.

The placement of a subarachnoid catheter to allow the provision of continuous spinal anaesthesia suffered a setback with the withdrawal of small spinal catheters in the USA. The drugs used for spinal anaesthesia are listed in Figure 1.

Local anaesthetics and adjuncts commonly used for spinal anaesthesia and analgesia

Local anaesthetics	Drugs used to prolong block	Opioids	Alternative analgesic drugs
Bupivacaine	Adrenaline (epinephrine)	Fentanyl	Ketamine
Lidocaine (lignocaine)	Phenylephrine	Morphine	Neostigmine
Tetracaine	Clonidine	Diamorphine	
		Pethidine	

Factors affecting block height (Figure 2): the term baricity in this context describes the specific gravity of a spinal injection relative to that of the CSF. A hyperbaric solution is heavier than CSF and will fall with gravity, and is often termed a ‘heavy’ solution. A hypobaric solution will rise against gravity. An isobaric solution will neither fall nor rise. Local anaesthetic solutions can be rendered hyperbaric by the addition of glucose and hypobaric by the addition of sterile water. Unadulterated local anaesthetic solutions (e.g. 0.5% and 0.75% bupivacaine) are effectively isobaric and the height of the block after their injection is dependent largely on the mass of drug injected. The final block height after the injection of hyperbaric and hypobaric solutions depends, to an extent, on the patient’s position. For instance, injection of a modest amount of hyperbaric solution in the sitting position will lead to a so-called ‘saddle block’, (i.e. a block of the sacral roots; the parts of the body that come into contact with a horse’s saddle). If a hyperbaric solution is injected and the patient is laid supine shortly after injection, the block height is likely to approximate to the root value of the most dependent part of the thoracic kyphosis (i.e. the mid-thoracic dermatomes). Adjusting the patient’s position after injection of a hyperbaric solution may encourage or limit spread. If a higher block is required, the patient can be turned to the head-down position. If no further cephalad extension of the block is required, the patient can be turned to a head-up position, being mindful of the potential this position has for leading to hypotension. The response to hypotension in a patient who has just undergone spinal anaesthesia with a hyperbaric solution should not include placing the patient head-down; this encourages further cephalad spread of the block.

Hypobaric solutions can be injected into a patient in the prone jack-knife position to encourage a sacral block or in the patient with, for instance, a fractured neck of femur, while lying on the unaffected side, encouraging a more unilateral block of the affected, uppermost hip. Positional changes after about
5 minutes have little value as the local anaesthetic is thought to be ‘fixed’ by this time, although the maximum block height after spinal anaesthesia can take 20 minutes to achieve.

Relation of factors to block height

Factors affecting block height
- Baricity of solution
- Patient position
- Mass of drug
- Direction of lateral bevel of spinal needle
- Gender
- Patient height (minor effect)
- Age (minor effect)

Factors not affecting block height
- Barbotage (the repeated injection and aspiration of solution during a spinal injection)
- Patient weight
- Rate of injection
- Coughing or straining
- Added vasoconstrictor

Physiological effects
The injection of local anaesthetics into the CSF causes blockade of the nerves of the cauda equina and the spinal cord. The degree and extent of the block depend on the mass of the drug, its concentration, its baricity and the position of the patient. Rather than the segmental block seen in epidural anaesthesia, spinal blockade affects all nerves at, and distal to, the maximum dermatomal height of the block. Nerve types are blocked in the traditional order, thus small nerve fibres serving the sympathetic nervous system, pain and temperature are blocked before touch and motor fibres. The use of low concentrations of local anaesthetic is thought to be able to produce a degree of ‘differential block’, leading to a spinal block that provides analgesia without significant impairment of motor function. This form of block is popular for the initiation of analgesia in labour.

Opioid drugs given on their own or in combination with local anaesthetics act on the opiate receptors in the spinal cord. Other drugs (see below) may be added to modify the baricity of the injectate or the duration of the block.

The physiological impact of a spinal block is proportional to its dermatomal height. Blockade of the sympathetic nerves arising from the mid-thoracic and upper thoracic segments causes significant venous pooling and results in hypotension. A spinal block to T10 has minimal cardiovascular impact. A block to T6 causes a decrease in arterial blood pressure in the order of 25%, and a block to T4 decreases it by about 30%. The cardiac sympathetic (cardio-accelerator) nerves have root values of T1–T4. Blockade of these nerves causes bradycardia and worsens hypotension.

Unopposed parasympathetic activity in the gut can cause hyperperistalsis with blocks above T5, which are therefore associated with nausea and vomiting.

In patients with significant lung disease, progressive blockade of intercostal muscles may give rise to dyspnoea. Extension of the block to the mid-cervical segments (C3–C5) affects the function of the phrenic nerves. Extension of the local anaesthetic through the foramen magnum allows it to bathe the hindbrain and causes unconsciousness, often called a ‘total spinal’.

Use of spinal anaesthesia
Spinal anaesthesia is safe and effective but consideration must be given to the following factors.
- Surgery should be on the lower abdomen/pelvis or on the lower limb.
- A single-shot spinal may have a duration of only 60–90 minutes. Continuous spinal anaesthesia may be used to prolong the block for operations longer than this.
- Contraindications are listed in Figure 3.
- The risk of headache should be considered (see below).
- Thought should be given to the provision of analgesia after the block has worn off.

The addition of opioids to the spinal injection may prolong analgesia for up to 12 hours. The use of a combined spinal-epidural will allow analgesia via an epidural catheter for a prolonged period.

Contraindications to spinal anaesthesia

Absolute
- Patient refusal may lead to legal action for assault
- Increased intracranial pressure may cause coning and death
- Severe coagulopathy may cause epidural haematoma or subarachnoid bleed

Relative
- Local sepsis may lead to epidural abscess or meningitis
- Systemic sepsis may lead to epidural abscess or meningitis
- Moderate coagulopathy (includes anticoagulent therapy) may cause epidural haematoma or bleeding
- Hypovolaemia may cause marked hypotension
- Mild coagulopathy (includes anticoagulant therapy) may cause epidural haematoma or subarachnoid bleed
- Neurological disease (e.g. multiple sclerosis may lead to deterioration – there is no convincing evidence to suggest that spinal anaesthesia causes a significant deterioration in chronic neurological conditions such as multiple sclerosis)

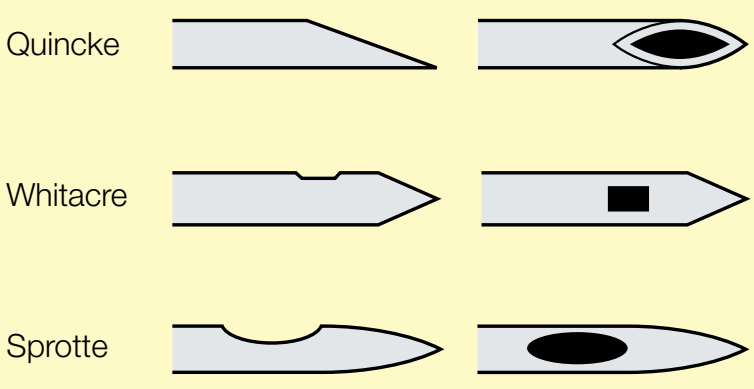
Complications
Hypotension: can be a desirable side-effect or an undesirable complication, depending on the clinical situation. It is customary to ‘preload’ patients undergoing spinal anaesthesia with moderate to large volumes of crystalloid or colloid in an attempt to minimize hypotension. Doubt has been cast on this approach and many anaesthetists now agree that “the solution to pharmacological vasodilation is pharmacological vasoconstriction”. The author will continue to use moderate preloading in patients not at risk of volume overload until the adverse effects of this practice are proven beyond reasonable doubt. However, it is mandatory to have access to vasoconstrictor drugs when administering spinal anaesthetics. The choice of drug is seldom critical. Ephedrine is popular for obstetric anaesthesia because of its beneficial effects on ovine placental blood flow. This is also logical because the hypotension is often a combination of vasodilatation and bradycardia, making a combined α- and β-adrenoceptor agonist a good choice. Methoxamine and metaraminol are also effective vasoconstrictors. Bradycardia should be treated with an anticholinergic drug, most popularly atropine. The occasionally dramatic hypotension seen with spinal anaesthesia to mid-thoracic levels makes the technique an unwise choice in patients with heart valve stenosis or a limited stroke volume for other reasons.

Post-dural puncture headache (PDPH): the incidence of PDPH is proportional to the size of the hole in the dura. Spinal needles in common use range from the large 18 G and 22 G needles used by physicians for diagnostic lumbar punctures to the 25 G, 27 G and 29 G needles favoured by anaesthetists. However, the shape of the hole may also be important. Spinal needles that have a conical tip (e.g. Whitacre, Sprotte) are less likely to cause PDPH than similar sized needles with a traditional cutting (Quincke) tip (Figure 4) because the conical tipped needles divide, rather than cut, the dural fibres. Similarly, a cutting bevel lined up with the longitudinal dural fibres is thought to be associated with a lower incidence of PDPH than a bevel cutting across the fibres (Figure 5).

The young suffer a higher incidence of PDPH than the old, and females fare worse than males, pregnant ones even more so. Multiple dural punctures are associated with a higher incidence of PDPH than a single puncture. The passage of a subarachnoid catheter, even though it necessitates the production of a relatively large hole in the dura, may enjoy a lower incidence of PDPH than an equivalent sized hole made for a single injection. The reasons are poorly understood, though oedema of the dural edges may be implicated. Traditionally, patients were not allowed to mobilize for some hours after spinal anaesthesia because this was thought to decrease the incidence of PDPH. This dogma is now being questioned.

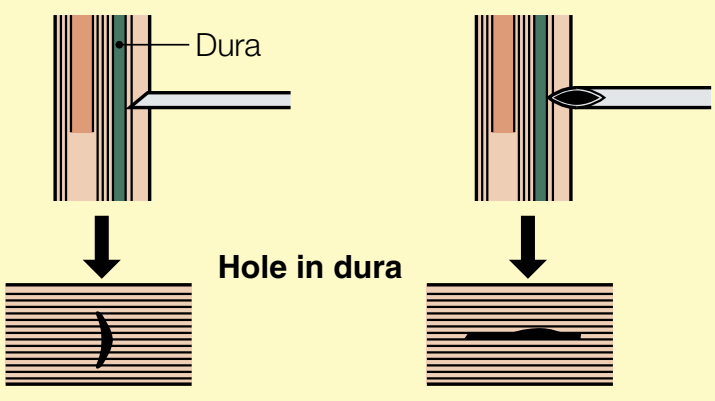
The management of PDPH includes bed rest, adequate hydration, good analgesia and, if severe or prolonged, an epidural blood patch.

Common tip designs for spinal needles



4

Number of fibres cut by different shaped needles



If the bevel of a spinal needle with a Quincke tip is aligned parallel with the fibres of the dura, fewer fibres are cut as shown on the right.

5

Failure: spinal anaesthesia is a simple procedure and, with training and experience, access to the CSF should be achievable in all but a few patients.

Neurological damage to the spinal cord or cauda equina can be caused by direct needle trauma or administration of neurotoxic drugs. Neurological damage is rare, and it should be noted that neurological damage from such conditions as anterior spinal artery syndrome can occur during general anaesthesia in the absence of spinal or epidural techniques. Anterior spinal artery syndrome comprises damage to motor nerves in the anterior part of the spinal cord due to inadequate blood supply from its nutrient artery, the anterior spinal artery. When seen, this rare condition is usually associated with a combination of widespread atherosclerotic disease and sustained hypotension.

Rare complications

- Infection of the meninges is a potential risk of spinal anaesthesia but convincing reports of its occurrence are rare.
- The use of spinal opioids may be associated with late respiratory depression. Cephalad spread of CSF containing opioid drugs gaining access to the respiratory centre located superficially in the floor of the fourth ventricle may cause delayed and potentially fatal respiratory depression. Doubt has recently been cast on whether the incidence of this complication is any higher or more significant than the risk of respiratory depression with opioids given by the intravenous or intramuscular routes. The risk of late respiratory depression with spinal opioids increases with increasing age, and the concomitant administration of opioids or CNS depressants by any other routes.
- There have been occasional reports of short-term deafness or cranial nerve dysfunction after spinal anaesthesia. Very rarely, sudden cardiac arrest may occur with no apparent cause in young adults undergoing spinal anaesthesia.

Spinal Anaesthesia and Spinal Cord Trauma

Felicity Reynolds

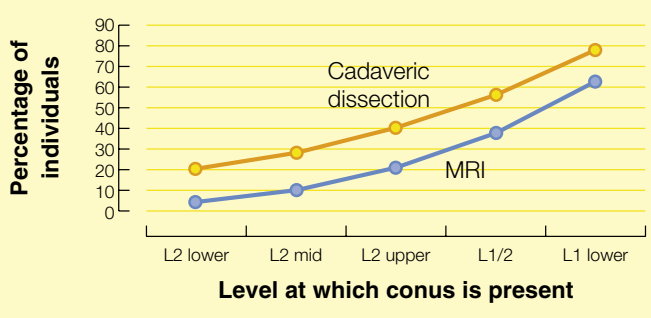
Felicity Reynolds is the Emeritus Professor of Obstetric Anaesthesia, St Thomas' Hospital, London

Spinal anaesthesia is simple to perform and in the field of obstetric anaesthesia it avoids the mortal risks associated with general anaesthesia and epidural blockade. As the local anaesthetic dose requirement for intrathecal anaesthesia is one-tenth that for epidural, the risk of total spinal blockade is minimized, while accidental intravenous injection is less likely and less dangerous. However, complications such as headache and nerve damage are more significant. Headache was so common in the obstetric population that it deterred many from using spinals until the reintroduction of atraumatic needles. Since then, spinal anaesthesia has exploded in popularity. In consequence, other sources of morbidity are of crucial importance.

The subarachnoid space deserves our respect. It contains not only the spinal cord, but also nerve roots that are devoid of the dural covering that protects them in the epidural space. This puts them at greater risk from neurotoxic injury and from trauma. Every injectate must be screened with care and every spinal needle inserted gently with control; paraesthesiae on needle insertion may presage prolonged symptoms.

More serious than nerve root damage is spinal cord damage. The conus medullaris, the tapering lower end of the spinal cord, is not at a constant segmental level. Although widely supposed to end at the lower border of the body of L1 in adults, in 1894 it was shown to reach L2 in 27% of men and 43% of women. Further studies of cadavers and adult MRI scans showed that the conus may reach the lower border of L2 in 2–20% of individuals, and L1/2 in 37–57% (Figure 1). Thus, choosing L1/2 for spinal insertion should be out of the question, while even the L2/3 space is unwise, but a genuine L3/4 is safe, other than in children or in the presence of a tethered cord (a rare congenital abnormality).

Proportion of adults in whom the cord would be present at each spinal level



Cumulative data, derived from: Reimann A F, Anson B J. *Anatomical Record* 1944; **88:** 127–38 and Saifuddin A *et al. Spine* 1998; **23:** 1452–6. Reproduced with permission from the publishers of *Anaesthesia*.

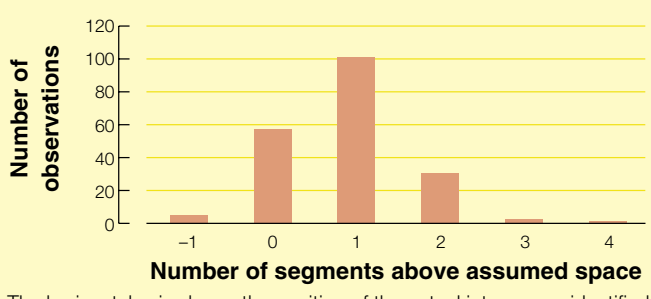
Identification of lumbar interspaces by Oxford anaesthetists



The horizontal axis shows the position of the actual interspace, identified by MRI, relative to the assumed space, in 200 observations. Data from: Broadbent C R *et al*. *Anaesthesia* 2000; **55:** 1122–6. Reproduced with permission from the publishers of *Anaesthesia*.

2

Medical students and preregistration house officers are recommended to use L4/5 for lumbar puncture, to avoid damage to the spinal cord. Anaesthetists, who have become accustomed to a relative freedom of choice with epidural insertion, may have become incautious with spinal needles, while some textbooks have condoned the selection of spaces as high as L1/2. Even experienced anaesthetists are inaccurate in identifying lumbar segmental levels, with 68% of chosen spaces being higher than assumed by anything up to four segments (Figure 2). Experience does not improve accuracy, because in the absence of universal radiological screening, there is no feedback. Thus, you are more likely than not to select a space that is higher than you think, which is erring on the side of danger. To identify the interspace, Tuffier's line is more widely used than the twelfth rib, or counting down from the vertebra prominens or up from the sacrum. Although Tuffier's line usually crosses the midline at L4/5, it may be as high as L3/4. Its accuracy can be improved, but only slightly, by palpating both iliac crests, rather than by dropping a perpendicular from one towards the midline. Obesity reduces the accuracy of interspace identification by any of the methods.

Does such inaccurate identification of lumbar interspaces really matter for spinal insertion? Yes it does. During the 1990s a number of cases of conus damage following spinal anaesthesia were reported, and many more are *sub judice*. The damage appeared to follow needle insertion alone; avoiding injection after painful insertion did not remove the risk. Patients suffered from persistent pain, paraesthesiae and sometimes numbness, usually unilateral, in dermatomes L4/5–S1, foot drop and in some cases disorders of micturition. On MRI scan an area of high signal on T2 was visible on the same side as the clinical lesion. This was variously reported as suggestive of a small syrinx, haematoma or infarct. Recovery was slow or partial. In most cases anaesthetists believed they had used L2/3, but L1/2 was probably selected. Using as a defence that a practice is condoned by a textbook may not be safe if the recommendation is not logical. Most, but not all, cases have followed the use of atraumatic needles, but these are so widely used that this is not evidence of their inherent danger.

Setting out to use any space above L3 for spinal anaesthesia, as for diagnostic lumbar puncture, is inadvisable, because of our inaccuracy and the variability of the position of the conus. A space in the lower lumbar region should therefore be our aim. Bear in mind the following:

- atraumatic spinal needles have at least 1 mm of blind tip beyond the hole
- from L1/2 the needle tip may reach the conus in about 60% of individuals
- from L2/3 it can reach the conus in 4–20%
- women are at greater risk than men
- Tuffier's line is not reliable
- the space you choose is probably higher than you think
- a spinal needle should not be inserted above the L3 spinous process. ◆

Upper Limb Nerve Blocks

Martin J Herrick
Tim J Clarke

Martin J Herrick is Consultant Anaesthetist at Addenbrooke's Hospital, Cambridge, UK. He qualified from Cambridge University and St Thomas's Hospital, London, and trained in anaesthesia in London, Portsmouth, Cambridge and King's Lynn. His interests include local and paediatric anaesthesia and training.

Tim J Clarke is Specialist Registrar in the East Anglia Deanery. His research interests are regional anaesthesia and high-altitude physiology.

The brachial plexus forms the entire somatic nerve supply to the upper limb except for the intercostobrachial and medial brachial cutaneous nerves, derived from T2, which supply the medial upper arm. The brachial plexus extends from the lateral aspect of the cervical vertebrae to the axilla, passing between the anterior and middle scalene muscles over the first rib, where it lies immediately behind the subclavian artery. Here it forms three trunks – upper, middle and lower. Below the clavicle, the plexus surrounds the axillary artery as three cords – medial, lateral and posterior.

The prevertebral fascia extends the length of the plexus and encloses the nerves with the subclavian then axillary artery to form a neurovascular bundle in a continuous sheath.

Figure 1 lists the prerequisites for regional anaesthesia.

Preparation for regional anaesthesia

- Explanation of procedure and risks, and obtaining consent
- Fasting
- Monitoring
  - blood pressure
  - ECG
  - pulse oximetry
- Intravenous access
- Resuscitation facilities
- Skilled technical support
- Aseptic technique
- Time
  - 15 minutes minimum for set-up and block
  - 45 minutes for anaesthesia (axillary block)

1

Nerve stimulation
Nerve stimulation facilitates nerve localization without generating painful paraesthesiae.

- The polarity of the needle should be negative to minimize the current required for stimulation.
- The stimulus frequency should be 2 Hz.
- An initial current of 1 mA is adequate. Higher currents may cause painful muscle twitches.
- When using needles with the whole bevel uninsulated, the needle tip is within 2 mm of the motor nerve when the muscle twitches at 0.5 mA (0.3 mA for those with only the bevel tip uninsulated).

Intraneural injection is unlikely if no muscle twitch occurs at 0.2 mA and the twitch ceases within 0.5 seconds after injection of 0.5 ml local anaesthetic. Resistance to injection should be minimal and the injection should be painless or generate only mild pressure sensation.

Brachial plexus block

The features of the three most common techniques for brachial plexus block, interscalene, subclavian perivascular and axillary, are outlined in Figure 2. With any of these techniques, a catheter can be inserted to provide prolonged analgesia. All approaches achieve sympathetic nerve block of the arm, while sympathetic block of the head, with Horner's syndrome, accompanies over 50% of procedures above the clavicle.

Although some anaesthetists use large volumes of 0.5% bupivacaine alone, apparently with a very low incidence of toxic reactions. 0.5% levobupivacaine or ropivacaine are less cardiotoxic alternatives. A mixture of 0.5% bupivacaine and 1% prilocaine reduces the toxicity potential and, in theory, promotes a quicker onset. Block duration averages 8–12 hours.

Three commonly used approaches to brachial plexus blockade

	Interscalene	Subclavian perivascular	Axillary
Blocks	C4–C6/7 roots	Upper/middle trunks ± lower trunk	Medial and lateral cord/ulnar and median nerves
Misses	C8–T1 roots	Lower trunk (in 10%)	Musculocutaneous nerve Posterior cord/radial nerve
Good for	• Shoulder • Upper arm	• Arm • Hand (? except ulnar)	• Ulnar forearm/hand • Continuous infusion • Children
Poor for	• Hand • Respiratory impairment	• Surgery on little finger • Coagulopathy • ? Emphysema	• Radial forearm
Local complications	• Phrenic nerve block • Subarachnoid block • Epidural block • Vertebral artery injection	• Pneumothorax • Haemothorax direct dural cuff • Subclavian artery puncture	• Phrenic nerve block • Recurrent laryngeal nerve block • Axillary artery puncture
Dose	• 0.5 ml/kg up to 40 ml	• 0.5 ml/kg up to 40 ml	• 50–60 ml

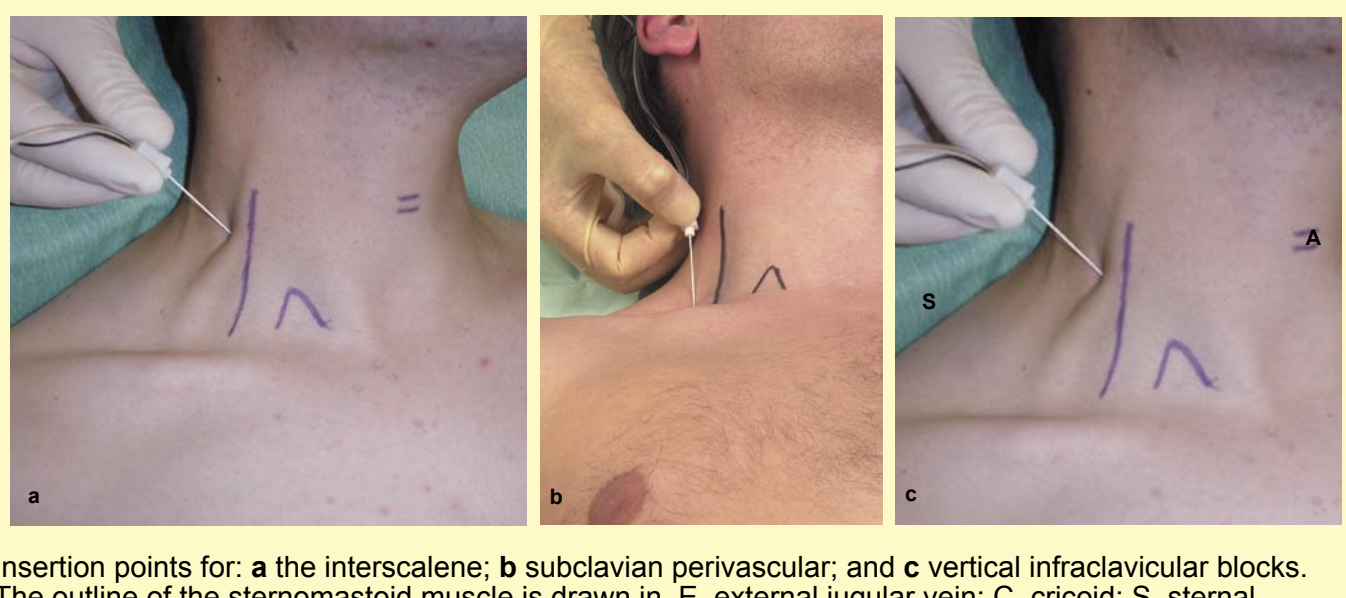
2

Interscalene block
Technique: the lateral border of the clavicular head of the sternomastoid muscle is identified at the level of C6, level with the cricoid cartilage. Palpating laterally, the shallow interscalene groove is identified at the same level. The external jugular vein usually crosses the groove at this point.

A 25-mm needle is inserted perpendicular to the skin and advanced medially, caudally and dorsally (Figure 3). With this angulation, the needle inserts on the transverse process of the vertebra if the roots are missed. The brachial plexus is usually only 1–2 cm deep at this point.

Using paraesthesiae to identify the plexus, sensation must be elicited below the shoulder; and, using muscle stimulation, a twitch should be evoked in the upper arm muscles. If nerve roots are not located, the needle reaches the lateral process of C6 (Chassaignac's tubercle) and is 'walked' anteriorly.

Landmarks are easily identified without special positioning, which is useful in patients with painful conditions. Caudal spread of local anaesthetic is encouraged by head-up positioning or digital pressure proximal to the injection site.



Insertion points for: **a** the interscalene; **b** subclavian perivascular; and **c** vertical infraclavicular blocks. The outline of the sternomastoid muscle is drawn in. E, external jugular vein; C, cricoid; S, sternal notch; A, acromion.

3

Complications: direct, horizontal insertion risks penetration of vertebral vessels, or the epidural or subarachnoid spaces through the intervertebral foramen. Phrenic nerve block (almost 100%) may be a hazard in patients with chronic pulmonary disease, though the risk is less than expected in those with emphysema (possibly because the diaphragm is already splinted by hyperinflated lung).

Subclavian perivascular block
Subclavian perivascular block, a supraclavicular approach to the brachial plexus, is an interscalene block, but it anaesthetizes the three trunks of the plexus as they cross the first rib.

The first rib runs approximately anteroposteriorly at the point where it is crossed by the trunks of the brachial plexus between the scalene muscles. The rib therefore acts as a 'backstop' to the advancing needle. As the lower trunk may lie under the subclavian artery, the medial antebrachial and ulnar nerves are the most commonly missed. This block is therefore unsuitable for surgery confined to the medial side of the limb.

Technique: the insertion point is in the inferior part of the interscalene groove, posterior to the subclavian artery (palpable in only 50% of patients). A 50-mm needle is aimed directly caudally (Figure 3). There must be no medial angulation to avoid the needle passing the medial edge of the first rib and entering the pleura. The plexus is usually 2–3.5 cm below the skin. If paraesthesiae are used to identify the plexus, clear sensation must be elicited below the shoulder. Using muscle stimulation, a twitch should be evoked in muscles below the elbow. If the needle inserts on the first rib, it should be redirected anteriorly or posteriorly.

Complications: pneumothorax may occur, but is less likely with subclavian perivascular block than with the classical supraclavicular approach, in which the risk is 2–25%. It may not become apparent for 8–12 hours. Emphysematous bullae at the apex of the lung are contraindications to this approach.

If the subclavian artery is punctured, it is difficult to apply pressure. This block is therefore not recommended in patients with bleeding diatheses.

Phrenic nerve block is less common with this approach than with interscalene brachial plexus block.

In children under 12 years of age, the first rib is not fully calcified, and may not prevent the needle penetrating pleura.

Axillary block
The axillary approach is technically easier for beginners, and is associated with fewer major complications. It is also the easiest approach for catheter insertion, which facilitates prolonged analgesia and sympathetic blockade following major reconstructive surgery.

Technique: with the patient's arm abducted to 90°, a finger is placed over the pulsation of the axillary artery in the groove between the pectoralis major and latissimus dorsi muscles. A 25-mm needle is inserted adjacent to the fingertip and towards the apex of the axilla. The position of the needle tip may influence the scope of the block (Figure 4).

Axillary block requires a high volume of local anaesthetic. Applying digital pressure distal to the injection site encourages proximal spread. The musculocutaneous nerve leaves the sheath above the axilla, and is usually missed unless an additional 7–10 ml of local anaesthetic are injected into the coracobrachialis muscle.

Relationship of the needle to the axillary artery for preferential nerve block

Nerve preferred	Needle relationship to artery	
Median	Lateral	(above)
Ulnar	Medial	(below)
Radial	Posterior	(behind)

4

Identification

- Nerve stimulation: the success rate is higher (85–95%) if separate branches are located and individually blocked.
- Transarterial: depositing local anaesthetic behind and in front of the artery has a high success rate (90–99%).
- Click: a click is felt on passing through the perivascular sheath, accompanied by transmitted pulsation from the artery. It has a success rate of 50–80%.
- Paraesthesiae: the risk of nerve damage may be higher.

Vertical infraclavicular block

Infraclavicular approaches have not been widely accepted because it is difficult to determine the exact insertion point and the angle of advancement. However, the vertical infraclavicular block is an improvement. The insertion point lies immediately below the clavicle at the mid-point between the anterior surface of the acromion and the suprasternal notch. The stimulating needle is advanced directly posteriorly (i.e. vertically in the supine patient) until flexion or extension of the wrist or fingers is obtained (Figure 3).

Pleural puncture, though apparently inevitable, is highly unlikely provided that:

- the insertion point is not medial to that described
- there is no medial angulation while advancing
- the needle is no longer than 50 mm.

It is usually easy to define the landmarks, even in obese patients; and the patient's arm may rest on the abdomen during the procedure, which is more comfortable following trauma.

Theoretically, there is a higher chance of blocking all the nerves, but a large volume of local anaesthetic (50 ml) is required, because at this point the sheath is at its broadest in the sagittal plane.

As yet there are few studies evaluating the effectiveness and the risks of vertical infraclavicular block compared with more conventional approaches.

Intercostobrachial and medial brachial cutaneous block

The intercostobrachial and medial brachial cutaneous nerves supply the skin on the medial side of the upper arm, an important fact to remember if an upper arm tourniquet is applied. They are blocked by subcutaneous infiltration over the axillary artery. Because this block is required only for the duration of surgery, 1% prilocaine or 1% lidocaine (lignocaine) is ideal. However, the dose of 3 ml, which is often quoted, is inadequate; 10 ml over the artery, extending to the anterior corner of the axilla under pectoralis major and to the posterior axillary fold, allows comfortable tourniquet use for 90 minutes.

Nerve blocks at the elbow

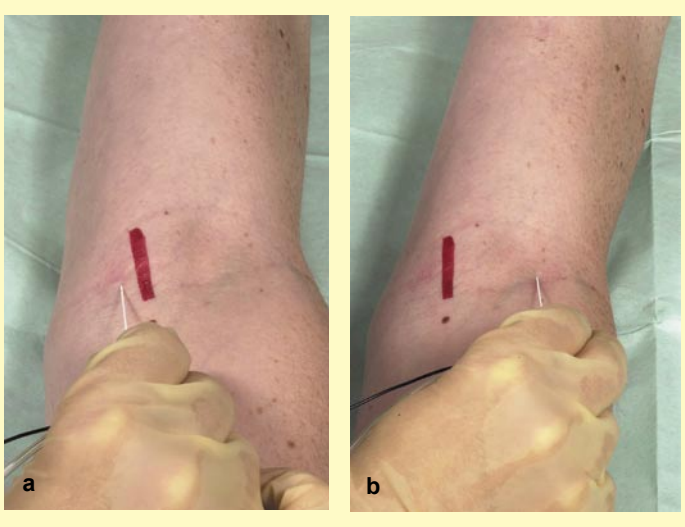
Nerve blocks at the elbow may augment an incomplete brachial plexus block and, using 0.5% bupivacaine, they can last for 12 hours or more. Except for ulnar nerve block for surgery to the little finger, they are not used as sole anaesthesia because:

- there are six nerves potentially requiring blockade, including sthe three cutaneous nerves of the forearm
- nerve distribution of the hand is variable with wide overlap
- there is no anaesthesia for an upper arm tourniquet.

Ulnar nerve passes between the medial epicondyle and the olecranon, in a tunnel formed by the two heads of flexor carpi ulnaris. It is blocked 2 cm proximal to this in order to minimize the risk of pressure neuropathy. Using a 25-mm stimulating needle, flexion of the little and ring finger or adduction of the thumb is sought. Wrist flexion should be ignored because this may be due to direct muscle stimulation. Only 3–4 ml of local anaesthetic is required.

Median nerve usually lies 1 cm medial to the brachial artery at the level of the intercondylar line (Figure 5). It is 0.5–1 cm deep to the bicipital aponeurosis. A 25-mm needle is inserted in a slightly cephalad direction until a 'pop' is felt as the aponeurosis is punctured. Flexion of the wrist or fingers indicates proximity to the nerve and 6–8 ml of local anaesthetic is injected.

Radial nerve may be blocked at the intercondylar level, in the groove between the biceps and brachioradialis muscles(Figure 5). If too distal, it is possible to block the deep (muscular) and miss the superficial (sensory) branches. The nerve is 2–3 cm deep and overlies the lateral epicondyle. Using a 50-mm stimulating needle, finger or thumb extension are sought. Direct muscle stimulation may cause wrist extension, which should be ignored. A local anaesthetic dose of 8 ml is sufficient.



5a Median and **b** radial nerve blocks anterior to the left elbow, showing insertion points at the intercondylar line. The surface marking of the brachial artery is drawn on the skin of the cubital fossa.

Nerve blocks at the wrist

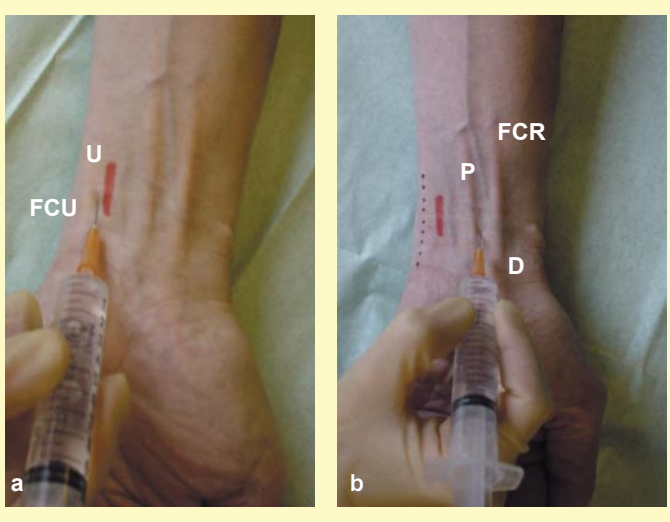
Nerve blocks at the wrist may be used for surgery on the distal palm or fingers, provided that a forearm tourniquet is suitable (the lower muscle mass reduces ischaemic tourniquet pain) and the maximum surgical time is 1 hour, because of the absence of anaesthesia for the tourniquet. Such nerve blocks are particularly suitable for day case surgery, because full arm control is maintained. Using 2% lidocaine (lignocaine), the onset of block is 5 minutes.

All three nerves are blocked 2 cm proximal to the distal skin crease of the wrist. Nerve stimulation is seldom successful. Consequently, the median and ulnar nerves are located by paraesthesiae using a 25 G needle. This makes the blocks unsuitable for anaesthetized patients or, arguably, for augmenting an incomplete brachial plexus block.

The nerve supply to the hand is variable. Furthermore the deep tissues of the hand do not reflect dermatomal distribution. The radial nerve is almost entirely cutaneous, while the ulnar nerve supplies deep tissues extending to the thenar eminence.

Ulnar nerve lies between the tendon of flexor carpi ulnaris and the ulnar artery (Figure 6). The needle is advanced with slight cephalad angulation until the patient feels paraesthesiae in the little or ring fingers. The needle is then withdrawn 1 mm and 3 ml of local anaesthetic slowly injected.

Median nerve is located deep to the flexor retinaculum, between the tendons of flexor carpi radialis and palmaris longus (Figure 6). In the absence of palmaris longus, the nerve is found 1 cm. to the ulnar side of flexor carpi radialis. The needle is advanced with slight cephalad angulation through the flexor retinaculum until the patient feels paraesthesiae in the thumb or index finger. After withdrawing 1 mm, 3 ml of local anaesthetic is injected. Because the superficial palmar branch arises proximal to the wrist, a further 3 ml of local anaesthetic is deposited subcutaneously.



6a Ulnar and **b** median nerve blocks of the left wrist. U, ulnar artery; FCU, flexor carpi ulnaris; FCR, flexor carpi radialis; P, palmaris longus; D, distal skin crease.

Superficial radial nerve divides 7 cm above the wrist. Using a 23 G long-bevelled needle, a subcutaneous weal of 6–8 ml of local anaesthetic is placed in a transverse line from the palmar edge of the radial styloid to the mid-dorsum of the wrist, taking care to avoid intravascular injection.

Day case surgery

The potential to avoid general anaesthesia, and thus minimize sedation and nausea postoperatively, makes regional anaesthesia attractive for day case surgery. Furthermore, it provides excellent postoperative analgesia. Selection guidelines for day surgery should be maintained, because failure of the block may necessitate general anaesthesia.

The techniques with lower risks include axillary brachial plexus block, wrist block and intravenous regional anaesthesia. Higher approaches to the brachial plexus are associated with more serious complications. With the interscalene brachial plexus block, complications are unlikely to occur more than 4 hours after the block is performed. This block is therefore excellent for major arthroscopic surgery of the shoulder as a day procedure. Pneumothorax resulting from other supraclavicular approaches may be delayed by up to 12 hours and these approaches may therefore be more appropriate for 23-hour stay procedures.

Anaesthesia for Bronchoscopy, Tracheal and Airway Surgery

Charles Gillbe
James Hillier

Charles Gillbe is Consultant Anaesthetist at the Royal Brompton Hospital, London. He studied at the University of Aberdeen and trained in Portsmouth and London. He is interested in most aspects of cardiac and thoracic anaesthesia. More recently he has become interested in the organization of training in anaesthesia and intensive care medicine.

James Hillier is Anaesthetic Specialist Registrar at the Imperial College School of Anaesthesia, London. He currently works at the Royal Brompton Hospital, and has an interest in cardiothoracic anaesthesia.

Flexible bronchoscopy is usually carried out under conscious sedation and topical local anaesthesia. The Academy of Medical Royal Colleges has published relevant procedural guidelines for flexible bronchoscopy.

Rigid bronchoscopy is performed to aid the diagnosis and management of transbronchial and pulmonary pathology, and, particularly in children, for the removal of inhaled foreign bodies. It is usually carried out under general anaesthesia.

Preoperative assessment: it is important to assess cardio-respiratory physiology, airway considerations, neck mobility and a history of smoking. Chest radiography for airway and pulmonary pathology is mandatory. Other investigations are clinically determined.

Induction: if the airway is patent, intravenous induction is used. Neuromuscular blockade is achieved with a drug chosen for an appropriate duration of action.

Bronchoscopy causes a profound vasopressor response that must be controlled, usually by short-acting opioids, short-acting intravenous β-blockade or magnesium sulphate. Remifentanil infusion combined with propofol or sevoflurane can provide good cardiovascular stability and rapid recovery.

Position: the patient is supine with the head resting on a single pillow. The eyes and vulnerable teeth or bridgework should be protected. As the bronchoscope is advanced it is usually necessary to extend the patient's neck.

Ventilation and airway management: the two ventilatory strategies used during bronchoscopy are a Sanders' injector or intermittent positive-pressure ventilation (IPPV) via the ventilating side-arm of the bronchoscope.

The injector uses a high-pressure oxygen supply to release a jet of oxygen from a needle at the operator end of the bronchoscope. This creates a Venturi effect, entraining atmospheric air, and provides an inspiratory gas mix of oxygen-enriched air. Using this technique it is essential that there is free passage of air from the upper airway, to enable entrainment of air and to allow passive expiration, thereby avoiding volutrauma.

The ventilating bronchoscope has a glass window or a rubber diaphragm to enable passage of instruments, and a side arm that can be connected to an anaesthetic circuit. Ventilation can be managed with an appropriate gas mix including a volatile anaesthetic agent. This technique is most commonly used in children and babies, hand ventilating via a T-piece.

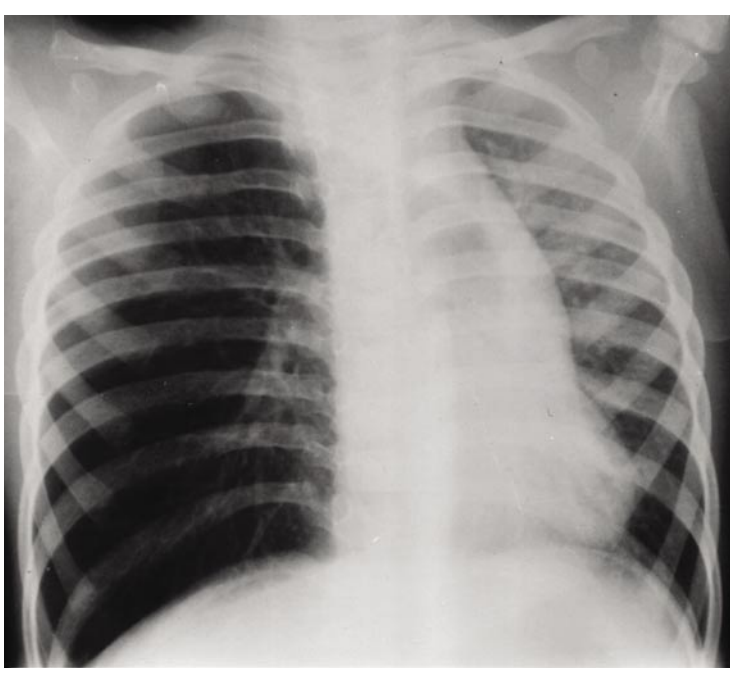
Maintenance of anaesthesia: the use of a Venturi injector necessitates an intravenous technique for maintenance of anaesthesia. Propofol is widely used and its rapid offset makes it an ideal agent in most cases. Whether intermittent boluses, infusion, or target-controlled infusion is used depends on individual preference. When a ventilating bronchoscope is used, a volatile agent can be used for maintenance of anaesthesia. Rapid emergence is desirable, therefore sevoflurane or desflurane are preferred.

Postoperative management: unless bronchoscopy is to be followed by a surgical procedure, a rapid emergence is desirable with airway reflexes and cough being restored. This allows secretions and blood to be cleared effectively.

Interventional bronchoscopy

Inhaled foreign body

An inhaled foreign body is most common in children under 3 years of age. It is not infrequent in the obtunded (e.g. in alcoholism) and may also occur in senile dementia. It may present in a number of ways from acute upper airway obstruction, to a more insidious presentation with a chronic cough, recurrent respiratory tract infections and unilateral wheeze, depending on where the foreign body lodges. Radiological examination may be normal, may reveal a radio-opaque foreign body or may show unilateral hyperinflation due to obstruction (Figure 1). An inhalational induction is traditional because IPPV may blow the foreign body distally into the smaller airways, or may cause a ball-valve effect, resulting in distal air trapping. The alternative school of thought is that any foreign body that requires bronchoscopic removal is impacted and unlikely to be displaced with IPPV. Intravenous induction, paralysis with suxamethonium, and passage of the bronchoscope provides the fastest, safest means to secure the airway. This approach relies on having a skilled bronchoscopist present at induction.



1 Plain chest radiograph of a 6-year-old child showing hyperinflation of the right lung caused by obstruction of the right main bronchus by a foreign body.

After removal, laryngeal stridor may develop because of repeated instrumentation of the airway. Intravenous dexa-methasone, 600 μg/kg/day in 4 divided doses, and nebulized adrenaline (epinephrine), 5 ml of 1:10,000, repeated every 2–4 hours, are normally sufficient to provide relief. In severe cases, re-intubation and a period of postoperative ventilation may be necessary.

Bronchoscopic stent insertion and tumour debulking

In critical stenosis, a tracheal stent can be sited, as palliation, or until definitive surgery is undertaken. Laser, diathermy and cryotherapy are used to debulk tumours obstructing the airway. Induction of anaesthesia may result in complete obstruction. The patient is preoxygenated, and anaesthesia induced cautiously by intravenous or inhalational means. Each technique has advantages and disadvantages. When an adequate depth of anaesthesia has been reached the airway should be assessed and ventilation taken over. It is essential that a skilled bronchoscopist is present: this may be the only way to relieve the obstruction if the airway is lost.

For laser resections, precautions must be taken to avoid airway fires .
- Use as low an inspired oxygen concentration as possible.
- Nitrous oxide should be avoided.
- Short bursts of laser should be used.
- All personnel should be trained in the use of the equipment.

Tracheal surgery

Tracheal surgery was first performed in the 1950s, and subsequent advances in anaesthetic and surgical practice have made increasingly radical resections possible. It may be possible to excise more than half the trachea. The challenges for the anaesthetist are:
- airway compromise
- airway sharing
- airway transection
- postoperative airway oedema.

Tracheal surgery requires close communication between anaesthetist and surgeon, and a planned strategy to deal with the airway and ventilation.

Indications: tracheal resection is indicated for stenotic or obstructive lesions of the trachea. Most commonly, these are benign strictures following intubation, or tracheostomy. The different causes of tracheal pathology are summarized in Figure 2.

Aetiology of tracheal pathology

Intrinsic tumours
Primary
- Malignant (adenoid cystic carcinoma, squamous cell carcinoma)
- Benign (neurofibroma, chondroma, chondroblastoma, haemangioma, pleomorphic adenoma)

Secondary
- Direct extension (thyroid, larynx, lung, oesophagus)
- Metastasis (lung, breast, lymphoma)

Inflammatory lesions
- Post-intubation
- Post-traumatic
- Post-infectious
- Burns
- Connective tissue diseases (systemic lupus erythematosus, Wegener's granulomatosis, amyloidosis)

Extrinsic lesions (NB not treated by tracheal resection)
- Goitre
- Vascular compression

Miscellaneous
- Sarcoidosis, osteoplastica tracheopathia, idiopathic

2

Preoperative assessment: in addition to cardiorespiratory assessment a full assessment of the site and extent of the stenosis is made. CT is the most useful investigation. In addition, pulmonary function tests provide functional information about the stenosis. It is important to assess neck movement because the neck is extended and flexed intraoperatively.

Induction: a selection of small tracheal tubes must be available, including uncuffed and armoured tubes. A surgeon must be ready with a rigid bronchoscope in case of obstruction. Intra-arterial monitoring should be established before induction, along with ECG, pulse oximetry and capnography. In cases of severe stenosis, induction should be performed cautiously, as described above. If the stenosis is less severe, intravenous induction can be performed safely and the bronchoscope inserted when the patient is paralysed.

Bronchoscopy is performed to assess the site and extent of the lesion and to assess the amount of healthy trachea proximal and distal to the lesion. Intubation is then performed. The tip of the tracheal tube should be above the lesion, unless the lesion is so proximal that the tube cannot be secured, in which case it should be passed beyond the stenosis.

Position: the position of the patient depends on the site of the lesion and the surgical approach. For high and mid tracheal lesions a collar incision is used with or without an upper sternotomy. The patient is placed supine with the neck in full extension. Before the anastomosis can be performed, the neck must be flexed to approximate the two ends. For low tracheal lesions the approach is via a right posterolateral thoracotomy incision, with the neck flexed. For carinal lesions a right posterolateral thoracotomy incision may be used, though a median sternotomy, or a clamshell incision may be chosen.

Ventilation and airway management

Many different ventilatory strategies have been used to deal with the problems associated with tracheal surgery. The site and extent of the lesion, and the preferences of the anaesthetist and the surgeon determine the technique used.

Manual jet ventilation: a Venturi injector can be used via a tracheal tube, bronchoscope, or small catheter to deliver oxygen and entrained air to the distal airway. This technique can be used for the entire procedure, but it is more often used during the period when the trachea has been transected, and the anastomosis created. To facilitate this, a small catheter is passed via the tracheal tube into the distal airway, to which the Venturi injector is connected.

Using this technique, the surgeon has good access to the surgical field, however, there are a number of disadvantages. Blood and debris can be sprayed across the surgical field or entrained into the distal airway. Manual jet ventilation often results in large tidal volumes, especially if too large an injector is used, causing volutrauma. If there is no route for egress of gas, barotrauma can result. Both of these are more likely if the catheter tip has migrated distally.

Mechanical jet ventilation may be used to provide a more controlled environment. There are several benefits to mechanical jet ventilation. Inflation pressures are lower than with conventional ventilation, but mean airway pressures are similar, which should decrease barotrauma and improve gas exchange through lung recruitment. It provides an unobstructed surgical field (as only a small catheter is passed into the distal airway), there is minimal lung expansion, or mediastinal movement, thus providing the surgeon with a quiet field, and because there is constant outflow of gas there is little chance of entrainment of blood or debris into the distal airways. However, if there is no route for free egress of gas from the lungs barotrauma will occur.

IPPV and distal tracheal intubation is the most commonly used technique. The trachea is intubated above the lesion. Once the trachea is opened the tracheal tube can be pushed across the lesion into the distal airway, or the surgeon places a sterile tracheal tube into the open distal trachea and the old tracheal tube is withdrawn into the proximal trachea. The diseased segment of trachea can be excised around the tracheal tube. To fashion the anastomosis it may be necessary to remove the tracheal tube for short periods of time. To facilitate these short apnoeic periods, ventilation should be with 100% oxygen during this part of the operation. When the posterior wall of the anastomosis is complete and the sutures are in place, the distal tracheal tube can be removed, the proximal tracheal tube carefully advanced across the anastomosis, and the anastomosis completed.

Other techniques: tracheal resection performed with the patient breathing spontaneously throughout the procedure has been described. However, there are many problems with this including the development of ventilatory acidosis, intraoperative coughing and aspiration of blood and debris into the distal airway.

Cardiopulmonary bypass appears to be a good way to ensure gas exchange and avoid the problems described above. However, it prolongs the procedure, has its own problems and is unnecessary. Systemic anticoagulation can cause bleeding, especially when the surgery is difficult.

Postoperative management
The anastomosis is protected from excessive traction. Guardian sutures are placed between the chin and the upper chest wall (Figure 3). This holds the neck in about 35° of flexion. They are left for 7–10 days, and is surprisingly well tolerated.

3 Guardian suture (arrowed) and minitracheostomy.

Several factors may compromise the postoperative airway. The trachea is oedematous and contains a vulnerable suture line. There may be a degree of soiling of the distal airway. The aims of early postoperative management are listed in Figure 4. ◆

Aims of early postoperative management

Early extubation
Positive-pressure ventilation and direct pressure from tracheal tube or its cuff may compromise the blood supply to the suture line

Clearance of secretions
- Humidification
- Physiotherapy
- Fibre-optic bronchoscopy
- Minitracheostomy

Decrease tracheal oedema
- Maintain a head-up position
- Nebulized adrenaline (epinephrine) and steroids (Note: these drugs may compromise anastomotic healing)

Anaesthetic Equipment for Thoracic Surgery

John W W Gothard
Tariq Hoth

John W W Gothard is Consultant Cardiothoracic Anaesthetist at the Royal Brompton Hospital, London. He qualified from St Mary's Hospital Medical School, London. He has written several textbooks on cardiac and thoracic anaesthesia and has a major interest in thoracic anaesthesia and anaesthesia for congenital heart disease.

Tariq Hoth is Specialist Registrar in the Intensive Care Unit at the Royal Brompton Hospital, London. He qualified in Germany and trained as an anaesthetist at the Imperial School of Anaesthesia, London.

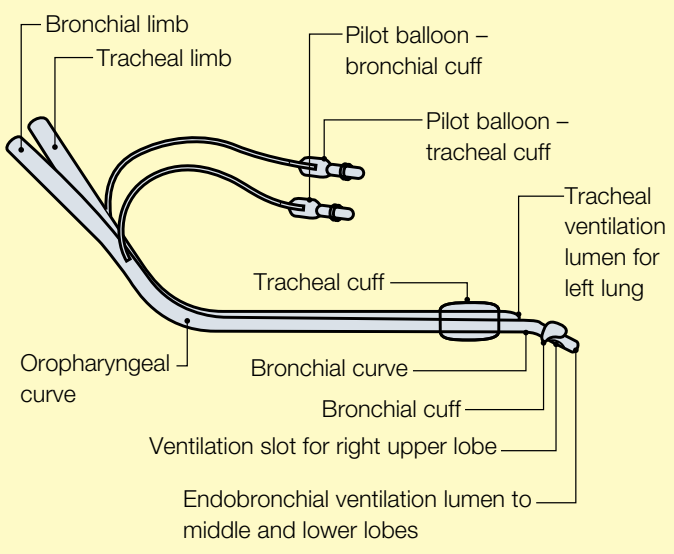
In 1931, Gale and Waters were the first to describe endobronchial intubation in clinical practice. Magill developed right and left single-lumen endobronchial tubes. Little changed until the introduction of the double-lumen endobronchial Carlens tube in 1949. This was initially used for differential broncho-spirometry but was adapted and used for selective ventilation during thoracic surgery; it is still used in some centres. It has a carinal hook, which in theory prevents placement of the tube too far distally but can also make laryngeal intubation difficult. Robertshaw, a Manchester anaesthetist, developed his own pattern of left and right double-lumen endobronchial tube in 1962. This design omitted the carinal hook of the Carlens tube and incorporated larger D-shaped lumina. The right-sided Robertshaw tube included a ventilation slot in the bronchial cuff to accommodate the early take-off of the right upper lobe from the main bronchus on this side.

In current practice, selective one-lung ventilation during thoracic surgery is most commonly achieved with a double-lumen endobronchial tube. These tubes also prevent spill-over of blood and infected secretions from one lung to another. Bronchial blockade can also be used to separate the lungs and there has recently been a resurgence of interest in this technique.

Double-lumen endobronchial tubes

Double-lumen tubes are similar to the original Robertshaw tube (Figure 1). In the UK, the two most widely used tubes are the Robertshaw (Phoenix Medical) and the Bronchocath (Mallinckrodt). Many other manufacturers (e.g. Rusch, Portex, Sheridan) also make double-lumen tubes.

Basic pattern of a right-sided double-lumen endobronchial tube



From: Gothard J W W. *Anaesthesia for Thoracic Surgery*. 2nd ed. Oxford: Blackwell Scientific Publications, 1993

1

Robertshaw tubes are available in four sizes ranging from large to extra-small. Bronchocath tubes are available in French gauge sizes of 35, 37, 39 and 41, with a small 28 tube for left endobronchial intubation only. Modern versions of both types of tube are disposable. The Robertshaw tube is made of rubber with a smooth outer coating, and the Bronchocath tube is made of polyvinylchloride (PVC). Both tubes are made in right and left forms, shaped to allow placement in the appropriate bronchus (Figure 1). There are two pilot balloons that allow inflation of tracheal and bronchial cuffs. The bronchial pilot balloons and cuffs are blue for easy identification. The right-sided Robertshaw tube has a ventilation slot built into the bronchial cuff. The equivalent Bronchocath tube has a ventilation slot distal to an eccentrically placed bronchial cuff. In general, the ventilation slot of the Robertshaw tube is larger than that of an equivalent size of Bronchocath tube and there is evidence that right upper lobe ventilation can be achieved more reliably with the Robertshaw tube.

Type and size of tube

It is preferable to use a left-sided double-lumen tube where possible. In UK practice, a right-sided tube is used if lung resection is to be undertaken on the left. In most other instances, including video-assisted thoracic surgery, a left-sided tube is used to obviate the problem of right upper lobe ventilation.

The size of tube selected and the insertion depth depend on the height, weight, body build and gender of the patient. Cohen has stated (see Further Reading) that a 37 FG tube can be placed in most women, while a 39 FG tube is used in the average man. However, the problem is not quite so simple. Bronchocath tubes are long and not designed to be inserted to 'the hilt'. Robertshaw tubes are designed to be inserted so that the bite-block (above which the tracheal and endobronchial portions separate) is approximately at the level of the patient's teeth. Even with this design feature, a large Robertshaw tube can easily be advanced too far in a large patient with a short neck so that an upper lobe is occluded. It has been suggested that a double-lumen tube should be inserted to a depth of 29 cm (from the teeth) in men and women 170 cm in height and that this depth should be increased 1 cm for each 10 cm increment in height of the patient.

The solution to these problems is to use a fibre-optic bronchoscope to check the position of the double-lumen tube.

Placement and position check

Double-lumen tubes are inserted into the airway using standard laryngoscopy with the tip of the tube pointing anteriorly/upwards. Once past the vocal cords the tube is rotated to the appropriate side and advanced until it is in place. The tracheal cuff is then inflated and the seal checked. The tracheal limb of the tube is then opened to air, via the upper suction cap, and the appropriate catheter mount clamped, leaving only the bronchial limb ventilated. The bronchial cuff is then inflated with the minimum amount of air to ensure cuff seal. Any gas leak should be eliminated from the intubated bronchus. This is detected as gas passing up the open tracheal limb. It should be remembered that bronchial rupture has been reported with double-lumen tube insertion, particularly on the left side.

Correct positioning of the tube is confirmed by auscultation and observation of chest movements. Particular attention should be paid to the ventilation of the upper lobe zones, which can easily be obstructed by a misplaced tube. In addition, the above checks should be repeated after positioning the patient for surgery. Double-lumen tubes are also known to migrate intraoperatively because they soften at body temperature and if the airway is handled surgically. An increased airway pressure or change in flow/volume loop configuration may warn of this occurrence before arterial desaturation.

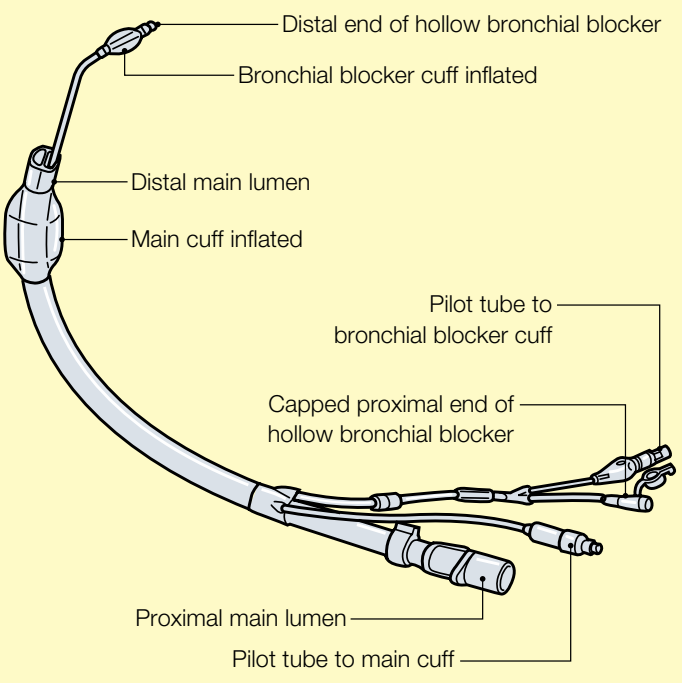
Bronchial blockade

Bronchial blockers have been used intraoperatively for many years to block individual lobes and to facilitate one-lung ventilation by blocking a main bronchus. Several devices, including Fogarty embolectomy catheters and urinary catheters, have been used as improvised bronchial blockers. There has been a renaissance in interest in using bronchial blockade over the last decade, particularly in Japan and North America. This has led to the development of a combined tracheal tube and bronchial blocker, the Univent tube, and the commercial availability of single endobronchial blockers such as that developed by Arndt.

The Univent tube

The Univent tube comprises a tracheal tube with a bronchial blocker (Figure 2). It was introduced into clinical practice by Inoue in 1982 and is probably the most commonly used blocker.

