For Windows and Mac users

The complete textbook of

Anaesthesia and intensive care medicine

on CD-ROM

Anaesthesia and intensive care medicine on CD-ROM presents a complete 3-year series of the journal in a fully-networkable electronic format – covering the equivalent of 36 monthly issues of the journal.

With a powerful searching facility, the CD-ROM is the ideal complement to the journal edition.

How to use...

Anaesthesia
and intensive care medicine
on CD-ROM
version 1.0

Windows Users

This CD-ROM is designed to be a complete system as it includes Acrobat Reader 6.0.
If you have the full version of Adobe Acrobat 6.0, you may prefer to use this, however, the CD-ROM opens automatically with Adobe Acrobat 6 Reader (which is in the Reader directory on the CD-ROM) and is adequate for reading all the articles.

If you do not have Adobe Acrobat you may go to www.adobe.com and follow the instructions to download it. You will be able to view all the articles on this CD-ROM using previous versions of Adobe Acrobat Reader but you may have difficulty searching for specific words or terms.

AppleMac Users

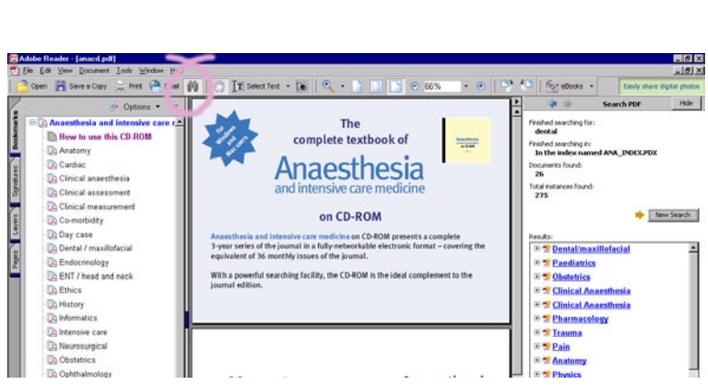
This CD-ROM contains a file called anacd.pdf, please click on this to open your Adobe Acrobat program. If you do not have Adobe Acrobat you may go to www.adobe.com and follow the instructions to download it.

Viewing articles

To view the articles, click on the specialty and then on the required article, this will display the first page of the chosen article. You may use the navigation bar on the right to browse through the entire specialty, article by article. To return to the specialty list, click on the **Main specialty index** link at the bottom of the article list.

To search for a word or term

To find an article containing a particular word or term, select Search from the Acrobat menu and enter the term or word for which you wish to search. The specialties which contain the search term are displayed in alphabetical order and within each specialty the term is displayed in its context. To view the article, click the underlined term.



For Acrobat 5 users, we have already indexed the CD-ROM to ana_index.idx to make searching faster.

To print

To print out articles, use the print function of Acrobat reader. You may need to adjust the settings to suit your printer and the tiling settings to see the whole page on A4 paper.

Extracting images and text

Acrobat 6 allows you to extract text by using the “select text” and “snapshot tool” functions.

Alternatively for images, you can use Print screen feature and place the image in your preferred graphic package.

Please note:

If you wish to reproduce any of the material (text or images) in print or electronic format (other than for educational purposes) please contact us for written permission. If you are in any doubt, please contact us for guidance:
Journals Manager, The Medicine Publishing Company, 62 Stert Street, Abingdon OX14 3UQ
Telephone: 01235 542802, Fax: 01235 554692, or email janet.heinrich@medicinepublishing.co.uk for copyright assistance

Support

If you have problems using this CD-ROM, please contact us:
Email: support@medicinepublishing.co.uk
Tel: +44 (0) 1235 542803 or FREECALL 0808 100 2587 (UK only)
Fax: +44 (0) 1235 554692

Our other journals...

Anaesthesia and intensive care medicine

Did you know that we publish journals other than **Anaesthesia and intensive care medicine**?

Medicine Psychiatry Surgery

To subscribe to any of these journals, contact us at:
The Medicine Publishing Company Limited, 62 Stert Street, Abingdon OX14 3UQ, UK
Telephone: +44 (0)1235 542800 or FREECALL 0808 100 2587 (UK only)
Fax: +44 (0)1235 554692
E-mail: subs@medicinepublishing.co.uk.
Web site: http:\\www.medicinepublishing.co.uk

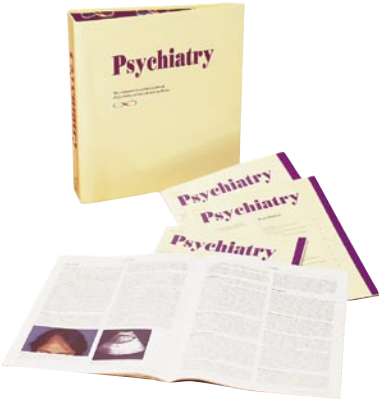
Special Offer for nurses and allied professionals
Nursing or allied professionals can take advantage of a special reduced rate and may subscribe to any of our titles for only £35.00 per year for a full subscription.
See our website for full details (www.medicinepublishing.co.uk).

Medicine

Medicine provides an authoritative account of the diagnosis, treatment and outcome of conditions across the spectrum of clinical medicine. It is published in three formats: journal, CD-ROM and Online, each benefitting from full colour presentation, with extensive use of photographs, charts and diagrams. **Medicine** draws on the expertise of specialists from around the world to present an up-to-date, reliable description of best practice.

Published now for over 30 years, **Medicine** is a crucial aid for all postgraduate examination candidates, recommended reading for undergraduates, and a reliable updating and reference resource for senior physicians and those engaged in general practice.

Psychiatry

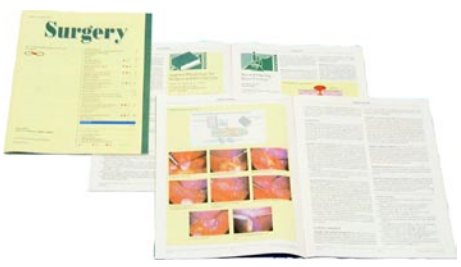


Launched in March 2002, Psychiatry builds month by month into a comprehensive and up-to-date description of psychiatric conditions, treatments and outcome. The level of the journal is appropriate for psychiatric clinicians, general practitioners and psychiatric nurses.

Topics covered in each 3-year series include:

Alcohol	Anxiety	Child psychiatry
Community psychiatry	Drugs	Deliberate self-harm
Eating disorders	Forensic psychiatry	Learning disability
Liaison psychiatry	Mood disorders	Neuroses
Old age psychiatry	Perinatal psychiatry	Personality disorders
Psychiatric ethics	Psychopharmacology	Psychotherapy
Post-traumatic stress disorder	Schizophrenia	Sexual disorders and psychoexual problems
Somatization	Somatoform disorders	Suicide
The role of the psychiatrist	Transcultural psychiatry	Unusual psychiatric syndromes

Surgery



Surgery is the unique monthly add-on journal that builds over 3 years into a comprehensive and highly illustrated text of the principles of surgical practice.

Surgery is authoritative, as any textbook should be, but it is also completely up to date, as no textbook can be. Each contribution is carefully assessed and discussed by the distinguished Board of Specialty Editors and can be finally revised, if necessary, within days of its publication.

Surgery's clearly written review articles provide details of the accepted practical and clinical skills required of the surgical trainee in surgery-in-general, and also the specialties of orthopaedics, cardiothoracic surgery, urology, plastic surgery, vascular surgery, paediatric surgery, neurosurgery and anaesthetics. The journal also features a dedicated basic sciences section.

Surgery's comprehensive coverage of the fundamentals of surgical practice make it indispensable for any trainee surgeon preparing for the Membership and Associate Fellowship examinations of the Surgical Royal Colleges of Great Britain and Ireland, or their overseas equivalents. **Surgery** is now a fully-integrated part of the STEP™ modules from The Royal College of Surgeons of England. Consultant Surgeons will find that **Surgery** is an indispensable teaching resource in the formal training of their junior staff.

Each issue is published in full colour, and articles are comprehensively illustrated, enabling better and faster understanding of the subjects under discussion.

Anatomy

Anaesthesia

on CD-ROM

The Abdominal Wall and Inguinal Region

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

Abdominal wall

There is only superficial fascia over the anterior abdominal wall. It is generally fatty but in the lower abdomen there is a deeper membranous layer (Scarpa's fascia) which blends inferiorly with the fascia lata of the upper thigh, invests the penis and scrotum (or labia), before gaining attachment to the ischiopubic rami and the perineal membrane. These attachments define the clinical picture that develops after injury to the posterior urethra when blood and/or urine may extravasate deep to this membranous layer into the perineum and lower abdomen but not into the thigh.

Laterally the anterior abdominal wall consists of three sheet-like muscles in layers, an outer external oblique, a middle internal oblique and an inner transversus abdominis. Each becomes aponeurotic anteriorly and these aponeuroses fuse to form a sheath around the rectus abdominis.

These four muscles form an elastic wall supporting the abdominal viscera. They assist in expiration and expulsive efforts such as defecation, micturition and parturition. They are supplied by the lower five intercostal nerves, the subcostal nerve and the first lumbar nerve. Deep to the muscles lie the transversalis fascia and the peritoneum. The skin of the abdominal wall is supplied by the sixth thoracic to the first lumbar nerves. T6 supplies the epigastric region, T10 the umbilical region and L1 the groin.

Rectus abdominis

These are paired vertical muscles lying in the midline anteriorly enclosed in fibrous sheaths. They extend from the 5th, 6th and 7th costal cartilages and the xiphoid to the pubic crests.

External oblique

From the outer surfaces of the lower eight ribs the fibres descend obliquely downwards to the iliac crest, with a free posterior border. Anteriorly it becomes aponeurotic to form the anterior layer of the rectus sheath and thereby gain attachment to the linea alba, a midline condensation of fibrous tissue, and through it to the body of the pubis. The pubic crest forms the base of a triangular defect in the aponeurosis, the superficial inguinal ring. Between the pubic tubercle and the iliac crest the lower aponeurotic border is thickened to form the inguinal ligament. To the ligament's inner surface is attached laterally the internal oblique and, deep to that, the transverse abdominis.

Internal oblique

Laterally, the internal oblique is attached to the thoracolumbar fascia, the anterior part of the iliac crest and the lateral part of the inguinal ligament. Posteriorly the muscle gains attachment to the costal margin but most fibres pass medially, become aponeurotic and this aponeurosis splits to enclose the upper two-thirds of the rectus abdominis. Inferiorly, the aponeurosis passes anterior to the rectus. Those fibres arising from the inguinal ligament pass medially and arch over the spermatic cord to unite with the transverse abdominis aponeurosis to form the conjoint tendon which gains attachment to the upper surface of the pubis.

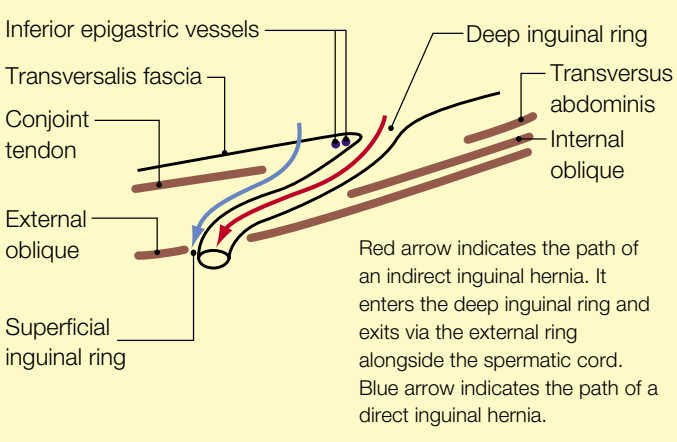
Transversus abdominis

Laterally, the transversus abdominis is attached to the inner surface of the lower six costal cartilages, the thoracolumbar fascia, the anterior iliac crest and the lateral part of the inguinal ligament. Medially, the fibres become aponeurotic and form the posterior part of the rectus sheath. Inferiorly, the aponeurosis blends with that of the internal oblique to form the conjoint tendon.

The inguinal region

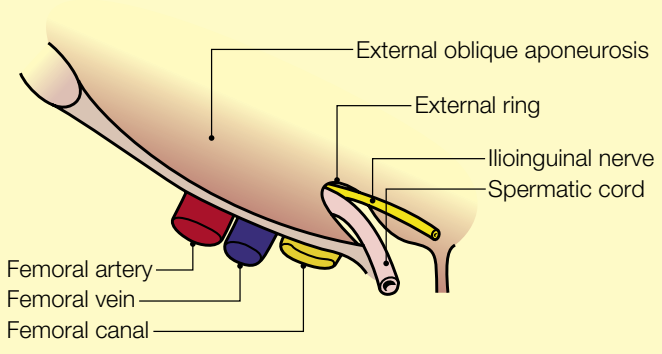
The inguinal canal (Figures 1 and 2) is an oblique path through the lowest part of the anterior abdominal wall. It extends from the deep inguinal ring, a deficiency in the transversalis fascia just above the midpoint of the inguinal ligament, to the superficial inguinal ring, a deficiency in the external oblique aponeurosis, lying above and medial to the pubic tubercle.

Horizontal section through the inguinal canal



1

Inguinal canal showing anterior wall



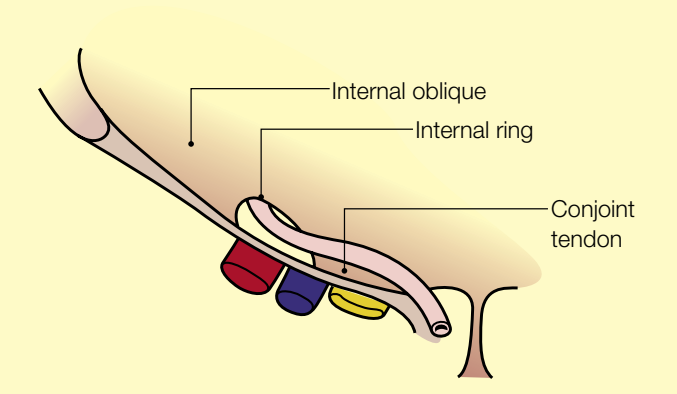
2

It is covered anteriorly by the external oblique aponeurosis which is reinforced laterally by the muscle fibres of internal oblique.

Its posterior wall is formed by transversalis fascia throughout but this is reinforced by the conjoint tendon medially.

Its floor is the re-curved edge of the inguinal ligament and its roof the lowest fibres of internal oblique (Figure 3).

Inguinal canal with external oblique removed

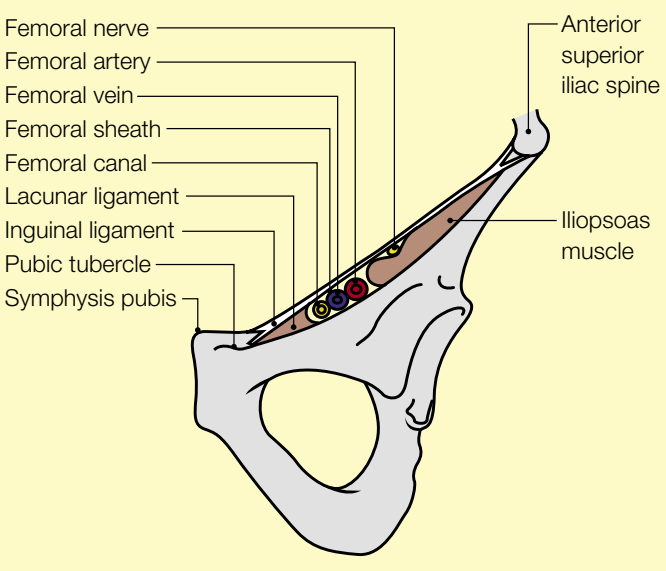


3

It contains the ilioinguinal nerve and the spermatic cord in the male and the round ligament of the uterus in the female.

The femoral artery lies deep to the inguinal ligament which separates it from the deep inguinal ring and its pulsation can be found at the midinguinal point, half-way between the anterior superior iliac spine and the symphysis pubis. Medial to the artery is the femoral vein. Both vessels are invested in a fascial sheath, the femoral sheath which also contains, medial to the vein, the femoral canal (Figure 4).

Structures lying deep to the inguinal ligament



4

Hernias

Hernias are common in the inguinal region. Congenital inguinal hernias, present from birth, are caused by the persistence of a patent peritoneal sac within the spermatic cord. The hernial sac pursues an oblique course through the length of the inguinal canal and is known as an indirect inguinal hernia. From middle age onwards the direct inguinal hernia is common. It results from weakness in the posterior wall of the inguinal canal. It presents as a forward protrusion of the peritoneal sac. Femoral hernias are less common. They occur via the femoral sheath through the narrow unyielding femoral ring immediately below the inguinal ligament. ◆

Anatomy of Tracheostomy and Laryngotomy

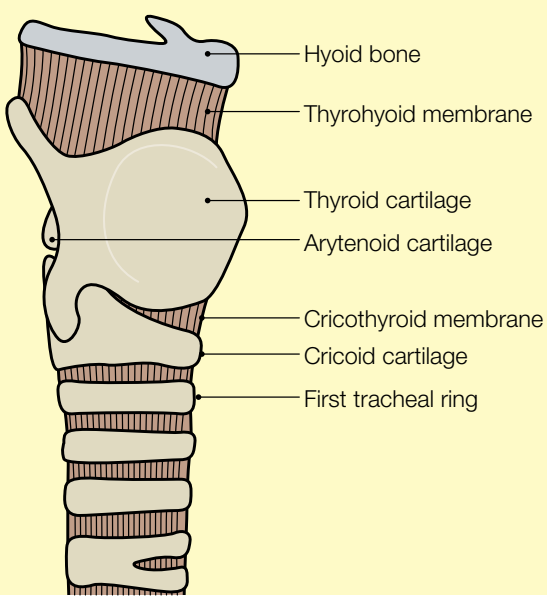
Anil Patel

Anil Patel is Consultant Anaesthetist at the Royal National Throat, Nose and Ear Hospital, London. He qualified from University College, London, and trained in anaesthesia at Guy's Hospital, London.

Knowledge of the anatomy of the upper respiratory pathway is essential for the safe practice of tracheostomy, in which a hole is made in the anterior tracheal wall, and laryngotomy or cricothyroidotomy, in which a hole is made through the cricothyroid membrane.

The larynx consists of articulating cartilages linked together by ligaments. It lies opposite the 4th, 5th and 6th cervical vertebrae. The thyroid notch of the thyroid cartilage can be palpated anteriorly and the cricoid cartilage below this (Figure 1). The cricothyroid ligament lies between the thyroid and cricoid cartilage.

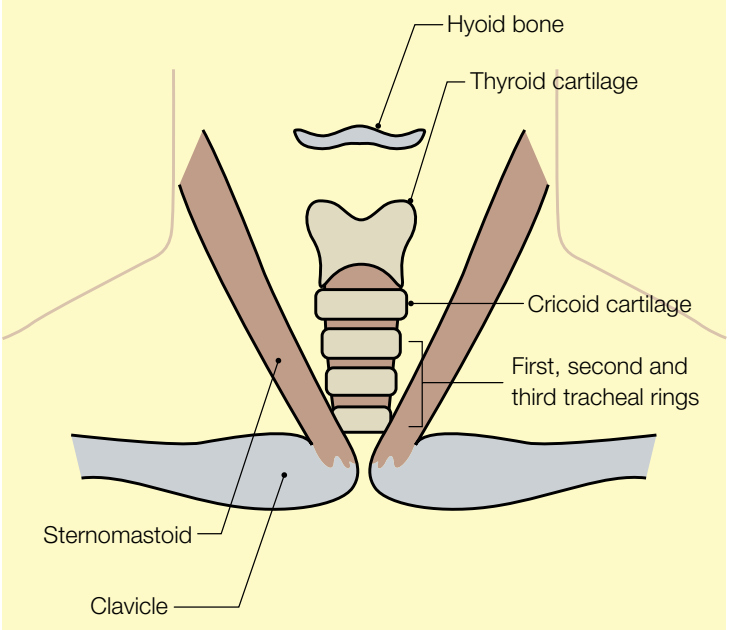
Anatomy of the trachea



1

The trachea starts at the lower end of the cricoid cartilage at the level of the 6th cervical vertebrae and descends through the superior mediastinum to terminate at the bifurcation at the 4th thoracic vertebrae (Figure 2).

Features of the throat



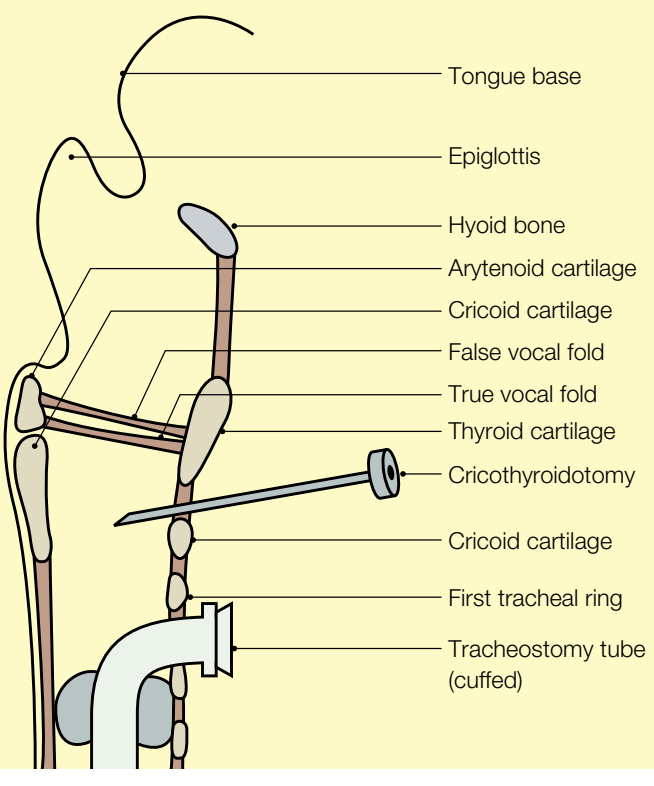
2

Anterior relations – anteriorly in the neck the trachea is covered by skin, superficial fascia, deep fascia, thyroid isthmus overlying 2nd, 3rd and 4th tracheal rings and lower in the neck strap muscles (sternohyoid and sternothyroid).

The blood supply of the larynx is from the superior and inferior laryngeal artery branches of the superior and inferior thyroid artery, respectively. Venous drainage is into superior and inferior thyroid veins.

Laryngotomy or cricothyroidotomy (Figure 3) – an incision is made through the skin, fascia and avascular cricothyroid membrane to enter the upper airway.

Position for cricothyroidotomy and tracheostomy



3

Tracheostomy (Figure 3) – an incision is made midway between the cricoid ring and suprasternal notch, the strap muscles are separated in the midline and retracted laterally, the thyroid isthmus is retracted upwards or divided and a circular window created between 2nd and 3rd or 3rd and 4th tracheal rings. ◆

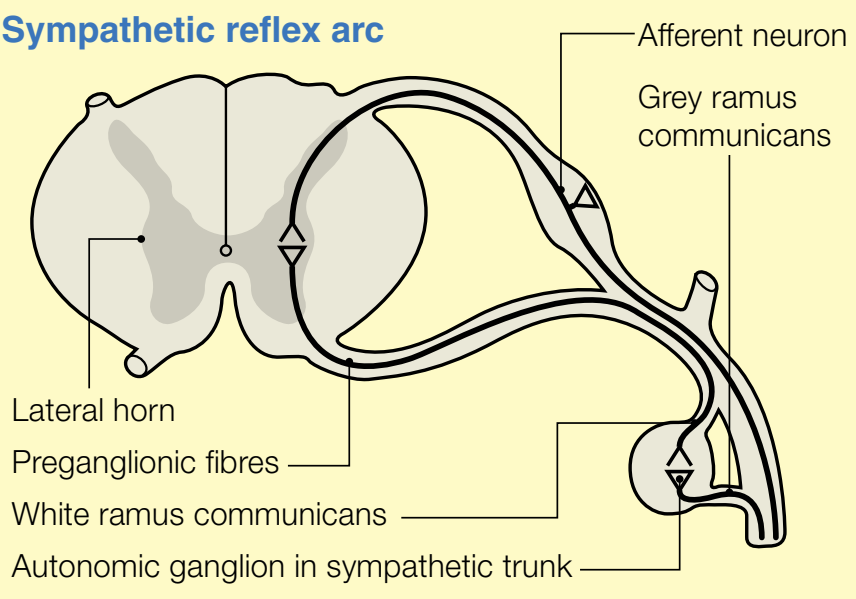
The Autonomic Nervous System

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

The autonomic nervous system supplies viscera, glands and smooth and cardiac muscle. Its fibres arise in the lateral columns of the spinal cord, synapsing with peripheral ganglion cells before supplying these structures (Figure 1). The two complementary parts of the autonomic nervous system (sympathetic and parasympathetic) leave the CNS at different sites and usually have opposing effects on the structure they supply through endings that are mainly adrenergic or cholinergic. The sympathetic system prepares the body for 'fight or flight' and the parasympathetic system controls its vegetative function.

Sympathetic reflex arc

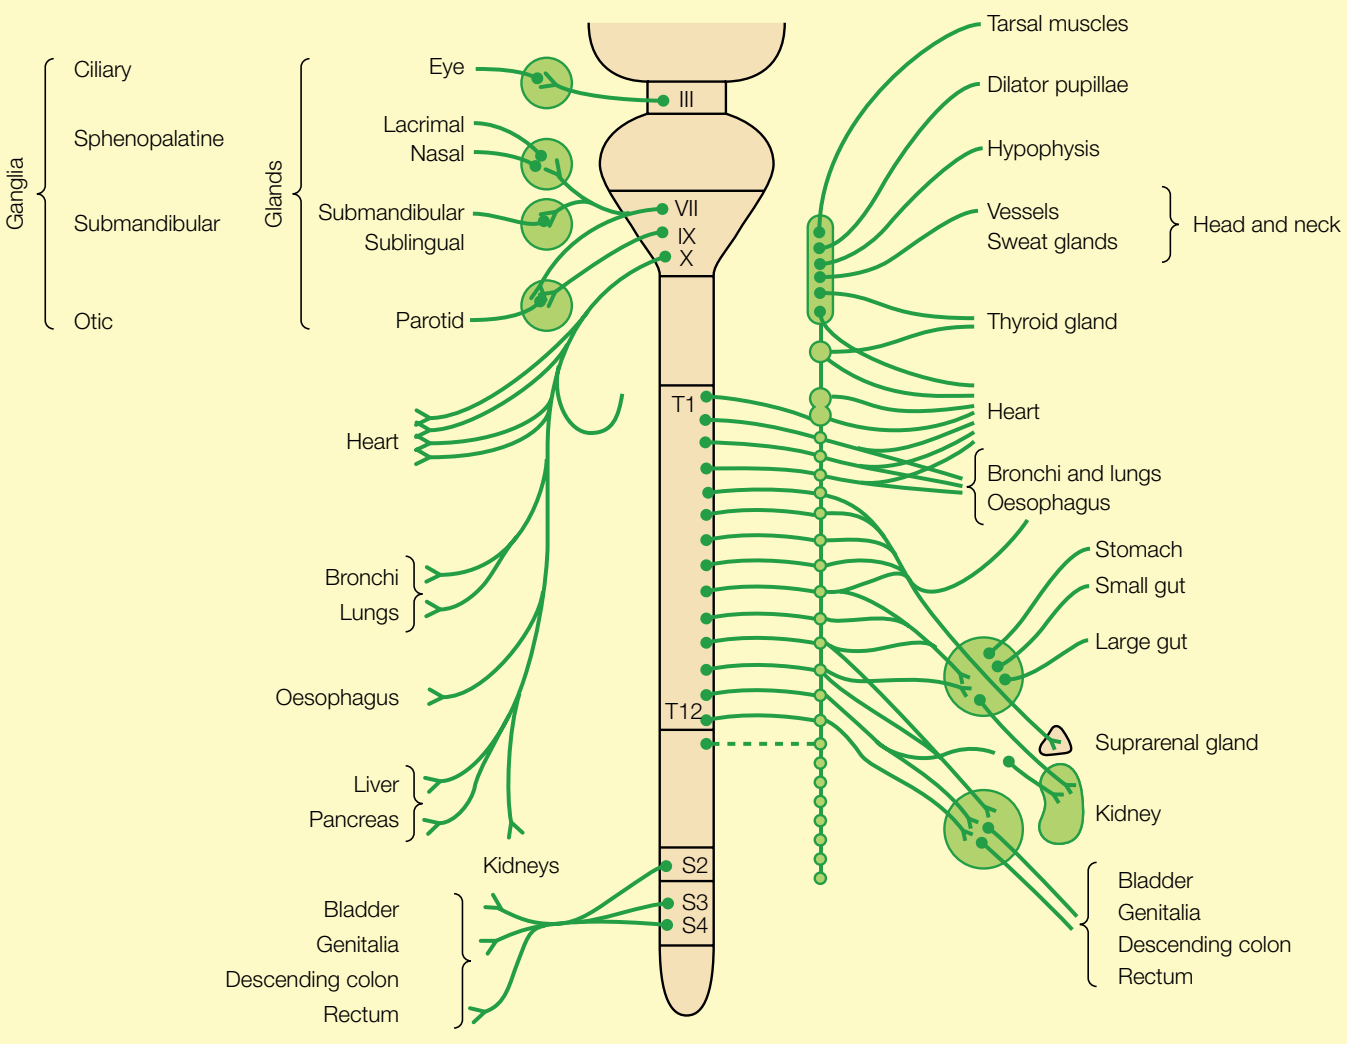


1

Sympathetic system
In the sympathetic system preganglionic fibres arise from the lateral columns in segments T1–L2, passing for a short distance in the anterior roots of the corresponding spinal nerves before leaving as white, myelinated, rami communicantes to join the sympathetic trunk.

The paired sympathetic trunks consist of ganglia and nerve fibres, and extend from the base of the skull to the coccyx. There are three cervical, eleven thoracic, four lumbar and four sacral ganglia and from each pass somatic and visceral fibres (Figure 2).

The autonomic nervous system



2

Somatic fibres are distributed as grey, non-myelinated, postganglionic rami communicantes to each of the 31 spinal nerves supplying vasoconstrictor fibres to arterioles, secretory fibres to sweat glands and pilomotor fibres to the skin. Grey fibres, unlike the white preganglionic fibres, do not run up or down the sympathetic trunk.

Visceral fibres pass to the:

- thoracic viscera and synapse in the cervical and upper thoracic ganglia; their postganglionic fibres pass to the viscera via the cardiac, oesophageal and pulmonary plexuses
- abdominal viscera and pass through the ganglia without synapsing, to enter one of the splanchnic nerves before synapsing in one of the prevertebral plexuses in the abdomen
- adrenal medulla and through the trunk without synapsing, travelling in the greater splanchnic nerve through the coeliac plexus to synapse with ganglion cells in the medulla
- cranial and facial structures (e.g. dilator pupillae, salivary glands) that accompany the carotid vessels; the larynx and pharynx are supplied by postganglionic fibres from the middle cervical ganglion which accompany the inferior thyroid artery.

The cervical sympathetic trunk and the stellate ganglion: see **ANATOMY**.

The thoracic sympathetic trunk comprises 11–13 ganglia and gives branches to all the corresponding spinal nerves; the first is usually fused with the lower cervical to form the stellate ganglion. Visceral branches pass from the upper six ganglia to the pulmonary and cardiac plexuses and three splanchnic nerves. The greater splanchnic nerve (T5–10) ends in the coeliac plexus, the lesser (T9 and 10 or T10 and 11) in the aortic plexus and the lowest in the renal plexus. The coeliac plexus lies around the origin of the coeliac artery and is formed from the greater splanchnic nerve and postganglionic fibres of L1. It is continuous with the network of sympathetic nerves on the aorta, the aortic plexus, the branches of which accompany the branches of the aorta.

The lumbar sympathetic trunk usually comprises four ganglia in each trunk. Its branches pass to the coeliac and hypogastric plexuses, and to each of the lumbar spinal nerves.

The hypogastric plexuses supply the pelvic viscera. The superior plexus receives branches from the coeliac plexus and the sympathetic trunks and its efferent fibres mainly travel in two hypogastric nerves descending on each side of the rectum supplying the rectum, bladder and genitalia. The plexus receives autonomic sensory fibres of pain and bladder and rectaldistension, from the pelvic viscera. The inferior plexus also receive parasympathetic branches from the nervi erigentes (S2–4).

Parasympathetic system
The parasympathetic system is much smaller and comprises a cranial and sacral component on each side. Its actions contrast with those of the sympathetic system – constriction of the pupils, decrease in the rate and conduction of the heart, broncho-constriction, an increase in peristalsis, sphincter relaxation and an increase in glandular secretion. Its pelvic component inhibits the bladder's internal sphincter and it is stimulatory to the bladder's detrusor muscle. Its medulated preganglionic fibres are much longer than those of the sympathetic system and synapse with postganglionic cells close to or in the walls of the viscera they supply. The cranial outflow is conveyed in the oculomotor, facial, glossopharyngeal and vagus nerves (Figure 2). The latter is the largest component and most widely distributed. The parasympathetic nerves of the oculomotor, facial and glossopharyngeal nerves are transmitted via four ganglia through which also pass sympathetic and somatic fibres.

- The ciliary, lateral to the optic nerve, from which passes postganglionic fibres to sphincter pupillae and ciliary muscles.
- The sphenopalatine in the pterygopalatine fossa is supplied by fibres from the greater petrosal branch of the facial nerve; postganglionic fibres supply the lacrimal gland, nasal and pharyngeal glands.
- The submandibular ganglion receives fibres from the facial nerve through the chorda tympani branch and via the lingual nerve which lies on the hyoglossus muscle. Preganglionic fibres pass in the lingual nerve to supply the submandibular and sublingual salivary glands, and oral and pharyngeal glands.
- The otic ganglion receives fibres from the glossopharyngeal nerve via the tympanic plexus and the lesser petrosal nerve; postganglionic fibres pass in the auriculotemporal nerve to the parotid gland.

The parasympathetic supply of the abdomen and pelvis is derived from the vagi and the pelvic splanchnics. The anterior and posterior vagal trunks are distributed through the coeliac plexus along the branches of the aorta to the alimentary tract and its derivatives as far as the splenic flexure. The pelvic splanchnic nerves (S2,3,4) pass to the hypogastric and pelvic plexuses. From the former, branches pass along the inferior mesenteric artery to supply the gut distal to the splenic flexure; from the latter are supplied the pelvic viscera. Their action helps in micturition and defecation by producing relaxation of bladder and bowel sphincters.

The Axilla

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

The axilla is a fat-filled space, the shape of a truncated cone, lying between the lateral thoracic wall and the arm. At its apex it is bound by the upper border of the scapula, the outer border of the first rib and the middle third of the clavicle and it is through this that structures pass from the posterior triangle of the neck to the upper limb. The base of the axilla is formed by skin and subcutaneous tissue. It is bounded anteriorly by the pectoralis major and, deep to that, pectoralis minor. The posterior wall extends lower than the anterior wall and is formed, from above downwards by subscapularis, latissimus dorsi and teres major muscles. The axilla is limited medially by the upper ribs and intercostal spaces, which are here covered by slips of the serratus anterior muscle. The lateral wall is thin and is represented by the narrow intertubercular groove of the humerus, into the lips of which the muscles of the anterior and posterior walls are inserted. It contains the axillary artery and vein, cords and branches of the brachial plexus, coracobrachialis and biceps, axillary lymph nodes and vessels, and fat.

The axillary artery begins as the continuation of the subclavian artery at the outer border of the first rib below the middle of the clavicle. It passes through the axilla to become the brachial artery as it leaves at the lower border of teres major. Throughout its course it lies on the muscles of the posterior wall of the axilla and is surrounded by the cords and branches of the brachial plexus. The axillary vein lies medial to this neurovascular bundle; coracobrachialis and the short head of biceps are lateral. Anteriorly, the vessels and nerves are crossed by the pectoralis minor. It supplies branches to the upper thoracic wall, the muscles of the axilla and the shoulder joint. Its largest branch, the subscapular artery, gives an important contribution to the scapular anastomosis, which provides a collateral circulation to the upper limb in the event of obstruction of the axillary artery by virtue of its communication with branches of the thyrocervical trunk, which arises from the subclavian artery.

The axillary vein is a continuation of the brachial vein and ascends through the axilla, medial to its artery, before leaving it to become the subclavian vein at the outer border of the first rib. Its branches correspond to those of the artery, apart from the cephalic vein which drains the superficial tissues of the upper limb. It ascends in the groove between pectoralis major and deltoid muscles before piercing the deep fascia just below the clavicle. Obstruction of the axillary vein by a thrombus, though not as common as that of the leg veins, occasionally occurs after prolonged infusion of hyperosmotic fluids and/or intravenous nutrition. It results in acute swelling of the arm and the possibility of pulmonary embolus.

The brachial plexus is described elsewhere. The three cords of the plexus (lateral, medial, posterior) are named according to their position around the axillary artery.

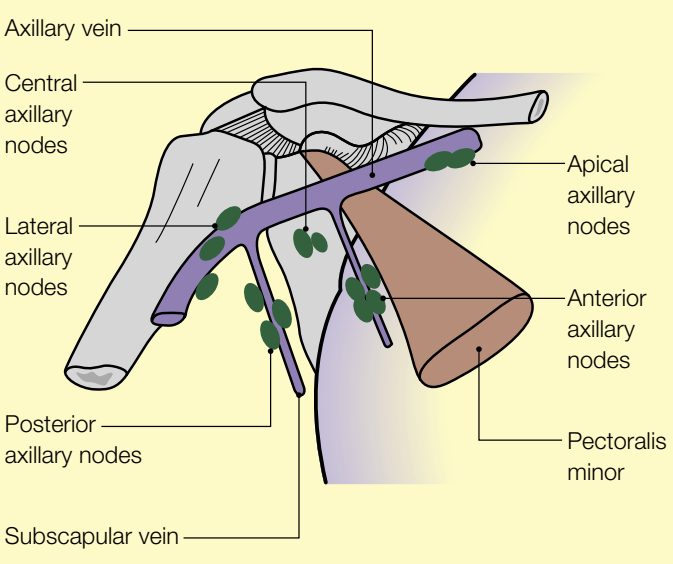
Lymph system

Lymph vessels are superficial or deep. The superficial group drains the skin; medially the vessels accompany the basilic vein and terminate in the axillary nodes; laterally the vessels accompany the cephalic vein and drain via infraclavicular nodes into the axillary nodes.

The axillary lymph nodes are of considerable clinical importance because they drain the arm, the upper abdominal wall and the pectoral region and also receive most of the lymphatic drainage of the breast. They are arranged in five groups (Figure 1).

- The anterior group lie deep to pectoralis major draining the lateral and anterior chest wall, the breast and the upper abdominal wall.
- The lateral group lie on the lateral wall of the axilla and receive the efferent vessels from the upper limb.
- The central group are arranged around the axillary vessels in the axillary fat.
- The posterior group lie to the lateral edge of the subscapularis muscle on the posterior wall of the axilla.
- The apical group lies at the apex of the axilla immediately behind the clavicle; they are continuous with the inferior deep cervical nodes and receive drainage from all the preceding groups.