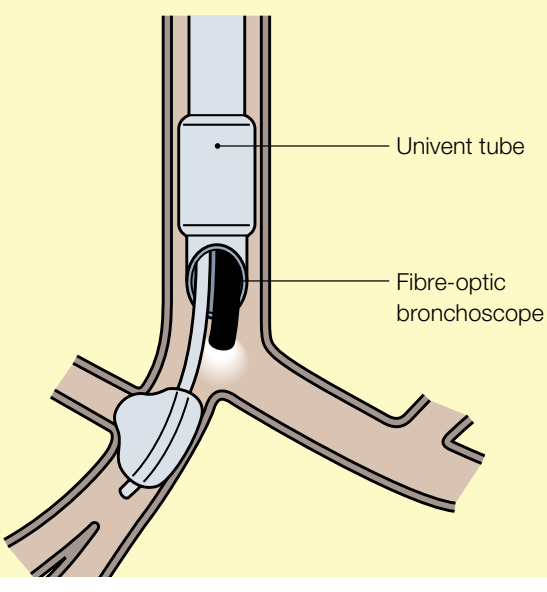
Univent tube – combined tracheal tube and bronchial blocker



2

The tube is made in a variety of sizes. It comprises a tracheal tube with a moveable blocker inserted through the anterior wall. The tube is placed in the trachea in the usual way and the blocker advanced, preferably under fibre-optic bronchoscopic control, to block the appropriate main or lobar bronchus (Figure 3). This blocker has the advantage that individual lobes can be blocked, but other potential advantages seem theoretical (Figure 4).

Bronchial blockade of the right upper lobe achieved with a Univent tube under fibre-optic bronchoscopic control



3

Advantages and disadvantages of the Univent tube

Advantages
- Lobar blockade possible
- Ease of use for difficult intubation
- Facilitates easy suction of secretions
- Eliminates tube change if ventilation required postoperatively

Disadvantages
- Less versatile than double-lumen tube
- Blocker can migrate
- More expensive than double-lumen tube
- Inflation/deflation of lung more difficult

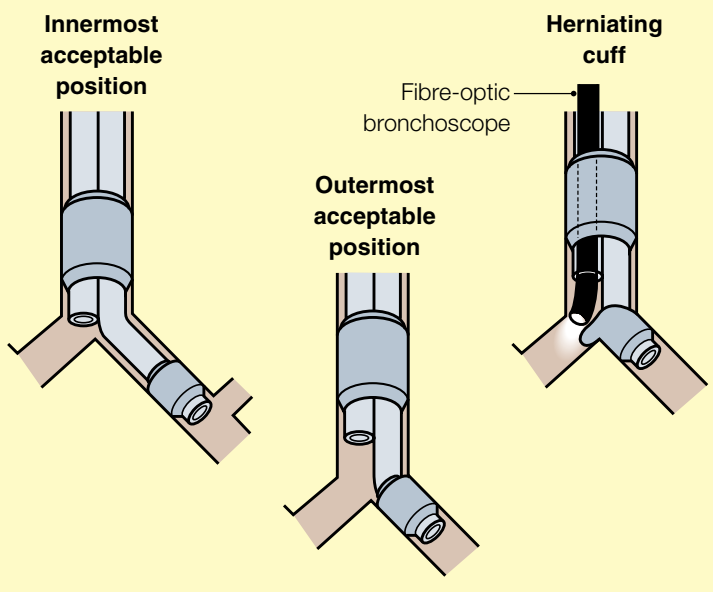
4

Fibre-optic bronchoscopy

Fibre-optic bronchoscopes and multi-purpose fibre-optic anaesthetic laryngoscopes (e.g. Olympus LF-2) are readily available. Therefore, it is easy to perform routine direct-vision assessment of endobronchial tube and bronchial blocker placement. The introduction of robust paediatric fibre-optic bronchoscopes (e.g. Olympus LF-P) allows this to be carried out with the smallest tubes.

The fibre-optic bronchoscope can be used at the utset of a procedure to aid in a difficult laryngeal intubation or it can be used to 'rail-road' an endobronchial tube into the appropriate bronchus under direct vision. More often it is used to check the position of double-lumen tubes following blind placement (Figure 5). Some authors consider this step to be mandatory.

Fibre-optic bronchoscopy used to check the position of a left-sided double-lumen tube



5

A previously placed double-lumen tube is checked by first passing the fibre-optic bronchoscope down the tracheal lumen to ensure a clear view of the non-intubated bronchus (i.e. no cuff herniating across the carina). It is then passed down the bronchial lumen to ensure that the left upper lobe is not obstructed or, alternatively, that the ventilation slot in a right-sided tube is opposed to the right upper lobe orifice. These checks should be repeated if the tube is repositioned and after the patient has been turned into the lateral thoracotomy position. Fibre-optic bronchoscopy may also become necessary if ventilation problems occur intraoperatively. It is essential to maintain and observe full monitoring of the patient during fibre-optic bronchoscopy.◆

Interpreting the Chest Radiograph

Ian J Runcie

Ian J Runcie is Consultant Radiologist at the Princess Royal Hospital and the Ashdown Nuffield Hospital, Haywards Heath, UK.

A system for looking at the film

Identification: check name and side marker are present.

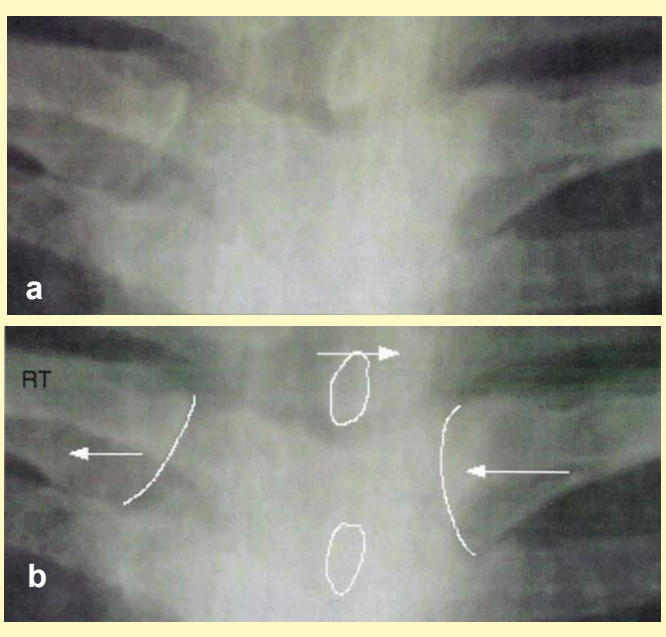
Film quality: an indication of how precise is the information on the film.

Penetration – a good film allows the localization of one or two thoracic disc spaces.

Inspiration – following good inspiration the diaphragm is normally at or near the level of the posterior 10th rib. The right diaphragm is usually higher than the left.

AP or PA, supine or erect – the radiographer should mark how the film has been taken. AP films have the scapula and magnified heart projected over the lung fields and heart size cannot be assessed. Most portable and all supine films are AP. Supine films show less of the lung fields and the mediastinum appears wide: it is pointless trying to decide if a patient has an aortic dissection on a supine film. Interpretation of a film of a patient with a marked kyphosis suffers from similar difficulties.

Centring – allow for rotation before evaluating mediastinal and tracheal shift by examining the relationship between the medial ends of the clavicle and the posterior spinous process. The side to which the patient is rotated usually becomes more translucent (black). But there are exceptions and marked degrees of rotation are required to produce significant changes in radiographic density (Figure 1).



a Patient rotated towards her right. **b** The medial ends of the clavicles and the spinous processes are outlined with their apparent direction of movement. The mediastinum and trachea being anterior structures move in the same direction as the clavicles.

1

Bones: start checking from the outside (i.e. humeri, shoulders, clavicles). Note if there are any secondaries, fractures or arthritis. Is the spine straight?

Ribs – look through the heart to where the ribs meet the spine. Check the lateral chest wall and the anterior end of each rib. Compare the two sides all the time. Many prefer to examine each rib as a whole but it is possible to miss one unless care is taken.

Soft tissues: briefly examine the muscles of the chest wall and note any surgical emphysema. The trachea should be central or it may be pushed slightly to the right of the midline in patients with aortic dilatation. Note the size, shape and position of the mediastinum and hila. Note any discrepancy of height in the diaphragm and examine the area below.

Lung fields: compare the two sides by mentally dividing them into six parts (i.e. right and left upper mid and lower zones). Go back to the difficult areas: apices, costophrenic angles, hila and through the heart. There is a lot of lung behind the heart. Note the position and thickness of the horizontal fissure which normally extends out from the centre of the right hilum.

Mediastinum

Cardiac shadow (Figure 2) – on a PA film the maximum width of the heart shadow compared with the maximum width of the combined lung fields approximates the cardiothoracic (CT) ratio. It is normally below 50% but can be up to 60% in elderly patients. The true CT ratio is the sum of maximum distances from the centre of the heart shadow to each heart edge over the maximum external bony thoracic wall.

2 A three-dimensional CT cardiac angiogram showing the approximate outline of the cardiac shadow. The anterior portions of the right atrium and right ventricle have been removed.

Assessment of chamber size is best done by echocardiography but the classic chest radiograph signs of left atrial enlargement are accurate (double right heart border, infilling of the concavity between the aortic knuckle and the pulmonary artery and splaying of the carina).

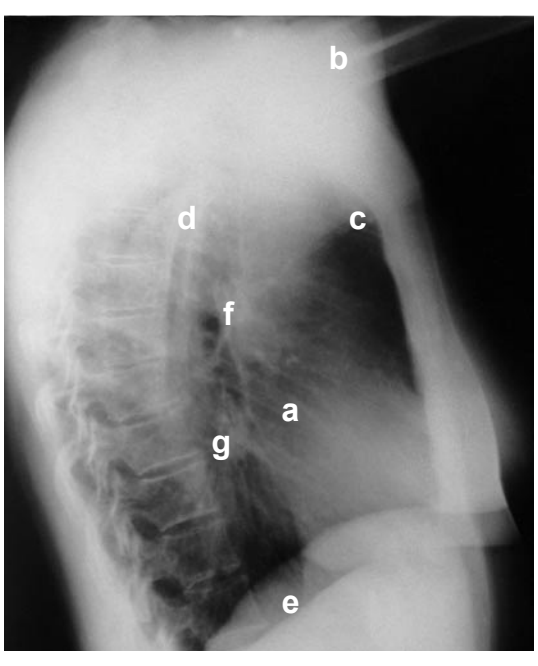
The hila are central mediastinal structures and the hilum on the side to which rotation has occurred may become obscured by the heart shadow. The anatomy of the pulmonary vessels is such that the left hilum is the higher. If this is reversed or if they are at the same level there is likely to be some collapse.

The diaphragm is normally at the level of the 10th posterior rib but the position is variable and its height depends on several factors, including the radiographic technique. It is a thin structure (3 mm) and if it appears to be thicker than this then the gas apparently delineating its lower surface is probably in the gut.

Lung fields should be of similar density. The basal arteries should look notably thicker and longer than those to the upper zones. The horizontal fissure should be at the level of the right hilum and is normally very thin. Bronchial walls, if seen at all, should be thin and restricted to the perihilar regions. Any measurable thickness indicates peribronchial thickening.

Only gross cases of vascular redistribution, plethora, air trapping and bronchiectasis are likely to be diagnosed with certainty. Low flat diaphragms may indicate emphysema but can also be produced by a massive breath in. About 10% of patients with pulmonary emboli have normal chest radiographs.

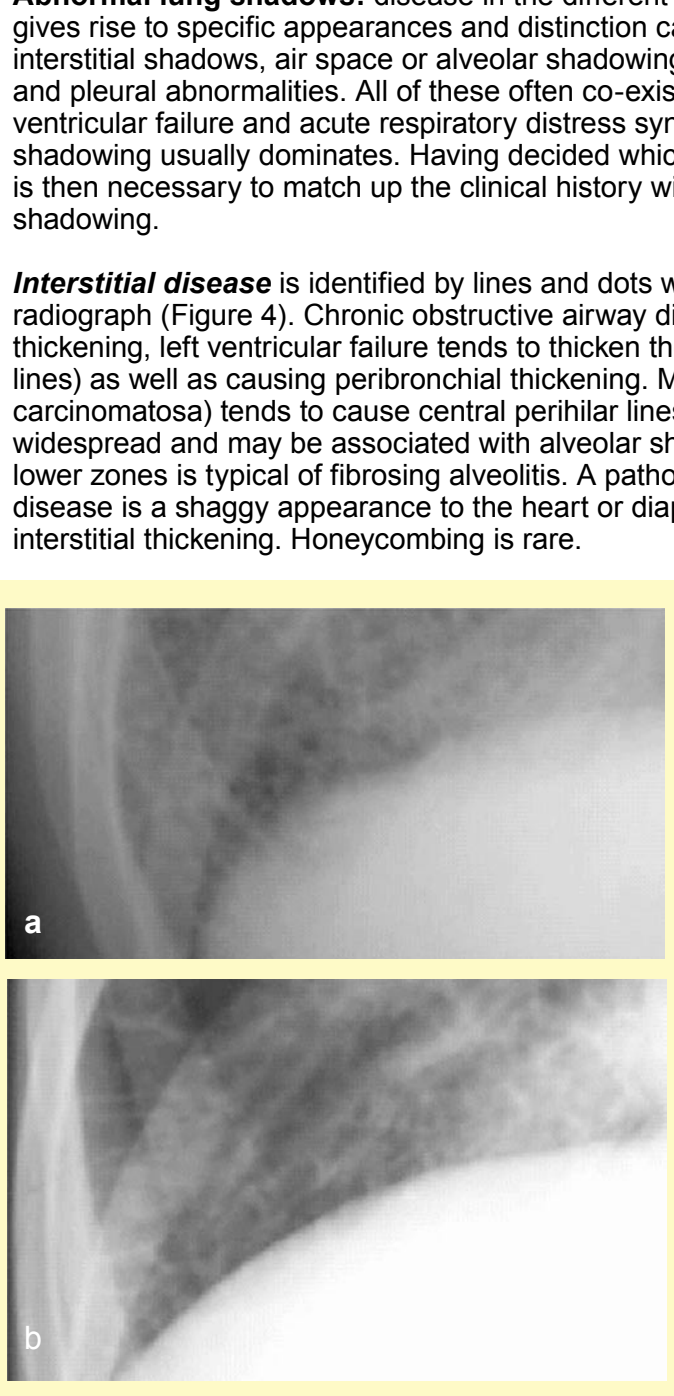
The lateral radiograph is sometimes helpful in the further localization of pathology (Figure 3). It may identify small effusions or basal pneumonia not seen on frontal chest radiographs. Good knowledge of the anatomy as seen on the lateral view is helpful in interpreting the frontal view. Posteriorly the lung is darkest just above the diaphragm. If not, there is probably some basal pathology, either an effusion or posterior consolidation. The shadows of the humeri, glenoids and scapulas can occasionally be misinterpreted. Look at the diaphragms. Note that you can see almost the whole length of the right one but not the anterior end of the left where it comes up against the heart.



3 Normal lateral chest radiograph. **a** Oblique fissure; **b** humerus; **c** soft tissue of arm; **d** scapulas (anterior borders); **e** inferior vena cava (posterior border); **f** hila; **g** confluence of pulmonary veins.

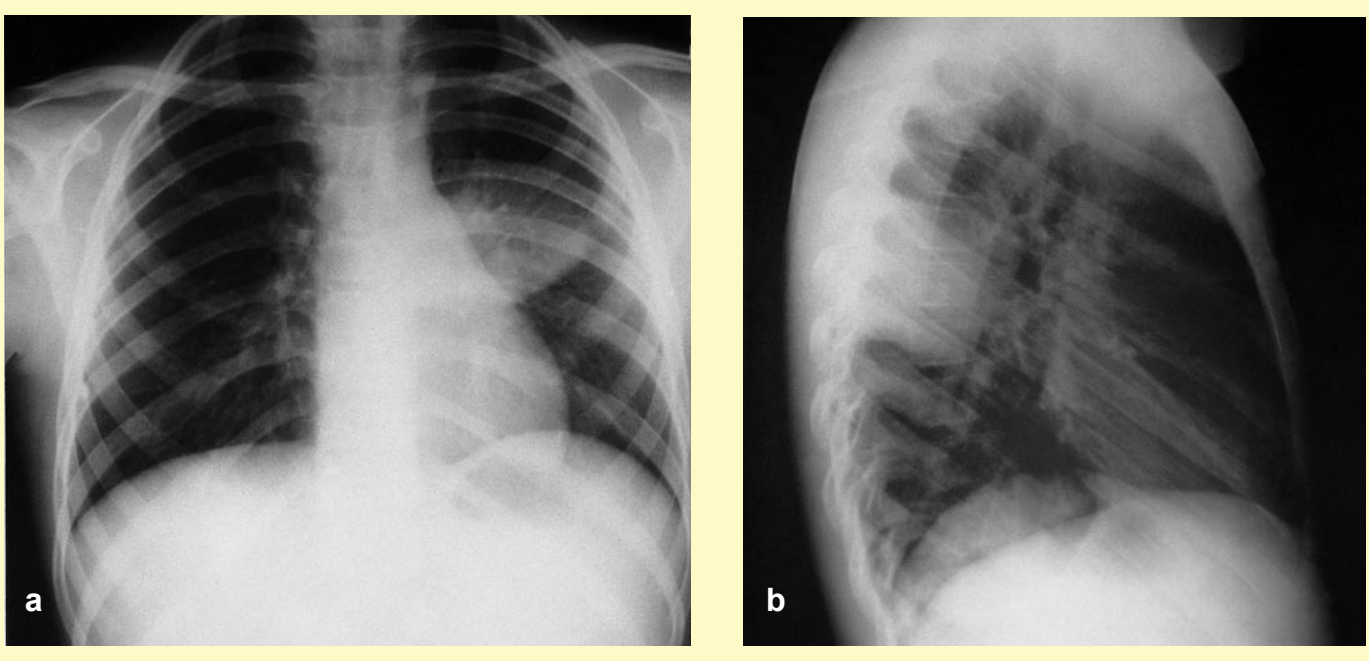
Abnormal lung shadows: disease in the different anatomical divisions of the lung gives rise to specific appearances and distinction can usually be made between interstitial shadows, air space or alveolar shadowing (often called consolidation) and pleural abnormalities. All of these often co-exist for example in pneumonia, left ventricular failure and acute respiratory distress syndrome (ARDS), but one type of shadowing usually dominates. Having decided which of these you are looking at, it is then necessary to match up the clinical history with the type and distribution of the shadowing.

Interstitial disease is identified by lines and dots with variable distribution on the radiograph (Figure 4). Chronic obstructive airway disease (COAD) causes peribronchial thickening, left ventricular failure tends to thicken the peripheral interstitium (Kerley B lines) as well as causing peribronchial thickening. Malignant involvement (lymphangitis carcinomatosa) tends to cause central perihilar lines. Drug reactions are often widespread and may be associated with alveolar shadowing. A reticular pattern in the lower zones is typical of fibrosing alveolitis. A pathognomonic appearance of interstitial disease is a shaggy appearance to the heart or diaphragm caused by adjacent interstitial thickening. Honeycombing is rare.



Two patients with interstitial shadowing. **a** Fibrosing alveolitis with the typical shaggy diaphragm. **b** Interstitial pulmonary oedema showing Kerley B lines. Note the relatively sharp diaphragm.

Alveolar shadowing – 'fluffy' shadows tending towards coalescence and fading away at the edges except where bounded by a fissure. Any shadowing with a sharp edge at a fissure or with a clear lobar or segmental distribution must be alveolar (Figure 5). Soft tissue borders adjacent to the shadowing are lost but any air-containing spaces in the shadowing are outlined and air bronchograms are a characteristic feature. Distribution of the alveolar shadowing is helpful. A lobar distribution suggests pneumonia. Central positioning suggests left ventricular failure or fluid overload. Widespread and changing alveolar shadowing may indicate opportunist, including fungal, infection.



5

a Consolidation adjacent to the upper left heart border; the heart border remains visible. This means that the consolidation must be posterior. **b** The consolidation is posterior, overlying the vertebral bodies. The consolidated segment is below the level of the oblique fissure and therefore must be in the apical segment of the lower lobe. If it were above the oblique fissure it would be in the posterior segment of the upper lobe.

Pleural fluid causes loss of the costophrenic angles and a homogeneous basal shadow with a concave upper border on the erect view; there may be thickening of the horizontal fissure. Smaller amounts of fluid may be seen on the lateral view in the posterior costophrenic recess.

Masses – check the size and whether they are well or ill defined. Ill-defined, spiculated masses are usually primary tumours. Note any other lesions and any adjacent pathology (e.g. collapse or overlying rib destruction). Thick walled cavitation suggests an abscess or tumour. Multiple cavities suggest abscesses or infarcts. Note whether a peripheral lesion is pulmonary or pleural. A lung lesion adjacent to the chest wall has a concave border. Check the bones to exclude secondaries.

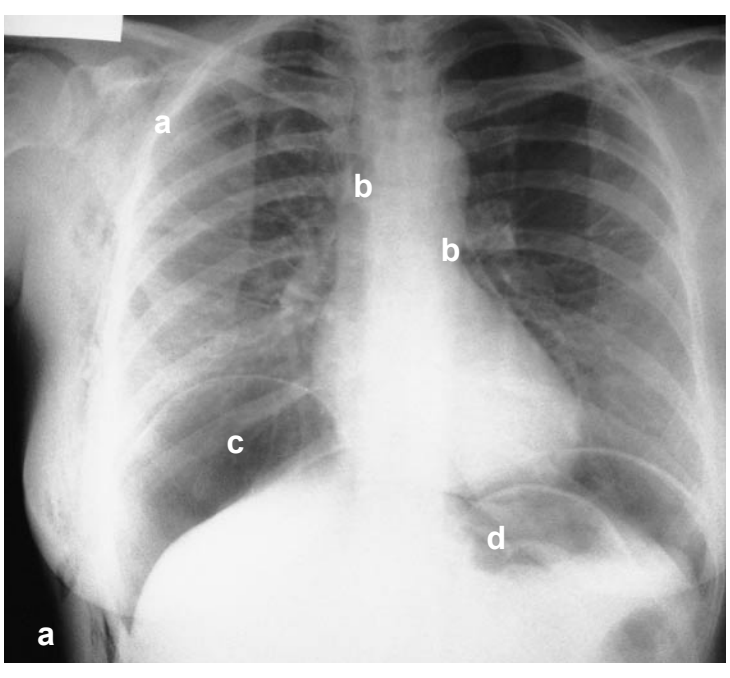
Emphysema produces bullae, low flat diaphragms (below the anterior 7th rib), lack of peripheral vessels and an increase in the branch angles of the arteries. Other pathology (e.g. left ventricular failure) may be difficult to identify.

The ICU film

The problems associated with supine and portable films are exacerbated by the condition of the patients in ICU. Patients are usually unable to cooperate and their lungs are often poorly compliant, causing unusual appearances to familiar pathologies. The information gained from a single ICU film may be limited. This may be counterbalanced by the availability of serial, usually daily, films allowing the progression of changes to be recognized.

Abnormally placed gas

The appearances of surgical emphysema and pneumo-mediastinum (recognized by air outlining the upper mediastinal structures) may indicate the presence of an unrecognized pneumothorax or possibly a pneumoperitoneum (Figure 6).



6 Patient with a massive pneumoperitoneum in whom the gas has tracked up behind the crura into the mediastinum and out through the thoracic inlet to cause surgical emphysema. **a** Surgical emphysema; **b** air in mediastinum; **c** diaphragms; **d** bowel wall.

Pneumothorax in the supine ICU patient seldom conforms to the classic appearance of a thin apical or upper zone line with no lung markings peripherally. A white line may be seen adjacent to the mediastinum or roughly parallel to the chest wall, or parts of the mediastinum may appear 'sharper' than usual. There may be no radiological evidence of a pneumothorax and a high degree of suspicion is necessary.

Pneumopericardium is recognized by the presence of air completely surrounding the heart shadow. It is usually benign except for the rare cases of tension but may point to the presence of serious pathology (e.g. fistulas, infection).

Pleural fluid

Pleural fluid in the supine or semi-erect patient lies over the posterior chest wall and does not have the familiar clear-cut upper edge. Usually a veil of increased density is seen in the lower parts of the lung fields. It may be distinguished from alveolar shadowing because the basal pulmonary vessels may be seen, and by the lack of an air bronchogram. However, the two pathologies often coexist. Ultrasound shows effusions well and can be used to guide drains if necessary. The sudden appearance of an effusion in a patient without fluid overload may suggest a haemothorax. Loculated effusions may show as well-defined masses or thickening of fissures and should raise suspicions of an empyema or bleeding. A fluid level going straight across the lung field on an erect film indicates fluid and air in the pleural space.

Alveolar shadows

Alveolar shadows can be associated with infection, pulmonary oedema, aspiration, contusion and ARDS.

Infections – a lobar or segmental distribution suggests lobar pneumonia. More diffuse shadowing in an immunocompromised patient suggests opportunist infection, including fungi. Persistent upper zone shadowing in association with cavitation and fibrosis may indicate tuberculosis. Cavitation anywhere could mean specific organisms (e.g. tuberculosis, *Staphylococcus, Pneumococcus*). Multiple 1–2 cm cavities suggest septic emboli.

Lung oedema is diffuse if linked with left ventricular failure, fluid overload and freshwater drowning. It may be localized following aspiration and linked to other changes (e.g. atelectasis).

Contusion may be localized to the site of injury and show progression for some days following the injury. Pulmonary haemorrhage can be diffuse and indistinguishable from pulmonary oedema.

ARDS can mimic almost any other acute condition. Radio-logically it is best identified by its relentless progression from central pulmonary alveolar shadowing to more generalized and persistent coverage of the whole lung.

Atelectasis varies from complete collapse of a lung as evidenced by massive mediastinal shift to the side of the collapse to small often temporary white lines in subsegmental atelectasis. It is seldom associated with demonstrable mucus plugging. The appearances of lobar collapse are discussed on page 375.

Lines

Radiographers should be informed if the chest radiograph is required for a specific line or tube because they may be able to vary the technique and may repeat the film automatically if the line is not shown well. Regarding line insertion, ultrasound measurements have shown that raising the patient's feet produces just as much jugular vein dilatation as tipping the patient head down.

A tracheal tube should be at least 5 cm above the carina because flexion or extension of the head can move it by as much as 4 cm. A small pneumomediastinum or surgical emphysema is not uncommon following the insertion of a tracheostomy tube.

On the chest radiograph a subclavian line can be expected to be entering the subclavian vein at the lateral edge of the first rib, the brachiocephalic vein at the sternoclavicular joint and the superior vena cava at the first anterior intercostal space. Common malplacements are upwards into the jugular vein and across the midline into the opposite brachiocephalic vein. A medially placed deviation at its lower end may indicate placement into the right ventricle. Rarely, the catheter can enter the azygos vein or the internal mammary vein, producing a localized kink near the superior vena caval origin.

Pneumothorax is the most common complication of line insertion. Complete malposition into the mediastinum is uncommon; it rapidly results in mediastinal widening and loculated pleural effusions.

A line that shows a small kink or a gentle deviation at its distal end may be up against the vessel wall with the potential of erosion. This particularly applies to pulmonary artery occlusion catheters in the relatively thin pulmonary arteries in the presence of pulmonary hypertension. The rare complication of catheter breakage should be dealt with as soon as possible, preferably by an interventional radiologist. Such large emboli can drift peripherally with time and can erode vessels rapidly, particularly in the pulmonary circulation.

Most pacemaker wires are inserted into the subclavian vein and directed into the apex of the right ventricle. A lateral view shows the distal end of the correctly placed wire coursing anteriorly. The course of the wires should be smooth on both the AP and lateral views and any localized kinks are suspicious. The most common site of wire fracture is between the clavicle and the first rib, usually well seen on the frontal view. Myocardial perforation can occur at the time of insertion. This may be seen as the tip of the wire being outside the cardiac silhouette but may not be obvious in the plane of a single film and is best identified by echocardiography. The pacemaker can continue to work satisfactorily in this situation.

Nasogastric tubes have holes along their distal 10 cm and need to be well into the stomach to stop gastro-oesophageal reflux occurring via these holes. They can enter the bronchial tree but bizarre-looking 'malplacements' are usually caused by the presence of a hiatus hernia rather than by oesophageal rupture.

CT (Figure 7) is useful in ICU patients, but requires planning and involves a demonstrable risk. The following are easily identified and localized: effusions, drains, pneumothoraces, pulmonary parenchymal disease including emphysematous changes and interstitial disease, tumours including secondaries, and pulmonary emboli up to second or third branch level. ◆

Pathophysiology of Respiratory Disease and its Significance to Anaesthesia

Brian Keogh
Nuala Lucas

Brian Keogh is Consultant in Anaesthesia and Intensive Care at the Royal Brompton Hospital, London. He graduated from Sydney University.

Nuala Lucas is Specialist Registrar at the Imperial School of Anaesthesia, London. She graduated from University College and Middlesex School of Medicine, London.

Many patients with respiratory disease present for anaesthesia. The patient's current status, in relation to their best personal baseline symptoms, quality of life and spirometry values, should be determined. If patients are at their best level, it is unlikely that they will be greatly improved by pre-surgical modification of therapy. However, recent exacerbations of airway disease, pulmonary infection or an increase in sputum production should be treated aggressively and new symptoms must be investigated.

Clinical examination should elicit signs of airway obstruction (inspiratory and expiratory), tachypnoea, dyspnoea or the use of accessory muscles, a 'barrel' chest and cyanosis. In patients ASA III or higher, or with dyspnoea, arterial blood gases should be measured in addition to non-invasive oximetry to determine the presence of elevated resting $PaCO_2$ levels. A recent chest radiograph is mandatory and in patients with borderline cardiopulmonary function, particularly with non-homogeneous pulmonary pathology, a CT scan may direct care.

Cardiac co-morbidity is common in patients with respiratory disease. ECG is mandatory and echocardiography should be performed in patients with advanced pulmonary disease to assess right ventricular function and the degree of secondary pulmonary hypertension. New or recent exacerbations of chest pain require specialist cardiological assessment. Guidelines for cardiac risk stratification in patients undergoing non-cardiac surgery have been published and should be incorporated into preoperative risk evaluation and the process of informed consent.

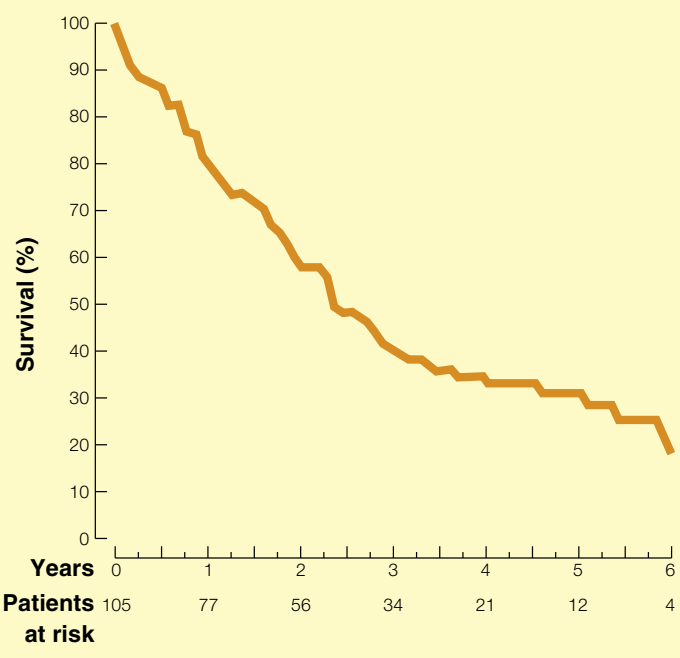
Chronic obstructive pulmonary disease (COPD)
Patients with COPD have alveolar emphysema and chronic airway inflammation. Patients with predominantly emphysematous changes exhibit lung hyperinflation with moderate derangement of gas exchange, while those with more severe airway inflam-mation are more likely to develop severe hypoxaemia, CO_2 retention and secondary pulmonary hypertension.

Emphysema results in increased lung compliance, decreased elastic recoil and closure of small airways in expiration, thus increasing both functional residual capacity (FRC) and residual volume (RV). Effort-independent expiratory flow limitation results, though inspiratory flow rates may be normal, and is exacerbated by airway constriction or oedema and mucous plugging. Chronic bronchitis (large airways) and bronchiolitis (terminal bronchioles) result in airway obstruction due to mucus, airway oedema or mucous gland hypertrophy, smooth muscle contraction and fibrosis induced airway distortion. Large airway changes have little effect but chronic bronchiolitis causes increased airway resistance, both in inspiration and expiration, resulting in locally reduced ventilation, reduced V/Q ratios and alveolar collapse leading to characteristic hypoxaemia of chronic airway inflammation.

Effect of anaesthesia: patients with severe COPD are at risk of exacerbation of V/Q mismatch under anaesthesia. Airway closure occurs at higher lung volumes and airway resistance is increased. Controlled ventilation is usually required but increases physiological dead space and may lead to inadvertent gas trapping in emphysema patients. Expiratory time should be set to allow for prolonged exhalation. Bronchodilator properties of volatile agents have little effect in COPD. Hypoxaemia is relatively uncommon in the ventilated patient with chronic bronchitis but may be a feature of induction and emergence. In such patients, continuous positive airway pressure in the recovery phase may be beneficial. Coughing and effective physiotherapy must be facilitated by effective postoperative analgesia.

Outcome: patients with COPD are two to five times more likely to suffer postoperative pulmonary complications, depending on the severity of disease. Patients with FEV_1 less than 1 litre are at high risk and likely to require high level postoperative care, especially if they exhibit resting CO_2 elevation (> 6.5 kPa) and FVC is less than 50% of that predicted. A recent study of patients with severe COPD (FEV_1 < 1.2 litre, FEV_1/FVC < 75%) undergoing non-cardiothoracic surgery revealed 6.6% mortality but disappointing survival rates (53% at 2 years, 30% at 4 years) – lower than longitudinal studies of COPD patients without surgery (Figure 1).

Long-term survival of patients with severe COPD



Observed survival rates in 105 patients (53 general, 52 regional or local). The higher mortality, compared with COPD without surgery, was thought due to effects of anaesthesia and surgery, or the underlying disease for which surgery was requried.

1

Perioperative interventions: there is little specific information on the efficacy of widely practised preoperative therapy. Patients who are not at their best baseline level should undergo aggressive preoperative optimization and surgery should be deferred until this is achieved. Data from the 1970s suggested that combinations of bronchodilators, antibiotics, physiotherapy, smoking cessation and corticosteroids could reduce the incidence of postoperative pulmonary complications in COPD patients.

Currently, combined nebulized inhaled β_2-agonists and ipratropium bromide are recommended, with additional inhaled steroids (e.g. budesonide) if there is a reversible airway component. A short course of systemic steroids may be effective in patients who do not achieve best personal baseline with bronchodilator therapy, although this potential benefit must be balanced against the risk of administering preoperative steroids. Causative organisms in pulmonary infection should be identified and directed antibiotic therapy instituted. Empirical antibiotic therapy in patients with increased sputum production is often recommended but remains controversial.

Intensive preoperative chest physiotherapy has been shown to reduce the incidence of postoperative complications in COPD patients, particularly in those who produce considerable sputum. Nutritional status is often poor in COPD and short-term benefits can be gained with preoperative supplements, even for 2 weeks.

Asthma
Asthma pathophysiology combines increased airway smooth muscle contraction, airway wall inflammation and oedema and mucous plugging due to increased production of tenacious mucus. Air flow resistance is consequently increased and maximum expiratory flow rates decrease. Pulmonary hyper-inflation occurs with an increase in FRC and RV.

Anaesthesia: asthmatic patients should be free of wheezing, be near to their best value peak flow rate and at least 80% of predicted values. Patients who are unstable or poorly compliant with therapy should be admitted for a period of supervised nebulized therapy. In brittle or resistant asthmatics, short courses of systemic steroids may be administered preoperatively and current evidence suggests that this is not associated with an increase in complications, particularly wound infections.

Volatile agents decrease airways resistance in asthmatics and halothane has been used therapeutically for this. Among the agents in widespread use, isoflurane has been most extensively investigated and has favourable bronchodilator properties. Well prepared, known asthmatics infrequently cause major difficulties and the incidence of clinically significant bronchospasm is less than 10%. More dangerous is the previously unrecognized asthmatic who unexpectedly develops severe acute asthma perioperatively. The American Closed Claims Project reported that, in 40 such patients, of whom 33 had died or sustained neurological damage, 50% had no history of asthma.

The principles of management of a severe asthma attack include nebulized and intravenous bronchodilators, cortico-steroids and volatile anaesthetic agents and cardiovascular support. In severe cases, adrenaline (epinephrine) infusions may be required to break the bronchospasm and both ketamine and high-dose magnesium sulphate have been used. Ventilation must ensure adequate oxygenation but severe gas trapping, with resultant haemodynamic compromise, must be actively avoided. Slow respiratory rates (6–10/minute) with prolonged expiratory times should be used and intermittent disconnection from the ventilator, to allow the lung to fall to its equilibrium volume, is valuable if haemodynamic compromise occurs. Some permissive hypercapnia is expected and desirable in these patients.

Upper respiratory tract infection (URTI)
Clinical studies of the implications of URTI have been performed almost exclusively in children, and, in view of an increased risk of adverse anaesthetic events (cough, laryngospasm or other airway obstruction, breath holding or desaturation), have advised postponement of elective surgery for up to 6 weeks following severe URTI. A 2-week delay is commonly advised for mild infections. In adult practice, evidence on the implications of URTI for anaesthesia is almost non-existent. URTI increases upper airway irritability, which correlates well with symptoms, for up to 15 days, suggesting that a 2-week delay and resolution of symptoms is advisable before elective surgery. New or increased production of purulent sputum in patients with underlying respiratory disease usually warrants antibiotic therapy. There is no information on the impact of mild, presumably viral, infections in patients with, or without, respiratory disease before anaesthesia; the prudent approach is to delay elective surgery. In more urgent surgery, the priority of surgery is likely to override concern about mild URTI.

Smoking
Smoking is associated with pathophysiological changes in the cardiovascular and respiratory systems that have significant implications for anaesthesia. In the airway, there is impaired clearance and increased production of mucus. Narrowing of small airways results in airway closure and increased ventilation–perfusion (V/Q) mismatch. Increased irritability and reflex sensitivity occurs in upper and lower airways. Cardiovascular implications include an increase in oxygen demand through nicotinic activation of the sympathoadrenergic system, as well as decreased oxygen supply to tissues due to increased carboxyhaemoglobin (COHb) levels and raised coronary vascular resistance. COHb levels of 5–15% may be encountered in smokers (normally 2% or up to 4% in city dwellers). Standard transmission type pulse oximeters interpret COHb as oxygenated haemoglobin (and may overestimate peripheral oxygen saturation (SpO_2) in smokers) and fail to reflect the left shift of the oxygen-haemoglobin dissociation curve that is induced by COHb.

Many studies have investigated perioperative complications in smokers. Pulmonary complications represent the major area of perioperative morbidity – smokers are 2–6 times more likely to suffer from atelectasis and pneumonia. Hyper-responsive airways render smokers more vulnerable to laryngospasm and bronchospasm, and coughing, in combination with impaired mucus clearance, may impact on pain-control requirements and adversely affect wound healing. Recent data suggest that continued smoking by patients at risk of coronary disease (> 65 years) increases the incidence of transient myocardial ischaemic events under anaesthesia.

Given the short half-lives of both nicotine (0.5–1 hour) and COHb (4 hours), a period of preoperative smoking cessation lasting 12–16 hours should normalize both levels. Smoking cessation of at least 8 weeks is required to reduce the risk of pulmonary complications in smokers. Paradoxically, the risk may be increased, due in part to short term changes in the balance of mucus production and clearance, during this interval period. A much longer period, at least 6 months, is required before complication rates approach those of non-smokers and the longer the period of abstinence, the better.

Cystic fibrosis (CF)
CF is characterized by airway mucous gland hyperplasia and the production of abnormal mucus that encourages bacterial growth. Most CF patients are colonized with *Pseudomonas aeruginosa*, which inflicts a course of recurrent infective exacerbation and remission. Repeated bacterial infection, atelectasis and mucous plugging eventually lead to cystic bronchiectasis and necrotizing pulmonary disease.

Anaesthetic implications: patients with CF present for disease- related procedures (pneumothorax, nasal polyps, insertion of vascular or enteral feeding access) and for unrelated procedures. While elective surgery is often performed in hospitals with CF units, an increasing adult population of CF patients may present to general hospitals for both simple and emergency surgical procedures. Survival data demonstrate increased survival with over 50% of CF patients alive at 25 years. Children born with CF in the 1990s are likely to survive up to four decades, regardless of the impact of advances in gene therapy.

Patients with CF exhibit increased intrapulmonary shunt and gas trapping. Total lung capacity and residual volume are increased while FEV_1 and FVC are both reduced. PaO_2 is often mildly reduced and $PaCO_2$ is usually normal. PaO_2 less than 7 kPa or $PaCO_2$ over 6.5 kPa usually reflects advanced disease with 2-year mortality from CF of about 50%.

Intraoperative management is often straightforward, particularly if patients are not suffering an infective exacerbation. Patients should perform physiotherapy exercises immediately before the procedure. Tracheal intubation is preferred for all but the shortest procedures and allows for tracheobronchial suction which should be performed regularly during the procedure. Controlled ventilation, usually with short-acting muscle relaxants is routine, and although reversal of neuromuscular blockade must be complete, pharmacological reversal may be undesirable in some patients owing to unpredictable effects on the tenacity of respiratory secretions. In advanced disease, the authors transfer patients sedated and ventilated to the recovery room where they undergo aggressive physiotherapy and tracheobronchial toilet for a variable period (e.g. 0.5–2 hours) during stabilization before extubation. Postoperative analgesia must allow effective coughing and regional techniques should be considered. The risk of respiratory depression with opiates is counterbalanced by the facilitation of coughing and physiotherapy in patients at risk of severe postoperative pain. ◆

Post-thoracotomy Analgesia

Maria Akrofi
Stephen H Pennefather

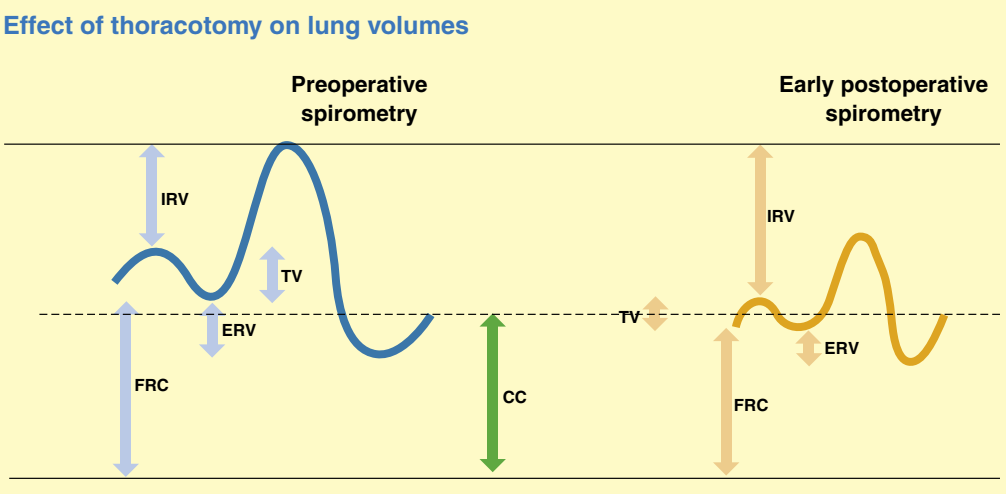
Maria Akrofi is Anaesthetic Fellow at the Cardiothoracic Centre, Liverpool, UK. She qualified from Legon University and trained in anaesthesia in Accra and Liverpool. Her interests lie in cardiothoracic anaesthesia.

Stephen H Pennefather is Consultant Anaesthetist at the Cardiothoracic Centre, Liverpool, UK. He qualified from Cape Town University, South Africa, and trained in general medicine and anaesthesia in South Africa and the UK. His research interests include the development of effective post-thoracotomy analgesic strategies.

A posterolateral thoracotomy usually involves about seven somatic dermatomes. The pain of a thoracotomy has been described as among the most severe of the many iatrogenic causes. Movement, including breathing and coughing, exacerbates the pain. Adequate postoperative analgesia is important for humanitarian reasons and to reduce the incidence of pulmonary and other morbidity occurring in patients undergoing thoracic surgery.

Normally, active tidal inspiration is followed by passive expiration. However, in a post-thoracotomy patient with inadequate analgesia, active tidal inspiration is followed by contraction of the expiratory muscles to limit further distraction of the injured skin, muscles, ligaments and bone. This active expiration results in a reduction in the functional residual capacity, usually to below the closing capacity, leading to airway closure and atelectasis. Splinting the chest, as a result of involuntary muscle contraction, reduces the inspiratory reserve volume and coughing becomes less effective. These spirometric changes (Figure 1) contribute to the development of postoperative atelectasis and sputum retention, which may progress to potentially fatal chest infection.

Effect of thoracotomy on lung volumes



FRC, functional residual capacity;
TV, tidal volume;
CC, closing capacity;
IRV, inspiratory reserve volume;
ERV, expiratory reserve volume

1

The techniques used to provide post-thoracotomy analgesia are summarized in Figure 2. However, in practice there are two widely used techniques:
- systemic opioids ± nerve block ± non-steroidal anti-inflammatory drugs (NSAIDs)
- epidural analgesia.

There is evidence that well-prepared patients experience less postoperative pain and most patients benefit from a clear explanation of what to expect postoperatively. When choosing post-thoracotomy analgesia the following must be considered:
- planned procedure (pneumonectomy versus pleurectomy)
- surgical technique (open versus thoracoscopic)
- patient's physiological reserve, co-morbities and preference
- resources available including hospital infrastructure and anaesthetic expertise.

Methods of post-thoracotomy analgesia

Opioids	**Local anaesthetic**
Intramuscular	Intercostal
Intravenous	Paravertebral
Patient-controlled analgesia (PCA)	Intrapleural
Epidural	Subcutaneous
Spinal	Spinal
Non-opioid	**Mechanical**
Non-steroidal anti-inflammatory drugs	TENS (transcutaneous electrical nerve stimulation)
Paracetamol	Cryoanalgesia

2

Systemic opioids ± nerve block ± NSAIDs
Opioids: systemic opioids have a narrow therapeutic window in the context of reducing pulmonary complications post-thoracotomy. Without analgesia, patients experience considerable pain, expire actively and splint their chest wall, coughing and sighing are suppressed and the probability of developing atelectasis is high. Titrated systemic opioids moderate pain, reduce chest wall splinting, enable passive expiration and involuntary sighing and therefore facilitate effective coughing. The likelihood of developing atelectasis is reduced. Additional systemic opioids further reduce pain but increase sedation, reduce coughing and sighing and thereby increase the likelihood of atelectasis developing. Maintaining this narrow therapeutic window is made more difficult by the fivefold patient-to-patient variability in opioid requirements and the well-known reduction in opioid requirements with time. Patient-controlled analgesia (PCA) systems are widely used. PCAs are effective because patients usually prefer some pain to excessive sedation. Post-thoracotomy, the analgesia provided by a PCA is seldom adequate and additional strategies are often used.

NSAIDs: the addition of NSAIDs improves analgesia but increases the potential for side-effects, particularly in this predominantly elderly population with a high incidence of renal dysfunction and peptic ulcer disease.

Paravertebral blocks: the thoracic paravertebral space is wedge- shaped. It is bounded medially by the intervertebral bodies and discs, anterolaterally by the parietal pleura, and posteriorly by the transverse processes and costotransverse ligaments. The paravertebral space contains the dorsal rami, rami communicantes, the sympathetic chain and the intercostal nerves. Paravertebral blocks can be achieved by single injections, repeated injections or catheter-facilitated paravertebral infusions. Paravertebral catheters can be placed percutaneously or under direct vision by the surgeon. Paravertebral blocks are usually contraindicated in patients with an empyema, paravertebral tumour or a skin infection at the site of needle insertion. Relative contraindications include haemostatic abnormalities and patients who have had a previous thoracotomy.

Technique – at an appropriate level, using aseptic precautions, a Tuohy needle is inserted 2.5 cm lateral to the superior aspect of the relevant spinous process and then advanced perpendicular to the skin, in all planes, until contact is made with the transverse process, usually at a depth of 2–4 cm. If contact is not made with bone at the expected depth, the Tuohy needle is fanned superiorly and inferior in the sagittal plane, to detect inadvertent advancement between two transverse processes, before advancing the needle further. After contact with bone is made the needle is walked, rostrally, off the transverse process and advanced until loss of resistance is felt, after confirming no blood on aspiration, an appropriate dose of local anaesthetic is given and, if required, a catheter sited. Paravertebrals are easier to insert than epidurals and are probably safer. However, in about 10% of patients they do not work and in the others the effect is variable.

Epidural analgesia
Meta-analysis has shown that the administration of local anaesthetic containing epidural solutions via a thoracic epidural to patients undergoing upper gastrointestinal surgery results in a significant reduction in pulmonary complications. The post-thoracotomy analgesia produced by a combination of local anaesthetic and opioids administered via a thoracic epidural is excellent (gold standard) and is now widely used. However, patient selection is important because of the possibility of spinal cord injury. The risk of spinal abscess can be reduced by meticulous asepsis and avoiding thoracic epidurals in patients with local or systemic sepsis. The risk of spinal haematomas can be reduced by avoiding thoracic epidurals in patients with haemostatic abnormalities detected by:
- obtaining a personal and family bleeding history
- inquiring about exposure to drugs effecting haemostasis
- measuring the platelet count and performing clotting studies.

Controversy remains about whether thoracic epidurals should be inserted in awake or anaesthetized patients. Many operators, including the authors, think it is safer to insert thoracic epidurals in conscious patients. This also allows confirmation of correct placement before surgery. For thoracic epidurals the use of a mixture containing a lipid-soluble, segmentally acting, opioid (e.g. fentanyl) is logical because this almost eliminates the risk of sudden late respiratory depression caused by the rostral spread of opioid in the CSF. Numerous different epidural mixtures have been studied but the most widely used solutions contain fentanyl, 4 μg/ml, in 0.125% bupivacaine. The excellent somatic dermatomal analgesia produced by thoracic epidural analgesia is often marred by severe ipsilateral shoulder pain. Disruption or irritation of the mediastinal or diaphragmatic pleura and/or pericardium result in visceral pain conducted via the phrenic nerve referred to the ipsilateral shoulder. Treating this referred pain is difficult. Phrenic nerve infiltration with lidocaine (lignocaine) is effective but of limited duration and may compromise ventilation. However, patients receiving thoracic epidural analgesia and phrenic nerve block experience almost no post-thoracotomy pain.

Patients receiving thoracic epidural analgesia should be assessed at least hourly. If patients are not monitored on a high dependency unit they should receive high dependency nursing on the ward. All patients receiving hydrophilic opioids epidurally should undergo continuous respiratory function monitoring. Slow rostral spread of hydrophilic opioids in the CSF may result in sudden delayed respiratory depression. ◆

Preoperative Assessment for Thoracic Anaesthesia

Brian Keogh

Brian Keogh is Consultant in Anaesthesia and Intensive Care at the Royal Brompton Hospital, London. He graduated from Sydney University.

Nuala Lucas is Specialist Registrar at the Imperial School of Anaesthesia, London. She graduated from University College and Middlesex School of Medicine, London.

Thoracic surgical procedures are associated with significant morbidity and mortality. Major postoperative respiratory complications (e.g. pneumonia, atelectasis, respiratory failure) occur in up to 20% of patients and account for most of the overall 3–4% mortality. Recent advances in care result in few patients being rejected by the anaesthetist as thoracic surgical candidates on the basis of preoperative pulmonary disease. In each patient a risk/benefit assessment should form part of the process of informed consent. For the general approach to preoperative assessment see *Anaesthesia and Intensive Care Medicine* **2:4:** 124. Specific preoperative assessment and optimization of cardiac and pulmonary function are vital. Medical optimization may involve pre-admission for physiotherapy, antibiotic or supervised bronchodilator therapy, cardiovascular stabilization and even nutritional support before surgery.

Cardiac assessment
History, examination, assessment of functional status and ECG should identify patients at high risk. Routine specialized cardiac screening is not indicated or cost effective. Patients require further investigation if they exhibit major or intermediate risk predictors (Figure 1).

Clinical predictors of increased perioperative cardiovascular risk

Major predictors
- Unstable coronary syndromes (recent myocardial infarction with evidence of ischaemia, unstable or severe angina)
- Decompensated congestive cardiac failure
- Severe valvular disease
- Significant arrhythmia (high-grade A-V block, supraventricular arrhythmias with uncontrolled ventricular rate, symptomatic arrhythmias with underlying heart disease

Intermediate risk predictors
- Mild angina
- Previous myocardial infarction
- Compensated or previous congestive cardiac failure
- Diabetes

Minor risk predictors
- Advanced age
- Abnormal ECG
- Cardiac rhythm other than sinus
- History of stroke
- Uncontrolled systemic hypertension

Modified from American College of Cardiology (ACC)/American Heart Association (AHA) Task Force Report on guidelines for perioperative cardiovascular evaluation for non-cardiac surgery, 1996.

1

Thoracic surgical patients with ischaemic heart disease may undergo optimization of medical therapy, angioplasty, with or without stenting, or coronary artery surgery. In those who require both coronary artery surgery and pulmonary resection, combined procedures can be undertaken but it is usual to delay the thoracic procedure for 4–6 weeks after cardiac surgery. The impact on outcome of angioplasty and/or coronary stenting in such patients is not known; modification of anticoagulant therapy to facilitate surgery may increase the risk of cardiac complications.

Patients who have suffered recent myocardial infarction (MI) should not undergo elective surgical procedures for 6 months. However, thoracic surgery for malignant disease is a relative emergency and surgery for pulmonary resection can be undertaken with acceptable risk 6 weeks after MI.

Severe valvular heart disease is a high risk predictor of perioperative cardiac events, but data on outcome are limited. Valve surgery should be advised on standard cardiological criteria, regardless of the need for thoracic surgery, and should ordinarily precede the thoracic procedure. The presence of valve disease increases the risk, but even if severe, this risk should not necessarily be prohibitive.

Assessment of respiratory function
An ASA Class I or II patient with full exercise capacity does not require special cardiorespiratory screening before thoracic surgery. ASA Class III patients, or those with limited exercise capacity, require more critical preoperative assessment, especially if substantial pulmonary resections are planned. No single respiratory function test has sufficient sensitivity or specificity to predict outcome following pulmonary resection. Slinger has recently advocated anaesthetic assessment combining elements of respiratory mechanics, gas exchange and cardio-pulmonary performance in prethoracotomy patients (Figure 2).

Prethoracotomy respiratory assessment

Respiratory mechanics	Cardiopulmonary reserve	Parenchymal function
ppo FEV_1 > 40% *	VO_{2max} > 15 ml/kg/min *	*ppo* D_LCO > 40% *
MVV, FVC, RV/TLC	Stair climb > 2 flights	PaO_2 > 8.3 kPa
	6 minute walk	$PaCO_2$ < 6.3 kPa
		Exercise SpO_2 fall < 4%

* most valid test

This 'three legged stool' concept has been proposed as a reasonably simple approach to anaesthetic assessment in thoracotomy patients. Of the parameters listed, *ppo* FEV_1 > 40%, *ppo* D_LCO% > 40% and VO_{2max} > 15 ml/kg/min represent thresholds below which patients face increased risk.

2

Respiratory mechanics – British Thoracic Society (BTS) recommendations highlight the screening value of simple spirometry and suggest that no further respiratory function tests are required if, for a lobectomy, the post-bronchodilator forced expiratory volume in 1 second (FEV_1) is over 1.5 litres or, for a pneumonectomy, is over 2 litres, provided there is no evidence of interstitial disease or unexpected disability due to dyspnoea.

In more formal respiratory function testing, parameters that correlate with postoperative outcome include FEV_1, maximal voluntary ventilation (MVV), forced vital capacity (FVC) and residual volume to total lung capacity ratio (RV/TLC), when expressed as a percentage of predicted volumes (corrected for age, gender and height), and particularly if postoperative values, based on the percentage of functioning lung tissue removed, can be predicted. The most valid single test for post-thoracotomy respiratory complications is predicted postoperative (*ppo*) FEV_1 percentage, calculated as preoperative FEV_1 % x (1 – % functional lung tissue removed/100). The percentage functional lung tissue removed is calculated by dividing the total lung tissue into segments (19) and assessing the number of functioning segments to be removed. Quantitative pulmonary perfusion scans can also be used to define the amount of functional tissue to be removed.

In terms of postoperative morbidity, *ppo* FEV_1% values over 40% predict a low risk of postoperative morbidity, values below 30% predict an extremely high risk and values of 30–40% define an intermediate risk group for which data are inconclusive.

Lung parenchymal function – preoperative arterial blood gas (ABG) analysis is routine in most patients undergoing thoracic surgery. Traditional alert values (PaO_2 < 8.3 kPa, $PaCO_2$ > 6.3 kPa) are commonly cited as risk factors but there are no large or prospective studies correlating ABG values with outcome. Elevated $PaCO_2$ values are generally considered to place patients at higher risk but no stratification is available and it is unclear at what level of $PaCO_2$ this risk might become prohibitive.

The most useful predictive test of gas-exchanging capacity is the diffusing capacity for carbon monoxide (D_LCO) and *ppo* values can be obtained by applying the same equation as for *ppo* FEV_1% above. A *ppo* D_LCO% below 40% predicts an increase risk of postoperative respiratory and cardiac complications, and a value over 40% indicates patients at low risk.

Cardiopulmonary performance – stair climbing (the number of steps climbed without stopping) is a simple test of cardiopulmonary reserve. The ability to climb three or more flights of stairs is associated with low perioperative mortality; inability to climb two flights reflects increased risk. Stair climbing provides a broad indicator of cardiopulmonary reserve but is not standardized.

Formal exercise testing is the gold standard for assessment of cardiopulmonary reserve and maximal oxygen consumption (VO_{2max}) correlates with postoperative morbidity (Figure 3). Patients with VO_{2max} values below 15 ml/kg/min require further assessment including consideration of *ppo* VO_{2max} values.

Preoperative VO_{2max} values and risk assessment in thoracic surgery

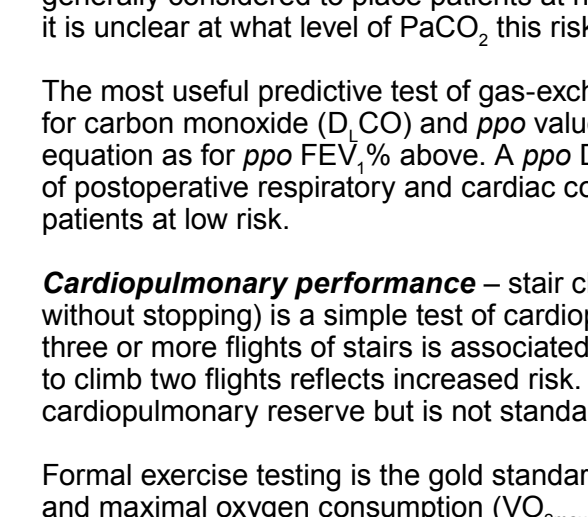
VO_{2max} (ml/kg/min)	Prediction
> 20	Favourable, low mortality, tolerate pneumonectomy
15–20	Acceptable risk benefit, may tolerate pneumonectomy
10–15	High risk, needs further assessment, limited resection
< 10	Very high risk, probably inoperable

3

Formal VO_{2max} testing is expensive and labour intensive. The 6-minute walk test correlates well with VO_{2max} in patients with severe pulmonary disease, and the inability to walk 200 m has been associated with poor outcome in those undergoing lung volume reduction surgery for emphysema. The shuttle walking test, a standardized and externally paced walking test, may correlate better with VO_{2max}. The inability to complete 25 shuttles strongly suggests a VO_{2max} below 15 ml/kg/min.

Oximetry values may also predict outcome. Resting peripheral oxygen saturation (SpO_2) below 90% and a reduction in SpO_2 of 4% or more during exercise predict major morbidity and prolonged stay in intensive care following pneumonectomy.

Ventilation–perfusion (V/Q) lung scans are sometimes performed in the preoperative assessment, particularly if pneumonectomy is planned. They accurately define areas of functioning or nonfunctioning lung (Figure 4).



4 CT scan showing severe emphysema and carcinoma of the left lower lobe bronchus. Pulmonary function tests were extremely unfavourable but V/Q scan revealed almost no perfusion to the left lung. Reassessment incorporating V/Q data conferred operability and the patient underwent an uncomplicated left pneumonectomy.

Algorithms for preoperative assessment
The use of assessment pathway algorithms in prethoracotomy patients has been reported. Prospective clinical evaluation of one algorithm, in 137 patients undergoing lung resections, resulted in a 50% reduction in complications, with the same percentage of inoperable patients (< 4%). Figure 5 is modified from the recommendations of the BTS Working Party (2001). The details are not important for examination candidates but it is important to recognize that these algorithms can be used to provide consistency in clinical evaluation and that there is evidence of improved outcome from this protocol-driven approach. Risk assessment and the limits of operability should be regularly reassessed to take account of new advances. BTS recommends that their guidelines be reviewed in 5 years. ◆

Principles and Practice of Thoracic Anaesthesia

John W W Gothard
Tariq Hoth

John W W Gothard is Consultant Cardiothoracic Anaesthetist at the Royal Brompton Hospital, London. He qualified from St Mary's Hospital Medical School, London. He has written several textbooks on cardiac and thoracic anaesthesia and has a major interest in thoracic anaesthesia and anaesthesia for congenital heart disease.

Tariq Hoth is Specialist Registrar in the Intensive Care Unit at the Royal Brompton Hospital, London. He qualified in Germany and trained as an anaesthetist at the Imperial School of Anaesthesia, London.

Most lung resections are carried out for the surgical treatment of primary malignant tumours (Figure 1). 80% of primary lung tumours are inoperable at presentation, therefore only about 3000 of these operations are performed annually in the UK. Mortality for pulmonary resection remains relatively high at 5% for pneumonectomy and 2.9% for lobectomy and therefore preoperative assessment of these patients is important.

Thoracic surgical results from 47 UK centres (1999–2000)

	Numbers	Deaths
Lung resection for primary malignant tumours		
Pneumonectomy	779	39 (5.0%)
Lobectomy/bilobectomy	2208	63 (2.9%)
Video-assisted thoracoscopic surgery (VATS) for pulmonary/pleural disease		
Lung biopsy	506	6 (1.2%)
Bullae	56	2 (3.6%)
Lung volume reduction surgery (unilateral)	50	3 (6.0%)
Lung volume reduction surgery (bilateral)	15	1 (6.7%)
Pneumothorax (various procedures)	735	6 (0.8%)
Pleural biopsy	499	5 (1.0%)
Pleural biopsy and chemical pleurodesis	932	18 (1.9%)
Pleurectomy	84	2 (2.4%)
Pleurectomy and drainage of empyema	154	4 (2.6%)

1

The appropriate management of anaesthesia and one-lung ventilation facilitates surgery and is likely to improve outcome. Recently there has been an increase in the number of thoracic procedures carried out using video-assisted thoracic surgery (VATS). These procedures almost all require one-lung ventil-ation at times and the observed physiological changes and principles of management are similar to those during pulmonary resection.

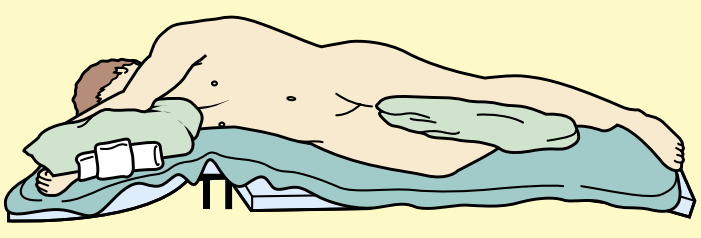
Thoracotomy and pulmonary surgery

Positioning the patient

Most pulmonary resections are undertaken with the patient in a lateral position. Following induction of anaesthesia, intubation, insertion of intravascular lines and confirmation of the side of surgery, the patient is turned into the lateral position. Several devices can be used to stabilize the patient on the operating table (Figure 2). The lower shoulder is pulled through anteriorly, allowing the flexed lower arm to be tucked under the pillow supporting the head. The upper arm is extended and placed over the head, taking care not to stretch the brachial plexus. Some surgeons who use a more anterior muscle-sparing incision, prefer to place the upper arm in a padded arm support attached to the head of the operating table.

The lateral thoracotomy position

The patient is stabilized by a comfortable mattress. Note the 'bridge' raised in the operating table, directly below the chest, to aid surgical access



From: J W W Gothard. *Anaesthesia for Thoracic Surgery.* Oxford: Blackwell Scientific Publications, 1992

2

Stability of the pelvis is achieved by flexing the lower leg at the hip and knee while the upper leg, padded with a pillow, is kept relatively straight. Further stability may be achieved with chest and pelvic supports. Once the patient is positioned and all vulnerable areas padded, a warm-air convective heating blanket is applied to minimize heat loss during surgery.

Physiological consequences: in the awake patient there is little or no additional ventilation–perfusion mismatch in the lateral position. An increase in perfusion to the lower lung, caused by the effect of gravity on the low pressure pulmonary circulation, is matched by increased ventilation because this lung is on the steep part of the compliance curve (Figure 3). During anaesthesia the situation changes. In the spontaneously breathing patient there is a reduction in inspiratory muscle tone (particularly the diaphragm) and a decrease in the volume of both lungs with a reduction in functional residual capacity (FRC). The non-dependent upper lung therefore moves to the steeper part of the compliance curve and receives more ventilation. Paralysis and intermittent positive-pressure ventilation (IPPV) are used during thoracotomy to overcome the problems of the open pneumo-thorax created by surgery. The compliance of the non-dependent lung is further increased in this situation. In practice, it is usual to selectively ventilate the lower lung (one-lung ventilation; OLV) at this point and allow the upper lung to collapse. This eliminates the preferential ventilation and facilitates surgical access but causes ventilation–perfusion mismatch.

Compliance curves for upper and lower lungs in the lateral position

3

Anaesthesia

The principles of anaesthesia for thoracic surgery are the same as those for any major surgery. Anaesthesia is usually induced intravenously. The choice of agent is seldom important. Patients presenting for lung resection are unlikely to have a co-existing airway problem and therefore a non-depolarizing neuromuscular blocking agent can be used to facilitate intubation and IPPV. A long-acting agent (e.g. pancuronium) is suitable for most operations but it is equally acceptable to use short-acting agents and give incremental doses as required. Special consideration must be given to patients with muscle weakness caused by myasthenia gravis or the myasthenic syndrome. Occasionally patients presenting for palliative VATS have an airway problem relating to tracheal or bronchial compression or an endobronchial tumour but patients undergoing lung resection are more likely to present as a 'difficult intubation' on the basis of conventional criteria.

Anaesthesia can be maintained with volatile agents delivered in an air/oxygen gas mixture or an oxygen/nitrous oxide mix. Alternatively, anaesthesia can be maintained intravenously with propofol, possibly in combination with remifentanil.

Hypoxic pulmonary vasoconstriction (HPV)

HPV is a homeostatic mechanism whereby pulmonary blood flow is diverted away from hypoxic or collapsed areas of lung. It might be expected to improve oxygenation during OLV, but *in vitro* experiments have shown that volatile agents inhibit HPV though *in vivo* studies have failed to demonstrate gross inhibition. Although volatile agents depress HPV directly, they also enhance it by reducing cardiac output. Therefore, HPV response is apparently unchanged in the presence of volatile agents during thoracotomy and OLV. Handling the lung also reduces HPV.

Potent inhaled anaesthetic agents (e.g. isoflurane) are not contraindicated during OLV and may be desirable because of their bronchodilator properties and ease of use. Significant inhibition of HPV is more likely with halothane, which should be avoided.

Intravenous agents (e.g. propofol) do not inhibit HPV and should improve arterial oxygenation during OLV. Evidence in the literature supports this contention, but it is inconclusive. Therefore, in patients with poor arterial oxygenation during OLV, it might be worth changing to a total intravenous technique.

Analgesia

If opioid drugs are to be used postoperatively it is logical to use the same drugs intraoperatively. If epidural analgesia is to be used postoperatively it should be established before surgery.

Monitoring

Monitoring and vascular access for major pulmonary surgery should be comprehensive (Figure 4). Pulmonary artery catheters can be placed in the lung contralateral to surgery only if radiological screening facilities are available. This is unnecessary in routine clinical practice. Transoesophageal echocardiography is not used during routine thoracic surgery but it may be used in the management of high-risk patients in the future.

Ventilation

Endobronchial tubes or bronchial blockers are inserted immediately following induction of anaesthesia or after preliminary bronchoscopy. Use of these devices to achieve lung separation and collapse of the lung on the operative side is described elsewhere.

Monitoring requirements for major pulmonary surgery

Electrocardiogram (ECG)

Pulse oximetry

End-tidal gas analysis
- Carbon dioxide trace particularly useful during one-lung ventilation (OLV)

Flow/volume loop
- Useful during OLV

Invasive arterial pressure measurement
- Arterial blood gas analysis invaluable during OLV

Nasopharyngeal temperature
- Heat loss significant during thoracotomy

Urinary catheter
- Appropriate for long procedures
- Consider if epidural analgesia is used or if renal function poor

4

Management of OLV: pulmonary blood flow continues to the upper lung during OLV, creating a true shunt where there is blood flow to the alveoli but no ventilation. This shunt is the main cause of hypoxaemia during OLV, though the alveoli with low ventilation–perfusion ratios also contribute. Venous admixture or shunt increases from a baseline of about 10% during two-lung ventilation to 20–30% during OLV.

OLV should be established so that it inflates the lung adequately but also minimizes intra-alveolar pressure and prevents diversion of pulmonary blood flow to the upper lung. This is not easy to achieve. High frequency jet ventilation for thoracic surgery provides ventilation at low airway pressures (see *Anaesthesia and Intensive Care Medicine* **3:6:** 204). Despite its potential advantages it is not in widespread use and this article discusses conventional IPPV.

It is reasonable to use an inspired oxygen concentration (F_IO_2) of 50% initially. When OLV is established this can be increased to 100%, if required. This cannot affect the true shunt in the upper lung but can improve oxygenation via the alveoli with low ventilation–perfusion ratios in the lower lung.

There is increasing evidence that over-inflating the single lung (volutrauma) can be detrimental and lead to acute lung injury. Deflation and inflation of the lung on the operative side with the potential for ischaemia or reperfusion injury has also been implicated in lung damage. The use of low tidal volumes improves outcome in ventilated patients with acute respiratory distress syndrome and this may also apply to OLV. Pressure- limiting ventilation is also likely to be beneficial. Limiting ventilation (Figure 5) can lead to carbon dioxide retention, but some permissive hypercapnia is preferable to lung trauma.

Guidelines for one-lung ventilation (OLV)

- Inspired oxygen concentration of 50–100% (Increase if oxygen saturation < 90%)
- Normal inspired:expired ratio (1:2) (Increase expiratory phase if gas trapping likely)
- Consider pressure-limiting ventilation
- Use small tidal volumes (e.g. 6–7 ml/kg)
- Allow permissive hypercapnia
- Use positive end-expiratory pressure
- Avoid over-inflation (volutrauma)

5

Hypoxia during OLV – it is difficult to predict which patients are likely to become hypoxic (arterial oxygen saturation less than 90%) during OLV. Patients with poor lung function are sometimes accepted for lung resection on the basis that their diseased lung is contributing little to gas exchange and this can be confirmed by ventilation–perfusion scanning. Conversely, patients with normal lung function are more likely to be hypoxic during OLV, presumably because an essentially normal lung is being collapsed to provide surgical access. A recent study found that the most significant predictors of a low arterial oxygen saturation during OLV were a right-sided operation, a low oxygen saturation during two-lung ventilation before OLV and a high (or more normal) forced expiratory volume in 1 second (FEV_1) preoperatively.

Once hypoxia occurs it is important to check the position of the endobronchial tube and readjust it if necessary. A high inflation pressure (more than 30–35 cm H_2O) indicates that the tube is displaced. It may be helpful to analyse a flow/volume loop or at least manually re-inflate the lung to get a feel for the compliance. If a tube is obstructing a lobar orifice only one or two lobes are being ventilated at most and hypoxia is likely. Suction and manual re-inflation of the dependent lung may also be helpful at this stage.

Other measures to improve oxygenation include increasing the inspired oxygen concentration, introducing positive end-expiratory pressure (PEEP) to the dependent lung or supplying oxygen to the upper lung via a continuous positive airway pressure (CPAP) system (thereby reducing the shunt). The introduction of PEEP to the lower lung with CPAP (100% oxygen) to the upper lung has also been described but this lowers cardiac output and thus oxygen delivery.

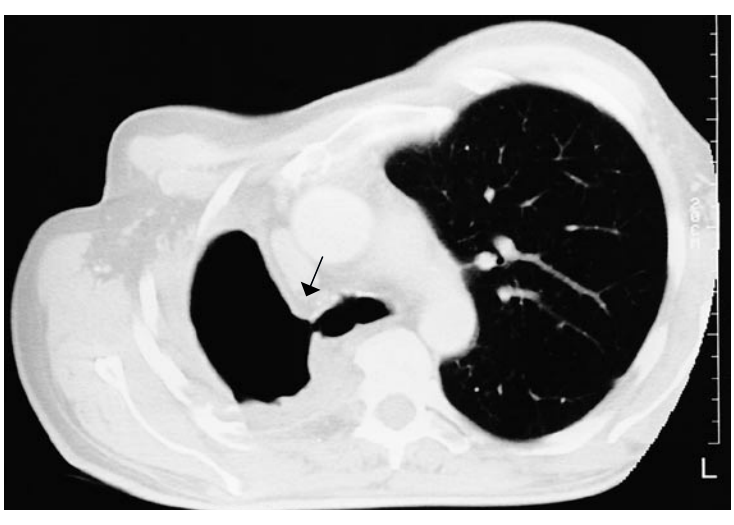
Chest drainage
Pleural or chest drainage is an essential part of the management of the thoracotomy patient. Chest drains allow the escape of air, blood or fluid from the pleural space to facilitate re-expansion of remaining lung and elimination of mediastinal shift. Drainage tubes inserted at operation are connected to an underwater seal drain, which acts as a one-way valve. Two chest drains are commonly inserted following lung resection (other than pneumonectomy). Low pressure, high volume suction is usually applied to the outlet of the drainage bottle to facilitate egress of air.

Air leak does not occur after pneumonectomy and therefore chest drainage is not mandatory. The chest can be closed without a drain if the surgeon is confident that there is no significant bleeding. If this approach is taken, air is aspirated from the pneumonectomy space to centralize the mediastinum once the patient has been turned into a supine position. Some surgeons leave a basal chest drain in for the first 24 hours following pneumonectomy. This drain is clamped but connected to an underwater seal drainage bottle. The clamp is released for about 2 minutes every hour to allow any accumulated blood to drain. Suction is never applied to a pneumonectomy drain because it pulls the mediastinum across and severely impedes or totally obstructs venous return.

Termination of anaesthesia and early postoperative period
Once chest drains are in place any remaining lung is suctioned and carefully re-inflated, keeping the pressure low. As chest wall closure is completed residual neuromuscular blockade is reversed and anaesthesia lightened. After a straightforward pulmonary resection it is usual to re-establish spontaneous respiration and extubate the patient in the operating theatre, or soon afterwards in a recovery area. This is best achieved with the patient in a sitting position. After complex or difficult surgery (e.g. lung resection combined with excision of chest wall) it may be prudent to ventilate the patient for a few hours postoperatively.

Specific procedures

Bronchopleural fistula
A bronchopleural fistula is a direct communication between the tracheobronchial tree and the pleural cavity (Figure 6). Causes include dehiscence of a bronchial stump following lung resection, trauma, inflammatory lesions (e.g. tuberculosis) and neoplasms. In developed countries, bronchopleural fistula has classically been described in relation to pneumonectomy. Its incidence following pneumonectomy is now low in specialized centres but its anaesthetic management remains an examination topic.



6 CT scan showing a chronic bronchopleural fistula following pneumonectomy. The mediastinum is pulled across towards the side of surgery (a normal finding), but there is also a clear communication between the bronchial stump and the thoracic cavity on the side of the pneumonectomy.

Bronchopleural fistula can occur at any time following pneumonectomy but usually occurs 3–15 days postoperatively. Hospitals accepting major trauma patients may admit patients with traumatic rupture of the major airways after high-speed traffic accidents. These injuries are a form of bronchopleural fistula and usually require surgical repair.

Bronchopleural fistula after pneumonectomy: the patient usually presents with symptoms related to infected space fluid flowing into the remaining lung. Acute onset with a large fistula presents with severe dyspnoea, with the patient coughing up brownish infected space fluid. Signs of cardiorespiratory failure are also apparent as a result of hypoxia and septicaemia. A chest radiograph confirms the diagnosis, showing loss of pneumonectomy space fluid and consolidation or increased shadowing in the remaining lung. Initial management includes general resuscitation. Oxygen is administered and an intravenous infusion commenced. The patient should be sat up to prevent any further spill-over of space fluid and a chest drain inserted on the pneumonectomized side to remove remaining fluid (suction should not be applied). When surgical repair is to be undertaken, the patient is transported to theatre in the sitting position, with the drain unclamped but with the drainage bottle below the patient.

Anaesthetic management: classically a post-pneumonectomy bronchopleural fistula should be isolated with an endobronchial tube placed in the remaining lung before IPPV is commenced. To secure the airway before the administration of a muscle relaxant two methods were advocated: awake endobronchial intubation using local analgesia of the upper respiratory tract; and an inhalational induction and intubation under deep inhalational anaesthesia. These techniques should be mentioned by an examination candidate but in practice both techniques are fraught with problems, particularly in these debilitated patients. Most thoracic anaesthetists use a conventional intravenous induction, following pre-oxygenation, with the patient in a sitting position and the drain open. An endobronchial tube can then be inserted safely in the main bronchus under fibre-optic bronchoscopic control after administration of suxamethonium. IPPV to the isolated lung can then be commenced and the patient positioned for surgery.

Video-assisted thoracic surgery (VATS)
VATS has been widely adopted for many procedures (Figure 1). A small, but important, group of patients also undergo lung volume reduction surgery for emphysema with the use of this technique. VATS is less invasive than open thoracotomy and is carried out through a series of ports inserted through the chest wall. It is vital to collapse the lung on the side of surgery for these procedures and therefore the use of endobronchial tubes and OLV is increasing to facilitate this surgery. There is usually less postoperative pain than after open thoracotomy and length of hospital stay may be reduced.

Anaesthetic techniques are similar to those used for lung resection. The operation is usually carried out with the patient in a lateral position, occasionally with the upper arm elevated in an arm rest.

It is essential to let the lung down before access ports and telescopes are introduced. Patients presenting for VATS may have abnormal lungs, particularly those scheduled for lung volume reduction surgery.

Lung collapse or deflation on the operative side can usually be achieved with a left-sided endobronchial tube, because this type of surgery does not breach the airway. Lung collapse during OLV is slow in the presence of marked emphysema and several techniques have been used to promote this. Some centres insufflate carbon dioxide into the pleural cavity. The gas is delivered at a low pressure and low flow (2 litres/minute) but presents a small risk of gas embolism. Others promote the idea that continued use of 50% nitrous oxide in oxygen as the inspired gas will promote lung collapse. The authors do not take any specific measures to promote lung collapse apart from ensuring that the lung is not partially ventilating via a leak around the cuff of the endobronchial tube. They occasionally apply gentle suction to the lung, although with marked emphysema this is relatively ineffective. Once the surgeons have visualized the space and divided adhesions, lung collapse is usually well enough established to allow definitive surgery to proceed.

For most VATS, OLV can be managed as described above for lung resection. Lung volume reduction surgery may be carried out bilaterally, therefore the second stage of the operation is carried out while the patient survives on the previously operated (and transiently damaged) lung.

The principles of OLV (Figure 5) also apply to general VATS. It is more important with lung volume reduction surgery to limit inflation pressure and to increase the expiratory phase of ventilation (I:E ratios of 1:3 or even up to 1:5) to prevent hyperinflation. PEEP is generally contraindicated for similar reasons. These limitations of ventilation almost certainly lead to hypercapnia but this is well tolerated in these patients. Gross over-inflation of the lung can lead to reduced venous return and cardiovascular collapse. If this is suspected, the patient should be disconnected from the ventilator to allow the ventilated lung to collapse and reduce intrathoracic pressure.

After most VATS the patients can be extubated in the normal way. Following lung volume reduction surgery it is desirable to establish spontaneous respiration as soon as possible to prevent exacerbation of air leaks and further trauma to the stapled or sutured lungs. The authors usually replace the endobronchial tube with a tracheal tube at the end of surgery and wean the patient from ventilation in the ICU over the ensuing few hours. It is mandatory to establish epidural analgesia to facilitate this. ◆

Radiographic Appearance of Lobar Collapse

Ian J Runcie

Ian J Runcie is Consultant Radiologist at the Princess Royal Hospital and the Ashdown Nuffield Hospital, Haywards Heath, UK. He qualified from Cardiff University and trained in Newcastle, UK. He has a special interest in interventional procedures, particularly vascular and urological.

Collapse or atelectasis is a reduction in the volume of an area of lung. There are three radiographic signs of lobar or segmental collapse.

Changes in density – are usually a late sign.
- The collapsing area may appear denser owing to approx-imation of the vessels within it.
- The surrounding lung may appear less dense owing to compensatory emphysema, usually identified by increased spaces between vessels compared with the other side rather than an obvious increase in blackness. A comparative vessel count is often useful.

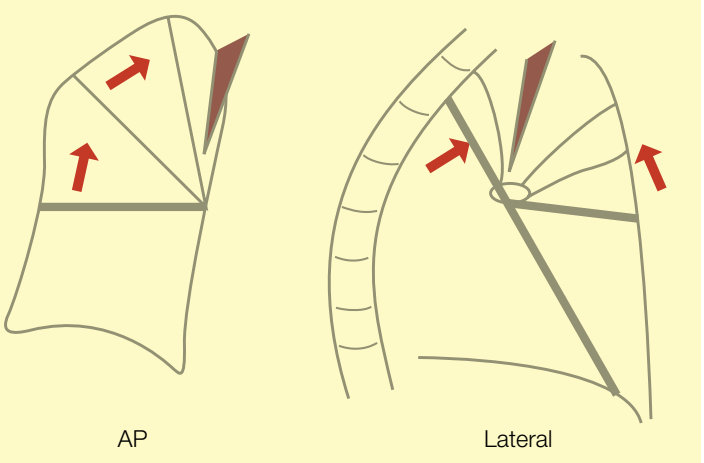
Changes in position – the hilum, mediastinum and diaphragm may shift towards the site of the collapse. Fissures show characteristic movement.

Borders adjacent to collapsed airless lung may be lost.

The following descriptions are of isolated lobar collapse. In practice there is often some associated consolidation or pre-existing disease (e.g. fibrosis) that alters the appearance. The appearances described below are only a guide to interpretation in practice.

Total collapse
Total collapse of a lung gives a whiteout on the affected side because of the airless lung and movement of the mediastinum and hemi-diaphragm to fill the space. Ribs on the affected side move closer. The other lung shows compensatory emphysema and may appear to cross the midline.

Right upper lobe collapse
The horizontal fissure moves from the horizontal towards the vertical and the upper end of the oblique fissure moves forward (Figure 1).



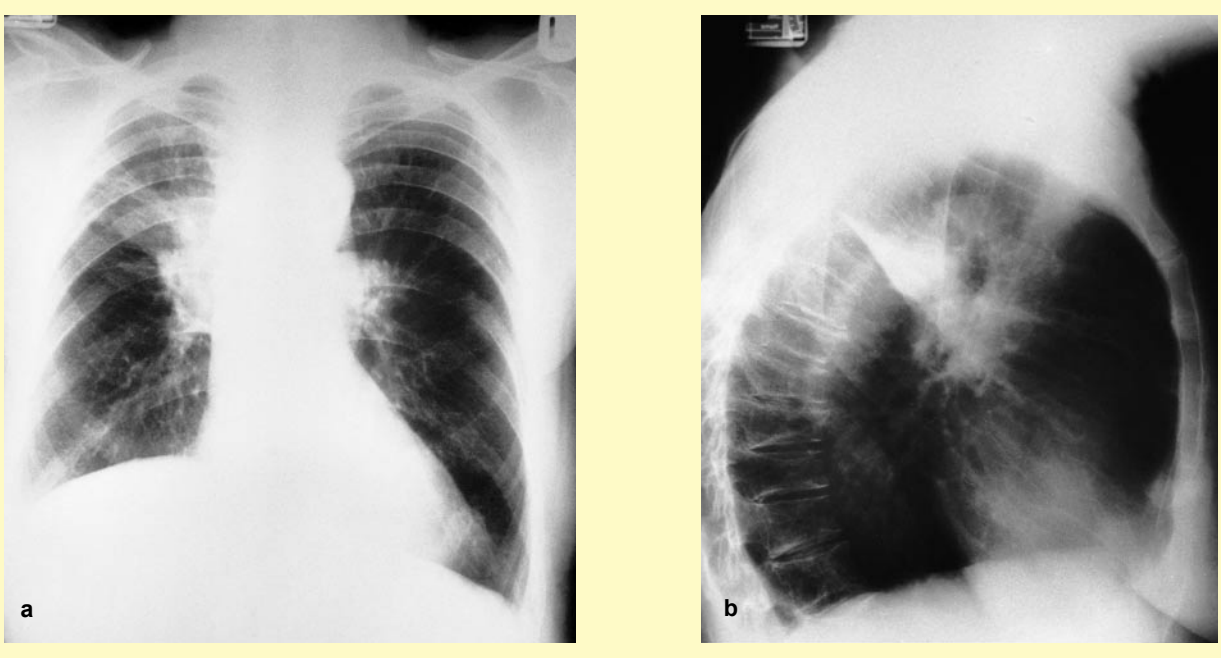
1

Changes in density
- Right upper lobe vessels move closer (Figure 2) and just before total collapse a density appears alongside the superior mediastinum.
- Compensatory emphysema occurs in the mid and lower zones.

Changes in position
- The horizontal fissure pivots on the hilum. Its lateral and anterior ends moving upwards. The upper half of the oblique fissure moves anteriorly. In severe collapse, the two meet up against the superior mediastinum. The trachea moves to the right.
- The right hilum is elevated and more prominent. Tenting may occur.

Borders – in severe collapse, the upper mediastinal border may be lost.

Tenting of the diaphragm is often a feature of upper lobe collapse or fibrosis, particularly following tuberculosis. If seen as a new feature it may be diagnostic of upper lobe collapse. It is caused by the elevation of the hilum pulling on the pulmonary ligament and accessory fissures. The pulmonary ligament is a strand of fibrous tissue between the hilum and the diaphragm.



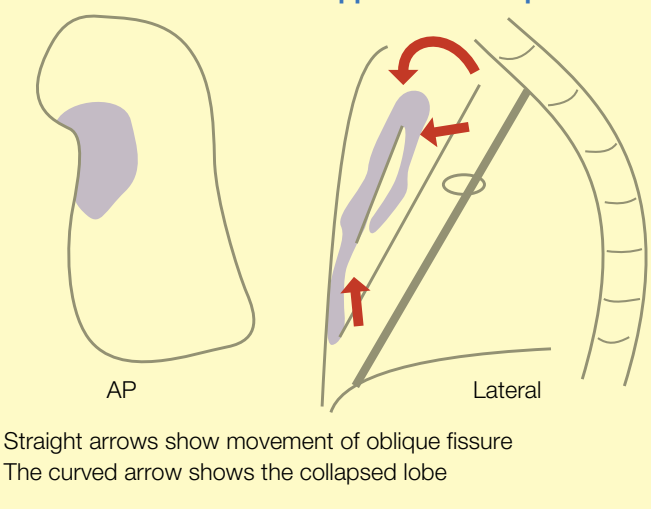
2

Example of right upper lobe collapse. **a** There is crowding of vessels in the right upper lobe (x) plus some increase in density which **b** shows to be caused by associated consolidation immediately superior to the oblique fissure in the posterior segment. The anterior segment is not consolidated. The consolidation demonstrates the anterior position of the oblique fissure. The normally positioned left oblique fissure can be seen more posteriorly (y). **a** The PA view shows the hila at the same level. Normally the right hilum is slightly below the left.

Left upper lobe collapse
The oblique fissure moves forwards (Figure 3) and comes to lie close to the anterior chest wall. In severe collapse the anterior part of the lobe moves posteriorly away from the anterior chest wall. The lower lobe then comes over the top of the collapsed lobe and comes to lie against the anterior chest wall. On the frontal view, the fissure is not seen but the collapsed lung may become evident against the upper mediastinum.

Changes in density
- The vessels in the left upper lobe approximate and a density appears around the aortic knuckle (PA view). The anterior part of the chest becomes increasingly denser (lateral view).
- Compensatory emphysema occurs in the left lower lobe.

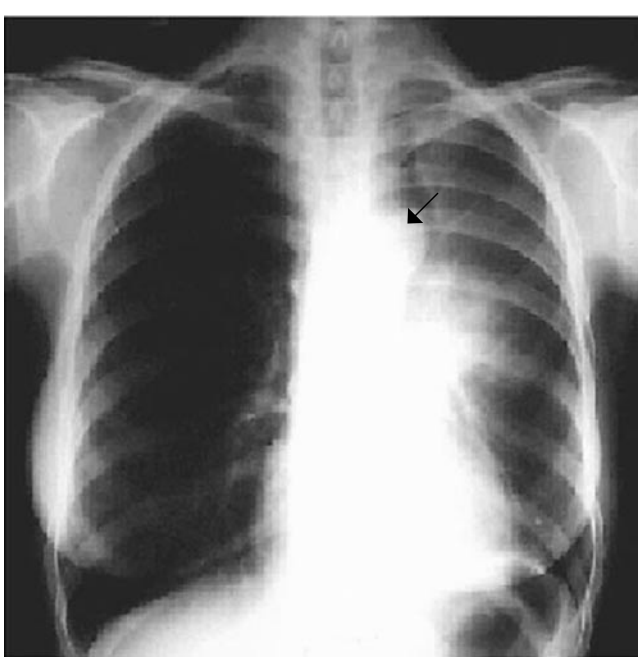
Changes in position – the fissure moves as shown in Figure 3.
The trachea moves left. As the left lower lobe expands, the diaphragm and the left hilum may elevate, and tenting may occur.



3

Borders – as the lobe collapses it rests against the aortic knuckle which lies anteriorly. As it loses air and becomes dense the aortic knuckle disappears. If the collapse advances further, the knuckle may be seen again, outlined against the lower lobe.

Figure 4 shows advanced left upper lobe collapse.



4 Advanced left upper lobe collapse. The collapsed lobe is closing down onto the hilum, becoming denser and causing the veil-like shadowing around the hilum. Note that there is no shift of the mediastinum, trachea, hemi-diaphragm or hilum. Nor is there any obvious compensatory emphysema. There is no pre-existing lung disease and the left lower lobe is sufficiently large and flexible to fill the available space. It is large enough to have come round medial to and above the collapsing lobe, causing the lucency around the aortic knuckle (arrow) and allowing this structure to be clearly seen.

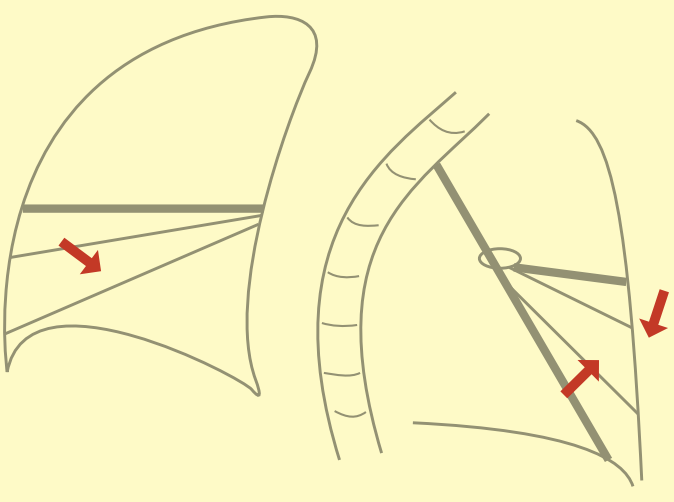
Right middle lobe collapse
The horizontal fissure and lower half of the oblique fissure approximate. The horizontal fissure is the more mobile. The collapsed lobe comes to lie against the heart border.

Changes in density – because the lobe is small, compensatory emphysema is seldom seen. There may be a vague density against the heart border (PA) better seen on the lateral view as a clear wedge-shaped opacity.

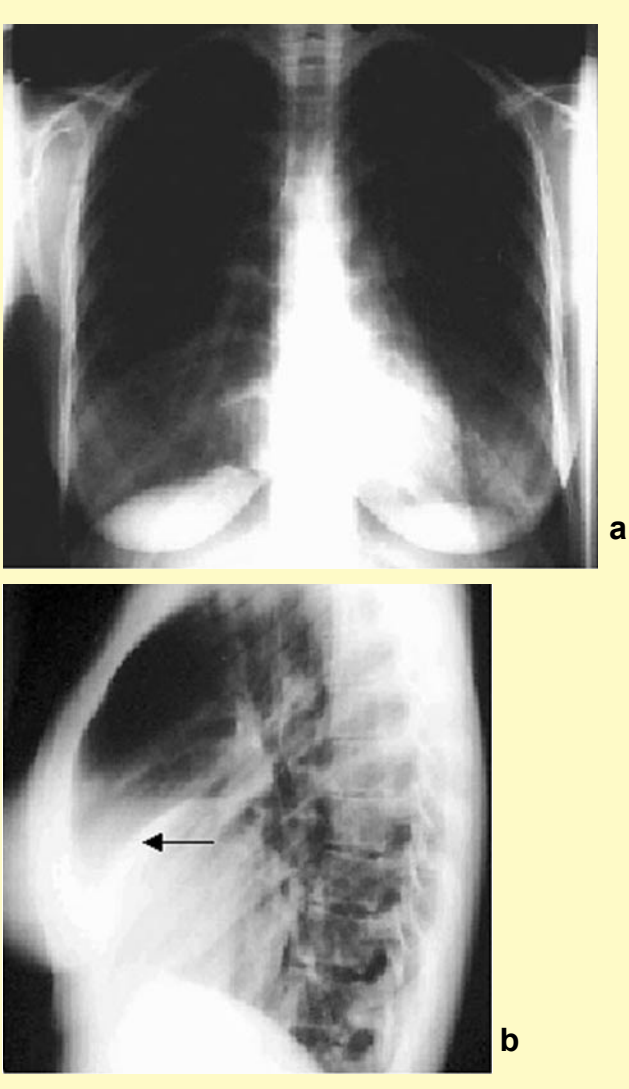
Changes in position – fissure movement is shown in Figure 5. It is best seen on the lateral view. On a PA film, if the horizontal fissure is not seen, any other changes may not be recognized.

Borders – in the late stages, the right heart border may be lost (Figure 6).

Lower lobe collapse
The pattern is similar on both sides (Figure 7). The oblique fissure moves backwards and medially. The fully collapsed lobe becomes a wedge of tissue lying up against the posterior mediastinum. The middle and upper lobes expand to fill the space lateral and anterior to the collapsing lobe.

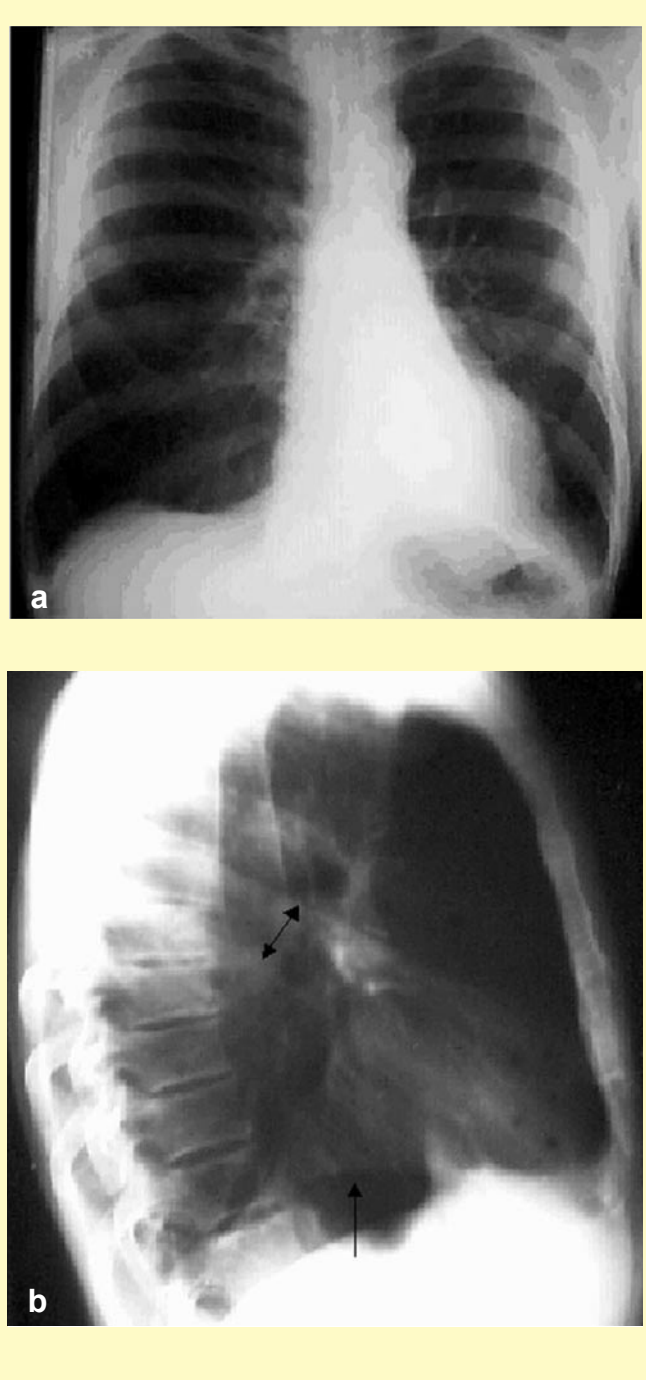


5



6

Example of middle lobe collapse. **a** There is loss of the right heart border. The horizontal fissure cannot be seen. **b** On the lateral view the horizontal fissure and the oblique fissure have approximated to each other leaving the middle lobe as a linear density overlying the heart shadow (arrowed).



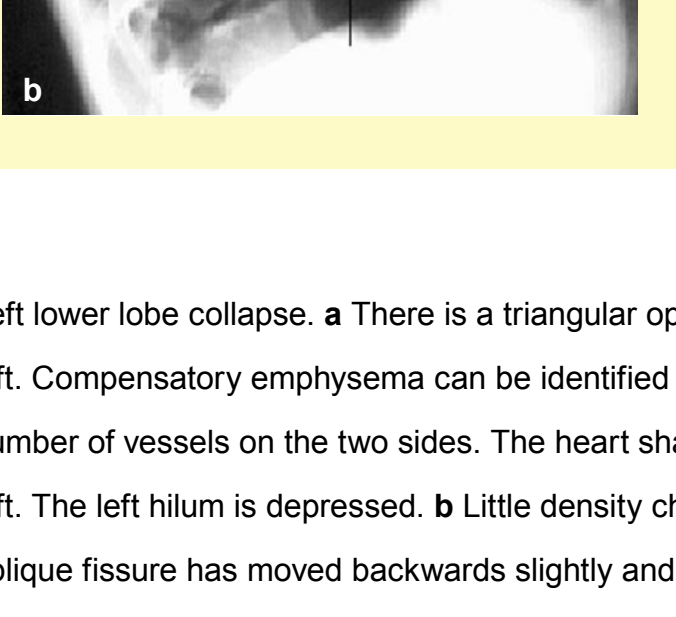
7

Left lower lobe collapse. **a** There is a triangular opacity behind the heart on the left. Compensatory emphysema can be identified on the left by comparing the number of vessels on the two sides. The heart shadow has moved slightly to the left. The left hilum is depressed. **b** Little density change can be identified. One oblique fissure has moved backwards slightly and can be seen behind the hilum. The other can still be seen in front of the hilum (double arrow). The posterior part of the left diaphragm cannot be identified though the stomach bubble (arrow) shows where it should be. Its anterior part can be identified in front of the little diaphragmatic ‘tent’ near to the inferior insertion of the oblique fissure. The right hemi-diaphragm can be clearly seen. This must mean that there is a considerable increase in the density of the collapsing lung, possibly with some associated consolidation.

Changes in density

- As the lobe moves posteriorly it becomes increasingly dense on the lateral view. On the AP view it may be seen as a wedge shape (through the heart shadow on the left).
- Compensatory emphysema occurs in right upper lobe.

Changes in position – the oblique fissure moves backwards (Figure 8). On the right the horizontal fissure may move in a similar way to right middle lobe collapse but the lung underneath it becomes less, rather than more, dense. There is movement of the heart shadow towards the side of the collapse and the hemi-diaphragm may elevate, especially if there is pre-existing lung disease limiting the compensatory emphysema. The hilum becomes depressed.



8

Lingular collapse

Lingular collapse is often involved in upper lobe collapse, but the lingula may collapse on its own. Features are identical to right middle lobe collapse except that there is no horizontal fissure. On the frontal view the only evidence may be a subtle loss of the left heart border.

Plate atelectasis or linear collapse

Areas of subsegmental collapse appear as lines of variable thickness. Plate atelectasis is often temporary and seen postoperatively or it may be long-standing and fibrotic, in which case it may be referred to as scarring. ◆

Respiratory Emergencies

Kenneth M Sim

Kenneth M Sim is Consultant Anaesthetist at the Queen Victoria Hospital, East Grinstead, West Sussex, UK. He qualified from the University of Edinburgh and trained in anaesthetics in London. He also studied non-conventional support strategies in acute lung injury patients at the Royal Brompton National Heart and Lung Hospital, London. His current interests include inhalation injury and metabolic management of burns patients.

Optimal gas exchange in the lung is achieved through matched distribution of ventilation and perfusion, with free diffusion of oxygen and carbon dioxide across the alveolar–capillary membrane. Acute interruption of the processes necessary to sustain gas exchange is rapidly life threatening. The causes may be multiple (Figure 1) and the pathology complex, but the ability to recognize and manage respiratory emergencies represents the sharp end of anaesthetic practice.

Respiratory emergencies may be encountered inside or outside hospital, in patients of all ages, and in circumstances that vary with regard to available equipment and support personnel. Appropriate management requires an ordered approach and the application of resuscitation principles promoted in the teaching of advanced trauma and cardiac life support.

- Assess the presenting condition of the patient.
- Administer supplemental oxygen.
- Use available techniques and equipment to establish effective ventilation.
- Consider requirements for advanced airway management including emergency intubation techniques.

Causes of respiratory emergencies

Trauma
- Mechanical disruption, foreign body, haemorrhage
- Pneumothorax, haemothorax
- Thermal injury

Infection
- Croup, bronchiolitis, epiglottitis
- Pneumonia

Neoplastic
- Tumour obstruction or compression

Perioperative respiratory events
- Obstruction or interruption of the ventilatory pathway
- Irritable airways with bronchospasm
- Barotrauma and pneumothorax
- Pulmonary oedema
- Anaphylaxis

Inflammatory
- Asthma
- Acute lung injury

Neurological
- High spinal cord transections
- Ascending polyneuropathy
- Brainstem lesions

Chemical
- Inhalational injury
- Carbon monoxide, cyanide toxicity
- Drug intoxication
- Aspiration pneumonitis

Vascular
- Pulmonary embolism and infarction
- Superior vena caval obstruction
- Pulmonary oedema

1

Respiratory obstruction

Airway oedema, inflammation and foreign body inhalation are examples of conditions leading to acute respiratory obstruction. Patients with these conditions have a marked increase in the work of breathing, with clinical features including intercostal recession, paradoxical respiratory efforts and stridor. Obstruction of the upper airway results in an inspiratory, or combined inspiratory and expiratory, wheeze. Obstruction below the level of the cords is generally associated with expiratory wheeze. Signs of deterioration include:

- hypoxia – associated with restlessness and increasing distress
- fatigue or deteriorating conscious level
- diminishing respiratory sounds.

These findings indicate that complete obstruction may be imminent and senior assistance is required urgently. Management options are limited to confirming the diagnosis and relieving or bypassing the obstruction. The methods are dictated by circumstance, experience and equipment.

If time allows, the patient should be transfered to theatre where the contents of the difficult airway trolley and skilled assistance improve management. More than one anaesthetist should be present. An experienced surgeon should be on site, ready to establish a surgical airway. Options to be considered include intravenous or inhalational induction of anaesthesia with direct laryngoscopy or fibre-optic bronchoscopic intubation either awake or with adjunctive transtracheal jet ventilation.

In practice, blood, oedema and lack of cooperation are impediments to awake intubation. An obstructed upper airway is a relative contraindication to transtracheal jet ventilation because a limited expiratory pathway and stacking of breaths can result in barotrauma. Anaesthetic techniques that maintain spontaneous breathing are generally safer than the use of muscle relaxants with positive pressure ventilation by mask. The view at laryngoscopy can be improved by using the McCoy laryngoscope. Intubation may be more easily achieved over a gum elastic bougie.

As in all difficult airway situations, it is important to consider alternative plans of action should the preferred option fail. Temporary control with a laryngeal mask or Combitube airway may be possible, but in a deteriorating emergency situation it is important to proceed without further delay to cricothyrotomy or tracheostomy.

Adjunctive airway management techniques should be practised in elective conditions. Simulator training can enhance the selection of appropriate choices in emergency airway care.

Close observation of the patient must continue after control of the airway has been achieved. Sustained high negative intrathoracic pressures can result in mechanical damage to the alveolar–capillary membrane. Pulmonary oedema as a sequel to upper airways obstruction has been reported in adults and children.

Asthma

Asthma is an inflammatory disease characterized by broncho-constriction, oedema of the airway wall and mucous plugging of the small airways. Severe acute asthma refers to a prolonged exacerbation of asthmatic symptoms unresponsive to usual medical treatment. Airway narrowing causes imbalance of ventilation and perfusion, lung hyperinflation, and increases the work of breathing which results in respiratory muscle fatigue. If therapy is delayed or inadequate, acute respiratory failure develops.

Severe acute asthma may present with slow onset in those with longstanding unstable asthma or in fulminant form in response to environmental triggers. Features of life-threatening asthma include agitation, exhaustion and altered mental state. Shortness of breath affects the ability to speak in sentences. A history of severe attacks, previous tracheal intubation or intensive care indicates a high risk of complications, including death.

Initial treatment

Initial treatment is based on the administration of high dose β_2-agonists, high flow oygen and systemic corticosteroids. Salbutamol and terbutaline are equally effective and should be given by the inhaled route initially. In hospital, delivery should be via an oxygen-driven nebulizer. The initial dose in those over 5 years is salbutamol, 5 mg, or terbutaline, 10 mg. The dose should be halved in those under 5 years of age. The clinical response is measured by following trends in heart rate, respiratory rate and peak expiratory flow. Nebulized β_2-agonists should be continued until significant clinical improvement is seen or serious side-effects, such as tachycardia or dysrhythmia occur. Nebulized ipratropium bromide can be added if the initial response to treatment is poor, but should not be considered first-line therapy. Oxygen saturation should be maintained above 92% with humidified high flow oxygen by face mask.

The anti-inflammatory action of corticosteroids in asthma has a delayed onset over several hours, therefore systemic corticosteroids should be given early in adequate doses. The dose recommended in adults is hydrocortisone, 100–200 mg intravenously. Classically, nebulized corticosteroids were thought to have no place in the initial management of severe acute asthma but recent work suggests that they may have a complementary role. Empirical antibiotic therapy is not recommended.

Circulation

Severe acute asthma can have a significant effect on cardio-vascular function. Lung hyperinflation affects venous return and the position of the interventricular septum and can adversely affect left ventricular filling and emptying. Pulsus paradoxus, a feature of severe acute asthma, refers to the significant reduction in arterial systolic pressure measured during inspiration. Sweating and fluid losses from the respiratory tract compound these circulatory effects and thus action to maintain circulating volume is required. Volume loading with 20–30 ml/kg body weight of a crystalloid solution may be necessary.

Investigations

A chest radiograph is unnecessary in the initial investigation of acute asthma unless the diagnosis is in doubt, for example if a foreign body is suspected. Arterial blood gas analysis is generally performed but is not predictive of outcome. Hypercapnia and respiratory acidosis are important markers of deterioration. A differential white cell count is indicated, especially if the patient is pyrexial or producing purulent sputum. High dose β_2-agonist therapy is associated with hypokalaemia and hypomagnesaemia. The ECG may reveal signs of right heart strain, but this usually resolves quickly with effective therapy. Trend measurements of heart rate, respiratory rate, peak expiratory flow rate and oxygen saturation should be recorded.

Progress

The decision to intubate the asthmatic patient is based mainly on clinical judgement, taking into account developing fatigue and asthmatic history. If intubation and ventilation become necessary, a ventilatory regimen that does not worsen the underlying dynamic hyperinflation should be chosen. Permissive hypercapnia, small tidal volumes and a long expiratory time may reduce the risk of barotrauma and hypotension. Mechanical ventilation supports gas exchange and unloads the respiratory muscles until aggressive medical treatment is effective.

Close monitoring of lung mechanics and experience are necessary to identify the appropriate time for weaning. The intensive care management of acute severe asthma is discussed in *Anaesthesia and Intensive Care Medicine* **2:9** 353. A full review of the patient's asthma management needs to be undertaken before discharge, in anticipation of subsequent asthma attacks.

Inhalation injury

All patients with a history of exposure to smoke or fumes in an enclosed space should be considered at risk of inhalation injury, even if the initial signs and symptoms do not suggest it. Component factors include direct thermal injury, toxic gas inhalation and the later development of a chemical pneumonitis.

Thermal injury to airway mucous membranes happens immediately and causes upper airway erythema and oedema, generally developing during the first 6–24 hours. Severe injury results in ulceration and haemorrhage. It is most common in flame burns patients with extensive (> 30%) surface area injuries who develop a generalized loss of vascular endothelial integrity, resulting in soft tissue oedema.

Intubation

The requirement for urgent airway intervention should be judged on the pattern of the presenting history and examination findings. Any combination of the following signs and symptoms indicates prophylactic tracheal intubation, especially if transfer to a specialist burns centre is required:

- prolonged entrapment at the scene of the fire
- obtunded conscious level
- combination of facial and oral burns
- voice changes
- coughing productive of carbonaceous sputum.

Protocol-based resuscitation procedures and delays in accessing a bed in a specialist burns centre have led to a low threshold for tracheal intubation. This is a safe approach in an adult major flame burn patient, even those with with equivocal degrees of severity of facial burns, in whom progressive swelling will still develop over 24–36 hours. Early examination may be falsely reassuring and the dynamic nature of the evolving injury must be appreciated. The history should be considered, to assess the risk of cervical spine injury, but otherwise the approach to intubation should be routine with rapid sequence induction where necessary.

Early management
Early management of patients with significant inhalation injury is symptomatic; high doses of analgesics and sedatives may be required. There is no need for pro-phylactic antibiotics. Early tracheal toilet, humidified gases and nebulized saline solution help to mobilize secretions. Fibre-optic bronchoscopy is generally performed soon after arrival at the specialist centre to assess the inital damage and enable bronchoalveolar lavage.

Scalding injuries
Scalding injuries are most common in young children and account for 80% of the burns seen in those under 5 years. Facial involvement is common but intubation is seldom necessary. The charred appearance of a major facial flame burn (Figure 2) can be compared with that of a facial scald, managed without intubation (Figure 3).

2 Full thickness burns to head and neck from a house fire.

3 Extensive facial scalds resulting from an assault.

Steam has a much higher specific heat capacity than dry air and can cause thermal injury further down the respiratory tract. In children scalded following ingestion of hot fluids or steam inhalation, thermal injury to the upper airway is rare but should be considered.

Children
Children with inhalation injuries who require intubation are prone to sloughing casts of endobronchial debris, causing sudden onset hypoxic episodes. Aggressive physiotherapy and regularly nebulized solutions possibly including sodium bicarbonate, n-acetyl cysteine and heparin are required to manage episodic airway obstruction and to prevent occlusion of the tracheal tube.

Later management
The possibility of systemic toxicity secondary to carbon monoxide and cyanide toxicity must be considered in burns patients with inhalation injuries. Carbon monoxide binds reversibly to haemoglobin with an affinity 200 times greater than oxygen, forming carboxyhaemoglobin. Oxygen is displaced and the systemic arterial oxygen content reduced. Other toxic effects include impaired cellular metabolism and binding to myoglobin, resulting in myocardial and skeletal muscle dysfunction.

Serial arterial blood samples to measure carboxyhaemoglobin levels are necessary, remembering that displayed oxygen saturation levels on pulse oximetry may be falsely elevated. The clinical presentation of acute carbon monoxide poisoning is variable, but observed symptoms approximately correlate with carboxyhaemoglobin levels (Figure 4).

Effects associated with carboxyhaemoglobin levels

Level	Signs and symptoms
< 10%	Usually asymptomatic
10–20%	Headache
20–40%	Dizziness, confusion and nausea
40–60%	Coma and seizures, cerebral oedema
> 60%	Increasing risk of mortality

4

Treatment for carbon monoxide poisoning is supportive, with supplemental oxygen given by a non-rebreathing circuit, mechanical ventilation and monitoring for cardiac arrhythmias. High inspired oxygen concentrations are necessary to reduce the half-life of carboxyhaemoglobin.

Persistent metabolic acidosis, despite otherwise successful resuscitation end-points, suggests cyanide toxicity. Treatment with sodium nitrite and sodium thiosulphate aims to induce methaemoglobin formation to bind cyanide, thus preserving mitochondrial cytochrome oxidase. Cyanide is detoxified by the hepatic enzyme rhodanase, a process hastened by sodium thiosulphate. This therapy has side-effects including significant methaemoglobinaemia; advice is available from the National Poisons Information Service in the UK.

Referral for hyperbaric oxygen therapy has been advocated, but the logistics of transfer and complications in managing any associated burns injuries leave few cases suitable for this therapy. Its place in patients with severe carbon monoxide toxicity without cutaneous burns is more contentious, but it has been advocated for carbon monoxide toxicity associated with prolonged neurological symptoms or myocardial ischaemia and in pregnancy.

Follow-up
It is important that the lessons learnt from emergency situations are acted upon. Those involved need time to consider the sequence of events and should have an opportunity to reflect and comment.

Critical incident reporting to the risk management process within the hospital helps to identify resource and organizational issues. Good record-keeping is an essential part of the response sequence – record, report and, where necessary, repair. ◆

Respiratory System: Applied Pharmacology

Roseanne Meacher
Jeremy Cordingley

Roseanne Meacher is Specialist Registrar in Intensive Care Medicine at the Royal Brompton Hospital, London, UK. She qualified from University College and Middlesex Hospital Medical School, London.

Jeremy Cordingley is Consultant in Intensive Care Medicine at the Royal Brompton Hospital, London, UK. He qualified from Charing Cross and Westminster Medical School, London, and trained in anaesthesia and intensive care medicine in London.

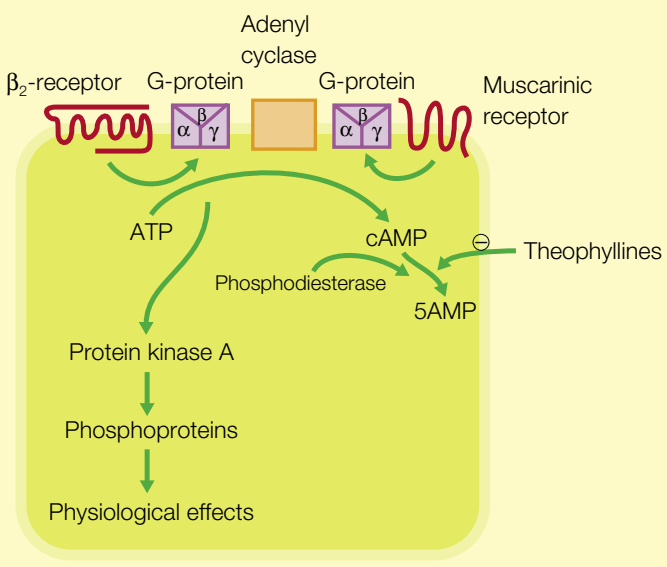
Asthma and chronic obstructive pulmonary disease (COPD) are common and knowledge of respiratory pharmacology is therefore essential for anaesthetists and intensivists.

Respiratory stimulants
Doxapram is a non-specific stimulant that acts on peripheral chemoreceptors and the respiratory centre to increase respiratory rate and tidal volume. In anaesthesia it is used to reverse postoperative respiratory depression without antagonizing opioid analgesia. Doxapram is given as an intravenous bolus of 1–1.5 mg/kg and has a duration of action of 5–12 minutes. For the treatment of type 2 respiratory failure, doxapram is infused at a rate of 1.5–4 mg/minute. It should not be used in patients with acute asthma or upper airway obstruction. Doxapram increases catecholamine release, resulting in tachycardia, hypertension and arrhythmias. This limits its use in patients with ischaemic heart disease, hypertension and thyrotoxicosis. Other important side-effects include agitation, hallucinations and (rarely) convulsions, which precludes its use in epileptics. A recent meta-analysis showed that the use of doxapram in COPD is only marginally superior to placebo in preventing blood gas deterioration and it has largely been superseded by non-invasive ventilation.

Naloxone and flumazenil are competitive antagonists that reverse the respiratory depressant effects of opioids and benzodiazepines, respectively. Both have a short duration of action when given by bolus and may require repeat doses or infusion. Flumazenil is given as boluses of 100 μg up to 1–2 mg. Side-effects include agitation, acute withdrawal, seizures, arrhythmias, hypertension, confusion, nausea, vomiting and raised intracranial pressure. Naloxone is administered in 100 μg increments to a maximum dose of 10 mg (10 μg/kg in children). Side-effects include nausea, vomiting, arrhythmias, tachycardia, reversal of analgesia, pulmonary oedema and cardiac arrest.

Bronchodilators
β_2-agonists such as salbutamol and terbutaline act on the β_2-receptors of airway smooth muscle cells to increase adenyl cyclase activity and raise intracellular levels of cyclic adenosine 3'5' monophosphate (cAMP) (Figure 1). Salbutamol may also inhibit release of histamine and other mast cell mediators. Maximal bronchodilation occurs after 15 minutes and lasts 4–6 hours.

Mechanism of action of bronchodilators



Muscarinic and β_2-receptors are linked to the adenyl cyclase enzyme via a transmembrane G-protein. When these receptors are stimulated, adenyl cyclase is activated and catalyses the conversion of adenosine triphosphate (ATP) to cyclic adenosine 3'5'-monophosphate (cAMP). Cyclic AMP activates protein kinase A which catalyses the phosphorylation of intracellular proteins thus altering their activity. Phosphodiesterase inactivates cAMP and is inhibited by theophyllines

1

At low doses, the β_2 effects of these agents predominate, but at higher doses, β_1 effects occur causing tachycardia, positive inotropy, hypertension and arrhythmias. Non-selective sympathomimetics such as adrenaline (epinephrine) have much greater cardiac effects and their use is reserved for acute emergencies such as anaphylaxis and acute severe asthma. Other important side-effects include tremor, agitation, paradoxical bronchospasm, vasodilatation, hypokalaemia and ketosis. Care should be taken in patients with thyrotoxicosis, heart disease and long QT syndrome. Initial concerns about the adverse effects of regular use of β_2-agonists in chronic asthma have not been confirmed. An increased risk of death reported with the β_2-agonist fenoterol may have been a reflection of increased disease severity. A later meta-analysis showed no association between risk of death in asthma and the use of β_2-agonists. However, it is recommended that to prevent tachyphylaxis β_2-agonists are used on a rescue basis for mild-to-moderate asthma.

β_2-agonists can be administered by inhalation, orally, subcutaneously (e.g. terbutaline) and intravenously. Techniques for inhalation include nebulizers, pressurized metered-dose inhalers, breath-activated aerosols, powder and spacer devices. Newer aerosols use non-chlorofluorocarbon (non-CFC) hydrofluoroalkane (HFA) propellant. Despite good inhaler technique and optimal particle size (2–5 μm) 80–90% of drug is deposited in the mouth and pharynx. Breath-activated devices require an inspiratory effort of 30 litres/minute. Spacer devices can overcome difficulties with inhaler technique and are useful in children under 5 years of age and in the elderly.

Nebulized β_2-agonists remain first-line treatment for acute asthma. Continuous nebulizers are more effective than inter-mittent treatment. High doses (e.g. salbutamol, 2.5–5 mg, terbutaline, 5–10 mg) are required in acute bronchospasm. It is important to use oxygen to nebulize because β_2-agonists may cause hypoxia by inhibiting hypoxic pulmonary vaso-constriction.