Lymph nodes of the axilla



1

A subclavian lymph trunk conveys the lymph from the apical group to the right jugular trunk or the thoracic duct. Lymphoedema, an excessive accumulation of tissue fluid, occurs when the lymph trunk becomes disrupted or obstructed. In the developed world, the most common cause of this occurring in the arm is a combination of radiotherapy and surgical excision of the axillary lymph nodes in the treatment of advanced breast cancer. ◆

Central Nervous System

John S P Lumley

John S P Lumley is Professor of Surgery and Honorary Consultant at St Bartholomew's Hospital, London, UK. He is past World President of the International College of Surgeons. His main clinical and research interests relate to the surgery of cerebrovascular diseases and microvascular surgery.

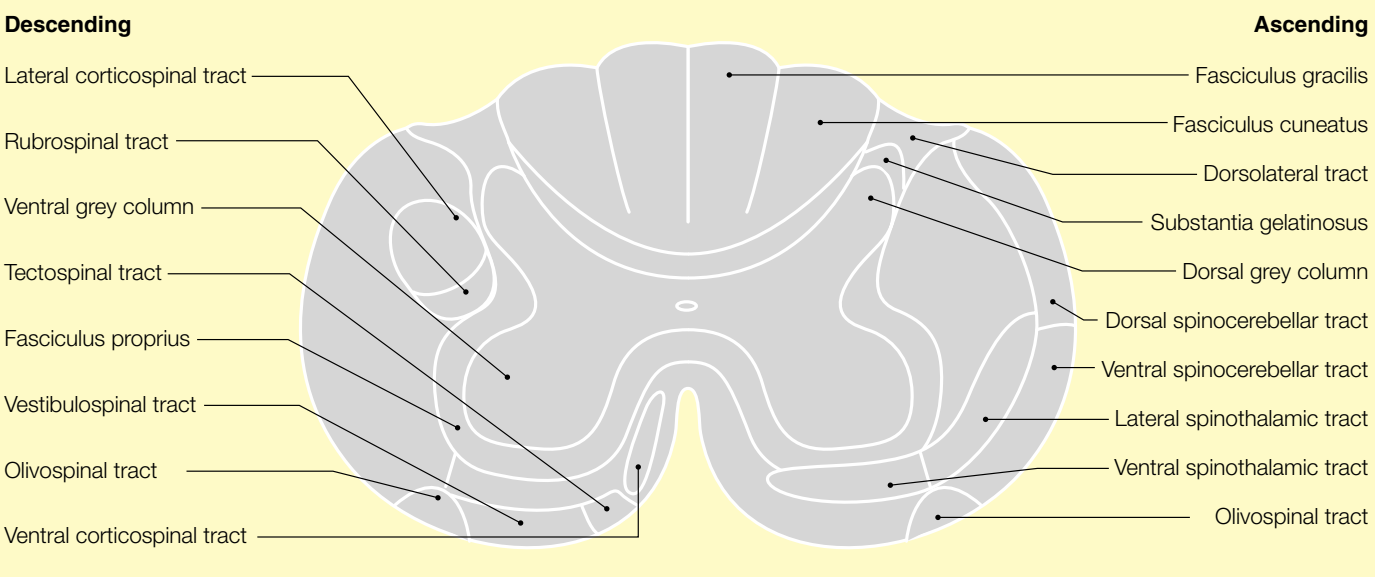
The brain and spinal cord develop from a longitudinal dorsal tube of neural plate ectoderm. The walls of the tube become greatly expanded by the cell bodies, dendrites and axons of the developing neurons, and peripheral neural extensions from the paired 12 cranial and 31 spinal (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal) nerves making up the peripheral nervous system. The spinal nerves carry somatic sensory fibres and innervate skeletal muscle. In addition, the cranial nerves carry special sensory fibres from the head and neck and supply branchial arch musculature.

The autonomic nervous system overlaps the central and peripheral nervous systems. It innervates smooth and cardiac muscle, and glands, and carries visceral sensory fibres. The complementary sympathetic and parasympathetic parts of the autonomic system are carried, respectively, in the thoracolumbar (T1–L2) and craniosacral (cranial nerves 3, 7, 9, 10 and S2, 3, 4) outflow.

Spinal cord

The spinal cord retains its longitudinal cylindrical form. Its fine central canal is surrounded by cellular grey matter. The dorsal horns have a predominantly sensory function and the ventral horns contain motor neurons. The fibres in the peripherally placed white matter are organized into tracts (Figure 1).

Principal descending and ascending pathways of spinal cord



1

Brain stem

The brain stem is made up of the medulla and pons of the hindbrain, and the midbrain. It is in continuity with the spinal cord below and the diencephalon of the forebrain above. Posteriorly the cerebellum is united to it by three paired cerebellar peduncles. The brain stem and cerebellum lie within the posterior cranial fossa, the midbrain passing through the anterior midline opening of the dural roof of the fossa – the tentorium cerebelli. The brain stem gives attachment to, and contains the nuclei of, the 3–12 cranial nerves. It gives passage to the ascending and descending fibres from forebrain to the spinal cord, and the afferent and efferent fibres to the cerebellum.

The crossed and uncrossed corticospinal pathways form the prominent pyramids of the anterior medulla. These bundles are broken up in their passage through the pons but form part of the cerebral peduncles in the midbrain. The olivary nuclei produce anterolateral oval longitudinal swellings in the upper medulla before forming the ipsilateral inferior cerebellar peduncles. The pons forms the prominent anterior convexity between the medulla and midbrain, and is formed of transversely running fibres passing posterolaterally to become the middle cerebellar peduncle.

The midbrain is formed anteriorly by the cerebral peduncles, containing frontoparietal and frontotemporal, as well as pyramidal fibres. Posteriorly are the paired inferior and superior colliculi concerned with the integration of auditory and visual sensation, respectively. The intervening tegmentum contains the prominent decussation of the superior cerebellar peduncles, passing to the red nuclei.

The cerebellum is attached by the inferior, middle and superior cerebellar peduncles, respectively, to the medulla, pons and midbrain. It comprises a central, midline vermis and a hemisphere on each side. A deep primary transverse fissure divides anterior and posterior lobes and the posterolateral fissure, across the caudal surface of the cerebellum, separates the posterior and flocculonodular lobes. The ridges (folia) of the greatly convoluted surface represent only one-sixth of this area, the remainder lining the deep sulci.

Most afferent fibres to the cerebellar cortex end in the middle granular and outer molecular layers, where a profuse dendritic network of flask-shaped, Purkinje fibres is situated. The complex circuitry of the cortical neuronal units and the profuse connections of the cerebellum uniting all major motor regions throughout the CNS, provide an integrative control of motor function, not only in locomotion but also in posture, tone and equilibrium.

The reticular formation is an extensive collection of nuclear masses in the brain stem, partly organized into median, medial and lateral columns. It forms an isodendritic core traversing the entire brain stem. The reticular formation has extensive connections, both crossed and uncrossed, with input and back projection to and from all parts of the CNS, including the spinal cord, diencephalon, limbic system and the neocortex. It influences somatic and visceral neural activity. Investigation has shown a complex facilitatory and inhibitory synaptic transmission. The diffuse nonspecific activity is linked with arousal, levels of consciousness, sleep patterns and biorhythms, together with providing an ascending sensory gating mechanism that influences all forms of behaviour.

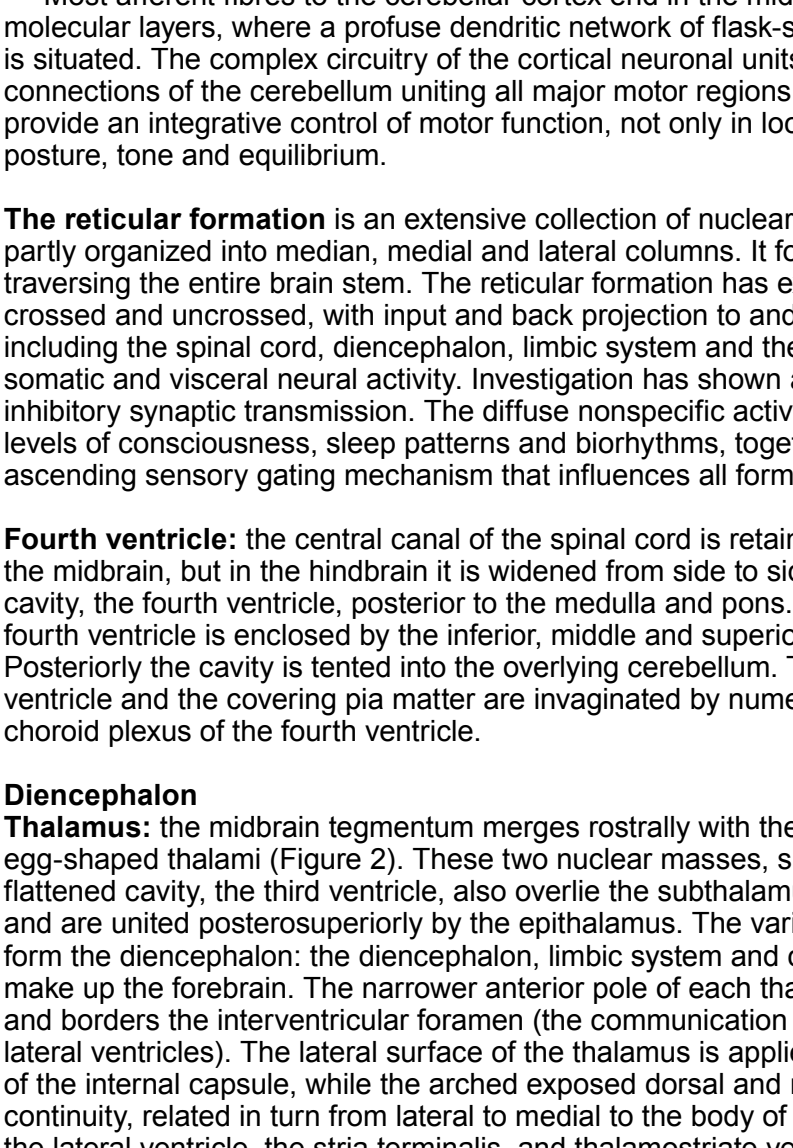
Fourth ventricle: the central canal of the spinal cord is retained as the aqueduct in the midbrain, but in the hindbrain it is widened from side to side into a diamond-shaped cavity, the fourth ventricle, posterior to the medulla and pons. On either side, the fourth ventricle is enclosed by the inferior, middle and superior cerebellar peduncles. Posteriorly the cavity is tented into the overlying cerebellum. The ependyma lining of the ventricle and the covering pia matter are invaginated by numerous vessels to form the choroid plexus of the fourth ventricle.

Diencephalon

Thalamus: the midbrain tegmentum merges rostrally with the inferior surface of the egg-shaped thalami (Figure 2). These two nuclear masses, sitting on either side of a flattened cavity, the third ventricle, also overlie the subthalamus and the hypothalamus, and are united posterosuperiorly by the epithalamus. The various thalamic structures form the diencephalon: the diencephalon, limbic system and cerebral hemispheres make up the forebrain. The narrower anterior pole of each thalamus is near the midline and borders the interventricular foramen (the communication between the third and lateral ventricles). The lateral surface of the thalamus is applied to the posterior limb of the internal capsule, while the arched exposed dorsal and medial surfaces are in continuity, related in turn from lateral to medial to the body of the caudate nucleus, the lateral ventricle, the stria terminalis, and thalamostriate vein, the stria medularis and the third ventricle.

Pain reaches consciousness at the thalamic level, though it is poorly localized, while thalamic injury alters the discrimination of all sensation. The thalamus serves to integrate somatic and visceral function. This has a powerful influence on emotional and endocrine activity, and profound effects on the arousal reaction.

Coronal section through the brain showing relations of thalamus and striatum



2

Subthalamus is that part of the diencephalon merging inferiorly with the red nucleus and substantia nigra of the midbrain; superiorly with the lateral thalamic nuclei; and anteriorly it lies adjacent to the hypothalamus. Anterolateral to the subthalamus the cerebral peduncles of the midbrain become the posterior limbs of the internal capsule. The area contains the discrete subthalamic nucleus on each side and a grey lamina, the zonar inserrata, passes rostrally in front of the thalamus.

The subthalamus is the site of integration of motor centres, particularly the midbrain tegmentum, the corpus striatum and dorsal thalamic nuclei. Prominent bands of fibres, the funiculus and ansa lenticularis, traverse the internal capsule, uniting the corpus striatum and dorsal thalamic regions. Lesions of the subthalamus produce hemibalismus, with disabling and violent uncontrolled choreiform movements, predominantly of the limbs, suggesting loss of corpus striatal control over the motor cortex.

Hypothalamus lies in the midline in the floor of the third ventricle anterior to the subthalamus and below the two thalami. Anteroinferior to the hypothalamus is the optic chiasm, and behind this an elevation (the tuber cinereum) gives rise to the stalk (infundibulum) of the pituitary. Two small elevations (the mamillary bodies) lie behind the tuber cinereum, and separate it from the posterior perforated substance and the cerebral peduncles of the midbrain.

The medial parts of the hypothalamus have a number of named nuclear masses, the more obvious being the preoptic, supraoptic, paraventricular, dorsomedial, ventral, ventro-medial, infundibular and posterior. Afferent fibres pass to the hypothalamus from the orbital surface of the frontal cortex, the septal nuclei, the hippocampus (through the fornix) and the amygdaloid nucleus (through the stria terminalis). Afferent fibres pass in the median forebrain bundle and dorsal longitudinal bundle to the midbrain reticular nuclei. Fibres from the mamillary bodies pass to the anterior nucleus of the thalamus (mamillothalamic tracts) and the midbrain (mamillotegmental tracts).

The hypothalamus has powerful influences on anterior and posterior lobe hormone production of the pituitary, but the associated behavioural changes, particularly those of an emotional nature, are closely linked to its connections with the limbic system. The area is concerned with temperature regulation and control of circadian rhythms. A rigid hypothalamic division of the autonomic regulation of the parasympathetic and sympathetic nervous systems is no longer supported, but the region has profound influence on the cardiovascular, respiratory and alimentary systems.

Epithalamus: the midline epithalamus is situated in the posterior wall of the third ventricle between the posterior ends of the thalami. It comprises the habenular nuclei and commissure, the posterior commissure and the pineal body. The habenular nuclei receive the stria medullaris, a narrow bundle of fibres passing backwards over the thalamus from the septal nuclei. Its efferents pass through the habenular commissure to the interpeduncular nucleus of the subthalamus. The habenular nuclei and connections contain a large number of neuromed-iators and these influence, particularly through hypothalamic connections, gastrointestinal function, metabolism and thermal regulation. The posterior commissure unites the two superior colliculi and the medial longitudinal bundles of the two sides. It is a focus of interaction of olfactory, visual and somatic afferent pathways.

The pineal body develops as an outgrowth from the third ventricle. It is an oval mass lying between the superior colliculi. It has a powerful inhibitory effect on the hypothalamus, releasing factors influencing thyroid, adrenal and gonadal hormone secretion. Serotonin secretion and melanin production are reduced by photic stimulation and the organ probably influences circadian rhythmicity.

Cerebral hemispheres
The dorsolateral aspect of each side of the primitive forebrain undergoes extensive expansion, at first backwards and then anteroinferiorly to form the hemisphere. The two limbs of this expanded hemisphere overlap a submerged area of cortex known as the insula. The line of contact is termed the lateral fissure. The areas of the hemisphere are named after the bones that overlie them. The anterior and posterior extremities are respectively the frontal and occipital poles of the frontal and occipital lobes, with the parietal lobe in between. The anteroinferior extension of the hemisphere is the temporal lobe, housed within the middle cranial fossa, its apex being the temporal pole.

The rostral end of the primitive forebrain persists as a thin glial sheet, the lamina terminalis, passing from the optic chiasm to the anterior commissure and corpus callosum. The adjacent area on the inferior surface of each hemisphere houses the olfactory bulb, tract and medial and lateral olfactory striae.

The surface of the hemisphere is convoluted, the exposed gyri being only one-third of the surface area, the rest being hidden from view in the sulci. The sulci and gyri have characteristic patterns (Figure 3). The central and calcarine sulci provide the anterior and posterior limits of the parietal lobe. The surface is covered by a cellular outer layer of grey matter – the cortex, or pallium. The human neocortex is a highly organized neuronal hemispheric covering with a great deal of functional localization. Conflicting literature on these subjects is partly a result of the evidence being predominantly derived from non-human studies. For example, Brodmann's mapping of 52 cortical areas in 1909, while providing a useful reference grid, was based on comparative studies of simian brains and did not include the human cortex.

Left hemisphere functional localization

3

Cortical cells are predominantly of two types: pyramidal (agranular) and stellate (granular). Pyramidal cells vary from small (10 μ) to very large (70 μ), the latter including the Betz cells characteristic of the human motor cortex. They have a large apical dendrite and each forms the core of a columnar unit extending through the cortex, having numerous horizontal communications, and many inter-hemispheric and projection fibres. This unit has enormous potential for intercommunication and interconnections, each column having more than a thousand interconnecting neurons. Stellate cells are 6–8 μ in diameter with a short axon and an extensive dendritic field: they are of various shapes (e.g. the basket cell). Different workers have used the dispersion of these cell types to identify major cortical areas. The most favoured system identifies six cortical layers: Brodmann's mapping was based on this template.

In spite of the variable phylogical patterns throughout the pallium, with the exception of the striate cortex, there is remarkable homogenicity of cellular numbers and ratios of the two prime cell types: independent of the thickness (1.5–4.5 mm). Two-thirds of neurons in any area are pyramidal and one-third stellate. The striate cortex, while representing only 3% of the surface, contains 10% of cortical neurons.

Anatomical localization based on single projections to an area is oversimplistic, because all areas of the pallium receive and project extensively by association and commissural fibres, to the dorsal and reticular thalamic nuclei, the corpus striatum and pons, and other areas throughout the CNS.

Initial focal pathology and anatomical localization of cortical somatomotor and sensory pathways were supported in humans by operative recording and stimulation, by Penfield and Rasmussen in the 1950s. However, stimulation of the motor cortex never produced a co-ordinated movement, emphasizing that functional localization is linked to association and efferent pathways, being more a mosaic than a clear body image. The trend has thus been to label the first or leading area (e.g. Brodmann 4 as MsI) and adjacent associated areas as secondary or tertiary fields (Brodmann 6, 8 as MsII, III). Secondary areas in motor and sensory localization are involved with coordination and discriminative interpretation, and generally linked with behavioural activity.

Asymmetrical localization was recognized by early workers undertaking cortical mapping, but Broca's classical studies linked speech with the left hemisphere. It became fashionable to attribute speech and linguistic comprehension to a 'dominant' hemisphere and although this was supported by pathological studies, other functions such as spatial comprehension and musicology can be attributed to the 'non-dominant' counterpart. In the intact brain, the complementary nature of the two hemispheres ensures appropriate concise complex bilateral responses to multifactorial stimuli.

Hemisphere white matter is organized into commissural fibres, uniting the two hemispheres across the midline; association fibres joining adjacent or widely separated gyri of the same hemisphere: and projection fibres to or from lower-lying parts of the CNS.

The largest commissural band is the corpus callosum in which 200 million fibres unite corresponding areas on the two sides. The callosum develops with the enlarging hemispheres extending in hook-like fashion from the lamina terminalis, at first forwards and then horizontally backwards over the diencephalon, the space between them being the transverse fissure. The point of continuation with the lamina terminalis is termed the rostrum, the anterior bend the genu, and the main bulk the body. The posterior thickest portion of the corpus callosum, overhanging the posterior thalami, epithalamus and midbrain colliculi, is termed the splenium. Despite this extensive point-to-point communication, the rare congenital absence of the structure in the human may go unnoticed.

Cortical projection fibres pass predominantly in the internal capsule, a broad V-shaped band lying between the caudate nucleus and thalamus medially, and the lentiform nucleus laterally. It fans out within the hemisphere as the corona radiata, interdigitating with the transverse fibres of the corpus callosum. The anterior limb of the capsule lies between the head of the caudate nucleus and globus pallidus, and is crossed by extensive intercommunicating pathways between these structures. It contains frontopontine fibres, from the frontal lobe to the nuclei of the pons, and thalamic and hypothalamic cortical pathways.

The genu, between the anterior and posterior limbs of the internal capsule, contains the corticonuclear fibres passing to the cranial nerve nuclei, while the adjacent part of the posterior limb carries corticospinal fibres from the motor cortex.

Corpus striatum is a group of large nuclear masses situated in the substance of the cerebral hemispheres adjacent to the internal capsule. The caudate nucleus has an expanded head bulging into the anteral horn of the lateral ventricle. It then tapers into a body and tail, curving around the lateral aspect of the thalamus in the wall of the lateral ventricle, at first in the lateral wall and then in the roof of its inferior horn.

The corpus striatum receives fibres from all areas of the neocortex, and also from the thalamus and brain stem. It has dense reciprocal connections with the subthalamus and substantia nigra. Its principal outflow is to the thalamus, particularly the ventral nuclei, the motor and pre-motor cortex, and to the reticular nuclei and thence to the reticulospinal and rubrospinal tracts.

It is involved in motor coordination and damage to the structure increases tone, producing resistance to stretch or rigidity. There is also loss of associated movement and sometimes accessory, choreiform, athetoid and ballistic movements and tremor, these being purposeless and uncontrolled. Ablation of the striatum produces poverty of movement and manipulative skills. It has also been used to reduce the tremor and rhythmicity of Parkinsonian movements, although the link with dopamine transmission is unconfirmed.

Limbic system: the median area of anterior fusion of the two hemispheres, together with their medial aspect, are drawn with the developing hemisphere into a C-shape round the thalamus and are developed into a number of distinct nuclear tracts (Figure 4). This region was originally termed the olfactory brain or rhinencephalon. However, the development of this area in the human renders this term meaningless, and the functional name of limbic system is more appropriate.

The system encompasses the bulb, tract, and medial and lateral olfactory striae, the anterior perforated substance between the striae, the adjacent inferior frontal (pre-piriform) cortex on each side, and the anterior commissure linking these structures. Three nuclear masses – the hippocampus, amygdala and septal nuclei, and their projections and commissural fibres, also contribute to the system.

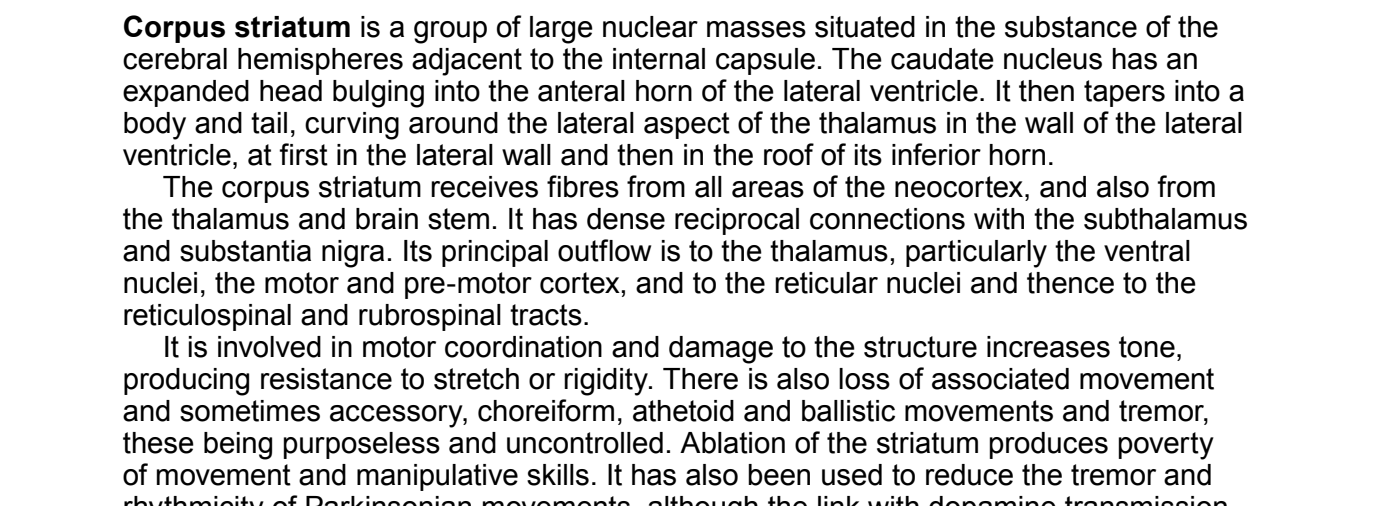
The hippocampus lies in the floor of the inferior horn of the lateral ventricle, three grooves in its distal enlargement giving it a paw-like shape and the name pes hippocampus. Its afferent fibres are from adjacent cortical areas but the sole efferent channel forms on its surface as the alveus, and passes backwards as the fimbria: the two fimbria meet in the midline to form the body of the fornix which projects to the anterior thalamic nuclei.

The amygdala is a composite nuclear mass situated in the roof of the inferior limit of the inferior horn of the lateral ventricle. It connects with its fellow on the opposite side via the anterior commissure and its main efferent pathway is the stria terminalis. This follows the curve of the caudate nucleus and passes anterior to the interventricular foramen and thence to the hypothalamus and septal nuclei. Some fibres then pass backwards within the striae medullaris to the epithalamus. Other fibres pass to the dorsal thalamus.

The septal nuclei are most prominent in humans and lie adjacent to the lamina terminalis. The anterior commissure is embedded within the lamina and carries fibres from the stria terminalis and commissural linkages between the medial olfactory tracts, the anterior perforated substance, the pre-piriform cortex and the amygdala. There are also extensive temporal neocortical connections of ill-defined function.

The complex network of nuclei, fibres and cortical areas in the limbic system is concerned with the interaction of olfactory, visceral and somatic information and is particularly concerned with emotional behaviour.

Limbic system



4

The third and lateral ventricles: the cavity of the forebrain is made up of the midline third ventricle, communicating through two interventricular foramina with the lateral ventricle on each side. The third ventricle lies between the two thalami. Posteroinferiorly, it communicates with the aqueduct of the midbrain and above this is related to the epithalamus, the cavity being recessed into the base of the pineal body. Anteriorly, the third ventricle is limited by the midline lamina terminalis, the original anterior limit of the primitive forebrain.

The lateral ventricle comprises a body and anterior, posterior and inferior horns. The cavity extends backwards from the interventricular foramen over the thalamus and then downwards in a C-shaped curve within the medial aspect of the hemisphere. It is limited laterally by the reciprocally curved body and tail of the caudate nucleus. The ventricle is overlain superiorly by the corpus callosum, as it curves into the temporal lobe; the inferior horn has the hippocampus and overlying fimbria in its floor and is overlain by the amygdala.

The body of the lateral ventricle is completed medially by the fused pial and ependymal layers, the tela choroidea, passing from the undersurface of the fornix to the upper border of the thalamus. In the third and lateral ventricles, the tela choroidea is greatly expanded and infolded into the ventricles to form the choroid plexus which has an extensive capillary network within it. It produces CSF, partly by filtration and partly by secretion from the blood stream. The fluid passes through the midbrain aqueduct into the fourth ventricle, and is added to by the choroid plexus invaginating the roof of the fourth ventricle. It then circulates into the subarachnoid space through pores in the tela choroidea of the fourth ventricle, known as the median foramen of Magendi and lateral foramina of Luschka, between the superior and inferior cerebellar peduncles on each side. The subarachnoid CSF is reabsorbed into the blood stream through venous sinuses and spinal veins, through areas termed arachnoid granulations.

Cervical and Brachial Plexuses

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

There are two plexuses of nerves in the neck:
• the cervical plexus supplies the diaphragm and the skin and muscles of the neck
• the brachial plexus supplies the upper limb.
Each lies on scalenus medius and is formed by the anterior divisions of spinal nerves.

The cervical plexus

The cervical plexus is formed by the upper four cervical nerves, which each receive *rami communicantes* from the superior cervical ganglion. Its most important cutaneous branches are the lesser occipital nerve (C2) and the great auricular nerve (C2, 3). They emerge from the middle of the posterior border of the sternocleidomastoid muscle to supply the neck and scalp posterior to the ear. The muscular branches of the cervical plexus supply the rhomboids, neighbouring prevertebral muscles and the diaphragm via the phrenic nerve (C4 with contributions from C3 and C5). The phrenic nerves contain motor, sensory and sympathetic fibres, which provide the sole motor supply to the diaphragm and sensation to its central portion and the mediastinal pleura. They travel down the neck behind the jugular vein on scalenus anterior and pass anterior to the root of the lung under the mediastinal pleura to reach the diaphragm

The brachial plexus

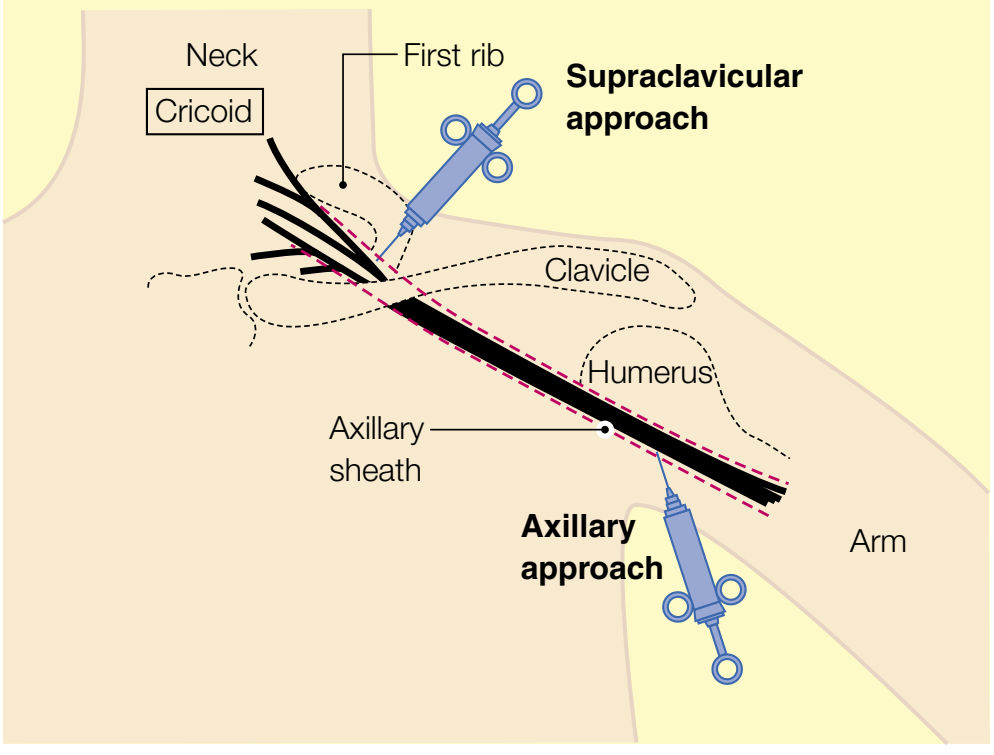
The brachial plexus lies in the posterior triangle of the neck along a line from the middle of the posterior border of the sternocleidomastoid to the middle of the clavicle (Figure 1). Knowledge of the anatomy of the brachial plexus and its branches is of great practical importance to the anaesthetist who may use it to induce regional anaesthesia in the upper limb.

The brachial plexus is formed from the anterior primary rami of the lower four cervical and the first thoracic nerves. These five roots of the plexus emerge between the middle and anterior scalene muscles and unite to form three trunks. The upper two roots (C5, 6) form the upper trunk, the middle root (C7) the middle trunk and the lower two roots (C8, T1) the lower trunk.

Behind the middle of the clavicle, at the apex of the axilla, each trunk divides into anterior and posterior divisions. The three posterior divisions join to form the posterior cord, the anterior divisions of the upper and middle trunks form the lateral cord and the anterior division of the lower trunk continues as the medial cord. The cords lie around the axillary artery related to it as their names imply (Figure 2) and are enclosed with the artery in a neurovascular sheath – the axillary sheath. The posterior cord and its branches supply structures on the dorsal surface of the limb and end by dividing into axillary and radial nerves.

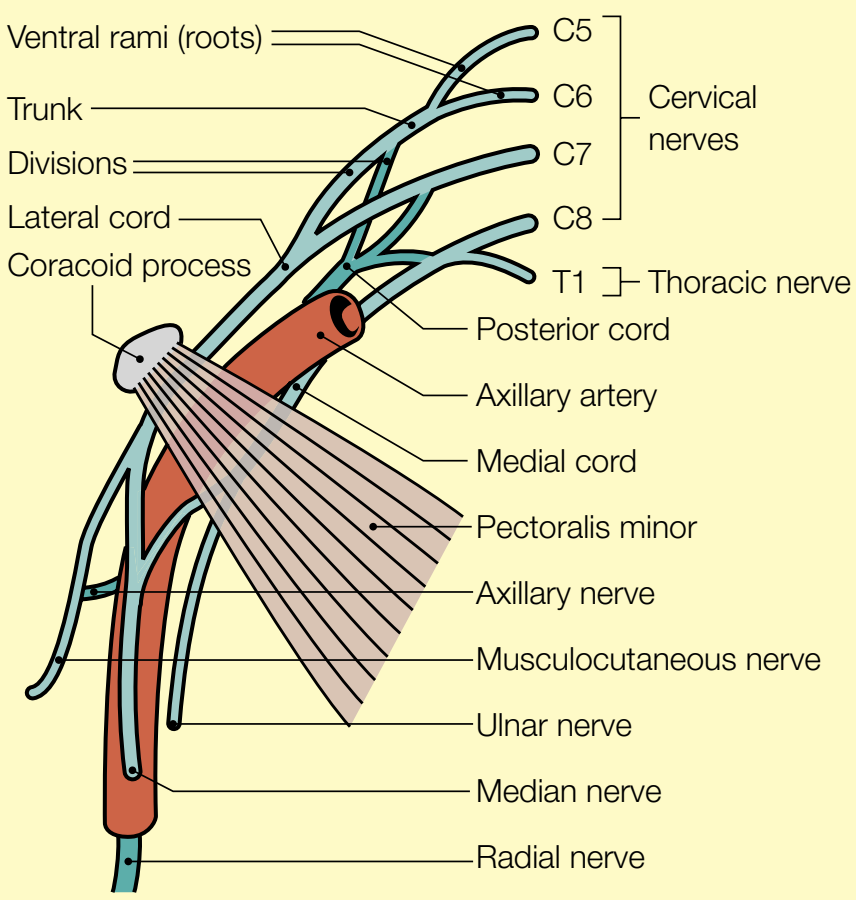
The medial and lateral cords and their branches supply structures on the flexor surface of the limb; the lateral cord ends by dividing into the musculocutaneous nerve and the lateral head of the median nerve, the medial cord ends as the ulnar nerve and the medial head of the median nerve (Figure 3).

Surface anatomy of the brachial plexus emphasizing the approaches for brachial plexus block



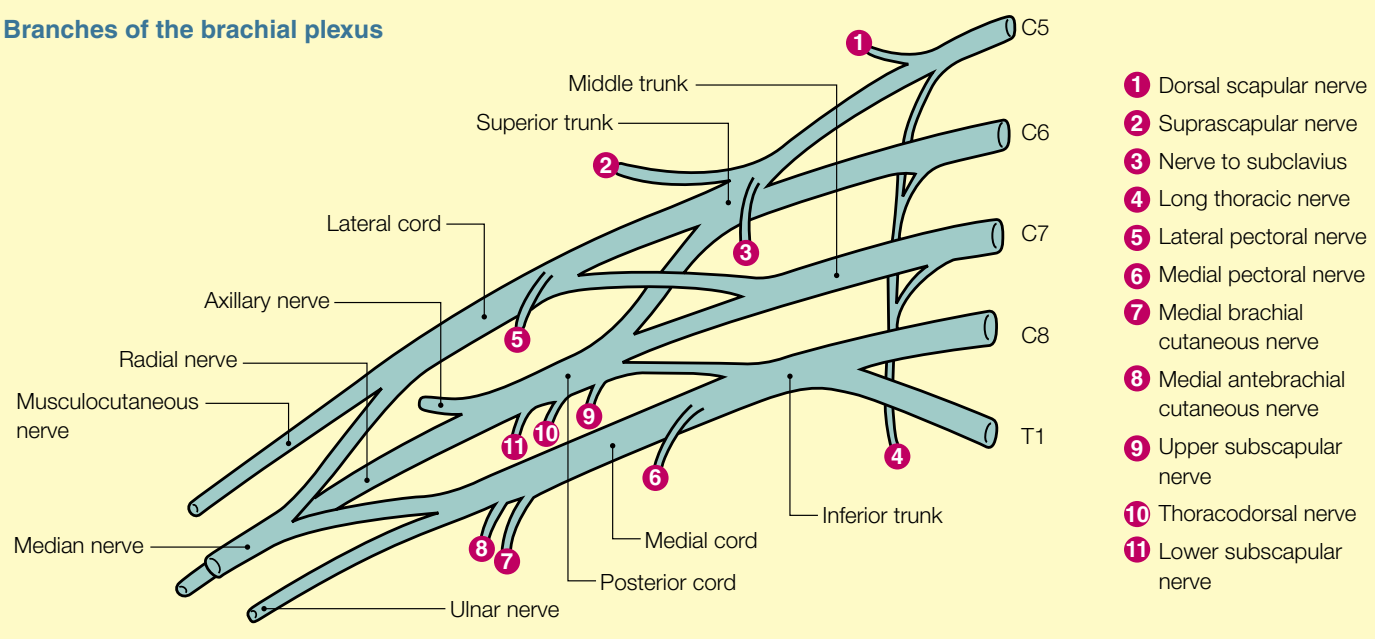
1

Relationship of the brachial plexus to the axillary artery



2

Branches of the brachial plexus



3

Branches of the plexus
From the roots: there are small branches to the back muscles, C5 contributes to the phrenic nerve, the long thoracic nerve passes posteriorly to the medial wall of the axilla to supply serratus anterior.

From the trunks: from the upper trunk arises the suprascapular nerve, which crosses the root of the neck to supply supraspinatus and infraspinatus.

From the lateral cord branches the lateral pectoral nerve, which supplies pectoralis major, the musculocutaneous nerve, which supplies coracobrachialis, biceps and brachialis, before becoming the lateral cutaneous nerve of the arm, and the lateral head of median nerve.

From the medial cord: the medial pectoral nerve supplies pectoralis major and minor, the ulnar nerve supplies flexor muscles in the forearm, small muscles in the hand and the skin of the medial side of the hand. Also branching from the medial cord are the medial head of the median nerve, the medial cutaneous nerves of the arm which supply skin on the medial side of the arm, and the medial cutaneous nerve of the forearm which supplies the skin of the medial side of the forearm.

From the posterior cord the subscapular nerves descend the posterior axillary wall to supply subscapularis and teres major. The thoracodorsal nerve supplies latissimus dorsi by entering its upper border. The axillary nerve descends on subscapularis and turns posteriorly around the surgical neck of the humerus supplying deltoid, teres minor and the shoulder joint before ending as the upper lateral cutaneous nerve of the arm, which supplies a small patch of skin over the insertion of deltoid muscle. The radial nerve is a terminal branch of the posterior cord and descends through the posterior compartment of the arm supplying triceps, brachioradialis and extensor carpi radialis longus and brevis and sensory branches to the skin on the posterior and medial sides of the limb and the posterior surface of the lateral three and a half fingers.