In an acute exacerbation of COPD there is often an element of reversible airways obstruction. Therefore, β_2-agonists can be beneficial though they may not be as effective as anticholinergic agents.

Salbutamol and terbutaline can be given intravenously though there is no evidence to support this therapy and side-effects are common. In adults, a bolus of salbutamol, 250 μg, is infused slowly with ECG monitoring.

Ventilated patients have beneficial responses to β_2-agonists given as nebulizers though drug delivery drops to 1–6% of the dose given, depending on respiratory rate and flow. Most drug deposits in the upper airway and on the tracheal tube.

Longer-acting β_2-agonists such as salmeterol and formoterol (eformoterol) are highly lipid soluble and dissolve in smooth muscle cell membranes at high concentration. This acts as a slow-release depot with a duration of action of 12 hours. They are given by inhalation and may improve nocturnal symptoms, poorly controlled asthma and COPD.

Anticholinergic drugs: ipratropium and oxitropium are muscarinic receptor antagonists resulting in vagal inhibition and bronchodilatation. They also block mast cell receptors thus reducing the release of inflammatory mediators. Inhaled ipratropium is given four times daily with maximum effect at 60 minutes and duration of 3–6 hours. Paradoxical bronchospasm can occur. Side-effects are usually local, because little drug is absorbed, and include dry mouth and blurred vision. In patients with glaucoma, the eyes must be protected. Systemic effects include urinary retention, decreased gastric emptying and constipation. Hypoxic pulmonary vasoconstriction is not affected and thus supplemental oxygen need not be given when nebulizing.

There is some evidence that nebulized ipratropium bromide is as effective as β_2-agonists in the treatment of acute asthma and COPD and improves lung function in chronic COPD, but β_2-agonists remain the first-line therapy.

Theophyllines: use is controversial because they are less potent bronchodilators than β_2-agonists but have greater potential for side-effects. Theophylline has several mechanisms of action including phosphodiesterase inhibition, antagonism of presynaptic adenosine receptors, and reduction of calcium influx into smooth muscle cells.

Theophylline, 200–600 mg, is administered orally three times a day. The addition of the salt, ethylenediamine to form aminophylline (86% theophylline), increases water solubility and allows intravenous administration. For intravenous use, a loading dose of aminophylline, 5–7 mg/kg, is given over 20–30 minutes to reduce the incidence of toxic effects. A maintenance infusion is continued at a rate of 0.5 mg/kg/hour with ECG monitoring and daily plasma levels checked. If patients have been on chronic therapy the loading dose should be omitted unless plasma levels are known.

Toxic effects include tachycardia, arrhythmias, agitation, convulsions, altered gut motility and hypokalaemia. Sup-plemental oxygen must be given because hypoxic pulmonary vasoconstriction is inhibited. The therapeutic range is 10–20 mg/litre though beneficial effects can be seen at lower concentrations and adverse effects may occur at concentrations less than 20 mg/litre. Theophylline is metabolized in the liver. Oral absorption is high but subject to varying first-pass metabolism. Changes in hepatic metabolism due to disease, age or induction/inhibition of the cytochrome P450 system (Figure 2) alter clearance and plasma levels. The half-life of theophylline is about 8–12 hours and tolerance does not develop.

Factors affecting clearance of theophylline

Increased	Decreased
• Smoking	• Liver disease
• Alcohol	• Cardiac failure
• Childhood	• Elderly
• Carbamazepine	• Neonates
• Rifampicin	• Viral infection
• Barbiturates	• Sepsis
• Phenytoin	• Cimetidine
	• Ciprofloxacin
	• Erythromycin
	• Fluvoxamine
	• Oral contraceptives

2

Currently, use of theophyllines is limited to acute severe bronchospasm and poorly controlled chronic asthma or COPD. There is no definitive evidence to support intravenous use in acute attacks though some studies have shown a trend in improving lung function and short-term improvements in COPD. Reported symptomatic improvement may be due to effects on diaphragmatic contractility.

Corticosteroids
Corticosteroids are used in the treatment of asthma, COPD, interstitial lung disease and the fibroproliferative phase of acute respiratory distress syndrome (ARDS). Use is restricted by side-effects. With long-term, high-dose corticosteroids, patients may become Cushingoid. Protein catabolism results in striae, thinning and bruising of the skin, and myopathy. Metabolic effects include glucose intolerance, fluid retention, adrenal suppression and osteoporosis. In addition, gastric bleeding, psychosis, cataracts and an increased risk of infection occur including possible reactivation of tuberculosis and chickenpox. In children, higher doses have been shown to suppress growth. A reduction to low-dose inhaled corticosteroids should therefore be achieved as soon as possible because they reduce the rate of growth but do not affect final adult height. Adrenal suppression can occur in any patient who has received more than 2 weeks of oral corticosteroid therapy in the preceding year and may also be seen after high-dose inhaled corticosteroids. Additional corticosteroids may be required during times of additional stress such as surgery or acute illness.

Inhaled corticosteroids have fewer systemic side-effects, but oral candidiasis and reversible vocal cord laxity can occur. Using a spacer device to decrease deposition in the upper airway reduces local adverse effects. Paradoxical bronchospasm is treated using a bronchodilator.

The three corticosteroids available for inhaled use are beclomethasone dipropionate, 0.2–1 mg b.d., budesonide, 0.2–2 mg/day, and fluticasone, 0.1–1 mg b.d. They are available in pressurized metered-dose inhalers and breath-activated aerosol or dry powder devices. There is no evidence that one is better than another. The lowest effective dose should be used. Inhaled corticosteroids should be used if inhaled β_2-agonists are required more than once a day.

A short course of oral corticosteroids can be used to treat acute attacks of asthma, to improve lung function and to reduce the frequency of hospital admission and relapse rates if started early. Prednisolone, 30–60 mg, is usual. Oral prednisone and prednisolone are absorbed well – prednisone is converted by first-pass metabolism to the active prednisolone. Increasing the dose of inhaled corticosteroids may have similar effects. Intravenous hydrocortisone, 400 mg/day in divided doses, can be used if oral corticosteroids cannot be taken or are poorly tolerated. The course can be stopped after 1 week if the patient is stable, but tailed off more slowly if unstable. In chronic asthma, long-term oral corticosteroids have a similar effect to high-dose inhaled corticosteroids but have more adverse effects and therefore patients should be converted to inhaled therapy. Long-term inhaled corticosteroids result in better symptom control, less use of supplemental drugs, improved lung function and decreased bronchial hyper-reactivity. In COPD, oral or high-dose inhaled corticosteroids improve lung function during acute exacerbations with a decreased relapse rate, but evidence of corticosteroid responsiveness during chronic therapy suggests that a diagnosis of reversible airways obstruction should be considered. Corticosteroids do not prevent COPD progression but may reduce the frequency of exacerbations.

Corticosteroids are commonly administered to treat the fibroproliferative phase of ARDS. A common approach is to give methylprednisolone, 2 mg/kg/day reducing over 28 days.

In croup, corticosteroids reduce the requirement for invasive ventilation and should be given early (e.g. dexamethasone, 0.3–0.6 mg/kg orally or by injection).

Newer drugs
Leukotriene receptor antagonists: (e.g. montelukast, zafirlukast) are taken orally as additional therapy for chronic asthma. They have numerous side-effects including hepatitis (zafirlukast) and a risk of Churg–Strauss syndrome. Their role is unclear – they may improve asthma control slightly, but are not yet recommended in place of regular inhaled corticosteroids.

Intravenous magnesium*:* the data do not support the routine use of intravenous magnesium in acute asthma, but it may have a role in severe refractory asthma when 5–10 mmol can be given over 20 minutes. Serum levels must be monitored if repeat doses are given. Magnesium toxicity can cause respiratory muscle weakness.

Effects of anaesthesia on the respiratory system

Induction of general anaesthesia commonly results in respiratory depression and upper airway obstruction due to reduction of pharyngeal tone and posterior displacement of the tongue. Airway reflexes are depressed, increasing the risk of pulmonary aspiration of gastric contents. During emergence, stimulation of the larynx may result in laryngospasm. This occurs more commonly in children and can be life threatening. Tracheal intubation can induce bronchospasm and vagally mediated bradycardia. The presence of a tracheal tube may cause airway oedema that presents only after removal, this is more significant in children

General anaesthesia commonly causes a 20% reduction in functional residual capacity. Atelectasis develops in dependent parts of the lungs resulting in shunting and hypoxia. The reduction in lung volume also leads to increased airway resistance and reduced lung compliance. These effects occur within minutes of induction and atelectasis commonly persists postoperatively. Ventilation is thus increased to non-dependent parts of the lungs. Neuromuscular blocking drugs and positive-pressure ventilation further increase ventilation to poorly perfused areas of lung, increasing physiological dead space. While maintaining alveolar recruitment and reducing shunt, positive-pressure ventilation reduces venous return and cardiac output thus decreasing mixed venous oxygen saturation. These effects are magnified by ventilatory adjustments that increase mean airway pressure such as the addition of positive end-expiratory pressure.

Administration of dry and cold gases is associated with impaired mucociliary function, increased mucus viscosity and decreased surfactant production. This can lead to airway plugging, atelectasis and worsening gas exchange. Thus, it is important to maintain the heat and humidity of inspired gases by using either a heat and moisture exchanger or a heated humidifier.

Volatile anaesthetic agents and gases depress respiration and the ventilatory response to hypercapnoea. Tidal volume is decreased but partially compensated for by increased respiratory rate. Volatile agents are bronchodilators: halothane and isoflurane are used most commonly for this purpose. Halothane and sevoflurane are the least irritant to the airways and are used for gaseous induction of anaesthesia. Nitrous oxide has a blood/gas partition coefficient 35 times that of nitrogen. Therefore, administration of nitrous oxide results in expansion of compliant gas spaces within the body including pneumothoraces. Termination of nitrous oxide causes diffusion hypoxia unless supplemental oxygen is given.

Intravenous induction agents (e.g. propofol, etomidate, thiopental (thiopentone)) cause dose-related respiratory depression and apnoea. Airway reflexes are depressed to a greater degree with propofol than with other agents. This results in a lower incidence of bronchospasm and laryngospasm on induction of anaesthesia. Thiopental (thiopentone) may cause histamine release. In contrast to other anaesthetic drugs, ketamine stimulates ventilation and is depressant only following large doses. Airway patency is usually maintained. Ketamine is a bronchodilator and is occasionally used to treat refractory bronchospasm. Benzodiazepines are also respiratory depressants and may cause apnoea, particularly if used in conjunction with opioids.

Analgesic drugs: morphine depresses the ventilatory response to the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) primarily by reducing respiratory rate rather than tidal volume. Morphine inhibits the cough reflex, can cause bronchoconstriction and should be avoided in asthmatics. Very large doses of opioids can lead to severe muscle rigidity making ventilation impossible. This rigidity is prevented by simultaneous use of a neuromuscular blocking drug. Sufentanil and remifentanil are extremely potent respiratory depressants. Pethidine can cause bronchiolar dilatation via a direct smooth muscle relaxant action and is therefore preferred to morphine for asthmatic patients. Tramadol causes less respiratory depression than morphine. Non-steroidal anti-inflammatory drugs can induce asthma in susceptible patients.

Other drugs used during anaesthesia: neuromuscular blocking drugs produce respiratory muscle paralysis and apnoea. This can be unusually prolonged following the use of suxamethonium in patients with abnormal plasma cholinesterase activity. All the neuromuscular blocking drugs can cause histamine release and bronchospasm but this is uncommon with vecuronium and rocuronium.

Atropine inhibits bronchial glandular secretion, stimulates the respiratory centre and increases anatomical dead space by its bronchodilatory action. The anticholinesterase neostigmine causes increased upper and lower airway secretions and bronchospasm and thus is always administered with an antimuscarinic agent (e.g. atropine, glycopyrrolate). ◆

Allergic Reactions in the Perioperative Period

David K Menon

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India, Leeds General Infirmary, The Royal Free Hospital, and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

The prevalence of major allergic reactions during anaesthesia is poorly defined; estimates range from 1/3,500 to 1/25,000, with little evidence of a true increase in incidence over the last two decades. These figures include anaphylactic and anaphylactoid reactions. Both are associated with mast cell histamine release with its attendant pathophysiological consequences. However, the former is the consequence of interaction of specific antigens with IgE antibody, while the latter are not IgE related. In practice, the mechanisms are of little relevance in the acute stage, and clinical management is governed by the severity of the reaction.

Several drugs used in the perioperative period have been associated with allergic reactions (Figure 1), in particular neuromuscular blocking drugs. Almost every anaesthetic drug has been implicated as a trigger. A previous history of exposure to the relevant drug is often not elicited.

Severe allergic reactions during anaesthesia and surgery are characterized by a different clinical profile from that seen with allergic reactions in the non-operative setting (Figure 2). Cutaneous symptoms and signs are less common, possibly because the skin is covered by drapes, but there is an increase in the percentage of cases presenting as cardiovascular collapse, perhaps because intravenous administration may result in more severe reactions. In the anaesthetized patient, drug-related allergic reactions may also present as angio-oedema (typically facial), unexplained desaturation, arrhythmias, rising airway pressures or an inability to ventilate the lungs. Manifestations usually appear 5–15 minutes after administration of the drug.

Agents commonly implicated in perioperative allergic reactions

- Muscle relaxants (vecuronium, atracurium, suxamethonium, pancuronium)
- Induction agents (barbiturates, etomidate, propofol)
- Opioids (morphine, pethidine, fentanyl)
- Colloids for intravascular volume expansion (particularly gelatins and some dextrans)
- Local anaesthetics
- Antibiotics
- Radiological contrast agents
- Blood and blood products
- Latex

1

Clinical manifestations of serious allergic reactions

Manifestation	Non-operative (n = 1158)	Perioperative (n = 484)	
		Anaphylaxis	Anaphylactoid
Cutaneous	98[1]	75.6	86
Cardiovascular			
Hypotension	21	18.0	20
Cardiovascular collapse	–	49.0	12
Dizziness, syncope	31	–	–
Respiratory			
Wheeze, bronchospasm	53	41.9	25
Death	0	< 1.0[2]	0

[1]All figures are percentages.
[2]May be higher depending on severity. A mortality of 3.5% is often quoted for severe reactions.

2

The treatment of an anaphylactic reaction does not depend on its cause, and standard management algorithms are available in most hospitals (Figure 3). The most important point is to consider the diagnosis and initiate therapy. The diagnosis is essentially clinical, but may be supported by an increase in plasma tryptase levels in a blood sample, ideally obtained 1 hour after the onset of the reaction. Tryptase is one of several neutral serine proteases contained in mast cells, which though not an important mediator, acts as a surrogate marker of other vasoactive substances released during mast cell degradation, because it has a long plasma half-life and it is stable in plasma stored at –20°C. It is important to emphasize that management of the allergic episode beyond the acute stage remains the responsibility of the attending anaesthetist. Comprehensive management should include resuscitation, acute aftercare and arranging for investigation of the patient in an allergy clinic.

Emergency management of perioperative anaphylaxis

The doses specified are for a 70 kg adult if not otherwise specified. Basic monitoring is assumed

Immediate therapy

1 Discontinue administration of the suspect drug
2 Summon help
3 Discontinue surgery and anaesthesia if feasible
4 Maintain airway, 100% oxygen (consider tracheal intubation and intermittent positive-pressure ventilation, if not already instituted)
5 Intravenous adrenaline (epinephrine) especially if bronchospasm present, 50–100 μg (0.5–1.0 ml 1:10,000)
Repeat as necessary for hypotension and bronchospasm
Prolonged therapy may be necessary
6 Start intravascular volume expansion with suitable crystalloid or colloid, 10 ml/kg rapidly
7 Consider formal cardiopulmonary resuscitation, including external cardiac massage

Secondary management

1 Adrenaline (epinephrine)-resistant bronchospasm: consider one of the following
salbutamol, 250 μg i.v. load, 5–20 μg/min maintenance
terbutaline, 250–500 μg i.v. load, 1.5 μg/min maintenance
aminophylline, 6 mg/kg i.v. over 20 min
2 Bronchospasm and/or cardiovascular collapse: corticosteroids
hydrocortisone, 300 mg i.v., or methyl prednisolone, 2 g i.v.
3 Antihistamines
chlorpheniramine, 20 mg i.v. given slowly
4 Measure arterial blood gases. If acidosis is severe after 20 min treatment, consider
sodium bicarbonate, 0.5–1.0 mmol/kg i.v. (0.5–1 ml/kg of 8.4% solution)
5 Catecholamine infusions:
adrenaline (epinephrine), 5 mg in 500 ml saline (10 μg/ml): 10–100 ml/hour
noradrenaline (norepinephrine), 4 mg in 500 ml dextrose (8 μg/ml): 10–100 ml/hour
6 Consider possibility of coagulopathy: clotting screen and blood products if needed
7 Draw 10 ml of venous blood about 1 hour after onset, send sample to laboratory to store plasma at –20°C for tryptase assay

Post-acute care – this is an anaesthetic responsibility

1 Ensure that physiological stability is maintained in recovery
2 Consider admission to ICU
3 Inform patient and warn regarding risks of re-exposure to drug (Need for *Medic-Alert* bracelet?)
4 Arrange for referral to allergy clinic

3

Allergy investigation may involve patch, prick or intradermal testing with low dilutions of the suspect drugs (cutaneous testing). A range of drugs is usually tested. Well-performed cutaneous testing has a high sensitivity and specificity. However, such tests must be conducted in appropriately supervised settings only by qualified people who are able to interpret them. They involve a small risk of serious allergic reactions and must be undertaken only where emergency care is readily available. *Ex vivo* tests for allergy to drugs include radioallergosorbent tests (RAST); enzyme-linked immunosorbent assays (ELISA) are available, but are less sensitive. The patient must be informed of the suspected risk of allergy as soon as possible, and encouraged to wear a *Medic-Alert* bracelet.

Latex allergy

Latex, a natural derivative of the rubber tree, is widely used in medical products because of its physicochemical characteristics and barrier properties. William Halstead introduced latex gloves in 1890, but latex allergy was not recognized until 1979. The epitopes responsible for inducing allergy to latex include native antigens in the rubber and neoantigens that are produced by mechanical and chemical processing of the raw material. Sensitivity to latex is acquired by repeated exposure to latex products. People at high risk of latex allergy include:

- those with repeated or long-term urinary catheterization
- those with spina bifida, myelomeningocele, spinal cord trauma (related to bladder catheterization?)
- healthcare workers (particularly operating theatre and dental staff)
- atopic individuals (risk is 4–5 times greater than general population)
- those with sensitivity to bananas, avocado, chestnuts, kiwi fruit, figs, blue grass, ragweed
- rubber workers.

Measurement of latex antibodies in blood donors or systematic testing in the preoperative period reveals a sensitivity rate of 0.125–2.4% in the general population, but staff in operating theatres and dental surgeries may have sensitivity rates as high as 20%.

Trigger exposure may be from direct contact in the form of latex gloves or equipment (e.g. barium enema catheters, bladder catheters, anaesthetic masks, adhesive tape, tourniquets, electrodes). Mucosal or peritoneal contact is a more effective trigger than cutaneous contact, and may be associated with more severe reactions. Patients may inhale latex from the operating room atmosphere, typically adsorbed on to glove powder. The operating room atmosphere may contain 88–974 ng latex protein/m^3. Such environmental contamination is not significantly attenuated by laminar air systems, but may be substantially reduced by using powder-free gloves.

The stoppers of most injection vials are made of latex, which may leach into the injectate (and result in anaphylactic shock), or be picked up when drugs are reconstituted in solvents that are injected through such stoppers. The latex injection bungs on intravenous access devices and giving sets are also a significant hazard.

Pathogenesis and clinical manifestations: serious clinical reactions are similar to other allergic reactions. However, anaphylactic reactions often manifest later (typically 30–60 minutes after starting surgery) especially if the trigger is surgical glove contact with a mucosal surface rather than reactions to anaesthetic drugs (administered at induction). A reaction to latex contact in the anaesthetic room can manifest earlier, and be difficult to distinguish from a drug-related reaction.

Occupational exposure may present as contact dermatitis or asthma, and may be difficult to identify as latex allergy, especially in the patient with pre-existing atopic disease. Occupational and clinical reactions may be due to Type I (IgE-mediated) or Type IV (T cell-mediated) responses, though serious clinical events are usually associated with the former. Healthcare workers may react to a different antigen (a 20 kDa protein) from that implicated in reactions in children with spina bifida (a 14 kDa protein).

Management: the acute management of an anaphylactic episode remains identical, regardless of the cause. However, specific management is required for the care of a patient known to be at risk of latex allergy, and for the investigation of latex allergy in patients or healthcare workers. The extent to which these guidelines are followed depends on the relative risk posed by a given patient. Patients may be categorized as:

- Group 1: previous anaphylactic reaction to latex
- Group 2: significant allergy to latex (urticaria, angio-oedema, bronchospasm)
- Group 3: at-risk group listed previously.

In general, Groups 1 and 2 are treated identically. Specific precautions are not universally advised in patients in Group 3; practice varies between hospitals.

Preparation and organizational details: preparation for anaesthesia in a patient at risk of latex allergy begins with a careful preoperative assessment and quantification of risk. It is essential to attend to organizational details; patients in Groups 1 and 2 need to be first on the operating theatre list, when the use of latex-free equipment is not negated by a high environmental load of latex from previous cases on the day. If such scheduling is impossible, the theatre must remain unused for at least 2 hours before surgery.

It is essential to ensure that the drugs and equipment required for the treatment of anaphylaxis are available and already drawn up, and an appropriate stock of latex-free anaesthetic and surgical equipment is available (Figure 4), and that latex-containing equipment and disposables are removed from the theatre suite (Figure 5). The anaesthetic machine (including the soda-lime canisters) should not have been contaminated by latex.

Latex-free equipment

• Gloves	Allergard (J & J); Dermaprene, Nitra Topuch, Touch N' Tuff (Ansell); Neoprene (Regent)
• ECG electrodes	3M; Medicotest
• BP cuff	Cover with tape or use J&J Disposa Cuff; Hewlett Packard
• Pulse oximeter	Hewlett Packard
• Pressure transducer	Ohmeda
• Temperature probes	Disposable probes can be used
• Oesophageal stethoscope	Hewlett Packard; Vital Signs
• Operating table	Avoid contact with mattress and trolley by covering with sheet
• Face masks	Rusch; Intersurgical; Vital Signs; Laerdal
• Breathing circuits	Mallinkrodt; Intersurgical; Vital Signs
• Rebreathing bags	Only if specified latex-free
• Guedel airways	Vital Signs; Universal Hospital Supplies
• Nasopharyngeal airways	Portex
• Endotracheal tubes	Portex; Mallinkrodt
• Catheter mounts	Portex
• Suction catheter	Pennine; Yankaeur; Sherwood; Argyle
• Nasogastric tubes	Vygon; Portex; Rusch
• Tape/dressings	Transpore, Tegaderm, Micropore (3M); Hyperfix (Smith & Nephew); Mepore (Molnlycke); SteriStrips (J&J)
• Syringes	B & D; Braun
• Cannulae	Abbott; Abbocath; Venflon; Ohmeda
• Central venous pressure monitor	Arrow
• 3-way taps	Vygon; Ohmeda
• Blood sets	Sangofix Braun
• IV extension	Letrocath, Lectrospiral (Vygon)
• Colloid	Gelofusine in Polyfusor bag
• Epidural catheter	Portex
• Spinal needle	Sprotte (Portex); Whitacre (B&D); Quincke (Vygon)
• Stimuplex	Braun
• Diathermy	3M plate and lead

This table is for guidance only. Any item used in an at-risk patient must be positively identified by the user as safe. Continue the latex-free environment in the recovery unit and on the ward

Equipment containing latex

Do not use the following equipment

• Gloves	Biogel, Diagnostic, Reveal, Super-sensitive (Regent); Nutex, Gammez, latex examination gloves (Ansell)
• Face masks	Rusch; Ohmeda; CDL; WSP
• Rebreathing bags	Ohmeda; Intersurgical; Vital Signs; Mallinkrodt
• Nasopharyngeal airways	Rusch
• Cannulae	Ycan (Wallace); any sets with a latex bung or injection port
• Tapes	Sleek; Elastoplast
• Pulmonary artery catheter	Most manufacturers (balloon is latex)
• Patient-controlled analgesia disposables	Vygon
• Theatre hats	Johnson & Johnson
• Limb exsanguinators	
• Tourniquets	

Use the following with caution

- Anaesthetic machines should be protected with a heat and moisture exchanger at fresh gas outlet and patient circuit
- Gum elastic bougie may be safe if silicone coat intact
- Vials with bungs: remove bung before drug mixing. Do not inject through any latex bungs
- For all regional anaesthesia packs other than those described above, replace syringe with latex-free model
- Pulse oximeter probes: wrap finger in *Tegaderm*

If anaphylaxis occurs, follow the anaphylaxis protocol
Continue to use latex-free anaesthetic and monitoring equipment

Premedication: the drug regimen described here has no proven benefit in preventing reactions but may reduce their severity and delay their onset. Premedication should include:

- methylprednisolone, 1 mg/kg 6 hourly i.v.
- ranitidine, 1 mg/kg 6 hourly i.v.
- chlorpheniramine, 10 mg i.v. 6 hourly (adult dose)
- salbutamol (2 puffs inhaler or 2.5–5 mg by nebulizer) 6 hourly (for patients with asthma).

At least two doses must be given preoperatively, and many protocols prescribe the need for intravenous administration. Diluents should not be added to the drugs via a needle through the bung. The bung should be removed and the solution reconstituted.

Management in theatre should focus on preventing contact between the patient and latex, directly, through exposure to aerosolized particles or through secondary contact.

Postoperative care: precautions should continue in the recovery room and beyond. Some patients may need postoperative critical care; special care is needed in this setting, which is a latex-rich environment. The precautions described above may be difficult to implement because ICUs are multi-patient environments where staff change over the course of the day, and the more prolonged clinical stay may result in vigilance fatigue.

Testing for latex sensitivity: epicutaneous testing provides the best diagnostic yield, and patch testing with 2.5 cm^2 of glove rubber may be useful in establishing contact dermatitis. Well-conducted cutaneous testing with prick or scratch tests has a sensitivity of 100%, a specificity of 99%, a positive predictive value of 79% and a negative predictive value of 100%. RAST and ELISA and Western blot techniques are less sensitive, and may detect only 50–60% of healthcare workers with IgE-mediated sensitivity reactions to latex.

Occasionally, provocative tests may be required to establish or exclude a diagnosis of latex allergy in health workers with negative prick or patch testing and a negative RAST. An inhaled challenge with pulmonary function testing may be useful in those in whom bronchospasm is the primary problem. Such challenge tests are risky, and must not be undertaken lightly. However, they may be essential in healthcare workers in whom latex allergy necessitates a change in occupation or employment, particularly if compensation or retirement issues have to be considered. ◆

Anaesthetic Management of the Transplant Patient

John Klinck

John Klinck is Consultant in Anaesthesia at Addenbrooke's Hospital, Cambridge, UK. A Canadian medical graduate, he pursued postgraduate training in Canada, the UK and Australia. His research interests include hepatic and renal transplantation, epidemiology and evaluation of perioperative risk.

Few fields in medicine have advanced as rapidly over the past 25 years as organ transplantation. Each year, many thousands of patients with irreversible diseases of the heart, lungs, liver, kidneys and pancreas now receive transplants. Advances in surgical technique, perioperative care and long-term immunosuppression, and increasing use of organs from living donors for renal and hepatic transplants, have created a large population of organ recipients. Up to 30% require surgical intervention after a successful transplant, and many present for surgery outside transplant centres. The anaesthetist may face complex problems related to reduced functional reserve in the graft, effects of the disease originally causing organ failure or complications of immunosuppression.

General considerations

After the immediate postoperative period, transplant recipients are more vulnerable to surgical conditions affecting the abdominal cavity (e.g. bowel perforation, pancreatitis, cholecystitis, peptic ulcer disease, bowel ischaemia and obstruction). Immunosuppressants, particularly corticosteroids, may be implicated, and may mask the signs and symptoms of peritonitis. Malignancy complicates immunosuppression in 2–7% of transplant recipients, most commonly lymphoproliferative disorders and primary carcinomas of skin and colon. These patients may require anaesthesia for diagnostic procedures or surgical intervention. Organ-specific late complications requiring surgical intervention include bronchial stenoses or leaks in lung recipients, uretero-vesical obstruction in kidney recipients, and biliary obstruction or leak in liver recipients.

Chronic rejection

Chronic rejection is the main cause of late, progressive graft dysfunction. Its cause is unknown, but all transplanted organs have intimal thickening in small arteries, which is associated with, and may be the cause of, distinctive lesions in each organ. These are obliterative bronchiolitis in the lung, transplant coronary artery disease in the heart, vanishing bile duct syndrome in the liver and interstitial lymphocytic glomerulopathy in the kidney. They occur more than 3 months after transplantation and are the most common cause of late graft failure and death. Impaired organ function due to chronic rejection is an important consideration when assessing the cause of graft dysfunction and its potential for amelioration.

Assessment of organ function

Assessment of organ function is carried out as for non-transplant patients, with caveats in the case of heart, heart and lung and liver recipients. Renal function is quantified by plasma creatinine or creatinine clearance, plasma potassium and urine output. Liver synthetic function is assessed by plasma albumin and prothrombin time. Raised alanine aminotransferase reflects hepatocellular injury, typically rejection or infarction, and usually before synthetic function is overtly impaired. Increased alkaline phosphatase and bilirubin indicate cholestasis, which may be caused by extrahepatic biliary obstruction, sepsis or chronic rejection. Clinical portal hypertension is uncommon in the long-term liver recipient, but if varices and ascites are present, disease in the graft is regarded as end-stage. Perioperative risk in these patients is increased, because general anaesthesia and surgery may be associated with hepatic decompensation, bleeding and encephalopathy.

Exercise tolerance is the mainstay of the clinical assessment of graft function in heart and lung recipients, supplemented in the presence of any significant limitation by echocardiography in heart and heart and lung patients and pulmonary function tests (spirometry and diffusion capacity) in lung and heart and lung patients. Heart recipients do not experience angina, because the heart is denervated, but have a high incidence of recurrent coronary disease (transplant coronary artery disease), which affects small arteries first and typically presents with global impairment of contractility, arrhythmias or sudden death. Resting electrocardiography may fail to identify advanced disease.

Underlying disease

The disease that originally led to organ failure and transplantation may affect other vital systems. Examples are diabetes mellitus and hypertension (kidney recipients), atherosclerosis, sarcoidosis and amyloidosis (heart recipients), cystic fibrosis (liver, lung and heart and lung recipients), and alcoholism (liver transplantation). Metabolic conditions treated by liver transplantation but potentially affecting other systems include oxalosis, haemophilia and familial amyloid polyneuropathy.

Immunosuppression

The perioperative management of immunosuppression is best discussed with the transplant centre treating the patient. The need for supplemental corticosteroid treatment has been questioned. A study of renal transplant patients taking long-term maintenance corticosteroids showed that clinical adrenal insufficiency associated with major surgery is a rare and readily treatable occurrence, and experience with liver recipients supports this. Higher corticosteroid doses may be detrimental in a carefully managed immunosuppression programme. Maintenance of existing immunosuppression in all but the most ill patients is usual.

Oral absorption is variable postoperatively and immunosuppressants should be given intravenously. Oral prednisolone is replaced with equal doses of intravenous methylprednisolone. Intravenous substitution of azathioprine is also done at equal dosage. Oral ciclosporin (cyclosporin) is only 25–40% absorbed, therefore about one-third of the oral dose is given intravenously, with regular monitoring of plasma concentration.

Antimicrobial prophylaxis for bacterial endocarditis follows guidance applied to non-transplant patients. Heart transplant patients are not considered at increased risk and prophylaxis is not routinely indicated. Postoperative analgesia regimens should generally omit non-steroidal anti-inflammatory drugs (NSAIDs) because of the prevalence of renal impairment and the increased risk of intestinal bleeding accompanying corticosteroid use. If NSAIDs are used, close monitoring of plasma creatinine is important and the addition of a proton-pump inhibitor advisable.

Side-effects of immunosuppressive drugs

Side-effects of immunosuppressive drugs are a substantial cause of clinical and subclinical morbidity in the transplant recipient and are described elsewhere.

Hypertension – the incidence approaches 50% and is commonly multifactorial in origin. Ciclosporin (cyclosporin) and tacrolimus may cause afferent arteriolar vasoconstriction in the kidney, and corticosteroids may induce fluid retention. In renal transplant patients, hypertension may also be related to chronic rejection, renal artery stenosis or the retained native kidney. Treatment, often with more than one agent, is typically with angiotension II receptor antagonists, angiotensin-converting enzyme (ACE) inhibitors, calcium antagonists and/or β-blockers. β-blockade and inhibition of the effects of angiotensin improve survival in patients with subclinical or overt cardiac failure, while calcium antagonists blunt ciclosporin (cylcosporin)-induced afferent arteriolar vasoconstriction. These agents may increase the likelihood of and the vulnerability of the kidney to hypotension.

Renal dysfunction – both ciclosporin (cyclosporin) and tacrolimus are nephrotoxic and associated with glomerulosclerosis, tubular atrophy and interstitial fibrosis. Some reduction in renal function is expected in all transplant recipients treated with these agents. Poorly controlled hypertension or hyperglycaemia may aggravate this, and careful attention to maintenance of intravascular volume is important.

Hypercholesterolaemia and coronary atherosclerosis – immunosuppressants, in particular ciclosporin (cyclosporin), tacrolimus and prednisolone, aggravate risk factors for atherosclerosis, including raised low density lipoprotein (LDL) and total cholesterol concentrations. The prevalence of both occult and symptomatic ischaemic heart disease, cerebrovascular and peripheral vascular disease is high in the transplant population, and these processes are accelerated by these effects. Statins and aspirin are often prescribed routinely.

Hyperglycaemia – ciclosporin (cyclosporin) directly inhibits insulin release from pancreatic islet cells and induces glucose intolerance and the incidence of treated diabetes in transplanted patients. Tacrolimus and corticosteroids have a similar effect.

Neurotoxic effects are commonly observed in transplant recipients, usually early in the postoperative period. Side-effects of ciclosporin (cyclosporin) include tremor, seizures, nerve and plexus palsies, impaired consciousness, hemiparesis and psychosis. Corticosteroids in high dose in the setting of acute rejection may also cause acute psychosis. Longer term neuropsychiatric symptoms (e.g. anxiety, depression, impaired memory, emotional lability) have also been attributed to corticosteroids. The possibility of neurotoxicity should always be considered when unexpected neurological symptoms or signs appear in the perioperative period.

Drug interactions

Drug interactions involving immunosuppressants are many, but few affect anaesthetic management. The principal risks are associated with increased or decreased plasma concentrations (toxicity and risk of acute rejection, respectively). Anaesthetic drugs have not been implicated. Ciclosporin (cyclosporin) potentiates atracurium and tacrolimus (also a cytokine inhibitor) is expected to do the same.

There are few published data on the pharmacokinetics and pharmacodynamics of anaesthetic drugs in the transplant population. Clinical experience suggests that the efficacy and side-effects of most agents in routine use are unaffected; the exceptions are described below.

Anaesthetic management

Preoperative assessment and preparation

Preoperative assessment and preparation is guided by the same principles applied to the general population. Elective procedures should be preceded by consultation with the transplant physician responsible for the patient's long-term care, who should advise on evaluation of graft function and on perioperative immunosuppression. Outside normal working hours, the co-ordinator at the transplant centre should be contacted; they can provide or obtain similar expert advice. Intercurrent opportunistic infection (signs of which may be subtle) and acute rejection should be excluded. Clinical and laboratory assessment should focus on graft function, adverse effects of immunosuppression and possible impairment of other organs affected by the underlying disease.

Left ventricular dysfunction and renal impairment both strongly indicate the need for a high-dependency setting after any major procedure. Hypertension, hyperglycaemia, hyperkalaemia, atrial fibrillation, angina, left ventricular dysfunction and gastro-oesosphageal reflux are common clinical features and their management must be optimized. If cannulation is planned, the patency of central veins should be evaluated by ultrasonography because all these patients will have had previous central venous catheters, often many. The patient's blood should be screened; most patients will have had previous blood transfusion and antibody problems may delay the provision of suitable bank blood. The patient's cytomegalovirus (CMV) antibody status should be ascertained and the CMV-negative patient given only CMV-negative products.

Insertion of intravascular catheters should be performed using full sterile precautions and a careful no-touch technique used when they are used for drug and fluid administration or blood sampling. Drug syringes should be kept capped and three-way taps protected from contamination at all times.

Heart recipients

Transplant coronary artery disease is common, typically affecting small peripheral vessels before larger, proximal ones. It presents as heart failure or new arrhythmias, including ventricular fibrillation and complete heart block. Sinus and/or atrio-ventricular (AV) nodal ischaemia leads to persistent bradycardia or AV conduction block in about 10% of patients, who require permanent pacing. Left ventricular contractility should be assessed by echocardiography, and specialist advice about the perioperative management of pacemakers obtained in patients with these devices. The pacemaker should be checked and a programming device made available for elective procedures. In an emergency, an external pacing unit and defibrillator should be immediately to hand. If diathermy must be used, the diathermy plate should be placed on the thigh and a bipolar attachment used.

Cardiac denervation has a fundamental effect on cardiac responses to reduced central blood volume, adrenergic stress and certain drugs (Figure 1).

Effects of cardiac denervation

- The patient does not experience angina
- Resting heart rate is increased 90–110/min, and the electrocardiogram may show atrial activity from the recipient atrial remnant alongside or superimposed on the donor P-wave
- The heart rate response to sympathetic stimuli is delayed and more limited than normal, and is a poor marker of depth of anaesthesia and hypovolaemia
- The chronotropic response to vagolytic drugs (e.g. atropine, glycopyrrolate) is absent
- Vagotonic drugs (suxamethonium, neostigmine) have no effect and the vagally mediated effect of digoxin on atrioventricular conduction is lost
- Denervation supersensitivity amplifies the effects of adenosine, adrenaline (epinephrine) and noradrenaline (norepinephrine); reduced doses are appropriate
- Cardiac output is highly sensitive to preload and to negatively inotropic drugs
- Drug-induced falls in systemic vascular resistance cause exaggerated hypotension, especially when preload is marginal

Anaesthetic technique is guided by the patient's general condition and the scale of the procedure. For a minor or intermediate procedure, spontaneous breathing with a laryngeal mask can be appropriate if left ventricular function is well preserved. In the presence of impaired left ventricular function, intubation and positive-pressure ventilation are advisable. Large-bore venous access, established before induction, is advisable because it allows rapid administration of aliquots of fluid to maintain preload when myocardial depression and reduced systemic resistance occur during anaesthesia. Ephedrine, an indirectly acting sympathomimetic, may be used to provide a modest chronotropic effect if needed; it also exerts positive inotropic and vaso-constricting effects. Cautious doses of adrenaline (epinephrine) also produce all these effects and provide a substitute for isoprenaline (no longer available in the UK) when ephedrine is inadequate. Pure vasoconstrictors (e.g. phenylephrine, metaraminol) may also be used to correct hypotension, but maintenance of intravascular volume usually suffices.

There are few published data to favour the use of any particular maintenance regimen for anaesthesia, but a target-controlled infusion of propofol may be associated with problematic hypotension in patients with limited cardiac reserve, as is remifentanil, and these should be avoided in less fit patients. Spinal and epidural blocks have also been associated with aggravated hypotension in heart recipients and should be used with caution, especially in the postoperative period when supervision must be very close. Peripheral and plexus blocks (e.g. femoral–sciatic, brachial plexus) are well tolerated and a welcome alternative to general anaesthesia in appropriate circumstances.

Lung recipients

As in the general population, routine preoperative tests assessing pulmonary function are typically less informative than the history. Some limitation is expected in virtually all these patients, but their anaesthetic management does not differ from that of other patients with chronic pulmonary disease. Lung denervation reduces the cough reflex distal to the bronchial anastomosis, increasing the importance of postoperative chest physiotherapy. Recipients of single lung transplants may be affected by differential compliance and ventilation–perfusion mismatch during anaesthesia, worsened by the lateral position or some vasoactive infusions. This is normally overcome by increasing the inspired oxygen fraction and/or the addition of modest positive end-expiratory pressure, but occasionally lung isolation and differential ventilation may be needed to alleviate hypoxia or to avoid barotrauma to the grafted lung.

Liver recipients

With good graft function, liver recipients present few anaesthetic problems. Responses to induction agents, relaxants (including suxamethonium) and opiates are typically normal. However, the scale of the liver transplant procedure makes any subsequent operation in the abdomen technically challenging and likely to cause significant bleeding. Prothrombin time, haemoglobin and platelet count are vital routine preoperative tests, and coagulopathy, though rare, should be aggressively corrected before surgery. A prothrombin time prolonged by more than 2 seconds should be treated with fresh frozen plasma, 1–2 units, before any significant procedure. The platelet count for a minor procedure should be above 50,000 (above 100,000 for a major procedure).

Patients with decompensated graft function present a major challenge. They present with coagulopathy and ascites, and both respiratory and renal function may be compromised. Nutritional impairment is usual, accompanied by hypoalbuminaemia and hyponatraemia. Infusion of blood products may be associated with ionic hypocalcaemia, and calcium administration may be needed to maintain haemodynamic stability. Responses to anaesthetic agents are predictable, but the effects of benzodiazepines and pancuronium may be prolonged. Regional techniques are used only when coagulation indices are normal.

Kidney recipients

Diabetes, hypertension and ischaemic heart disease are the most common co-morbidities in kidney recipients and are managed perioperatively as in the general population. In the elective setting, antihypertensives and other cardiovascular drugs are taken on the morning of surgery with the patient's usual immunosuppressants. Most patients continue to have mild-to-moderate renal impairment and should be managed accordingly. Many have limited concentrating ability, therefore prolonged fasting should be avoided and perioperative crystalloid replacement should be generous. Anaemia is common, even in patients treated with erythropoietin. Suxamethonium is safe in the absence of hyperkalaemia, but the effects of non-depolarizing relaxants should be monitored closely. Atracurium and cisatracurium are the most predictable agents but even these may exert a prolonged effect in patients with marginal graft function, particularly in the presence of ciclosporin (cyclosporin) and acidosis.

The need to spare antecubital and lateral forearm veins for possible future arteriovenous fistula formation should be kept in mind, preference being given to the dorsum of the hand and to veins on the medial aspect of the middle third of the forearm. Subclavian vein cannulation should be avoided because subsequent stenosis or thrombosis may render the whole limb incapable of tolerating the high flows produced by a fistula. If central venous access is required, the right internal jugular is the vein of choice. When positioning the patient for surgery, care should be taken to protect any existing fistula from compression or proximal venous obstruction.

Spinal or epidural analgesia is not contraindicated in the kidney recipient, but sustained hypotension, both intraoperatively and postoperatively, must be avoided. NSAIDs (with the exception of low-dose aspirin) are contraindicated.

Pancreas recipients

Pancreas recipients have all the end-organ complications of longstanding insulin-dependent diabetes, including overt and silent ischaemic heart disease, renal impairment, and autonomic and peripheral neuropathy. Gastroparesis and reflux are common, and intubation is more likely to be difficult than in the general population. Blood glucose instability is less common than in other insulin-dependent diabetics, but blood sugars should be monitored at least hourly during surgery. Maintenance of graft perfusion by careful attention to intravascular volume is essential. Peripheral nerve injury and nosocomial infection are common in these patients and every effort should be made to reduce these risks. ◆

Anaesthetic Problems in Renal Transplantation

Fay J Gilder

Fay J Gilder is Consultant Anaesthetist at Addenbrooke's Hospital, Cambridge, UK. She qualified from St George's Hospital, London, and trained in anaesthesia in Chichester, East Anglia, and Toronto. Her subspecialty interests include paediatric and transplant anaesthesia.

In 2001, in the UK, 1691 kidney-only transplants were performed; of these, 358 (21%) were from living donors. The current UK 1-year graft survival figures are 86% for cadaveric and 95% for living donor grafts. This is associated with a quality of life and long-term survival significantly better than dialysis in most forms of end-stage renal disease. As a result of this success, kidney transplantation is being offered to a wider population of high-risk patients (including those with advanced cardiovascular disease, type II diabetes, morbid obesity, sickle cell disease and various forms of vasculitis). In 2001, in the UK, 4846 patients were on the waiting list, and while the total number of transplants performed per year remains fairly constant, the waiting list continues to grow because the inclusion criteria are being widened. Cadaveric transplants have slowly decreased in number, but living related transplants have tripled since 1992.

Preoperative assessment and preparation

Both the causes (Figure 1) and sequelae (Figure 2) of end-stage renal disease must be considered when assessing the potential transplant patient. Preoperative assessment must include a careful evaluation of hydration status (hypovolaemia risks graft failure), blood pressure control, cardiovascular disease, diabetes management, electrolyte status, magnitude of anaemia and coagulation abnormalities. Preoperative dialysis is routine, with the aim of dialysing the patient to within 0.5 kg of ideal body weight. Sites of any arteriovenous (AV) fistulae should be noted. If there is a history of previous central venous cannulation for monitoring or dialysis, ultrasound examination of the neck veins should be considered because the patient may have narrowed or thrombosed vessels.

Common causes and prevalence of end-stage renal disease

- Types I and II diabetes mellitus (44% and 4%)
- Glomerulonephritides (10%)
- Polycystic kidney disease (6%)
- Pyelonephritis/interstitial nephritis (6%)
- Hypertensive nephrosclerosis (3%)

1

Sequelae of chronic renal disease relevant to anaesthesia

Haematopoiesis and coagulation
Anaemia
- Decreased erythropoietin production
- Reduced red cell half-life
- Reduced red cell production

Platelet dysfunction
- Reduced platelet factor III activity
- Abnormal platelet aggregation

Cardiovascular
Coronary artery disease
- Accelerated atherosclerosis

Congestive heart failure (CHF)
- Primary: uraemic cardiomyopathy
- Secondary: fluid overload

Pericarditis/pericardial effusion (secondary to uraemia)
Dysrhythmias
- Hyperkalaemia
- Hypocalcaemia

Hypertension

Respiratory
Pulmonary oedema (secondary to CHF/fluid overload)
Pleural effusions
- CHF/fluid overload/peritoneal dialysis

Electrolyte disturbances
Hyperkalaemia
- Dysrhythmias

Hypermagnesaemia
- Potentiation of neuromuscular blockade
- Hypotension

Acid–base regulation
Metabolic acidosis

Gastrointestinal
Oesophageal sphincter dysfunction
Diabetic gastroparesis
Gastrointestinal bleeding
- Platelet dysfunction
- Peptic ulcer disease

Hepatic
Hypoalbuminaemia
Cytochrome P450 abnormality

Endocrine
Secondary hyperparathyroidism
- Correct calcium and phosphate abnormalities preoperatively

Diabetic autonomic neuropathy
- Gastroparesis
- Risk of sudden death

Dialysis-related problems
Peritoneal dialysis
- Peritonitis
- Pneumonia, atelectasis, pleural effusion
- Volume overload
- Hypoproteinaemia, hyperglycaemia, hyperlipidaemia
- Pain

Haemodialysis
- Systemic anticoagulation due to residual heparin effect
- Metabolic acidosis
- High output cardiac failure due to shunting through the arteriovenous fistula
- Hypovolaemia, hypotension
- Disequilibrium syndrome (cerebral oedema after acute dialysis)

2

Perioperative morbidity is increased in recipients with diabetes mellitus, generally due to cardiac events. Cardiovascular assessment should be performed carefully and any evidence of ischaemic heart disease investigated. Joint rigidity can occur in patients with longstanding diabetes because of advanced glycosylation of joint tissue; it may affect the temporomandibular joint. Airway evaluation should be carried out with this in mind.

The most common electrolyte abnormality of concern in renal transplant recipients is hyperkalaemia. A preoperative serum potassium of less than 5.5 mmol/litre is desirable in all cases but essential in live donor transplants, which are elective procedures in which all aspects of risk must be minimized. If serum potassium is 5.6–5.9 mmol/litre, acceptability depends on co-morbidity in the recipient. The risk may be prohibitive in the presence of ischaemic heart disease or increased surgical risk (significant blood loss). It should be treated preoperatively. Repeat dialysis is advisable if serum potassium is greater than 5.9 mmol/litre (Figure 3).

All antihypertensive medication should be continued perioperatively with the exception of angiotensin-converting enzyme (ACE) inhibitors, which can exacerbate hypotension at induction of anaesthesia. In addition, ACE inhibitors have been associated with profound hyperkalaemia in uraemic patients, therefore potassium should be closely monitored.

Routine preoperative medication includes immunosuppressive drugs and antibiotic prophylaxis. Consideration should be given to aspiration prophylaxis and an anxiolytic.

Treatment of perioperative hyperkalaemia

Preoperative serum potassium > 5.5 mmol/litre
- Nebulized salbutamol, 10 mg
- Dextrose/insulin, 50 ml D50W, 10 iu insulin

Intraoperative serum potassium > 5.5 mmol/litre
As above plus
- Wash all bank blood using cell saver before transfusion

Intraoperative serum potassium > 6.0 mmol/litre
As above plus
- 8.4% $NaHCO_3$ 50 ml
- Consider 13.4% $CaCl_2$ 10 ml if any ECG changes (increased QRS widening)
- Urgent dialysis/haemofiltration if potassium remains over 6 despite the above

3

Surgical technique

The procedure can be divided into three stages: exposure and preparation of the iliac vessels; revascularization of the donor kidney; and construction of urinary drainage. In living donor transplants, the procedure is complicated by the fact that the renal artery and renal vein are shorter than those in a cadaveric organ and no patches can be taken from the aorta and inferior vena cava, respectively. Revascularization of the kidney is a critical time for the anaesthetist.

Anaesthetic technique

Monitoring and vascular access: central venous pressure (CVP), neuromuscular blockade and temperature are monitored in addition to routine anaesthetic monitoring. CVP is essential for monitoring intravascular volume. Neuromuscular monitoring is important because the extraperitoneal positioning of the graft makes it vulnerable to expression and injury if the abdominal muscles contract before closure of the wound.

When establishing vascular access, the non-fistula arm is used. A large-bore peripheral intravenous cannula is placed in a hand vein if possible, so preserving the forearm and antecubital veins for possible future AV fistula formation. Arterial cannulation is not indicated unless there is overriding concern about intraoperative haemodynamic instability. If direct arterial monitoring is necessary, the dorsalis pedis or femoral artery on the opposite side to the proposed graft site is used. This spares the vessels of the upper limb for possible future AV fistula formation.

Consider placing central venous access in the internal jugular vein on the opposite side to any functioning AV fistula; subclavian venous access is relatively contraindicated because subsequent thrombosis or compression by haematoma may make the entire limb unsuitable for AV fistula formation.

Theatre preparation and positioning: the patient is positioned supine. If an AV fistula is present this arm should be placed on an arm board and the fistula protected from compression. The non-invasive blood pressure cuff should be placed on the arm opposite any AV fistula. Warming devices including a warming mattress, forced air warmer and blood warmer are used. 0.9% saline is standard for initial intravenous infusion.

Anaesthesia: fluid loading before induction may be necessary in patients in whom hypovolaemia is suspected. All patients are intubated and ventilated without exception. Consideration should be given to the need for a rapid sequence induction, in particular for diabetics with autonomic neuropathy who may also have gastroparesis. Anaesthesia may be induced slowly with propofol, thiopental (thiopentone) or etomidate. Suxamethonium causes a rise in serum potassium of up to 0.6 mmol/litre. Fentanyl, atracurium (by infusion), isoflurane or desflurane are used for maintenance. Total intravenous anaesthesia with propofol/remifentanil or alfentanil has also been used successfully.

Sevoflurane can be used for induction but produces inorganic fluoride ions during prolonged use. No evidence of nephrotoxicity has been found, but isoflurane or desflurane are safe alternatives. Enflurane is contraindicated.

Atracurium or cisatracurium are the muscle relaxants of choice because they are metabolized independently of the kidney. Vecuronium and rocuronium are not contraindicated.

Morphine can be given late in the procedure with patient-controlled morphine analgesia planned for postoperative pain control. Epidural analgesia is avoided because of the risks associated with uraemic coagulopathy and difficulties maintaining intravascular volume intraoperatively and postoperatively in the face of marked postoperative polyuria (up to 2 litres/hour).

Specific intraoperative considerations

Graft function: the most important intraoperative measures that improve the likelihood of immediate graft function are the maintenance of adequate intravascular volume and satisfactory perfusion of the transplanted kidney. High blood flow through the graft immediately on clamp release is associated with early renal function, a decreased mortality rate and increased graft survival. Therefore CVP should be maintained at 10–15 mm Hg (if pulmonary artery pressure is being monitored the mean value should be 15–20 mm Hg) from immediately before reperfusion.

Urine output: early onset of urine output is associated with a significantly increased likelihood of graft survival. Furosemide (frusemide), 80–250 mg, mannitol, 20–50 g, and dopamine, 2.5 μg/kg/min, are used to stimulate urine output. Albumin, calcium channel blockers and dopexamine have also been used successfully. Most centres have their own cocktail of drugs to be given at the time of revascularization of the transplanted kidney. Intraoperative anuria or oliguria must be aggressively investigated and both mechanical and non-mechanical factors excluded and treated. Prerenal mechanical factors include arterial or venous stenosis or thrombosis; postrenal mechanical factors include outflow tract obstruction, leakage of urine at the uretovesicle junction or external compression of the kidney, its vessels or ureter. Non-mechanical factors include hypovolaemia, hypotension, acute tubular necrosis or acute rejection.

Perioperative hyperkalaemia is common, particularly in diabetics and patients taking ACE inhibitor or β-blockers. A treatment protocol is suggested in Figure 3.

Postoperative care

Most patients can be extubated soon after surgery is completed. Early postoperative management focuses on adequate renal perfusion and urine output. Continuous CVP monitoring and hourly urine output measurement are standard, aiming for a CVP of 8–12 mm Hg and output of 200 ml/hour. The major concerns at this time are of renal artery or vein thrombosis and allograft failure due to rejection. Renal thrombosis is a particular risk because of the decreased activity of coagulation inhibitors and the fibrinolytic system and the effects of immunosuppression on the vascular endothelium.

Immunosuppression

In the UK, methylprednisolone, ciclosporin (cyclosporin) A and tacrolimus are the immunosuppressants most commonly used for renal transplants. They are associated with few perioperative concerns. Interleukin-2 (IL-2) and the IL-2 receptor have a predominant role in the immunogenic reaction to transplantation. The IL-2 receptor includes three protein chains: α (CD25), β (CD122) and γ (CD132). Stimulation of T lymphocytes by antigen induces expression of CD25. CD25 is responsible for the rapid association of IL-2 with the β and γ chains, which in turn triggers proliferation of T lymphocytes and therefore acute rejection. Selective CD25 monoclonal antibody preparations including the mouse monoclonal antibody OKT3 have been introduced as an effective part of the immunosuppression regimen. However, OKT3 can cause a severe cytokine release syndrome and is used only in severe cases of resistant rejection in the UK. Newer CD25 monoclonal antibody preparations are being introduced into practice in which mouse constant regions have been replaced with human counterparts, resulting in minimal immunogenicity. Trials have shown no cytokine response syndrome to these newer agents.

Management of kidney donors

Perioperative management of the kidney donor plays an important part in the viability of the transplanted kidney.

Living donors – in 2001, 21% of donated kidneys came from living donors. In the USA, 50% of transplanted kidneys come from live donors. Living donors must be in excellent health with no evidence of hypertension, diabetes or other chronic illness that increases the risk to the donor. Donor nephrectomy is performed with the patient in the acutely flexed lateral decubitus position. Pressure points must be carefully padded and excessive stretch on peripheral nerves avoided. During anaesthesia, particular attention is paid to forcing a diuresis of 2–4 ml/min to reduce the incidence of acute tubular necrosis in the transplanted kidney. Therefore, all donors receive large volumes of fluid, mannitol and furosemide (frusemide). Postoperative analgesia is usually provided using an epidural because the flank incision is extremely painful. Increasingly, this operation is being performed laparascopically to reduce morbidity and mortality in the donor.

Cadaveric donors – most kidney recipients receive organs from cadaveric donors. However, the incidence of acute tubular necrosis is much higher in cadaveric kidneys. Absolute contraindications to kidney procurement are prolonged hypotension and hypothermia, metabolic disorders, generalized bacterial or viral infections, malignancies, systemic collagen disorders. Relative contraindications include older age, diabetes mellitus, severe vascular diseases, high serum creatinine before procurement and use of vasopressors. Intraoperative management of the cadaveric donor includes ensuring adequate haemodynamics and urine output. Intraoperative use of vasopressors (i.e. high dose dopamine, adrenaline (epinephrine) and noradrenaline (norepinephrine)) is associated with a significantly lower incidence of immediate renal allograft function and an increased incidence of acute tubular necrosis. ◆

Inflammation: Cellular Responses and Cytokine Production

I Robert Ghosh
Geoff Bellingan

I Robert Ghosh is Consultant Physician in Intensive Care at St Bartholomew's and Homerton University Hospitals. He qualified from Edinburgh University and trained in intensive care, general medicine, neurology and clinical neurophysiology in Edinburgh, St Bartholomew's and the Royal London Hospitals. His research interests include assessment of anoxic coma, critical illness polyneuropathy and the application of general internal medicine in intensive care.

Geoff Bellingan is Clinical Director of Intensive Care at University College Hospitals, London. He qualified from Charing Cross Hospital and trained in respiratory and general medicine at the Hammersmith Hospital, London, and in Edinburgh and then in intensive care at University College Hospitals and at Case Western Reserve University, Cleveland, USA. His research interests include cellular mechanisms in the resolution of inflammation. His clinical interest is the pathophysiology and management of acute respiratory distress syndrome.

Sepsis is commonly seen in all areas of medical practice. It is the most common cause for admission to ICU, and has a high mortality, especially in the setting of multi-organ dysfunction syndrome (MODS) and septic shock. Non-infective conditions may lead to inflammatory physiological changes similar to those seen in sepsis. The terms used in the inflammatory process (systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock) are clearly defined and should be applied accurately in the clinical setting (Figure 1). Over the last 20 years, the mortality rates in sepsis have decreased, probably as a result of earlier and better resuscitation. However, continued awareness of the pathogenesis of sepsis, the controversies in research and rationale of treatment will ensure greater understanding of this condition and thus optimal care.

Criteria for defining sepsis and the systemic inflammatory response syndrome (SIRS)

SIRS
Inflammation, for example caused by:
- Infection
- Pancreatitis
- Ischaemia
- Trauma
- Haemorrhage

Plus two or more of the following:
- Temperature > 38ºC, < 36ºC
- Heart rate > 90 beats/min
- Tachypnoea (respiratory rate > 20 breaths/min, partial pressure of carbon dioxide in arterial blood ($PaCO_2$) < 4.25 kPa)
- White blood cells > 12 x 10^9/litre, < 4 x 10^9/litre with > 10% immature neutrophils

Sepsis
- SIRS criteria resulting specifically from infection

Severe sepsis
- Sepsis with evidence of organ dysfunction (there are specific definitions for each organ; see Bone in Further Reading)

Septic shock
- Sepsis with hypotension (systolic blood pressure < 90 mm Hg or fall of > 40 mm Hg from baseline systolic pressure despite adequate intravascular filling)

1

Cellular inflammatory process

Leukocyte activation: leukocytes normally circulate in the quiescent state, though they can be activated rapidly to aid clearance of pathogens. The agents most commonly responsible for initiating an inflammatory response are bacterial cell-wall components from Gram-positive bacteria (teichoic acid and peptidoglycans) and potently, Gram-negative bacteria (lipopolysaccharide (LPS) endotoxins). It would be impossible to maintain leukocytes in a state of persistent activation without inducing uncontrolled leukocyte plugging, free radical release, high metabolic demand, with consequent tissue damage and MODS. One consequence of this activation system is the risk of underperformance or overperformance. Underperformance would lead to failure to clear the pathogens and overwhelming sepsis, while overperformance would lead to an overwhelming pro-inflammatory response, killing the bacteria, but also threatening the survival of the host (Figure 2).