Brachial plexus block
The two techniques most commonly used are described here (Figure 1).

Axillary approach: the patient lies supine, arm abducted to a right angle with the humerus externally rotated. A weal of local anaesthetic is raised over the palpable axillary artery and the needle advanced until the neurovascular sheath is felt to be entered. Anaesthetic solution can then be injected. Finger pressure over the artery distal to the point of injection will prevent the downward spread of the analgesic. There are few complications following this technique and the anatomical landmark is easy to find, but the shoulder joint, supplied by the suprascapular nerve is not anaesthetized.

Supraclavicular approach: the patient lies supine, head rotated away from the side of injection. A weal is raised 1 cm above the midpoint of the clavicle just lateral to the palpable pulsation of the subclavian artery. The needle is advanced downwards, inwards and backwards towards the spine of T4 until a motor jerk or sensation indicates that the needle has pierced the neurovascular sheath. The local anaesthetic solution can then be injected. A cough would suggest that the pleura has been touched or pierced by the needle. This is a more difficult approach to perform safely. Pneumothorax and haematomas due to vessel trauma are well-recognized complications.

Cervical, Thoracic and Lumbar Vertebrae

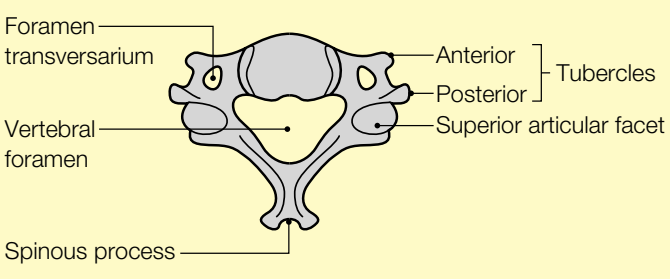
John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

The 33 vertebrae of the vertebral column have a basic form though they show regional differences. They each have a body, neural arch and a vertebral canal. The body is short and cylindrical, with flat upper and lower articular surfaces. The neural arch is made up of paired pedicles that arise from the posterior surface of the body and paired flattened laminae that fuse in the midline posteriorly to form a spinous process. Each arch bears lateral paired transverse processes that arise close to the junction of the laminae and the pedicles, and paired upper and lower articular processes. Each pedicle is notched superiorly and inferiorly and these, with those of their neighbour, form a intervertebral foramen which transmits a spinal nerve. Cervical, thoracic and lumbar vertebrae are recognizable by characteristics that are most marked in their central members, while those at either end of the group tend to resemble in part those of the adjacent group.

A typical cervical vertebra (Figure 1) has an oval small body. Its superior articular surface has lateral lips that articulate by synovial joints with the articular surface of the vertebra above. The vertebral foramen is large. The short wide transverse processes enclose a foramen transversarium, containing the vertebral vessels, and end laterally in anterior and posterior tubercles. The articular processes on the junction of the lamina and the transverse process are large, the superior faces backwards and upwards and the inferior in the opposite direction. The spine is bifid and gives attachment to the neck extensor muscles. The 1st, 2nd and 7th cervical vertebrae vary from this pattern.

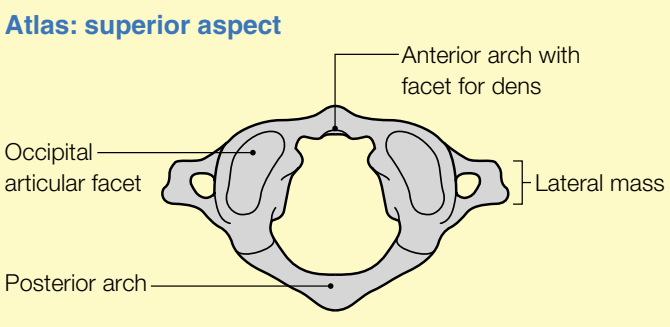
A typical cervical vertebra: superior aspect



1

The 1st cervical vertebra, the atlas, allows free movement of the head and is modified to comprise a ring of bone with neither body nor spine (Figure 2). Two bulky articular lateral masses are united by a short anterior and a longer posterior arch. The superior articular facets are large and oval and articulate with the occiput, the lower facets are smaller. The posterior surface of the anterior arch has a small midline facet for articulation with the dens of the axis, and lateral to this there are two tubercles on the medial surface of the lateral mass for attachment of the transverse ligament of the atlas. The superior surface of the posterior arch is grooved laterally on each side by the vertebral artery. The transverse processes are long and wide and the tip of each is palpable behind the angle of the mandible.

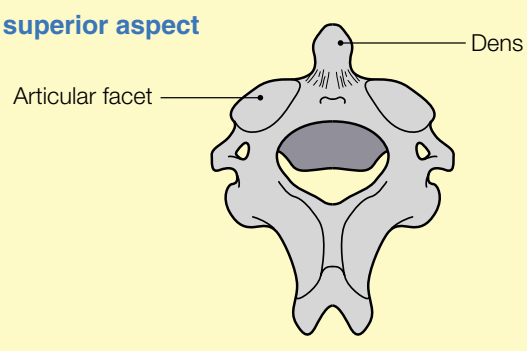
Atlas: superior aspect



2

The 2nd cervical vertebra (Figure 3), the axis, bears a conical projection, the dens on its upper surface which articulates with the anterior arch of the atlas and is held in position by the transverse ligament of the atlas. Lateral to the dens are two large circular upward-facing articular facets.

Axis: superior aspect

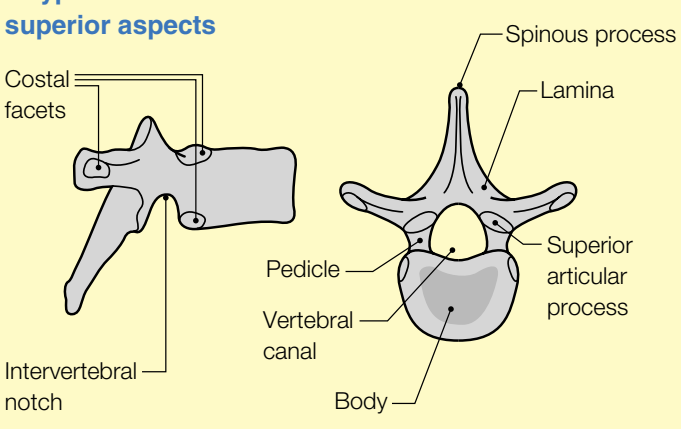


3

The 7th cervical vertebra is also known as the vertebra prominens because it has a long spine, easily palpable on the back of the neck at the lower end of the nuchal furrow.

A typical thoracic vertebra (Figure 4) has a wedge-shaped body that is shallower anteriorly. Each side of each body articulates with a rib at superior and inferior costal facets towards the back of its upper and lower borders. The transverse processes point backwards and laterally, and bear articular facets for articulation with the tubercle of the corresponding rib. The broad laminae and the downward-projecting spines overlap with those of the vertebra below. The bodies of the upper thoracic vertebrae are smaller and narrower; the spines of the lower vertebrae are more horizontal. The transverse processes of the lower two thoracic vertebrae do not bear costal facets. The costal facets on the bodies of the 10th, 11th and 12th vertebrae are normally single and complete.

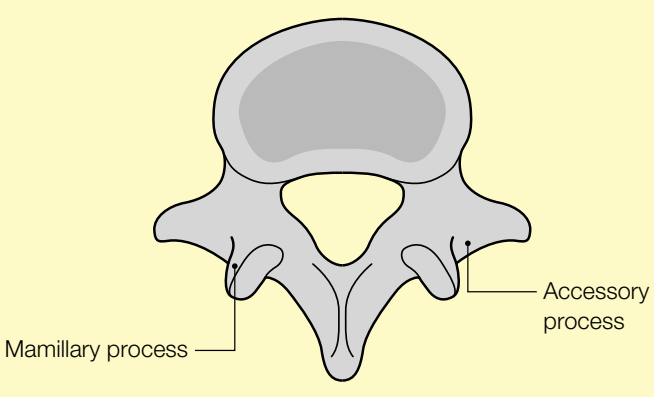
A typical thoracic vertebra: lateral and superior aspects



4

A typical lumbar vertebra (Figure 5) has a larger kidney-shaped body that is wider from side to side. The transverse processes are bulky and project directly laterally. The superior articular facets face backwards and medially, and each spinous process is broad and projects horizontally backwards. The 5th lumbar vertebra is untypical – its body is wedge-shaped, being thicker anteriorly and its transverse process is small and conical.

A typical lumbar vertebra: superior aspect



5

Joints and ligaments

Hyaline cartilage covers the articular surfaces of the vertebral bodies, which are united by a thick fibrocartilaginous inter-vertebral disc. The peripheral fibrous part, the anulus fibrosus surrounds a gelatinous centre, the nucleus pulposus. The discs are, in part, shock absorbers and contribute about 25% of the length of the vertebral column. They are thicker in the cervical and lumbar regions. The vertebral bodies are united by anterior and posterior longitudinal ligaments, which are also attached to each intervertebral disc and extend the length of the vertebral column. The ligamenta flava are formed of elastic tissue and play a part in maintaining the shape of the spine. They unite adjacent laminae. There are also supraspinous, interspinous and intertransverse joints.

Adjacent vertebrae also articulate by plane synovial joints between the paired articular processes. The atlanto-occipital joints are synovial joints with only weak capsular ligaments and the accessory anterior and posterior atlanto-occipital membranes. There are three atlanto-axial joints; two lateral synovial joints between the lateral masses of the two vertebrae and a median joint between the dens of the axis and the ring formed by the transverse ligament of the atlas and its anterior arch. ◆

Cranial Nerves: Part I

John S P Lumley

John S P Lumley is Professor of Surgery and Honorary Consultant at St Bartholomew's Hospital, London, UK. He is past World President of the International College of Surgeons. His main clinical and research interests relate to the surgery of cerebrovascular diseases and microvascular surgery.

The twelve pairs of cranial nerves originate from the forebrain (I–II), midbrain (III–IV) and hindbrain (V–XII), and leave the skull through foramina in the anterior (I), middle (II–VI) and posterior cranial fossae (VII–XII). Collectively, the cranial nerves carry general somatic motor and sensory fibres; general visceral motor and sensory fibres; special somatic sensory fibres; and special visceral motor and sensory fibres. The general somatic motor fibres, passing to somatic mesoderm, are carried in the IIIrd, IVth, XIth and XIIth cranial nerves. The general somatic sensory fibres passing to the skin of the face are carried by the Vth cranial nerve. The general visceral motor and sensory fibres making up the cranial component of the parasympathetic (craniosacral outflow) nervous system, are carried in the IIIrd, VIIth, IXth and Xth cranial nerves. The special somatic sensory fibres comprise the organs of vision (II), and hearing and balance (VIII). The special visceral motor fibres innervate mesoderm derived from the branchial arches, and are carried in the Vth, VIIth, IXth and Xth cranial nerves. The special visceral sensory fibres carry smell (I) and taste (VII and IX).

Damage to cranial nerves may be the first indication of an intracranial lesion and nerve damage is characteristic of various types of head injuries. The identification of cranial nerve lesions and a knowledge of their anatomy are thus an essential part of clinical practice. Cranial nerves I–VI are described in this article, the other cranial nerves will be described in *Anaesthesia and Intensive Care Medicine* **3:5**.

Olfactory nerve (I)

The olfactory mucosa is situated on the upper nasal septum, the roof and the superior concha on the lateral wall of the nose. The 15–20 olfactory nerves innervating this area on each side pass through the sieve-like cribiform plates of the ethmoid bone to the olfactory bulbs. The nerves may be sheared off in anteroposterior impact head injuries, and this may be accompanied by a CSF leak through the nerve channels or through an associated fracture of the cribiform plate.

Optic nerve (II)

The optic nerve passes from the back of the eyeball through the orbit and enters the middle cranial fossa through the optic canal. In the middle cranial fossa the nerves from each side meet in the midline and their medial (nasal) halves decussate at the optic chiasm, before reforming as the right and left optic tracts that pass to, and synapse in, the lateral geniculate body. Each lateral geniculate body projects ipsilaterally through the optic radiation to the visual cortex. (Other fibres from the lateral geniculate body pass to the adjacent ipsilateral superior colliculus of the midbrain; these are concerned with optic reflexes.)

The optic nerve is purely sensory. Its cell bodies form the ganglion layer of the retina and its fibres converge posteriorly at the optic disc. The disc is sited medial to the axis of the eyeball and has no retinal rods or cones; it thus produces the blind spot on visual field mapping. The nerve pierces the sclera to lie within a meningeal sheath that extends from the middle cranial fossa through the optic canal to the back of the eyeball. The sheath is embedded in orbital fat and lies within the cone of extraocular muscles. The ciliary ganglion and the ophthalmic artery lie on its lateral side, the artery is also a lateral relation within the optic canal. Its retinal branch pierces the meningeal sheath about 1 cm behind the globe and for a short distance lies within the CSF, before entering the nerve to become the central artery of the retina.

The optic chiasm lies in the floor of the third ventricle above the hypophysis cerebri and anterior to its stalk. The chiasm lies medial to the termination of the internal carotid artery above the cavernous sinuses. The optic radiation passes distally in the posterior limb of the internal capsule, grooving the floor of the posterior horn of the lateral ventricle. The fibres converge on to the superior and inferior margins of the calcarine sulcus along the medial aspect of the occipital lobe.

Spatial orientation is preserved through the length of the visual pathways. Fibres from the nasal half of each retina (receiving light from the temporal field) cross in the optic chiasm;thus the optic tract, lateral geniculate body, optic radiation and visual cortex of each side receive visual information from the contralateral side. Fibres from the lower retina pass through the temporal lobe to the inferior margin of the calcarine sulcus. Upper quadrant fibres pass through the parietal aspect of the optic radiation and to the upper margin of the calcarine sulcus. The macula is the most sensitive part of the retina, and makes up about 25% of the visual cortex.

Assessment

Assessment of vision is carried out by history, and tests of acuity, visual fields and ophthalmoscopy. The history in-corporates questions on near and distant vision, visual loss, visual phenomena (e.g. blurring, flashes, double vision), ocular pain and headache. Tests of visual acuity and of the visual fields are undertaken in each eye separately (the other eye being covered with a hand or card) and then together. Abnormalities of acuity are predominantly refractory, and patients are assessed with and without their spectacles. Near vision is assessed with varying sized text, distant vision with Snellen charts, and colour with Ishihara cards. Further tests of acuity are carried out by an optician using an appropriate series of lenses.

Clinical assessment of the visual fields is by confrontation of the examiner and subject, each covering in turn an opposing eye, the examiner's other hand is brought in from each quadrant. A red-topped hatpin is used to identify the blind spot and any central defect (scotoma). Both the examiner's hands are used to determine visual preference or suppression of an image on one side. Normal pupils react to light and accommodation.

Ophthalmoscopy is used to examine the anterior aspect of the eye, the cornea, the anterior chamber, iris and lens, and then the posterior chamber and retina.

Abnormalities of vision

Vision is affected by abnormalities of the eye and the neural pathways: these may co-exist. The former include abnormalities of the lens (e.g. refractory errors, cataract) or retina (e.g. detachment, ischaemia, hypertension, diabetic eye disorders); macular degeneration; inflammation; or trauma to the globe. Lesions of the various parts of the visual pathway produce characteristic visual field defects (Figure 1).

Visual defects

1 Tunnel vision with damage to peripheral visual field with night blindness: glaucoma, papillitis, chorioretinitis, retinitis pigmentosa, papilloedema, migraine, hysteria, syphilis

2 Enlargement of blind spot; enlargement of optic head, papillitis, papilloedema

3 Central scotoma with spectrum from enlarged blind spot, patchy scotoma and arcuate lesions to blindness: advanced papilloedema, optic nerve damage or tumours, demyelination, toxic (e.g. methyl alcohol) symmetrical, nutritional, vascular

4 Unilateral blindness: damage to optic nerve, tumours, vascular malformation, severe trauma. In blindness, the visual light reflexes are lost, but the consensual pupillary responses are retained

5 Bitemporal hemianopia: midline pituitary tumours and suprasellar meningiomas

6 Ipsilateral nasal field loss: aneurysms of the internal carotid artery and its proximal divisions, tumours

7, 8, 9 Homonomous hemianopia: tumours, trauma and vascular damage of the optic tract, lateral geniculate body or optic radiation, producing incongruous defects (i.e. unequal involvement of the two half fields)

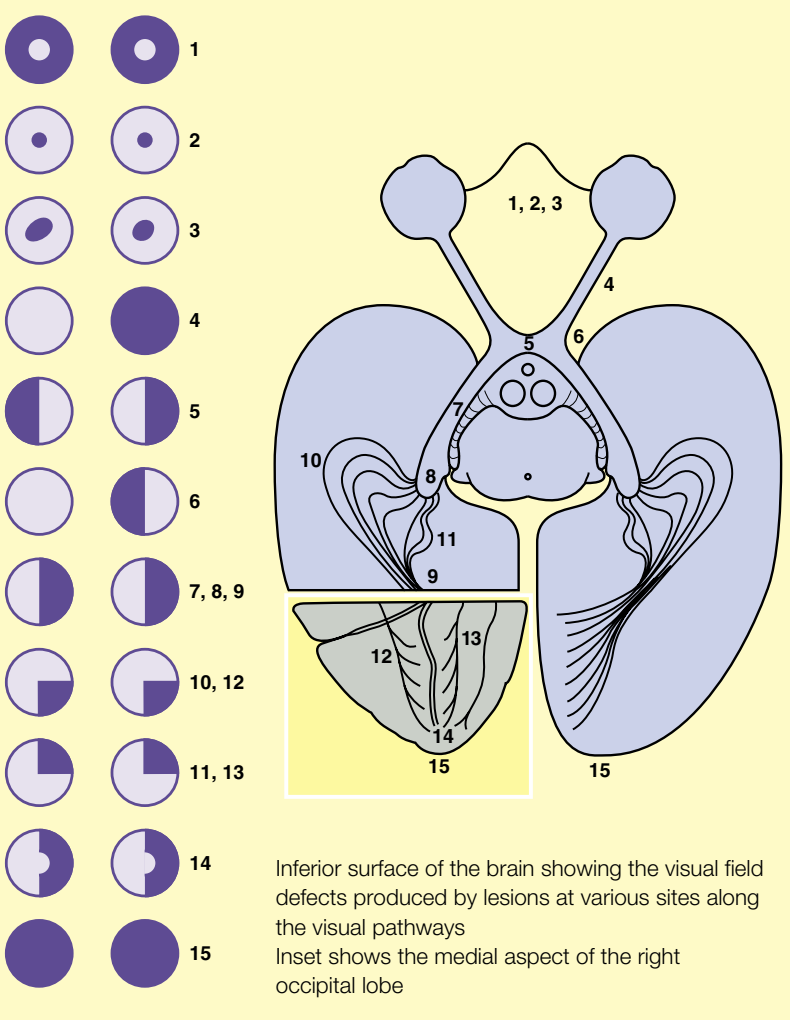
10 Lower quadrantic hemianopia, with incongruous defects, and suppression or loss of image with simultaneous delivery from each side, parietal lobe tumours, particularly with lesions of the non-dominant hemisphere

11 Upper quadrantic hemianopia: temporal lobe lesions, due to occlusion of the middle cerebral or the thalamogenicular branch of the posterior cerebral artery

12, 13 Lower and upper quadrantic hemianopia: respectively from lesions above and below the calcarine fissure.

14 Homonomous hemianopia, congruous defects with macular sparing due to the large cortical representation of the macula: reading is preserved: posterior cerebral artery occlusion

15 Cortical blindness: degenerative arterial disease with bilateral ischaemic infarction of the occipital lobes, near drowning, basilar artery spasm in severe migraine



Inferior surface of the brain showing the visual field defects produced by lesions at various sites along the visual pathways
Inset shows the medial aspect of the right occipital lobe

Oculomotor (III), trochlear (IV) and abducent (VI) nerves

The oculomotor, trochlear and abducent nerves carry somatic motor fibres to the extraocular muscles. In addition, the oculomotor nerve carries parasympathetic fibres that synapse in the ciliary ganglion and supply the pupillary and ciliary muscles. The nuclei of the three nerves are in the periaqueductal grey matter of the upper (III) and lower (IV) midbrain, and in the lower pons (VI).

The oculomotor nerve passes anteriorly through the midbrain, and emerges between the cerebral peduncles; it passes through the posterior and middle cranial fossae to divide into superficial and inferior branches near the supraorbital fissure. In the posterior cranial fossa the nerve passes near the edge of the tentorium cerebelli. In the middle cranial fossa the nerve pierces the cerebral layer of dura to pass forwards on the lateral wall of the cavernous sinus. The superior division passes through the superior orbital fissure and supplies the superior rectus and levator palpebrae superioris. The inferior division supplies the medial and inferior recti, and inferior oblique muscles. The nerve to inferior oblique gives the parasympathetic branch to the ciliary ganglion.

The trochlear nerve is the thinnest cranial nerve. It passes posteriorly and undergoes a dorsal decussation with its fellow of the opposite side caudal to the inferior colliculus. The nerve then passes through the posterior and middle cranial fossae and enters the orbit through the superior orbital fissure to supply the superior oblique muscle. In the posterior cranial fossa, the nerve passes forward around the midbrain. In the middle cranial fossa, it pierces the cerebral layer of dura, and lies between the oculomotor and ophthalmic nerves in the lateral wall of the cavernous sinus. It passes through the superior orbital fissure outside the tendinous ring and passes medially between levator palpebrae superioris and the roof of the orbit, to reach and supply the superior oblique muscle.

The abducent nerve leaves the inferior border of the pons near the midline, passing forwards through the posterior and middle cranial fossae, the cavernous sinus and the orbit to reach and supply the lateral rectus muscle. In the posterior cranial fossa the nerve lies between the pons and the basilar part of the occipital bone and passes over the apex of the petrous temporal bone, through the cavernous sinus lateral to the internal carotid artery. It enters the orbit through the superior orbital fissure within the tendinous ring.

Assessment

When examining the IIIrd, IVth and VIth cranial nerves, first check the extraocular movements (LR_6, SO_4 provides a way of remembering the muscles supplied by the IVth and VIth nerves). In addition, the IIIrd nerve is responsible for the pupillary responses to light and accommodation, and eyelid elevation by the levator palpebrae superioris (PERLA – pupils react to light and accommodation). Note any squint or nystagmus.

Horizontal movements are brought about specifically by the lateral and medial recti muscles, but other movements are more complex: upward and downward gaze should be assessed in extremes of abduction and adduction (i.e. in H fashion). The eyes are examined together but when abnormalities of conjugate gaze are present, or the patient complains of diplopia, the eyes are examined independently.

With abnormalities of the IIIrd nerve, there is:
- weakness of elevation and adduction (i.e. a divergent strabismus is present, the eye looking downwards and outwards on forward gaze)
- ptosis – the patient is unable to elevate the eyelid (compared with retention of voluntary lid-raising in Horner's syndrome)
- a dilated pupil non-reactive to light or accommodation, though the consensual light reflex is retained
- proptosis, as a result of muscular relaxation
- diplopia.

In IVth nerve paralysis, there is torsion of the globe on downward gaze. The head may be tilted to the opposite shoulder, so the patient can achieve binocular vision. Although the superior oblique muscle directs the eye downwards and outwards, adduction is also produced by the inferior rectus and the prime defect is that of intorsion (i.e. the patient cannot look at the tip of their nose). Damage to the VIth nerve produces a convergent strabismus, the patient is unable to abduct the eye and diplopia is a prominent feature.

The three nerves can be damaged by tumours within the orbit and the nasopharynx. In lesions of the superior orbital fissure (Tolosa-Hunt syndrome) there is additional damage to the ophthalmic division of the trigeminal nerve, producing pain. In the middle cranial fossa, caroticocavernous fistulae and aneurysms of the internal carotid artery may produce nerve damage, and in the posterior fossa, aneurysms, particularly of the posterior communicating artery. The three nerves commonly provide important signs in head injuries; in tentorial coning, the IIIrd nerve is first stimulated and then progressively paralysed, the pupil becoming fixed and dilated. The IVth nerve is damaged in reversed coning from expanding lesions in the posterior fossa. The effect can be the result of direct nerve pressure on the lateral edge of the tentorium, or posterior shift of the brainstem with pressure of the tentorium on the third and fourth nerve nuclei in the midbrain. The VIth nerve can produce false localizing signs owing to its long intracranial course.

Trigeminal nerve (V)

The trigeminal nerve is the largest cranial nerve. It emerges from the cerebellopontine angle as a large sensory (general somatic) and a smaller motor (special visceral) root. The roots pass over the apex of the petrous temporal bone to the trigeminal ganglion, pushing a pouch of dura (Meckel's cave) into the middle cranial fossa. The semilunar (Gasserian) ganglion lies lateral to the cavernous sinus in the middle cranial fossa. The ophthalmic, maxillary and mandibular divisions arise from the anteroinferior aspect of the ganglion. The motor root, passing medial to the ganglion, joins the mandibular division.

The ophthalmic division is the smallest. It lies in the lateral wall of the cavernous sinus below the oculomotor and trochlear nerves. Near the superior orbital fissure, it divides into lacrimal, frontal and nasociliary branches that pass through the fissure into the orbit. The lacrimal nerve supplies the lacrimal gland (conveying parasympathetic fibres from the zygomaticotemporal branch of the pterygopalatine ganglion), the upper eyelid and the lateral conjunctiva. The frontal nerve divides into supraorbital and supratrochlear branches, supplying the upper eyelid, medial forehead and the scalp as far as the vertex. Only the nasociliary branch passes through the tendinous ring. It divides into anterior ethmoidal and infratrochlear nerves, supplying the ethmoidal and sphenoidal air sinuses, the upper eyelid and the adjacent nose. Long ciliary branches carry sympathetic dilator pupillae fibres that pass through the ciliary ganglion.

The maxillary division passes forward, lateral to the cavernous sinus in the middle cranial fossa to the pterygopalatine fossa to enter the inferior orbital fissure and become the infraorbital nerve. The pterygopalatine ganglion is suspended from it in the pterygopalatine fossa where it is also related to the terminal branches of the maxillary artery. Through the ganglion, the maxillary nerve supplies sensory fibres to the lateral nose and nasopharynx. The zygomatic nerves supply skin over the cheek and temple. Posterior superior alveolar nerves supply the maxilla, and upper molar and premolar teeth. The infraorbital nerve emerges through the infraorbital foramen on the face to supply the lower eyelid and conjunctival side of the nose and upper lip. Its middle and anterior superior alveolar branches, given off in the infraorbital canal, supply the premolar, canine and incisor teeth, and the lateral wall of the nose and maxillary air sinus.

The mandibular division leaves the middle cranial fossa through the foramen ovale to lie between tensor palati and the lateral pterygoid muscles, with the otic ganglion on its medial side. The surface marking of this opening is 4 cm medial and just anterior to the neck of the mandible, the nerve may be anaesthetized using these relationships. The motor branches supply the muscles of mastication, tensor tympani and tensor palati.

The sensory branches have a wide distribution to the meninges of the middle cranial fossa, the skin and mucous membrane in the cheek, through the buccal nerve, the temporal region of the scalp, tympanic membrane, external auditory meatus and the anterior auricle through the auriculotemporal nerve. This nerve also carries parasympathetic fibres from the otic ganglion, and sympathetic fibres from the plexus around the middle meningeal artery, to the parotid gland. The inferior alveolar branch of the mandibular nerve enters the mandibular foramen and passes along the mandibular canal to supply the gums and teeth. The mental nerve emerges through the mental foramen, and supplies the skin and mucous membrane of the lower lip, and gum. The inferior alveolar nerve also carries motor fibres, that pass to the mylohyoid and anterior belly of the digastric muscles, before the nerve enters the mandibular canal.

The largest branch of the mandibular nerve is the lingual, which is formed between the tensor palati and lateral pterygoid muscles. It passes forward between the medial pterygoid and ramus of the mandible, and under the mucous membrane, over the root of the third lower molar tooth (an important relation for dental anaesthesia) and then between hyoglossus and mylohyoid. On the hyoglossus, the lingual nerve is overlapped by the submandibular gland and has the submandibular ganglion suspended from it. The nerve supplies sensory branches to the anterior two-thirds of the tongue, the floor of the mouth and the lingual gums. 3 cm below the base of the skull, the nerve is joined by the chorda tympani branch of the facial nerve, carrying parasympathetic fibres; these synapse in the submandibular ganglion and pass to the submandibular and sublingual salivary glands, and taste fibres for the anterior two-thirds of the tongue.

Assessment

Examination of the three divisions is by assessment of sensation over the forehead, cheek and lower jaw, together with the corneal reflex. Motor fibres are assessed by palpation of the masseter and temporalis, on jaw-clenching, protrusion of the jaw by the pterygoid muscles and the jaw jerk. The proximal divisions may be damaged by caroticocavernous fistulas and aneurysms in the middle cranial fossa, and by fractures, aneurysms, meningiomas, acoustic neuromas and other intracranial tumours in the middle and posterior cranial fossa. Brainstem lesions such as vascular, tumours and syringobulbia produce a bulbar palsy, and bilateral cortical lesions produce a pseudobulbar palsy, affecting the motor component, and the nerve is subject to trigeminal neuralgia. ◆

Cranial Nerves: Part II

John S P Lumley

John S P Lumley is Emeritus Professor of Vascular Surgery and Honorary Consultant at St Bartholomew's Hospital, London, UK. He is past World President of the International College of Surgeons. His main clinical and research interests relate to the surgery of cerebrovascular diseases and microvascular surgery.

This article describes cranial nerves VII–XII. Cranial nerves I–VI are described in *Anaesthesia and Intensive Care Medicine* **3:3:** 116.

Facial nerve (VII)

The facial nerve carries special visceral, and autonomic, motor and sensory fibres. The special visceral motor fibres supply the muscles of the second pharyngeal arch mesoderm, which are primarily those of facial expression, while the special visceral sensory fibres carry taste from the anterior two-thirds of the tongue to the tractus solitarius, they pass through the chorda tympani branch to the lingual nerve. Parasympathetic fibres are secretomotor to the submandibular, sublingual and lacrimal glands, and glands of the mucous membrane of the nose, pharynx and mouth, branches passing via the pterygopalatine and submandibular ganglia.

Sensory (nervus intermedius) and motor roots leave the lower lateral surface of the pons and enter the internal auditory meatus, passing to the geniculate (facial) ganglia. The nervus intermedius also carries the parasympathetic fibres. The nerve turns sharply posteriorly through a bony canal medial to the middle ear and then downwards, related to the posterior aspect of the middle ear, through the temporal bone to emerge at the stylomastoid foramen. The nerve then turns forwards into the parotid gland where it divides into temporal, zygomatic, buccal, mandibular and cervical motor branches, to supply facial muscles, buccinator and platysma.

The greater petrosal branch

The greater petrosal branch leaves the geniculate ganglion to pass through the petrous temporal bone and middle cranial fossa to join the deep petrosal nerve (sympathetic branches from the internal carotid plexus) and pass through the pterygoid canal to the pterygopalatine ganglion.

The chorda tympani branch

The chorda tympani branch arises from the nerve in the temporal bone, just above the stylomastoid foramen, and passes forward through the middle ear between the tympanic membrane and the handle of the maleus. It passes forward through the temporal bone to emerge from the petrotympanic fissure, to join the lingual nerve 3 cm below the base of the skull.

Assessment

Motor function is assessed by facial symmetry (forehead wrinkles, nasolabial fold, corner of mouth) and expression, and power of eye closure, whistling and blowing out the cheeks actively and against resistance. Lower motor neuron damage produces paralysis of the ipsilateral face, whereas in upper neuron damage, only the contralateral lower face is paralysed, sparing the muscles of the forehead and eyebrow, which are bilaterally innervated. Sensory examination is of taste over the anterior two-thirds of the tongue.

The most common lower motor neuron lesion is Bell’s palsy, but the nerve may be damaged by lesions and surgery of the parotid gland, basal skull fractures, Hunt's syndrome, otitis media and tumours of the posterior cranial fossa, particularly acoustic neuromas. Nuclear lesions include vascular, tumours, syringobulbia and multiple sclerosis. Supranuclear lesions are primarily vascular or tumours. Bilateral facial weakness may be part of a pseudobulbar palsy of vascular origin, Guillain-Barré syndrome, bilateral parotid disease and skull fractures. The onset following a skull fracture may be delayed owing to oedema, this has a better prognosis than primary nerve damage. Isolated loss of taste is unusual, but may be related to middle ear infection, damaging the chorda tympani.

Vestibulocochlear nerve (VIII)

This special somatic sensory nerve consists of vestibular fibres, concerned with balance, and cochlear fibres, concerned with hearing. The latter originate in the organ of Corti and pass in the bipolar cells of the spiral ganglia within the modiolus. Vestibular fibres pass from the semicircular ducts, saccule and utricle to the bipolar cells in the vestibular ganglion in the internal auditory meatus. The two components of the nerve unite in the internal auditory meatus and pass medially to enter the cerebellomedullary angle of the brainstem, to reach the nuclei in the floor of the fourth ventricle.

Assessment

Assessment of hearing includes examination of the external auditory meatus to identify disease of the canal or eardrum, and the appreciation of soft noises, such as a watch tick or a whisper. Rinne’s test assesses whether air conduction of the sound of a clinical 512 Hz tuning fork is better than bony conduction of the base of the fork placed over the mastoid process (the normal pattern). In Weber’s test sound transmission from the base of the tuning fork placed in the centre of the forehead is transmitted equally to the two ears (normal).

Deafness may be related to:

- wax
- infective and other diseases of the external auditory meatus, tympanic membrane and middle ear
- tumours, particularly acoustic neuromas and those of the skull base
- toxicity (e.g. streptomycin and alcohol) and degenerative disease such as excess environmental exposure
- otosclerosis and bony abnormality (e.g. Paget’s disease).

Abnormalities of balance are usually detected by the patient’s history and they may be associated with nystagmus and vertigo. They may be caused by acute labyrinthitis, Menière’s disease, drug toxicity and motion sickness, as well as trauma, and lesions of the skull base and brainstem.

Glossopharyngeal nerve (IX)

General visceral sensory fibres arise from the pharynx, posterior third of the tongue, the carotid sinus and carotid body, taste from the posterior third of the tongue and parasympathetic fibres synapsing in the otic ganglia supplying the parotid and pharyngeal glands.

The glossopharyngeal nerve carries special visceral motor fibres to the tylopharyngeus muscle. The nerve rootlets leave the medulla lateral to the olive and the nerve passes through the jugular foramen medial to the vagus and accessory nerves, descending between the internal and external carotid arteries to enter the pharyngeal wall, between the superior and middle constrictor muscles.

The tympanic branch of the nerve passes through the petrotympanic fissure to the tympanic plexus in the middle ear, from whence lesser petrosal nerve fibres pass to the otic ganglion, carrying parasympathetic fibres to the parotid gland. The sinus nerve descends between the internal and external carotid arteries to supply the carotid body and carotid sinus.

Isolated nerve damage is uncommon, but produces loss of sensation over the anterior pillar of the fauces (gag reflex) and loss of taste from the posterior third of the tongue, including the circumvalate papillae, and impairment of carotid sinus and carotid body reflexes. The gag reflex is reduced with age. Lesions resemble those of the Xth nerve, to which it is closely related intracerebrally.

Vagus nerve (X)

The vagus nerve has a more extensive distribution than any other cranial nerve. It carries:

- visceral motor fibres to the striatal muscle of the palate, pharynx and larynx
- parasympathetic visceral motor and sensory fibres to the mucosa of the palate, pharynx and larynx and to the heart, lungs and alimentary tract as far as the splenic flexure
- somatic sensory fibres to the posterior aspect of the external auditory meatus and tympanic membrane, via its auricular branch
- a few taste fibres.

The nerve is formed from a number of rootlets emerging lateral to the olive and leaves the posterior cranial fossa through the internal jugular foramen, between the IXth nerve medially and the XIth laterally. It has swellings within and just below the jugular foramen; these ganglia are somatic and visceral sensory in nature. It lies posteriorly in the carotid sheath as it descends through the neck and in the thorax, the two vagal nerves pass posteriorly to each bronchus to form the pulmonary plexus and then converge on the oesophagus to form the oesophageal plexus, and thence the anterior and posterior vagal nerves (the left and right vagal trunks, respectively) for distribution to the alimentary tract.

The various branches include pharyngeal, cardiac and pulmonary, together with two constant branches to the larynx. The superior laryngeal nerve descends between the pharynx medially and the internal carotid artery laterally. It divides below the hyoid bone into the internal laryngeal nerve that pierces the hyoid membrane to supply the mucous membrane of the larynx above the vocal folds, and the external laryngeal nerve, that descends on the larynx to supply the cricothyroid muscle. The recurrent laryngeal nerves hook round the subclavian on the right and the aortic arch on the left, to ascend in the groove between the trachea and oesophagus, closely related to the thyroid gland, entering the larynx deep to the inferior constrictor muscle to supply the mucous membrane below the vocal folds and all the intrinsic muscles except the cricothyroid.

Assessment

The muscles of the palate are assessed by watching:

- the uvula and palate rise when saying ‘aah’
- the pharynx for evidence of regurgitation when swallowing a cup of water
- the larynx by coughing and saying a high ‘ee’.

Clinically demonstrably abnormal signs are limited to the pharynx and larynx. Pareses produces lateral displacement of the uvula, coughing and spluttering on swallowing, implying fluid regurgitating into the larynx rather than passing down the oesophagus, and a bovine cough because the vocal cords are not fully approximated. Bilateral recurrent laryngeal nerve injuries may produce stridor and respiration obstruction.

The vagal nuclei lie on the medulla and are the dorsal motor and sensory (parasympathetic) and the nucleus ambiguous (special visceral motor), taste fibres pass to the nucleus of the tractus solitarius.

Lower motor neuron lesions are produced by tumours of the posterior fossa and around the skull base, aneurysms, chronic meningitis and Guillain-Barré syndrome. Nuclear abnormalities are produced by tumours, syringobulbia and motor neuron disease. The bilateral pyramidal innervation requires bilateral lesions to produce a pseudobulbar palsy, this is usually secondary to cerebrovascular disease.

Accessory nerve (XI)

This somatic motor nerve supplies sternomastoid and trapezius muscles, the fibres having their nuclei in the upper five cervical segments of the cervical cord. The fibres ascend through the foramen magnum to the posterior fossa, and the nerve leaves the fossa through the jugular foramen, lateral to the IXth and Xth nerves. It then passes laterally, anterior to the internal jugular vein and the transverse process of the atlas into the substance of the sternomastoid, crossing the posterior triangle of the neck, over levator scapulae, to reach the deep surface of the trapezius. Inside the posterior fossa, the cranial root of the accessory nerve, carrying fibres from the nucleus ambiguus, joins the accessory, but those fibres ultimately return to the vagus.

Examination of the nerve is by assessing the bulk of the trapezius and sternomastoid muscles, asking the subject to turn the head to the opposite side against resistance, and watching shoulder shrugging.