Different pathways for the inflammatory response

Overperformance	Balanced	Underperformance
• Overwhelming proinflammatory response • Leukocyte plugging • Excessive enzyme and free radical release • Metabolic derangement	Signs of sepsis: • Calor • Rubor • Dolor • Tumour	• Overwhelming sepsis • Bacterial proliferation
Consequences		
• Hypoxia • Hypotension • Acidosis	• Retained organ function	• Progressive organ dysfunction from bacterial invasion
Outcome		
• Shock • Multi-organ dysfunction syndrome (MODS) • Death	• Resolution	• Shock • MODS • Death

2

Leukocyte influx: the inflammatory and immune responses to triggers such as sepsis, trauma and burns may be widespread, though regulated inflammatory cell activation and mechanisms for the attachment of leukocytes provide specificity and focus to the cellular response. Pro-inflammatory cytokines and chemotactic agents drive local endothelial activation and, through functional adhesion molecule upregulation, promote leukocyte adhesion and subsequent transmigration from vascular into extravascular compartments, where the foci of infection usually lie. These adhesion molecules include the selectins, expressed on both leukocytes and endothelial cells, which bind weakly and lead to slowing of the white cells as they flow through the vessels. This slowing allows more formal adhesion to occur through integrin-mediated events and finally transmigration into the tissues, which requires the function of other key molecules including very late antigen (VLA)-4 and platelet endothelial adhesion molecule (PECAM)-1.

Inflammatory mediators: concurrently with leukocyte activation, potent inflammatory mediator cascade systems are activated, leading to many of the typical features of inflammation (calor, rubor, tumour, dolor). This response may remain compartmentalized or can become systemic. These mediators include the complement, kinin and coagulation proteolytic cascades. In addition, there is release of lipid mediators such as platelet activating factor (PAF), peptide mediators including the chemokines, cytokines and soluble receptors and release of free radicals. Leukocyte degranulation can lead to release of numerous enzymes including elastase, myeloperoxidase, proteases, collagenase and plasminogen activator. Key pro-inflammatory cytokines include tumour necrosis factor (TNF)-α and interleukin (IL)-1 and IL-8. These are all produced early in the inflammatory response and are essential for survival. TNF-α and IL-1 are vital to the upregulation of many pro-inflammatory mechanisms including adhesion molecule expression, leukocyte activation, chemotaxis and degranulation. IL-8 is a particularly powerful neutrophil chemotactic agent. Although these responses are fundamental to the clearance of invading pathogens, they are also responsible for tissue damage. Many of the features of severe sepsis, including severe hypotension, fever and acute lung injury, may be mimicked in animal models by exogenous administration of TNF-α or IL-1. Antibodies that block these cytokines can dramatically prevent death in these models. IL-8 is also present in high concentration in the lungs of patients at risk of acute respiratory distress syndrome (ARDS) before the development of respiratory problems. These cytokines may therefore be directly involved in the disease processes.

Anti-inflammatory response: to protect against unopposed inflammation, the body also mounts an endogenous compensatory anti-inflammatory response syndrome. A number of cytokines have some anti-inflammatory properties, including IL-1 receptor antagonist (IL-1ra), IL-4, IL-10 and IL-13. These cytokines are produced as part of the normal response, for example IL-1ra is found in high concentrations in the urine of patients with sepsis. An excessive anti-inflammatory response may be as dangerous as a pro-inflammatory one. It is now recognized that with persisting inflammation the immune system can become anergic with a reduced ability to respond. Also well recognized for host survival is the importance of the endocrine system, including the cortisol stress response as well as other less well-characterized mediators such as macrophage migration inhibitory factor.

Resolution of inflammation: as inflammation progresses, the nature of the cellular response changes. Initially the main cells are the neutrophils, but over time they are replaced by macrophages and lymphocytes. Finally, with the elimination of bacteria, many of the survival stimuli for the neutrophils wane, leading to local neutrophil apoptosis and subsequent phagocytosis by macrophages. This is an anti-inflammatory process and induces the macrophage to release further IL-10 and other anti-inflammatory mediators thus 'switching off' the inflammatory response, allowing the tissues to return to their normal structure and function.

Fibrosis: if inflammation persists, or is excessive, there may be activation of an aggressive or abnormal fibrotic healing response. Fibrosis is a vital part of normal healing but, when excessive, can lead to severe consequences. This is typified by ARDS but is also a feature of chronic inflammation such as cirrhosis. The fibrotic response begins earlier than previously recognized with profibrotic mediators apparent in lung lavage on the first day of ARDS. A different range of cytokines are traditionally thought of for fibrosis, including transforming growth factor (TGF)-α and TGF-β but other cytokines (e.g. TNF-α) may also have an important role.

Haemodynamic response to sepsis

The main haemodynamic response to sepsis is vasodilatation-induced hypotension. In the early stages there is a compensatory high cardiac output, but this may diminish with time owing to myocardial depression. Hypovolaemia secondary to increased capillary leakage (though there may be a component of direct fluid depletion) also contributes to the hypotension. Blood vessels are normally maintained in a state of partial vasoconstriction by the balance of vasodilator and vasoconstrictor agents. The mechanism of sepsis-induced vasodilatation is complex and incompletely understood.

Normal vasoconstrictor response: agents involved in vasoconstriction include calcium, catecholamines, angiotensin II and endothelin. Vascular smooth muscle contraction is initiated by receptor-mediated release of calcium from intracellular stores and this is added to by calcium influx through voltage-gated calcium channels on the cell surface. This leads to myosin kinase activation and subsequent smooth muscle contraction. The resting membrane potential of the smooth muscle cell is relevant because depolarization enhances the opening of these voltage-gated channels and thereby promotes vasoconstriction. The main mediators for resting membrane potential seem to be ion channels, particularly potassium channels. A key potassium channel is the K_{ATP} channel, which by staying closed, keeps potassium in the cell and the cell depolarized.

Vasodilator response in sepsis: vasodilatation is mainly regulated by nitric oxide (NO), which is synthesized by the action of NO synthases (NOS) on L-arginine. There are several different NO synthases including endothelial NOS (eNOS) and an inducible NOS (iNOS) mainly found in inflammatory cells. In sepsis, iNOS is powerfully induced and this has the ability to generate large quantities of NO. The perceived mechanism by which NO achieves vasodilatation is thought to be via activation of guanylyl cyclase, which in turn leads to the formation of cyclic GMP (cGMP). This activates myosin light chain phosphatase, leading to the dephosphorylation of myosin and subsequent smooth muscle relaxation. Vasodilatation may also be mediated by changes in the function of the voltage-gated calcium channels described above. In contrast to depolarization-mediated vasoconstriction, the hyperpolarized state of the smooth muscle cell leads to the closure of these channels and resistant vasodilatation.

Sepsis and coagulation

The inflammatory response affects coagulation and is thought to have a role in the pathogenesis of MODS. The endothelium, which normally has concurrent anticoagulant and procoagulant properties, develops a predominant procoagulant state in sepsis.

Endothelial anticoagulant mechanisms: in the normal state, a net anticoagulant balance is achieved by activated protein C, antithrombin III and tissue factor pathway inhibitor (TFPI). Thrombomodulin binds thrombin on the endothelial surface, and this increases activation of protein C. The latter binds to protein S, leading to degradation of factors Va and VIIIa, thereby enhancing anticoagulation, especially in the microcirculation. Antithrombin III exerts an anticoagulant action on the endothelial surface by directly inhibiting the activated proteases IXa, Xa and thrombin.

Sepsis-induced procoagulation: in severe sepsis, acquired deficiency of activated protein C (85% of patients), diminished thrombomodulin activity and decreased antithrombin III levels are consistent features. Studies of sepsis in animals have shown that administration of activated protein C, antithrombin III and TFPI have been beneficial, though it is not clear whether the benefits are secondary to anticoagulant or to the potential anti-inflammatory actions of these agents. The latter theory may be strengthened by the recognition that tissue ischaemia secondary to microthrombi may generate IL-8, IL-1 and TNF-α release, and thrombin may lead to increased endothelial adhesion molecule expression with subsequent neutrophil adhesion. The most recognized procoagulant state in sepsis is that of disseminated intravascular coagulation in which widespread intravascular coagulation consumes platelets, increases consumption of coagulation factors, increases production of fibrinogen degradation products and leads to a severe bleeding tendency. Loss of the endothelial anticoagulant state in sepsis is also thought to contribute to the development of MODS because microvascular coagulation may lead to leukocyte and platelet plugs, local shunting and progress to MODS.

Assessment and treatment

Early detection and diagnosis: the evolution of 'outreach' services allied to intensive care potentially enables at-risk patients to be speedily identified and appropriately treated before systemic pro-inflammatory mechanisms have 'taken hold'. The benefits of early oxygen and fluid resuscitation particularly apply to septic patients; for example, hypoxia can lead to enhanced pro-inflammatory cytokine release. Similarly, early detection and treatment of new onset sepsis in the ICU should decrease the duration of stay, though it may be challenging to make this diagnosis in a patient with residual inflammatory features from a recent event. As part of the inflammatory response a fever is a powerful sign, however, severe sepsis may lead to hypothermia, which is a poor prognostic feature. A number of markers of the inflammatory and acute-phase response including C-reactive protein, IL-6 and pro-calcitonin levels may also be used to track the progress of the condition.

Identification and treatment of the infection: the septic or inflammatory focus may be clearly identifiable or completely unknown, though there are usually helpful clinical features. Steps involved in the identification and eradication of the source may include microbiological analysis, imaging, surgical intervention and administration of antibiotics. The advantage of empirical antibiotic therapy and early pathogen elimination may be offset by the development of antibiotic resistance among non-pathogenic organisms, therefore focused prescribing once the pathogen is identified is best practice.

Therapeutic manipulation of the immune response: much time and effort has been spent on developing agents (immunomodulators) that may aid suppression of the inflammatory response and therefore limit tissue damage. Most of these attempts have failed, including the use of agents to block endotoxin, IL-1 and PAF. Limited success has been achieved with anti-TNF therapy, though for other inflammatory conditions including inflammatory bowel disease it is proving more hopeful. These therapies are successful in many animal models, therefore these failures probably represent a failure in our detailed understanding of the pathogenesis of sepsis. The mediators being blocked are part of an adaptive immune response and their complete elimination is probably just as detrimental as when produced in excess. Improved understanding of the septic process may allow us to identify the appropriate timing and degree of suppression required to achieve a balance. This balance will probably be unique for different scenarios and different pathogens.

Corticosteroid treatment should be considered for sepsis and ARDS. A number of large studies had suggested that their use in severe sepsis and ARDS at best held no benefit and at worst was harmful. In these trials, the corticosteroids were prescribed at a high dose, early in the course and for a short duration. Studies within the last 4 years suggest that low dose corticosteroids prescribed for longer may be beneficial in severe sepsis or septic shock and in promoting the resolution of ARDS. Several large studies for sepsis and ARDS are under way. These should help to identify the appropriate dose and timing and whether treatment should depend on the strength of the endogenous stress response, as assessed by a synacthen test, or should be given to all.

Assessment and treatment of haemodynamics

Monitoring: the aims in haemodynamic management are to optimize tissue perfusion and cardiac stroke work, therefore the mainstays of treatment in established sepsis are aggressive fluid management and sympathomimetic therapy. Most agree that central venous pressure monitoring is the bare minimum, while many maintain that additional transoesophageal Doppler or pulmonary artery catheter monitoring is essential. Trans-oesophageal Doppler monitoring provides stroke volume and corrected flow time and allows calculation of cardiac output/index and systemic vascular resistance/index. Pulmonary artery catheter monitoring also incorporates cardiac stroke work, pulmonary capillary wedge pressure and equivalent right heart correlates. Mixed venous oxygen saturation provides an assessment of tissue oxygenation.

Fluid therapy: the large fluid requirement commonly seen in sepsis is the result of intravascular fluid depletion, mainly inflammatory driven capillary leakage, and the expanded intravascular compartment caused by pathological vasodilatation. To improve tissue perfusion and correct this intravascular hypovolaemia requires aggressive, but closely monitored, infusion of fluids. Despite the controversies regarding the choice of fluid (gelatins, starches or crystalloids), it is likely that there are no significant differences in efficacy between them. 'Early filling' may obviate, and should predate, rapid escalation in sympathomimetic therapy, to avoid severe tachycardias. Fluid infusion is maintained until the intravascular compartment is full; this may be manifested by a rapid rate of rise of central venous pressure (or pulmonary capillary wedge pressure) in the absence of a significant rise in mean arterial pressure (or cardiac output/corrected flow time).

Sympathomimetic therapy: the aim is to maximize tissue perfusion, taking into consideration the complications of raised cardiac stroke work. The choice of agent depends on the circulatory state, with vasoconstrictors such as noradrenaline (norepinephrine) being the mainstay of sympathomimetic therapy for septic shock with vasodilatation and a high cardiac output. In late sepsis with myocardial depression there may be a requirement for inotropic agents such as adrenaline (epinephrine). Noradrenaline (norepinephrine) is virtually a pure vasoconstrictor, achieving this by α-receptor agonism; the mild β_1- and β_2-receptor agonism (and hence inotropy and chronotropy) is usually thought not to be clinically significant. Adrenaline (epinephrine), with α-receptor agonism and more potent β_1- and β_2-receptor agonism, is probably as commonly used worldwide, though dopamine with β_1- and β_2-receptor agonism at low doses and α-receptor agonism at higher doses is also used.

Other vasoconstrictors: analogues of antidiuretic hormone (ADH), particularly terlipressin, have been used as rescue therapy for sepsis. Although they have a role in decreasing noradrenaline (norepinephrine) requirements, it is unclear whether they have a beneficial effect on outcome. The same assessment may be made of another vasoconstrictor, intravenous methylene blue, which inhibits guanylate cyclase, eNOS and iNOS. It may be reasonable to reserve ADH analogues and/or methylene blue for occasions when there is rapid escalation in the dose of existing vasoconstrictor(s) without obvious benefit. The only large trial to address NO inhibition in sepsis, using the iNOS inhibitor LNMMA (N^G-monomethyl-L-arginine), caused increased mortality.

Treatment of microvascular coagulation

After long-standing septic insult (or earlier in those with small vessel disease) microvascular hypoperfusion may manifest as digital ischaemia. Cold peripheries with poor capillary refill may lead to permanent pallor and evidence of necrosis. Although the use of vasoconstrictors has been blamed, it should be remembered that the microvasculature is relatively depleted in α-receptors compared with β-receptors. Therefore at least part of the pathogenesis of microvascular ischaemia may be the procoagulant and inflamed state of the vessels, leading to 'sludging'. For therapy, warming blankets, low dose vasodilators (dobutamine, dopexamine, dopamine and nitrates) and prostacyclins are used in various centres, so far with only anecdotal reports of success.

Activated protein C: one important advance has been publication of the recent multicentre phase III, prospective, double-blind trial of activated protein C (drotrecogin-α) in the setting of severe sepsis. This examined 1690 patients with severe sepsis and a significant benefit was seen at 28 days for the treatment group as mortality fell from 30.8% for those receiving placebo to 24.7% for those receiving drotrecogin- α. This equated to a number needed to treat of 16 to save one life. The US and UK regulatory bodies have approved this as the first biological treatment for sepsis. This drug is costly and figures suggest that maximal benefit may be seen in patients with severe sepsis and organ failure. It may be that it should be reserved for those with high APACHE II scores (over 25) or those with several organ failures. A balance needs to be struck because treatment should also be restricted to those in whom the process has not become irreversible. ◆

Principles and Complications of Immunosuppression

Ruby Sharma

Ruby Sharma is Specialist Registrar in Anaesthesia and Intensive Care at Addenbrooke's Hospital, Cambridge, UK. She qualified from Delhi University, India, from where she was also awarded the degree of MD in Anaesthesia. She has gained experience in the management of transplant recipients while working at Cambridge.

Mike Lindop is Consultant in Anaesthesia and Intensive Care at Addenbrooke's Hospital, Cambridge, UK.

Organ transplants are allogenic – organs from 'another'. The body's immune system is structured to recognize 'self' and reject 'other'. This rejection of 'other' proteins is mediated by cellular and humoral responses. These responses must be controlled if an allograft is to survive. In some instances, long-term grafts have developed immune tolerance and there is much excitement about finding methods of inducing such tolerance. Until this can be achieved, immune suppression is the mainstay of management.

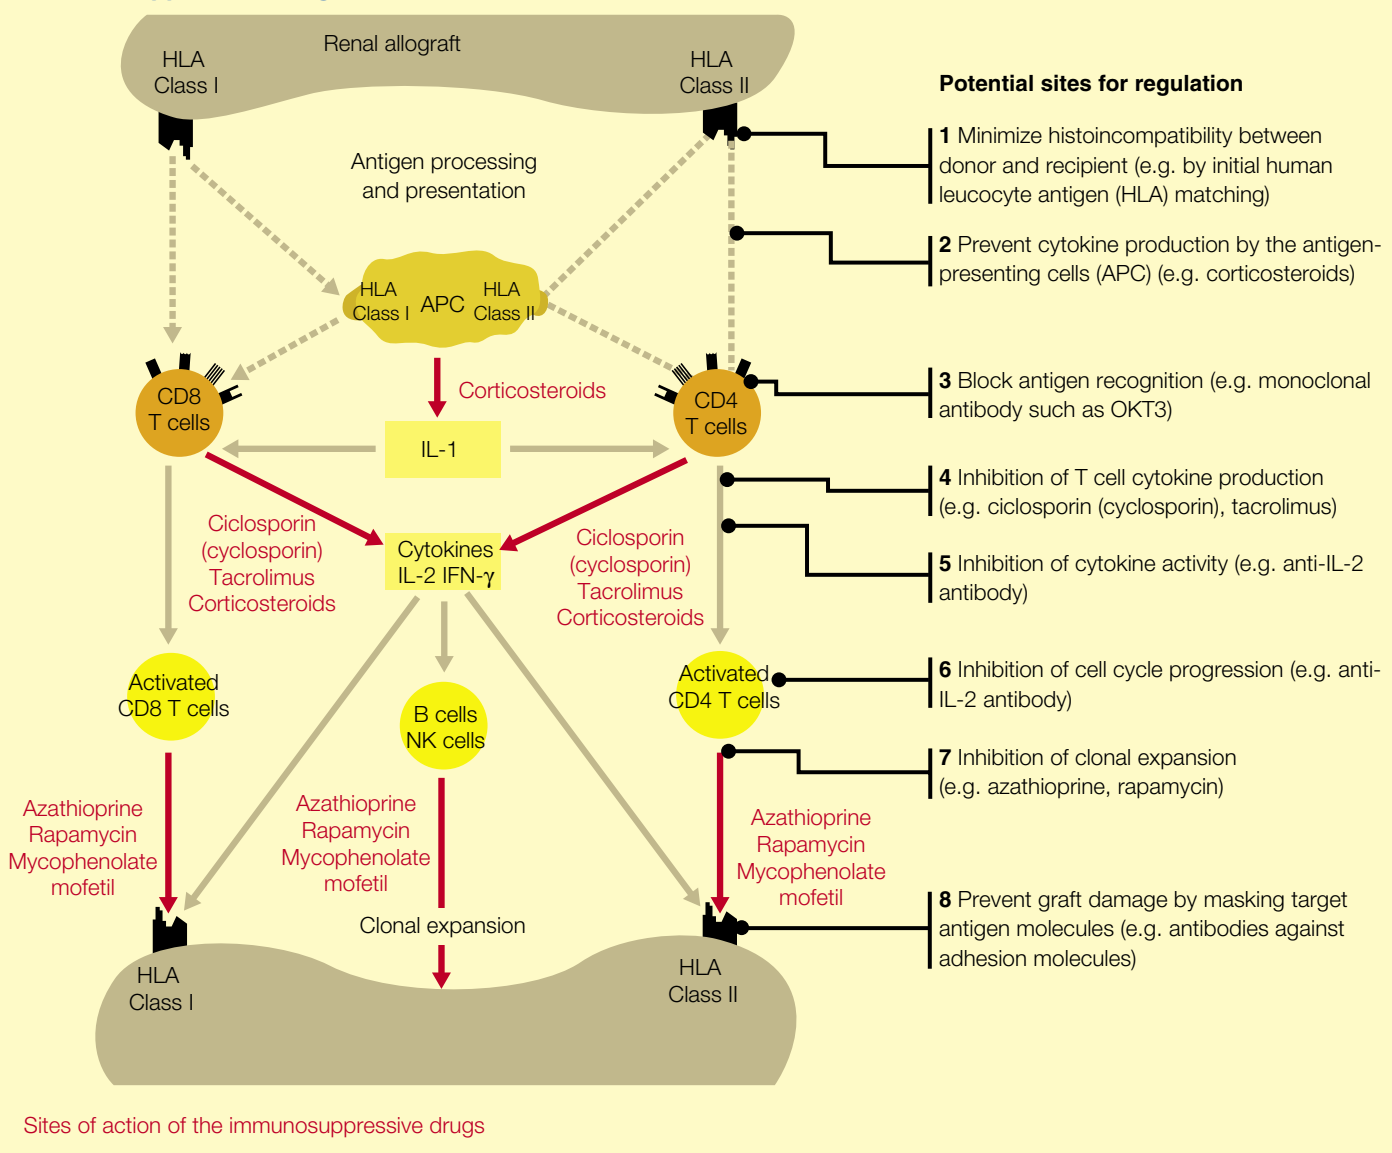
Mechanism of rejection

Cellular response: the main cellular mechanism is the activation of the helper T (thymic) cells. Macrophages scavenge the tissues sampling soluble and particulate matter. When non-self matter is found they act as antigen-presenting cells (APCs). They express high levels of major histocompatibility complex (MHC), which is a glycoprotein on all nucleated mammalian cells and is the root of recognition of self and non-self. MHC class I molecules are expressed on most cells and allow healthy cells to be recognized as 'self'. When cells are diseased (e.g. infected by viruses) these molecules display non-self peptides, allowing clearance by the immune system. MHC class II molecules are displayed exclusively by antigen-presenting cells. They present foreign antigen to immune cells and stimulate the proliferation of antigen-specific T helper cells which further amplify the inflammatory response by stimulating macrophages, B cells (blood lymphocytes becoming plasma cells), cytotoxic T cells and natural killer cells (the latter two are responsible for final cytotoxicity). In the process, many different cytokines, such as interleukins IL-1 and IL-2, are produced. Cytokines are soluble proteins that facilitate communication between cells and may be stimulatory or inhibitory.

Humoral response: lymphocytes recognize non-self antigen fragments and, by a mechanism involving helper T cells, MHC and cytokines IL-4 and IL-5, they proliferate and create antibodies. These antibodies can lead to cell-mediated cytotoxicity and to vascular occlusion. One mechanism of vascular injury is the change of endothelial cells from a non-adhesive to an adhesive state, binding platelets and inflammatory cells. This is mediated by up-regulation of adhesion molecules.

Control of the immune response: Figure 1 shows some of the pathways involved in the immune response and how they can be blocked.

Allograft immune response pathway specifying the sites and mechanisms of action of various immunosuppressive drugs



Sites of action of the immunosuppressive drugs

APC, antigen-presenting cell; CD, lymphocyte surface antigen coding; HLA, human leucocyte antigen; IFN-γ, interferon-γ; IL, interleukin; NK, natural killer

1

Complications of immune suppression

Apart from the specific side-effects of the immunosuppressive agents used in transplantation (see below), three main side-effects of current non-specific immunosuppression are infection, cancer and cardiovascular disease.

Infection: immunosuppression weakens the ability to fight against microorganisms and consequently over 80% of transplant recipients have at least one clinical infective episode postoperatively. During the first month after transplant the usual postoperative infections predominate, as do infections from any organisms present in the graft. The level of immunosuppression is usually at its highest during months 1–6 and opportunistic viral and fungal infections (e.g. cytomegalovirus, *Candida*, *Aspergillus*) predominate. Thereafter, common bacterial infections and slow-developing fungal and mycobacterial infections predominate.

Rapid diagnosis is essential, and patients with fever, hypoxia and whose radiographs show pneumonic signs should receive aggressive treatment. Diagnostic bronchoscopy should be considered in the absence of an early response. In the presence of unexplained fever, central vascular and urinary catheters should be removed and cultured. Antibiotic treatment is usually started empirically pending culture and sensitivity results. Infectious complications can be difficult to diagnose in the immunocompromised patient and a high index of suspicion is essential. The temperature may not rise in a patient taking corticosteroids or in a neutropenic patient. White cell count is an unreliable sign of infection because of the effects of azathioprine (reduced count) and/or corticosteroids (elevated count). Infection must always be suspected if the patient's condition deteriorates.

Aseptic techniques must be strictly adhered to during instrumentation and intravascular cannulation. Pathogens that are relatively innocuous in non-immunocompromised patients may cause severe infections in transplant patients because of their altered immune system.

Tumours: transplantation and consequent immunosuppression increases the incidence of several malignancies. This increase is particularly evident in cancers with a putative viral aetiology (e.g. non-Hodgkin's lymphoma, squamous cell cancers of the skin, Kaposi's sarcoma and cervical cancer in women). However, there is an increased risk of all cancers, lymphomatous (often called post-transplant lymphoproliferative disease) or otherwise. Overall, the rate of malignancies is increased 3–4-fold, varying with the severity of immunosuppression used. Surveillance for these complications is an integral part of post-transplant management and simple advice, such as avoiding excessive exposure to sun, can cut down the risk in the case of photosensitive skin cancer. Lymphomas respond favourably to reduced immunosuppression and anti-viral agents, though traditional chemotherapy may also be required. Other tumours may require radical excision. Preoperative chest radiographs may reveal undiagnosed intrathoracic malignancy that might affect cardiopulmonary function or airway patency.

Cardiovascular disease: aggressive atheromatous disease occurs in many transplant recipients. It is usually associated with an increased incidence of hypertension and hyperlipidaemia, which are side-effects of many immunosuppressive drugs. However, it may also be a consequence of non-specific immunosuppressive therapy *per se* through mechanisms currently obscure. In heart transplant recipients, the incidence of coronary atherosclerosis increases about 10–15% each year after transplantation, the reported incidence at 5 years being 40–67%. Cytomegalovirus infection accelerates the coronary artery disease. Owing to graft denervation, coronary ischaemia may be painless in cardiac allografts and may manifest as fatigue and dyspnoea. Silent myocardial ischaemia is also common in kidney transplant recipients. A history revealing poor exercise tolerance is important in determining the extent of further investigations required for anaesthetic assessment.

Specific complications of immunosuppressant drugs

The immunosuppressants in current use are relatively non-specific, in the sense that they inhibit many lymphocyte subsets other than those directed against donor-specific alloantigens. To minimize side-effects almost all the anti-rejection regimens use combinations of several drugs in relatively lower doses. The main groups of drugs are:

- calcineurin inhibitors (ciclosporin (cyclosporin), tacrolimus (FK 506))
- antiproliferative drugs (azathioprine, mycophenolate mofetil (MMF))
- corticosteroids
- polyclonal antibodies (antilymphocyte globulin (ALG), monoclonal antibodies (OKT3)).
- mTOR inhibitors (rapamycin (sirolimus), everolimus (mTOR – mammalian target of rapamycin kinase))
- other agents (leflunomide (FTY 720)).

Apart from the non-specific side-effects of immunosuppression discussed above, these drugs also have specific side-effects (Figure 2). The commonly used drugs are discussed below.

Common immunosuppressive drugs and their main side-effects

Group	Principal relevant side-effects
• Corticosteroids (e.g. prednisolone, methylprednisolone)	Glucose intolerance, hypertension, psychosis
• Calcineurin blockers (e.g. ciclosporin (cyclosporin), tacrolimus)	Hypertension, nephrotoxicity, hepatotoxicity, confusion, fits
• Antiproliferatives (e.g. azathioprine, mycophenolate mofetil)	Leucopenia, thrombocytopenia, anaemia, pancreatitis, gastro-intestinal upset, cholestatic jaundice Azathioprine slightly potentiates muscle relaxant drugs
• Antilymphocyte antibodies (e.g. OKT3, Campath)	Fever, serum sickness, leucopenia, thrombocytopenia, hypotension, pulmonary oedema

2

Ciclosporin (cyclosporin) is a cyclic peptide molecule derived from a soil fungus. It is highly lipid soluble and diffuses passively through cell membranes where it binds to intracellular proteins. It became the mainstay of immunosuppression after the recognition that its use promoted transplant survival among unrelated subjects comparable with that achieved between identical twins. Together with azathioprine and prednisolone, ciclosporin (cyclosporin) forms the ubiquitous 'triple therapy' immunosuppression regimen.

Its major actions are thought to be inhibiting activated macrophages from producing IL-1 (3 in Figure 1), inhibiting T lymphocytes from secreting the key lymphokine IL-2, and blocking activation of helper (CD4) T lymphocytes (4 in Figure 1). Ciclosporin (cyclosporin) has significant side-effects, the most serious of which, in all forms of organ transplantation, is nephrotoxicity.

Nephrotoxicity – the effects of ciclosporin (cyclosporin) on the kidney are acute and chronic. Acute functional nephrotoxicity presents as various features with otherwise functional kidneys. The usual findings are hyperkalaemia with an inappropriately raised creatinine concentration. This responds rapidly to a decrease in the plasma concentration of ciclosporin (cyclosporin). The aetiology may be related to an alteration in the cortical and medullary blood flow. Chronic nephrotoxicity is a major clinical problem. Its cause is unknown and may be related to a generalized sympathetic overactivity that may also account for the hypertension found in patients taking ciclosporin (cyclosporin). About 10% of patients have chronic renal impairment, which is shown on renal histology by vascular sclerosis, interstitial fibrosis and thickened tubular and basement membranes.

Hypertension is the other main complication occurring in 50–70% of patients. It is associated with an increase in systemic vascular resistance and is relieved following withdrawal of the drug. The current treatment is administration of calcium channel blockers.

Hepatotoxicity following ciclosporin (cyclosporin) manifests as a rise in transaminases and plasma alkaline phosphatase.

Other side-effects of ciclosporin (cyclosporin) include gingival hypertrophy, hirsutism, hypertrichosis and, at higher serum levels, tremors or seizures.

Tacrolimus (FK 506) is a potent immunosuppressive macrolide antibiotic. It has a similar mechanism of action to ciclosporin (cyclosporin) but is a very dissimilar molecule. On a weight-to-weight basis it is 10–100 times more potent than ciclosporin (cyclosporin). In trials, it reduces acute and refractory rejection in humans and the need for OKT3. However, the side-effects are similar to those of ciclosporin (cyclosporin) including nephrotoxicity and neurotoxicity. Diabetes requiring insulin therapy may be precipitated by ciclosporin (cyclosporin) or tacrolimus but is probably more common with the latter.

Azathioprine is a purine analogue. It is an antiproliferative agent and inhibits DNA and RNA synthesis by preventing the synthesis of adenylic and guanylic acid from inosinic acid. As a result, T and B cell proliferation is inhibited. Production of other formed elements in bone marrow is also suppressed leading to anaemia, thrombocytopenia and leucopenia. Careful monitoring of white cell count is an important method of monitoring the dose. Hepatotoxicity and dysfunction of any other organ system that has a high rate of cell proliferation (e.g. gastrointestinal, skin) also occurs. Azathioprine increases non-depolarizing relaxant requirements modestly by presynaptic inhibition of the motor nerve terminal.

Mycophenolate mofetil (MMF) is a powerful new immunosuppressant. It is an antiproliferative drug that inhibits the enzyme in a key step in the *de novo* pathway of purine synthesis. It has a specific effect on T and B lymphocytes. In contrast to azathioprine, MMF inhibits a single enzyme in DNA synthesis and does not interfere with repair of DNA or become incorporated into it. It is expected to be less mutagenic to DNA. In clinical trials, MMF has reduced the incidence of biopsy-proven renal allograft rejection to 50%. It also reduces the need for ALG/OKT3 to treat corticosteroid-resistant rejection. Its main side-effects are gastrointestinal and haematological (e.g. diarrhoea, abdominal pain, dyspepsia, leucopenia, anaemia, thrombocytopenia). It is not nephrotoxic or hepatotoxic. Thus, in renal transplantation, MMF has achieved a role of prime adjunct to ciclosporin (cyclosporin) and tacrolimus, in place of azathioprine.

Corticosteroids are potent anti-inflammatory drugs and are widely used immunosuppressive agents. They alter lymphocyte function and decrease the number of circulating lymphocytes. This action is via direct cell lysis and by redistribution of lymphocytes throughout the body. The degree of lymphopenia is dose dependent; a high dose can reduce lymphocyte numbers by a maximum of 50–75%. They also block the production and release of a number of inflammatory cytokines, prostaglandins and leukotrines. Major side-effects are adrenal suppression, glucose intolerance, peptic ulceration, aseptic osteonecrosis, hypertension and integumental necrosis. There may also be fluid retention, psychological disturbance, hypokalaemia and myopathy. Nevertheless, glucocorticoids are a vital component of maintenance and rejection/rescue immunosuppression regimens.

Antibodies (polyclonal and monoclonal)

Polyclonal or antilymphocyte globulin (ALG) preparations are derived from animals immunized with human lymphocytes. Most often T lymphocytes obtained from the thymus are used because they play a predominant role in graft rejection. The active immunoglobulin is largely in the IgG fraction. After injection, ALG attaches to circulating lymphocytes and a complement-dependent process lyses them. The antibodies may also bind to the antigen receptor sites on lymphocytes and thus ‘blind’ the lymphocyte to its targets. ALG may cross-react with antigens other than T lymphocytes, producing marked leukopenia and thrombocytopenia. Systemic symptoms (e.g. fever, pruritus) can also occur, as can frank serum sickness.

Monoclonal antibodies have been developed to reduce the toxicity of the polyclonals and to increase efficacy in preventing rejection. OKT3 is a monoclonal mouse antibody directed against the CD3 protein complex, specific to human T cells. OKT3 binds to CD3, blocking recognition of MHC antigens on foreign cells and the subsequent immune response. OKT3-bound T cells are then removed from circulation and destroyed by the reticulo-endothelial system. The initial dose of OKT3 is usually accompanied by mild systemic symptoms (e.g. fever, hypotension, tachycardia) and occasionally by pulmonary oedema and aseptic meningitis. Patients receiving these antibodies are pretreated with diphenhydramine and corticosteroids. The use of polyclonal antibodies has decreased because OKT3 is less toxic and comparably effective in reversing rejection. ◆

Assessment and Management of Adult Trauma Patients

Richard Thomas
Charles D Deakin

Richard Thomas is Specialist Registrar in Anaesthesia. He graduated from St Mary's Hospital, Paddington, London, and is now training with the Wessex School of Anaesthesia. He has a clinical interest in trauma and is an ATLS instructor.

Charles D Deakin is Eponymous Professor at the Royal College of Anaesthetists. He qualified from Cambridge University and King's College Hospital, London, and trained in London and Southampton. His interests include cardiac anaesthesia, pre-hospital care and resuscitation.

Since the introduction of the Advanced Trauma Life Support (ATLS) programme in the UK in 1988, there have been major improvements in educating healthcare professionals in the principles of assessment and management of the traumatized patient.

In-hospital preparation: each hospital should ensure that an adequately equipped area is available to receive the patient. A 'trauma team', including members of the accident and emergency, anaesthetic/ICU, orthopaedic and surgical departments, should attend all major trauma cases and team members should be aware of their roles. When arriving at the accident and emergency department with the patient, para-medics should give a detailed handover to hospital staff. This should include the mechanism of injury, because this is important in anticipating likely injuries.

Primary survey: assessment and resuscitation

Life-threatening injuries must be identified and treated simultan-eously in order of clinical priority using the ABCDE sequence.

A Airway maintenance with cervical spine control
Recognizing the high risk of cervical spine injury associated with multisystem trauma (especially in patients with blunt trauma or altered consciousness), airway patency should be confirmed while the cervical spine is immobilized manually or using a correctly sized hard collar, lateral supports and fixation (see page 282).

Interventions such as removing foreign bodies, chin lift or jaw thrust or the institution of a definitive airway (tracheal intubation or surgical airway) may be required.

High concentration oxygen should be administered to all traumatized patients. Loosening the cervical collar to avoid rises in intracranial pressure may follow spine stabilization using head blocks and tape.

B Breathing with ventilation
Assessment of breathing must exclude simple or tension pneumothorax, flail chest, pulmonary contusion and haemo-thorax. Needle decompression is a temporary measure for tension pneumothorax; tube thoracocentesis is the definitive therapy. Inadequate ventilation should be assisted.

C Circulation with haemorrhage control
The degree of hypovolaemia should be assessed using capillary refill, peripheral temperature, blood pressure and the conscious level. Blood pressure cannot be predicted accurately merely by the presence or absence of particular peripheral pulses.

The most common aetiology of shock in trauma is haemorrhagic hypovolaemia. External haemorrhage should be managed by direct manual pressure and elevation of the affected part. If peripheral intravenous access is impossible, femoral vein cannulation or surgical cut-down can be life saving.

Limited evidence suggests that crystalloid solutions may be better than colloids; whichever are chosen, they are best administered warm. O negative blood should be available immediately to maintain the haemoglobin level above 8.0 g/dl, but full cross-matching should also be undertaken.

Non-haemorrhagic causes for shock should be identified and treated. For instance, cardiac tamponade requires pericardio-centesis or pericardiotomy.

Specific manoeuvres may be required for pregnant trauma patients. For instance, the gravid uterus should be displaced laterally, using a wedge or blankets under the left hip, to avoid hypotension associated with aorto-caval compression. If the patient requires immobilization on a spinal board, the wedge should be placed underneath the board.

Occasionally the patient has to undergo salvage surgery (i.e. laparotomy for exsanguinating abdominal haemorrhage) as part of the primary survey.

D Disability
A rapid assessment of neurological status, using the AVPU (see *Anaesthesia and Intensive Care Medicine* **3:7:** 235) or Glasgow Coma Score (GCS; see *Anaesthesia and Intensive Care Medicine* **3:4:** 132) systems, capillary size and reaction should be performed as part of the primary survey. An altered conscious level may indicate hypoxaemia or shock. Therefore, the 'ABCs' should be re-evaluated before ascribing the neurological state to CNS trauma. Regular re-evaluation of disability is essential to monitor trends.

A comatose patient (GCS < 8) requires intubation. Secondary brain injury is minimized by ensuring adequate oxygenation (patent airway), adequate ventilation (to prevent cerebral vasodilation caused by hypercapnia) and normotension to ensure adequate cerebral perfusion. Timely consultation with a neurosurgeon is recommended, particularly in patients who have clinical or radiographic evidence of expanding space-occupying lesions.

E Exposure and environment control
The patient's clothing should be removed to allow a complete examination. Log roll the patient and examine the back. Hypothermia is common and can be minimized by warming the room, warming inspired gases and intravenous fluids, using blankets and warmed-air devices (e.g. BairHugger®).

Adjuncts to the primary survey
- All trauma patients should be monitored using ECG, blood pressure, pulse oximetry, temperature and capnography.
- A gastric tube should be placed in all patients with life- threatening injuries, but the nasal route is contraindicated in those with basal skull fracture (risks of intracerebral migration via fractured cribriform plate).
- Urinary catheters permit accurate measurement of urine output, but urethral injury should be excluded before catheterization (suspected by blood at penile meatus, perineal bruising, scrotal haematoma or a high-riding prostate on rectal examination).
- Plain anteroposterior radiographs of chest, pelvis and lateral cervical spine should be taken in the resuscitation area. They may provide information to guide resuscitative efforts (e.g. pelvic fracture can explain hypotension resistant to fluid infusion).
- Diagnostic peritoneal lavage and abdominal ultrasonography may reveal occult abdominal haemorrhage.

Transfer: depending on the patient's injuries and the local facilities, intra- or inter-hospital transfer may be required. This can be facilitated by administrative staff, but the patient should be stable before being moved. Occasionally, transfer of a patient to salvage surgery (i.e. laparotomy for exsanguinating abdominal haemorrhage) may form part of the primary survey.

Secondary survey

The secondary survey, a meticulous head-to-toe evaluation (including log-roll), should not commence until the primary survey is complete. It is also a useful time to re-evaluate injuries identified in the primary survey and to arrange targeted radiological and laboratory tests.

History: the important aspects of patient history are covered by the mnemonic AMPLE (Allergies, Medications, Past illness/pregnancy, Last meal and Events/environment related to injury).

Physical examination: clinical examination should be systematic. All injuries should be documented for clinical and medico-legal reasons.

Head and skull – the entire head and scalp should be examined for lacerations, contusions and fractures. Eyes should be examined early, in case eyelid oedema precludes subsequent examination. Auditory canals should be examined for CSF leak, tympanic membrane integrity and haemotympanum.

Maxillofacial – facial burns and trauma can lead to airway obstruction or major blood loss. Patients with mid-face fractures should be assessed for nasal CSF leak and ocular mobility (entrapment of extraocular muscles may occur with orbital fractures).

Cervical spine and neck – patients with injuries above the clavicles should be assumed to have an unstable cervical spine injury. Immobilization should continue until the spine has been cleared of bony, ligamentous and neurological injury. Patients who have suspected trauma to neck vasculature may require angiographic examination.

Thoracic and lumbar spine – examine for deformity, tenderness and neurological signs. The mechanisms of injury are important clues.

Chest – repeated evaluation is required to ensure a patent airway and adequate ventilation. Any deterioration of the patient should trigger a repeat of the primary survey. Positive-pressure ventilation may rapidly convert a small simple pneumothorax into a life-threatening tension pneumothorax. Plain chest radiography does not always detect rib fractures. An apparently widened mediastinum is common in portable, supine chest radiographs, but should trigger suspicion of an aortic injury; contrast aortography is required to exclude the diagnosis.

Abdomen – early surgical assessment is vital to identify and manage covert intra-abdominal injury. Bleeding from the liver and spleen can be predicted from the mechanism of injury and bruising patterns, but remains under-recognized, especially in unconscious patients who are unable to complain of pain. Diagnostic peritoneal lavage and ultrasonography can be performed at the bedside; more complex radiological evaluation (e.g. angiography) should be reserved for stable patients. Exploratory laparotomy may be required as a diagnostic procedure in some patients.

Perineum (including rectal and vaginal examination) – rectal examination is required before urethral catheterization and may provide information about pelvic fractures, integrity of the rectal wall and anal tone (spinal injury). A pregnancy test should be undertaken in women of childbearing age.

Musculoskeletal – a 'look, feel, move' approach is required for every bone and joint. Neurovascular assessment of extremities should be performed and repeated after any manipulation. Pelvic mobility should be assessed once only. Injuries to the extremities are often overlooked, but remain a major source of litigation; the secondary survey is the time to discover them.

Neurological – early consultation with a neurosurgeon is required in all patients with neurological injury. The most important measures to minimize secondary brain injury are the maintenance of adequate oxygenation, ventilation and cerebral perfusion. The management of acutely raised intracranial pressure and convulsions is best discussed locally, because neurosurgical preferences differ.

Adjuncts to the secondary survey
The specialized diagnostic tests indicated by the findings of the secondary survey (e.g. CT, angiography, bronchoscopy) involve transfer of the patient away from the resuscitation area. As a general rule, the patient should be stable and should be accompanied by a team and equipment that permits continuing resuscitation.

Post-resuscitation monitoring and re-evaluation
The successful management of trauma depends on frequent re-evaluation. Invasive blood pressure monitoring may be a useful adjunct to the monitoring previously described. Intravenous opiates (e.g. morphine, 2 mg increments) should be titrated to effect. An anti-emetic should also be administered.

Definitive care
Definitive care usually involves early surgery or admission to ICU. Control of haemorrhage and optimization of oxygen delivery to all organs is vital in minimizing mortality and morbidity from major trauma. ◆

Burns and Smoke Inhalation

Stephen Cockroft
Carolyn Way

Stephen Cockroft is Consultant in Anaesthetics and Intensive Care at Salisbury District Hospital, Wiltshire, UK. He qualified from Cambridge University and trained in anaesthetics and intensive care at St Bartholomew's Hospital, The Royal London and Southampton. His clinical interests include respiratory failure and trauma management.

Carolyn Way is Specialist Registrar in Anaesthesia and is training on the Wessex rotation, currently working in Portsmouth hospitals. She qualified from King's College, London.

In the UK, there are 250,000 burn injuries annually, resulting in 16,000 hospital admissions. About 1000 of these are severe burn injuries requiring fluid resuscitation (500 are children) and 300 deaths result. The size of the burn injury affects patient outcome – those with a 75% total burn surface area (TBSA) have a 60% mortality.

Pathophysiology

The skin represents 15% of body mass and tolerates temperatures up to 40°C without risk of injury.

Thermally injured skin consists of three parts, a central area of coagulation and necrosis, a surrounding zone of stasis and an outer zone of hyperaemia. Within these, capillary endothelial destruction occurs causing an increase in permeability. This is the result of direct thermal destruction and indirect release of inflammatory mediators.

Loss of epidermal integrity increases evaporative water loss from the burn site (up to 200 ml water/m^2/hour). Increased heat loss results causing hypothermia. Gram-negative bacterial colonization occurs rapidly, even if strict asepsis is enforced. Plasma fluid accumulates within the interstitial tissue spaces causing hypoalbuminaemia and hypovolaemic shock. This tissue swelling may compromise the airway, cause compartment syndromes or increase skin necrosis. Systemic oedema occurs through loss of plasma oncotic pressure (low plasma albumin concentrations) and this may contribute to a further decline in organ function.

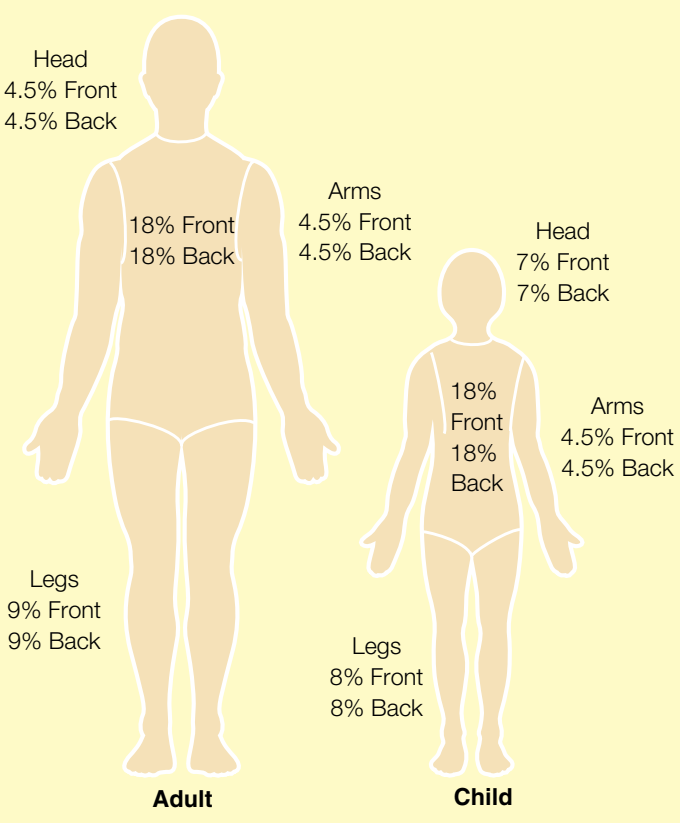
Initially, the haematocrit rises, but after 24–48 hours, anaemia occurs owing to increased haemolysis and reduced red cell haemoglobin content. Anaemia persists as a result of surgical blood loss, sepsis-induced bone marrow suppression and malnutrition.

Following burn injury, the metabolic rate increases which persists until wound closure is established. This is mediated by increased glucagon, cortisol, catecholamines and cytokines. As a consequence, carbon dioxide excretion and oxygen consumption increase coupled with protein catabolism and hyperglycaemia.

Assessment of burn injury

The extent of any burn-injured site is measured in terms of the depth of injury and the area of body surface involved. The total burnt surface area can be assessed using the rule of nines (Figure 1), mapping out the areas of partial- and full-thickness injury. An alternative means of assessment is based on the assumption that the palm of the patient's hand corresponds to 1% of their body surface area.

Calculation of total burn surface area



1

Superficial burns (first degree) involve only the epidermal layer and are characterized by erythema, redness and blistering. They are painful but desquamate and heal quickly.

Partial-thickness burns (second degree) involve the entire epidermis and upper dermal layer. They are always associated with blisters, are painful and take longer to heal (10–14 days). Because epidermal islands (hair follicle and sweat glands) remain intact, these burns may not require grafting to achieve wound closure. If deeper dermal destruction has occurred, the injury is less painful (because nerve endings have been destroyed), takes longer to heal and may require excision and grafting.

Full-thickness burns (third degree) involve total destruction of the epidermis and dermis. They are painless and the wound has a black, brown or pale waxy appearance. Early excision and grafting is required to reduce infection and preserve limb function.

Inhalational thermal injury

Inhalational thermal injury adds up to 50% to the expected burn mortality. From the history and clinical examination, thermal injury to the airway is expected in association with:

- facial burns and burnt eyebrows
- dysphagia, drooling, dysphasia
- carbon present within oropharynx
- carbon in sputum
- fire within a confined space
- history of an explosion
- history of loss of consciousness.

Airway trauma and respiratory failure can result from several processes (Figure 2).

Mechanisms of thermal injury to the airway and respiratory system

Heat
Direct thermal trauma caused by inhalation of hot gases often confined to the upper airway (glottis protects lower airway). Steam injuries often destroy distal lung tissue owing to higher specific heat capacity than dry gases

Blast
Shockwave (velocity 220 m/s) causes pulmonary barotrauma, lung contusion and blunt chest injuries

Chemical poisoning

- *Choking agents*

Aldehydes, nitrogen oxides, chlorine, sulphur oxides, carbon cause bronchospasm, ciliary dysfunction, epithelial necrosis, mucus secretion and pulmonary atelectasis

- *Carbon monoxide*

Over 20% carboxhyhaemoglobin is significant and causes metabolic acidosis or coma
Treat with high inspired oxygen fraction and consider hyperbaric oxygen

- *Cyanides*

Toxic over 50 ppm. Generated by partial combustion of plastics (polyurethane, polyacrilonitryl and acrocyanates). May present as a metabolic acidosis or coma, associated with high venous oxygen saturation
Treatment includes high fraction of oxygen in inspired air ($FiO_2$1.0) and ventilation

Asphyxia
Oxygen consumption by combustion (firestorms) or displacement by other gases (carbon dioxide or other fire extinguisher agents within a confined space)

2

Management

Patients should be removed from the source of trauma and decontaminated. Assessment and initial management should follow Advanced Trauma Life Support (ATLS) guidelines.

Airway management

The airway should be maintained, protected and high concentration oxygen administered via a non-rebreathing bag and face mask. A high index of suspicion of cervical spine injury is required.

Where indicated, tracheal intubation is best performed early, because evolving swelling of the lips, tongue, palate, epiglottis or arytenoids may make this impossible later. Fibre-optic nasendoscopy may assist in confirming the presence of airway injury. Absolute indications for tracheal intubation include the presence of stridor, respiratory failure, circumferential or full-thickness burns to the face or neck and a reduced conscious level.

Unless airway obstruction is suspected, a rapid sequence induction should be performed. Reliable intravenous access should be obtained and hypovolaemia corrected. Suxamethonium, 1–1.5 mg/kg i.v., is safe to use in the first 24 hours following a burn injury and an appropriate induction agent should be administered (ketamine, 2 mg/kg, is ideal in the presence of hypovolaemic shock). If airway obstruction is suspected or oedema of the airway is present, then awake fibre-optic intubation, inhalational induction or an emergency surgical airway may be required.

A tracheal tube of sufficient length should be inserted, because subsequent airway oedema may 'draw' the tube out of the trachea. The tube should be secured, avoiding further trauma to the face. The tracheal tube should be of adequate diameter because bronchoalveolar lavage may be required to clear mucus and debris (a nasotracheal tube may prove too narrow). While securing the airway, it is vital to site a nasogastric tube to decompress the stomach and permit early feeding. Often, a tracheostomy is contraindicated because burnt tissue adjacent to the proposed stoma site increases the risk of infection and haemorrhage. Therefore, the tracheal tube may be required for an extended period with extubation possible only after airway and facial oedema have resolved.

Respiratory support

Respiratory function should be monitored and hypoxaemia corrected. Chest radiography detects most blunt chest injuries or areas of lung collapse. Owing to skin tissue destruction and oedema, or the presence of carbon monoxide, pulse oximetry may be unreliable and intermittent arterial blood gas sampling allows determination of oxygenation and adequacy of ventilation. In addition, co-oximetry provides accurate measurement of any carboxyhaemoglobin. Inhalational thermal injuries, and the likely development of acute respiratory distress syndrome, may require advanced respiratory support. Such techniques may include pressure control, inverse ratio, prone ventilation, high frequency oscillation, therapeutic paralysis and use of inhaled pulmonary vasodilators (prostacyclin or nitric oxide). In addition, the use of nebulized N-acetyl cysteine and heparin have been described.

High levels of carboxyhaemoglobin (> 30%) are treated by administration of 100% oxygen. Several hours therapy with an FiO_2 of 1.0 may be required to disassociate carbon monoxide from its haemoglobin binding sites. Hyperbaric oxygen therapy has a role in severe carbon monoxide poisoning (if a suitable facility is available that is capable of managing a critically ill patient).

Significant cyanide poisoning occurs following partial combustion of plastics (Figure 2). It may present as a severe metabolic acidosis that is out of proportion to the degree of hypovolaemic shock present. Treatment with 100% oxygen accelerates inactivation of the cyanide anion to thiocyanate.

Circulatory support
Restoration of the blood volume and maintenance of organ perfusion are crucial to patient survival and often difficult to achieve. Reliable intravenous access is required for resus-citation and is best sited away from burnt tissue. In patients with extensive burns there may be few cannulation sites available, though the femoral triangle is often spared.

Cardiovascular monitoring may be complicated by tissue destruction with sites being unavailable for placement of ECG electrodes or blood pressure cuffs. Adequacy of cardiovascular function may be assessed by placement of a urethral catheter and monitoring urine production and composition. Often central venous or pulmonary arterial occlusion pressure measurement is required. Oesophageal Doppler may also have a role in guiding fluid therapy to correct hypovolaemic shock. Temperature monitoring is essential.

There are various fluid resuscitation formulas for calculating early fluid requirements following thermal injury (Figure 3). These serve as a guide and do not account for daily fluid maintenance or other fluid requirements. ATLS guidelines suggest the use of a crystalloid-based regimen, though many UK burns centres still use colloid resuscitation (often with albumin). Whether to use crystalloid or colloid has yet to be resolved, and advantages and disadvantages are well described for each.

Initially when they present in the Accident and Emergency Department, patients are seldom hypovolaemic, but significant fluid loss occurs within the first few hours after the burn. Septic shock often develops after several days.

Burn injury fluid resuscitation formulas

Parkland (crystalloid)
- 24-hour fluid replacement following injury
- (ml) Hartmann's solution = 4 x body weight (kg) x TBSA[1] (%)
  50% given over 8 hours
  50% given over next 16 hours

Muir and Barclay (colloid)
- 36-hour fluid requirement following injury
- (ml) 4.5% albumin = 0.5 x body weight (kg) x TSBA[1] (%)
  This volume to be administered over six time periods:
  three periods of 4 hours
  two periods of 6 hours
  one period of 12 hours

Renal support
Acute renal tubular necrosis is associated with extensive burn injuries and is often caused by pre-renal failure secondary to hypovolaemia. However, myoglobin and free haemoglobin may further contribute to acute renal failure. If myoglobinaemia is suspected, urinary alkalinization may preserve renal function, but is notoriously difficult to achieve. If required, renal support is best undertaken using continuous veno-venous haemofiltration or dialysis. The development of acute renal failure is a bad prognostic sign.

Surgical care and infection
Early surgical excision and grafting of partial- and full-thickness burns reduces muscle catabolism, encourages early healing, decreases the incidence of sepsis and reduces mortality. Complete surgical excision of these burns is limited by the extent of intra-operative blood loss, ability to maintain patient core temperature and availability of donor sites to provide tissue coverage. To provide temporary coverage, cadaveric or artificial skin substitutes are available to facilitate wound closure after extensive injuries. Compartment syndromes may develop (associated with circumferential burns) and should be sought and decompressed as required.

Infection and sepsis are common causes of mortality in burn injury. Silver sulphadiazine, which reduces Gram-negative bacterial infection, is incorporated in standard burn dressings. Systemic antibiotics are best given in response to accurate culture and sensitivity rather than prophylactically.

Gastrointestinal support
Nutrition should be commenced early in any burn exceeding 10% TBSA. This reduces infection, preserves body mass and protects against bacterial translocation. Enteral nutrition especially protects against stress ulceration. Parenteral nutrition should be avoided, unless the enteral route has failed. Individual nutritional requirements are extensive. As a guide, 1 g of nitrogen may be required per 100 kcal of energy provided. Owing to catabolism, up to 60 kcal/kg energy may be required daily and is best provided by part lipid and carbohydrate (to minimize carbon dioxide production).

Exogenous glucagon and insulin may encourage protein sparing, preserve immunological function and promote wound healing. However, long-chain and polyunsaturated triglycerides may preferentially encourage synthesis of proinflammatory mediators; hence medium-chain triglycerides may have more value. Certain non-essential amino acids can become supply-dependent and leucine, isoleucine, valine, arginine and glutamine may require supplementation.

Electrical injury
Electrocution injuries often occur in the workplace and in the USA result in 1000 deaths per year. Electrocution is often associated with injury to the head, spinal cord or chest. The victim becomes part of the electrical circuit, with current flowing through the path of least resistance (muscle or vasculature). Current flows of 10 mA generate local muscle spasm; higher currents cause generalized spasm, which may throw the patient some distance. At flows in excess of 30 mA, cardiac arrhythmia may occur. The current path is unpredictable and small wounds often conceal extensive and remote damage.

These injuries are always underestimated and invasive monitoring should be instituted early. Immediate surgical debridement is required and often locates further tissue injury. Muscle necrosis often causes rhabdomyolysis requiring renal support.

Anaesthesia for the burned patient
After the initial resuscitation period, patients with burns have to return to theatre daily for dressing changes or further grafting. Many will have been discharged from the ICU and will be nursed on conventional wards.

Suxamethonium causes acute hyperkalaemia, owing to extra-junctional migration of acetylcholine receptors following a burn injury. It is safe within the first few hours of injury, but, subsequently, should not be used for the following 12 months. Burned patients also develop resistance to non-depolarizing relaxants, which persists for up to 10 weeks. Ketamine is often used for induction in the early phase of burns management, but is best avoided once the patient is more stable because it causes emergence phenomena. Propofol is a good alternative.

Requirements for sedation and opioid analgesia may be vast owing to tolerance and they should be given intravenously to avoid unpredictable absorption. Once the patient is awake, patient-controlled analgesia (PCA) devices work well, provided hand injuries are not extensive. Oral analgesia can be added, when feeding is established, but care should be taken with non-steroidal anti-inflammatory drugs because of the increased risk of gastric ulceration.

Burns patients have high calorific requirements and repeated trips to theatre interfere with their ability to meet daily nutrition targets. It has been suggested that preoperative fasting times may be reduced to 1 hour without increased risk of aspiration. Intubated patients do not need to have feeding discontinued before and during surgery.

Fluid balance should be corrected preoperatively, because blood and evaporative water loss during burn debridement is extensive. Reliable intravenous access, availability of blood products and fluid-warming devices are essential. ◆

Chest Injuries

Peter Ford
Jerry P Nolan

Peter Ford is Specialist Registrar in Anaesthesia at the Bristol Royal Infirmary, Bristol, UK. He qualified from St Bartholomew's Medical School, London. He trained in intensive care medicine in Australia. His interests include intensive care medicine and trauma management.

Jerry P Nolan is Consultant Anaesthetist and Lead Clinician in Intensive Care at the Royal United Hospital, Bath, UK. He qualified from Bristol University and trained in anaesthesia and intensive care in Bristol, Bath, Plymouth, Southampton and Baltimore. He is Co-chairman of the Advanced Life Support Working Group of the European Resuscitation Council.

In the UK, chest injuries are mainly caused by blunt trauma. One in four trauma deaths is attributed to chest trauma; 10% of patients with chest injuries die at the scene, mainly from damage to the great vessels or heart, and 5% die within 1 hour of reaching hospital from airway obstruction or cardiac tamponade. Of the remainder, only 15% require surgical intervention.

Primary survey
The primary survey includes the application of high concen-tration oxygen, maintenance of the airway, stabilization of the cervical spine and identification and treatment of immediately life-threatening injuries.

Tension pneumothorax: reduced chest movement, reduced breath sounds, and a resonant percussion note on the affected side, along with respiratory distress, hypotension and tachy-cardia, indicate a tension pneumothorax. Deviation of the trachea to the opposite side is a late sign, and neck veins may not be distended if the patient is hypovolaemic. Treatment involves immediate large-bore needle thoracocentesis in the second intercostal space, in the mid-clavicular line on the affected side. Once intravenous access has been obtained, a large chest drain (36 F) should be inserted in the fifth intercostal space in the anterior axillary line, and connected to an underwater seal drain (Figure 1).