Lesions occur through trauma of the base of the skull, tumours of the posterior cranial fossa and skull base, poliomyelitis, syringomyelia, motor neuron disease and Guillain-Barré syndrome. The nerve may be damaged by trauma or surgery in the neck. These muscles may also be involved in muscular dystrophies.

Hypoglossal nerve (XII)

The hypoglossal nerve provides the somatic motor supply to all the intrinsic and extrinsic muscles of the tongue except palatoglossus. Its nucleus is situated in the medulla in the floor of the fourth ventricle. The nerve emerges from the medulla between the pyramid and the olive and leaves the posterior cranial fossa through the hypoglossal canal, above the occipital condyle. It descends behind the carotid sheath, then passes forwards round the pharynx between the internal carotid artery and the internal jugular vein to cross in turn the internal and external carotid arteries, the loop of the lingual artery on the middle constrictor, and the hyoglossus muscle. It is covered laterally by the posterior belly of the digastric, the submandibular gland and the mylohyoid muscle. The hypoglossal nerve also receives branches from the first cervical nerve near the base of the skull and conveys these fibres to the geniohyoid and thyrohyoid muscles, they then form the descendens hypoglossi nerve which supplies the infrahyoid muscles through the ansa hypoglossi.

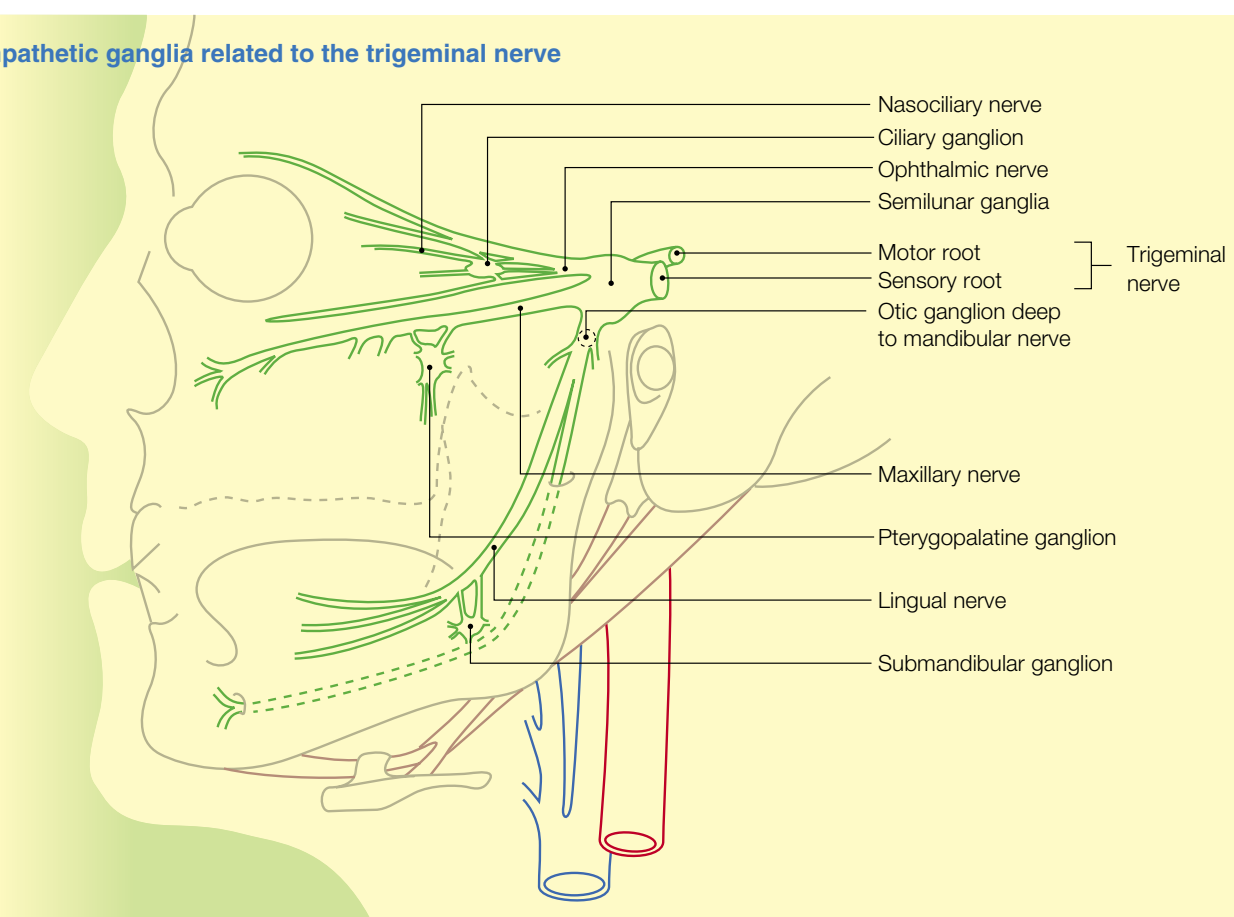
In lower motor neuron lesions, the tongue is observed for wasting, weakness, and fasciculation and dysarthria: the tongue is protruded towards the side of a lesion.

Upper motor neuron defects are unusual in view of the bilateral innervation, but may occur in vascular diseases. Nuclear lesions are seen in motor neuron disease, tumours, thrombosis of the vertebral artery, syringobulbia and lower motor neuron lesions due to tumours and aneurysms of the posterior cranial fossa, trauma, chronic meningitis, Arnold-Chiari malformation, poliomyelitis and the Guillain-Barré syndrome.

Parasympathetic cranial ganglia

Whereas the sympathetic nerve fibres relay in a proximally placed series of ganglia in the sympathetic chain (T1–L2), the ganglia of the parasympathetic system (craniosacral) are sited near the organs they innervate. There are four well-defined cranial ganglia: the ciliary, pterygopalatine, submandibular and otic (Figure 1).

Parasympathetic ganglia related to the trigeminal nerve



1

Ciliary ganglion

The ciliary ganglion is the smallest and the size of a pin head; it is situated between the optic sheath and the lateral rectus muscle, near the apex of the orbital cavity. It is usually lateral to the ophthalmic artery.

The parasympathetic fibres arise in the Edinger–Westphal nucleus in the midbrain and are carried by the short ciliary nerves to the back of the eyeball to supply the sphincter pupillae and ciliary muscles.

Sympathetic fibres from the superior cervical ganglion reach the ciliary ganglia via the plexus on the ophthalmic artery and pass without synapse to the blood vessels and smooth muscle of the eyeball.

Sensory fibres pass without relay through the ganglia to the eyeball, reaching the ciliary ganglion through the long ciliary branches of the nasociliary nerve.

Pterygopalatine (sphenopalatine) ganglion

The pterygopalatine (sphenopalatine) ganglion is the largest of the peripheral parasympathetic ganglia. It is situated in the pterygopalatine fossa suspended from the maxillary nerve receiving afferent and efferent branches from it.

Parasympathetic fibres originate in the VIIth nerve nuclei, leaving the nerve in the temporal bone as the greater petrosal nerve. This receives sympathetic fibres from around the internal carotid artery as the deep petrosal nerve, to form the nerve of the pterygoid canal that passes to the ganglion. The numerous branches of the ganglion, including nasal, nasopalatine and pharyngeal, are primarily derived from the maxillary nerve but carry postsynaptic secretomotor fibres to the palate, pharynx and nasal glands, and also via the connection to the zygomatic frontal nerve to the lacrimal gland.

Sympathetic fibres are similarly distributed to the smooth muscle of the blood vessels of the palate, pharynx and nose.

Submandibular ganglion

The submandibular ganglion lies on the hyoglossus muscle, suspended from the lingual nerve by afferent and efferent branches, and above the deep part of the submandibular gland. Its parasympathetic fibres originate in the seventh nerve, and pass with the taste fibres via the chorda tympani nerve. Parasympathetic fibres originate in the superior salivary nucleus in the midbrain and the taste fibres in the tractus solitarius. Postsynaptic parasympathetic fibres pass via the lingual nerve and direct branches to the submandibular, sublingual and other oral glands, accompanied by sympathetic fibres derived from the superior cervical ganglion and reaching the submandibular ganglion via the facial artery.

Otic ganglion

The otic ganglion lies between the tensor palati muscle laterally and the auditory tube medially, with the middle meningeal artery posteriorly. It is closely related to the nerve to the medial pterygoid muscle.

Parasympathetic fibres are derived from the inferior salivary nucleus of the IXth nerve, passing through the foramen ovale to the otic ganglion. Efferent fibres pass via the auriculotemporal nerve to the parotid gland.

Sympathetic fibres derived from the superior cervical ganglion pass via the plexus on the middle meningeal artery and through the otic ganglion without synapse, to be distributed to the blood vessels of the parotid gland. ◆

The Cubital Fossa

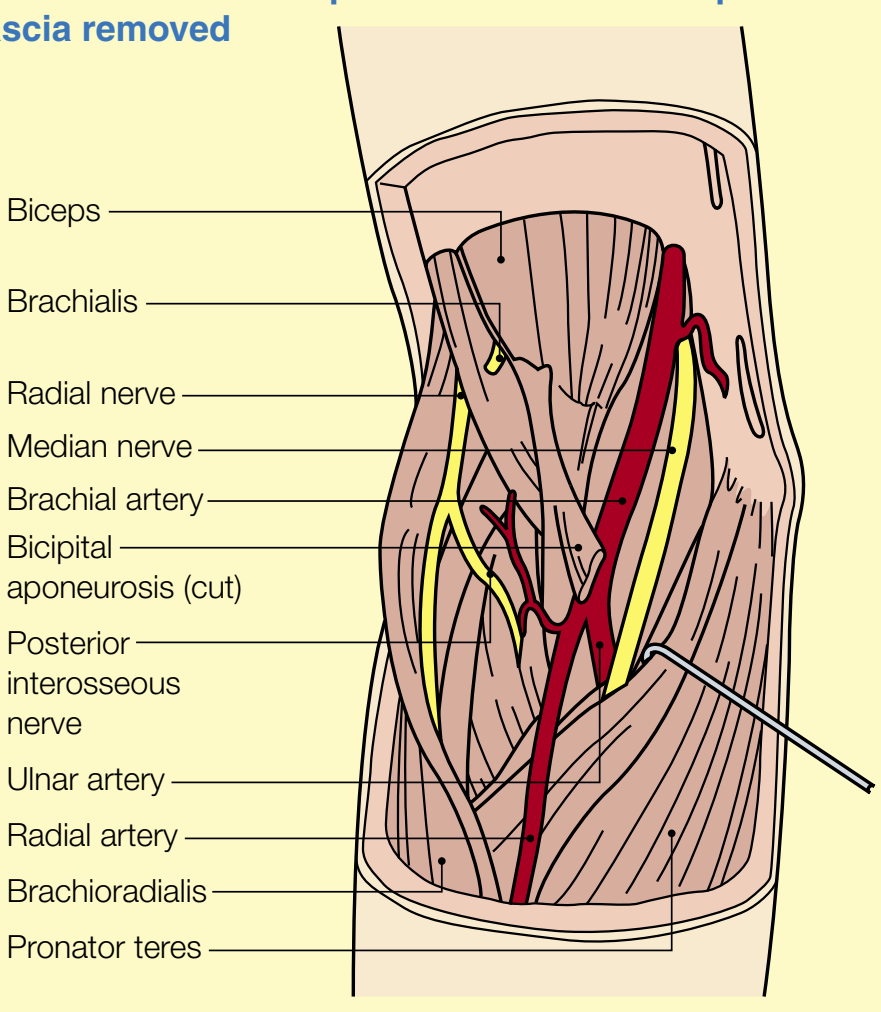
John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

The cubital fossa is a triangular hollow area that lies in front of the elbow joint. It is bounded (Figure 1):

- superiorly by an imaginary line connecting the medial and lateral epicondyles
- medially by the pronator teres muscle
- laterally by the brachioradialis muscle.

Cubital fossa with superficial veins and deep fascia removed



1

Its floor is formed of the brachialis and supinator muscles overlying the capsule of the elbow joint. The deep fascia of the forearm forms its roof, which is strengthened by fibres of the bicipital aponeurosis. Lying on the roof in the superficial fascia are the anterior branches of the medial and lateral cutaneous nerves of the forearm and the median cubital vein which joins the cephalic and basilic veins.

The cephalic, basilic and median cubital veins are usually easily seen and palpated in the roof of the fossa, and this is therefore a common site for venepuncture. It is worth noting that variations in venous anatomy at this site are common (Figure 2). The use of the cubital fossa for intravenous fluid therapy is not recommended because movement of the elbow joint disturbs the cannula and irritates the vein wall with the consequence that thrombosis of the vein quickly occurs.

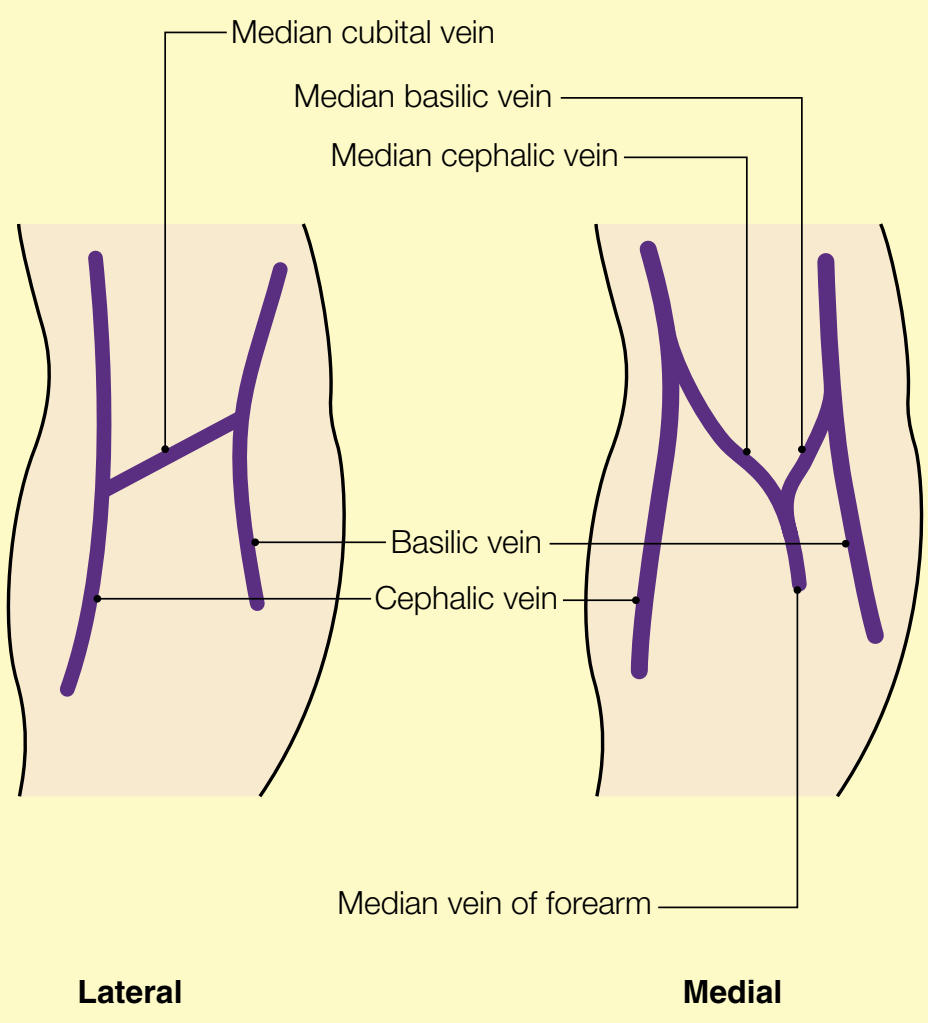
The contents of the fossa from medial to lateral are:

- median nerve
- brachial artery and its terminal branches, the radial and ulnar arteries
- biceps tendon and bicipital aponeurosis (which separates the median cubital vein from the brachial artery)
- radial and posterior interosseous nerves, which are often overlapped by the fibres of brachioradialis.

The brachial artery is palpated here when the arterial pressure is being taken by a sphygmomanometer but, because of the bicipital aponeurosis, the elbow should be fully extended so that the artery is pressed back on to the elbow joint, which renders palpation a little easier. The brachial artery is in close relation to the medial nerve, which lies on its medial side. Awareness of this relationship should minimize the incidence of nerve trauma during arterial puncture for blood sampling or the insertion of arterial catheters for cardiac or other investigations. Rarely, the cubital fossa is used for distal nerve blocks.

The median nerve can be anaesthetized by injecting 5 ml of local anaesthetic solution through a weal raised midway between the outer side of the tendon of biceps and the medial epicondyle. This anaesthetizes the lateral half of the palm and fingers.

Common arrangements of veins in the cubital fossa



2

The Diaphragm, its Action and Innervation

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

The diaphragm is a musculotendinous septum that separates the abdominal and thoracic cavities. It has a peripheral muscular portion, which attaches to its central tendon. It is attached peripherally to:

- the sternum − by two muscular slips from the back of the xiphoid process
- the ribs − from the inner surfaces of the lower six ribs and costal cartilage where its fibres interdigitate with fibres of transversus abdominis
- the upper lumbar vertebrae.

It is attached to the sides of the upper lumbar vertebrae by two crura and from the medial and lateral arcuate ligaments on each side. The right crus attaches to the first three vertebral bodies and the left crus to the first two. The right crus is the larger and passes forwards and to the left, surrounding the oesophageal opening.

The medial arcuate ligament, the thickened upper edge of the psoas fascia extends in front of the psoas from the body of the first lumbar vertebra to its transverse process. The lateral arcuate ligament lies anterior to the quadratus lumborum attached between the transverse process of the first lumbar vertebra and the 12th rib. The central attachment of the diaphragm is to the margins of a trilobed central tendon.

Nerve supply

The right and left phrenic nerves (C3,4,5) supply the corresponding halves of the diaphragm.

- The right phrenic nerve descends on the lateral wall of the right brachiocephalic vein then on the pericardium over the superior vena cava, the right atrium and the inferior vena cava before passing through the caval opening of the diaphragm. It is covered throughout its course by the mediastinal pleura.
- The left phrenic nerve enters the thorax between the left subclavian artery and the left brachiocephalic vein and descends to cross the aortic arch and the pericardium over the left ventricle. It too is covered laterally by the mediastinal pleura.

Both nerves also supply sensory fibres to the central part of the diaphragm, the mediastinal and diaphragmatic pleura, the pericardium and the diaphragmatic peritoneum. The peripheral part of the diaphragm receives sensory fibres from the lower intercostal nerves.

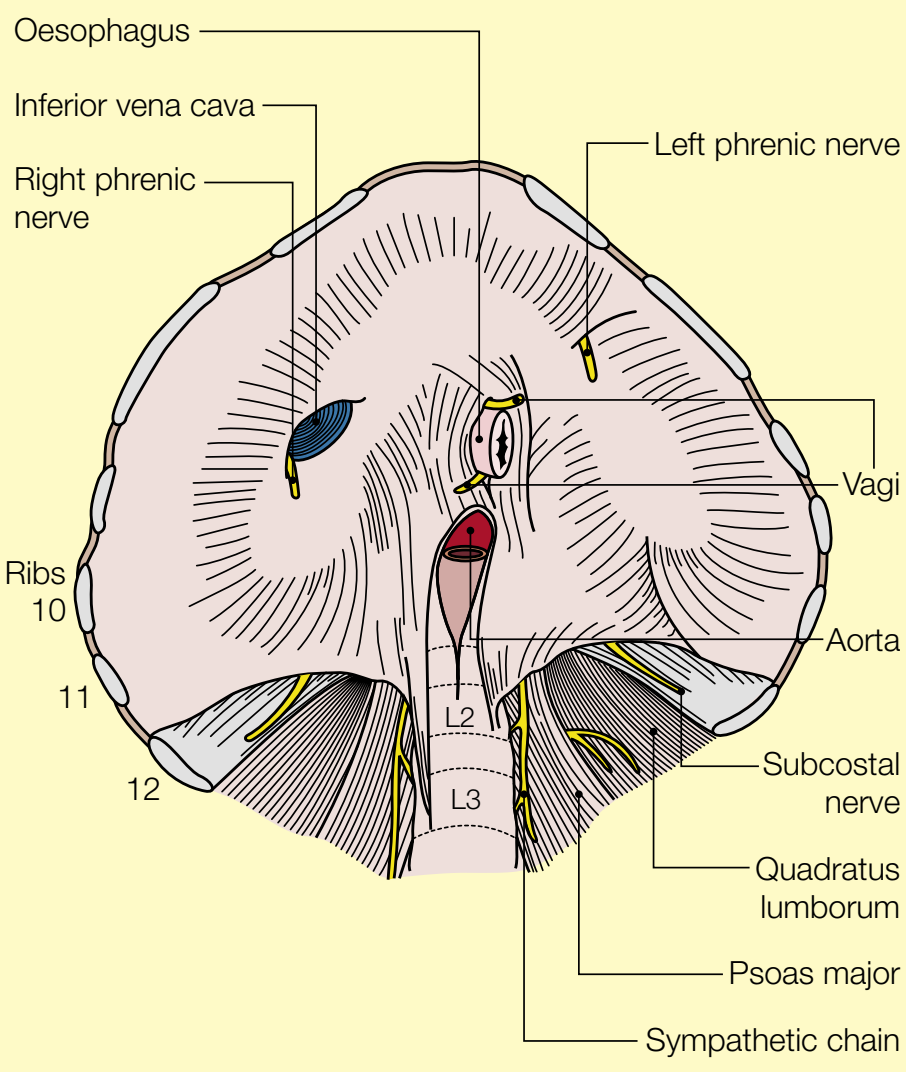
Pain from inflammation of the diaphragmatic pleura or peritoneum may be referred to the ipsilateral shoulder tip, the cutaneous area which is innervated by the supraclavicular nerves, mainly originating like the phrenic nerve, from the C4 segment of the spinal cord.

Openings in the diaphragm

There are three openings in the diaphragm (Figures 1 and 2). From the posterior, they are for the aorta, oesophagus and inferior vena cava.

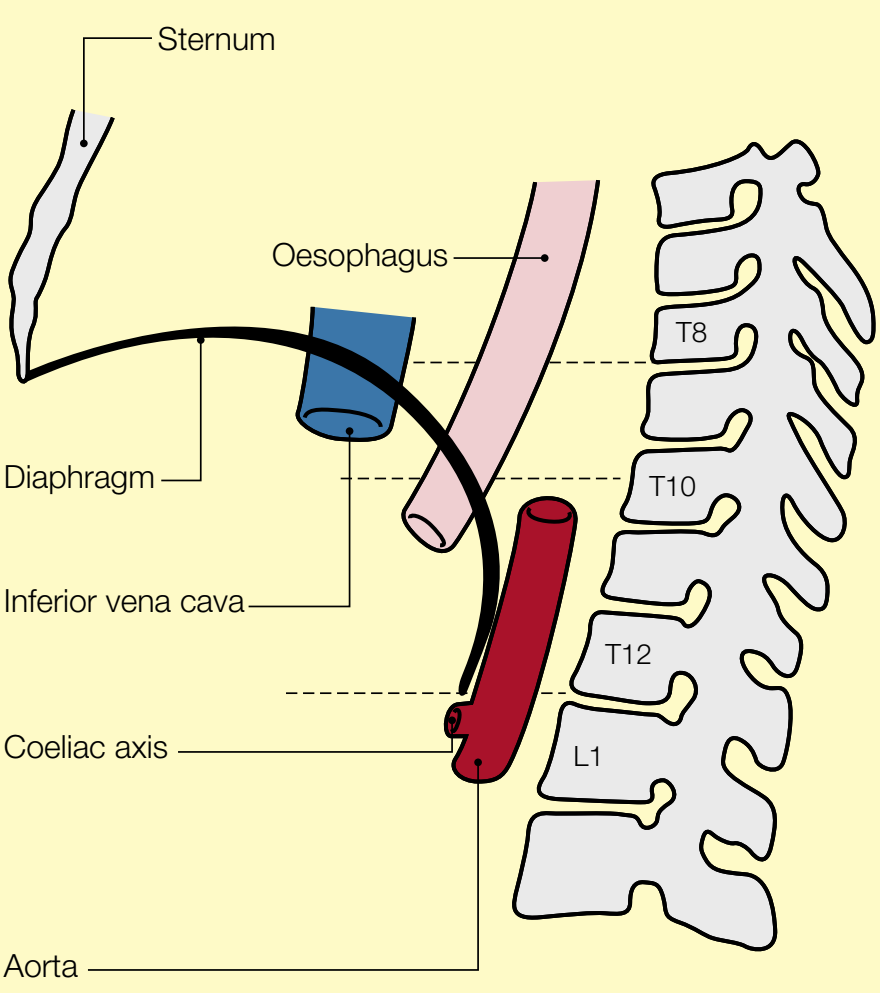
- The opening for the aorta lies between the crura of the diaphragm in front of the 12th thoracic vertebra, which also transmits the thoracic duct and the azygos vein.
- The opening for the oesophagus lies within the right crus at the level of the 10th thoracic vertebra, which also transmits the anterior and posterior gastric branches of the vagus nerves and the oesophageal branches of the left gastric vessels.
- The opening for the inferior vena cava lies to the right of the midline within the central tendon, which also transmits the right phrenic nerve.

Inferior view of the diaphragm



1

Level of the diaphragmatic openings



2

Relationships

The heart and lungs lie within the pericardial and pleural sacs, respectively, on the upper surface of the diaphragm. The pericardium is adherent to the central tendon. Below the diaphragm on the right side are the liver, the right kidney and suprarenal gland and, on the left, the fundus of the stomach, spleen, left kidney and suprarenal gland.

Respiration

Inspiration and expiration are produced by increasing or decreasing the volume of the thoracic cavity. Quiet respiration is produced by diaphragmatic action alone.

Inspiration
The diaphragm contracts and descends, the first rib is fixed by the scalene muscles and the external intercostals elevate and evert the succeeding ribs which increases the anteroposterior diameter of the upper chest and, by elevating the costal margin, increases the transverse diameter of the lower chest. Forced inspiration is achieved by fixing the shoulder girdle, which allows serratus anterior and the pectoral muscles to raise the ribs.

Expiration
Expiration is produced mainly by recoil of the lung tissue and the costal cartilages but simultaneous contraction of the abdominal wall muscles forces the diaphragm upwards, an action that is exaggerated in forced expiration.

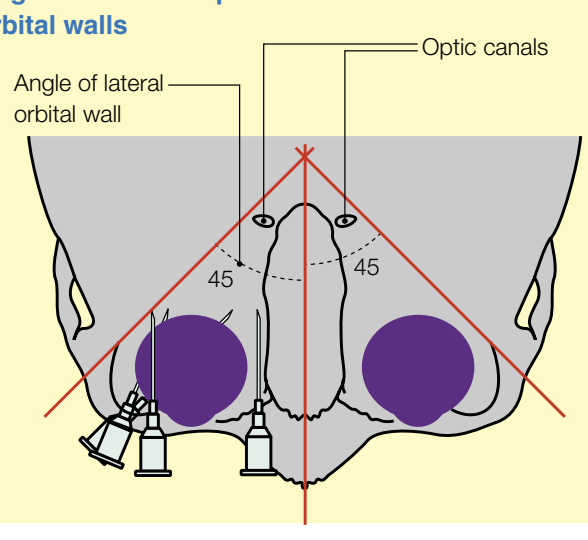
Eye and Orbit

Hari Jayaram

Hari Jayaram is a Basic Surgical Trainee in Ophthalmology. He qualified from the Universities of Cambridge and Oxford and is currently working in the Department of Neurosurgery at the National Hospital, Queen Square, London.

Anatomy
Orbit: each orbit is pyramidal in shape with its base anteriorly and its apex posteromedially directed towards the optic canal. The average dimensions are 40 mm wide, 35 mm high and 25 mm deep. The angle between both lateral walls is 90° and between lateral and medial walls of the same side is 45° (Figure 1). The medial walls are almost parallel to the sagittal plane. Needles introduced in this plane travel a greater distance towards the orbital apex and can potentially cause more damage, compared with those inserted laterally along the orbital wall.

Angular relationships of medial and lateral orbital walls

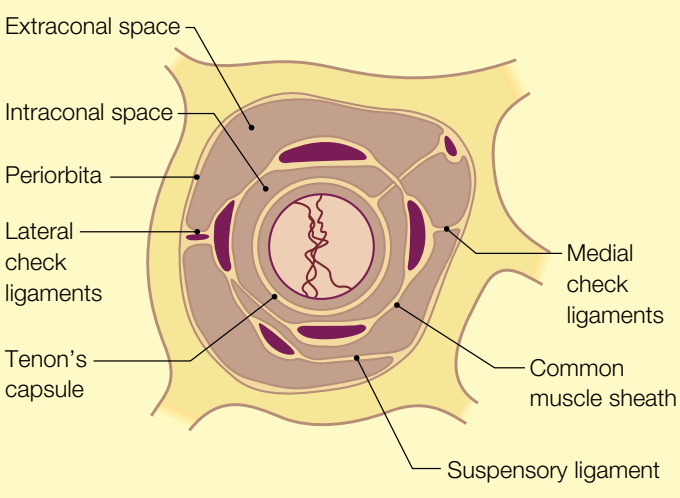


1

Globe: the globe is located anteriorly within the orbit in a superolateral position; its dimensions vary. Myopic eyes are longer with thin sclera, and are at greater risk of needle perforation. An axial length over 26 mm should hazard caution. A 'socket' is formed by Tenon's capsule, which extends from the optic nerve meninges posteriorly to within millimetres of the corneoscleral limbus anteriorly. This layer is pierced by the extraocular muscle tendons, which pass to insert into the sclera. The globe itself has three layers. The outermost fibrous sclera which envelops the globe except the anterior transparent cornea, the vascular pigmented layer (choroid, iris and ciliary body) and the innermost sensory retina. The conjunctival mucosa lines the inner surface of the eyelids and the anterior aspect of the eyeball.

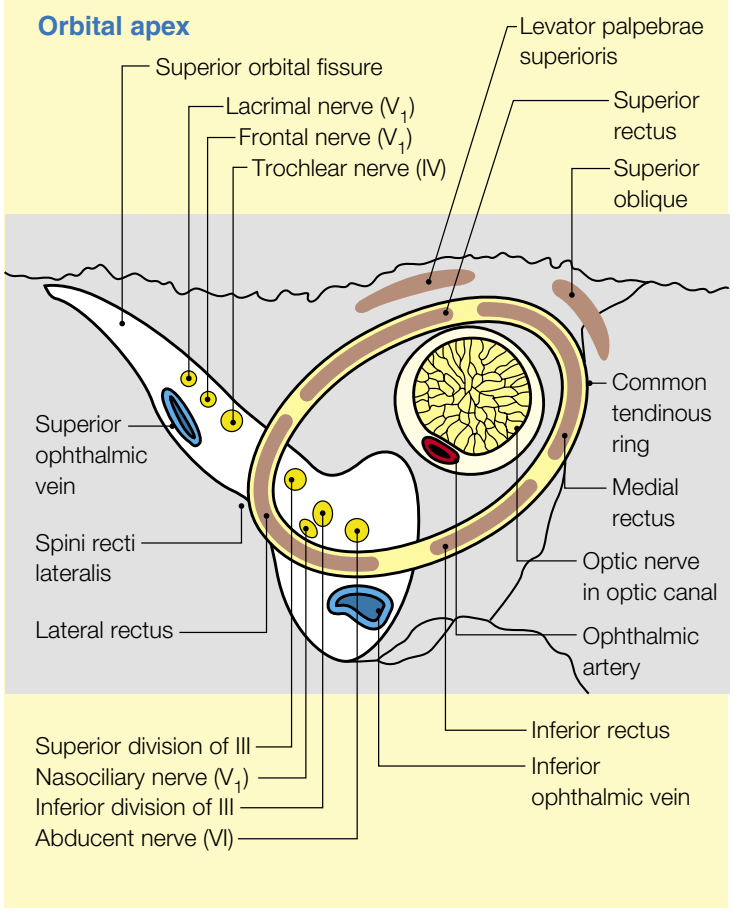
Orbital apex: the four recti muscles arise from a common tendinous ring formed from periosteum at the orbital apex, which lies medial to the globe. This ring encloses the optic canal and the medial portion of the superior orbital fissure. The cone formed by the recti muscles passing towards the globe, helps define an incomplete extraconal (peribulbar) and intraconal (retrobulbar) space (Figure 2). The relationship of the important anatomical structures to this muscular cone is shown in Figure 3.

Conal space and fibrous septa



2

Orbital apex



3

Fibrous septa: there is no strict anatomical separation of the extraconal and intraconal spaces. A matrix of connective tissue gives support, allows dynamic function and controls the spread of injectate within fibro-adipose compartments (Figure 2).

Blood vessels: the main supply is from the ophthalmic artery. This is a branch of the internal carotid after it emerges from the cavernous sinus. It initially lies within the subarachnoid space, but pierces the optic nerve sheath meninges after leaving the optic canal. It first runs inferiolateral to the nerve, but then moves above and towards the superomedial orbit with a tortuous course. Behind the medial upper lid, the facial and supraorbital veins pass posterolaterally as the superior ophthalmic vein. The venous plexus on the anterior orbital floor contributes to the inferior ophthalmic vein.

Nerves: the abducent nerve supplies lateral rectus, trochlear nerve supplies superior oblique and the other muscles are supplied by the oculomotor nerve, which also gives a branch to the upper lid levator. The skin and conjunctiva of the upper lid are supplied by the lacrimal and frontal branches of V_1 (extraconal), and those of the lower lid by the infraorbital nerve (terminal branch of V_2). The nasociliary division of V_1 gives branches to the ciliary ganglion, medial aspect of eyelid skin and conjunctiva, ciliary body and cornea.

Lacrimal gland is located in the superolateral orbit. Drainage is via superior and inferior puncta near the medial lid margins. Each punctum leads to the respective canaliculus, which passes medially to the lacrimal sac. This drains via the nasolacrimal duct to the inferior meatus of the nose. Injection between the caruncle and canthal fold will avoid these structures, and anaesthetize the medial aspect of the eyelids and cornea.

Anaesthesia
Injection into avascular regions such as the medial or preferably inferolateral compartment, can provide adequate regional anaesthesia while minimizing complications. The superomedial compartment must be avoided, because of the risk of damaging the vasculature, muscles and optic nerve at the orbital apex. Current guidelines suggest the use of fine, short needles (25 mm or less), though the issue of blunt versus sharp is still being debated. ◆

The Great Vessels of the Thorax, Abdomen and Neck

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

Aorta

The aorta arises from the left ventricle and ascends for a short distance before arching backwards to descend through the thorax and abdomen.

The ascending aorta ascends to the right from the aortic orifice to the sternal angle. It is about 5 cm long and lies within the fibrous pericardium in a sheath of serous pericardium directly behind the sternum. Above each of the semilunar valvules of the aortic valve is an aortic sinus – the right and left coronary arteries arise from the anterior and left posterior sinuses.

The arch of the aorta ascends from the sternal angle and arches backwards and leftwards over the root of the left lung before descending to the left side of the fourth lumbar vertebra. On its left side lie the phrenic and left vagus nerves under the mediastinal pleura and on its right side, from front to back lie the superior vena cava, right phrenic nerve, trachea, oesophagus, thoracic duct and the body of the fourth thoracic vertebra. It has the following branches.

- The brachiocephalic artery ascends to behind the sternoclavicular joint to divide into the right subclavian artery and right carotid artery.
- The left common carotid artery ascends the neck to divide into the internal and external carotid arteries at the upper border of the thyroid cartilage.
- The left subclavian artery ascends to the neck, lateral to the oesophagus and trachea and medial to the left pleura.

The descending aorta descends in the posterior mediastinum inclining medially from the left side of the fourth thoracic vertebra behind the root of the left lung to the front of the twelfth thoracic vertebra where it passes through the diaphragm. It is in contact with the left pleura throughout its course. It has the following branches:

- third to eleventh posterior intercostal arteries and the subcostal artery
- small bronchial branches
- small oesophageal branches.

Severe deceleration trauma, for example, in a car crash, can cause injury to the aorta. The arch of the aorta is relatively fixed by its branches but the more mobile descending part continues to travel forwards during severe deceleration, producing a shearing force and tearing at the junction. If the adventitia remains intact, a false aneurysm is caused, resulting in mediastinal widening which is visible on radiography. Urgent surgical attention must be sought.

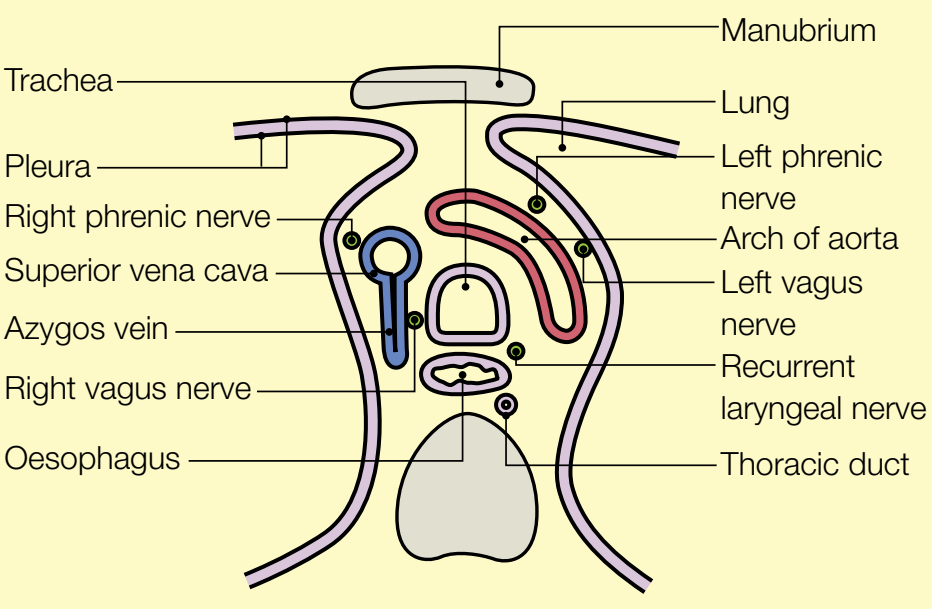
The abdominal aorta enters the abdomen between the two crura of the diaphragm in front of the twelfth thoracic vertebra and descends on the posterior abdominal wall slightly to the left of the midline. On its left side is the inferior vena cava. It is surrounded by networks of autonomic nerves and ganglia, lymph vessels and nodes. Anteriorly it is covered by the lesser sac, pancreas, duodenum and small intestine. It ends on the body of the fourth lumbar vertebra by dividing into two common iliac arteries. It has the following branches.

- The coeliac trunk arises above the pancreas. Its three branches (the left gastric, common hepatic and right gastric arteries) supply the lower oesophagus, stomach, duodenum, liver, pancreas and gallbladder.
- Superior mesenteric.
- Inferior mesenteric.
- Paired branches: the suprarenal, renal and gonadal arteries supply their respective organs.
- Parietal branches: the four pairs of lumbar arteries supply the posterior abdominal wall and spinal cord.
- Terminal branches: the two common iliac arteries each descend without branches away from the midline to divide into internal and external iliac arteries anterior to the sacroiliac joint. The external iliac artery continues to descend and passes below the midpoint of the inguinal ligament to form the femoral artery. The internal iliac artery passes backwards, anterior to the internal iliac vein, to provide branches to the pelvic viscera, perineum and buttock.

Vena cava

The superior vena cava is a wide vessel about 7 cm long formed by the union of the two brachiocephalic veins at the right border of the manubrium. It descends behind the sternum to enter the right atrium at the level of the third right costal cartilage. It has no valves. Its lower half is covered by fibrous and serous pericardium and on its lateral side lies the right pleura and phrenic nerve. The azygos vein is its only tributary, entering it posteriorly (Figure 1).

Structures seen in a cross-section of the mediastinum at the level of the fourth thoracic vertebra



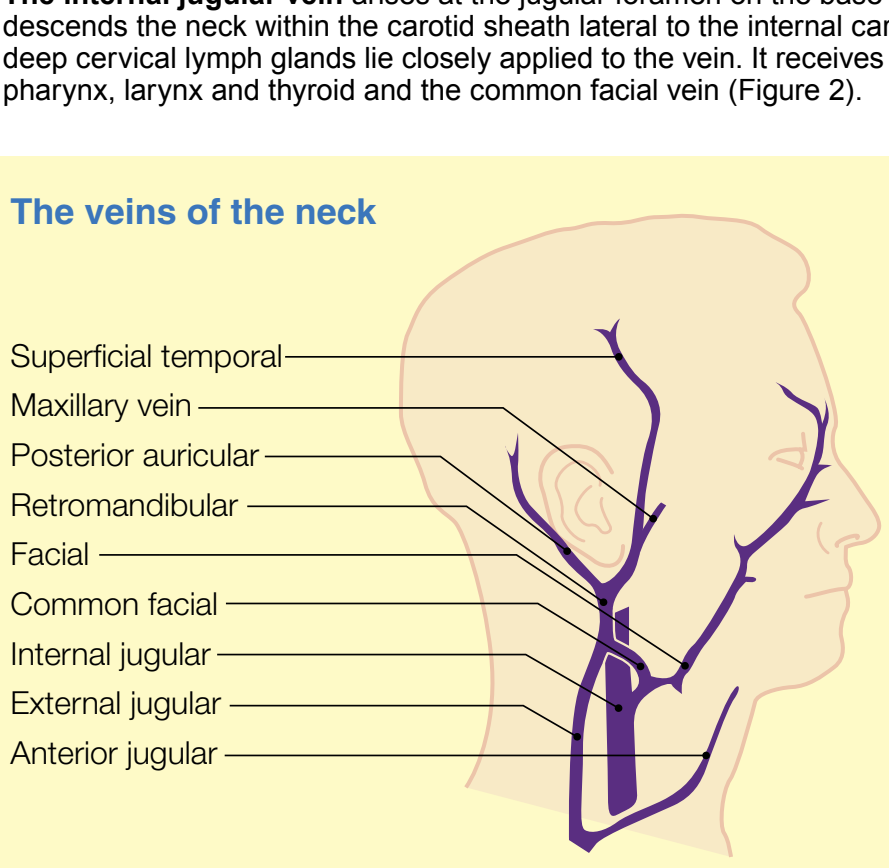
1

The brachiocephalic veins are formed behind the sternoclavicular joints by the union of the corresponding internal jugular and subclavian veins. The right brachiocephalic vein is 3 cm long and descends behind the right border of the manubrium. The right phrenic nerve lies on its lateral surface. The left brachiocephalic vein, about 6 cm long, descends obliquely behind the manubrium above the arch of the aorta and anterior to its branches.

Tributaries from the neck muscles, the thyroid and the anterior chest wall enter both veins and the thoracic duct enters the origin of the left brachiocephalic vein.

The internal jugular vein arises at the jugular foramen on the base of the skull and descends the neck within the carotid sheath lateral to the internal carotid artery. The deep cervical lymph glands lie closely applied to the vein. It receives tributaries from the pharynx, larynx and thyroid and the common facial vein (Figure 2).

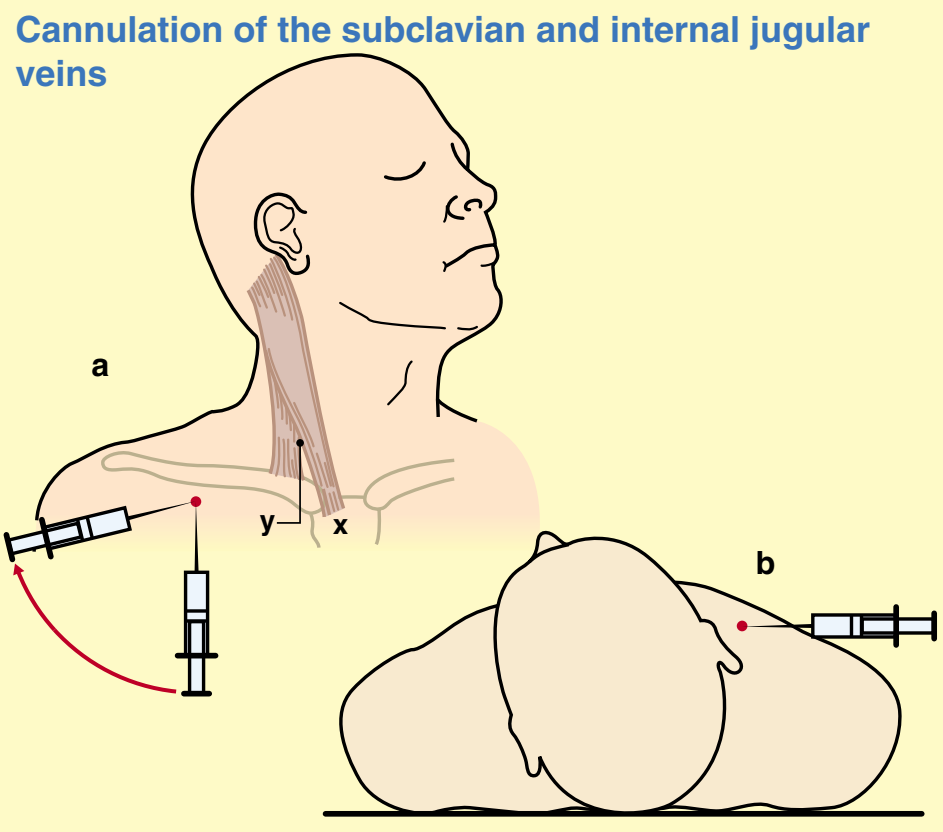
The veins of the neck



2

The subclavian vein is the continuation of the axillary vein, beginning at the outer border of the first rib. It joins the internal jugular vein behind the sternoclavicular joint. Central venous catheterization is an important clinical technique widely used to measure central venous pressure, to administer rapid fluid replacement and for long-term administration of chemotherapy and intravenous feeding (Figure 3).

Cannulation of the subclavian and internal jugular veins



Cannulation of the subclavian vein is best achieved by an infraclavicular approach. **a** The needle is inserted below the midpoint of the clavicle and aimed toward the sternal notch (**x**). **b** The danger of pneumothorax is minimized by keeping the needle horizontal as it is being advanced. Cannulation of the internal jugular is achieved on a supine patient by insertion of the needle at the apex of the triangle formed by the clavicular and sternal heads of sternomastoid (**y**) and guiding it towards the posterior aspect of the sternal notch

3

The inferior vena cava formed in front of the body of the fifth lumbar vertebra by the union of the two common iliac veins ascends the posterior abdominal wall, to the right of the midline through the caval opening of the diaphragm. It has a short intrathoracic course before it opens into the right atrium. The right sympathetic trunk lies behind it. Anteriorly it is covered by the parietal peritoneum below and is crossed by the pancreas and duodenum. Superiorly it lies behind the right lobe of the liver in which it is embedded. The aorta is in contact with its left side.

Right and left common iliac veins are formed anterior to the sacroiliac joints by the union of the internal and external iliac veins. They each ascend obliquely to join their fellow to the right of the body of the fifth lumbar vertebra.

The internal iliac vein is formed by tributaries draining the venous plexuses which drain the pelvic viscera. Both veins lie behind their arteries.

The external iliac vein is the proximal continuation of the common femoral vein which enters the abdomen under the inguinal ligament medial to its artery.

In the case of total occlusion of the inferior vena cava by thrombus or tumour, extensive oedema of the lower body follows. A collateral circulation develops between tributaries of the inferior vena cava which include the superficial and inferior epigastric veins. These convey the blood to the thoraco-epigastric and superior epigastric veins and thence to the superior vena cava. This collateral flow is evident as tense and tortuous veins visible over the trunk

Great vessels of the neck

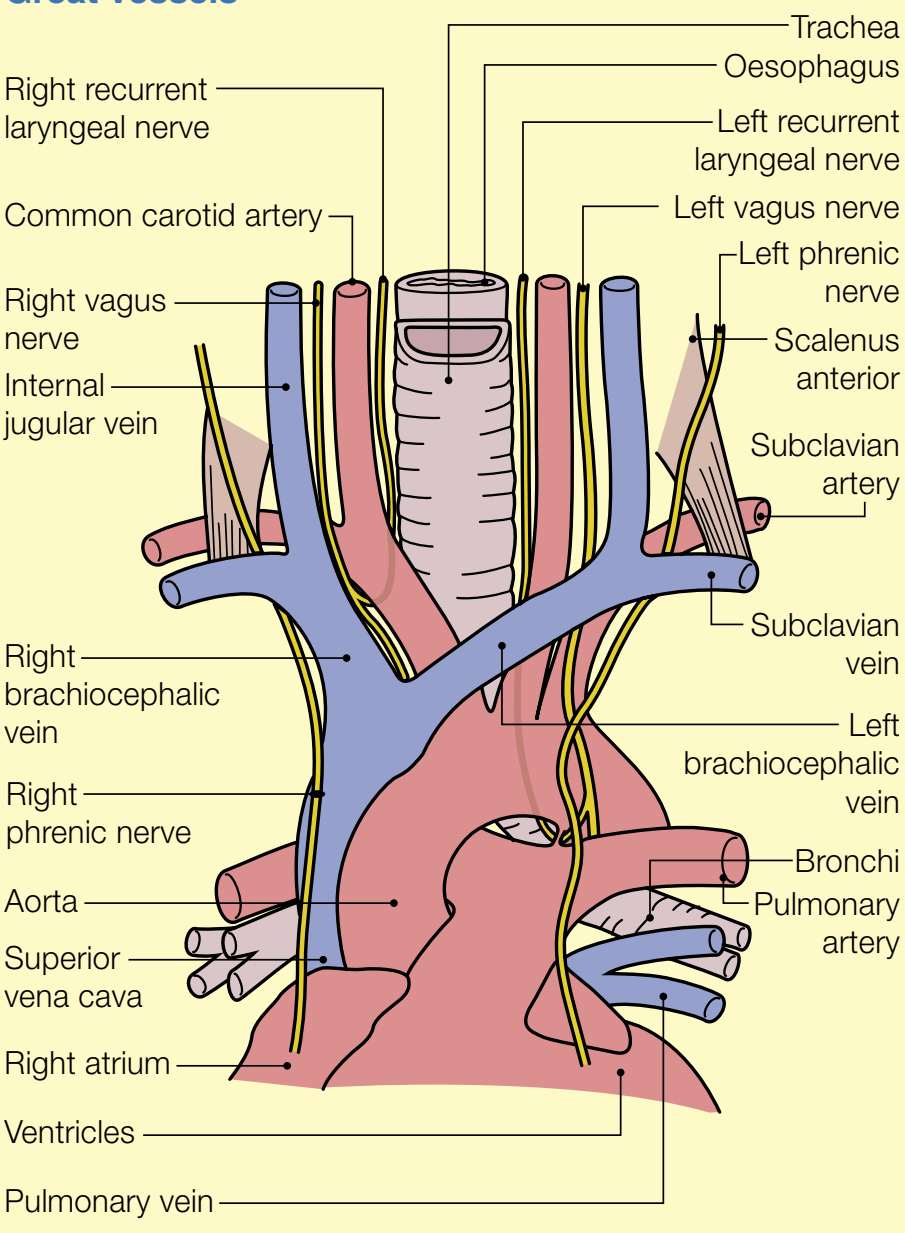
Arterial blood supply
The head, neck and upper limbs are supplied by the three large branches of the aortic arch: the innominate, and the left carotid and subclavian arteries (Figure 4). The innominate artery divides into the right common carotid and right subclavian arteries: the common carotid arterial supply to the head and neck is supplemented by the vertebral branch of each subclavian artery, arising as this vessel passes over the apex of the lung.

Each common carotid artery ascends through the neck from behind the sternoclavicular joint and divides into its terminal (and only) branches, the internal and external carotid arteries, lateral to the upper border of the thyroid cartilage (fourth cervical vertebra). The artery lies within the fascial carotid sheath, accompanied by and medial to the internal jugular vein, with the vagus lying between and posterior to both.

The left common carotid artery in the thorax lies between the innominate, anteromedially, and the left subclavian artery, posterolaterally; the trachea, oesophagus and recurrent laryngeal nerve lie posteromedially. Anterolaterally, the common carotid is covered by the pleura, the left lung and the thymic remnant. The left phrenic and left vagus nerves descend anterior to the artery, and the vessel is crossed by the left brachiocephalic vein.

Each common carotid artery in the neck lies on the transverse processes of the fourth to the sixth cervical vertebrae, separated by the prevertebral muscles and the sympathetic chain. Medially are the trachea and larynx and behind this, the oesophagus and pharynx, with the recurrent laryngeal nerve descending in the groove between these structures. The lateral lobe of the thyroid gland overlaps the proximal common carotid artery in the neck. The artery is overlain by the sternomastoid muscle with its deep fascial coverings: the platysma and skin become direct relations of the distal common carotid above the medial border of the sternomastoid. The common carotid artery is crossed anteriorly by the superior belly or the intermediate tendon of the omohyoid muscle, and the inferior thyroid and common facial veins.

Great vessels



4

The internal carotid artery of each side continues distally from the carotid bifurcation to the base of the skull. It passes through the latter within the carotid canal of the petrous temporal bone and within the dural coverings of the cavernous sinus, before piercing the dural roof and dividing into its middle and anterior cerebral terminal branches. It gives off the ophthalmic artery in its intracavernous portion.

In the neck, the posterior relations are similar to those of the common carotid artery with the transverse process of the upper three cervical vertebrae, the prevertebral muscles and the sympathetic chain posteriorly, the internal jugular vein laterally, with the vagus posteriorly between them, and the pharynx medially. The proximal internal carotid artery is covered with deep investing fascia, platysma muscle and skin, but it is crossed by the hypoglossal nerve and then the posterior belly of the digastric, with the occipital artery below and the posterior auricular artery above the muscle.

As the internal carotid artery approaches the skull base, the styloid process and the attached muscles lie anterolaterally. The stylopharyngeus, accompanied by the glossopharyngeal nerve, pass between the internal and external carotid arteries.

The external carotid artery is at first medial to the internal, but then becomes anterior and lateral, and also crossed by the hypoglossal nerve, the posterior belly of the digastric muscle and adjacent arteries. As it ascends laterally it reaches and passes through the carotid sheath and thence through the substance of the parotid gland, anterior to the facial nerve, dividing within the gland into terminal, superficial, temporal and maxillary branches, respectively passing to the scalp and pterygoid regions. Other branches are the superior thyroid, passing to the superior pole of the lateral lobe of the thyroid gland, an inconstant ascending pharyngeal, a lingual branch to the tongue, a facial branch and the occipital.

The distal end of the common carotid artery is expanded to form the carotid sinus and this may also include the origin of the internal carotid artery. The adventitia of the sinus contains stretch receptors, and these pressure-sensitive baroreceptors provide a rapid mechanism for responding to changes in blood pressure. They are innervated by the carotid sinus branch of the glossopharyngeal nerve descending medial to the internal carotid artery. The nerve also supplies to the carotid body, a vascular chemoreceptor situated posterior to the distal common carotid or external carotid artery. The receptor is stimulated by hypoxia, hypercapnia or increased hydrogen ion concentration, producing reflex increase in the rate and volume of ventilation.

The vertebral artery arises from the superoposterior aspect of the first part of the subclavian artery, as it arches over the apex of the pleura, lung and suprapleural membrane. It passes between the prevertebral muscles to enter the transverse process of the sixth cervical vertebra and ascends through the canal in the proximal six transverse processes, accompanied by its vein. It turns medially over the posterior arch of the atlas to pierce the cervical dura and enter the posterior fossa, joining its fellow on the opposite side to form the basilar artery.

The internal jugular vein
The main venous drainage of the head and neck is through the internal jugular vein. Additional superficial contributions come from the anterior jugular vein over the anterior aspect of the neck (passing laterally deep to the sternomastoid to enter the internal jugular) and the external jugular vein passing from the angle of the jaw superficially over the sternomastoid muscle to pierce the deep fascia and enter the subclavian vein behind the midpoint of the clavicle.

The internal jugular vein is the continuation of the sigmoid sinus, commencing at the jugular foramen in the occipital bone, and descending vertically in the neck to terminate behind the medial end of the clavicle, joining the subclavian vein to form the right or left innominate vein. A slight dilatation near its termination contains a pair of valves.

The relations of the internal jugular vein in the neck are similar to those of the common and internal carotid arteries. It lies lateral to them within the carotid sheath, with the vagus nerve between and posterior to both.

The internal jugular vein is related posteriorly to the tips of the transverse processes of the first to sixth cervical vertebrae and the attached muscles, their covering prevertebral fascia and the cervical sympathetic chain. Posteromedially are the rectus capitus and prevertebral muscles, while posterolaterally are the attachments of levator scapulae and the scalenus anterior muscles. The latter overlies the scalenus medius with the roots of the cervical and brachial plexuses between. The phrenic nerve passes on to the anterior surface of scalenus anterior and descends across the muscle deep to the internal jugular vein. It is at this site it is approached surgically, and may be damaged in approaches to the subclavian and common carotid arteries, or the sympathetic chain.

Inferiorly, the internal jugular vein passes anterior to the first part of the subclavian artery and its thyrocervical trunk, together with the vertebral vein, and either the right mediastinal lymph trunk or the thoracic duct.

The internal jugular vein lies lateral to the internal and common carotid arteries, and at the skull base is related to the last four cranial nerves. The twelfth passes medially, anterior to the internal carotid artery, the eleventh passes laterally anterior to the internal jugular vein, the tenth descends in the carotid sheath posterior to those vessels, and the ninth passes medially between the internal and external carotid arteries.

The sternomastoid muscle overlies the anterior and lateral surfaces of the internal jugular vein with the superior belly of the omohyoid muscle and the anterior jugular vein passing between them. The descendens hypoglossi descends over the anterior aspect of the interior jugular vein before turning laterally to become the ansa hypoglossi. The deep cervical lymph nodes are grouped around the vessel, the cranial nodes lying more medially and termed the retropharyngeal nodes, and in the lower neck a more laterally placed group is termed the supraclavicular nodes.

The tributaries of the internal jugular vein are the inferior petrosal sinus, and the facial, laryngeal, pharyngeal, and superior and middle thyroid veins, together with the right mediastinal lymph trunk or, on the left side, the thoracic duct.

The common carotid artery and internal jugular vein provide important sites of vascular access. The common carotid artery runs distally from behind the sternoclavicular joint towards the angle of the jaw, and can be palpated or compressed on the transverse processes of the fourth and sixth cervical vertebrae. This is either through, or above, the sternomastoid muscle.

The internal jugular vein, lying lateral to the common and internal arteries, runs over the tips of the transverse processes, the transverse mass of the atlas being palpated deeply between the angle of the jaw and the mastoid process. If the artery is not palpable the surface marking of the internal jugular vein is from the earlobe to the medial end of the clavicle. A constant and useful site of access to the lower internal jugular vein is between the sternal and clavicular heads of the sternomastoid muscle.

The jugular venous pressure can be observed within the internal jugular vein by rotating the head to the opposite side and appropriate positioning of the trunk. The level can be modified by deep breathing and a Valsalva manoeuvre.

Anatomy of the Heart

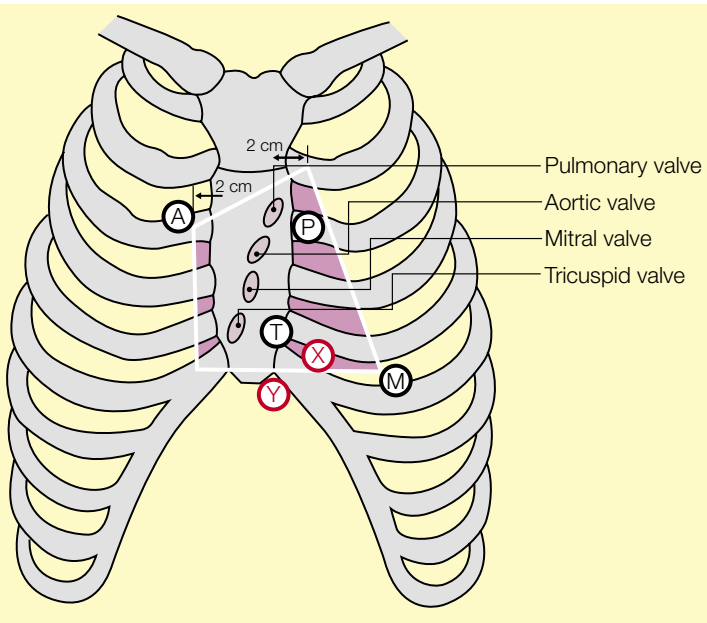
Anatomy of the Heart

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

The heart is a cone-shaped organ that lies obliquely in the mediastinum within the pericardial sac, suspended by the large vessels (Figure 1). Its four chambers, the left and right atria, and the left and right ventricles are demarcated on its surface by coronary and interventricular sulci. Its square base lies posteriorly and is formed largely of the left atrium, which receives the four pulmonary veins at each corner. The inferior vena cava enters the right atrium at its right postero-inferior angle, which rests on the central tendon of the diaphragm; the superior vena cava enters the upper part of the atrium.

Position of the heart

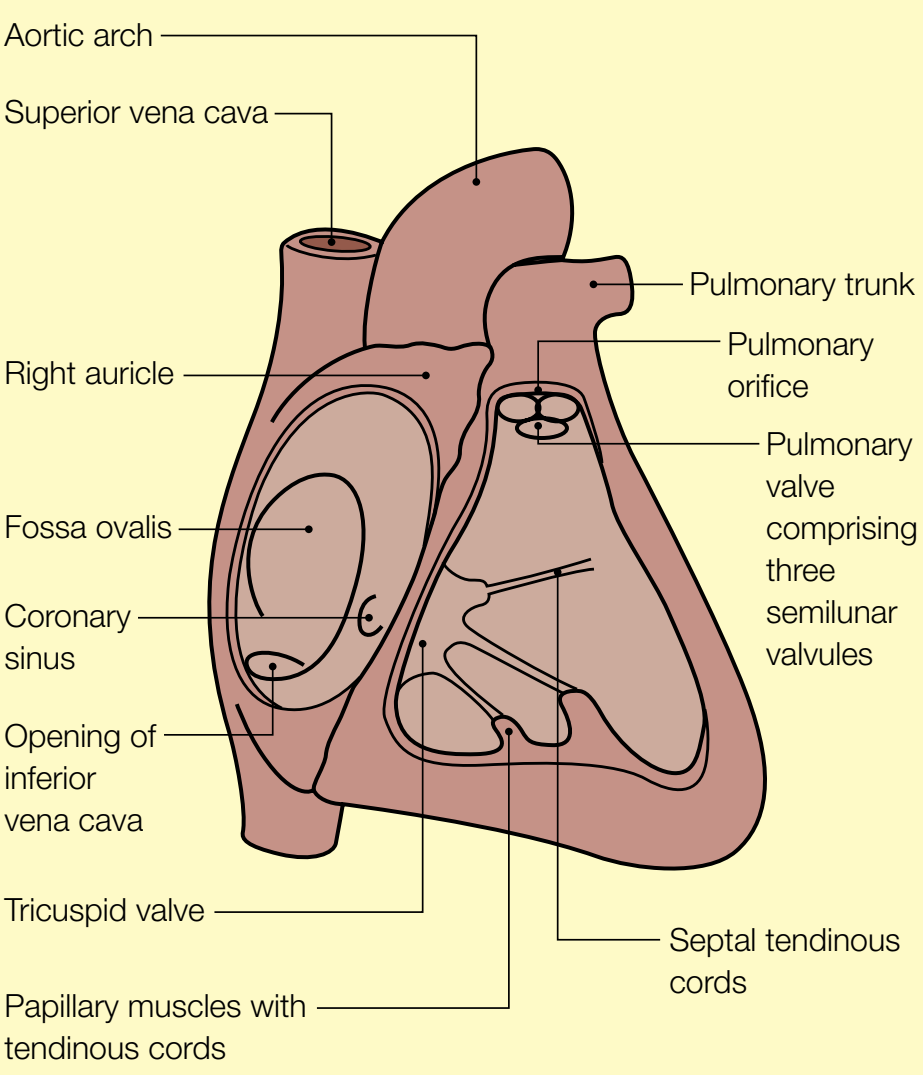
The right border lies 2 cm from the sternal edge between the 3rd and 6th right costal cartilages; the inferior border lies between the latter point and the 5th left interspace in the midclavicular line. A line from this point to the 2nd left costal cartilage, 2 cm from the sternal edge, defines the left border. The valves (pulmonary, aortic, mitral and tricuspid) lie obliquely behind the sternum. However, their sounds are best heard at the auscultatory areas over the chamber or vessel into which blood is pumped (P, A, M, T, respectively). An intracardiac injection can be made through the medial aspect of the 5th intercostal space (X). Pericardial aspiration, in cases of effusion or tamponade, can be achieved by a needle inserted alongside the xiphisternum (Y), which is directed deep to the sternum towards the left shoulder



1

The right atrium is a thin-walled chamber. It forms the right border of the heart and has a small projection, the right auricle, overlapping the origin of the ascending aorta (Figure 2). Its posterior wall behind the caval openings is smooth and marked by a shallow depression, the fossa ovalis, which is the remnant of the fetal opening.

Interior of the right atrium and right ventricle



2

The right ventricle is a thick-walled chamber that projects to the left of the right atrium forming part of the heart's anterior and inferior surfaces. The interventricular septum separates the right from the left ventricle and bulges into the right cavity, making it crescentic in cross-section. The atrioventricular (AV) orifice lies postero-inferiorly guarded by the tricuspid valve, comprising three cusps each consisting of thin fibrous tissue covered on both sides by endocardium. The atrial surfaces of the cusps are smooth and the ventricular surfaces are rough and anchored to the ventricular walls by tendinous cords arising directly from the septum or from two papillary muscles. The muscles tighten the cords during ventricular contraction and thereby prevent eversion of the cusps into the atrial cavity. The pulmonary orifice is a fibrous ring lying at the upper end of the ventricle, the infundibulum. A valve, comprising three semilunar valvules lies at the entrance to the orifice.

The left atrium is a thin-walled chamber that lies behind the right ventricle and forms most of the base of the heart. Superiorly, the left auricle, a small projection, overlies the origin of the pulmonary trunk. The four pulmonary veins enter each corner of the posterior wall. Their orifices possess no valves. The left AV orifice lies in the anterior wall. The posterior wall of the left atrium is separated from the oesophagus and the left bronchus by the pericardial sac.

The left ventricle extends forwards and to the left from the left atrium, and lies mainly behind the right ventricle. It forms the apex, the left border and surface, and part of the anterior and inferior surfaces of the heart. Its walls are thick and surround a conical cavity with two orifices, the left AV orifice posteriorly and the aortic orifice superiorly. The left AV orifice is guarded by the mitral (bicuspid) valve, the two cusps of which are attached to a fibrous ring surrounding the orifice. The free margins of the cusp are anchored to papillary muscles on the ventricular wall by tendinous cords. The aortic orifice is a fibrous ring guarded by a valve of three semilunar valvules similar to the pulmonary valve. The thick interventricular septum is marked on the surface by anterior and posterior interventricular sulci; the right ventricle lies anterior to the left ventricle.

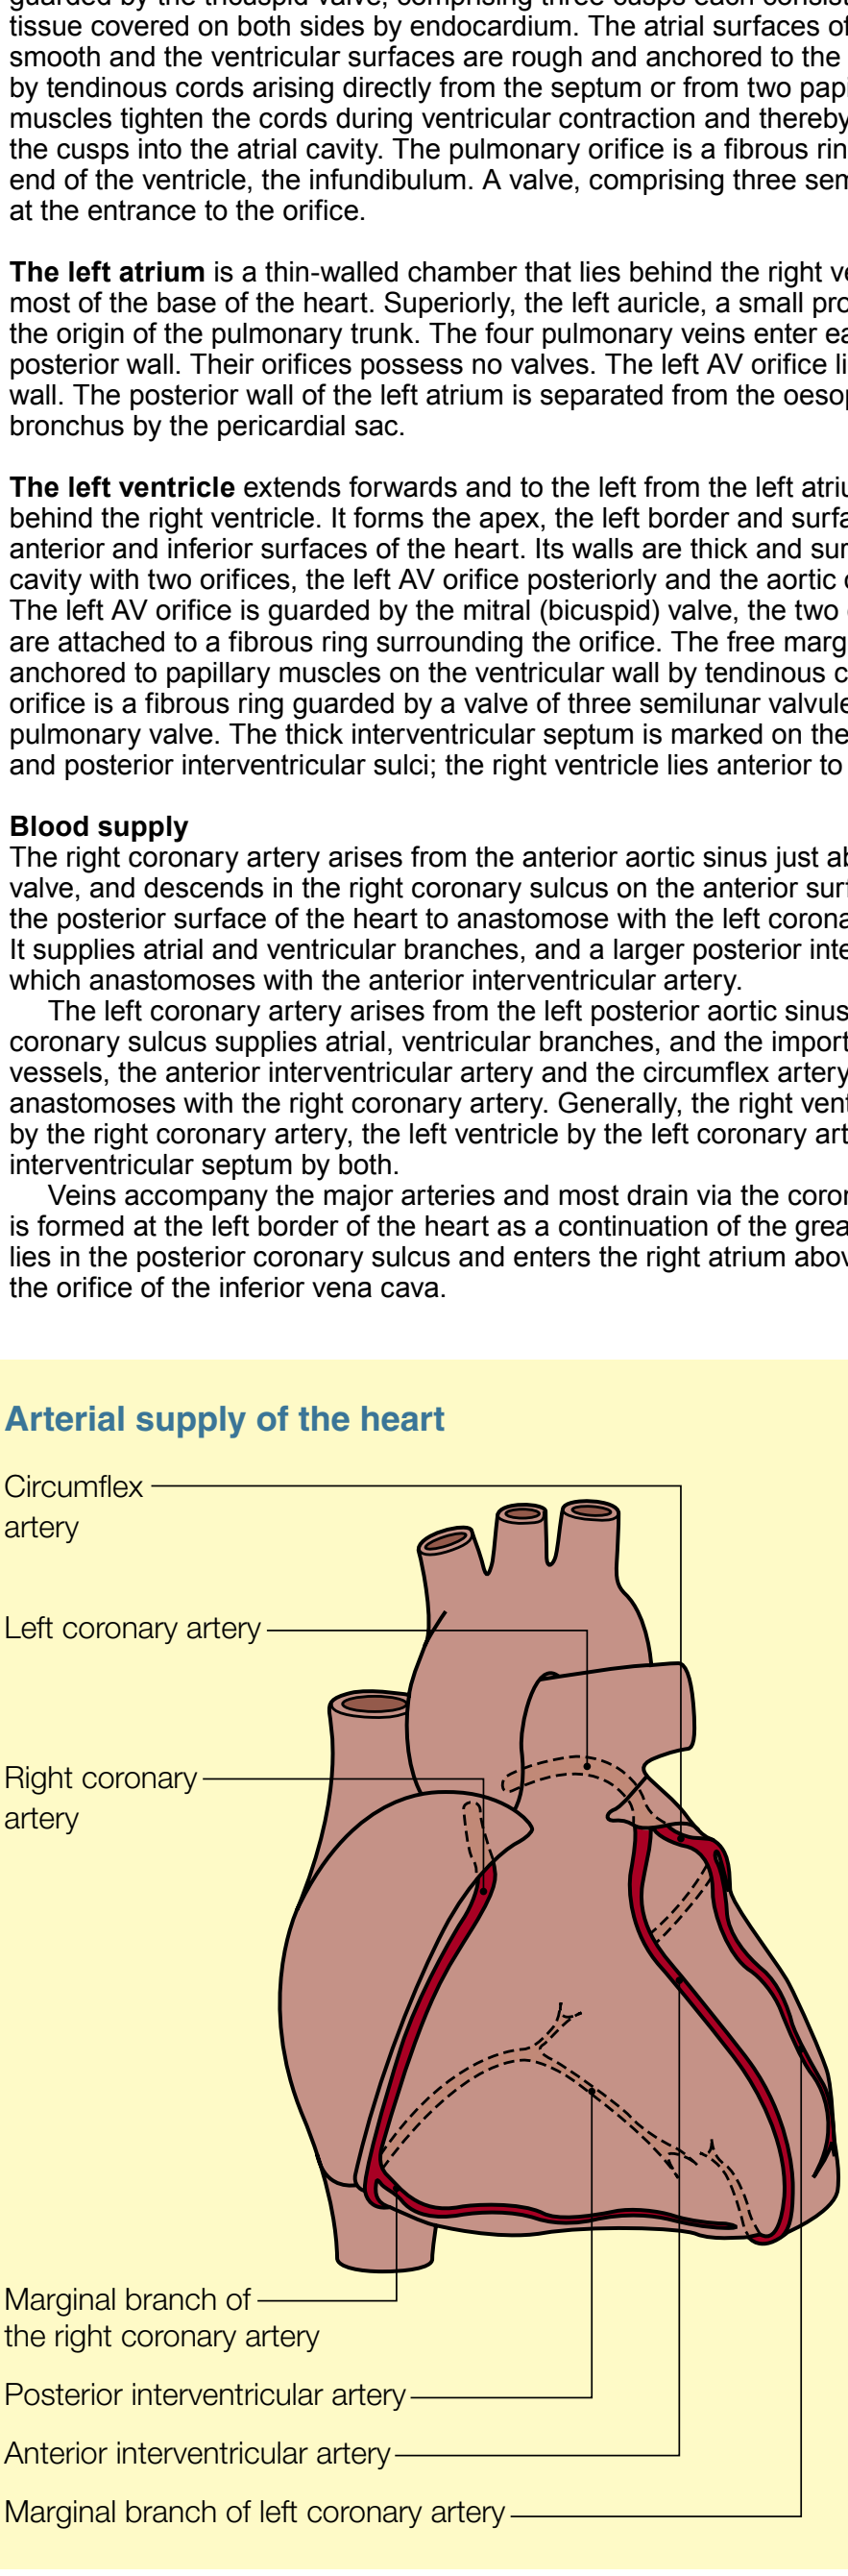
Blood supply

The right coronary artery arises from the anterior aortic sinus just above the aortic valve, and descends in the right coronary sulcus on the anterior surface and crosses the posterior surface of the heart to anastomose with the left coronary artery (Figure 3). It supplies atrial and ventricular branches, and a larger posterior interventricular artery, which anastomoses with the anterior interventricular artery.

The left coronary artery arises from the left posterior aortic sinus and, in the left coronary sulcus supplies atrial, ventricular branches, and the important anastomotic vessels, the anterior interventricular artery and the circumflex artery. The latter anastomoses with the right coronary artery. Generally, the right ventricle is supplied by the right coronary artery, the left ventricle by the left coronary artery and the interventricular septum by both.

Veins accompany the major arteries and most drain via the coronary sinus, which is formed at the left border of the heart as a continuation of the great cardiac vein. It lies in the posterior coronary sulcus and enters the right atrium above and posterior to the orifice of the inferior vena cava.

Arterial supply of the heart



3

Nerve supply

The nerve supply is by vagus and sympathetic fibres through the cardiac plexus. The fibres are distributed with the coronary vessels. Parasympathetic ganglion cells are found in the heart walls. Sensory fibres subserving reflex activity pass in the vagus and pain fibres in the spinal nerves (T1–3).

The conducting system of the heart is formed of specialized heart muscle cells. It comprises the sinoatrial node, the AV node, the AV bundle (of His), its right and left branches, and a terminal subendocardial plexus of Purkinje fibres. The conducting system initiates the muscle contractions of the cardiac cycle and controls its regularity.

The sinoatrial node (pacemaker) is a small vascular area of conducting tissue in the anterior wall of the right atrium to the right of the superior vena caval opening. Impulses are conducted from it through the atrial wall to the AV node, a similar nodule in the septal wall of the right atrium above the coronary sinus opening. The AV bundle arises from the node, descends in the interventricular septum, and divides into right and left branches to supply their respective ventricles. If the AV bundle is damaged, as it may be following infarction, total heart block occurs and the ventricles contract slowly at their own rate, independent of the atria, which continue to contract at the rate determined by the sinoatrial node.

Large Veins of the Neck

John Craven

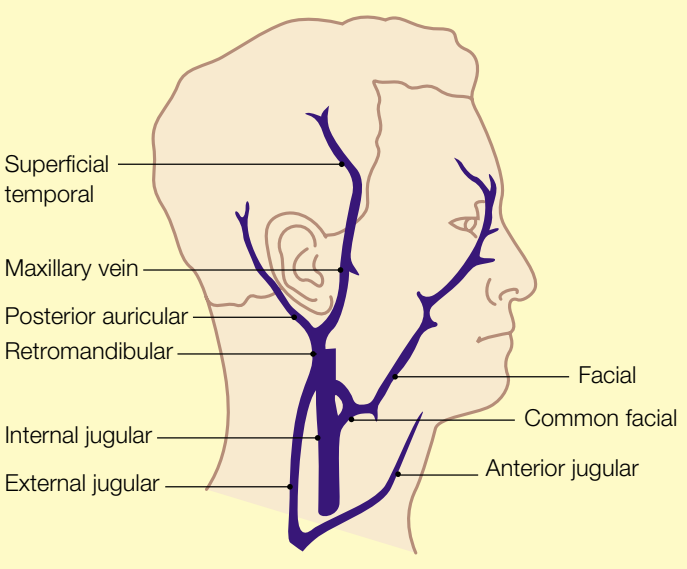
John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

The internal jugular vein drains blood from the intracranial region and the head and neck. It arises at the jugular foramen on the base of the skull as a continuation of the sigmoid venous sinus, passes downwards through the neck and, behind the medial end of the clavicle, is joined by the subclavian vein to form the brachiocephalic vein. The vein has a dilatation at each end, the superior and inferior jugular venous bulbs and a fairly constant pair of valves just above the lower bulb.

The vein lies within the carotid sheath with the vagus nerve behind and the internal or common carotid arteries medially. The deep cervical lymph nodes lie around it. At the base of the skull it lies lateral to the last four cranial nerves. Posteriorly it lies on the sympathetic chain, prevertebral fascia and muscles, the phrenic nerve and, inferiorly, the subclavian artery. It is crossed laterally by the accessory nerve passing downwards and laterally, then by the posterior belly of digastric and the omohyoid muscles.