Indications for chest drain insertion

- Simple or tension pneumothorax (following immediate decompression)
- Open pneumothorax
- Haemothorax
- Severe lung injury together with the need to transfer by ground or air
- Suspected significant lung injury (multiple rib fractures or expanding surgical emphysema) in patients requiring general anaesthesia and/or positive-pressure ventilation

1

Open pneumothorax should be sealed on three sides with an occlusive dressing; tube thoracocentesis should follow.

Massive haemothorax is present when there is more than 1500 ml of blood in a hemithorax; it results in reduced chest movement, a dull percussion note, hypoxaemia and hypo-volaemia. Tube thoracocentesis should be undertaken once volume resuscitation has begun.

Cardiac tamponade: neck vein distension in the presence of hypotension may indicate cardiac tamponade, though these signs may also occur in patients with myocardial contusion or tension pneumothorax. If tamponade is suspected, and the patient is deteriorating despite treatment, pericardiocentesis should be performed. In the presence of a suitably experienced surgeon, open pericardiotomy is more effective.

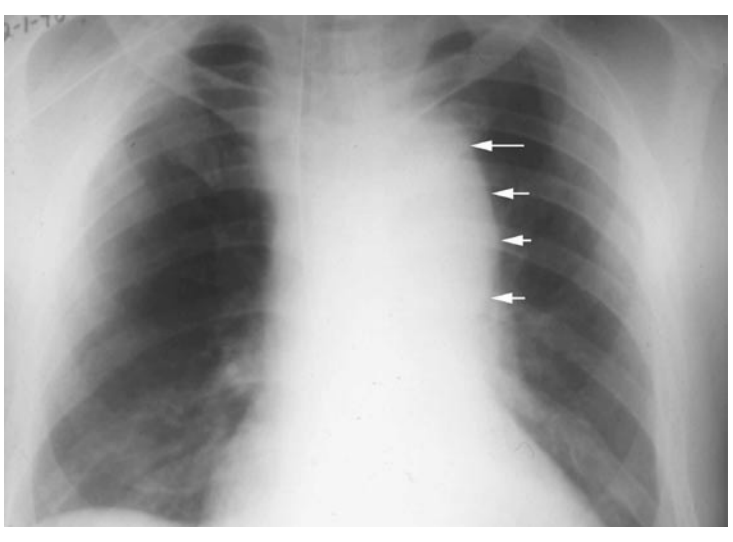
Flail chest: multiple fractures in adjacent ribs cause a segment of the chest wall to lose bony continuity with the thoracic cage. Although this flail segment moves paradoxically with inspiration, the life-threatening consequence is underlying lung contusion, which can cause severe hypoxaemia. Assisted ventilation, via a tracheal tube or by a non-invasive technique, is required if hypoxaemia persists despite supplemental oxygen and adequate analgesia.

Secondary survey
The following potentially life-threatening injuries may be identified during the secondary survey.

Pulmonary contusion: inspection of the chest may reveal signs of a deceleration injury, (e.g. seat-belt bruising). Pulmonary contusion is the most common, potentially lethal, chest injury – young adults and children have compliant ribs and considerable energy can be transmitted to the lungs without fracturing them. The earliest indication of pulmonary contusion is hypoxaemia (reduced PaO_2:FiO_2 ratio). The radiograph may be normal initially, but eventually shows patchy infiltrates over the affected area. Patients may require a high FiO_2 and mask continuous positive airway pressure (CPAP), or tracheal intubation and intermittent positive-pressure ventilation (IPPV). During IPPV, the use of small tidal volumes (5–7 ml/kg), a low peak inspiratory pressure (< 35 cm H_2O) and low FiO_2 ($\leq$ 0.5) are advised. The patient requires adequate fluid resuscitation, but fluid overload compounds the lung contusion.

Cardiac contusion should be suspected in any patient with severe, blunt chest trauma, particularly if there is a sternal fracture. Cardiac arrhythmias and ST changes on the ECG may be present but are non-specific. The right ventricle is most often injured, but it is not well evaluated by a 12-lead ECG. An elevated creatine kinase isoenzyme of cardiac muscle (CK-MB) is insensitive for diagnosing myocardial contusion; serum troponin I is better. Echocardiography confirms the diagnosis of cardiac contusion. Patients with severe cardiac contusion are likely to require inotropic support and tend to have other injuries that require ICU admission.

Blunt aortic injury: the thoracic aorta is at risk in any patient sustaining a significant decelerating force (e.g. fall from a height or high-speed crash). Only 10–15% of patients with blunt aortic injury reach hospital alive. The most common site for injury is just distal to the origin of the left subclavian artery. Intimal and medial tears may involve either part or the entire circumference of the aorta. In survivors, the haematoma is contained by an intact aortic adventitia and mediastinal pleura. Patients sustaining traumatic aortic rupture usually have multiple injuries and may be hypotensive at presentation. However, upper extremity hypertension is present in 40% because the haematoma compresses the true lumen. The chest radiograph shows a widened mediastinum in most cases (Figure 2). Although this is a sensitive sign of aortic rupture, it is non-specific – in 90% of cases it is caused by venous bleeding. Other radiological signs suggesting possible blunt aortic injury include pleural capping, a left-sided haemothorax, deviation of the trachea or nasogastric tube to the right and depression of the left main stem bronchus.



2 Chest radiograph showing widening of the aorta (arrows) in a patient with blunt aortic injury.

The definitive investigation is helical CT and/or arteriography. Once a rupture of the thoracic aorta is suspected, the systolic blood pressure should be maintained at 80–100 mm Hg using a β-blocker (e.g. esmolol, 0.5 mg/kg over 1 min then 50–200 μg/kg/min as an infusion; under anaesthesia these doses need to be reduced). Pure vasodilators (e.g. nitroprusside) increase the pulse pressure and shear forces on the aortic wall.

Rupture of the diaphragm occurs in 5% of patients sustaining severe blunt trauma; 75% occur on the left. The stomach or colon commonly herniates into the chest. Signs and symptoms include ipsilateral diminution in breath sounds, chest pain and respiratory distress. The chest radiograph may show an elevated hemidiaphragm, gas bubbles above the diaphragm, and a nasogastric tube in the chest. The diagnosis is confirmed by instilling contrast media through the nasogastric tube and repeating the radiograph.

Oesophageal rupture: a severe blow to the upper abdomen may result in a torn lower oesophagus as gastric contents are forcefully ejected. The conscious patient will complain of severe chest and abdominal pain. Mediastinal air may be visible on the chest radiograph and gastric contents may appear in the chest drain. The diagnosis is confirmed by contrast study of the oesophagus or endoscopy. Urgent surgery is essential because accompanying mediastinitis carries a high mortality.

Tracheobronchial injury: laryngeal fractures are uncommon. Signs of laryngeal injury include hoarseness, subcutaneous emphysema and crepitus. Transections of the trachea or bronchi proximal to the pleural reflection cause massive mediastinal and cervical emphysema. Injuries distal to the pleural sheath lead to pneumothoraces that do not resolve after chest drainage. Most bronchial injuries occur within 2.5 cm of the carina and the diagnosis is confirmed by bronchoscopy. Tracheobronchial injuries require urgent repair through a thoracotomy.

Rib fractures
Up to 10% of blunt trauma victims have rib fractures. Fractures of the lower ribs are associated with hepatosplenic injury. Multiple rib fractures in elderly patients and those with co-morbidity often cause death. The pain caused by fractured ribs impairs respiratory function. Adequate analgesia is essential. The options include:

- simple, regular, oral analgesia (paracetamol and non-steroidal anti-inflammatory drugs)
- intercostal analgesia (provides pain relief for up to 6 hours)
- intrapleural analgesia using bupivacaine infused through an epidural catheter inserted into the pleural space
- opiates (using intramuscular or intravenous patient-controlled analgesia; PCA)
- thoracic epidurals (provide better analgesia than PCA and may reduce pulmonary morbidity).

Anaesthesia
Anaesthesia for chest-injured patients may include use of a double lumen tube and one lung ventilation, bronchial blockers and extracorporeal support. Anaesthesia for a multiply injured patient with chest trauma follows that for any critically ill patient (e.g. adequate volume resuscitation, avoidance of hypothermia), but the following points should be noted.

- Myocardial contusion is common yet often unrecognized; during anaesthesia it may present with volume resistant hypotension and arrhythmias.
- Portable, supine chest radiographs miss small haemothoraces and anterior pneumothoraces.
- 10% of pulmonary contusions are not visible on the initial radiograph. They may develop insidiously with increasing oxygen requirements and may require advanced ventilatory modes.
- Up to 33% of occult pneumothoraces progress and about 15% will tension. A low threshold should be adopted for tube thoracocentesis before general anaesthesia in patients suspected of having a significant lung injury.
- Nitrous oxide should be avoided because it may double the volume of a pneumothorax in 10 minutes. ◆

Hormonal and Metabolic Responses to Trauma

Grainne Nicholson

Grainne Nicholson is Senior Lecturer and Honorary Consultant Anaesthetist at St George's Hospital Medical School, London, UK. She qualified from University College Galway, Ireland, and trained in Dublin and Sydney before moving to the UK. Her research interests include the stress response to surgery and perioperative management of vascular surgery patients.

The neuroendocrine and inflammatory aspects of trauma and surgery are part of the overall stress response and similar changes are found with haemorrhage, burns and severe exercise. Surgery serves as a useful model of the stress response because the changes that occur can be observed from a well-defined starting point. These result in substrate mobilization, muscle protein loss, and sodium and water retention. Such changes may have evolved to aid survival in a more primitive environment, when fluid retention together with glucose, lipid and protein mobilization would be beneficial to the organism. In modern surgical practice, such physiological disturbances may be easily prevented or rapidly corrected, therefore the benefits of the stress response are less obvious. It has been argued that attenuating the metabolic and endocrine changes associated with surgery may improve patient outcome, though no accepted definitions of outcome or recovery exist.

Initiation of the response

Management of the hormonal and metabolic changes following trauma demands an understanding of the causative factors and their interactions. The magnitude of the metabolic response is proportional to the severity of injury. Afferent neuronal input, both somatic and autonomic from the site of trauma, activates the hypothalamic–pituitary axis and the sympathetic nervous system. In addition to a marked increase in catabolic hormone secretion there is suppression of the anabolic hormones insulin and testosterone, and the normal negative feedback controls no longer prevail. Release of cytokines also plays an important role.

Hormonal aspects – increased pituitary hormone secretion results in secondary effects on hormonal output from target organs (Figure 1). A significant feature of the hormonal response to trauma is the failure of normal feedback mechanisms that control secretion. Cortisol release by the adrenal gland fails to inhibit further output of adrenocorticotrophin (ACTH) by the pituitary, and similarly hyperglycaemia fails to inhibit growth hormone secretion.

Summary of hormonal changes associated with metabolic response to trauma

	Secretion increased	Secretion increased/decreased	Secretion decreased
Pituitary	• Growth hormone • Adrenocorticotrophic hormone • β-endorphin • Prolactin • Arginine vasopressin	• Thyroid-stimulating hormone • Luteinizing hormone • Follicle-stimulating hormone	
Adrenal	• Catecholamines • Cortisol • Aldosterone		
Pancreas	• Glucagon		• Insulin
Other organs	• Renin		• Testosterone • Oestrogen • Triiodothyronine

1

Cortisol has both glucocorticoid and mineralocorticoid effects. It increases blood glucose concentrations by stimulating protein catabolism and promoting glucose production in the liver by gluconeogenesis. It reduces peripheral glucose utilization by an anti-insulin effect. Cortisol promotes lipolysis, which increases the production of gluconeogenic precursors from the breakdown of triglyceride into glycerol and fatty acids. It also has well-recognized anti-inflammatory effects mediated by inhibition of the accumulation of macrophages and neutrophils into areas of inflammation, a decrease in production of inflammatory mediators (e.g. leukotrienes, prostaglandins) and inhibition of cytokine synthesis.

Growth hormone has diabetogenic and protein anabolic effects. It promotes lipolysis and has an anti-insulin effect. It is unlikely that the values achieved following trauma have significant effects on glucose metabolism; however, interest has focused recently on its potential for preventing muscle protein breakdown and promoting tissue repair. The anabolic effects of growth hormone are mediated via polypeptides synthesized in the liver. These are termed somatomedins or insulin-like growth factors (IGFs). The main protein is somatomedin C or IGF-1 and attempts have been made to use human recombinant growth hormone and/or IGF-1 to reduce muscle catabolism and improve wound healing in severely catabolic patients. At present, experience is limited.

Arginine vasopressin is released by the posterior pituitary. In addition to its antidiuretic role, it also has important vasopressor and haemostatic effects. It also promotes the release of ACTH via secretion of C reactive protein from the hypothalamus.

Insulin is the key anabolic hormone. It is usually secreted in response to hyperglycaemia and promotes glucose uptake and storage as glycogen, inhibits lipolysis and decreases muscle protein loss. There is a failure of insulin secretion in response to the hyperglycaemia associated with trauma. Absolute values of insulin may vary but are inevitably low relative to the blood glucose value. The reduction in insulin secretion is due, primarily, to α-adrenergic inhibition of insulin secretion. Significantly lower insulin values are found in patients receiving β-blockade therapy during surgery. Failure of the usual cellular response to insulin, the so-called 'insulin resistance' following trauma may also contribute to hyperglycaemia. This resistance results from a defect of the insulin receptor, but the exact mechanism has yet to be elucidated.

Catecholamines – hypothalamic activation of the sympathetic nervous system results in increased secretion of catecholamines from the adrenal medulla and release of noradrenaline (norepinephrine) from presynaptic nerve terminals. The increased sympathetic activity results in tachycardia and hypertension. Renin is released from the kidney in response to sympathetic stimulation and promotes conversion of angiotensin I to angiotensin II. Angiotensin II stimulates secretion of aldosterone from the adrenal cortex resulting in sodium resorption from the distal convoluted tubule of the kidney. Sympathetic stimulation of the pancreas results in an increase in glucagon secretion and inhibition of insulin secretion. Other metabolic effects of catecholamines include breakdown of glycogen in liver and muscle resulting in increased plasma concentrations of glucose and lactate, as well as mobilization of free fatty acids from lipid stores.

Cytokines are a heterogeneous group of low molecular weight glycoproteins. They are released locally in response to tissue injury and act locally and systemically via specific receptors. The term cytokine includes the interleukins (IL-1–17), the interferons and tumour necrosis factor. They are synthesized mainly by cells of the macrophage/monocyte series, but are also produced by other cell types such as fibroblasts, endothelial cells and glial cells. Cytokines have a major role in the inflammatory response to surgery and trauma. They mediate and maintain the inflammatory response to tissue injury and initiate some systemic changes.

IL-6 is the main cytokine released after routine surgery. Changes occur 2–4 hours after the start of surgery, with peak values occurring after 6–12 hours. Laparoscopic techniques lead to smaller increases than those following conventional, open surgery. IL-6 is a prime inducer of acute phase protein synthesis in the liver. These proteins include C reactive protein, fibrinogen, proteins of the complement system, serum amyloid A, α_1-antitrypsin and ceruloplasmin. They limit tissue damage and promote haemostasis, repair and regeneration. Their synthesis usually occurs at the expense of decreased production of other proteins (e.g. albumin, transferrin). Concentrations of circulating cations (e.g. zinc, iron) decrease, partly as a result of changes in the production of transport proteins.

Acute phase response

The acute phase response is characterized by changes in metabolic, immunological and haematological functions. It comprises a complex series of reactions:

- acute phase protein synthesis in the liver
- hepatic sequestration of iron and zinc
- pyrexia
- neutrophil leucocytosis
- increased muscle proteolysis
- changes in vascular permeability
- activation of the hypothalamic–pituitary axis (*in vitro*)
- lymphocyte differentiation.

The acute phase response prevents further tissue damage, isolates and destroys infective organisms, activates the repair processes necessary to return the organism to normal function and is considered an integral part of wound healing and repair.

The immune system and the neuroendocrine system are interconnected because cytokines IL-1 and IL-6 stimulate secretion from isolated pituitary cells *in vitro*. In surgical patients, cytokines may augment pituitary ACTH secretion and subsequently increase the release of cortisol. Glucocorticoids inhibit cytokine production in a negative feedback system. It has been suggested that the cytokines are responsible for the hypercortisolaemia that persists in burns patients.
Metabolic consequences of substrate mobilization

Carbohydrate metabolism hyperglycaemia is a prominent feature of the metabolic changes after trauma and the increase in blood glucose is approximately proportional to the severity of injury. Glucose production in the liver, by glycogenolysis and gluconeogenesis, is increased and glucose utilization is impaired. Major surgery can result in a marked elevation of blood glucose. Further iatrogenic increases may be caused by administration of glucose infusions or as blood or blood products. Deleterious effects of sustained hyperglycaemia (blood glucose > 12 mmol/litre) include increased risk of infection and impaired wound healing, water and electrolyte loss, as well as exacerbation of ischaemic damage to the nervous system and myocardium.

Protein metabolism – a major effect of trauma is an increase in muscle protein loss. Following major abdominal surgery, losses of up to 0.5 kg/day lean body mass can occur. The amino acids released by proteolysis, especially glutamine and alanine, are used for gluconeogenesis and for synthesis of acute phase proteins by the liver. Concomitantly, albumin synthesis is decreased. More recently the cytokines, particularly IL-1 and IL-6, have been implicated in promoting muscle breakdown and stimulating acute phase protein synthesis.

Lipid metabolism after trauma has received little attention compared with glucose. In general, there are few changes in lipid mobilization unless starvation becomes a major factor postoperatively. Lipolysis of triglycerides to free fatty acids is promoted by adrenaline and glucagon, potentiated by cortisol and inhibited by insulin. The oxidation of free fatty acids to acetyl CoA is promoted by high glucagon concentrations and low insulin concentrations. Acetyl CoA is converted in the liver, via acetoacetyl CoA, to the ketone bodies acetoacetate, β-hydroxybutyrate and acetone. These can be utilized as energy sources by tissues other than the liver. Dramatic increases in free fatty acid concentrations are seen during cardiac surgery because heparinization activates lipoprotein lipase, but less so with the newer 'cleaner' heparins.

Management of endocrine and metabolic responses

Preoperative factors that can affect the metabolic response include personality and preoperative mental status, anxiety and fear, dehydration and partial starvation. During surgery, haemorrhage and hypothermia may alter the metabolic response while postoperative immobilization, infection, hypoxia and alterations in normal diurnal rhythms may cause metabolic changes.

It is common to view the stress response as an inevitable consequence of trauma, but many approaches to decreasing the metabolic sequelae have been tried. It is important to prevent the sympathetically-mediated cardiovascular responses of tachycardia and hypertension to surgical stress or trauma, particularly in patients with ischaemic heart disease. Modern anaesthetic practice strives to maintain physiological homeo-stasis by using techniques that prevent, or obtund, the stress response to surgery but no single anaesthetic or surgical technique is wholly successful in achieving this aim. Effective pain control and nutrition have not significantly improved postoperative recovery. Reducing postoperative catabolism may improve perioperative morbidity and hasten recovery.

Anaesthesia – many investigators have studied the effects of anaesthesia and different anaesthetic techniques on the neuroendocrine response to surgery. The intravenous induction agent etomidate is a potent inhibitor of adrenal steroidogenesis. It is no longer licensed for long-term sedation because it causes increased mortality in critically ill patients.

Analgesics – morphine inhibits the hypothalamic–pituitary–adrenal axis. Intravenous fentanyl, > 50 μg/kg, can abolish the hormonal response to pelvic surgery and higher doses (> 100 μg/kg) prevent catabolic hormone secretion to upper abdominal surgery. However, the consequence is profound and prolonged respiratory depression, which precludes its use in routine surgery. High-dose fentanyl is widely used in cardiac surgery where patients routinely need postoperative ventilatory support.

Regional anaesthesia provides excellent pain relief and prevents the response to surgery in pelvic and lower limb surgery by preventing afferent neuronal input. However, cytokine-mediated responses, which occur as a consequence of tissue trauma, are not altered. For upper abdominal and thoracic procedures, regional anaesthesia has less effect on the neuroendocrine response. Although regional anaesthesia has well-documented beneficial effects on thromboembolic complications, pulmonary function, cardiac and gastrointestinal function, it has not been proved to reduce postoperative morbidity and length of stay in hospital.

Laparoscopic surgery – obtunding the inflammatory response, rather than the neuroendocrine response, may improve recovery after major surgery or trauma. Laparoscopic surgery causes less tissue injury than conventional open procedures and thus the increase in inflammatory mediators (e.g. IL-6, C reactive protein) is less. For many intra-abdominal and intra-thoracic procedures, there is improved outcome and enhanced recovery compared with laparotomy and open thoracotomy. In general, laparoscopic techniques reduce perioperative immunosuppression and infection risks, and lead to an earlier hospital discharge.

Parenteral nutrition does not reduce muscle protein loss, except in severely malnourished patients. Enteral feeding is beneficial because it maintains the integrity of the gastrointestinal mucosa and reduces the incidence of bacterial translocation and septic complications. Recent attention has focused on the addition of arginine, glutamine, nucleotides and omega-3 fatty acids to enteral feeds because they appear to act as immunomodulators.

Glutamine, an amino acid used by lymphocytes and rapidly dividing cells of the gut mucosa, acts as a precursor for renal production of ammonia. Plasma glutamine values decline rapidly following surgery or injury. Glutamine supplementation of parenteral nutritional regimens improves nitrogen balance, but an overall improvement in outcome has not been demonstrated. Arginine stimulates the secretion of several hormones, including insulin and growth hormone. It may also be involved in the local regulation of tissue blood flow because it is a precursor of nitric oxide. The omega-3 fatty acids were thought to enhance immune defences through increased production of prostaglandin E3, but they also have effects on the release of thromboxane A_2 and prostacyclin and inhibit a variety of cellular and humoral immunological mechanisms. The administration of RNA or synthetic polynucleotides may enhance cell-mediated immunity and T lymphocyte function but convincing evidence is lacking.

Research into recovery after surgery is important for information, planning and economic reasons. A clear definition of recovery must be found together with an effective method of measuring this variable. ◆

Hypovolaemic Shock

Phil Moss
Gary B Smith

Phil Moss is Consultant in Accident and Emergency Medicine at Newham General Hospital, London. After qualifying from St George's Medical School, he undertook training in Birmingham and London. Before taking up his consultant post, he flew as a flight registrar with the London Helicopter Emergency Medical Service and worked as Clinical Fellow in Intensive Care Medicine at Portsmouth Hospitals NHS Trust. His main interests are the interface between A&E and critical care and pre-hospital trauma care.

Gary B Smith is Consultant in Intensive Care Medicine at Portsmouth Hospitals NHS Trust and Honorary Senior Lecturer in Critical Care in the School of Postgraduate Medicine at the University of Portsmouth. After qualifying from the University of Southampton, he trained in anaesthesia and medicine in the South of England and at Yale University, USA. His main interests are multiprofessional education, cardiopulmonary resuscitation and pre-hospital trauma care.

Hypovolaemic shock is present when a reduced circulating volume causes tissue perfusion to be inadequate for its metabolic requirements. True hypovolaemia is caused by loss of blood, plasma, intracellular fluid or extracellular fluid (Figure 1). Relative hypovolaemia may occur if there is pooling of a normal blood volume; this occurs in sepsis, after spinal anaesthesia or due to the effect of venodilating drugs (Figure 1). Fluid loss as a result of internal haemorrhage or redistribution of the circulating volume may not always be apparent. However, identification of the cause of hypovolaemia is fundamental to its reversal. The remainder of this article considers hypovolaemic shock caused by acute haemorrhage.

Causes of hypovolaemia

	Common causes
True hypovolaemia	
Blood loss	Surgery Trauma Leaking abdominal aortic aneurysm Haematemesis Massive haemoptysis
Plasma loss	Burns Toxic epidermal necrolysis
Loss of extracellular or intracellular fluid	Vomiting Diarrhoea Pyrexia Diabetic ketoacidosis Haemodialysis or haemofiltration Diuretics Sepsis Anaphylaxis
Relative hypovolaemia	Anaphylaxis Drugs (e.g. nitrates, loop diuretics) Spinal or epidural anaesthesia Sepsis

1

Physiological response to acute blood loss
The physiological response to acute blood loss involves several processes described in *Anaesthesia and Intensive Care Medicine* **2:1**: 17; **2.4**: 149; **2.4**: 155. Compensatory mechanisms produce the following effects that attempt to increase cardiac output.

Increased heart rate and cardiac contractility involves baroreceptor reflex, adrenal secretion of catecholamines and stimulation of the peripheral chemoreceptors.

Sodium and water retention involves reduced glomerular filtration, alterations in Starling's forces in capillaries, increased sodium reabsorption from distal convoluted tubules (aldosterone) and reduced water loss from distal convoluted tubules and collecting ducts.

Vasoconstriction involves baroreceptor reflex, adrenal secretion of catecholamines, stimulation of the peripheral chemoreceptors, renin-angiotensin system and circulating catecholamines.

Increased circulatory volume – splenic contraction injects 'stored' blood into the circulation.

Prevention of further blood loss is mediated by the coagul-ation cascade and platelets.

Signs and symptoms
The signs and symptoms of haemorrhagic shock are attributable to the underlying physiological responses described above. They include:

- skin pallor
- peripheral cyanosis
- cool digits, nose and ears
- prolonged capillary refill time
- tachycardia or a rising pulse rate
- absent peripheral pulses
- systolic hypotension or a falling systolic blood pressure
- low jugular venous pressure or central venous pressure
- reduced pulse pressure
- thirst
- irritability, confusion, low Glasgow Coma Score (GCS) and coma
- oliguria
- coronary ischaemia
- tachypnoea
- diaphoresis
- mydriasis.

Often, the only early sign of haemorrhage is a rising pulse rate, because compensatory vasoconstriction can maintain blood pressure. However, elderly patients have little physiological reserve and are prone to rapid, cardiovascular decompensation. Children often maintain normal blood pressure despite severe volume depletion, until they suffer a sudden, life-threatening circulatory collapse. Athletes have low heart rates; a pulse of 80 beats/minute may indicate significant shock. β-adrenergic receptor antagonist therapy, the presence of a fixed rate pacemaker, high spinal injury and spinal or epidural local anaesthesia may limit or prevent a compensatory tachycardia during haemorrhage.

Classification of haemorrhagic shock
The classification of haemorrhagic shock (Figure 2) emphasizes that the response to continuing blood loss is a dynamic process.

Classification of hypovolaemic shock

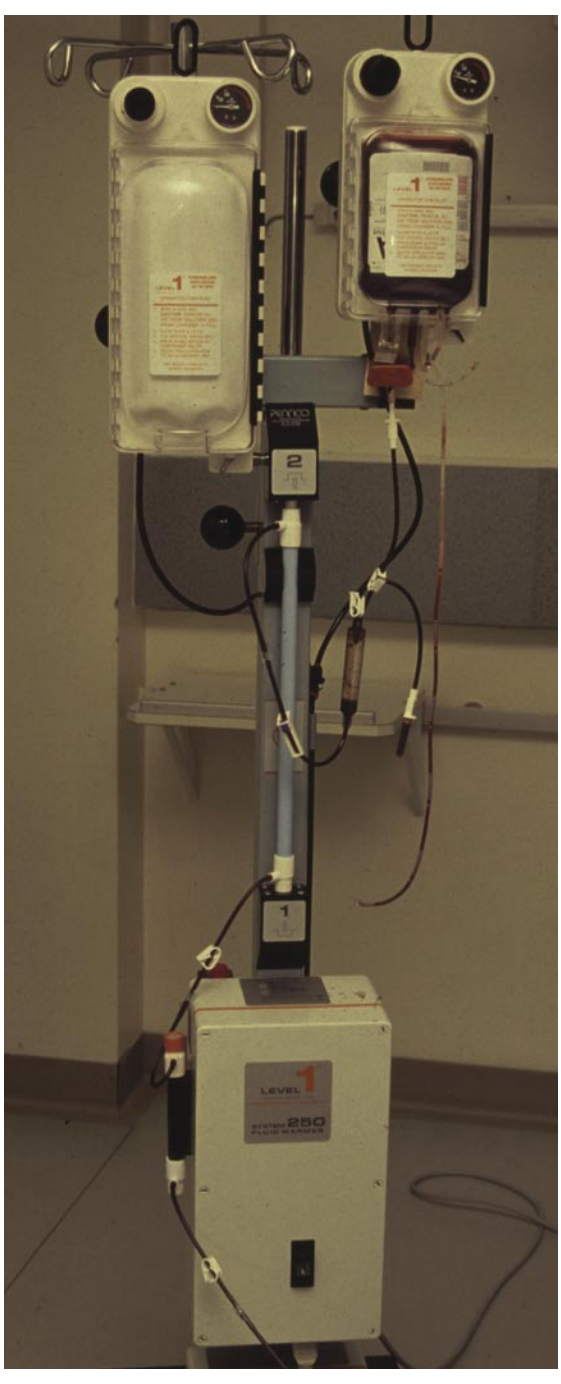
	Class I	Class II	Class III	Class IV
Blood loss (ml)	Up to 750	750–1500	1500–2000	> 2000
Blood loss (%)	Up to 15%	15–30%	30–40%	> 40%
Pulse rate	< 100	> 100	> 120	> 140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate	14–20	20–30	30–40	> 35
Capillary refill	≤ 2 s	> 2 s	> 2 s	> 2 s
Urine output (ml/hour)	> 30	20–30	5–15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused and lethargic
Fluid replacement	Crystalloid	Crystalloid: colloid 2:1	Crystalloid/ colloid + blood	Crystalloid/ colloid + blood

2

Treatment
It is essential to ensure airway patency and the adequacy of respiration, before attending to control of haemorrhage. All bleeding patients should receive 100% oxygen.

The goal of treatment is to improve cardiac output and tissue perfusion by increasing cardiac preload. Consequently, the main aim is replenishment of the circulating volume; vasopressors should not be used. Peripheral haemorrhage can often be controlled by simple elevation of the limb and local pressure; pneumatic antishock garments may be required to control haemorrhage from the lower limbs, pelvis and abdomen. In general, limb tourniquets are not advised. Severe haemorrhage requires the rapid infusion of fluid via large bore cannulas placed in large veins. In practice, the easiest sites for venous access include the antecubital, femoral and saphenous veins and for central access the internal jugular or subclavian veins. For central access, a cannula with a single, large lumen should be used, because flow is related to the fourth power of the radius of the cannula. Venous access may be difficult in hypovolaemic children; the interosseous route is potentially the quickest and easiest alternative. Occasionally, surgical cut-down onto the long saphenous vein is necessary in adults and children.

Although blood replacement is required in many cases, the choice of initial fluid is usually immaterial. Suitable fluids include isotonic electrolyte solutions (e.g. Hartmann's, normal saline) or colloid solutions (e.g. gelofusine). Each ml of blood loss requires replacement with 3 ml of crystalloid because it distributes in the interstitial and extracellular spaces. Colloids are probably better retained within the circulation. An initial rapid infusion (i.e. over 15 minutes) of 1000–2000 ml fluid in an adult, or 20 ml/kg in a child, is appropriate for most circumstances, but the infused volume should be tailored to the clinical circumstances and the observed response. All infusion fluids should be warmed before infusion (Figure 3).



3 Devices such as the Level 1 warmer (SIMS) permit the rapid infusion of large volumes of warmed infusion fluid or blood.

If blood has been lost, the ideal replacement fluid is blood. However, correct cross-matching takes time and, in critical situations, uncross-matched O negative blood may be given. In elective surgery, previously donated and stored autologous blood may be used; alternatively, blood lost during surgery can be recovered and, after processing, re-infused as part of 'blood salvage'.

If large volumes of blood are used (e.g. 5 units within 1 hour) the potential effects of massive transfusion should be considered, including:

- impaired oxygen delivery
- impaired coagulation
- hypothermia
- hypocalcaemia
- hyperkalaemaia
- metabolic acidosis
- fluid overload
- adult respiratory distress syndrome.

During volume resuscitation, the underlying cause of shock should be sought and reversed. Occasionally, this is achieved only by surgical intervention (e.g. laparotomy).

Monitoring and end-points of successful resuscitation

Regular evaluation of physiological parameters and the effects of interventions, using simple measures (e.g. capillary refill time, pulse rate, blood pressure, GCS, urine output, central venous pressure) is essential. However, the end-points of successful resuscitation are not always easy to determine. Return of cardiovascular parameters, such as heart rate and blood pressure, to normal probably gives the best indication of adequate fluid replacement. However, these may be influenced by other factors, for example pain, and normovolaemia may exist despite a high heart rate. Other factors such as end organ perfusion are useful indicators. For instance, a urine output greater than 0.5 ml/kg suggests normal renal perfusion and a normal GCS indicates normal cerebral perfusion. If the cardiovascular system is monitored using a central venous pressure catheter, normal values may be obtained despite inadequate fluid replacement. This may be due to myocardial depression (e.g. ischaemia or cardiac tamponade), raised intrathoracic pressure (e.g. tension pneumothorax, haemothorax) or a high venous tone. Monitoring acid–base status may also give a guide to the adequacy of the circulation, because a persistent acidosis may reflect inadequate replacement or continuing haemorrhage. ◆

Major Incident Management Outside Hospital

Paul Diprose
Charles D Deakin

Paul Diprose is Fellow in Cardiac Anaesthesia at the Wessex Cardiac Centre. He graduated from Southampton University Medical School. He initially pursued a career in accident and emergency medicine before changing to anaesthesia. He has an active interest in resuscitation.

Charles D Deakin is Eponymous Professor of the Royal College of Anaesthetists. He qualified from Cambridge University and King's College Hospital, London, and trained in London and Southampton. His interests include cardiac anaesthesia, pre-hospital care and resuscitation.

An incident is classified as major when the number of casualties or the severity of their injuries requires that special arrangements be made inside and outside hospital. Major incidents can be subdivided into:

- compensated incidents, which can be managed simply by mobilizing extra resources
- uncompensated incidents in which the number of casualties exceeds the maximum that can be treated.

In compound (rather than simple) major incidents the infrastructure (e.g. communications, roads, healthcare systems) is affected as part of the event. Most major incidents are simple, compensated and man-made (e.g. a train or aeroplane crash).

The effective management of a major incident scene involves the close coordination of all the emergency services (police, fire, ambulance), the voluntary services (e.g. Red Cross and St John's Ambulance), medical teams from local hospitals and doctors from the British Association for Immediate Care (BASICS). One of the biggest problems, and a challenge for all those managing a major incident, is effective communication between these groups at the scene and the receiving hospitals and other support services.

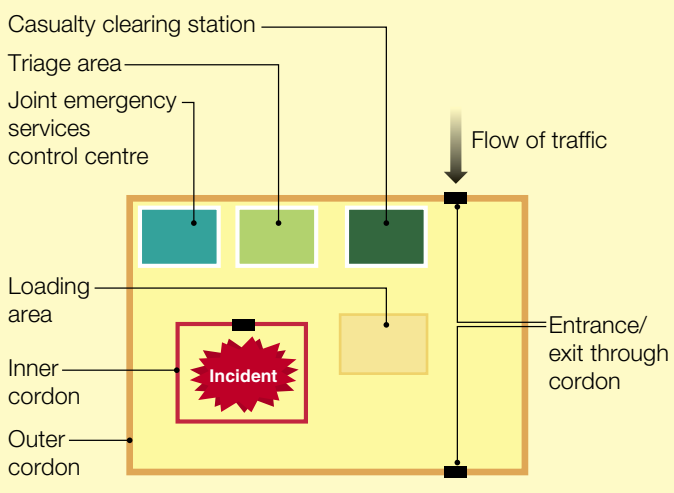
Advance preparation for major incidents, comprising theoretical and practical exercises, and carefully agreed plans and operating protocols, is vital. Specially designed courses (e.g. the Major Incident Medical Management and Support (MIMMS)) can give excellent additional training.

This article concentrates on the aspects of major incident management of particular importance to those providing a medical response out of hospital.

Command and control structure

At the scene of a major incident, areas are cordoned off and controlled by the police. The inner cordon encompasses the heart of the incident and includes areas that remain hazardous. The outer cordon encloses all other areas involved in the incident management (Figure 1).

Command and control layout of a typical major incident



1

All emergency services adopt a gold/silver/bronze hierarchy of command. Gold control is usually located at the headquarters of the emergency service. Silver control is located at the joint emergency services control centre inside the outer cordon. Bronze control usually comprises specific individuals directly controlling rescue activity.

Each emergency service has its own role in a major incident. The police remain in overall control, unless the incident involves fire, chemicals or nuclear material when the fire service is in command. The responsibility of the ambulance service and on-site medical teams is to assess patients, perform any early treatment required and then to facilitate transfer to receiving hospitals.

Communication within and between emergency services at the scene is vital for an effective coordinated response. It is equally important that good communication lines are established with gold control, receiving hospitals and other supporting services.

Safety

It is important that the rescuers do not become victims. Personal safety involves the use of good quality, protective, high visibility clothing and previous appropriate training in major incident management. The presence of any potential hazards at the scene should be considered in consultation with the fire service; special precautions (e.g. for chemical spillage or nuclear leakage) may be required. The safety of casualties should also be maintained.

The Medical Incident Officer (MIO)

The duties of the MIO include:

- obtaining information on the potential hazards present
- determining the number of casualties and the severity of their injuries (via the forward medical incident officer/triage doctor)
- liaison with the ambulance incident officer
- liaison with receiving hospitals.

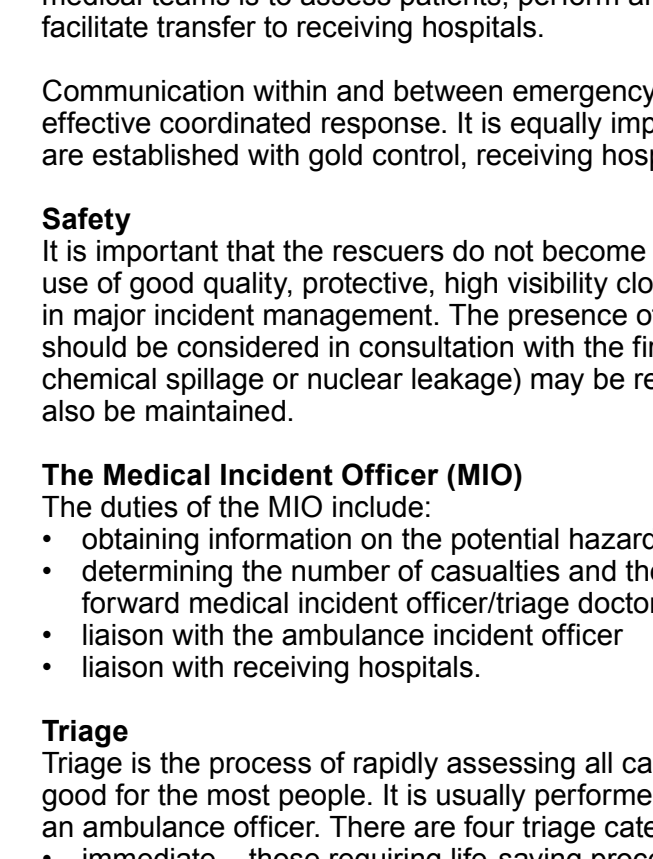
Triage

Triage is the process of rapidly assessing all casualties with the aim of doing the most good for the most people. It is usually performed by the triage doctor in conjunction with an ambulance officer. There are four triage categories:

- immediate – those requiring life-saving procedures (e.g. intubation, limb amputation)
- urgent – those who will require some form of early intervention within a few hours of the incident
- delayed – those who can wait for treatment
- dead/expectant (likely to die regardless of intervention).

These categories are often colour coded to aid identification with cards such as that in Figure 2.

The initial triage (triage sieve) is followed by a 'triage sort' at the casualty clearing station. A triage sieve may simply assess whether the patient can walk (delayed priority), whether they are not ambulant but have a normal respiratory rate and capillary refill (urgent priority), or abnormal respirations or capillary refill, in which case they become immediate priority. The triage revised trauma score (TRTS) can been used to perform a triage sort, by assigning a variable from 0–4 for values of respiratory rate, Glasgow Coma Score (see *Anaesthesia and Intensive Care Medicine* **3:4:** 132) and systolic blood pressure. The total TRTS can then be used to assign treatment priority, but should also be used in conjunction with the available information on anatomical injury.



2 Cruciate triage label. The label can be folded to display the triage category.

Treatment

The MIO should not be directly involved in the treatment of casualties; these duties should be delegated to the ambulance service and medical teams. Generally, procedures should be performed in the casualty clearing station, away from the hazards of the incident. However, occasionally medical teams have to provide treatment in the inner cordon of the incident site (e.g. trapped casualties). This should be done only after permission from the service in charge of site safety.

Treatment at the scene should largely be confined to securing the airway (with adequate spinal stabilization), ensuring adequate breathing and oxygenation, controlling major external haemorrhage and initiating circulatory support. Excessive treatment at the scene delays definitive care and risks hypothermia.

Anaesthesia may be required to allow the performance of amputations, extrications or for securing the airway in the major trauma patient. The exact conduct of anaesthesia in these circumstances is not as important as the general principles of maintaining adequate oxygenation and perfusion of the patient at all times. It should always be remembered that although anaesthesia may have an important role in the management of casualties with major trauma, the prerequisites of triage often preclude its use in a major incident.

Transport

The safe mobilization of casualties away from the incident scene to appropriate hospitals is the responsibility of the ambulance incident officer in consultation with the MIO. Decisions on the type of transport to be used depend on local circumstances, including the availability and capacity of the different modalities, as well as individual suitability. Usually, casualties are transferred in order of their triage category with the most seriously injured going first, but there may be circumstances in which this is not the most efficient way of using resources.

In some incidents there are large numbers of dead casualties. A temporary mortuary is usually set up close to the incident site, away from areas that are accessible to the media and public. Bodies are usually transferred there after the pronouncement of death (usually by a designated member of the medical team) and as soon as any relevant forensic evidence has been gathered.

Aftermath

Involvement in the management of a major incident can be emotionally traumatic. De-briefing of staff is essential to assist them in coming to terms with what they have witnessed and also allows the system and individuals to learn from the experience. The MIO is required (with the other service team leaders) to provide a formal report of the incident; careful and accurate documentation during the incident is therefore essential. ◆

Managing the Airway in Trauma Patients

Ruth Spencer
David A Gabbott

Ruth Spencer is Specialist Registrar at Gloucester Royal NHS Trust, Gloucester, UK. She qualified from Bristol University and initially worked in general medicine as an SHO and then Registrar. She is now on the Bristol SpR anaesthetic rotation.

David A Gabbott is Consultant Anaesthetist at the Gloucestershire Hospitals NHS Trust, Gloucester, UK. He qualified from Oxford University and trained in anaesthesia in Bristol, Exeter and Gloucester. He spent a year working in the Shock/Trauma Centre in Baltimore, USA. His interests include difficult airway management and resuscitation. He chairs the Resuscitation Committee at Gloucester, is a member of the Executive Committee of the Resuscitation Council and is Chairman of the Advanced Life Support Committee of the Resuscitation Council.

Emergency airway management in trauma victims is a challen-ging situation, with limited time for preparation. Some patients with blunt or penetrating injuries to the head and neck have obvious, extensive disruption of normal anatomy. Others may have an apparently normal airway, which can prove unexpectedly difficult. Therefore, it is essential to plan the initial approach to securing the airway and develop a fail-safe back-up strategy.

Airway obstruction may occur because of oedema, blood, debris or foreign bodies (e.g. teeth). A flail maxilla or mandible may also cause obstruction if there is posterior displacement of a mobile fracture. Such patients may adopt positions (e.g. lateral or prone) in which they can best maintain their own airway, but these may make orotracheal intubation difficult. If the patient is agitated, because of hypoxaemia, pain, cerebral injury or drugs, the use of techniques that require patient cooperation can be challenging. Trauma patients almost inevitably have a full stomach, risking pulmonary aspiration; many also have a suspected cervical spine injury that requires immobilization with a collar and lateral supports. These make laryngoscopy difficult. Normal manoeuvres to open the airway (e.g. chin lift, head tilt or oral airway insertion) may be contraindicated, cause further trauma or fail to help.

In the cooperative patient with stable injuries and a patent airway, fibre-optic intubation, an inhalational induction or tracheostomy under local anaesthetic may be appropriate to secure the airway. However, these techniques may prove impossible owing to bleeding or poor patient cooperation; inhalational induction also risks regurgitation and may not prevent airway obstruction at lighter planes of anaesthesia. If immediate airway control is required, a rapid sequence induction of anaesthesia with bimanual cricoid pressure, manual in-line stabilization of the neck and orotracheal intubation is preferred. The cervical collar should be undone, because it increases the chance of successful laryngoscopy and permits the application of cricoid pressure.

Nasotracheal intubation is contraindicated if a basal skull fracture is suspected, because intracranial penetration may occur via a fractured cribriform plate.

Rapid sequence induction in trauma patients

Many components of rapid sequence induction present problems in trauma patients.

- Pre-oxygenation may be impossible in an agitated patient though oxygenation may improve cooperation if hypoxaemia is the cause.
- Trauma victims often have a combination of hypoxaemia, a reduced cardiac output and anaemia. Therefore, it is often necessary to ventilate patients after induction of anaesthesia, before attempting orotracheal intubation.
- Cricoid pressure is contraindicated in cases of laryngeal trauma.
- If a cervical fracture is suspected, bimanual cricoid pressure should be used, with one hand supporting the posterior spine.

Improving the chances of successful intubation

A number of devices and techniques can be used to increase the chances of a successful orotracheal intubation.

- The gum elastic bougie is particularly useful if the neck must be maintained in a neutral position
- A number of laryngoscopes are available to help make laryngoscopy easier, including the McCoy blade. It consists of a standard Macintosh blade, with a hinged tip and is useful in Cormack and Lehane grades 3 and 4 laryngeal views (see *Anaesthesia and Intensive Care Medicine* **1:1:** 32) when the neck is in a neutral position. It also requires less force to expose the laryngeal inlet and this reduces the haemodynamic response to intubation and the force applied to the cervical spine.
- A dental mirror, positioned on the posterior pharyngeal wall may provide a reflected view of the laryngeal inlet and can guide the passage of a bougie.
- If normal laryngeal anatomy cannot be identified at laryn-goscopy, gentle pressure on the chest may force air bubbles out of the laryngeal inlet, indicating the position of the trachea.

Management of failed intubation in trauma patients

There must be a contingency plan for failed orotracheal intubation. Multiple attempts at intubation result in hypoxaemia and can lead to progressive airway oedema. The priority is to oxygenate the patient adequately, using techniques such as two-person, bag-mask ventilation. A number of airway adjuncts (e.g. laryngeal mask airway (LMA), Combitube) can be used in the emergency situation. Ideally, they should be easy to insert, be reliable in the presence of an abnormal airway and provide some protection against aspiration.

Laryngeal masks

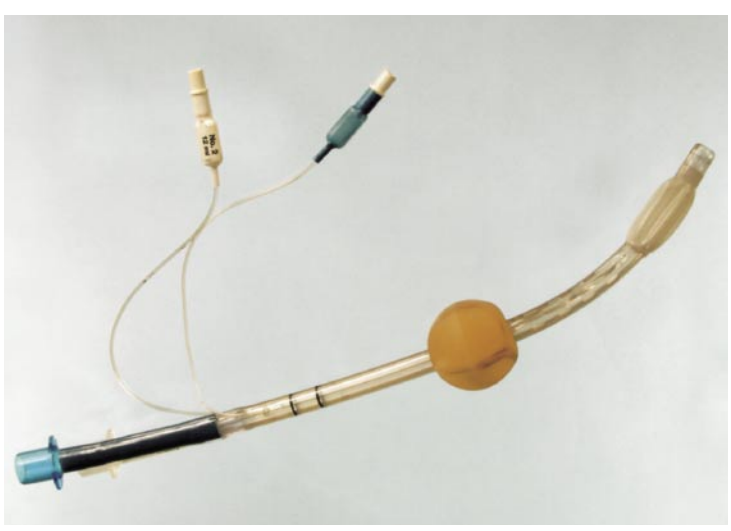
The LMA offers the overwhelming advantage of familiarity in a stressful situation. It is available in several sizes and can be placed rapidly, blindly and with the neck in a neutral position. Airway pressures up to 20 cm H_2O are easily generated, and it provides some, but not complete, protection of the lower airway from soiling. After placement, it may act as a conduit for intubation via a fibre-optic scope. However, the use of cricoid pressure significantly impairs the insertion and function of the LMA, to the extent that pressure must usually be relaxed or released. Furthermore, because it is a supraglottic device, the LMA cannot overcome laryngospasm.

In recent years, the intubating laryngeal mask (ILMA) has become available. It consists of a rigid metal tube, anatomically curved to fit the airway, and incorporates a laryngeal mask head with an epiglottic elevator bar. A flexible tracheal tube with a uniquely shaped tip is passed blindly or with the aid of a lighted stylet through the ILMA and enters the trachea, usually within a few attempts. It provides the least traumatic of all blind insertion techniques and has been used successfully for awake orotracheal intubation with topical anaesthesia. It is easier to insert than a standard LMA with the neck in a neutral position, reduces the haemodynamic stress of intubation and can be used for ventilation, generating pressures up to 30 cm H_2O. Like the LMA, the ILMA is functionally impaired by cricoid pressure and there is concern about the amount of force imparted to the cervical spine by the metal component of the device.

The Proseal LMA, which has an additional oesophageal lumen running in parallel with the airway lumen, is a further development. An extra posterior cuff significantly improves airway sealing and permits ventilation pressures in excess of 40 cm H_2O in a number of patients. The oesophageal lumen allows venting of stomach contents and the passage of an orogastric tube.

The Combitube

The Combitube (Figure 1) is a double lumen device with eight supraglottic tracheal apertures, a single distal oesophageal aperture and two cuffs, each with an independent pilot balloon. It is passed blindly into the pharynx where, although it almost always enters the oesophagus, it still allows ventilation of the lungs. There are two sizes, but 37 F is appropriate for all adults.



1 The Combitube.

The Combitube has a number of potential advantages. It can be inserted with the head in a neutral position and can generate airway pressures up to 30 cm H_2O. Aspiration is usually prevented, because the small volume distal cuff occludes the oesophagus and the stomach contents can be drained via one of the lumens. In addition, the oesophageal balloon can remain inflated, protecting the airway, while attempts are made to intubate the trachea. Arterial oxygenation may also be improved because the small exhalation apertures of the Combitube create a positive end-expiratory pressure.

Problems occur because the Combitube is a bulky device that requires reasonable mouth opening for insertion. It can also cause pharyngeal and laryngeal trauma, often because of over-distension of the large volume pharyngeal cuff. Other problems include an inability to suction the trachea and difficulty with insertion in the presence of a hard cervical collar. The Combitube is a single-use device, making it an expensive option for teaching and clinical use.

Newer airway adjuncts, such as the Airway Management Device and Laryngeal Tube have not been evaluated in trauma patients.

Cricothyrotomy

If adequate ventilation and oxygenation cannot be achieved by other means, it is essential to gain access to the trachea at a point below the larynx. The cricothyroid membrane is the most suitable anatomical site because it is relatively avascular, requires minimal neck extension for exposure and has some protection posteriorly from the cricoid cartilage. The techniques available for cricothyrotomy each have advantages and disadvantages, though a formal surgical airway has the highest complication rate. The use of a simple needle and cannula technique requires a high pressure oxygen source and does not permit adequate exhalation. The best compromise is to use a purposely designed large bore trocar and cannula (e.g. Quicktrach VBM Medical (Figure 2), Melker cricothyroidotomy cannula Cook Critical Care) that allows exhalation, permits suction and to which an anaesthetic circuit can be attached. Cricothyrotomy should not be deferred until the patient is moribund and should be used early to secure the airway in those who have severely disrupted anatomy. ◆

2 Quicktrach (VBM Medical).

Near Drowning and Hypothermia

Giles Morgan

Giles Morgan is Consultant in Anaesthesia and Intensive Care at the Royal Cornwall Hospital, Truro. He qualified from St Thomas' Hospital, London. He has been a consultant in Truro since 1983 and is part of a team that has promoted the development of critical care medicine on a multidisciplinary, multiprofessional basis.

Drowning is death from asphyxiation in water. In near drowning, the victim survives the initial immersion but may suffer complications related to associated physical injuries or caused by hypoxaemia, hypothermia or the inhalation of water.

Outcome from near drowning depends on the severity of the injuries. Initial cardiovascular and cerebral dysfunction are unreliable in predicting death or disability, because of the effects of hypothermia. In general, a favourable outcome is expected in patients who have not lost consciousness and survival is more likely if bystander resuscitation is performed. In over 300 incidents from Cornwall, only three deaths occurred in patients who had not suffered a cardiac arrest before hospital admission. A poor outcome is expected in patients who have a Glasgow Coma Score of 5 or less, or who are asystolic on arrival at hospital. If neurological function remains poor 24 hours after restoration of a stable circulation, death or severe neurological impairment is likely. 20% of children who require cardiopulmonary resuscitation sustain permanent neurological damage.

In the UK, more than 500 people die by drowning each year. It is the second most common cause of accidental death in children. In the USA, 50% of deaths from drowning occur in children below the age of 4 years. The incidence is higher in men than in women. There is an association with intoxication with alcohol and other recreational drugs. Disorders that could potentially render a patient unconscious such as epilepsy, heart disease and cerebrovascular accident are relatively rare associations. The incidence of near drowning is six to ten times more common than drowning and many cases are not documented.

Pathophysiology of drowning

Early events: asphyxiation is central to the early stages of drowning. The temperature of the water influences the initial physiological behaviour of the patient and may influence survival. The composition of the water is of less importance than the temperature. Sudden immersion submits the victim to substantial hydrostatic pressure that increases venous return, pulmonary blood volume, cardiac output and stimulates a diuresis. Pressure on the abdominal wall increases the work of breathing by 65%. Three reflexes may be activated.

Airway irritation – aspiration of water into the pharynx leads to swallowing, coughing, glottic closure and, when water is eventually aspirated into the airway, laryngospasm and bronchospasm.

Cold shock – in response to sudden total body immersion in cold (< 25°C) water, the victim first takes a large gasp and then begins to hyperventilate. Breath holding time may be reduced to less than 10 s. The effect increases as water temperature falls to a maximum at 10°C.

Diving reflex – cold water in contact with the face and eyes causes bradycardia, peripheral vasoconstriction and apnoea. The effect is more marked in children.

Drowning without aspiration of water (dry drowning) occurs in less than 10% of cases, but is more likely to occur in thermo-neutral water when cold-stimulated reflexes are minimal. The larynx remains closed during submersion until the victim loses consciousness. Aspiration may be minimal. A rapid fall in the partial pressure of oxygen in arterial blood, and subsequent loss of consciousness, may occur as alveolar oxygen is utilized.

Drowning with aspiration of water: 90% of drowning victims have aspirated significant volumes of water. In cold water, the cold shock response leads to hyperventilation and aspiration. In thermoneutral water, glottic closure is either overcome by the victim or occurs when the victim becomes unconscious, leading to aspiration and bronchospasm.

Nature of the water: aspiration of fresh water causes a reduction in pulmonary surfactant rendering the lungs inelastic and poorly compliant. Absorption of water and alveolar collapse causes ventilation–perfusion abnormalities, pulmonary shunting and hypoxaemia. Neurogenic pulmonary oedema may occur if cerebral hypoxaemia ensues. Absorption of fresh water into the circulation can cause haemodilution and haemolysis, but about 800 ml is required to produce a significant effect in adults. Usually only small quantities of water are inhaled and haemolysis and dangerous electrolyte changes are rare.

Sea water is hypertonic and has an osmolality about three times that of blood. It tends to draw water into the alveoli from the blood, but this is of little clinical significance. Its effect on surfactant is less than that of fresh water. Vomit and particulate matter suspended in water are also likely to be inhaled and may cause infection.

Hypothermia

The highest sea temperature round the UK is about 15°C during the summer and about 5°C during the winter. Hypothermia (33–36°C) is usual in immersion victims. At 35°C victims may become unaware of danger. Loss of consciousness occurs at about 32°C. Ventricular fibrillation or asystole occur at about 28°C.

Management

All patients who have been rescued from an immersion incident resulting in near drowning should be taken to hospital. Widespread organ system dysfunction may occur as a result of hypoxaemia, but the onset may be delayed by several hours. To aid management, patients are categorized into four groups.

- Group 1: Conscious and breathing adequately with no clinical evidence of aspiration.
- Group 2: Conscious and breathing adequately with clinical evidence of aspiration.
- Group 3: Conscious or unconscious with inadequate ventilation.
- Group 4: Not breathing and no cardiac output.

The principles applicable to the management of general trauma patients should be applied to the management of immersion victims because head, spinal and other injuries may have been sustained during the near-drowning incident.

Group 1 patients may display reluctance to accept medical attention because of moderate hypothermia or a feeling of relief that they have had a lucky escape. However, in 3% of cases, ventilatory distress may supervene several hours after the incident. Patients in this group should be monitored for at least 6 hours and discharged only if pulmonary function is normal.

Group 2: aspiration of water is indicated by tachypnoea, wheeze, paroxysmal cough, retrosternal pain and the production of grey sputum. Chest radiography may show areas of patchy consolidation. Blood gas analysis may show hypoxaemia or a metabolic acidosis. Electrolyte abnormalities are unusual and there is unlikely to be haematological evidence of haemolysis. Hypo-thermia may be evident. Patients in this group should be admitted to hospital until their temperature is normal. They may be discharged after 6 hours, only if examination of the respiratory system reveals no abnormalities and their arterial oxygen saturation is normal when breathing air.

Group 3 patients may have evidence of poor tissue oxygenation and organ dysfunction. Admission to a critical care area is mandatory.

Respiratory system – aspiration of water leads to broncho-spasm, reduced compliance, increased shunting and ventilation–perfusion mismatch. Initial treatment includes high concentration oxygen therapy and continuous positive airway pressure. Patients with minor breathing difficulties plus evidence of hypoxaemia may deteriorate and require ventilation. Ventilation should be commenced using strategies to prevent alveolar overdistension and barotrauma.

Cardiovascular system – cardiovascular instability is common. Initially, patients may have profound vasoconstriction, a low cardiac output and prolonged capillary refill time. Intravenous access may be difficult and in children intra-osseous access may be the best option. Chest radiography shows bilateral infiltrates suggestive of pulmonary oedema due to the acute respiratory distress syndrome, rather than myocardial dysfunction. Measurement of cardiac output and pulmonary artery occlusion pressure can be a useful adjunct to intravascular volume resuscitation and the use of inotropic drugs. Pulse oximetry is unreliable in cold vasoconstricted patients.

CNS – cerebral injury from hypoxaemia can occur in as little as 5 minutes at normothermia, but hypothermia may provide protection for periods as long as 1 hour. Cerebral hypoxaemia is associated with cerebral oedema; raised intracranial pressure (ICP) should be expected. There is no evidence that measurement of ICP has a positive impact on outcome, but this may be related to the poor outcome in patients who have sustained a significant hypoxic brain injury. Other causes of a reduced level of consciousness must be excluded, including head trauma, cerebrovascular accident, drugs and metabolic causes such as hypo- and hyperglycaemia. Standard measures for the management of hypoxic brain injury (e.g. 15° head elevation, mild hyperventilation, sedation to obtund coughing) should be implemented. If no improvement can be demonstrated within 24 hours of the incident, the outcome is likely to be poor for patients who were admitted unconscious and normothermic.

Renal and metabolic – common metabolic abnormalities include a profound metabolic acidosis and hyperkalaemia. These may be associated with hypothermia, rhabdomyolysis and reperfusion injury. A persistent metabolic acidosis, despite adequate circulatory resuscitation and treatment with intra-venous sodium bicarbonate, should raise suspicions of liver or bowel ischaemia. Specific measures to reduce plasma potassium should be introduced if levels are greater than 5.5 mmol/litre (i.e. 50% glucose, 50 ml, with soluble insulin, 15 units intravenously over 30 minutes). Intravenous calcium chloride (10%) should be given to treat dysrhythmias associated with hyperkalaemia. A urinary catheter should be inserted. Haemo-filtration should be commenced if renal failure occurs.

Prophylaxis against sepsis – it is common to withhold the use of antibiotics until there is clinical or laboratory evidence of sepsis, because unusual organisms may be cultured.