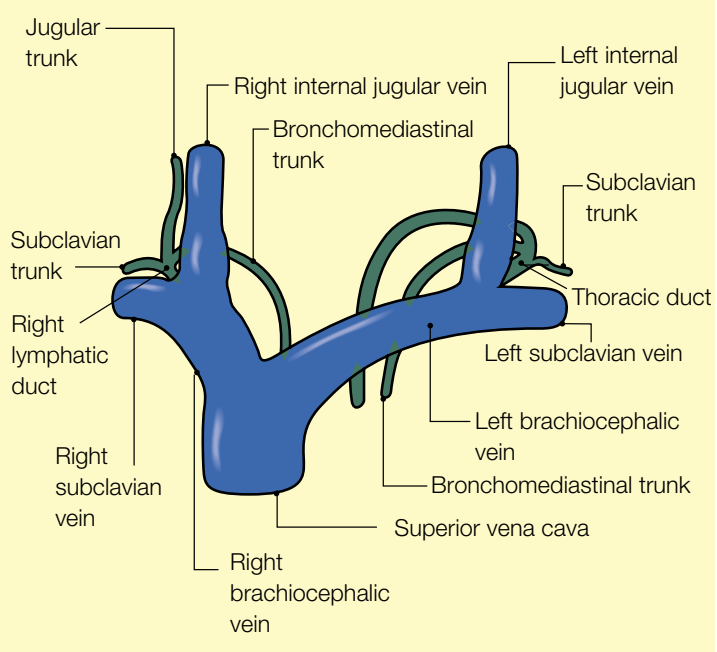
Further laterally, from above downwards, are the styloid process and its muscles, the sternocleidomastoid muscle and the medial end of the clavicle. Its tributaries are the pharyngeal plexus, facial vein, lingual vein and the superior and inferior thyroid veins. On the left side, the thoracic duct may enter the vein and on the right the right lymph duct (Figures 1 and 2).

Veins of the neck



1

Termination of the thoracic and right lymphatic ducts



2

Most techniques for cannulating the internal jugular vein depend on identifying the sternal and clavicular heads of sternocleidomastoid muscle. One preferred technique is to insert the needle in the triangular gap between the clavicular and sternal heads of sternomastoid just above the clavicular. The needle is inserted at the apex of the triangle at an angle of 40° and advanced caudally and slightly medially behind the clavicle along the posterior border of the sternocleidomastoid cephalic to the point where the external jugular vein can be seen crossing the posterior border. The needle is directed towards the sternal notch and aimed about 10◦ above the coronal plane.

The maxillary vein and superficial temporal vein join below the ear to form the retromandibular vein in the substance of the parotid gland.

The external jugular vein, a superficial vein, is formed behind the angle of the mandible by the union of the posterior auricular and a branch of the retromandibular vein. It descends in the subcutaneous tissues over sternocleidomastoid and pierces the cervical fascia above the midpoint of the clavicle to enter the subclavian vein.

The anterior jugular vein begins below the hyoid bone near the midline and passes downwards and laterally, crossing the thyroid isthmus deep to the sternomastoid to enter the external jugular vein behind the clavicle. ◆

The Larynx

Lynn M Carragher
John Shaw-Dunn

Lynn M Carragher is Specialist Registrar in Anaesthesia at the Royal Infirmary, Glasgow, UK.

John Shaw-Dunn is Senior Lecturer in Anatomy at the University of Glasgow. His main research interest is clinical anatomy.

The larynx started life among the lungfish as a simple circular collar of muscle fibres, which could tighten and prevent water entering the lung buds while the fish was submerged. In modern humans, the larynx is still needed to protect the air passages, but has evolved into a complex sphincter with sophisticated control, which is needed for breathing, coughing, lifting and speaking.

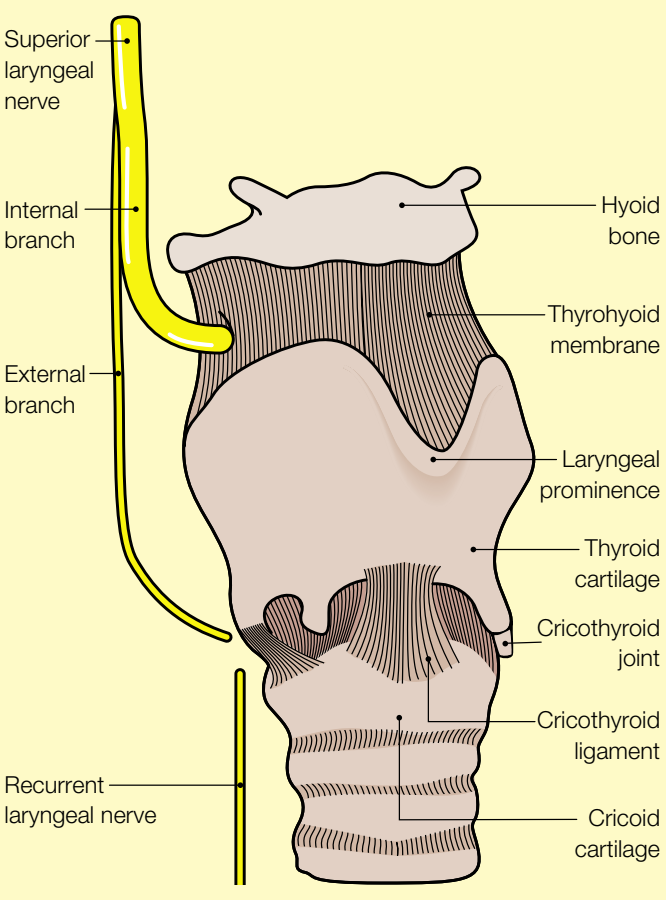
Anaesthetists and Intensive Care Specialists require a thorough knowledge of the anatomy of the larynx for direct laryngoscopy, tracheal intubation, regional anaesthesia for awake intubation, cricothyroid puncture for retrograde intubation and cricothyroidotomy in the 'can't intubate can't ventilate' situation.

Skeleton of the larynx

The larynx lies level with the third to sixth cervical vertebrae in adult men. In women and children, it is slightly higher.

The laryngeal skeleton (Figure 1) is part of the primitive skeleton of the pharynx derived from the pharyngeal arches. It is composed of the hyoid bone and nine cartilages (three single and three paired). The hyoid bone is U-shaped and best felt gently from the sides. The thyroid cartilage, shaped like the prow of a ship, projects forward at the laryngeal prominence and is well marked in men, while the cricoid cartilage is like a signet ring, with the narrower arch in front. It forms most of the posterior wall of the larynx and the lower part of the anterior and lateral walls. It is the only complete skeletal ring of the airway and is of relevance in the application of cricoid pressure during rapid sequence inductions.

Anterolateral view of the larynx with a scheme of the laryngeal nerves



1

The epiglottis (Figure 2) is visible from inside the pharynx. It is a large elastic cartilage, classically leaf-shaped and projecting obliquely up behind the tongue and the hyoid bone. The paired arytenoid cartilages, pyramidal in shape and sited superolaterally on the cricoid lamina, are best seen from the back of the larynx. The corniculate cartilages, over the apices of the arytenoid cartilages and the cuneiform cartilages, complete the skeleton of the larynx.

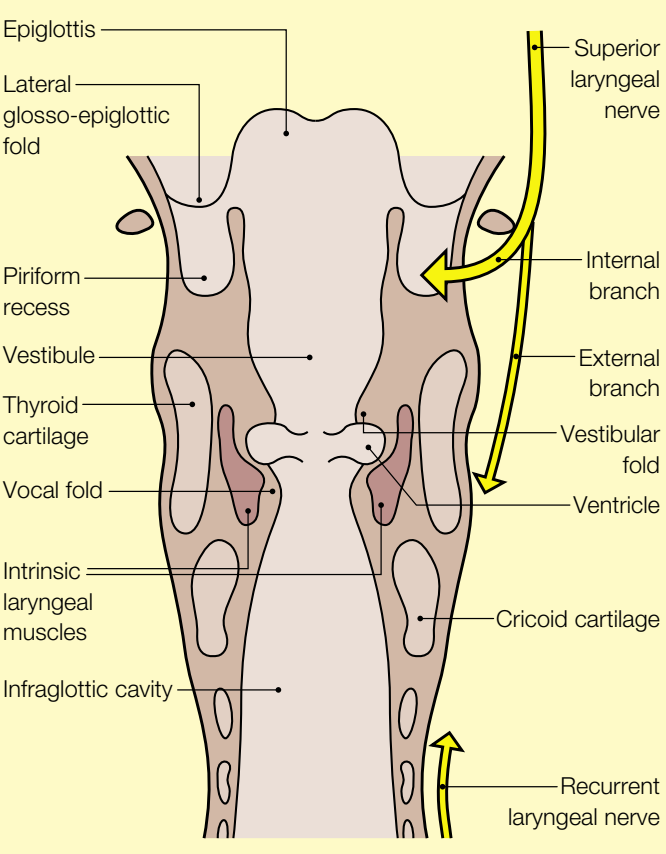
The cartilages articulate with each other at tiny synovial joints and are connected by fibroelastic membranes. The thyrohyoid membrane lies above the thyroid cartilage and the cricothyroid ligament below. The position of each can be felt with the tips of the fingers. Knowledge of the relationship of the internal branch of the superior laryngeal nerve to the thyrohyoid membrane and hyoid bone is important because the nerve can be blocked at this site. The cricothyroid ligament is the membrane punctured in cricothyroidotomy and in the infiltration of local anaesthetic, if required, for awake intubation and bronchoscopy.

Muscles and interior of the larynx

The laryngeal muscles are divided into extrinsic and intrinsic groups. The extrinsic muscles are attached to the outside of the cartilages and the hyoid bone, whereas the intrinsic muscles are confined to laryngeal attachments.

The cavity of the larynx extends from the laryngeal inlet to the lower border of the cricoid cartilage (Figure 2). Mucosa, extending from the tongue to the anterior surface of the epiglottis, forms the midline-raised fold called the median glosso-epiglottic fold and on either side, the lateral glosso-epiglottic folds. The depression formed between the folds is the vallecula, into which the standard Macintosh blade is inserted for laryngoscopy.

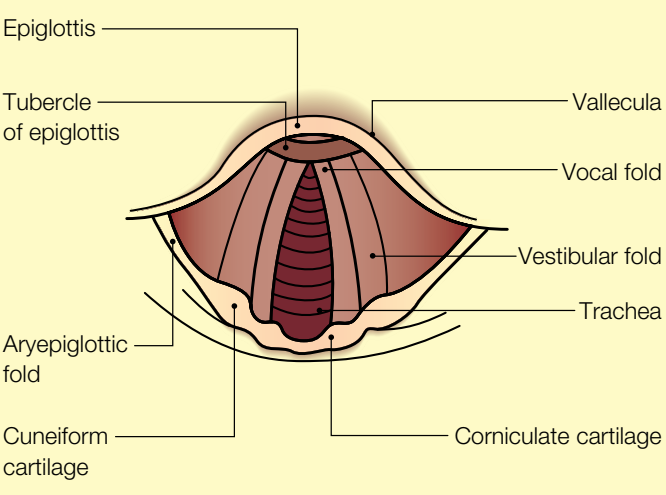
Coronal section of the larynx looking forwards to the anterior comissure



2

From the epiglottis, the mucosa sweeps down in the aryepiglottic folds to the vestibular folds (false cords) and then to the vocal folds (true cords) below. This forms a three-tier sphincter, bounding a series of compartments – the vestibule, the ventricle and the infraglottic cavity. These structures can be seen, typically foreshortened, at direct laryngoscopy (Figure 3).

View of the larynx as seen on direct laryngoscopy



3

The upper sphincter is the laryngeal inlet, with the epiglottis in front and the aryepiglottic folds at the side, almost in a vertical plane. The vocal folds form the lower sphincter, surrounding the glottis or rima glottidis. The vocal folds are wedge-shaped and contain the vocalis muscle. The mucosa is covered by stratified squamous, non-keratinized epithelium, which, firmly bound to the underlying ligament, gives the typical pale appearance. In the adult, this is the narrowest part of the larynx. In children, less than 8–10 years of age, the cricoid ring is the narrowest part. With the exception of the vocal folds, the whole interior of the larynx is covered with pseudostratified ciliated respiratory epithelium.

During quiet respiration the folds swing outwards and inwards with the tidal flow of air. The folds adduct completely and close off the glottis in speech and in cough, as well as in effort. The arytenoids probably rock inwards and downwards to close the glottis.

The intrinsic muscles of the larynx, apart from the crico-thyroid, lie between the mucosa and the laryngeal skeleton. It is easiest to think of a ring of muscles that close the sphincters (the lateral cricoarytenoids and the transverse and oblique arytenoids) and a pair of dilator muscles that open them (the posterior cricoarytenoids). Much of the opening and closing of the sphincters may be biomechanical and depend on longitudinal compression of the larynx, causing the folds to buckle inwards like the pleated folds of a jack-in-the-box.

Nerve supply

The larynx develops from the pharyngeal arches and this relationship can be seen in the nerve supply, which comes from the superior laryngeal nerve, the nerve of the fourth arch and the recurrent laryngeal nerve, the nerve of the sixth arch. Both are derived from the vagus nerve.

The superior laryngeal nerve arises below the inferior vagal ganglion and divides, usually within the carotid sheath, into an internal branch (sensory and autonomic) and an external branch (motor). The larger internal branch pierces the thyrohyoid membrane with the superior laryngeal artery and supplies sensory fibres to the laryngeal mucosa, above the vocal cords (Figure 1). Two methods of nerve blockade of the internal branch for awake intubation are infiltration of local anaesthetic where the nerve pierces the thyrohyoid membrane or direct application of cotton pledgets soaked in local anaesthetic into the piriform recesses, using Krause's forceps. The external branch runs downwards to reach the cricothyroid and the inferior pharyngeal constrictor muscles.

The recurrent laryngeal nerve loops around the aortic arch on the left and the subclavian artery on the right. It ascends on the trachea and passes behind the cricothyroid joint in the wall of the larynx. It supplies all the intrinsic laryngeal muscles except the cricothyroid and sensation to all the mucosa below the vocal folds. It is an important nerve on the afferent limb of the cough reflex. Various reviews and case reports suggest that there may be some overlap between the different territories of supply, even across the midline. ◆

Joints and Ligaments of the Vertebral Column

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

The articular surfaces of the bodies of adjacent vertebrae are covered by hyaline cartilage and united by a thick fibrocartilaginous intervertebral disc. The disc centre (nucleus pulposus) is gelatinous and surrounded by a fibrous part, the annulus fibrosus. The disc is a shock absorber. Occasionally the semisolid nucleus protrudes through a defect in the annulus; it may press on the spinal cord or a spinal nerve to produce symptoms and signs of nerve compression. Adjacent vertebrae articulate by two synovial joints between the paired articular processes. The vertebral bodies are united by anterior and posterior longitudinal ligaments.

The anterior ligament extends from the occiput to the sacrum and is attached to each vertebra. Its deep fibres blend with the intervertebral discs.

The posterior ligament extends from the occipital bone to the sacrum and is attached to each vertebral body and disc. Its superior part, from the body of C2 to the occiput is known as the tectorial membrane.

The ligamenta flava unite the adjacent laminae. They contain a large amount of yellow elastic tissue and are strong. Because of their elasticity they remain taught during flexion and extension of the spine, maintaining the curvature of the spinal column and supporting it when it is flexed. The ligaments have no sensory supply and can be pierced painlessly when a lumbar puncture is performed.

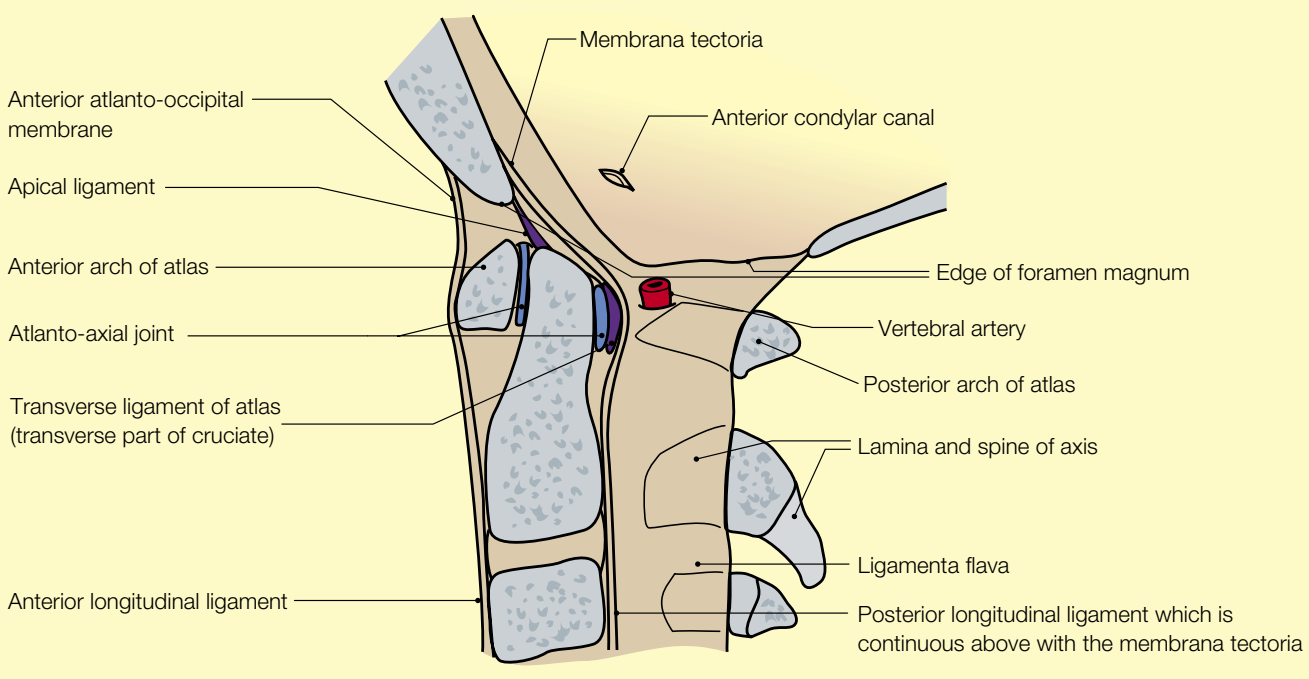
The supraspinous, interspinous and intertransverse ligaments help to unite adjacent vertebrae. The supraspinous is a strong ligament connecting the tips of the spinous processes from C7 to the sacrum. Above C7 it forms the ligamentum nuchae which attaches to the occipital protuberance and provides attachment to neck muscles. The intertransverse ligaments are weak but best developed in the lumbar region.

The articular ligaments around the joints of the articular facets provide additional support.

All these ligaments contribute to supporting the spinal column when it is in the flexed position.

The occipito-atlanto-axial articulation: the atlanto-occipital and atlanto-axial joints (Figure 1) are modified to allow free movement of the head. Radiographs taken through the wide open mouth are used to demonstrate these joints.

Median section to show ligaments of axis, atlas and occiput



1

The atlanto-occipital joints are condyloid synovial joints between the convex occipital condyles and the concave upper articular surfaces of the atlas. Flexion and extension occur at these joints. The joints are supported by the posterior longitudinal ligament, here known as the membrana tectoria, and the anterior atlanto-occipital membrane, which connects the anterior margin of the foramen magnum with the anterior atlas.

The atlanto-axial joints comprise two lateral synovial plane joints between the lateral masses of the two vertebrae and a midline synovial pivot between the dens or odontoid process, a stout pillar projecting vertically from the body of the vertebra in the midline, and a ring formed by the anterior arch and the transverse ligament of the atlas. Rotation occurs at this joint. The joint is strengthened by accessory ligaments; the apical ligament attaches the apex of the odontoid process to the foramen magnum, laterally there are two alar ligaments attaching the odontoid process to the margin of the foramen magnum, the membrana tectoria covers the entire joint and connects the back of the axis, the occiput and the adjacent cruciate ligament.

Functional aspects

Curvature and mobility – in fetal life the vertebral column is flexed – its primary curvature. After birth, two secondary curvatures develop: extension of the cervical region by the muscles raising the head; and extension of the lumbar region after adoption of the erect posture. The primary curvature is retained in the thoracic and sacral regions. These curvatures and the intervertebral discs give some resilience to the column.

Muscles – the extensor muscles of the back and neck extend the head and vertebral column. They form a large composite mass lying deep to trapezius and girdle muscles and extend from the sacrum to the occiput. The largest and most powerful are the erector spinae muscles but these are supported by shorter muscles attached to adjacent vertebrae and to nearby ribs. These muscles play a large part in maintaining posture and are in constant action when standing at rest for the centre of gravity lies anterior to the vertebral column. The muscles attached to the skull produce extension, lateral flexion and rotation of the head.

Movements – only limited movements are possible between adjacent vertebrae but because these can augment each other it is possible to produce extensive movement of the whole vertebral column. Flexion is most marked in the cervical region, rotation in the thoracic, and extension and lateral flexion in the lumbar region (Figure 2).

Muscles causing movement of the vertebral column

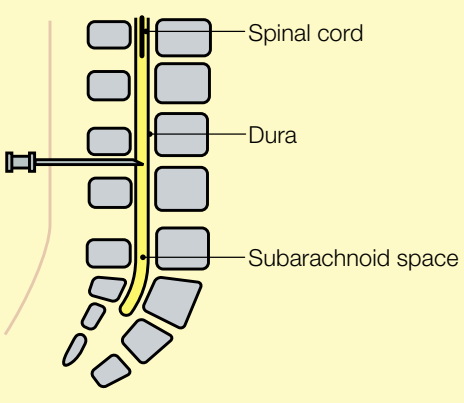
Movement	Muscles
Trunk	
Flexion	Rectus abdominis and prevertebral muscles
Lateral flexion	The oblique abdominal muscles and quadratus lumborum
Neck	
Rotation	Sternocleidomastoid, trapezius
Flexion	Longus capitis and the muscles depressing the fixed mandible
Extension	Postvertebral muscles
Lateral flexion	Sternocleidomastoid and trapezius

2

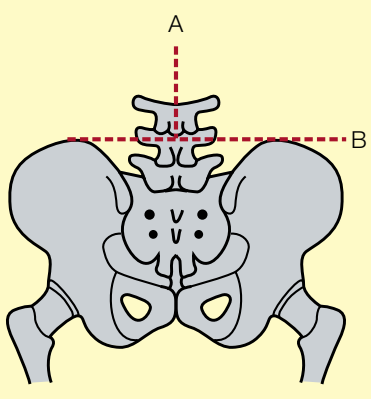
Stability depends almost entirely on the pre- and post-vertebral muscles helped by the ligamenta flava; neither the bones nor ligaments alone could withstand the large forces occasionally acting on the column. Most vertebral functions do not produce instability of the vertebral column for the intervertebral ligaments are not easily torn. If, however, the ligamenta flava and interspinous ligaments are ruptured, the vertebral column is unstable and subsequent displacement may produce compression of the spinal cord and irreversible nerve damage. Fracture of the odontoid process allows the forward displacement of the arch of the atlas together with the skull and fractured part of the odontoid process; a similar forward displacement follows a rupture of the transverse ligament of the atlas. Only 15% of such injuries are followed by neurological damage because the spinal canal is wide at this level.

Vertebral canal – a bony ligamentous structure that extends from the foramen magnum to the sacral hiatus. The spinal cord ends at L2, the dural sac at S2, the supracristal plane, which lies between the highest points of the iliac crests, crosses the spine of L4 (Figure 3).

Site of lumbar puncture



a The site of choice for lumbar puncture is between L3 and L4. The spinal cord is out of danger. Cauda equina not shown.



b The usual site for lumbar puncture is shown as the intersection of the midline (A) with the intercristal plane (B).

3

Lumbar puncture – a needle inserted just above the spine of L4 passes through the interspinous ligament and ligamentum flavum entering the epidural space and then the dura to enter the spinal canal, from which cerebrospinal fluid can be drawn off for examination. Local anaesthetic solution can be injected into the extradural (epidural anaesthesia) or into the spinal (spinal anaesthesia) canal. The dural sac, with its contents, the spinal cord, the spinal nerves and the cerebrospinal fluid, is separated from the walls of the spinal canal by the extradural space, in which lie the emerging spinal nerves and vertebral venous plexus. ◆

Lumbar, Sacral and Coccygeal Plexuses

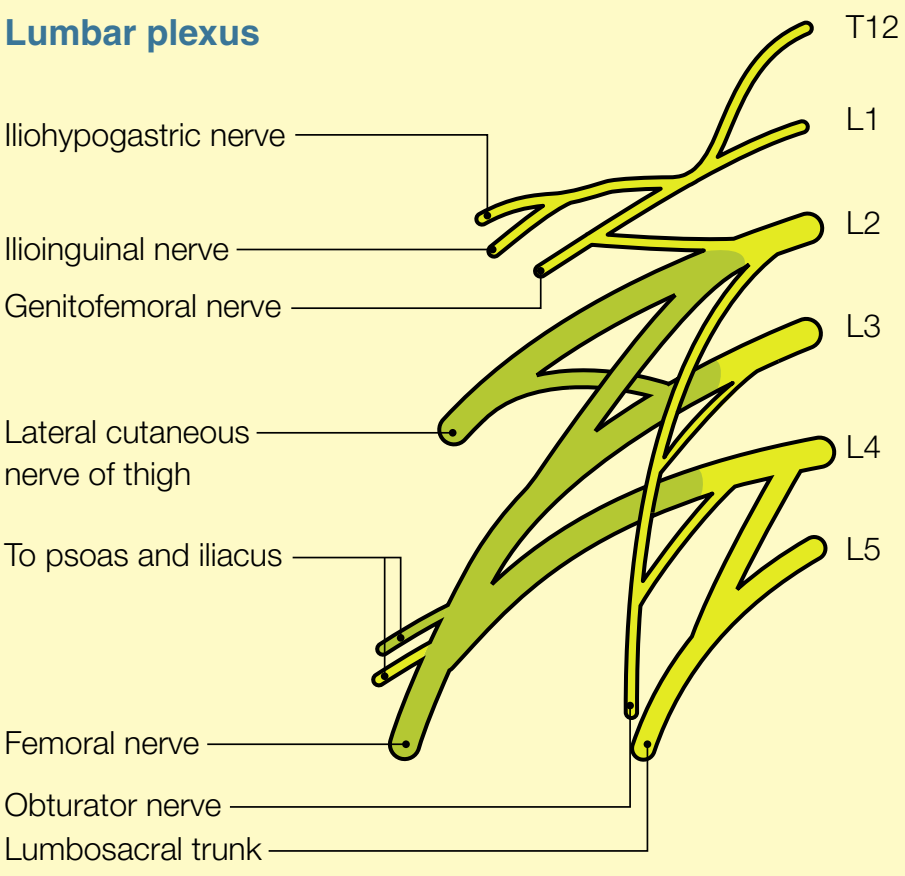
John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

Lumbar plexus
The lumbar plexus (Figure 1), is formed by the anterior primary rami of L1–L4 nerves. It lies within psoas major on the posterior abdominal wall. All nerves receive grey rami communicantes from the sympathetic trunk. From the plexus emerge:

- the obturator nerve (L2–4) supplying the thigh adductors
- the femoral nerve (L2–4) supplying iliacus and the knee extensors
- the lumbosacral trunk (L4–5), which descends over the sacrum to contribute to the sacral plexus
- the ilioinguinal (L1), and the iliohypogastric (L1) nerves, which obliquely traverse the abdominal wall muscles, supplying them and the inguinal and suprapubic skin
- the lateral femoral cutaneous nerve (L2–3) entering the thigh just medial to the anterior superior iliac spine to supply the skin of the anterolateral surface of the thigh
- the genitofemoral nerve, (L1–2) supplying the skin of the genitalia and the femoral triangle.

Lumbar plexus



The yellow branches are derived from the anterior and the green branches from the posterior divisions of the anterior primary rami of the lumbar nerves

1

Sacral plexus
The sacral plexus is formed by the lumbosacral trunk, a conjunction of the anterior divisions of the L4 and L5 nerves and the upper four sacral nerves (S1–S4). It lies in front of the sacrum on piriformis deep to the pelvic fascia (Figure 2). Its branches can be divided into pelvic branches and those leaving the pelvis.

In the pelvis there are muscular branches to the piriformis, levator ani, coccygeus and the external anal sphincter. Pelvic splanchnic nerves arise from the anterior primary rami of S2–4 to supply the pelvic viscera. These have a vasodilator function when acting on the erectile tissue (nervi erigentes), an inhibitor action on the internal anal and vesical sphincters and a motor function on the smooth muscle of the rectum and bladder.

Leaving the pelvis – most of these branches pass through the greater sciatic foramen, above or below piriformis.

Above piriformis – the superior gluteal nerve supplies gluteus medius and minimus.

Below piriformis

- The sciatic nerve (L4–5, S1–3) descends in the posterior compartment of the thigh to end by dividing into the tibial and peroneal nerves just above the popliteal fossa. It supplies the hip and knee joints and the hamstrings, semimembranosus, semitendinosus and biceps. The sciatic nerve lies midway between the ischial tuberosity and the greater trochanter and may be injured by a carelessly placed intramuscular injection. The only safe area in which to place injections is the upper, outer quadrant.
- The pudendal nerve, S2–3 enters the perineum via the lesser sciatic foramen and runs forward in the pudendal canal on the medial surface of obturator internus. It supplies levator ani, the perineal muscles, including the external anal sphincter, and the perianal and perineal skin. It carries parasympathetic fibres to the corpora of the penis or clitoris. A pudendal nerve block can be achieved by inserting a finger into the vagina, to guide the needle to the ischial spine and injecting local anaesthetic there. An effective nerve block results in relaxation of levator ani, anaesthesia over the vulva and loss of the anal reflex.
- Muscular branches supply gluteus maximus, obturator internus and quadratus femoris.
- Cutaneous branches supply the back of the thigh and the gluteal region.

Major nerves of the leg – the sciatic nerve branches at or above the popliteal fossa into the tibial and common peroneal nerves. The tibial nerve descends vertically in the popliteal fossa through the flexor compartment of the leg to reach the back of the medial malleolus where it divides into medial and lateral popliteal nerves. Its branches are:

- the sural nerve, which descends on gastrocnemius then passes behind the lateral malleolus, to supply the skin of the back of the leg and lateral surface of the heel and foot
- muscular branches to gastrocnemius, soleus, tibialis posterior, flexor hallucis longus and flexor digitorum longus.

The common peroneal nerve descends laterally through the popliteal fossa and divides in peroneus longus into:

- the superficial peroneal nerve, which descends between peroneus longus and brevis, supplying them, and ends by dividing into cutaneous branches, which supply the skin of the lower lateral part of the leg and the dorsal surface of the foot and lateral four toes
- the deep peroneal nerve, which lies subcutaneously and winds round the neck of the fibula, and descends in the extensor compartment of the leg supplying the long extensor muscles before passing in front of the ankle to divide into medial and lateral terminal branches to supply the ankle joint, extensor digitorum brevis and the skin of the first interdigital cleft.

Lateral wall of pelvis showing sacral plexus

Nerve blocks
Lower and upper limb nerve blocks are discussed elsewhere.

The Lungs and their Relations

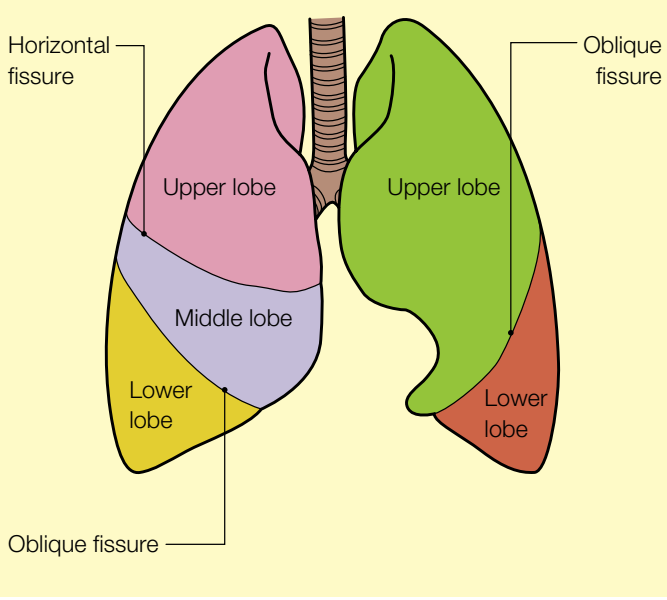
John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

Each lung lies in a pleural sac (see page 315) attached by the pulmonary vessels to the mediastinum. Each is cone-shaped to conform to the contours of the thoracic cavity and is spongy and elastic in texture. The right lung is slightly larger (620 g) than the left (560 g). Each lung has an apex in the root of the neck and a base resting on the diaphragm. The base is separated by a sharp inferior border from a lateral convex surface and a medial concave mediastinal surface. In the centre of the mediastinal surface the structures forming the root of the lung are surrounded by a collar of reflected pleura. The medial surface of the left lung is concave to accommodate the left ventricle of the heart and the anterior border of the left lung is indented by the heart to form the cardiac notch. In both lungs the posterior border is rounded and lies in the paravertebral sulcus.

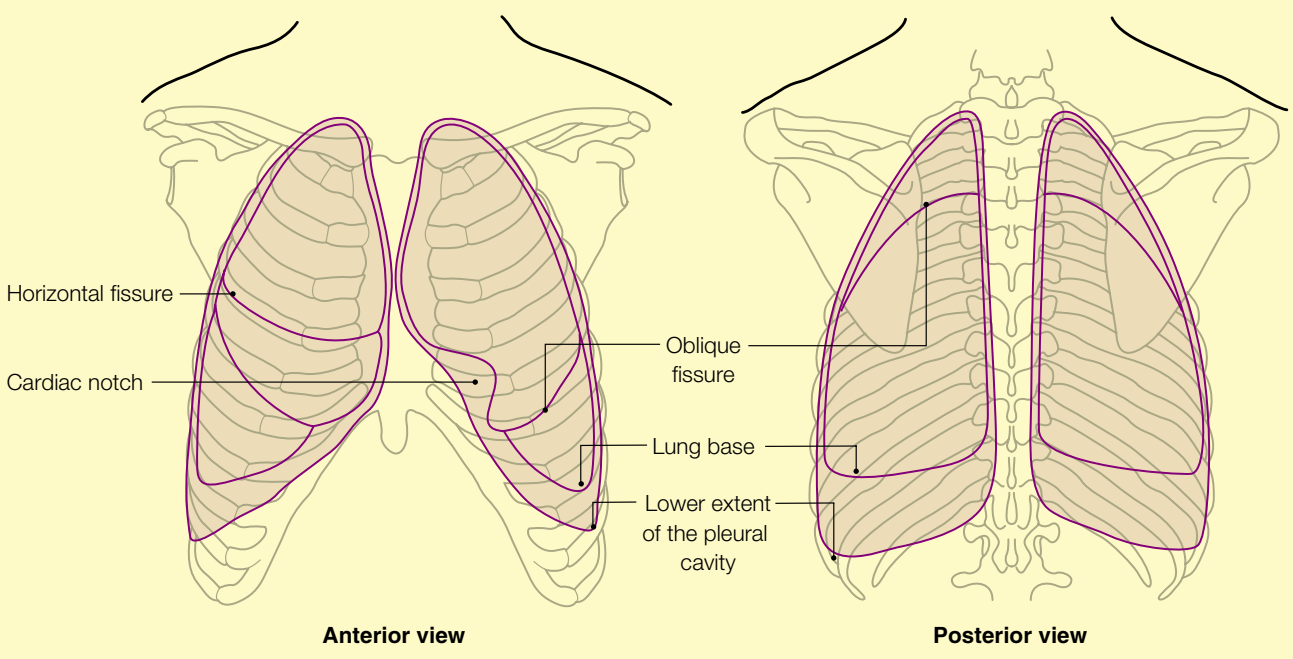
Each lung is divided into lobes by fissures that extend deeply into their substance (see *Anaesthesia and Intensive Care Medicine* **3:5:** 191). An oblique fissure divides the left lung into an upper and a lower lobe. In the right lung, oblique and horizontal fissures divide the right lung into upper, middle and lower lobes (Figure 1). In both lungs the surface marking of the oblique fissure is a line extending round the chest wall from the spine of the third thoracic vertebra to the sixth costochondral junction. The horizontal fissure is marked on the surface by a horizontal line passing laterally to the oblique fissure from the fourth right costochondral junction (Figure 2).

Lobes and fissures of the lungs



1

Surface anatomy of pleurae and lungs



2

The lower lobes of both lungs lie below and behind the oblique fissure and comprise most of the posterior and inferior borders and parts of the medial and costal surfaces.

The upper lobe of the left lung lies above and in front of the oblique fissure and comprises the apex, large parts of the mediastinal and costal surfaces and the whole of the anterior border. The equivalent part of the right lung is divided by the horizontal fissure into a large upper lobe and a smaller, wedge-shaped, anteriorly placed middle lobe. Some variation exists in this lobar pattern. Fissures may be missing or incomplete.

The hilus of each lung contains a main bronchus, pul-monary artery, two pulmonary veins, the pulmonary nerve plexus and lymph nodes. It is surrounded by the collar of pleura reflected from the lung onto the mediastinum, the narrow inferior extension of which is known as the pulmonary ligament.

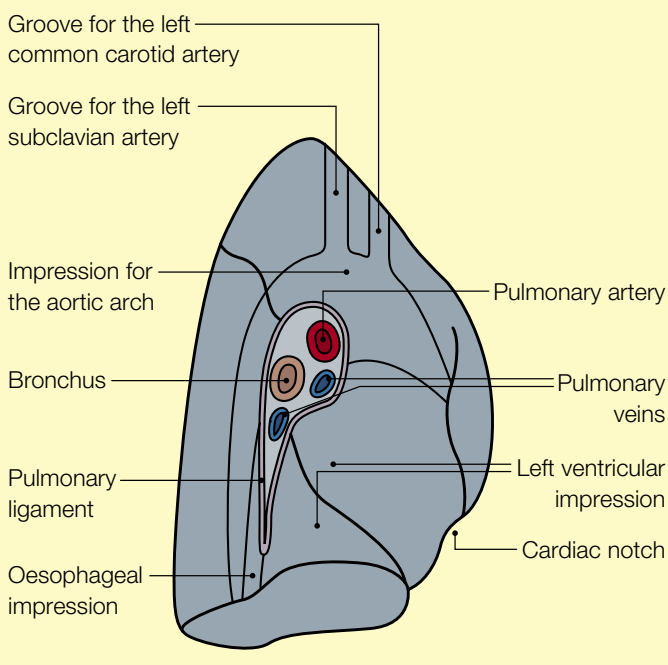
Parietal relations
The borders of the lungs closely follow the lines of pleural reflection on the chest wall except where the inferior border of the lung lies about two intercostal spaces above the inferior limit of the pleura and in front on the left side where the cardiac notch lies about 3 cm lateral to the pleural refection (Figure 2). The costal surface is related to the thoracic wall. The base is separated by the diaphragm, on the right side from the right lobe of the liver, and on the left side from the left lobe of the liver, the stomach and the spleen. The apex is covered by the dome of the pleura and the suprapleural membrane and above them arch the subclavian vessels.