Group 4 patients appear to be dead. Hypothermia causes unconsciousness at temperatures below 33°C and ventricular fibrillation or asystole may occur at or below 30°C. Peripheral pulses may not be palpable. The carotid pulse should be palpated continuously for at least 60 s and an ECG recorded to exclude profound bradycardia or pulseless ventricular fibrillation. Recovery is possible, therefore the danger of assuming death from cardiac arrest in the presence of hypothermia cannot be overestimated. Prolonged submersion in very cold water is compatible with recovery.

Restoration of body temperature – warming the victim is difficult because resuscitative measures require the patient to be undressed. Resuscitation should be continued until the core temperature has reached 32°C. This may take 2–3 hours. Below 32°C, attempts to restart the heart are likely to be unsuccessful. All wet clothing should be removed and the patient dried. Room temperature should be increased and doors and windows closed. Whenever possible, the patient's body should be covered and warmed using warm-air devices (e.g. BairHugger). Further warming can be achieved by warming inspired gases and intravenous fluids to 35°C. The stomach, urinary bladder and peritoneal cavity can be irrigated using warmed fluids. Extracorporeal circuits, in particular those used in cardiac surgery, have been used effectively to warm patients in a more controlled environment. ◆

Spinal Cord Injury

Gordon R Craig

Gordon R Craig is Consultant in Intensive Care and Anaesthesia at Queen Alexandra Hospital, Portsmouth, UK. He qualified from Southampton and trained in the Wessex and South West Regions. He has worked with the International Red Cross, at the Shock/Trauma Centre, Baltimore, USA (regional spinal unit), and in Perth, Australia. His interests include 'field' and trauma medicine and education in intensive care.

Spinal cord injury is an uncommon but devastating event. Patient management is complex, long term and requires a team approach. In the UK, there are 12 spinal injuries units, therefore initial management is usually in a non-specialist hospital. This article concentrates on three areas of particular concern for anaesthesia and intensive care.

In the UK, there are 500–700 spinal cord injuries each year. Most are caused by road traffic accidents and falls. Any trauma patient is potentially at risk of vertebral and/or spinal cord injury. The aim of management is to identify spinal injuries early to prevent further damage and to commence treatment. Diagnosis of spinal cord injury is based on the presence of spinal pain, sensory disturbance and weakness. Abnormalities are difficult to determine in an unconscious patient in whom a high index of suspicion must be maintained and injury assumed until proved otherwise. In conscious patients, it is important to establish the level of injury and whether it is complete or incomplete because this affects the prognosis. The presence of any 'distracting' injury should be noted. Neurological examination must include assessment of sensation to pinprick (spinothalamic tracts), fine touch and joint position (posterior columns), muscle power (corticospinal tracts), reflexes (including anal) and cranial nerve function. Signs that do not fit a classic pattern must not be dismissed because injuries can be caused by impaired vascular supply and affect only some areas of the cord.

The cervical spine is at particular risk because of its mobility in relation to the relatively fixed thoracic cage: 44% of spinal injuries involve the cervical region and up to 3% of major trauma cases have a cervical spine injury. 10% of patients with a cervical spine injury have another vertebral injury.

Airway management

Immediate: patients with spinal injuries have often sustained multiple trauma and may require intubation and ventilation urgently. Most evidence supports the use of rapid sequence induction using manual in-line immobilization to minimize neck movement and cord damage during laryngoscopy. Suxamethonium can be used safely for up to 48 hours following injury but can produce a hyperkalaemic response subsequently. Patients with spinal cord injury above the level of the cardiac sympathetic supply (T1–T4) should be pretreated with atropine or glycopyrollate before any airway manoeuvre to avoid a profound bradycardia/asystole associated with unopposed vagal action.
A lateral cervical spine radiograph may miss up to 10% of injuries. Consequently, radiographs cannot exclude cervical spine injury, do not alter airway management and are not essential before intubation. The neck must be immobilized at all times either using manual in-line immobilization or '3-point fixation' of collar, headblocks and tape; collars alone are insufficient.

Emergent: patients with spinal cord injury who do not require immediate anaesthesia should have the level and stability of their injury determined by clinical and radiological investigation. They may subsequently require intubation for operative procedures (including spinal stabilization) or if ventilation becomes compromised by ascending cord oedema, diaphragm fatigue or sputum retention. The choice for airway control in these patients depends on individual factors and operator expertise. The options include:

- awake fibre-optic intubation (Figure 1)
- standard induction/laryngoscopy
- the intubating laryngeal mask airway (LMA)
- blind nasal intubation.

1 Patient in head calipers undergoing awake fibre-optic intubation.

In all cases the cervical spine should be stabilized either by the prior application of callipers under local anaesthetic or by manual in-line stabilization. Particular care is required on induction to avoid hypotension in cases of high spinal cord injury with sympathetic block and bradycardia.

Preventing secondary cord injury

Secondary cord injury occurs after further mechanical disruption or ischaemic necrosis following vasospasm and oedema. A complex biological cascade is initiated involving lipid peroxidation and elevations in intracellular calcium, oxygen-free radicals and proteolytic enzymes, which propagate injury. The mainstays of management from the time of injury are therefore to treat hypoxia and hypotension and maintain spinal stability. Although high spinal cord injury may cause hypotension, trauma victims must be assumed to be hypovolaemic until proved otherwise. Evidence is lacking about the ideal target mean arterial pressure required to optimize spinal cord perfusion but it should probably be at least 'normal' for that patient.

The role of steroids: neuroprotection and limitation of cord oedema by administration of methylprednisolone for 24 hours has been widely promoted for acute non-penetrating spinal cord injury since the publication of the National Acute Spinal Cord Injury Study (NASCIS 2) trial results in 1990 and 1992. The NASCIS 3 trial (1997/1998) recommended the 24-hour infusion of methylprednisolone for those presenting within 3 hours of injury and a 48-hour infusion for those presenting within 3–8 hours of injury. The use of methylprednisolone is under debate given other level 1 evidence suggesting no benefit and an increased incidence of pneumonia, sepsis and gastrointestinal bleeding in those treated for 48 hours. In March 2002, the American College of Neurosurgeons stated that use of methylprednisolone should not be considered a 'standard of care' but as an option in acute spinal cord injury. Local policies should be discussed with the regional spinal unit. Other neuroprotective agents have shown promise in animal studies only.

'Clearing' the cervical spine in unconscious patients

The normal conditions required to 'clear' a cervical spine are:

- a conscious patient, not under the influence of drugs or alcohol
- no neck pain
- no abnormal neurological signs
- no distracting injury (e.g. long bone fracture).

These are impossible to achieve in most ICU patients. Failure to 'clear' the cervical spine and having to maintain immobilization are associated with the following problems:

- cervical collars cause pressure sores and may raise intracranial pressure
- positioning patients for chest physiotherapy, prone ventilation and pressure area care is difficult
- the inability to extend the neck impedes tracheostomy
- weaning 'irritable' patients is hampered by spinal immobilization.

Pressure areas can be minimized by switching rigid, pre-hospital collars to fitted, semi-rigid collars (e.g. the Aspen). The use of kinetic beds (Figure 2) aids chest physiotherapy, pressure area care and oxygenation.

There is considerable benefit in 'clearing' the cervical spine in unconscious patients especially those likely to be ventilated for more than 48 hours. A survey by Gupta and Clancy showed a woefully inadequate and variable approach to the cessation of spinal immobilization in unconscious ICU patients. The following imaging should be considered.

2 Kinetic bed therapy with spinal immobilization.

Radiography and CT: three complete views of the cervical spine (lateral, anterioposterior and odontoid peg) reviewed by a specialist exclude about 95% of injuries. CT scanning of higher risk (C1/C2) and difficult-to-visualize areas in conjunction with radiographs detects about 98% of injuries (i.e. 2% of cervical spine injuries may not be identified by three radiographs with CT supplementation (EAST report)). Further imaging is required for patients in whom the mechanism of injury is associated with a high risk of spinal cord injury (e.g. road traffic accidents at over 35 mph; deaths at scene; falls over 10 feet).

MRI and dynamic fluoroscopy: MRI is superior at delineating ligament and cord damage particularly in the first 48 hours. MR angiography has shown that vascular injury occurs in up to 40% of patients with cervical spine injury. However, access to MRI is limited in some hospitals and even with appropriate MRI-compatible equipment the process is labour intensive. High-risk patients should undergo dynamic flexion/extension views under image-intensifier control to assess spinal stability before removing immobilization. This can be performed on ICU if patients cannot be moved. These further imaging techniques should be undertaken in daylight hours in conjunction with orthopaedic/radiology specialists. ◆

Anaesthesia for Abdominal Vascular Surgery

Fiona Gamlin

Fiona Gamlin is Consultant Anaesthetist at St James's University Hospital, Leeds, UK. She qualified from Newcastle University, and trained in anaesthesia in Newcastle and Leeds. Her interests are perioperative cardiovascular monitoring and the modification of cardiovascular risk factors.

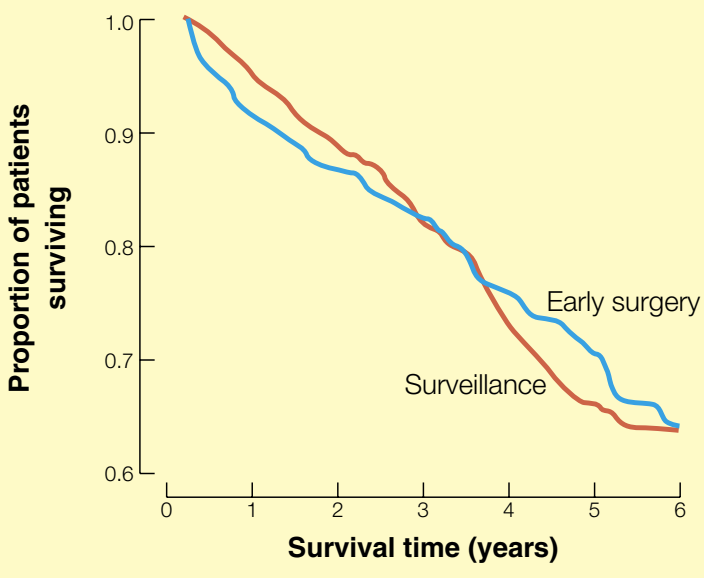
Surgery on the abdominal aorta may be required for aneurysmal dilatation or for symptomatic occlusive atherosclerosis.

The risks of non-surgical management of aortic aneurysm depend on aneurysm diameter. Aneurysms greater than 6 cm carry a risk of rupture within 1 year of about 25%. In addition, larger aneurysms expand more rapidly, further increasing the risks. In patients with smaller aneurysms (< 5 cm), it may be thought appropriate to operate early when the patient is younger and fitter, but there seems to be no benefit to long-term survival from early surgical intervention (Figure 1). The operative mortality figures for elective aortic surgery are 2–10%, reflecting the higher incidence of associated risk factors:

- ischaemic heart disease
- renal impairment
- increasing age
- diabetes mellitus
- obstructive pulmonary disease
- hypertension
- smoking.

The principal causes of perioperative morbidity and mortality are myocardial ischaemia or infarction, organ failure and respiratory complications. Although improvements in perioperative monitoring and management have reduced morbidity and mortality in elective surgery, the mortality from emergency surgery remains high at about 70%.

Overall survival of patients given early surgery compared with ultrasound surveillance in the management of small aneurysms



Number at risk

Abdominal aortic surgery

Preoperative assessment and optimization

Assessment of patients for abdominal vascular surgery is aimed at identifying the risk factors outlined above, and ameliorating them when possible. The most significant factor affecting outcome is perioperative myocardial ischaemia and failure. In addition to baseline ECG and chest radiography, most patients warrant further evaluation of cardiac function (e.g. echocardiography and/or stress testing). Close liaison with the cardiology department helps to optimize the medical management of hypertension, ischaemia or failure before surgery. There is evidence that patients with ischaemic heart disease benefit from perioperative β-blockade, which results in reduced perioperative silent myocardial ischaemia and adverse events.

General anaesthetic considerations

Most patients will be taking cardiac medication, and this should be continued up to and including the day of surgery. Admission to a high-care area for invasive monitoring and optimization of oxygen delivery in high-risk patients has been shown to improve outcome, but few units have the capacity to achieve this and the benefits probably apply only to those in high-risk groups.

The aims of anaesthesia are to avoid exaggerated responses to surgical stimulation, reduce myocardial work and therefore oxygen demand, and maintain cardiac output and oxygen delivery to the tissues. Additional goals include attenuation of the stress response to surgery, preservation of renal function and the provision of postoperative analgesia.

Various general anaesthetics can be used, most having some benefits appropriate to aortic surgery (Figure 2), however, many units employ a combination technique of opioid, oxygen, air and low-dose volatile agent to optimize the beneficial effects while minimizing side-effects.

The addition of regional anaesthesia in the form of a thoracic epidural has several beneficial effects. There is a reduction in haemodynamic instability, the stress response to surgery, and general anaesthetic requirement. There is an increase in endocardial blood flow, and the high-quality analgesia in the postoperative period reduces the incidence of respiratory and other complications.

The main problem related to the use of a thoracic epidural in vascular surgery is the requirement for heparinization for cross-clamping, and therefore the potential risk of spinal haematoma. Reports from large numbers of patients suggest that the technique is safe and that the potential benefits outweigh the risks. Some units advocate insertion of the catheter the day before surgery, but most accept insertion on the day of surgery, allowing at least 1 hour between catheter insertion and heparin administration. Most patients also receive thromboprophylaxis with low molecular weight heparin (LMWH) during their admission. It is recommended that an epidural should not be placed less than 2 hours before or 12 hours after administration of LMWH.

General anaesthesia for use in aortic surgery

Agent	Advantages	Disadvantages
Opioids	• Cardiovascular system stability • Analgesia • Reduced stress response	• Prolonged postoperative respiratory depression
Volatile agents	• Reduced afterload (vasodilator) • Reduced myocardial oxygen consumption • Titratable	• Reduced myocardial contractility • Reduced diastolic pressure/coronary blood flow • Coronary steal at higher minimum alveolar concentration
Nitrous oxide	• Rapid onset and offset • Analgesia	• Myocardial depression
Propofol (total intravenous anaesthesia, target-controlled infusion)	• Titratable • Reduced afterload (vasodilator) • Postoperative sedation	• Reduced myocardial contractility

Monitoring

Usual baseline monitoring is required, with the addition of invasive arterial and central venous blood pressure, core temperature and urine output. A five-lead ECG, displaying leads II and V5, is more sensitive than a standard three-lead ECG for the detection of myocardial ischaemia.

Pulmonary artery flotation catheters are not beneficial for routine use in abdominal vascular surgery. Their use is associated with an increase in fluid administration with no improvement in outcome, and it may increase the morbidity associated with excessive fluid. However, these catheters provide additional information in patients with poor left ventricular filling which guides fluid management and the use of inotropic agents to improve cardiac output.

Transoesophageal echocardiography is a relatively non-invasive real-time monitoring technique. Ventricular filling can be assessed rapidly, and ejection fraction and cardiac output calculated. Ventricular segmental wall motion abnormalities can be visualized and are more sensitive markers of ischaemia than ECG changes. However, the equipment is expensive and requires a trained operator to interpret the images. If an anaesthetist performs the echocardiography, another is needed to deliver the anaesthetic safely.

Oesophageal Doppler monitoring is a relatively non-invasive technique for assessing cardiac output. However, the results are variable if used by an inexperienced operator, and are difficult to interpret when the aortic clamp is in place. In this situation, trends can give valuable information but absolute figures may be inaccurate.

Blood preservation

Blood loss during abdominal vascular procedures increases with the complexity of the surgery and with surgery involving a more proximally sited aortic cross-clamp. Transfusion is often recommended if the haematocrit falls below 30% (0.30), and there is some evidence that levels below 28% (0.28) are associated with a higher incidence of myocardial ischaemia in patients with vascular disease. Regular sampling from the arterial line for estimation of the haematocrit allows for logical transfusion of blood products. Other ways to minimize the use of homologous blood transfusion include pre-donation, haemodilution and intraoperative cell salvage. Cell salvage allows for the re-infusion of fresh RBCs with normal concentrations of 2,3-diphosphoglycerate, and without anticoagulant, acid–base or electrolyte disturbance.

Wide-bore cannulae, either peripheral or central, are required to allow rapid transfusion of blood and other fluids, preferably warmed. If severe haemorrhage is anticipated, rapid infusion systems capable of delivering large volumes of warmed fluids should be available.

Large-volume blood loss and transfusion results in coagulopathy, requiring fresh frozen plasma and platelet transfusion. Further coagulopathy may occur following gut ischaemia in supra-coeliac clamping, especially if the ischaemic time exceeds 30 minutes. Laboratory coagulation tests, bench-top activated clotting time and thromboelastography can all be used to guide appropriate use of clotting factors. Fibrinolysis may be a problem in complicated or supra-coeliac cases, requiring the use of antifibrinolytic agents (e.g. aprotinin, tranexamic acid).

Temperature control

Mild hypothermia has been thought of as protective in abdominal aortic surgery, but it is associated with vasoconstriction, tachycardia, hypertension and increased myocardial oxygen requirement. In addition, blood viscosity is increased and coagulation adversely affected. Maintenance of normothermia is associated with less biochemical disturbance, improved clinical variables and less myocardial ischaemia. Warming is achieved more effectively by forced-air warming devices than by a circulating mattress, and all infused fluids should be warmed. The area below the cross-clamp is not actively warmed while the clamp is in place.

Fluid management

In addition to blood loss, there is excessive evaporation from abdominal contents, and also third-space fluid loss, especially into the retroperitoneal space. Replacement with crystalloid or colloid is titrated against central venous or pulmonary artery occlusion pressure, and regular electrolyte analysis is required to detect and correct disturbances of potassium, calcium and magnesium.

Aortic cross-clamp

The placement of an aortic cross-clamp has significant effects on the cardiovascular and neuroendocrine system, the severity increasing the more proximally the clamp is placed. In addition, blood flow to vital structures including the kidneys, spinal cord and gastrointestinal tract may be interrupted if supra-renal or supra-coeliac clamping is required. The cardiovascular effects of cross-clamping are less severe in occlusive aortic disease owing to the development of collateral circulation.

Cardiovascular effects and management: following placement of an aortic cross-clamp, systemic vascular resistance rises causing an increase in mean arterial pressure and left ventricular afterload. An increase in left ventricular end systolic pressure and wall tension, and a reduction in ejection fraction and cardiac output of up to 40% accompany this. The reduction in cardiac output is greater in patients with inadequate intravascular volume, and the cardiovascular changes in general are more severe in supra-coeliac clamping when the splanchnic circulation is interrupted. Patients with normal coronary arteries and myocardial function tolerate these changes and maintain cardiac contractility reasonably well. However, in patients with ischaemic heart disease the combination of increased myocardial workload and greater intraventricular pressures inhibiting subendocardial blood flow may lead to myocardial ischaemia. This further affects cardiac contractility, central venous and left atrial pressures rise, and left ventricular failure and dysrhythmias may ensue.

Before placing the clamp, the patient requires adequate intravascular filling. Afterload reduction is usually achieved by increasing the depth of anaesthesia with a volatile agent. Nitrates, including glyceryl trinitrate and sodium nitroprusside, are generally required only in compromised or emergency patients in whom the additional preload reduction and improved coronary blood flow are beneficial. Inotropic agents may be required if cardiac output is not improved with normalized preload and afterload.

During cross-clamping the period of ischaemia causes vasodilatation distal to the clamp, and the accumulation of H^+, lactate and other vasoactive metabolites. The release of these agents into the circulation on reperfusion in combination with vasodilatation results in low systemic vascular resistance, reduced venous return and reduced cardiac output. Acidosis and metabolites may directly depress the myocardium and, if hypotension is severe, low coronary blood flow exacerbates the problem. A combination of adequate filling to a central venous pressure above 10 cm H_2O or pulmonary artery wedge pressure of 12–15 before de-clamping, and the use of vasoconstrictors and inotropes help to reduce cardiovascular instability. Surgical techniques that minimize the effects are short cross-clamp times and careful, slow release of the clamp.

Renal preservation: renal impairment is a significant cause of perioperative morbidity and mortality in abdominal aortic surgery. Up to 10% of patients have preoperative renal impairment, and the overall rate of perioperative renal failure in aortic surgery is of the order of 3%. Mortality associated with renal failure exceeds 25%.

Risk factors for the development of renal failure are shown in Figure 3. Although suprarenal clamping is associated with much higher rates of renal complications (up to 50%), all levels of cross-clamp impair renal blood flow. The combination of increased vascular resistance, reduced cardiac output, activation of the renin-angiotensin system and sympatho-adrenal stimulation all serve to impair renal blood flow even with infra-renal cross-clamp. There may also be intra-renal blood flow redistribution away from the medulla, increasing the risk of medullary ischaemia.

Risk factors for perioperative renal failure

Preoperative renal impairment
- Renal artery atherosclerosis
- Hypertension
- Diabetes mellitus
- Contrast toxicity
- Heart failure

Age

Dehydration
- Osmotic diuresis from intravenous contrast
- Preoperative starvation

Operative factors
- Suprarenal cross-clamp
- Hypotension
- Hypovolaemia
- Large-volume blood transfusion

3

Oliguria is a poor predictor of renal dysfunction, because many patients demonstrate a reduction in urine output without developing renal impairment. Similarly, maintaining urine output has not been shown to improve outcome. However, it is the only perioperative monitor of renal function available. The most important factors in the prevention of renal impairment are the maintenance of adequate intravascular volume (pulmonary artery wedge pressure 12–15) and cardiac output, and the avoidance of hypotension. If oliguria persists despite these precautions, various agents are used to re-establish or maintain urine output (Figure 4). Although these agents increase urine output, and have theoretical benefits, they have not been shown to improve renal function or outcome when compared with volume expansion alone. Most units employ one or more of these techniques to augment urine output during surgery, especially if a supra-renal clamp is required.

Beneficial effects of drugs affecting renal function

Mannitol
- Plasma expansion
- Improved cortical blood flow
- Osmotic diuresis
- Free-radical scavenging

Loop diuretic (e.g. frusemide)
- Diuresis
- Sodium excretion

Dopamine
- Decreased systemic vascular resistance, increased cardiac output, β-adrenergic effects
- Increased renal blood flow, dopaminergic effects
- Increased glomeruler filtration rate and urine output

4

Spinal cord ischaemia: normally the spinal cord receives most of its blood supply via the anterior spinal artery. This artery receives blood from the aorta via medullary branches, the most important being the artery of Adamkiewicz, which generally arises between T8 and T12, but may arise anywhere between T1 and L1. Distal supply is via the iliac vessels. Interruption to this blood supply may result in spinal cord ischaemia and a flaccid paralysis, which may be transient or develop into long-term paraplegia. The overall incidence is low (about 0.25%) in aortic aneurysm surgery, but increases in supra-renal or thoraco-abdominal procedures, and in emergency surgery.

The most important factors in the preservation of spinal cord function are avoiding prolonged periods of cross-clamp (over 30 minutes), and the identification, preservation and re-implantation of critical vessels. Anaesthetic considerations are principally the maintenance of adequate blood pressure proximal to the clamp to optimize anterior spinal artery perfusion, and the avoidance of hyperglycaemia. Various techniques have been advocated for higher-risk supra-renal surgery including:
- somatosensory evoked potentials for the early detection of ischaemia
- cord cooling via an epidural catheter
- CSF drainage to improve spinal artery perfusion pressure
- corticosteroid administration to reduce cord oedema
- magnesium administration as a free-radical scavenger.

However, there is no clear evidence of improved outcome.

Endovascular aortic stent procedures

The technique of endovascular stent repair of aortic aneurysm via the femoral artery was first described in 1991. If the procedure is technically possible, it is associated with less physiological disturbance, morbidity and mortality than open procedures. Mortality in those thought fit for open repair is reported as 2.3% in the Eurostar database, and in those unfit for open repair as 12.5%. Rate of conversion to open repair is low (5%), but conversion is associated with a high mortality. There is no clear evidence of the long-term effectiveness of stent procedures, and they are generally limited to patients considered unfit for conventional surgery, or to those included in randomized controlled trials.

Anaesthetic considerations
Patients tend to be in the high-risk group for anaesthesia and surgery, therefore careful consideration must be given to preoperative assessment and optimization of medical problems.

Site: the procedure can be performed in a theatre suite with portable imaging, but about half of the units in the UK prefer to use the higher-quality imaging available in the radiology department. This results in the problems associated with anaesthesia in a distant site not primarily designed for general anaesthesia. The most important consideration is to anticipate everything that could be required, and have it available. A trolley specially set up with all the appropriate drugs and equipment makes the situation less stressful for the anaesthetist. The area is often cramped, with large numbers of staff and bulky equipment. The temperature is usually kept low for optimal equipment function, but too low for optimal patient function, and therefore warming with a forced-air warmer will be required because warming mattresses under the patient interfere with the imaging. The table on which the patient lies will not tip, therefore anaesthesia must be established before transfer from a theatre trolley or bed. In addition, the mattress is thinner than that on an operating table, and because procedure times can be prolonged, pressure areas need protection.

Anaesthesia and analgesia: general and epidural anaesthesia are possible for stent procedures, however, because heparin is administered during the procedure, the timing of the epidural is important. In addition, if epidural anaesthesia is to be used without general anaesthesia, sedation may be required to help the patient to tolerate prolonged procedures. Overall, the choice of anaesthetic technique depends on the general physical state of the patient.

Monitoring: baseline monitoring is principally the same as for open repair. Although there is not the same potential for third- space or evaporative fluid losses there is usually a continual, and occasionally brisk, blood loss from the femoral arteriotomy. In addition, though the aorta is occluded for only short periods of time during graft deployment, one femoral artery is occluded for most of the procedure. This may cause significant cardiovascular effects on reperfusion. Urine output also needs careful monitoring, especially if large volumes of potentially nephrotoxic radiological contrast are required. Carbon dioxide may be used as an alternative contrast agent, but the image quality is adversely affected.

Recovery: following an uneventful stent procedure, most patients can be woken up and transferred to a recovery area with appropriate monitoring. Most patients are in the high-risk group, therefore 24 hours in a high-dependency area are usually indicated.

Anaesthesia for Patients with Haemoglobinopathies

Elizabeth J Haxby
Caroline Bateman

Elizabeth J Haxby is Consultant Cardiothoracic Anaesthetist at the Royal Brompton Hospital, London, UK. She qualified from St George's Hospital, London, UK, and trained in anaesthesia in London. Her interests include anaesthesia for beating heart cardiac surgery.

Caroline Bateman is Senior Clinical Fellow in Cardiothoracic Anaesthesia at the Royal Brompton Hospital, London, UK. Her interests include cardiothoracic anaesthesia and intensive care.

It is estimated that 4.5% of the world population carries a haemoglobinopathy trait. Haemoglobinopathies result from the formation of an abnormal globin. The most common and clinically significant are sickle cell haemoglobin (HbS) and the thalassaemias. Patients may be heterozygous (HbAS), homozygous (HbSS) or a compound heterozygote for the sickle gene and an interacting abnormal haemoglobin such as HbC or β thalassaemia. The presence of HbS produces clinical symptoms of varying severity. Sickle cell trait (HbAS) is benign, requiring extremely hypoxic or acidotic conditions before sickling occurs. Homozygous (HbSS) or doubly heterozygous (HbSC or HbS β thalassaemia) forms produce chronic incurable illness. In children less than 6 months, HbF is protective but under adverse conditions sickling can occur in the newborn.

Sickle cell disease affects all organ systems (Figure 1). The abnormal haemoglobin shortens the survival time of RBCs and causes anaemia. Patients with thalassaemia present with anaemia or complications from repeated transfusion, such as iron overload manifesting as damage to the heart, liver and endocrine organs, or infection. There is no cure for these diseases, though a number of therapies have been tried including bone marrow transplantation. In these patients, careful preoperative preparation and perioperative manage-ment contribute to improved outcome, and a multidisciplinary approach is essential.

Complications of sickle cell disease

- Anaemia
- Jaundice
- Reticulocytosis
- Hepatosplenomegaly
- Autosplenectomy
- Hand–foot syndrome
- Enlarged skull and long bones
- Dactylitis
- Pulmonary infarcts
- Vitreous haemorrhages
- Stroke
- Leg ulcers
- Avascular necrosis of bone
- Priapism
- Acute chest syndrome
- Ischaemic pain crisis
- Haemolytic crisis
- Aplastic crisis
- Sequestration syndrome

1

Preoperative preparation

It is recommended that all patients of non-European origin are screened for variant haemoglobins preoperatively. Sickle forms, even in small numbers, are diagnostic on blood film but specific haemoglobin type and percentage can be confirmed only by electrophoresis. The sickle solubility test (*Sickledex*) does not identify low levels of HbS and false-negative results are common before the age of 6 months. Above this age, a negative *Sickledex* renders clinical problems with sickling unlikely.

Preoperative assessment should focus on signs and symptoms of end-organ damage, including pulmonary hypertension and cor pulmonale from pulmonary infarction, liver disease and renal dysfunction. Patients with sickle cell trait can be regarded as healthy before surgery, though sickling can occur in exceptional circumstances. Prolonged fasting and dehydration should be avoided.

Preoperative transfusion

Transfusion reduces the proportion of HbS and improves the oxygen-carrying capacity of the blood, which may improve microvascular perfusion. Its use to terminate acute crises is controversial. In general, preoperative transfusion should be undertaken to reduce HbS to less than 30% of total Hb without increasing haematocrit above 36%. This may require partial exchange. However, raising the haemoglobin to 10 g/dl may be as effective in preventing perioperative complications and result in fewer transfusion-associated complications.

Perioperative management

The mainstay of anaesthesia is to avoid factors likely to precipitate sickling such as dehydration, acidosis or hypothermia. The anaesthetic technique is less important than the care with which it is administered. General and regional techniques have been used successfully, though there is evidence that complications related to sickle cell disease are more common in patients with HbSS receiving regional anaesthesia. Adequate fluid replacement is essential and hypotension should be treated with fluids in preference to pressor agents, which produce vasoconstriction and stasis. Maintenance of normothermia using warming devices and increasing ambient temperature is essential.

Oxygenation should be optimized. Preoxygenation is advisable and postoperative oxygen therapy should be continued for 24 hours after major surgery. Patients with sickle cell disease are at high risk of postoperative pulmonary complications and chest physiotherapy should be routine. Sickle crisis may manifest postoperatively as the acute chest syndrome, a serious complication with 10% mortality. Features include severe chest wall pain, fever, cough, hypoxia and pulmonary infiltrates. High-dependency care is necessary and ventilatory support is occasionally required. Good analgesia is essential, together with rehydration and treatment of infection. Sickle crises can occur during surgery and symptoms are masked by anaesthesia and postoperative analgesia.

Tourniquets may be used, provided the patient is adequately hydrated and periods of inflation are limited. Hyperventilation may be useful. Pregnant women with HbSS, HbSC or HbS β thalassaemia may pose particular problems. Severe anaemia and sickling in intrauterine blood vessels may cause intrauterine growth retardation, abortion or stillbirth. Labour and delivery can precipitate crises. Meticulous management of regional anaesthesia with regard to hydration, blood transfusion, oxygen supplementation and postoperative analgesia is required. The effect of haemoglobinopathies on the outcome of cardiac surgery is uncertain. Cardiopulmonary bypass imposes a major physiological insult but profound hypothermia may protect against sickling. If adequate perfusion and oxygenation are ensured, using vasodilators and crystalloids to reduce viscosity, low temperature may be beneficial. Recommended levels of HbS before cardiopulmonary bypass are less than 30% in adults and less than 5% in children. Timing of transfusion is controversial because it may precipitate fluid overload and pulmonary oedema in susceptible patients.

Pain management

Sickle crises cause severe pain, which is often underestimated. Precipitating causes should be identified and treated. Pain control requires opiates, and patient-controlled analgesia devices have been widely used. Non-steroidal anti-inflammatory drugs are a useful adjunct in the treatment of bone pain. Regional blocks have been used successfully for localized pain, but many patients suffer repeated crises and chronic pain syndromes can develop.

Anaesthesia for Vascular Surgery on Extremities

Andrew B Lumb
Sue Smith

Andrew B Lumb is Consultant Anaesthetist specializing in vascular surgery at St James's University Hospital, Leeds, UK. After medical training at St Mary's Hospital Medical School, London, he trained in anaesthesia at a variety of London hospitals.

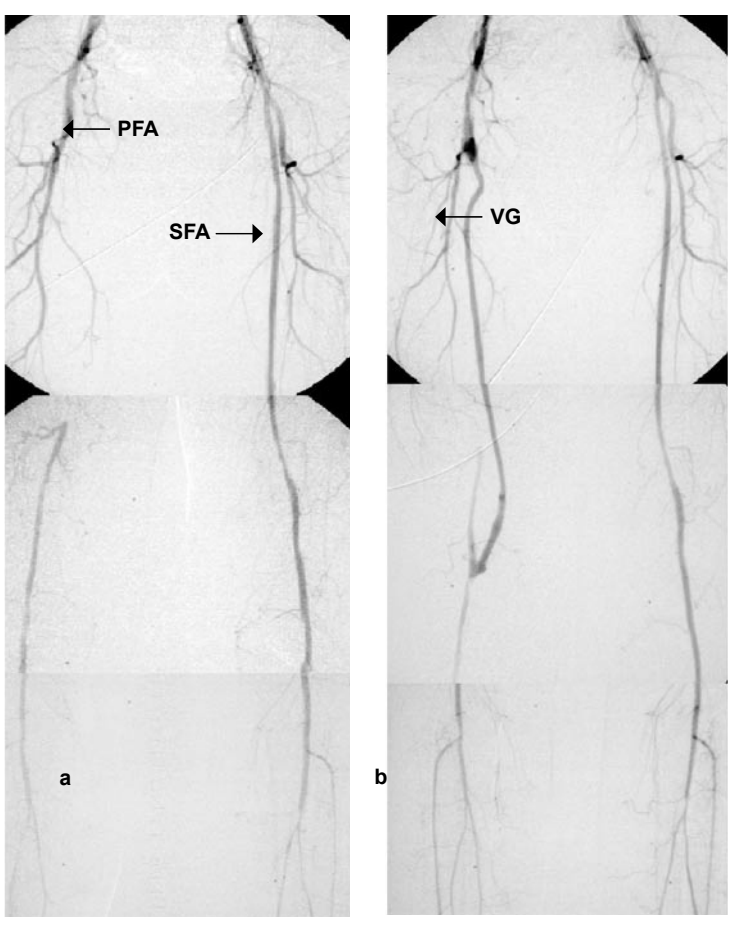
Sue Smith is Specialist Registrar in Anaesthesia at St James's Hospital, Leeds, UK. She qualified from Cambridge University and the Royal London Hospital, and trained in anaesthesia in Sheffield, Bradford and Leeds. She is a flexible trainee, with research interests in obstetric anaesthesia.

Lower limb surgery

Most patients presenting with lower limb ischaemia are elderly, often with concomitant medical disease. Early symptoms include intermittent claudication and leg ulcers, progressing to critical ischaemia (rest pain) or acute ischaemia (white leg) and gangrene. Patients commonly have widespread atherosclerosis involving coronary, cerebral and renal vasculature, and 10-year mortality in these patients is 45%, mainly as a result of coronary and cerebral events. Revascularization of the leg normally involves bypass of the diseased arterial segment with either synthetic tube grafts or vein. Figure 1 shows arteriograms before and after revascularization.

Medical treatment of lower limb ischaemia includes cessation of smoking, exercise programmes, aspirin and control of diabetes mellitus and hypertension. With these simple measures many patients with intermittent claudication improve spontaneously, but 20% of patients progress to critical ischaemia or gangrene within 6 years and require surgery. Smoking increases the risk of surgical intervention to 80% in 6 years.

Perioperative mortality for lower limb revascularization is 2–6%, increasing with age and more distal bypass surgery. Causes of death are cardiac complications, cerebrovascular accidents or multi-system failure in equal numbers. Morbidity is more common and includes myocardial ischaemia and infarction, and less often heart failure, respiratory and renal complications.



1 Angiograms before and after revascularization.
a Preoperative angiogram. The superficial femoral artery (SFA) is occluded at its origin, but reconstitutes in the mid-thigh region via collaterals from the profunda femoris artery (PFA).
b Postoperative angiogram showing reversed vein bypass graft (VG) between the common femoral and above-knee popliteal arteries.

Anaesthetic technique

Recent studies suggest that the mortality and cardiovascular morbidity of surgery is similar with a regional or general anaesthetic technique. Figure 2 shows the advantages and disadvantages of each technique. Prolonged surgery and potential harvesting of arm veins are important surgical factors in the choice of anaesthetic technique.

Advantages and disadvantages of general and regional anaesthesia

General

Advantages
- 100% reliable
- Cardiovascular control easier during surgery
- No patient discomfort during long procedures

Disadvantages
- Postoperative cardiovascular instability
- Unpredictable postoperative analgesic requirement
- Nausea and vomiting
- Hypercoagulable state postoperatively
- Respiratory complications

Regional

Advantages
- Patient self-monitors for cardiovascular and respiratory problems
- Vasodilatation improves graft blood flow and tissue perfusion
- Reduced stress response to surgery
- Good respiratory function and analgesia postoperatively
- Reduced incidence of deep vein thromboses

Disadvantages
- Technical difficulties in elderly population
- Vasodilatation and hypotension require careful fluid management
- Patient agitation if used alone for long procedures
- Risk of post-dural puncture headaches
- Rare neurological complications

2

General anaesthesia: induction of anaesthesia is usually with an intravenous agent followed by a short-acting opioid, and a non-depolarizing muscle relaxant to facilitate intubation and ventilation. Maintenance is achieved with inhaled anaesthetic or intravenous infusions. For both induction and maintenance, care must be taken to administer appropriate doses of anaesthetic agents in elderly patients with poor cardiovascular reserve. Longer-acting opioids (e.g. morphine) may be used for analgesia during maintenance, the effects of which will continue into the postoperative period, but more commonly analgesia is achieved by the simultaneous use of a regional technique.

Regional anaesthesia: the sympathetic blockade associated with regional anaesthesia improves graft blood flow and reduces thrombotic tendency, and therefore may reduce the incidence of early graft failure. Aspirin, low molecular weight heparin (LMWH), and intravenous heparin during surgery all contribute to a theoretical increase in the risk of spinal haematomas with the use of regional anaesthesia in vascular patients. To minimize this risk, the following guidelines should be followed.
- Epidural catheters should only be sited or removed more than 12 hours after LMWH is administered.
- Intravenous heparin should not be given within 60 minutes of an epidural or spinal injection.
- Activated clotting time should be monitored during surgery.
- Appropriate neurological monitoring should be performed following surgery, usually in a high-dependency area.

Technical difficulties with regional techniques are common owing to degenerative disease of the spine. The level of epidural insertion is usually middle to high lumbar, depending on the proposed surgery. A test dose is given to detect subarachnoid or intravenous injection. Epidural regimens vary, but in the authors' unit 0.5% bupivacaine is used for regional anaesthesia alone, or 0.25% bupivacaine if combined with general anaesthesia. Postoperatively, low-concentration infusions are used (e.g. 0.1% bupivacaine) to minimize motor block while maintaining adequate analgesia and sympathetic blockade. Epidural opiates are not normally required for peripheral vascular surgery.

In this group of patients, cardiovascular compromise should be limited by:
- avoiding excessive preoperative dehydration
- aggressive fluid replacement
- appropriate depth of anaesthesia
- invasive monitoring
- gradual achievement of regional blockade
- the use of vasopressors when adequate intravenous volume is achieved.

Monitoring

In addition to standard monitoring, consider the following.

Cardiovascular: ECG using either a five-lead or CM_5 configuration is useful to detect rhythm and ST segment changes more reliably than a standard three-lead system. Invasive blood pressure measurement is normally used – a radial arterial line sited under local anaesthetic provides accurate monitoring during the potential cardiovascular instability of induction with minimum discomfort for the patient. A multi-lumen central venous catheter is often required, using either the internal jugular or subclavian veins. Patients with poor left ventricular function, poorly controlled heart failure, pulmonary oedema or severe valvular cardiac disease may require a pulmonary artery flotation catheter. Oesophageal Doppler monitoring can be used as an estimation of cardiac output in the absence of a pulmonary artery flotation catheter. In patients at high risk, transoesophageal echocardiography is useful for detecting ventricular segmental wall motion abnormalities during ischaemia or infarction.

Temperature: central temperature should be monitored and heat loss minimized by ensuring adequate theatre air temperature, a warming mattress under the patient, warming intravenous fluids and blood products, and using a circle breathing system to warm and humidify inspired gases. The use of forced-air warming blankets has facilitated the prevention of hypothermia but these devices should not be used over body areas with poor or absent arterial blood supply.

Renal: urine output is a valuable monitor of renal function, adequate renal perfusion and intravascular fluid status.

Haematology, blood gases and coagulation: the arterial catheter allows convenient access to sampling of blood for haemoglobin concentration, biochemical analysis, calcium, acid–base status and coagulation studies. Activated clotting time monitoring is easily performed in the operating theatre and, in patients with normal coagulation preoperatively, provides a useful measure of *in vivo* heparin activity during surgery. The activated clotting time should be maintained at about 200 seconds during arterial clamping, compared with a normal value of 70–110 seconds.

Intraoperative management

Vein harvesting: veins are harvested for graft formation from the same or contralateral leg, but previous venous surgery, such as varicose vein or coronary artery bypass surgery, may necessitate the harvest of arm veins. The operative arm should then be avoided for intravenous access and monitoring.

Anticoagulation: intravenous heparin is given before clamping of the arterial supply to the limb. Usually, 3000–5000 iu are required, and the effects monitored by activated clotting time. A degree of anticoagulation is beneficial postoperatively for graft patency, and therefore protamine is not normally required.

Reperfusion: during clamping, ischaemic vasodilatation occurs and, following clamp release, there is a drop in systemic vascular resistance, venous return and left ventricular end diastolic pressure. Lactic acid and anaerobic metabolites influx into the systemic circulation, causing hypotension, myocardial dysfunction, renal vasoconstriction and a metabolic acidosis. Reperfusion effects can be minimized by increasing fluid replacement before clamp release, keeping clamp time short, and sequential release of the profunda and superficial femoral arteries. Pharmacological correction of reperfusion effects may be required, including vasopressors and calcium.

Hyperaemia of the limb may continue for over 24 hours postoperatively and predisposes to the development of systemic inflammatory response syndrome and multi-system failure.

Fluid management: a balance must be achieved between normal to increased intravascular volume and fluid overload, left heart failure and pulmonary oedema. Continuous monitoring of central venous pressure, arterial blood pressure and urine output is therefore useful.

Crystalloid and colloid solutions should be administered early to replace preoperative dehydration and insidious blood loss. Haemoglobin estimation provides an indication of blood loss and haemodilution. A haemoglobin level of 10–12 g/dl provides a balance between adequate oxygen delivery to the tissues and reduction of viscosity to improve graft blood flow.

Amputation

Amputation may be a primary procedure for overwhelming sepsis or intractable pain, or secondary to failed revascularization procedures. Amputation represents a huge reduction in the quality of life for the patient and an increase in dependency on carers and the rehabilitation services, but may be the only option to offer some relief from pain.

The morbidity and mortality following amputation of the lower limb is high. Mortality rates range from a median survival of 2 years for unilateral below-knee amputation to 6 months for bilateral above-knee amputations.

Phantom limb pain: continuing perception of pain from the leg following amputation is common. Three-quarters of amputees experience some pain in the phantom limb within the first few weeks after surgery and, in about 10%, this persists in a severe form. The incidence is increased if chronic pain was present preoperatively, or severe pain occurred immediately before surgery (e.g. in trauma victims). Two small studies, involving 49 patients, have suggested a benefit from preoperative epidural anaesthesia in reducing the long-term incidence of phantom limb pain. The risks of epidural analgesia in this group of patients and logistical difficulties with providing preoperative epidurals preclude universal use of the technique. However, in patients at high risk of phantom limb pain, such as those with significant ischaemic pain preoperatively, early establishment of epidural analgesia should be considered.

Anaesthetic technique: patients requiring amputation often have multi-system disorders and require optimization preoperatively, and should be managed in a high-dependency area throughout the perioperative period.

The choice of anaesthetic technique is general, regional or selective nerve blockade. Unilateral spinal blocks provide excellent analgesia with minimal cardiovascular compromise.

A regional anaesthetic alone usually requires a degree of sedation to reduce the psychological stress from the noise of surgery. When general anaesthesia is used, this may be supplemented with an epidural, nerve or plexus block and/or opiates to provide analgesia into the postoperative period. If regional techniques are contraindicated, a perineural catheter may be placed during surgery directly into the sciatic nerve sheath (for above-knee amputations) or the anterior tibial nerve (for below-knee amputations). Postoperative perineural infusion of local anaesthetic (e.g. 0.5% bupivacaine, 3–5 ml/hour) may reduce opiate requirements.

Upper limb surgery

Thoracic outlet syndrome

Thoracic outlet syndrome is caused by compression of the subclavian vessels or brachial plexus between the clavicle, first rib and scalene muscles. Symptoms include severe pain and paraesthesia usually in the distribution of C8–T1, and occasionally muscle wasting and weakness. Surgery is indicated in 5% of patients. Techniques vary from partial to full resection of the first rib, scalenectomy, subclavian aneurysm repair and major vessel reconstruction.

Anaesthetic considerations: the potential for major blood loss is high, and blood should be cross-matched if arterial surgery is proposed, and invasive monitoring instituted. The non-operative arm is used for cannulation, induction of anaesthesia and invasive monitoring. Rib resection is painful postoperatively and opioid analgesia is usually required, often in the form of a patient-controlled analgesia system.

Thoracoscopic sympathectomy

Thoracoscopic sympathectomy is performed for palmar hyper-hidrosis. It involves gas insufflation into the pleural space and division of the cervical sympathetic chain between T2–T5.

Anaesthetic considerations: patients are usually young and fit, and may require only a baseline chest radiograph for preoperative investigations. The airway is maintained with an endobronchial tube to allow ventilation of one lung. After carbon dioxide insufflation of the pleural space by the surgeon, the thoracoscope is inserted to check lung deflation, and the insufflation pressure limit set to a maximum of 5 mm Hg. Excessive pressures or volumes can cause physiological changes consistent with a tension pneumothorax (i.e. hypotension, hypoxia, bradycardia). Immediate release of carbon dioxide volume from the chest cavity should reduce the intrathoracic pressure and re-establish cardiovascular stability.

Complications include cardiac arrhythmias (owing to the partial sympathetic denervation of the heart by division of the T2 to T4 fibres) and hypoxaemia due to one-lung ventilation and a large pulmonary shunt. Following nerve destruction, the lung is fully re-expanded under direct vision of the thoracoscope. A chest drain is not usually required, though a postoperative chest radiograph often reveals a small apical pneumothorax which usually resolves spontaneously. Pain may be severe following thoracoscopy and perceived as lower neck and back pain. Methods to alleviate pain include opiates, NSAIDs, which are effective for pleuritic pain, and intrapleural local anaesthetic.

Anaesthetic Techniques for Carotid Surgery

Mark Stoneham

Mark Stoneham is Consultant Anaesthetist at the John Radcliffe Hospital, Oxford, UK. He qualified from Cambridge and St Thomas's Hospital, London, spent 5 years in the Royal Navy and Royal Marines before starting anaesthetics. He trained in the South West, Ann Arbor, Michigan and Oxford. His clinical and research interests are in vascular anaesthesia.

Carotid endarterectomy is performed for patients with embolic or ischaemic symptoms (e.g. transient ischaemic attack, cerebrovascular accident or amaurosis fugax) who have 70% or more internal carotid artery stenosis. The fundamental problem is maintenance of cerebral oxygenation during carotid cross- clamping. The perioperative mortality rate from stroke and myocardial infarction approaches 5%, thus there is considerable interest in improving surgical and anaesthetic techniques to reduce this risk.

Regional or general anaesthesia may be used. A multi-centre, randomized, controlled comparison of general and local anaesthesia is under way in the UK (GALA (General Anaesthesia versus Local Anaesthesia) trial). Non-randomized studies have suggested that regional anaesthesia gives better cerebral perfusion monitoring and, perhaps, reduces cardiovascular, pulmonary and neurological complications. However, there are strong advocates for general anaesthesia the advantages of which include:

- a reduction in the cerebral metabolic rate for oxygen
- an increase in cerebral blood flow by isoflurane
- absolute control of the airway
- tight control of partial pressure of carbon dioxide in arterial blood
- patient comfort.

Cerebral perfusion monitoring

Techniques used for cerebral perfusion monitoring during general anaesthesia include:

- carotid artery stump pressure measurement
- EEG processing
- somatosensory evoked potential monitoring
- transcranial Doppler ultrasound of the middle cerebral artery (which gives audible indication of particulate embolization during dissection around the carotid artery)
- near infrared spectroscopy.

These techniques may be used to indicate which patients have inadequate collateral circulation. A shunt may then be used to bypass the internal carotid during cross-clamping. However, the poor sensitivity and specificity of these techniques mean that some surgeons use a shunt on all patients. Alternatively, blood pressure may be augmented pharmacologically to maintain cerebral perfusion.

Using regional anaesthesia, changes in speech, cerebration or motor power following carotid cross-clamping provide a more direct monitor of cerebral perfusion. The requirement for shunting is thereby reduced to 10%.

General anaesthetic techniques

The prerequisites for general anaesthetic techniques are maintenance of haemodynamic stability, reduction in cerebral oxygen consumption and rapid emergence to allow immediate postoperative neurological assessment. A conventional technique might include preoxygenation, intravenous induction with propofol or thiopental (thiopentone), supplemented by fentanyl, 2−5 μg/kg and neuromuscular relaxation to facilitate tracheal intubation and ventilation with a suitable gas mixture. Monitoring includes five-lead ECG, invasive and non-invasive arterial pressure, pulse oximetry, capnography, and the usual oxygen and pressure alarms. Central venous access is unnecessary − indeed inadvertent contralateral carotid puncture may lead to cancellation of the surgery.

Most anaesthetists control partial pressure of carbon dioxide in arterial blood and oxygenation with intermittent positive-pressure ventilation (IPPV). Spontaneous ventilation may cause hypercapnia, leading to an undesirable steal effect. The drawback of IPPV is the need for intubation and extubation, which may cause hypertensive crises. At extubation, the brain is no longer protected by the tight carotid stenosis against sudden increases in perfusion pressure. Remifentanil may be used to prevent such hypertensive crises, permitting intubation and ventilation without muscle relaxation and, when used in conjunction with superficial cervical block, allows rapid recovery with excellent postoperative analgesia. Another way of reducing this risk is to replace the tracheal tube with a laryngeal mask airway (LMA) before emergence. The LMA has been used as sole airway control during carotid endarterectomy, but cerebral blood flow is decreased by the LMA cuff. The significance of this in patients with carotid stenosis is unknown.

Regional anaesthetic techniques

Cervical epidural anaesthesia

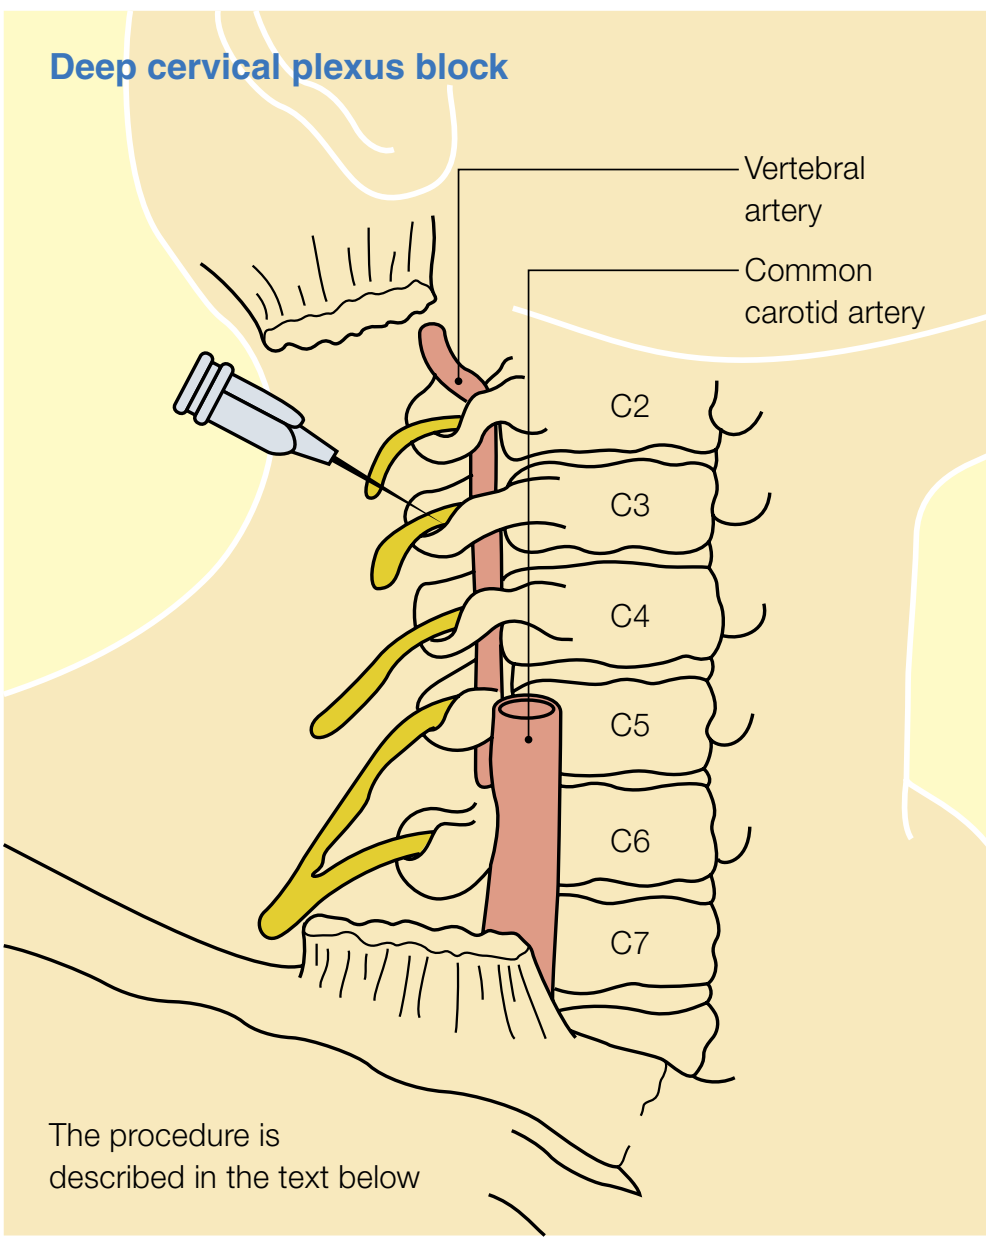
Cervical epidural anaesthesia is used infrequently in the UK and USA, though there are large case series reporting its simplicity and success, particularly in France. However, as all cervical and upper thoracic nerve roots bilaterally are affected, there is a high incidence of side-effects, including hypotension and bradycardia, respiratory failure, dural puncture and bloody tap.

Cervical plexus block

Cervical plexus block is easier to perform, affects unilateral nerve roots only and has fewer side-effects than epidural anaesthesia. Deep and/or superficial cervical plexus block is commonly used.

Deep block may be performed at C3 or C4 (Figure 1). The patient lies supine, slightly sitting up, with the head turned contralaterally. After skin disinfection, the cervical transverse processes are palpated 1 cm behind the posterior border of sternocleidomastoid. The third cervical transverse process is located by counting up from the sixth (Chassaignac's) tubercle at the level of the cricoid cartilage. After intradermal infiltration of 1% lidocaine (lignocaine), a 1" 25 G needle is introduced at C3 perpendicular to the skin, but aiming slightly caudad to avoid intrathecal injection. The transverse process is located 1−2 cm under the skin.

The patient may report paraesthesia in the distribution of the cervical plexus. 0.375% bupivacaine, up to 20 ml, is then injected after careful aspiration by a second operator,



1

Superficial block is a simpler technique. With the patient similarly positioned, an intradermal 'bleb' of 1% lidocaine (lignocaine) is raised at the midpoint of the posterior border of the sternocleidomastoid. 0.375% bupivacaine, 10−20 ml, is injected in the subcutaneous plane along the posterior body of the sternocleidomastoid in cranial and caudal directions from this point.

Complications

Deep block is more difficult to perform than superficial block and may have more serious complications, though it is more reliable and gives better postoperative analgesia. Serious potential complications include:

- intravascular injection producing immediate unconsciousness or seizures
- subarachnoid injection producing total spinal anaesthesia
- phrenic nerve palsy.

Phrenic nerve palsy occurs in 60% of deep block recipients, but is tolerated well, except in patients with underlying respiratory disease, who should receive superficial block alone.

Other potential side-effects of cervical plexus block include local haematoma, hoarseness, dysphagia, stellate ganglion block and Horner's syndrome. Aspiration of blood during placement of cervical plexus blocks is common, occurring in up to 30% of patients. Frequent aspiration is therefore vital to avoid intravascular injection of local anaesthetic, which may cause immediate epileptic seizure.

Regional techniques for carotid endarterectomy are seldom perfect. In some patients, the carotid disease extends so high that the incision needs to be extended into tissues innervated by cranial nerves. Additionally, despite apparently having good surgical anaesthesia, patients sometimes complain of pain from the carotid sheath. This may reflect sympathetic afferent carotid innervation. Half the patients will require local anaesthetic supplementation, which is not a failure of the technique. Patients occasionally complain of pain referred to the jaw, molar teeth or the ear, which may be relieved by moving the surgical retractor, by local anaesthetic supplementation or by mandibular nerve block.

Sedation A target-controlled infusion of propofol, 0.2−2 μg/ml provides reversible, predictable sedation during block placement and dissection to enhance patient cooperation. During carotid cross- clamping, constant neurological assessment is vital, therefore sedation must be minimal at this stage.

If the patient complains of pain, sedation is no substitute for augmentation of the block by the surgeon with supplemental local anaesthetic.

Perioperative management

Oxygen is administered via a standard face mask. Monitoring consists of five-lead ECG, invasive arterial pressure measured from the contralateral radial artery, non-invasive blood pressure cuff, pulse oximetry and capnography, estimated by sampling within the oxygen face mask.

The patient's head must be readily accessible. Verbal communication and grip strength are tested before block placement and regularly throughout the operation, particularly following carotid cross-clamping. Slurring of speech, altered grip strength or an alteration in conscious level are indicators for shunt insertion to maintain ipsilateral carotid flow.

The patient's normal cardiovascular medications are administered on the morning of surgery to help maintain haemodynamic stability. Blood pressure is maintained within 20% of awake values, provided absolute systolic values are 120−180 mm Hg. Ephedrine, phenylephrine, metaraminol, labetalol and intravenous nitrates should all be available for close haemodynamic control as appropriate. Significant blood loss is uncommon, therefore minimal fluids are administered to avoid the problem of a patient needing to void during surgery.

Postoperative problems

Haemodynamic complications such as hypertension, hypotension, arrhythmias and myocardial ischaemia are common, therefore invasive arterial pressure and ECG monitoring are continued in recovery. Analgesia is not usually required following regional anaesthesia, however, patients recovering from general anaesthesia without regional block may require small doses of morphine titrated against their pain. If patients are haemodynamically stable after 4 hours, they are discharged to the ward. There is some evidence that patients who develop neurological dysfunction after cross-clamping are at greater risk of permanent postoperative deficit. These patients may benefit from closer observation on a high-dependency unit.

Compromise of the airway as a result of oedema or haematoma is not uncommon. Wounds are observed carefully for signs of swelling and, if required, opened in recovery and explored immediately in the operating theatre. This may be done without additional local anaesthetic supplementation following a regional technique. Neurological deficit developing postoperatively requires immediate surgical consultation because it may indicate developing cerebral ischaemia due to haemorrhage, embolus or obstruction to blood flow.

Blood Groups, Cross-matching and Haemovigilance

Christopher Walker
Cliff Morgan

Christopher Walker is Consultant in Cardiothoracic Anaesthesia and Intensive Care at the Royal Brompton and Harefield Hospitals, London, UK. He graduated from the University of London and trained in anaesthesia at the Charing Cross and Harefield Hospitals, London, before specializing in cardiothoracic anaesthesia at the Royal Brompton and Harefield Hospitals and the University of Natal, Durban, South Africa.