Posteriorly the apex is separated from the neck of the first rib by the anterior primary ramus of the first thoracic nerve, the superior intercostal artery, the sympathetic trunk and the pleura.

Medial relations
The medial relations of the two lungs differ (Figures 3 and 4). On the left lung there is a concavity antero-inferiorly for the left ventricle, which is continuous superiorly with a groove for the aortic arch passing in front of and above the hilum. Above this groove the surface is in contact with the left brachiocephalic vein, left common carotid and left subclavian arteries and the oesophagus.

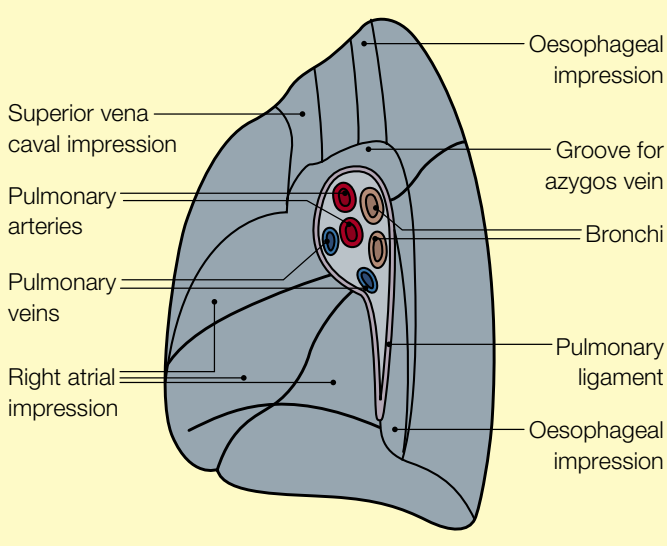
Medial surface of the left lung

The hilus is surrounded by the cut edges of the pleura and pulmonary ligament (inferiorly)



3

Medial surface of the right lung



4

On the right lung there is a shallow concavity in front of the hilum for the right atrium which is continuous above and below with shallow grooves for the superior and inferior vena cavae. Above the superior groove the surface is in contact with the left brachiocephalic vein, the left common carotid and subclavian arteries and the oesophagus.

Blood supply
The heart returns mixed venous blood to the lungs by the pulmonary trunk. After respiratory exchange the blood is then returned by the pulmonary veins.

The pulmonary trunk is a wide vessel, about 5 cm long. It begins at the pulmonary valve, ascends posteriorly to the left of the aorta and bifurcates under the concavity of the aortic arch into right and left pulmonary arteries.

The right pulmonary artery passes horizontally to the hilus of the right lung behind the ascending aorta and in front of the oesophagus and right main bronchus before dividing into branches that follow the segmental bronchi, ending in a capillary network within the alveolar walls.

The left pulmonary artery passes to the left lung hilus in front of the left bronchus and the descending aorta (see *Anaesthesia and Intensive Care Medicine* **3:2**: 76, Figure 1). It is connected by the ligamentum arteriosum, normally fibrosed shortly after birth, to the lower surface of the aortic arch. It also divides within the substance of the lung, its branches following the segmental bronchi.

Bronchial arteries: lung tissue is supplied, not by the pulmonary arteries, but by the bronchial arteries, which are small branches of the descending thoracic aorta. The corresponding bronchial veins drain into the azygos or hemiazygos veins. Some of the bronchial arterial blood drains back to the heart in the pulmonary veins.

The pulmonary veins are short, wide vessels that pass directly horizontally into the left atrium. There are usually two (upper and lower) from each lung. In the lung hilus they lie below the pulmonary artery; on the right they lie behind the superior vena cava and the right atrium and on the left behind the left atrium and in front of the aorta. The pulmonary veins are formed by the union of smaller veins that drain oxygenated blood from the capillary bed in the alveolar walls.

Lymphatic drainage
Lymphatic drainage of the lungs is via a superficial subpleural lymph plexus and a deep plexus of lymph vessels accompany-ing the bronchi. Both groups drain through hilar or broncho-pulmonary nodes to tracheobronchial nodes and thence to mediastinal lymph trunks.

The tracheobronchial nodes lie alongside the trachea and bronchi and receive afferents from the lungs, bronchi, trachea and heart. Their efferents drain to the bronchomediastinal lymph trunks which ascend alongside the trachea to end in the right lymph duct and, on the left, the thoracic duct.

Nerve supply
Innervation of the lung is by the pulmonary plexus which conveys both the sympathetic (bronchodilator) fibres from the upper four thoracic sympathetic ganglia and parasympathetic (bronchoconstrictor) fibres from the vagus. Sensory fibres pass largely in the vagus nerves. ◆

Anatomy of the Nose, Mouth and Pharynx

N Woodall
John Shaw-Dunn

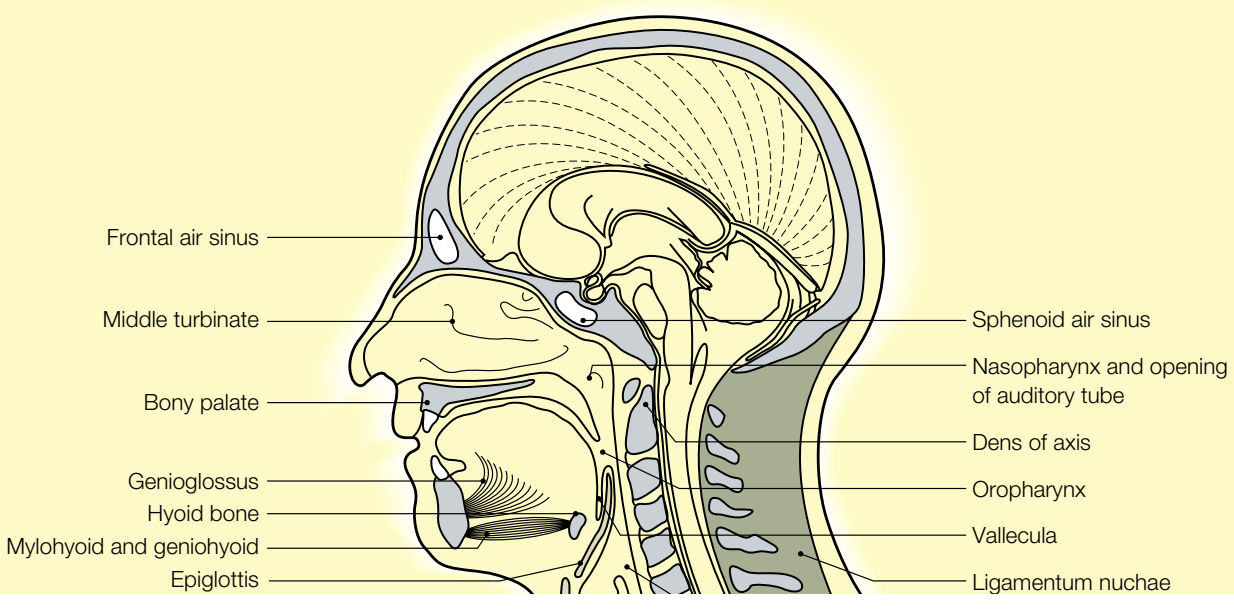
N Woodall is Consultant Anaesthetist at the Norfolk and Norwich University Hospital NHS Trust. He qualified from Liverpool University and trained in anaesthesia in the North-West, London, and California. His clinical research interests include airway problems and training in airway management.

John Shaw-Dunn is Senior Lecturer in Anatomy at the University of Glasgow, UK. His main research interests are in clinical anatomy.

The nose: within the external nose the hair-lined vestibules act as a nasal valve, causing turbulence to improve air conditioning. Each nasal cavity is about 10–14 cm long in the adult.

The floor of the nasal cavity is the bony palate (Figure 1). The arched roof includes the delicate cribriform plate of the ethmoid bone, which separates the nasal cavity from the anterior cranial fossa. The septum contains cartilage anteriorly and the vomer more posteriorly. The septum is seldom midline, perhaps because of microtrauma during labour. Three delicate turbinates project from the lateral wall of each cavity. Air sinuses open on to the lateral wall as do the nasolacrimal ducts. The nasal cavity and sinuses have a thick mucosa with cilia which warms, moistens and cleans incoming air, an action lost during intubation.

Sagittal section of mouth, nose and pharynx



1

Sensation to most of the nasal cavity is provided by branches of the sphenopalatine ganglion, which is accessible to topical anaesthesia behind the middle turbinate.

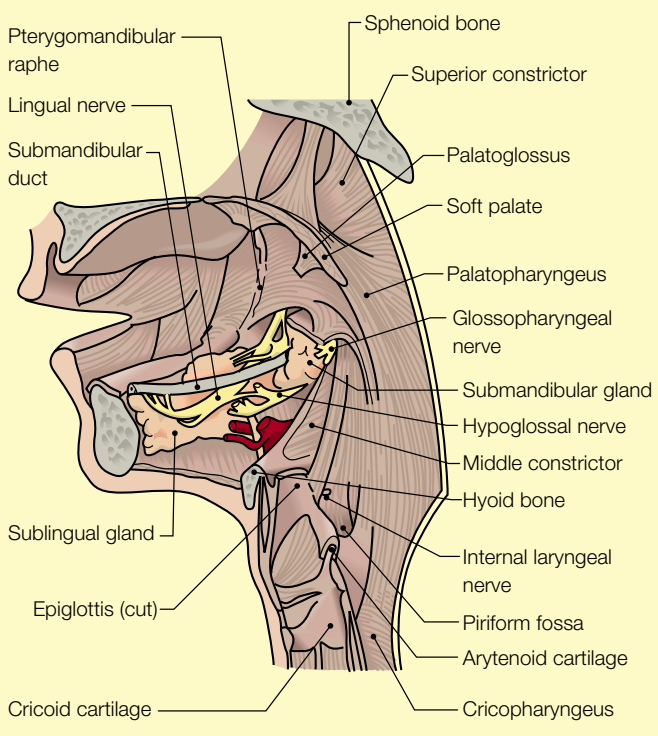
The mouth: the lips and cheeks contain the orbicularis oris and buccinator muscles and form the outer wall of the vestibule. The mouth cavity is limited posteriorly by the fauceal isthmus.

The tongue: the buccal surface of the tongue is separated from the posterior pharyngeal portion by a V-shaped groove behind a row of large vallate papillae with taste buds. The pharyngeal portion has multiple lymphoid nodules, which produce an irregular pebble-like appearance. The intrinsic muscles of the tongue modify its shape and the extrinsic group alter its position. Genioglossus, which forms the bulk of the tongue mass, protrudes the tongue. It originates from the mid-line mental spine on the inner surface of the mandible. During sleep and anaesthesia, reduced muscle tone may allow the tongue to fall backwards and obstruct the airway. This can sometimes be relieved by extending the neck with the mouth closed, stretching the extrinsic muscles like a washing line.

Floor of mouth: the mylohyoid creates a muscular floor for the mouth. On the outside it is covered by deep fascia, platysma and skin. Infection, swelling or bleeding into the deep layers may elevate the tongue, or spread backwards into the pharynx leading to problems with direct laryngoscopy or obstruction of the pharynx.

Salivary glands: the parotid ducts open into the vestibule at the level of the second upper molar crown. Each submandibular gland duct (Figure 2) opens at the sublingual papilla lateral to the frenulum linguae, which connects the underside of the tongue to the floor of mouth. Multiple sublingual glands drain directly into the sublingual folds.

Dissection of constrictor muscles and nerves of the pharynx from the medial side



Redrawn from Romanes G J. Cunningham's *Manual of Practical Anatomy*. Oxford: Oxford University Press, 1986, by kind permission of the publishers.

2

Teeth: the 24 deciduous teeth are replaced by up to 32 permanent teeth. Permanent teeth are recorded numerically in each quadrant. 1 and 2 correspond to the central and lateral incisors anteriorly, 3 the canines, 4 and 5 the premolars and 6, 7, and 8, the molars, posteriorly. Deciduous teeth are recorded alphabetically in the same way.

Nerve supply: the anterior and posterior superior alveolar nerves supply the upper jaw, while the lower is innervated by the inferior alveolar nerve. Lateral to the pterygomandibular raphe a needle can be inserted through the buccinator into the pterygomandibular space to block the inferior alveolar nerve. The anterior two-thirds of the tongue are supplied by the lingual nerve, though fibres conveying taste pass via the chorda tympani to the facial nerve. Extrinsic and intrinsic muscles of the tongue are innervated by the hypoglossal nerve except the palatoglossus muscle, supplied by the vagus.

The pharynx is a muscular tube lined by mucosa extending from the base of the skull to the lower border of the cricoid cartilage at the level of C6.

The nasopharynx lies behind the nasal cavity. The lateral wall bears the opening of the Eustachian tube. This cartilaginous structure, with attachment to the salpingopharyngeus muscle, produces the tubal elevation that is often visible during fibre-optic endoscopy. Behind it lies the blind pharyngeal recess. High on the superior pharyngeal constrictor are the pharyngeal tonsils, which when enlarged become the adenoids. Deep to the pharyngeal muscle layer are the arch of the atlas, the axis and the cervical vertebrae. During nasotracheal intubation, contact with the posterior wall forces the tube tip downwards. Insertion may be impeded by a prominent vertebral arch, tubercles or osteophytes.

The oropharynx is entered through the nasopharyngeal isthmus, formed by the soft palate, uvula and the superior pharyngeal constrictor. Anteriorly, the oropharynx communicates with the mouth via the oropharyngeal or fauceal isthmus, bounded by palato-
glossus and palatopharyngeus between which lie the tonsils.

The laryngopharynx commences at the upper level of the epiglottis and extends to the lower level of the cricoid cartilage. The base of the tongue is separated from the epiglottis by the vallecula, with the median glossoepiglottic fold in the midline. The larynx bulges posteriorly into the laryngopharynx producing a recess on either side, the piriform fossa. The internal laryngeal nerve which mainly provides sensation to the mucosa of the larynx pierces the thyrohyoid membrane and passes beneath the mucosa of the piriform fossa. At this point it may be anaesthetized, by the application of swabs soaked in local anaesthetic.

The pharyngeal wall is surprisingly thin and nerves and blood vessels are vulnerable to penetrating injury. The back and sides of the pharyngeal wall are reinforced by three flattened constrictor muscles, which overlap. They meet in a raphe, which extends from the pharyngeal tubercle on the sphenoid bone to merge with the oesophagus. During swallowing, the bolus is propelled downwards through the cricopharyngeal sphincter into the oesophagus by peristaltic waves in the constrictors. A pouch can develop between the sphincter and the thyropharyngeal portion of the inferior constrictor at Killian's dehiscence. Accumulation of undigested material here may be a potential source for aspiration.

Nerve supply: sensation to the pharynx is supplied by the glossopharyngeal nerve via the pharyngeal plexus. Sensation to the anterior surface of the epiglottis is therefore glossopharyngeal in origin but the inferior or posterior surface, which is anatomically part of the larynx, is supplied by the vagus. Transcranial electrical stimulation shows that one side of the brain is usually dominant in control of the pharynx, which may explain why cerebrovascular accidents on one side of the brain often cause dysphagia. ◆

The Pericardium

John Craven

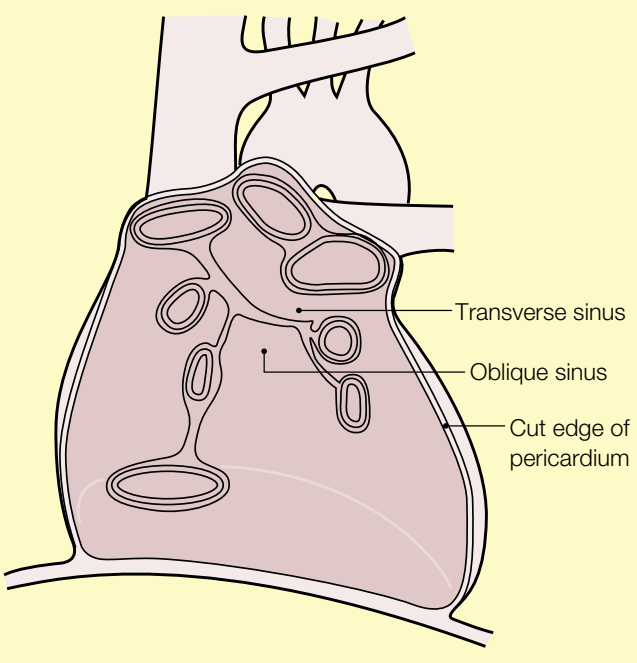
John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

The pericardium is a fibroserous membrane investing the heart and the great vessels entering and leaving it. It is composed of two distinct layers, the outer fibrous pericardium and the inner serous pericardium.

The serous pericardium is a closed serous sac invaginated by the heart. It has visceral and parietal layers, which enclose a potential space, the pericardial cavity. The visceral pericardium covers the entire outer surface of the heart and is reflected to become continuous with the parietal pericardium, which lines the inner surface of the fibrous pericardium. These lines of reflection form:

- the oblique sinus behind the left atrium bounded by the four pulmonary veins and the inferior vena cava
- the transverse sinus below the reflection around the superior vena cava and also behind the left atrium (Figure 1).

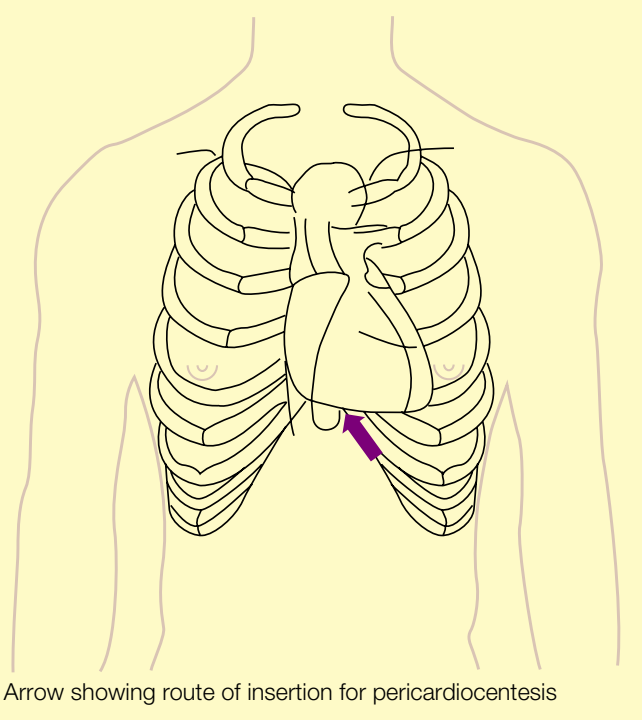
Interior of pericardium viewed after removal of heart and anterior part of pericardium



1

The fibrous pericardium forms a strong conical sac around the heart and the serous pericardium, blending inferiorly with the fibrous tissue of the central tendon of the diaphragm and the adventitia around the inferior vena cava. Superiorly, it blends with the adventitia around the aorta, pulmonary trunk and superior vena cava and posteriorly with that of the pulmonary veins. Anteriorly, the pericardium is closely related to the posterior surface of the body of the sternum, the 2nd to 6th costal cartilages and the thin anterior borders of both lungs (Figure 2). Posteriorly, it is related to the oesophagus, the descending aorta and the vertebral bodies T5–T8 and laterally to the mediastinal pleura. The entire thoracic part of the inferior vena cava, about 2 cm long, is within the pericardium.

Surface marking of pericardium



Arrow showing route of insertion for pericardiocentesis

2

The pericardial cavity in health contains no more than a thin film of fluid but a pericardial effusion may occur as the result of heart failure, generalized oedema and infection. If the effusion is extensive, the excess fluid in the pericardial cavity interferes with the action of the heart because the fibrous pericardium is inelastic. Similar cardiac embarrassment may occur as the result of blood accumulating within the pericardium after stab wounds to the heart. The condition is known as cardiac tamponade; the heart is compressed and its output falls. The veins of the neck and face become engorged because of constriction of the superior vena cava as it enters the pericardial sac. Pericardiocentesis, drainage of fluid from the pericardial sac, is readily achieved using a large-bore venous cannula inserted into the pericardial sac. It is inserted beneath the costal margin at its border with the xiphoid process and directed towards the left shoulder at an angle of 45° to the horizontal. ◆

The Pleura

John Craven

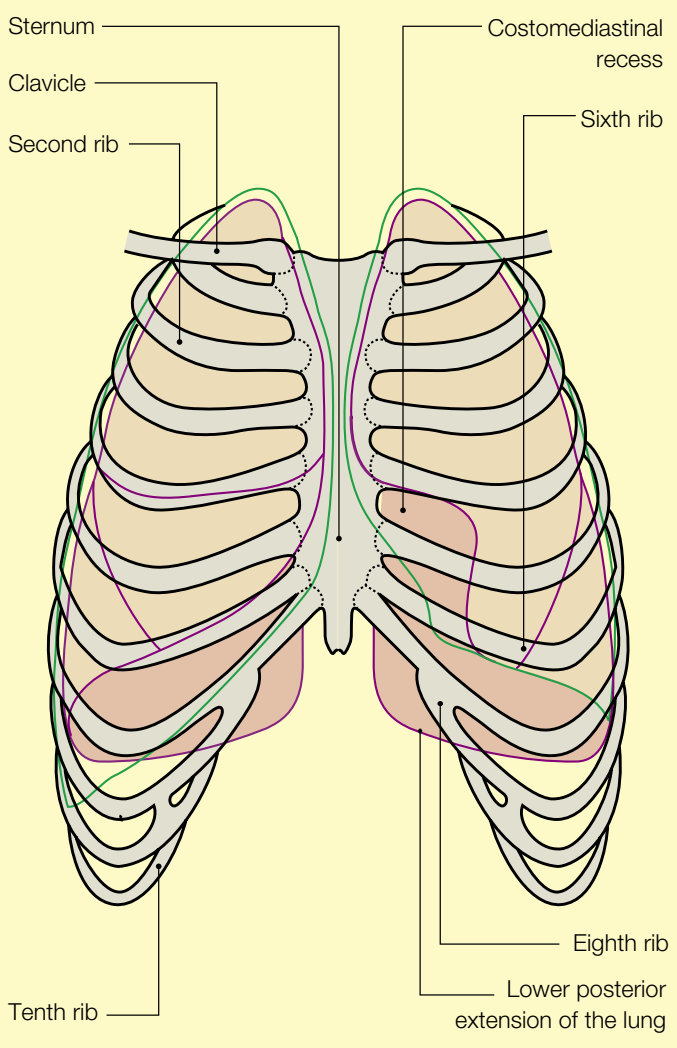
John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

Each pleural cavity is a closed cavity of serous membrane invaginated by the lung. The visceral layer covers the lungs and the parietal layer covers the inner surface of the thoracic cavity. The layers are continuous around the root of the lung and separated by only a thin layer of serous fluid. Thus, the two layers glide easily over each other but are prevented from separating by the negative pressure within the thoracic cavity and the surface tension of the pleural fluid. This ensures that when the thoracic cage expands so does the lung and air is then drawn in from the trachea.

The pleura is a fibro-elastic membrane lined by squamous mesothelial cells; parietal pleura line the ribs, costal cartilages and intercostal muscles, the lateral surface of the mediastinum and the upper surface of the diaphragm. Superiorly it extends, above the thoracic inlet into the neck forming the cervical dome of the pleura. The apical pleura is covered by a fascia, the suprapleural membrane (Sibson's fascia) which is attached to the inner surface of the first rib and prevents the lung expanding too far into the neck on inspiration. At this point, the pleural cavity is at risk of being entered during surgery in the root of the neck or during subclavian cannulation. On the left side, anteriorly, in front of the heart the costal and mediastinal surfaces are in contact, forming the costomediastinal recess**.** The mediastinal pleura loosely invests the main bronchi and pulmonary vessels and continues on to the lung to form the pulmonary (visceral) pleura which covers the lung and extends into its interlobar fissures.

On both sides of the lung the cervical pleura extends about 3 cm above the middle of the clavicle (Figure 1). Anteriorly, on both sides, the lines of reflection (where the parietal pleura meets the visceral layer) descend behind the sternoclavicular joint to meet in the midline at the level of the second costal cartilage. They descend side by side to the fourth costal cartilage where the left pleural reflection deviates laterally, descending along the lateral border of the sternum to the sixth costal cartilage. The right pleural reflection, however, continues downwards near the midline to the same level. Thereafter the course of the reflection line is similar on both sides. Each passes laterally behind the costal margin, reaching the eighth rib in the midclavicular line, the tenth rib in the midaxillary line and the twelfth rib in the paravertebral line. The lower limit of the pleura medially is below the twelfth rib and thus at risk during renal or adrenal surgery. The posterior reflection line ascends, on each side, about 3 cm from the midline. A pneumothorax is best drained, with a catheter and underwater seal, by catheter insertion in the second intercostal space in the midclavicular line. A pleural effusion should usually be drained by insertion of the catheter in the sixth or seventh space in the midaxillary line.

Surface relationship of the lungs and pleural cavities



Only the anterior pleural markings are shown; posteriorly the pleural reflection reaches 1–2 intercostal spaces below the lung base.

1

The pleura gains its blood supply from adjacent tissues. Though the pulmonary pleura has no pain fibres the parietal pleura is richly supplied by the nerves in the subjacent tissues, the intercostal and the phrenic nerves. Therefore, pleurisy may produce pain referred to the upper abdomen from inflammation of the lower sixth intercostal nerves or referred to the root of the neck from the phrenic nerve. ◆

The Ribs and Intercostal Spaces

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

The thoracic contents are contained in an osteocartilaginous cage formed by the thoracic vertebrae behind, the sternum in front and between them the ribs and costal cartilage.

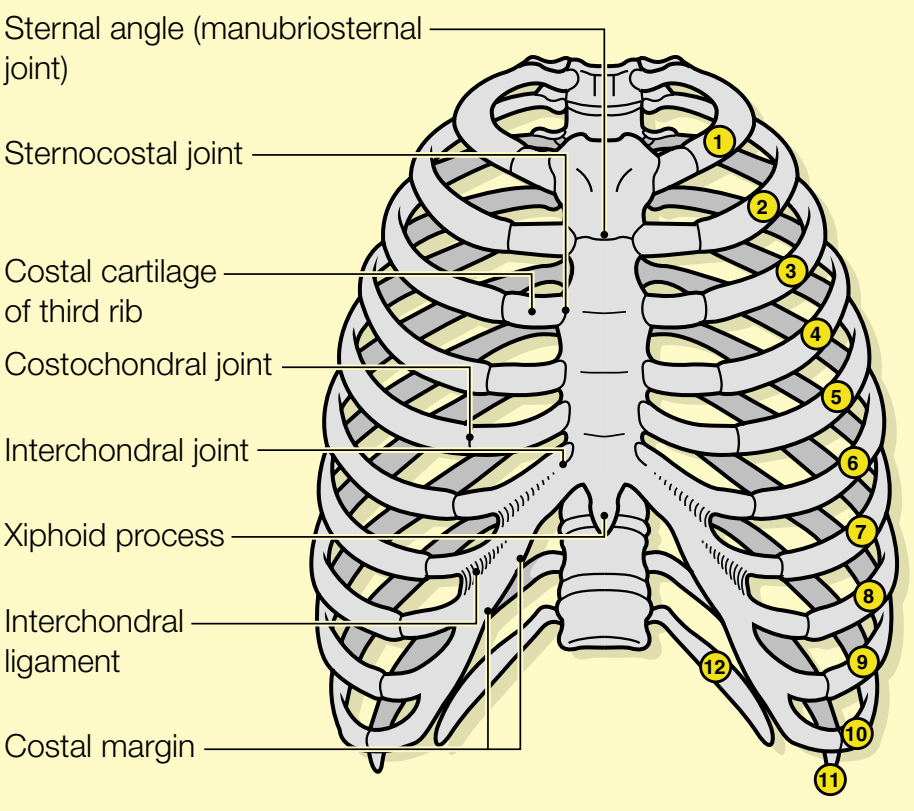
Ribs

The ribs (Figure 1) are narrow, curved flat bones. The first seven or eight pairs of ribs attach the vertebrae to the sternum through their costal cartilage. The eighth to tenth pairs are known as 'false ribs' because their cartilage articulates with the cartilage above them and not with the sternum. The eleventh and twelfth pairs of ribs are known as 'floating ribs' because their cartilage ends in the muscles of the posterior abdominal wall.

A typical rib (ribs 3–9) comprises a head bearing two facets. The lower facet articulates with its corresponding vertebra and the upper facet articulates with the vertebra above that. Lateral to the head (2–3 cm) is a tubercle that articulates with the transverse process of the corresponding vertebra (Figure 2). Close to this, the costotransverse ligament gains attachment. Beyond the tubercle, the shaft of the rib becomes flatter and wider and the inner surface of its lower border is grooved (costal groove) to accommodate the intercostal nerves and vessels.

The first rib is short, wide and flattened. On its upper surface the scalene tubercle separates an anterior groove for the subclavian vein and a posterior groove for the subclavian artery and brachial plexus. The heads of ribs 1 and 10–12 bear a single facet.

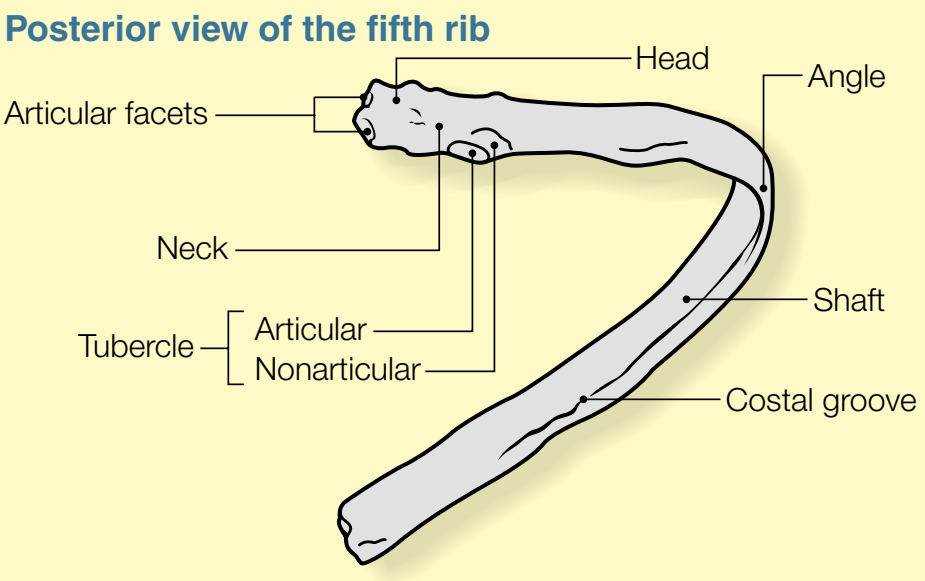
Anterior view of thoracic cage



The ribs are numbered 1 to 12.

1

Posterior view of the fifth rib



2

Intercostal spaces

The intercostal spaces are bounded by adjacent ribs and costal cartilage and contain the intercostal muscles, vessels and nerves. Deep to them lies the pleura. The external intercostal muscle is the most superficial. Deep to it is the internal intercostal muscle and deepest of all is the incomplete sheet of the innermost intercostal muscle attached to the inner surfaces of the sternum, costal cartilage and ribs. The vessels and nerves lie together in the costal groove between the internal and innermost muscles. The artery lies between the vein superiorly and the nerve inferiorly in the neurovascular bundle (Figure 3).

Twelve pairs of thoracic spinal nerves supply the muscles and skin of the thoracic and abdominal wall. The cutaneous distribution of each nerve is striplike and is known as a dermatome (Figure 4). Though there is overlapping of the dermatomes, knowledge of their distribution allows the clinician to determine the extent of sensory deficiencies and the proximal extent of anaesthesia after, for instance, a spinal block.

The parietal pleura has a similar segmental 'dermatomal' distribution. Thus, inflammation of the pleura results in pain being referred to the cutaneous distribution of the nerve affected which, in the case of the lower pleura, is the anterior abdominal wall.

The intercostal arteries supply the chest wall and its overlying muscles and the breast. They anastomose with branches of the internal thoracic artery and its terminal branches.

Intercostal space

Cutaneous distribution of dermatomes

4

Procedures

Drainage

Fluid (e.g. blood, pus, inflammatory exudate) or air may be drained from the thorax for diagnostic or therapeutic reasons. This is done by inserting a narrow-bore or wide-bore needle through an intercostal space previously infiltrated with local anaesthetic. Radiography determines the level at which the fluid is best aspirated. The needle should be passed along the superior border of the rib to avoid the neurovascular bundle. There is a risk of penetrating the diaphragm if aspiration is attempted below the seventh intercostal space.

Anaesthesia

Local anaesthesia of intercostal nerves has an important role to play in managing the pain arising from fractured ribs or reducing the pain of a thoracotomy. The appropriate nerve and the two nerves above and below (because of the overlapping supply) are infiltrated at or around the rib angle. In each space, the needle is advanced until the rib is met, then withdrawn and guided under the inferior angle for 0.5 cm. If no blood is then aspirated, 1–4 ml of local anaesthetic solution is injected.

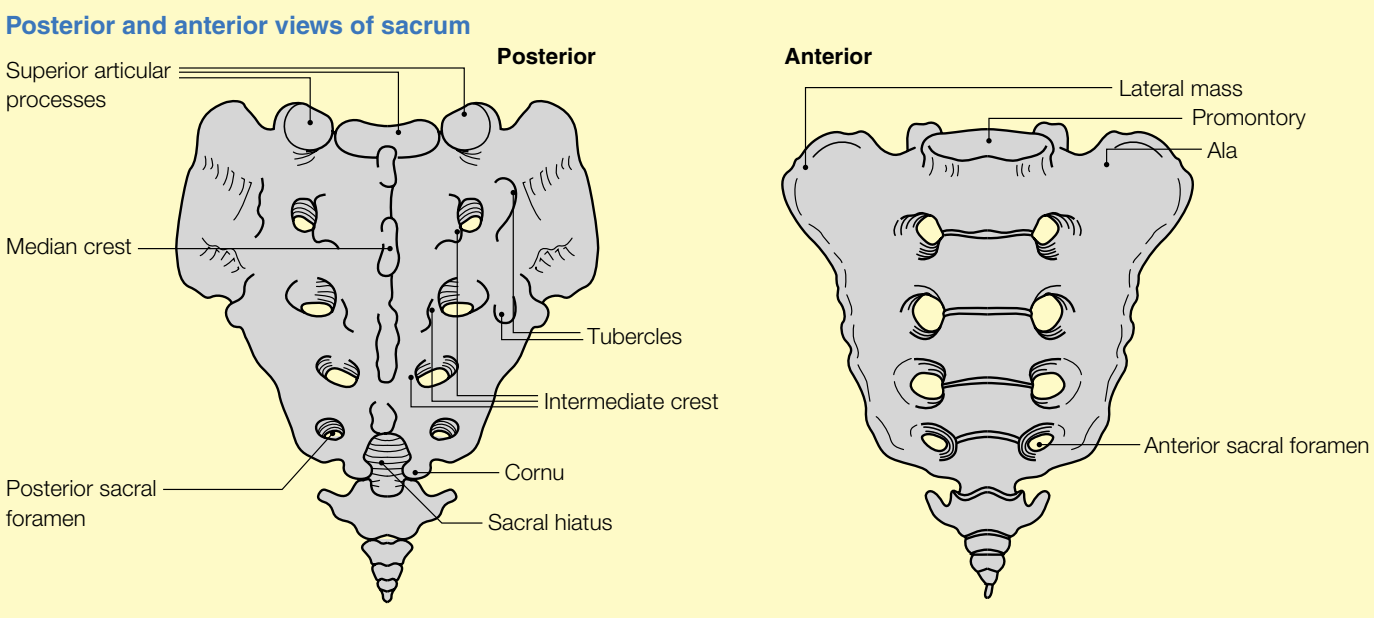
Sacrum and Sacral Hiatus

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

The sacrum is formed from the five fused sacral vertebrae (Figure 1). It is triangular and possesses a base superiorly, an apex inferiorly and dorsal (posterior), pelvic and lateral surfaces. Two rows of foramina on its dorsal and pelvic surfaces divide it into a median portion, the body, formed from the fused vertebral bodies, and two lateral masses formed from the fused transverse processes. The paired pelvic and dorsal sacral foramina communicate by intervertebral foramina with the central sacral canal and convey the ventral and dorsal rami of the sacral nerves. The base, directed upwards and forwards is formed from the upper surface of the first sacral vertebra and contains an oval concavity, the articular facet, for the disc that separates it from the 5th lumbar vertebra. Lateral to this the lateral masses of the sacrum are at their widest and form the prominent ala. The anteriorly protruding central part of the superior surface is known as the promontory. Behind the body, superiorly, is the upper opening of the sacral canal on each side of which project the superior articular processes for articulation with the 5th lumbar vertebra. The small apex articulates with the coccyx.

Posterior and anterior views of sacrum



1

The pelvic surface is concave and the smooth lateral masses give attachment to the piriformis muscle. Superiorly this surface is related to the peritoneum and inferiorly to the rectum. The posterior surface is convex and rough, and in the midline where it roofs the sacral canal it bears a median sacral crest, which is subcutaneous and palpable, and two less prominent intermediate sacral crests more laterally. Each row of dorsal sacral foramina lie lateral to the intermediate sacral crests. The posterior wall of the sacral canal is deficient posteriorly, forming the sacral hiatus which is covered by fibrous tissue. The hiatus is bounded on each side by the palpebral sacral cornua with which the coccyx articulates.

The sacral canal is triangular in transverse section and contains the cauda equina and CSF with the meninges. The dural sac ends at the 2nd sacral vertebra on a line joining the posterior superior iliac spines. Extradurally lie the spinal nerves and the internal vertebral venous plexus, the bulk of which lies anteriorly in the canal. The dorsal surface gives attachment to erector spinae, gluteus maximus and the thoracolumbar fascia.

The lateral surface is the roughened articular surface forming part of the sacroiliac joint. Strong interosseous ligaments connect the sacrum and ilium.