Cliff Morgan is Consultant in Anaesthesia and Critical Care at the Royal Brompton Hospital, London, UK. He qualified from Southampton University and trained in critical care and anaesthesia at Winchester, Edmonton Alberta, Vancouver BC, Charing Cross Hospital and the Brompton Hospital. He has been involved in a number of activities and committees supporting the UK National Blood Service.

Blood groups

RBCs have antigens on their surface, the most important of which are the carbohydrate 'ABO' type antigens (Figure 1). The next most important antigen class is the Rhesus polypeptide type (antigen present = Rh positive). There are over 50 Rhesus antigen types but five (D, C, E, c, e) are involved in 99% of Rh-system antibody–antigen reactions. Of these five, the Rh(D) antigen is the most important. Rh(D) matching of donor and recipient is important but is essential if the recipient is:

- an Rh(D) negative woman who may have had prior Rh(D) exposure during pregnancy and childbirth
- an Rh(D) negative woman in the reproductive years who may subsequently be exposed to Rh(D) antigens during pregnancy and childbirth
- Rh(D) negative but may have been exposed to Rh(D) antigen in previous transfusion episodes
- young and may therefore be exposed to future transfusion episodes.

There are over 200 other non-ABO/Rh antigens, and they are often classified as either common (e.g. Kell, Duffy, Kidd) or uncommon (e.g. Diego, Lutheran, Y1). Antibody reactions to most of the non-ABO/Rh antigens, though rare, can cause both immediate and delayed haemolytic transfusion reactions.

Typically about 70% of unmatched RBC transfusions are compatible purely by chance. Statistically, about 30% of unmatched transfusions are incompatible and then as little as 10 ml of incompatible blood may trigger a serious haemolytic reaction involving intravascular destruction of RBCs, activation of coagulation and inflammatory cascades and disseminated intravascular coagulation. This is fatal in 10% of cases.

ABO blood groups defined by RBC antigens and plasma antibodies

Blood group	UK population (approximate %)	RBC antigens (ABO)	Plasma antibodies (ABO type)	Can donate RBCs to	Can receive RBCs from
A	42	A	Anti-B (IgM)	A or AB	A or O
B	9	B	Anti-A (IgM)	B or AB	B or O
AB	3	A + B	None	AB	Any
O	46	None	Anti-A (IgG) Anti-B (IgG)	Any	O

1

Cross-matching and screening

ABO typing is determined *in vitro* with direct agglutination of RBCs with anti-A and anti-B reagents. Rh(D) grouping is determined routinely as is an antibody screen against the common non-ABO RBC antigens (incidence is 0.3% in donor population). The incidence of uncommon non-ABO antigens is less than 0.01% and screening for them is not performed routinely. Cross-matching requires incubation of recipient and donor blood *in vitro* to check for potential reactions not predicted by the ABO grouping and antibody screen. This takes about 45 minutes and is responsible for a significant proportion of the delay between the blood sample arriving in the transfusion laboratory and the issue of the cross-matched blood. Where blood is required in an extreme emergency non-cross-matched but group-specific blood may be issued. There is obviously a risk that an important Rh or non-ABO incompatibility may result but this has to be weighed against the clinical urgency of the recipient's situation. In some cases, such as massive haemorrhage where the victim is in extremis, or during major incidents involving multiple casualties, it may be appropriate to start the resuscitation using Group O Rh(D) negative blood. However, full group testing and compatibility matching should be achieved whenever possible, minimizing the antigen exposure of the recipient and conserving this valuable resource for real need.

Donated blood is screened for a number of pathogens that may be responsible for transfusion transmitted infection (TTI). Confidential screening questions are used to detect and defer potential blood donors who have 'at risk' behaviour patterns. There is an understandable trend to introduce more and more sensitive screening tests to further improve the detection of these pathogens but with the risk of TTI already so low (< 1/500,000 transfusion episodes), there is not likely to be a great improvement in safety. However, the cost of blood products has increased substantially as a result.

Haemovigilance

The true incidence of complications of transfusion and the frequency and nature of human and systematic errors can only be derived from a national haemovigilance system. In the UK, Serious Hazards of Transfusion (SHOT) was launched as a voluntary reporting scheme run by healthcare professionals in 1996 and has produced an annual report every year. Over 80% of UK hospitals have taken part, accounting for about 90% of all the blood product usage during the period (about 3 million individual blood products per year). All suspected or definite transfusion-related errors or complications are collated, followed up and reported by the SHOT team. Successive reports have highlighted the importance of human error resulting in incorrect blood component transfused as the most common serious hazard of transfusion (more than 50% of all SHOT events and accounting for four deaths between 1996 and 1999). Inadequate labelling of cross-match sample tubes and deviation from mandatory recipient identity checks are factors. These accidents typically occur in the context of other clinical pressures such as haemodynamic instability of the transfusion recipient. However, urgency of the need for the transfusion is no excuse for reduction in the care of the identity checks.

Figure 2 shows the importance of transfusion errors and the relatively low importance of TTI. The incidence of transfusion- related acute lung injury (TRALI) was higher than would have been predicted before SHOT and has been shown to be associated with serious morbidity (i.e. almost 100% associated with ICU admission and ventilation) and significant mortality (about 25%). TRALI is distinct from other causes of respiratory distress such as trauma, cardiac dysfunction and volume overload. It is thought to result from interaction between antigranulocyte antibodies in the transfused product with corresponding antigens in the recipient, leading to neutrophil aggregation and trapping in the lungs with complement activation and other inflammatory mechanisms setting up severe acute lung injury. This is usually in the context of another event such as hypoxia, massive transfusion, major surgery, infection and inflammation or cytokine therapy. Cases of TRALI may be unrecognized and some non-specific pulmonary complications may be wrongly attributed to TRALI, but careful investigation of suspected cases clarifies the situation. Follow-up by the transfusion service is extremely important, because it may be necessary to defer donors found to have been the source of the antigranulocyte antibodies in confirmed TRALI episodes.

Blood is a limited resource and transfusion carries significant risk. Therefore every clinical decision concerning blood transfusion must consider whether the benefit of transfusion outweighs the risk of complications and the costs involved. A number of strategies have been described to safely reduce the frequency of blood transfusion. The simplest is the strict application of indications for transfusion of blood or products. It is generally accepted that RBC transfusion is not indicated when the haemoglobin concentration is above 8 g/dl, provided that the patient is not actively bleeding, is adequately volume resuscitated and is otherwise stable. Dependence on donor blood can be reduced or eliminated by collection of the patient's own blood before or during surgery in one of the following ways.

- Autologous predeposit, which requires strict planning well before scheduled surgery.
- Normovolaemic haemodilution where blood is collected at the start of surgery with appropriate volume replacement and returned later in place of, or in addition to, donor blood.
- Intra-operative blood salvage where shed blood may be salvaged from the operating field, filtered and centrifuged to remove debris and suspended in heparinized saline for re-infusion.

Artificial oxygen carrying blood substitutes show promise but have enjoyed little clinical application. There is no substitute for careful surgical technique that avoids unnecessary blood loss.

Summary of incidents reported to SHOT from 1996 to 1999

	1996/97	1997/98	1998/99
Incorrect blood component transfused (IBCT)	81	121	144
Acute transfusion reaction (ATR)	27	30	34
Delayed transfusion reaction (DTR)	27	27	34
Post-transfusion purpura (PTP)	11	13	10
Transfusion-associated graft versus host disease (TA-GVHD)	4	4	3
Transfusion-related acute lung injury (TRALI)	11	16	16
Transfusion-transmitted infection (TTI)	8	4	7
Unclassified	7		
Total	169	215	252

All data taken from Table 2 of the Serious Hazards of Transfusion (SHOT) Report for 1998–1999. http// www.shot.demon.co.uk

■ Most important transfusion-related complications.

Coagulopathies

Christopher Walker

Christopher Walker is Consultant in Cardiothoracic Anaesthesia and Intensive Care at the Royal Brompton and Harefield Hospitals, London, UK. He graduated from the University of London and trained in anaesthesia at the Charing Cross and Harefield Hospitals, London, before specializing in cardiothoracic anaesthesia at the Royal Brompton and Harefield Hospitals and the University of Natal, Durban, South Africa.

Haemostasis

Disorders of haemostasis may be congenital or acquired (including drug treatment aimed at inhibiting normal coagulation), and may involve platelets, clotting factors or both.

Congenital platelet disorders
Inherited platelet disorders are uncommon. Von Willebrand's disease is the most common hereditary bleeding disorder in humans (incidence > 1/10,000). It is caused by the defective production of von Willebrand factor, which is required for platelet adhesion and as a vehicle for factor VIII transport (there is no primary platelet defect). Blood products are seldom required for treatment and levels of von Willebrand factor may be increased to normal in the more common autosomal dominant variant with preoperative 1-deamino-8-D-arginine vasopressin (DDAVP). The severe autosomal recessive variant may require treatment with purified plasma products under haematological guidance.

Congenital factor deficiencies
Haemophilia A is caused by a deficiency of factor VIII (incidence 10/100,000) and haemophilia B (Christmas disease) by a deficiency of factor IX (incidence 2/100,000). Both are X-linked recessive, and can be classified as mild, moderate or severe. Treatment in the past has been based on purified, pooled plasma factors, exposing patients to blood-borne viruses (e.g. hepatitis C, human immunodeficiency virus). Perioperative management is aimed at increasing factor levels to 50% of normal for minor procedures and 100% of normal for major operations. In the milder form, this may be achieved with DDAVP, but moderate and severe variants and/or major surgery require synthetic factor concentrates.

Haemophilia C is a deficiency of factor XI (autosomal dominant or recessive) and is common in Ashkenazi Jews (5%). Factor XI concentrate may be required, but often fresh frozen plasma is adequate. There are many other rare congenital factor deficiencies, but they are beyond the scope of this review.

Acquired platelet disorders
Dysfunction: the most common cause of platelet dysfunction is the use of non-steroidal anti-inflammatory drugs (NSAIDs). The subsequent reduction in platelet thromboxane A_2 reduces platelet activation and aggregation. Systemic conditions such as renal or liver failure may alter the biochemical environment sufficiently to affect normal platelet function.

Thrombocytopenia is defined as a platelet count below 150 x 10^9/litre. There may be excessive consumption of platelets (owing to tissue injury or platelet activation), dilution caused by massive transfusion, reduced production from bone marrow, or increased destruction in the spleen. Pregnancy commonly induces thrombocytopenia (Figure 1). Extracorporeal circuits for cardiopulmonary bypass activate platelets and retain them within the circuit – others are damaged by the mechanical nature of the circuit and are removed from the circulation by the spleen.

There are many autoimmune thrombocytopenias; they may be primary (idiopathic) or secondary (Figure 1). Treatment involves immunosuppression and often splenectomy.

Prolonged heparin administration can lead to heparin-induced thrombocytopenia. An antibody to platelet factor 4 is formed after 5–10 days of heparin therapy. It precipitates platelet aggregation, leading to widespread thrombosis and a fall in the platelet count. Thrombus formation in large vessels may render limbs ischaemic and carry the risk of amputation. Heparin-induced thrombocytopenia may recur on subsequent exposure to heparin. Treatment includes the immediate cessation of heparin and continued anticoagulation with hirudin or danaparoid while warfarin is commenced.

Secondary thrombocytopenias

Autoimmune
Malignancy
- Carcinoma
- Non-Hodgkin's lymphoma
- Chronic lymphocytic leukaemia

Immunosuppressive
- Human immunodeficiency virus
- Radiotherapy
- Chemotherapy
- Transplantation

Systemic autoimmune diseases
- Thyroid
- Systemic lupus erythematosus

Pregnancy
- Benign gestational thrombocytopenia
- Pre-eclampsia
- HELLP (haemolysis, elevated liver enzymes and low platelet count) syndrome
- Disseminated intravascular coagulation
- Autoimmune (as above)

1

Acquired factor disorders
Drugs: heparin binds to antithrombin III, markedly accelerating the rate of inactivation of factors IIa (thrombin), VIIa, Xa, IXa and XIa. Warfarin inhibits vitamin K-epoxide reductase, reducing the carboxylation (and therefore activation) of factors II, VII, IX and X.

Consumption: disseminated intravascular coagulation (DIC) is the most common consumptive coagulopathy. It results in the formation of multiple thrombi throughout the vascular tree. Usually an underlying condition (Figure 2) triggers uncontrolled coagulation, overwhelming the normal mechanisms of clot localization. This may be from acute or chronic (prolonged) stimulation of the coagulation system, which consumes and depletes the factors controlling normal coagulation. In addition to thrombocytopenia, excessive fibrinolysis causes hypofibrinogenaemia, elevating levels of fibrin degradation products and D-dimers. Fibrin degradation products have anticoagulant properties in high concentrations and inhibit the normal cross-linking of fibrin monomers, as well as platelet aggregation.

Therapies involve treating the precipitating disease process and haematological support with blood products. Further measures have been advocated, and include antithrombin III and protein C concentrate, prostacyclin, heparin and aprotinin.

Aetiology of disseminated intravascular coagulation

Pregnancy
- Pre-eclampsia
- Placental abruption
- Placenta praevia
- Septic abortion
- Amniotic fluid embolus

Infection
- Systemic sepsis
- Viraemia
- Protozoa

Shock
- Trauma
- Burns

Malignancy
- Haematological
- Metastatic

Extracorporeal circulation

Liver disease

Transplantation

2

Dilution: massive transfusion of crystalloid, colloid or stored blood dilutes endogenous coagulation factors. Packed RBCs have little plasma and few functional platelets, and about 60 ml of every unit of blood is anticoagulant citrate solution.

Liver disease: most of the clotting factors (except factor VIII) are synthesized in the liver, as are the anticoagulants antithrombin III, proteins C and S and plasminogen. The liver also clears activated clotting factors and fibrin degradation products. Therefore, liver disease causes significant disruption to the normal clotting pathways.

Vitamin K deficiency leads to the abnormal synthesis of factors II, VII, IX, and X, as well as proteins C and S. Vitamin K is present in leafy vegetables, and absorption requires the presence of bile salts in the jejunum. Deficiency occurs with malabsorption syndromes, biliary and gastrointestinal obstruction, and liver and pancreatic insufficiency.

Extracorporeal blood circulation: cardiopulmonary bypass, renal dialysis and intraoperative cell salvage lead to dilution of clotting components and expose platelets to a large surface area of inert material. Platelet activation occurs and some are consumed (see thrombocytopenia above).

Prothrombotic states

There are many underlying causes of hypercoagulable states in addition to those related to lifestyle (obesity, smoking, immobility).

Genetic causes include deficiencies of endogenous anti-coagulants such as antithrombin III and proteins C and S, and the presence of abnormal factor V (factor V Leiden). All predispose to venous thromboembolism. Hyperhomocysteinaemia has been linked to arterial thrombosis.

Acquired causes include the synthetic female hormones in oral contraceptive and hormone replacement preparations which predispose to a prothrombotic state. Malignancy and polycythaemia are implicated in venous thromboembolism, as is perioperative immobility.

Management of Vascular Emergencies

Alastair F Nimmo
John A Wilson

Alastair F Nimmo is Consultant Anaesthetist at the Royal Infirmary of Edinburgh, UK. He qualified from the University of Aberdeen. His interests include anaesthesia for vascular surgery, intravenous anaesthesia and regional anaesthesia.

John A Wilson is Clinical Research Fellow in Anaesthesia at the University of Edinburgh. His interests are vascular anaesthesia and neuropathic pain, particularly phantom limb pain.

Patients usually have emergency vascular surgery because of acute arterial bleeding, acute arterial occlusion or trauma.

Ruptured abdominal aneurysm repair

Presentation and diagnosis
Emergency repair of an abdominal aortic aneurysm is performed either because bleeding has occurred from the aneurysm (ruptured or leaking aneurysm) or because the aneurysm has become acutely painful and tender and there is considered to be a high risk of rupture (symptomatic aneurysm).

Ruptured aneurysm usually occurs in patients older than 60 years and is more common in men. Many patients die before reaching hospital, and of those who reach hospital typically 50% survive.

Classically, the patient presents with abdominal or lower back pain associated with shock or collapse and a pulsatile abdominal mass. However, the presentation may be atypical. An abdominal ultrasound scan can show if the patient has an abdominal aneurysm but cannot reliably tell if the patient has bled from it. Without surgery, death is inevitable, so repair of a ruptured aneurysm is attempted in most cases.

Preoperative assessment and preparation for surgery
Once the diagnosis and decision to operate have been made, the patient should be transferred immediately to the operating room. Catastrophic further haemorrhage may occur at any moment and there is no place for prolonged resuscitation or investigation in the accident and emergency department or for the use of an anaesthetic induction room.

When faced with a shocked, hypotensive patient, the natural instinct is to give large amounts of intravenous fluid rapidly to correct the hypovolaemic state. However, after initial bleeding from the aneurysm, clot formation together with retroperitoneal tamponade and hypotension may limit further bleeding. Fluid resuscitation before aortic cross-clamping may raise blood pressure, dislodge clot and result in further haemorrhage. The authors' practice is not usually to give intravenous fluid before induction of anaesthesia. Fluids are reserved for the patient showing signs of myocardial or cerebral ischaemia. In these patients, urgent cross-clamping of the aorta is required.

Oxygen should be given by face mask and two large intravenous cannulae (14 G) should be inserted. Blood samples should be taken for blood grouping and antibody screening, a full blood count, coagulation screening, urea and electrolyte assessment and a blood glucose test. 10 units of blood; plus fresh frozen plasma and platelets should be requested urgently.

A brief history should be taken from the patient or the relatives, asking about previous health, current medications and allergies. A brief examination should take place with particular regard to heart rate, blood pressure, peripheral perfusion and conscious level. The blood pressure may differ between the arms (usually because of subclavian artery stenosis) and the higher pressure should be regarded as being correct. Assess the airway, noting the presence of dentures and any likely difficulty in tracheal intubation. Surgery should not be delayed to wait for the result of blood tests. While an ECG and chest radiograph are useful investigations, surgery should not be delayed significantly to get them, and on no account should the patient be transferred to the radiography department.

Preparation for anaesthesia
Satisfactory management of a patient with a ruptured aneurysm requires two anaesthetists. Anaesthesia should be induced in the operating room with the abdomen already disinfected and draped and the surgeons ready to begin. Before induction, the patient is connected to the ECG, non-invasive blood pressure monitoring and oxygen saturation monitors. Both blood and clear fluids should be connected to the patient via large-bore cannulae using a pressure-infusion and warming system. If no grouped blood is available, group O blood may be used.

Drugs (including vasopressors) should be prepared. The suggested drugs are listed in Figure 1.

Invasive arterial pressure monitoring during induction is useful but surgery should not be delayed by prolonged attempts at arterial cannulation. It is not necessary to insert a central venous catheter before induction unless a large peripheral intravenous cannula cannot be inserted. In that case, a large-gauge central line should be used. Place one or both arms out on arm boards to permit access to intravenous and arterial cannulae. A urethral catheter is usually inserted.

Suggested drugs to draw up for anaesthesia in a patient with ruptured anaeurysm

- Etomidate, 20 mg
- Suxamethonium, 100 mg
- Fentanyl, 500 μg
- Muscle relaxant (e.g. atracurium, 50 mg)
- Ephedrine, 30 mg in 10 ml
- Methoxamine, 20 mg in 10 ml
- Adrenaline (epinephrine) 1:100 000, 10 ml
- Atropine, 0.6 mg
- Calcium gluconate, 10% 10 ml
- Glyceryl trinitrate infusion, 1 mg/ml in a 50 ml syringe
- Adrenaline (epinephrine) infusion, 3 mg in a 50 ml syringe

1

Induction of anaesthesia
A rapid sequence induction is used; etomidate and suxamethonium are suitable agents. Surgery may start as soon as the patient is anaesthetized. A non-depolarizing relaxant should be given after intubation.

At induction, there is a reduction in sympathetic drive and circulating catecholamines. Anaesthetic drugs may cause vasodilatation and myocardial depression. Positive-pressure ventilation causes reduced venous return and muscle relaxation may result in a reduction in tamponade and further haemorrhage. These factors combined may produce a catastrophic drop in blood pressure, which can lead to cardiac arrest. If blood pressure is not being monitored invasively, some indication of changes in blood pressure and of cardiac output may be given by an assistant with a finger on a pulse and by observing the pulse oximeter and capnography waveforms.

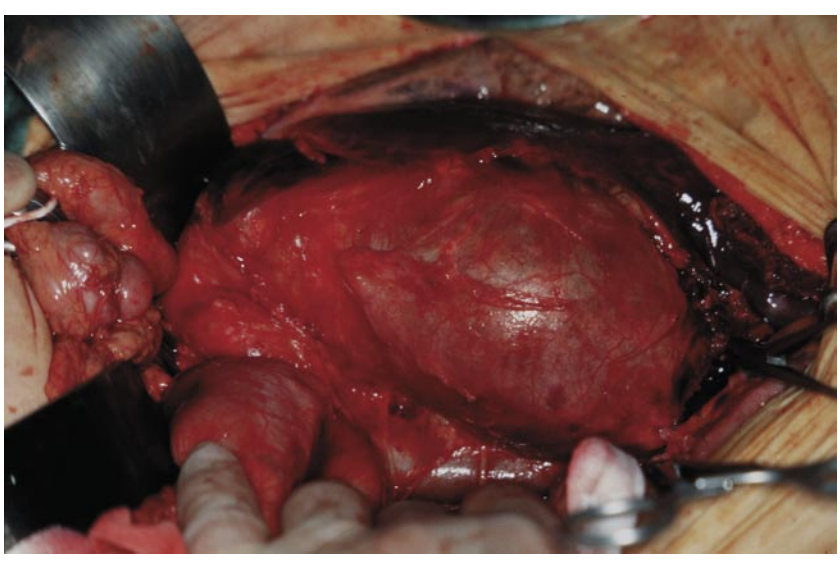
It is essential to be able to prevent or treat an excessive fall in blood pressure on induction by infusing fluids rapidly and giving pressor agents. It is important to give both RBCs and clear fluids or a severe dilutional anaemia may rapidly occur. Rapidly infused blood can produce a dangerous temporary hyperkalaemia. If this is suspected, intravenous calcium should be given. Remember that vigorous ventilation of the lungs reduces venous return. Head-down tilt may help raise blood pressure. Before clamping the aorta, however, the aim should be to prevent severe hypotension that might lead to cardiac arrest or cardiac or cerebral ischaemia – not to restore normal blood pressure. On the other hand, laryngoscopy and surgery may result in hypertension with the risk of further bleeding and myocardial ischaemia. To attenuate this response, an opioid such as fentanyl or alfentanil should be given before induction unless the patient is moribund or already drowsy because of previous opioids.

Conduct of anaesthesia following induction
Anaesthesia may be maintained with a volatile agent or a propofol infusion. Nitrous oxide should be avoided because it causes bowel distension and may contribute to postoperative raised intra-abdominal pressure. Morphine is best avoided because postoperative renal impairment is common and accumulation of morphine metabolites may occur. Boluses of fentanyl or an alfentanil infusion can be used. Adequate muscle relaxation should be maintained.

The surgeon will dissect and cross-clamp the (usually infra-renal) neck of the aneurysm (Figure 2). There is a risk of tearing the left renal vein or its tributaries during the dissection and the resulting venous bleeding may be impossible to control. After clamping the aneurysm neck, the iliac arteries are clamped. Intravenous heparin is not usually given.

Cross-clamping may cause the patient to become hypertensive and this may be treated by deepening anaesthesia and or by infusing glyceryl trinitrate. The latter should also be used if signs of cardiac ischaemia develop and the blood pressure is normal or raised. After the aorta is cross-clamped, the following should be inserted:

- a central venous catheter (and/or a PA catheter)
- an arterial cannula (if not already in place)
- a nasogastric tube
- a temperature probe.



2 A large ruptured abdominal aortic aneurysm. The patient's head is to the left of the picture. The aneurysm had ruptured posteriorly and to the patient's left (top of picture). The aortic clamp is on the left of the picture and two iliac clamps on the right. Blood clot is seen around the left side of the aneurysm at the top of the picture.

Cardiovascular goals and fluid management
After aortic clamping, the aim is to maintain blood pressure and central venous pressure close to normal levels. Haemoglobin, arterial gases and plasma electrolyte levels should be measured, preferably by near-patient analysers situated in or close to the operating room. Haemoglobin should be maintained above 80 g/litre (90 g/litre in patients with cardiac disease).

Coagulopathy is usually present. After cross-clamping, fresh frozen plasma and platelets should be given. It is not practical to wait for laboratory coagulation results at this stage. Further blood product administration should be guided by laboratory results and clinical assessment of bleeding. Ideally, near-patient coagulation testing should be available in the operating room.

Renal function
Patients undergoing emergency aortic surgery are at risk of renal failure because of haemorrhagic shock, aortic cross-clamping, trauma or emboli to the renal arteries and postoperative hypotension and low cardiac output. The risk of renal failure may be reduced by minimizing the duration of any period of supra-renal aortic clamping; avoiding hypotension and a low cardiac output during and after surgery; and avoiding the use of nephrotoxic drugs (e.g. NSAIDs). There is no convincing evidence that mannitol, frusemide or dopamine preserve renal function. Sometimes an infusion of an inotrope is required to maintain an acceptable blood pressure level during or after surgery but it is important to correct hypovolaemia, if present, and to remember that inotropes may cause myocardial ischaemia.

Temperature maintenance
Hypothermia is associated with impaired coagulation and increased blood loss, postoperative vasoconstriction and myocardial ischaemia, and more infections. However, warming ischaemic lower limbs is harmful. The chest, upper limbs and head should be warmed (e.g. by forced-air warming), and intravenous fluids should be warmed.

Clamp release and completion of surgery
When the iliac artery clamps are released, reperfusing the pelvis and lower limbs, hypotension and myocardial depression occur. This results from the refilling of empty dilated vessels, anastomotic blood loss, myocardial depression secondary to the release of metabolites from the ischaemic limbs and pelvis, and pulmonary hypertension caused by microemboli. The surgeon should warn the anaesthetist that the clamps are about to be released. In anticipation of release, the patient should be well filled with fluid (central venous pressure of at least 10 mm Hg). Any vasodilator such as glyceryl trinitrate should be discontinued a few minutes before unclamping. Suitable vasopressors (e.g. ephedrine) should be immediately to hand. Each leg should be reperfused in turn. Significant hypotension should be treated with fluid and or vasopressors. It may be necessary for the surgeon to reclamp or manually compress the artery if the fall in blood pressure is excessive. The filling pressure of the heart should be watched closely. A rising filling pressure in the face of falling blood pressure indicates myocardial dysfunction, which may require the use of an inotrope.

It is usual for a rise in end tidal carbon dioxide, a transient fall in oxygen saturation and a metabolic acidosis to occur following clamp release. Minute ventilation may be increased provided that the patient is not unduly hypotensive. If there is no drop in blood pressure following clamp release, the reason may be that the leg has not been reperfused because there is thrombus or embolus present. Reperfusion also results in lung injury.

The patient should be transferred to the ICU after surgery and ventilation continued until he is warm and normovolaemic, metabolic acidosis has resolved, and pulmonary gas exchange is satisfactory. Although postoperative complications are common, typically 50% or more of the patients undergoing surgical repair of a ruptured abdominal aortic aneurysm will be discharged from hospital alive and their long-term survival and quality of life is little different from that of an age- and sex-matched control population.

Symptomatic non-ruptured aneurysm

A symptomatic but non-ruptured aneurysm can be difficult to distinguish from a small contained rupture (which may bleed further at any moment). The anaesthetist can consider managing the anaesthetic as for an elective abdominal aortic aneurysm repair if the patient has not been hypotensive at any time, has not suffered an episode of collapse or blackout, has no signs of shock (including no otherwise unexplained tachycardia) and the surgeon thinks it unlikely that a contained rupture has already occurred. Otherwise, the patient should be treated as having a ruptured aneurysm.

Acute limb ischaemia

Acute limb ischaemia typically presents with pain, pallor, pulselessness, paraesthesia and paralysis. It may be caused by thrombosis, usually in patients with pre-existing peripheral vascular disease, or by embolism – most commonly from the heart (e.g. as the result of atrial fibrillation). Ischaemia thought to be caused by thrombosis may be treated by the administration of a thrombolytic agent directly into the affected artery and/or by surgical reconstruction. Embolic occlusion of an artery is treated surgically using a Fogarty balloon embolectomy catheter.

Anaesthesia for acute lower limb ischaemia

Embolectomy may be performed under infiltration with local anaesthesia. However, the patients are usually frail and elderly and an anaesthetist should oversee monitoring and any sedation that is required. A low dose propofol infusion is suitable for sedation, being easily titratable and not resulting in prolonged drowsiness after surgey.

If embolectomy or thrombolysis is unsuccessful, a bypass graft may be required. If muscle damage has occurred, fasciotomies may be performed to prevent compartment syndrome. Amputation is sometimes necessary. General or regional anaesthesia may be used for these procedures. However, spinal and epidural analgesia are contraindicated if a thrombolytic agent has been given before surgery or is likely to be given intra-operatively, and are usually avoided if anticoagulant administration has resulted in an international normalized ratio (INR) above 1.5 or an activated partial thromboplastin time more than 1.5 times normal at the time of surgery.

Anaesthesia for acute upper limb ischaemia

Acute ischaemia of the upper limb is less common than acute ischaemia of the lower limb. It occurs more often in women than in men and is often the result of embolism. Embolectomy may be carried out following local infiltration of anaesthetic. Alternatively, a brachial plexus block or general anaesthesia may be used.

Postoperative Care and Pain Relief in Vascular Surgery

L D Caldicott

L D Caldicott is Consultant Anaesthetist at St James's Hospital, Leeds, UK. He qualified from St George's Hospital, London, and trained in anaesthetics in Leeds and Sheffield. His interests include vascular surgery, the use of local anaesthesia for postoperative pain relief and the perioperative care of the surgical patient.

Postoperative care of vascular surgical patients involves the same principles as the care of any surgical patient and includes:
- oxygenation
- maintenance of a stable cardiovascular system
- fluid balance and urine output
- pain relief
- deciding on the appropriate level of postoperative care.

Many vascular operations are prolonged and may involve large blood losses. When combined with the generally poor medical condition of the average vascular patient, this predisposes to a high rate of postoperative complications. Meticulous attention to detail in the postoperative management of surgical patients can help to avoid the slow decline in which one complication follows another leading to admission to ICU, multi-organ failure and death.

Specific problems

Postoperative myocardial infarction (MI) is the greatest cause of death after vascular surgery and occurs in 2–5% of patients. It has a number of clinical features.
- Mortality is 50–75%
- It occurs on day 1–3 postoperatively.
- Presentation is often 'silent' due to opioid administration, diabetes and altered perioperative pain thresholds.
- It presents as low blood pressure, heart failure, sudden death, unstable angina or ventricular arrhythmia.
- It can be diagnosed clinically by sequential ECGs, and measurement of myocardial bound creatine kinase and cardiac troponin 1 levels.
- Treatment is as for MI in medical patients except that thrombolysis cannot be used.

Possible explanations for the occurrence of MI in the postoperative period include:
- increased myocardial oxygen demand perioperatively
- increased coagulability of blood postoperatively
- hypoxaemia at night and with opiates.

Thrombosis: most vascular patients are hypercoagulable and the coagulability of the blood increases postoperatively. Prevention of deep vein thrombosis (DVT) and graft occlusion is important. Standard regimens of low molecular weight heparin and thromboembolic disease stockings, when appropriate, should be used, but despite their use an incidence of DVT after vascular surgery of 3–8% has been reported. Conversely, patients being treated with aspirin and heparin may suffer postoperative bleeding at the site of surgery.

Compartment syndrome: restoration of blood flow to ischaemic tissue can cause oedema, release of free radicals and rhabdomyolysis. If the swelling occurs in tight fascial compartments, the pressure can rise to such an extent that capillary blood flow is stopped. Subsequently, muscle cell death releases myoglobin and creatine kinase. Clinically, the limb is extremely tender and the urine is low in volume and dark in colour. Myoglobin will precipitate in the renal tubules producing renal failure if the urine is acidic. Treatment includes fasciotomies and forced alkaline diuresis using sodium bicarbonate, mannitol and large volumes of crystalloid to maintain urinary pH above 6.5 and a urine volume of 300 ml/hour.

Sites of postoperative care

Intensive care is defined as 'a service for patients with potentially recoverable conditions who can benefit from more detailed observation and invasive treatment than can safely be provided on the general wards or high-dependency areas'. These patients usually have respiratory failure and require mechanical ventilation, and often have other system failure requiring support. In ICU, the nurse:patient ratio is usually 1:1, and 24-hour dedicated medical cover is available.

High-dependency unit (HDU) is an area that can provide a greater level of care and monitoring than can be provided on the ward. Patients on the HDU have actual or impending single organ failure (not respiratory), and invasive central or arterial pressure monitoring can be performed. The nurse:patient ratio is usually 1:2. Most postoperative vascular patients are cared for in HDU.

Peripheral vascular surgery

Arterial surgery below the umbilicus can be prolonged, but does not usually involve large blood losses. The use of perioperative epidural analgesia in these patients is controversial, but has a number of advantages including:
- excellent analgesia
- sympathetic paralysis and improved blood flow to the limb
- reduced stress response to surgery with possible reduction in postoperative hypercoagulability and improved graft flow
- a possible reduction in DVTs postoperatively
- less impairment of respiratory function postoperatively.

Although many studies have been conducted, consistent advantages in terms of patient or graft survival are difficult to demonstrate and the real difference is likely to be small. It is therefore reasonable to limit epidural analgesia to patients at highest risk of early graft failure (femoral distal grafts or redo surgery). If the decision to use epidural analgesia is taken, potential problems should be anticipated.
- Patients should be nursed only in a ward where the nursing staff are able to look after the epidural properly.
- Vasodilatation requires careful fluid management to avoid hypotension.
- Bilateral motor block hinders mobilization and surgeons often want the epidural removed 24–48 hours postoperatively.
- Neurological complications, though rare, may occur, especially if the patient is taking anticoagulants, and appropriate monitoring is necessary.

Lumbar plexus blocks: posterior insertion of a lumbar plexus block, either with a nerve stimulator to evoke contraction of the quadriceps or a loss of resistance to saline, may have advantages over lumbar epidural. In unilateral surgery, it is illogical to block both legs because this increases the risk of hypotension and severely hinders mobility. Lumbar plexus block is essentially a lumbar paravertebral block and reliably produces unilateral blockade of the femoral nerve. This maximizes analgesia to the area of surgery and minimizes hypotension. Mobility is also improved.

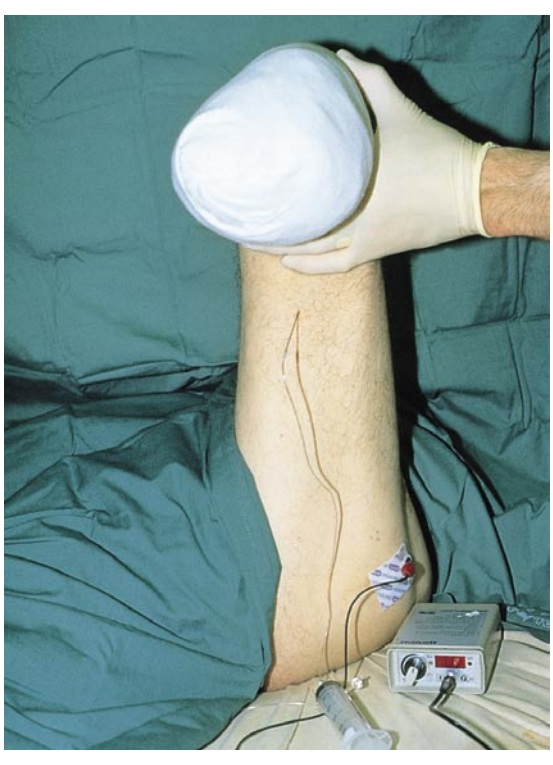
Other analgesic techniques: femoral nerve block from the front can be performed, either preoperatively or perioperatively by the surgeon under direct vision, with insertion of a catheter for postoperative pain relief if desired. Patient-controlled analgesia is popular, but is often used only overnight after which oral paracetamol, codeine or morphine can be started.

Amputations

Patients undergoing amputations are among the most severely ill vascular patients. Cardiac, respiratory and renal failure are common, and infection and dead tissue lead to the development of systemic inflammatory response syndrome or progress to multi-organ failure.

All blocks of the lower limb can be used to produce analgesia, often for up to 12 hours, including sciatic and/or femoral nerve block by all the available routes (Figure 1). Amputation of toes can easily be managed under ankle block or metatarsal block, taking care not to inject too much local anaesthetic to avoid compressing the blood vessels. Otherwise morphine, administered intravenously, intramuscularly or orally and combined with paracetamol, dihydrocodeine or diclofenac (if not contraindicated) can be used.

The role of anaesthetic technique in cases of chronic pain in the 'phantom' limb has been well documented. After early reports of good results with preoperative epidural analgesia, more recent reports seem to suggest that anaesthetic technique does not alter the incidence of phantom limb pain. It does seem illogical to assume that abolishing central neural input with spinal or epidural anaesthesia at the time of surgery will abolish the chronic pain pathways that have built up in the preceding days or weeks. Ketamine, an N-methyl-D-aspartate receptor antagonist, has been shown to reduce phantom limb pain and may have a role in the management of severe postoperative phantom limb pain.



1 Block of the sciatic nerve in the popliteal fossa, using nerve stimulation, in a patient undergoing trimming of stump.

Carotid endarterectomy

Carotid endarterectomy takes 1–3 hours and is not usually associated with severe postoperative pain. An oral or intramuscular opiate, or codeine and paracetamol, is usually all that is required. Mortality and major morbidity are due to MI and stroke.

Cardiovascular problems: baroreceptor function is altered postoperatively for up to 24 hours and low blood pressure is common as the full force of the systolic blood pressure distends the carotid sinus. Increased firing of the carotid sinus nerve follows, together with reflex vagal-mediated bradycardia and hypotension. This can be treated with glycopyrrolate and fluids, but occasionally inotropic support is required (e.g. ephedrine or low-dose dopamine infusion). If this occurs perioperatively, surgeons can instil local anaesthetic to numb the nerve. Some surgeons leave a viral filtered epidural catheter *in situ* for local anaesthetic to be instilled postoperatively if severe hypotension associated with bradycardia occurs.

Hypertension may be due to pain or preoperative essential hypertension. Unexplained hypertension is possible and may be due to cerebral renin and/or noradrenaline release, or cerebral oedema. Both increases or falls in blood pressure can cause strokes and, after carotid endarterectomy, patients should receive invasive blood pressure monitoring and rapid correction of abnormalities for at least 4–6 hours postoperatively. Any appropriate drug can be used in small titrated doses; for example, β-blockers or hydralazine to reduce blood pressure and dopamine infusions to raise blood pressure. Ideally, the patient should be cared for in an HDU, but if a place is unavailable prolonged monitoring in the post-anaesthetic care unit is acceptable. After 24 hours, the baroreceptors have usually 'reset' themselves and the frequency of monitoring can be reduced.

Neurological problems: 60–70% of strokes occur peroperatively and most of these are a result of embolic events. Post-operatively, neurological observations should be carried out every 15 minutes. Any deterioration should prompt urgent Doppler ultrasound because urgent surgical removal of a carotid thrombosis can reverse a developing hemiplegia and allow total recovery. Patients suffering a stroke and loss of consciousness or bulbar palsies and airway problems may need to be ventilated and admitted to ICU.

Cranial nerve palsies may occur, but usually resolve in the first 6 months postoperatively.
- Recurrent laryngeal palsy causes hoarseness, difficulty coughing and vagal damage to the fibres on the surface.
- In hypoglossal nerve palsy, the tongue deviates to the side of the lesion.
- Palsy of the mandibular branch of the facial nerve causes the corner of the mouth to droop, which may be confused with a stroke.
- Spinal accessory nerve palsy results in weakness and aching of the shoulder.
- Superior laryngeal nerve palsy leads to difficulty with high-pitched sounds, and is not usually noticed by the patient.

Hyperperfusion syndrome: rarely, blood flow through the newly endarterectomized artery can be excessive and produce headaches, facial pain, seizures, confusion, cerebral oedema or haemorrhage, probably caused by precapillary cerebral spasm from unaccustomed flow. This usually occurs 5–7 hours postoperatively and hypertension is commonly present. Treatment is aimed at reducing blood pressure, and mannitol and dexamethasone are sometimes used if cerebral oedema is present. Transcranial Doppler ultrasound, which will show high intracerebral blood flow velocities, can be used in diagnosis.

Airway: bleeding around the site can be due to hypertension, aspirin use or a residual effect of heparin. The haematoma does not usually obstruct the airway directly, but causes venous and lymphatic obstruction, and leads to oedema. This can present as life-threatening airway obstruction. Emergency evacuation of the clot (after gas induction and intubation) is indicated and a period of postoperative ventilation is needed until the oedema has resolved. A surgeon should be standing by to perform urgent tracheostomy if needed.

GALA (General Anaesthesia versus Local Anaesthesia) trial: there is no definitive evidence that carotid endarterectomy (or any other type of surgery) results are better when performed under local anaesthesia compared with general anaesthesia, though some studies suggest the incidence of cardiac events is lower under local anaesthetic. The GALA trial, which is a large multi-centre trial that is hoping to recruit 400–600 patients, is under way in the UK to answer this question.

Elective aortlc aneurysm surgery

Site of postoperative care: many centres advocate the availability of an ICU bed before starting elective aneurysm surgery. The unpredictable nature of the surgery, the potential for prolonged surgery with large blood loss and the need for postoperative ventilation cannot be excluded. If the surgery proceeds without problems, the level of postoperative care can be downgraded to HDU.

Epidural: most vascular anaesthetists elect to insert a low thoracic epidural (T7–T9) for aortic anaeurysm surgery, because of the intraoperative stability and postoperative analgesia they provide. Postoperative analgesia regimens usually include an infusion of 0.1–0.25% bupivicaine with or without fentanyl or diamorphine at a rate of 6–12 ml/hour, which can be continued for 2–4 days postoperatively. In addition to the excellent analgesia and a low level of sedation compared with a patient-controlled analgesia (PCA) pump, there is also a shorter duration of ileus. If epidural analgesia is contraindicated, morphine via a PCA pump is used instead.

Fluid balance: after aortic aneurysm repair, there are large fluid losses into the gut (third space) and central venous pressure monitoring is useful to guide fluid replacement, which may be many litres in the first postoperative day. Haemoglobin levels should be measured and, if there is pre-existing cardiac disease, it is safest to maintain the level at about 10 g/dl. Hourly urine measurement is essential to ensure adequate renal perfusion; low urine output is usually due to hypovolaemia not frusemide deficiency.

Enteral feeding: there is some evidence that stomach emptying is relatively normal 18 hours after aortic aneurysm surgery and enteral feeding should be started early, perhaps on day 2, because this stimulates blood flow to the gut.

Ischaemic colitis presents as left-sided abdominal pain and diarrhoea. Infarcted bowel can ensue, and a metabolic acidosis and septic shock result. Emergency laparotomy and bowel resection is needed, but carries a high mortality.

Emergency abdominal aortic surgery

Patients undergoing emergency abdominal aortic surgery have a high mortality due to the severity of the preoperative insult and, if they survive surgery, the development of multi-organ failure. Poor prognostic factors include:

- age over 80 years
- low blood pressure or cardiac arrest preoperatively
- acidosis
- transfusion of more than 15 units of blood.

Postoperatively, patients are always admitted to ICU for care, which includes the following.

- Management of a large blood transfusion, with clotting factors, platelets and more blood as required to normalize haemoglobin levels and clotting times.
- Warming the patient.
- Maintaining an adequate cardiac output and cardiovascular system; inotropic support to the myocardium may be needed.
- A period of ventilation and possibly prolonged weaning if respiratory function is poor.
- Optimizing renal function, including the insertion of a pulmonary artery catheter and maintaining adequate urine output (renal failure is associated with a poor prognosis); dopamine, mannitol or dopexamine can also be used.

Preoperative Assessment of Vascular Patients

L D Caldicott
P J Hall

L D Caldicott is Consultant Anaesthetist at St James's Hospital, Leeds, UK. He qualified from St George's Hospital, London, and trained in anaesthetics in Leeds and Sheffield. His interests include anaesthesia for patients undergoing vascular surgery, the use of local anaesthesia for postoperative pain relief and the perioperative care of the surgical patient.

P J Hall is Specialist Registrar in Anaesthetics on the Leeds rotation. He qualified from Leeds University and trained on the Pennine rotation. His interests include obstetric and vascular anaesthesia.

Vascular surgical patients are usually elderly and have a high incidence of significant medical problems. Preoperative history and examination should mainly address the functional capacity and integrity of the following systems and diseases:
- cardiovascular
- respiratory
- renal
- diabetes.

Cardiovascular system

Vascular surgical patients have a high incidence of symptomatic and asymptomatic coronary artery disease. This is responsible for the relatively high postoperative cardiac morbidity and mortality of this type of surgery (5–10%). Adverse cardiac events (ACE) in the postoperative period are due to thrombus formation on a ruptured atheromatous plaque leading to a Q-wave myocardial infarction (MI), or long-duration subendocardial ischaemia causing a non Q-wave infarction. This can present in the early postoperative period as:
- sudden death
- sudden onset of low blood pressure/cardiogenic shock
- acute left heart failure/pulmonary oedema
- onset of severe ventricular arrhythmias.

Preoperative assessment of these patients involves history, examination and simple tests in order to:
- identify and optimize cardiac conditions medically, radiologically and occasionally surgically, to reduce postoperative cardiac problems
- decide when, how and in which patients further testing (possibly invasive) is justified
- quantify the risk of surgery to allow the risk:benefit ratio to be calculated and to decide on the level of intraoperative monitoring and postoperative care required.

Many factors that predispose to an ACE in the postoperative period have been identified and many scoring systems have been described for cardiac risk assessment (Figure 1); high scores indicate patients at high risk. In general, most of the information needed can be gained from details of the history and examination, and a few simple tests. More invasive investigation is seldom necessary, but occasionally coronary angiography and coronary artery or valve surgery may be indicated. Preoperative cardiovascular factors that can be optimized include coronary artery disease, cardiac failure, valve disease and hypertension.

Cardiac risk indices

Cardiac condition	Goldman Index (points)	Detsky Index (points)	Eagle Index (present or absent)
Third heart sound	11		
History of pulmonary oedema	5		
Pulmonary oedema in the last week	10		
Unstable angina within 6 months	10		
Angina (CCSC III)[1]		10	
Angina (CCSC IV)[1]		20	
Angina (any)			✓
Preoperative myocardial infarction < 6 months	10	10	
Q wave on ECG			✓
Preoperative myocardial infarction > 6 months		5	
More than five ventricular ectopic beats per minute at any time	7	5	
Important aortic stenosis	3	20	
Ventricular arrhythmias			✓
ECG not sinus rhythm	7	5	
Age > 70 years	5	5	✓
Intraperitoneal, aortic or intrathoracic operation	3		
Poor medical condition	3	5	
Diabetes			✓
Emergency operation	4	10	
High risk score	> 12	> 15	3 or more

[1]In Canadian Cardiovascular Society Classification (CCSC) of heart disease, III is marked limitation of activity (i.e. walking 100–200 metres on the level) and IV represents an inability to do anything without pain, which may even occur at rest.

Angina
Symptomatic myocardial ischaemia, perhaps surprisingly, has not consistently been found to predict postoperative ACE. It is now known that myocardial ischaemia is often silent and can be detected only by ST-segment analysis of a 24-hour ECG. Myocardial ischaemia is a risk factor in the development of a perioperative ACE. Symptomatic angina therefore represents only a small proportion of the total myocardial ischaemia that occurs. In general, increasing severity of angina is related to increased risk. Low-grade chronic stable angina conveys a small added risk, but unstable angina occurring at minimal activity, at reduced exercise tolerances or at rest is a medical emergency and must be treated before any operation other than in exceptional circumstances. The degree of activity needed to provoke symptoms is the most important part of the history; the frequency of angina attacks is less important because people vary in their willingness to provoke the pain.

Exercise tolerance in vascular patients is difficult to judge because of the high rate of claudication, strokes and amputations. In these patients, more invasive tests may be warranted to clarify the situation before major surgery. Tests for myocardial ischaemia or coronary artery disease are sensitive but not very specific; a large number of patients test positive, only a few of whom will have a postoperative ACE. Thus, a negative test is a good sign, in that it is extremely unlikely that the patient will suffer a perioperative ACE.

Many vascular procedures are also relatively urgent (e.g. critical limb ischaemia, tight carotid stenosis with transient ischaemic attacks, large abdominal aneurysm), and often only a short time is available for optimization.

Further testing and treatment: studies have shown that aggressive investigation and surgical treatment of coronary artery lesions before vascular surgery does not influence the overall mortality in the short term, because of the deaths associated with coronary artery bypass grafting (CABG). This route should be followed only if the angina is severe and not responding to maximal medical treatment. Angina should be investigated and treated if it warrants further investigation and treatment in itself, and not just because the patient is facing an operation.

Advances in angioplasty techniques and practice may alter the future treatment of angina preoperatively as more difficult lesions become accessible, stent design improves and complication rates decrease. It may be possible to provide quick and relatively safe treatment of coronary lesions preoperatively without recourse to CABG.

Dobutamine stress echocardiography – the heart rate is increased by the administration of dobutamine, 20–40 μg/kg/minute and or atropine, 0.6 mg, and the function of the heart observed using ultrasound to detect wall motion abnormalities induced by ischaemia.

Dipyridamole–thallium scanning – dipyridamole is a vasodilator that reduces blood pressure and causes a reflex tachycardia. Normal coronary arteries dilate and the myocardium they supply shows a large uptake of thallium (a potassium analogue). Narrowed or blocked coronaries show little uptake. In the 4 hours after the dipyridamole, the thallium is redistributed to all the viable myocardium leaving irreversible defects in areas of infarction. Ischaemic areas show up as reversible defects in thallium uptake.

Ambulatory ECG is carried out preoperatively and can show the presence of silent myocardial ischaemia. Patients without silent myocardial ischaemia are at a very low risk of perioperative cardiac complications.

Coronary angiography is the gold standard in the assessment of coronary artery anatomy and allows measurement of intraventricular pressures, ventricular function and gradients across valves.

CABG is indicated for the treatment of angina refractory to medical treatment, left main stem disease and triple vessel disease, especially if there is poor ventricular function.

Coronary angioplasty is a developing area. It allows percutaneous treatment of coronary artery lesions, avoiding the need for cardiac surgery.

Medical treatment includes:
- nitrates (long-acting)
- β-blockers (cardioselective, atenolol or metoprolol)
- calcium antagonists (diltiazem or amlodipine)
- aspirin.

In practice, cardiological referral for medical optimization is common, while referral for invasive investigation, coronary angiography and CABG is relatively rare.

Previous MI
In patients with a history of a previous MI, the risk of perioperative infarction during subsequent surgery is 5–6%. Earlier studies suggested that this risk was much higher if surgery was carried out less than 3 months after the initial infarction (Figure 2). Later studies, however, have failed to show such a relationship (Figure 2). This may be due to an increase in invasiveness of perioperative monitoring and general improvements in postoperative care and management. Nevertheless, it is still recommended that truly elective surgery should be postponed for 6 months after a MI.

Risk of perioperative reinfarction

Study	Number of patients	Reinfarction risk from time of myocardial infarct (%)		
		0–3 months	4–6 months	> 6 months
Tarhan 1972	422	37	16	5-6
Steen 1978	587	27	11	4-5
Rao 1973–76	364	36	26	5
Rao 1977–82	733	5.7	2.3	< 2
Shah 1990	275	4.3	0	5.7

Cardiac failure
Cardiac failure indicates severe myocardial dysfunction, carries a poor long-term prognosis and places the patient at high risk of ACE. Like angina, the degree of failure is related to the operative risk. Frank cardiac failure with a third heart sound and pulmonary oedema is an extremely high-risk situation, and the need for surgery should be carefully considered. Preoperative echocardiography can provide qualitative measurement of myocardial contractility and an estimation of ejection fraction. A low (< 50%) ejection fraction does not necessarily predict perioperative ACE, but will indicate those patients in whom more invasive monitoring, inotropes and postoperative ICU management are indicated. Pulmonary artery catheterization may be useful to allow logical selection of inotropic agents. Symptoms should be optimized preoperatively by treatment with:
- diuretics
- digoxin
- angiotensin converting enzyme inhibitors
- β-blockade under cardiological supervision.

Aortic stenosis
A pressure gradient of more than 50 mm Hg across the aortic valve is considered severe. On induction of anaesthesia, vasodilatation and myocardial depression cause a drop in blood pressure that reduces coronary artery blood flow. This is already compromised due to the high intraventricular pressures and myocardial oxygenation is reduced, cardiac output drops and blood pressure spirals downwards until cardiac arrest occurs. Blood pressure must be maintained in the perioperative period. If possible, severe stenosis may need to be corrected surgically before vascular surgery.

Hypertension
Hypertensive patients are prone to extreme rises and falls in blood pressure in the perioperative period. Although not identified as a factor for the development of ACE in all studies, it is generally accepted that surgery in untreated hypertensive patients with a diastolic blood pressure greater than 110 mm Hg should be cancelled and the hypertension treated to reduce operative risk. Patients with a diastolic blood pressure above 110 mm Hg are at risk of:
- myocardial ischaemia/MI
- dysrhythmias
- neurological events
- renal failure.

Ideally, blood pressure should be controlled according to general medical guidelines and be less than 160/100 mm Hg. Treatment is gradually increased until blood pressure is satisfactory, though the optimal period for blood pressure stabilization before surgery is unclear. Treatment includes:
- diuretics
- β-blockers
- calcium channel blockers
- angiotensin converting enzyme inhibitors
- β-blockers (doxazocin).

In the elderly (> 80 years), the treatment of high blood pressure is associated with more morbidity than if the patient had been left untreated.

Arrhythmias
Frequent ventricular ectopics are a significant risk factor for postoperative ACE but, following the results of large trials, suppression of these ectopics with antiarrhythmic drugs is contraindicated because it increases mortality.

Atrial fibrillation (AF) is common and should be investigated fully. In long-term AF, the ventricular rate should be slowed to below 90 beats/minute with digoxin, and anticoagulation should be considered if the patient has another medical problem or is between 60 and 80 years old. Cardioversion can be considered if the patient is young, has no medical problems or the AF is of short duration. This can be achieved either pharmacologically with amiodarone or flecainide, or electrically after a period of 4 weeks of anticoagulation to prevent embolus.

Preoperative pharmacological optimization
In recent years, two seemingly contradictory regimens for managing high-risk patients have been proposed and both purport to show impressive improvements in outcome.

- The concept of 'preoptimization' of patients presenting for major surgery uses preoperative insertion of a pulmonary artery catheter to measure cardiac output and oxygen delivery to the tissues, and careful fluid and inotrope therapy to raise this to predetermined 'goals'. In high-risk patients presenting for major surgery, this has been shown to produce impressive reductions in mortality and morbidity.
- The use of preoperative β-blockers for 1 week before vascular surgery has, in studies in the USA, shown a significant reduction in mortality which, surprisingly, was maintained for a long time after the surgery.

These two totally different philosophies seem to produce significant improvements on standard 'best care' management, but it is not easy to explain how. Which option to chose in an individual patient is also unclear. It would be foolish to choose to fluid load, give inotropes and seek to achieve large increases in cardiac output in a patient with angina on minimal exertion for whom a 'cardioprotective' β-blocker would be more appropriate. However, this approach may be justified in a patient without significant coronary artery disease presenting for aortic aneurysm surgery. Carotid artery and peripheral vascular surgery are probably not sufficiently 'major' to justify invasive monitoring and inotrope therapy, and β-blocker therapy is more appropriate. Patients should be approached individually after consideration of their cardiac status.

Respiratory system

Many vascular patients have been (or still are) lifelong smokers and have varying degrees of chronic obstructive airway disease. Alveoli that have been destroyed cannot be recreated, but various measures can be taken to ensure the patient is in optimal condition preoperatively.

- If the chest condition is seasonal, try to perform the operation at the best time of year.
- Encourage the patient to stop smoking for 6–8 weeks preoperatively to allow ciliary function to return to normal.
- Provide physiotherapy and breathing exercises for 2–3 days preoperatively so that the patient can practise and become familiar with the routine.
- Help the patient to lose any excess weight.
- Bronchodilators and corticosteroids may be used if it is thought there is a reversible component to the airway disease.
- Signs of active chest infection should be excluded (e.g. pyrexia, radiographic changes, sputum culture).

The severity of the lung disease is best assessed by pulmonary function testing. A forced expired volume in 1 second (FEV_1) is a good measure of ventilatory capacity. An FEV_1 below 1 litre indicates severely impaired function, which will cause difficulty in coughing postoperatively and predicts an increased risk of postoperative mechanical ventilation. Forced vital capacity indicates the severity of diffuse parenchymal disease. It is easy to measure and should be compared with standard nomograms derived from healthy people of the same height, weight and sex. A value less than 50% of expected is considered high risk and arterial blood gases should be measured. This can prove useful as a baseline and detect hypoxaemia, but may also identify the occasional patient who is retaining carbon dioxide and relying on hypoxic drive – the so-called 'blue bloater'. In these patients it is difficult to resume breathing postoperatively and a period of ventilation in ICU is almost inevitable.

A preoperative chest radiograph is useful to detect anatomical abnormalities, such as pneumothorax and bronchial carcinoma, but is an extremely poor indicator of lung function. It can be useful, however, in detecting the cardiomegaly of heart failure and, if there is evidence of pulmonary oedema (i.e. Kerley B lines, upper lobe diversion), the patient is likely to be at high risk.

Renal function

Many studies have shown a greatly increased morbidity and mortality in patients developing renal failure in the perioperative period. Vascular patients may have hypertensive or diabetic renal damage, or renal artery stenosis, and care must be taken to preserve existing renal function and prevent new damage. Maintenance of renal function depends on:

- avoiding drugs that are nephrotoxic
- maintaining renal perfusion by ensuring a normal circulating blood volume, and maintaining a normal blood pressure for that patient
- monitoring urine output closely and acting quickly with appropriate treatment to prevent the development of acute renal failure. Nephrotoxicity induced by contrast media can occur in response to the high osmolality and increased intrarenal production of adenosine. This is due to a reduction in renal perfusion and damage to the tubular cells and is thought, in part, to be due to the release of free radicals during the breakdown of adenosine. Risk factors for renal impairment after administration of contrast media include:
- pre-existing renal impairment (especially diabetic nephropathy)
- dehydration
- congestive cardiac failure
- type and amount of contrast media given; contrast media with lower osmolalities are safer.

Patients should be well hydrated (with intravenous fluids overnight if necessary) and administration of the adenosine antagonist, theophylline, before angiography helps prevent deterioration in renal function. Carbon dioxide angiography, involving the injection of 50 ml of carbon dioxide gas into the vessels to displace blood, produces good pictures after digital subtraction. It is absorbed very quickly into the tissues with no renal side-effects.

Fenoldopam is a new dopamine agonist which shows promise as a drug able to offer 'renal protection' in the perioperative period. Exact clarification of its role is awaited.

Diabetes

Diabetes is common in the vascular patient population. As well as the associated medical problems (e.g. ischaemic heart disease, renal failure, neuropathy), there are specific anaesthetic considerations. Furthermore, myocardial ischaemia is often silent in these patients.

Blood glucose control: most hospitals have their own regimen for perioperative blood sugar control. This usually takes the form of an insulin and glucose/potassium infusion in which the insulin component is varied according to a standard sliding scale and the results of frequent blood glucose sugar readings. Blood sugar should be measured peroperatively to exclude hypoglycaemia.

Perioperative management: autonomic neuropathy can lead to an unstable cardiovascular system during the operation. The patient is unable to tolerate induction of anaesthesia and positive pressure ventilation, and large drops in blood pressure and heart rate can occur, which are difficult to treat. The sweating and tachycardia of hypoglycaemia may be absent. There have also been reports of sudden death in patients with autonomic neuropathy, which can be due to sudden cardiac or respiratory arrest in the perioperative period or an abnormal response to hypoxia. Gastric stasis, with the increased risk of aspiration, is also possible and a rapid sequence induction with cricoid pressure may be wise. Autonomic neuropathy can be identified by the loss of sinus arrhythmia. There is usually a difference in heart rate on deep breathing of 15 beats/minute, though in these patients it is usually less than 5 beats/minute. The lack of the normal tachycardic response to a bedside Valsalva manoeuvre and postural hypotension of more than 30 mm Hg can also be useful.