Spinal and caudal anaesthesia techniques are so commonly used that it is important to be aware of the anatomical abnormal-ities that may be encountered:

- the sacral hiatus may be displaced upwards or downwards
- the sacral canal may be narrowed or obliterated
- the fibrous sheet covering the hiatus may be ossified
- the dural sac may extend distally as far as S3 or, occasionally, S4. ◆

Segmental Bronchi and Structure of the Lung

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

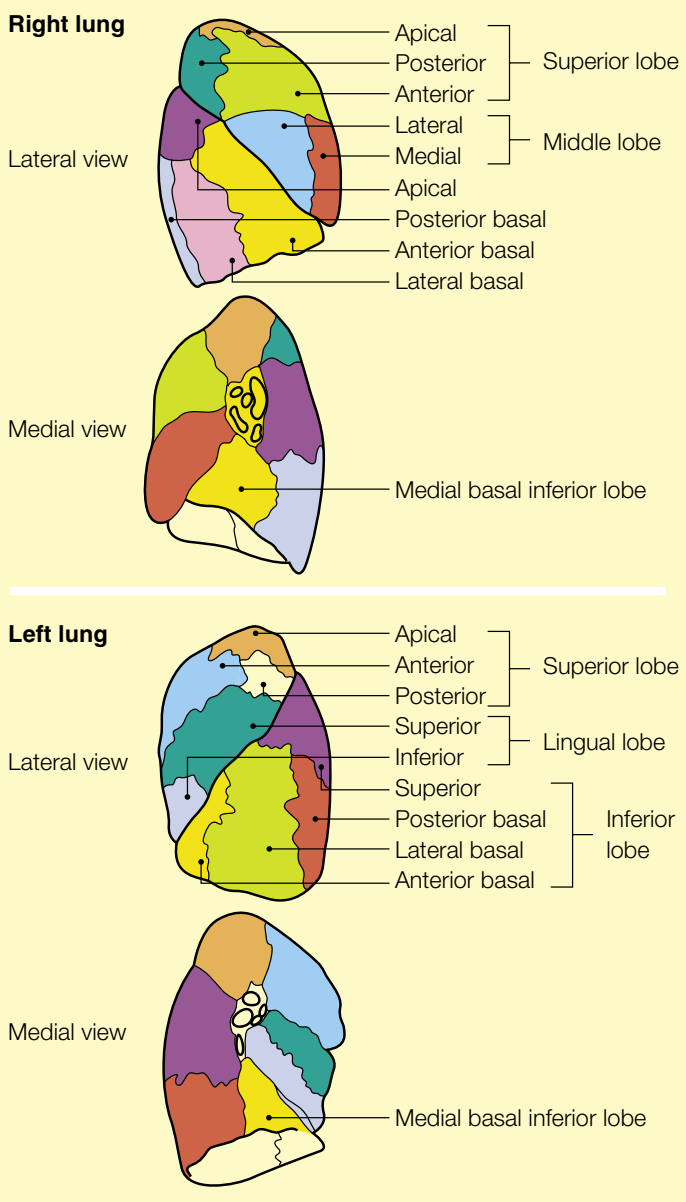
The segmental structure of the lungs is significant because infection and neoplastic processes are often localized to one or more adjacent segments. Knowledge of the anatomy of the intrapulmonary bronchial tree is important for:

- understanding lung radiology
- interpreting diagnostic bronchoscopy
- therapeutic application of bronchoscopy to sputum retention
- effective application of postural drainage for sputum retention
- the surgical resection of diseased segments of the lungs.

Although the lung appears to be a homogeneous entity, each lung consists of ten bronchopulmonary segments, which are in continuity. The parenchyma of each segment is distinct from that of its neighbours and there is little vascular anastomosis between them. Each segment has its own bronchus and is supplied by one or more pulmonary arteries and drained by its own veins. The arteries and bronchus have a central position in the segment, but the veins tend to lie peripherally along the intersegmental planes. Segmental resection along intersegmental lines is possible with little bleeding or leakage of air.

Each bronchopulmonary segment has a constant position, is wedge-shaped with its apex at the hilum, and its base extending on to the pleural surface of the lung (Figure 1). The differences in the anatomical arrangement of each side are slight; the arrangement on the two sides would be similar but for the fact that the lingular bronchus branches from the left upper lobe bronchus.

Bronchopulmonary segments



1

The right lung

The upper lobe – the three segments are anterior, posterior and apical (which forms the dome of the lung). The posterior segment of the right upper lobe is often the site of infective processes, especially aspiration pneumonitis. The most common lesion of the anterior segment of the upper lobes is neoplastic.

The middle lobe is divided vertically into a lateral and medial segment. The middle lobe bronchus is long and surrounded by hilar lymph nodes and therefore is subject to pressure and external compression by their enlargement. Thus, viral infections, bronchiectasis and tuberculosis may be the cause of middle lobe collapse.

The lower lobe is the largest. There is an apical or superior lobe and four basal lobes (medial, lateral, anterior, posterior) that are related to the diaphragm.

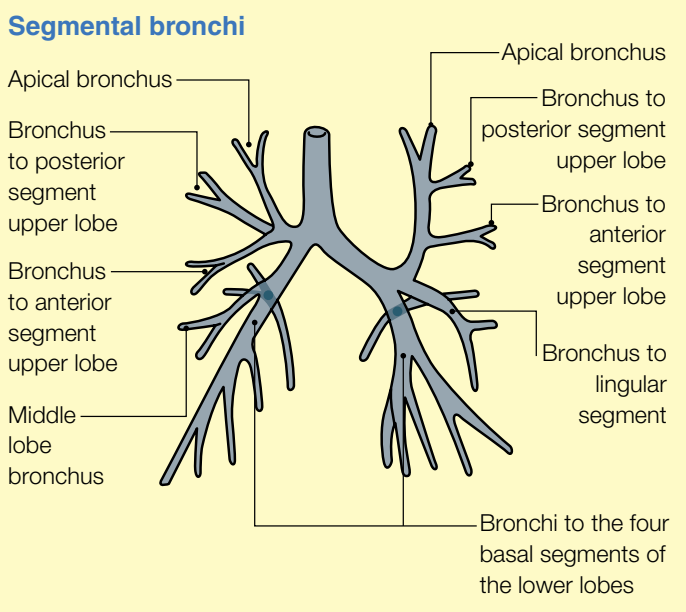
The left lung

The upper lobe consists of five segments. The lower two comprise the superior and inferior lingual segments. The remaining segments of the upper lobe are arranged in the same way as those on the right side – apical, anterior and posterior.

The bronchial tree (Figure 2)

The right main bronchus is wider, shorter and more vertical than the left and therefore more subject to accidentally inhaled foreign bodies. The upper lobe bronchus passes laterally for l cm before branching into its three divisions (apical, anterior, posterior). The pulmonary artery lies anteriorly to it and below this the middle lobe bronchus arises anteriorly to divide into medial and lateral branches. Beyond the origin of the middle lobe bronchus all other branches are destined for the segments of the lower lobe.

Segmental bronchi



2

The left main bronchus is longer than the right and about 5 cm from its origin it divides into a lateral branch (the left upper lobe stem bronchus) and the bronchus to the lower lobe. Just beyond the bifurcation, the upper lobe stem bronchus bifurcates into the bronchus to the lingular segment, which divides into two segmental branches, the anterior and posterior lingual branches. The stem bronchus to the upper lobe divides to give the anterior and then the apical and posterior branches. The left lower lobe bronchus usually gives off a posterior branch to the apical (superior) segment of the lower lobe and branches to the remaining segments arise distal to that.

The structure of the bronchi

The bronchi are strengthened by horseshoe-shaped rings of cartilage, similar to those of the trachea, and divide as they continue into the substance of the lungs into progressively smaller structures until they are reduced to a diameter of less than l mm when they lose their cartilaginous support. The bronchial tree is lined throughout by mucous, submucous and connective tissue coats that become progressively thinner in their distant ramifications. Plain muscle fibres bridge the intervals between the cartilaginous rings or plates and replace them in the bronchioles. The submucous coat contains mucous glands and the mucous coat consists of an elastic lamina on which lies the respiratory epithelium as far as the respiratory bronchioles where the abundant goblet cells and the cilia disappear. Each bronchiole ends in an alveolar sac. Fine elastic cells continue into the alveolar walls. The alveolar walls are invested in a dense capillary network.

Bronchial vessels

The bronchial vessels arise, one on each side, from the aorta or, sometimes from the intercostal vessels to supply the lung parenchyma. The bronchial and pulmonary vessels communicate freely on both the arterial and venous sides. These anastomoses are of significance in chronic inflammatory lung disease when the bronchial arterial system enlarges considerably. The bronchial circulation is an arteriovenous shunt; the artery arises from the systemic circulation, but the veins enter the pulmonary system.

Nerve supply

The pulmonary plexuses lie anterior to the hilum of the lung and derive fibres from both the vagi and the sympathetic trunk. Their efferent fibres pass to the bronchial musculature and they receive afferents from the mucous membranes of the alveoli and the bronchioles. ◆

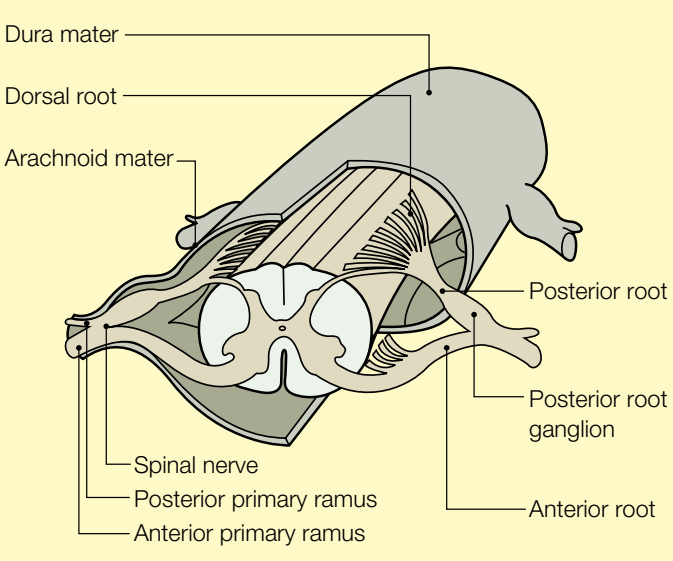
Spinal Nerves and Dermatomes

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

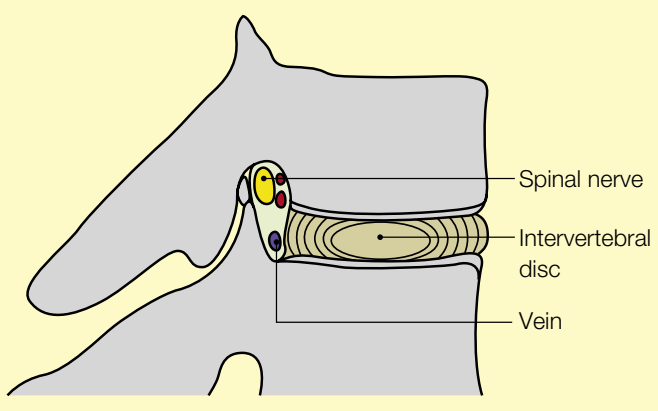
There are 31 pairs of spinal nerves, each attached to its appro-priate segment of the spinal cord, by anterior and posterior nerve roots which unite just beyond the posterior root ganglion (Figure 1). The nerves leave the vertebral column through the intervertebral foramina (Figure 2). They are numbered after their corresponding vertebra except the 8th cervical nerves, which pass out below the 7th cervical vertebrae, because there are only seven cervical vertebrae. The remaining spinal nerves take the name of the vertebra below which they emerge, there are 12 thoracic, five lumbar, five sacral and one coccygeal nerve. The segment of the spinal cord from which each pair of spinal nerves arises takes the same name and number as its nerves.

Spinal cord



1

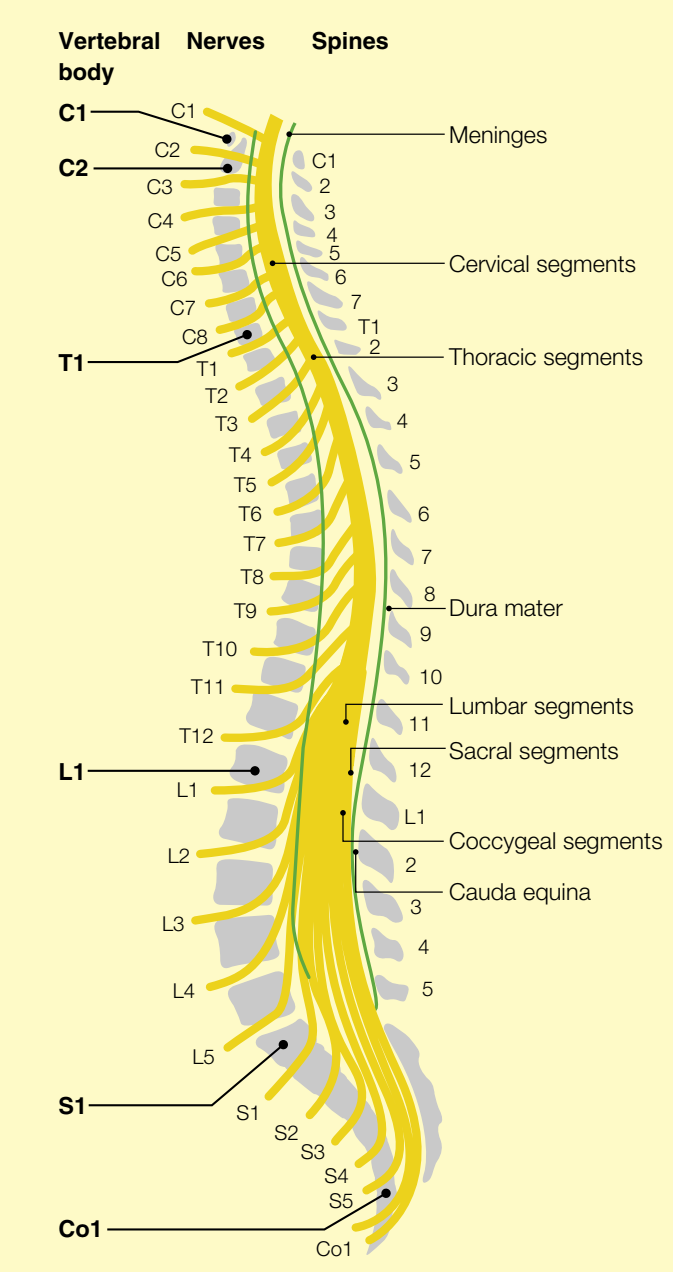
Intervertebral foramen and spinal nerve



2

The anterior and posterior nerve roots emerge separately through the cord's meninges. Each posterior root ganglion lies without the dural sac and, apart from the first two and the last two spinal nerves each lies in its intervertebral foramen. The adult spinal cord is shorter than the vertebral column and thus there is a progressive obliquity of the spinal nerve roots and the length of the nerve roots increases as the lower end of the vertebral column is approached (Figure 3). The lumbar and sacral nerve roots are the longest and most of these contribute to the bundle of nerve roots in the subarachnoid space caudal to the end of the spinal cord (the cauda equina).

Spinal cord in vertebral canal showing relationships of spinal cord segments, spinal nerves and dural sac to vertebral bodies and spines



3

The dorsal roots contain afferent or sensory fibres from the skin, subcutaneous and deeper tissues and often from viscera. The ventral roots contain efferent or motor fibres to skeletal muscles and most contain preganglionic autonomic fibres. The cell bodies of axons contributing to the ventral roots lie in the ventral grey horns of the spinal cord, but the cell bodies of axons contributing to the dorsal roots lie outside the cord in the dorsal root ganglion. Once the nerve lies outside the intervertebral foramen it is connected to the sympathetic nervous system by rami communicantes. The 12 thoracic and first two lumbar nerves each send a white ramus communicans to the sympathetic trunk and each receives back a grey ramus communicans, the fibres of which are then distributed with the branches of the spinal nerve. The spinal nerve then divides into anterior and posterior primary rami (Figure 1). The posterior primary rami supply the skin and the muscles of the back, the anterior primary rami supply the skin and muscles of the lateral and anterior parts of the trunks and both upper and lower limbs. It is the anterior primary rami that form the cervical, brachial and lumbosacral plexuses.

Dermatomes

The body skin is innervated in simple continuous strips, from behind forwards by branches of the posterior and anterior primary rami. Although there is great complexity of the several plexuses of the anterior roots, the nerve fibres of each spinal segment, irrespective of their differing courses, are distributed to one strip (dermatome) of skin. The dermatomes overlap each other so that on the trunk, for example, alternate dermatomes meet each other. Segments whose nerves are primarily concerned with limb innervation are absent or restricted from any innervation of the trunk. Muscles, which are derived from myotomes, are also segmentally innervated.

Clinical importance

The relationships of the nerves, nerve roots and spinal cord segments to the vertebral bodies and spines is of the greatest
clinical importance. Some useful surface markings include:

- the spine of C7 (vertebra prominens) is easily palpable
- the spine of T3 is opposite the medial portion of the spine of the scapula
- the spine of T7 is opposite the inferior angle of the scapula (with the arms to the sides)
- a line drawn between the summits of the iliac crests intersects L4 or the L4/5 interspace
- the dimples overlying the posterior superior iliac spines are on a line crossing the second posterior sacral foramen; the dural sac in the adult usually ends at this point.

Figure 3 summarizes the relationship of the spinal cord and the meninges to the vertebrae and their spines. ◆

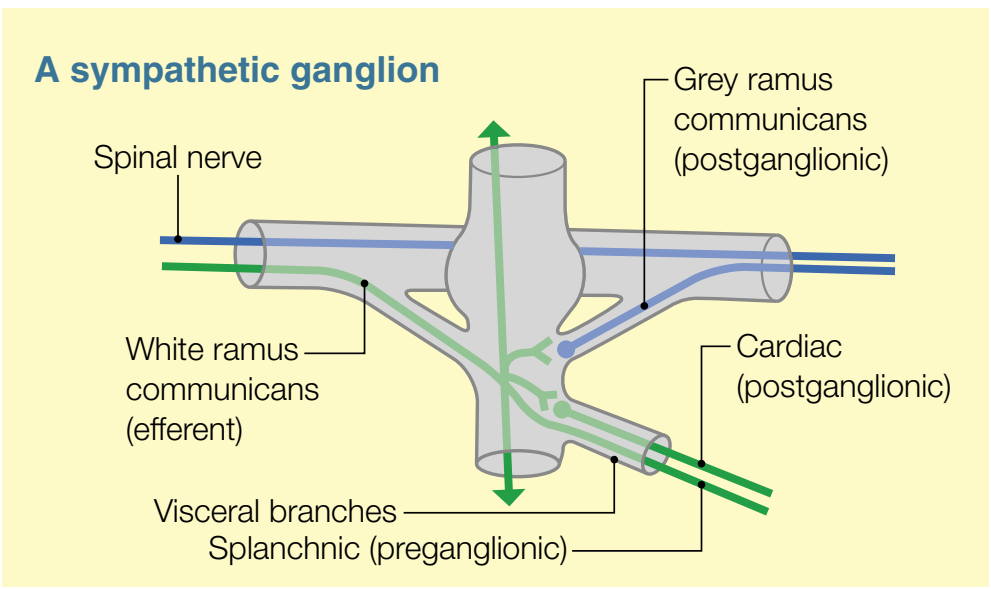
The Sympathetic Trunk and Stellate Ganglion

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is in gastric cancer.

The sympathetic nervous system has motor and sensory functions. The important motor functions are the vasoconstriction of blood vessels and pilomotor and sudomotor control to the skin; they are conveyed by efferent fibres, which pass in the white (medullated) rami communicantes to synapse in a ganglion of the sympathetic trunk (Figure 1). The medullated, preganglionic fibres arise only from cells in the lateral horns of T1–L2 and are conveyed within their anterior primary rami to enter the sympathetic trunk. Within the trunk, fibres destined for the head and neck, arising from the uppermost thoracic segments, ascend to one of the three cervical ganglia (upper, middle or lower). In the ganglion, the fibres synapse with postganglionic, non-medullated nerves.

The afferent (sensory) fibres reach the sympathetic trunk travelling on blood vessels, within somatic nerves or within sympathetic nerves supplying sympathetic plexuses. They pass from the sympathetic ganglia in the white rami communicantes to the posterior root ganglion conveying visceral sensations such as colic or visceral pain. Each sympathetic ganglion has a somatic and a visceral branch; the somatic branches of the three cervical ganglia accompany the cervical nerves, the inferior cervical ganglion giving branches to C7 and C8. The three cervical ganglia each supply vascular branches, which allows wide distribution to the skin of the head and neck; each also has a cardiac branch passing to the cardiac plexus. Visceral branches of the superior cervical ganglion supply the dilator pupillae muscle and levator palpebrae superioris muscle. The paired sympathetic trunks are formed of ganglia connected by nerve fibres. They extend from the base of the occiput to the coccyx lying on the prevertebral fascia. Developmentally there are ganglia for each spinal nerve but their number has been reduced by fusion, producing three cervical, 11 thoracic, four lumbar and four sacral ganglia.



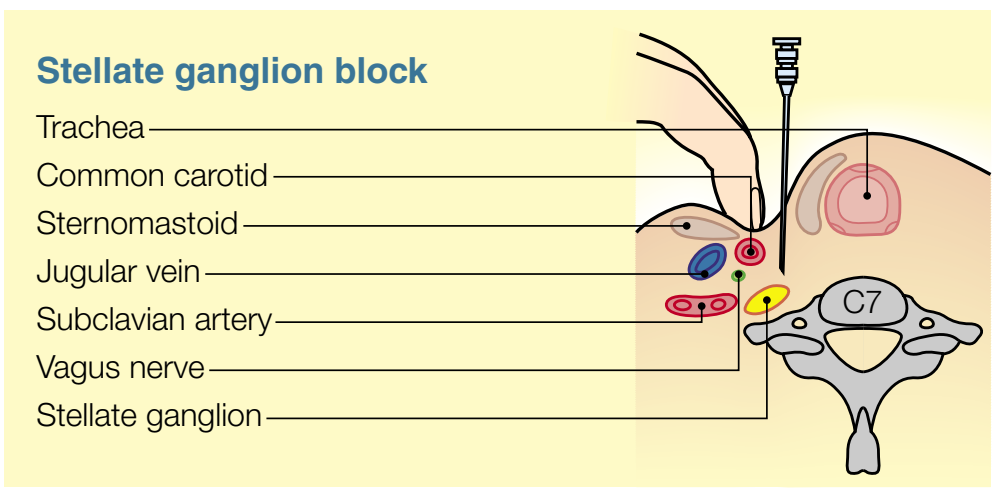
1

The stellate ganglion

In 80% of the population, the inferior cervical ganglion is fused with the first thoracic ganglion to form the large stellate ganglion, which lies on the neck of the first rib behind the cervical pleura. Its branches are conveyed by grey (non-medullated) rami communicantes to the C7, C8 and T1 spinal nerves and, via a plexus, to the subclavian artery and its branches, from where they are distributed to the upper limb. It is of clinical significance that the sympathetic nerve supply of the pupil and levator palpebrae superioris joins the sympathetic trunk from the grey rami of the first thoracic segment at the stellate ganglion.

Cervical sympathectomy: removal of the second and third thoracic ganglia is required occasionally to abolish the excessive sweating of hyperhidrosis, the vasospasm of Raynaud's disease and, more controversially, to relieve the pain of causalgia (complex regional pain syndrome type 2) after trauma to the upper limb. The aim of the operation is to obtain sympathetic denervation of the upper limb without dividing the oculopupillary fibres and thus producing the complications of ptosis, constriction of the pupil and loss of sweating on the affected side of the face (Horner's syndrome).

Sympathetic ganglion block with local anaesthetic solution (0.5% lidocaine (lignocaine)) can be attempted to establish whether benefit can be expected from sympathectomy (Figure 2). The patient lies supine, head and neck extended. A 6 cm needle is directed posteriorly, 1.5 cm superior and 1.5 cm lateral, to the suprasternal notch between the trachea and the carotid sheath alongside the body of the VIIth cervical vertebra until it strikes its transverse process. The needle is then withdrawn 0.5 cm, suction applied to ensure it is extravascular and 10 ml of anaesthetic is injected. A temporary Horner's syndrome results if the block is successful.



2

The Thoracic Inlet and First Rib

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

The thoracic inlet, small and kidney-shaped, is about 10 cm wide and 5 cm anteroposteriorly. It slopes forward and is bounded by the first thoracic vertebra posteriorly, the upper border of the manubrium anteriorly and the first rib and costal cartilage laterally. It transmits the oesophagus, the trachea, and the large vessels comprising the right and left subclavian arteries, and the right and left brachiocephalic veins, which unite behind the lower border of the right first costal cartilage to form the superior vena cava. Lying on the neck of the first rib posteriorly is the sympathetic trunk. On each side is the apex of the lung, some 3 cm above the medial third of the clavicle, covered by the dome of the pleura (Figure 1).

The subclavian arteries commence behind the sternoclavicular joint and curve laterally in front of the apex of the lung before passing on to the upper surface of the first rib. Both subclavian veins lie anterior to their respective arteries curving medially from the middle third of the clavicle to form the brachiocephalic vein by joining their internal jugular vein behind the sterno-clavicular joint.

The first rib (Figure 2) is short, wide, flattened and lies in an oblique plane, sloping forwards and downwards. It possesses a head that articulates with the body of the first thoracic vertebra, a rounded neck, a posterior tubercle and a body. The anterior end of the body bears the costal cartilage, which articulates with the manubrium. Its head bears a single facet for articulation with the first thoracic vertebra and posteriorly it bears a small tubercle posteriorly on its angle. The lower surface of the body is smooth and lies on the pleura. A small scalene tubercle on its medial border marks the attachment of the scalenus anterior muscle and this tubercle, on the upper surface of the body, separates an anterior groove for the subclavian vein from a posterior groove for the subclavian artery and the lower trunk of the brachial plexus which lies behind the artery. Scalenus medius is attached to the upper surface of the body behind the groove for the artery. Anterior to the neck of the rib and behind the pleura lie, from medial to lateral, the sympathetic trunk and the large branch of the first thoracic nerve to the brachial plexus.

The proximity to the surface and the constancy of their surface anatomy allows percutaneous access to the large veins in this region; the subclavian vein can be catheterized for intravenous feeding or monitoring central venous pressure. The infraclavicular approach is preferred because there is less chance of accidental puncture of the pleura by this route (Figure 3). The needle is inserted one finger's width below the midpoint of the clavicle and directed medially and as far anteriorly as possible (to ensure that neither the pleura nor the subclavian artery is pierced) towards the jugular notch of the manubrium. The subclavian vein should be entered as it curves over the body of the first rib.

3

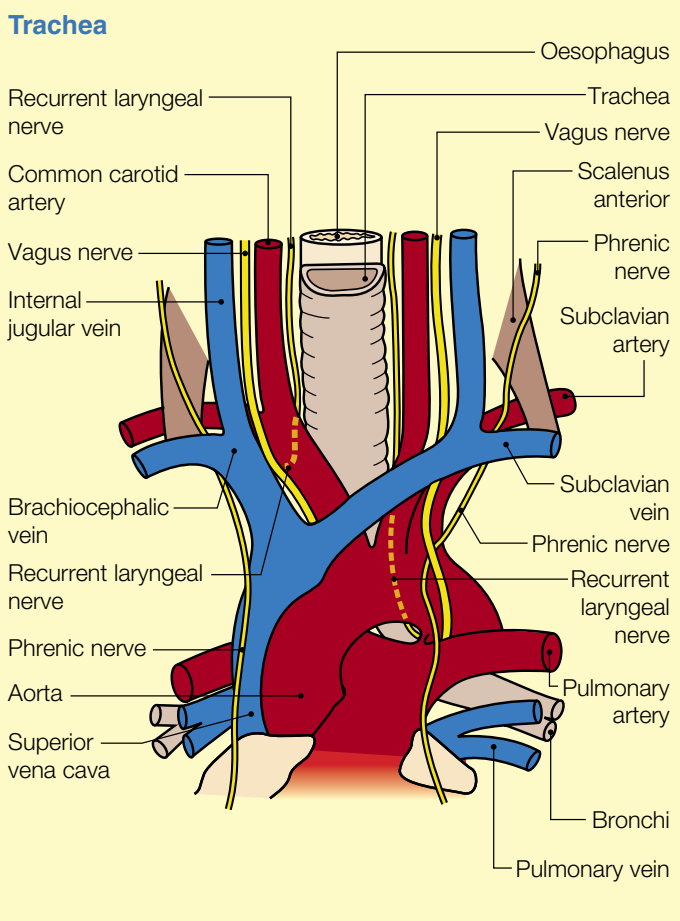
The Trachea and Extrapulmonary Bronchi

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England. His particular interest is gastric cancer.

The trachea, beginning at the level of the 6th cervical vertebra, descends from the larynx through the neck and thorax to its bifurcation into the two bronchi at the sternal angle, at the level of the 4th thoracic vertebra. In the adult, it is about 10 cm long and 2 cm in diameter. It is covered by the pretracheal fascia, which is attached superiorly to the hyoid bone and the thyroid cartilage. The fascia splits to enclose the thyroid gland, below which it blends into the carotid sheaths (Figure 1).

Trachea

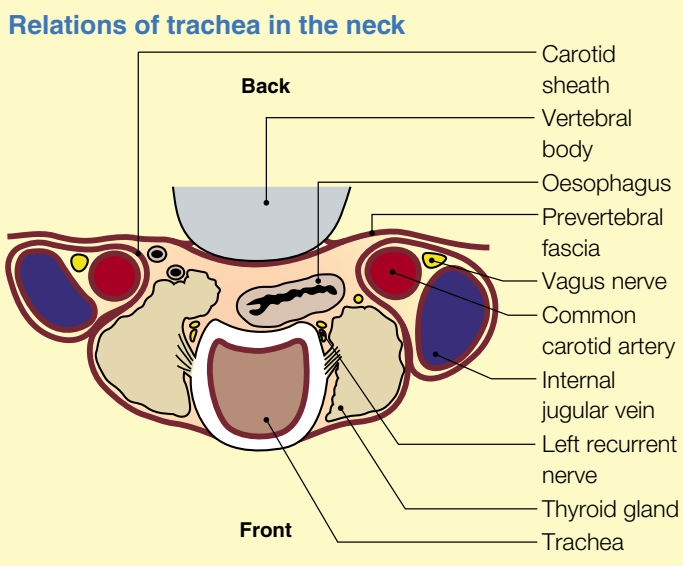


1

The wall of the trachea is formed of fibrous tissue reinforced by 15–20 cartilaginous rings. These are incomplete posteriorly where the trachea rests on the oesophagus and are there united by fibroelastic and smooth muscle tissue. The trachea is lined interiorly by respiratory epithelium. It lengthens and widens slightly during inspiration and recovers during expiration because of the elastic tissue within its walls.

Relations in the neck (Figure 2): the trachea lies anterior to the oesophagus with the recurrent laryngeal nerve lying laterally in the groove between them. Anteriorly it is covered by the cervical fascia and the infrahyoid muscles and is crossed by the isthmus of the thyroid gland and the left brachiocephalic vein. To its lateral aspect lies the lateral lobe of the thyroid gland, the inferior thyroid artery and the carotid sheath.

Relations of trachea in the neck

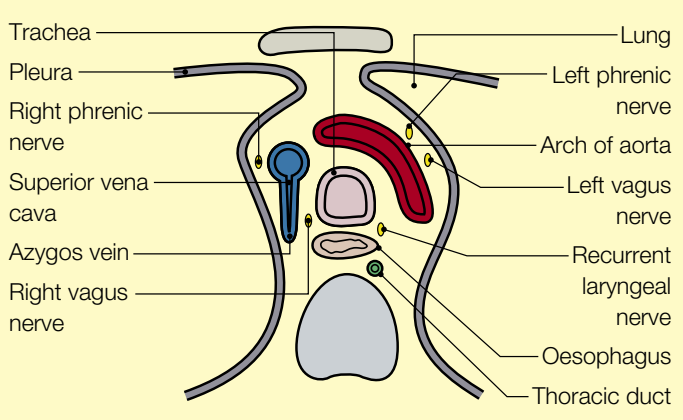


2

Relations in the thorax (Figure 3): the brachiocephalic artery and, below it, the arch of the aorta separate the trachea from the manubrium. The oesophagus descends behind the trachea. On its left lie the common carotid and subclavian arteries above and the aortic arch below, to the right lie the mediastinal pleura, the right vagus nerve and the azygos vein.

The tracheal bifurcation, the carina, lies anterior to the oesophagus and to its left lies the bifurcation of the pulmonary trunk. Tracheobronchial lymph nodes lie on either side.

Transverse section through the mediastinum at the level of the 4th thoracic vertebra



3

The extrapulmonary bronchi: each arises at the carina and descends laterally to enter the hilum of the lung where it divides to form the intrapulmonary bronchial tree. Their structure is similar to that of the trachea.

The right bronchus is about 3 cm long. It is wider and more vertical than the left bronchus, which is why inhaled foreign bodies tend to enter it more often. The right upper lobe bronchus arises from it just before it enters the hilum of the lung. Anteriorly, the right pulmonary artery separates it from the pericardium and the superior vena cava. The arch of the azygos vein is above it and the bronchial vessels lie posteriorly.

The left bronchus is about 5 cm long. Anteriorly, the left pulmonary artery separates it from the left atrium. The arch of the aorta is above it and posteriorly the bronchial vessels separate it from the oesophagus and the thoracic aorta. ◆

The Veins of the Lower Limb

John Craven

John Craven was formerly Consultant Surgeon at York District Hospital, York, UK. He trained in Manchester, Uganda and Cardiff. He is past chairman of the primary examiners of the Royal College of Surgeons of England.

The veins of the lower limb are classified as superficial, deep or communicating (perforating) veins. Valves are present in all the larger vessels including the communicating veins.

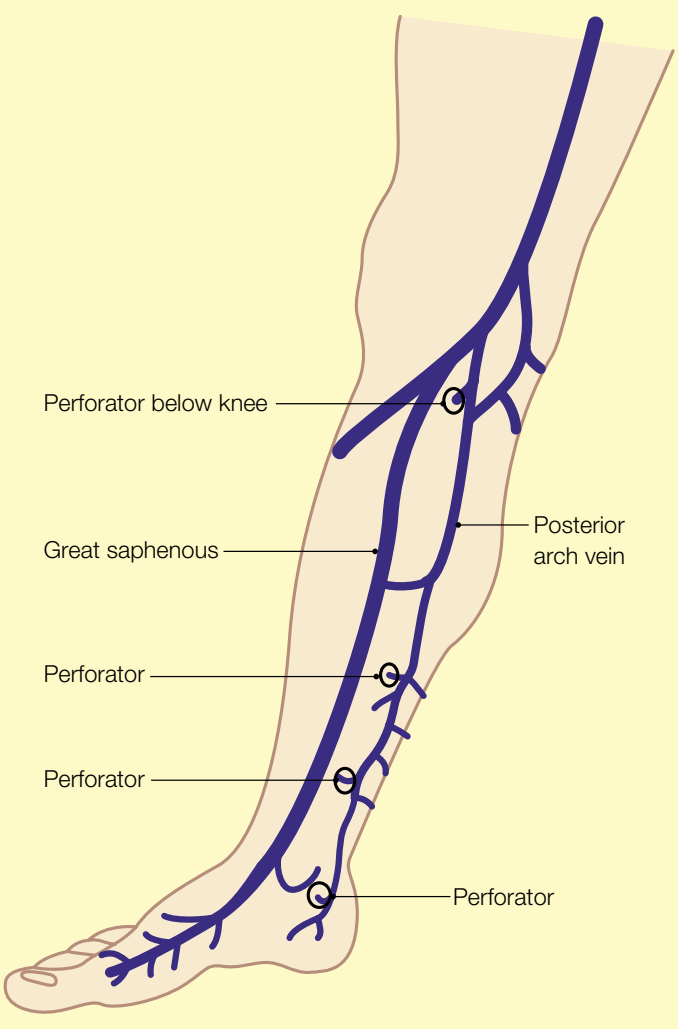
Superficial veins

The superficial veins drain the subcutaneous tissue and terminate in the two large longitudinal channels, the great and the small saphenous veins.

Great (or long) saphenous vein

The great (or long) saphenous vein originates from the medial side of the dorsal venous arch beginning just in front of the medial malleolus. It ascends the medial side of the calf and thigh (accompanied in the calf by the saphenous nerve) and passes through the saphenous opening of the deep fascia 1.5 cm below the inguinal ligament to enter the femoral vein. Its tributaries drain the leg, thigh, inguinal region and the pubic region but its most clinically important branches are the several communicating branches (or perforating veins) that drain from it into the deep veins of the calf and thigh, perforating the deep fascia generally on the medial side of the leg (Figure 1).

The long saphenous vein and calf perforators

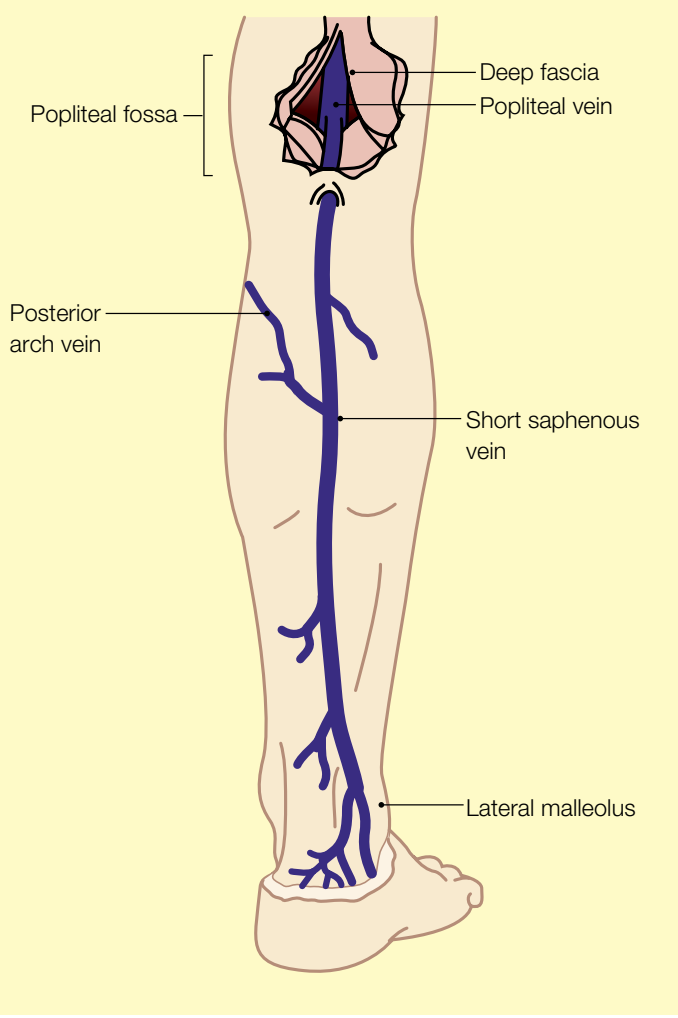


1

Small (or short) saphenous vein

The small (or short) saphenous vein originates from the lateral end of the dorsal venous arch. It ascends behind the lateral malleolus along the back of the calf to end by piercing the deep fascia a variable distance below the popliteal fossa to end in the popliteal vein. In its lower course it is accompanied by the sural nerve. It has tributaries communicating with the deep veins of the calf and one or more that join with the great saphenous nerve (Figure 2).

Short saphenous vein entering popliteal vein (deep fascia has been incised)



2

Deep veins

The deep veins comprise the soleal plexus, the popliteal and the femoral veins. They communicate with the superficial veins by ‘perforators’, veins that perforate the deep fascia (Figure 1), the valves of which are arranged to allow blood to flow only towards the deep veins. The soleal plexus, which lies within the muscles of the calf, drains into the popliteal vein, which drains into the femoral vein and both accompany their corresponding artery deep to the deep fascia. The soleal plexus has a large volume and it is the pressure of the contracting calf muscles (the soleal pump) that is an important factor in ensuring venous return from the lower limb to the heart. The soleal pump is dependent for its efficiency on the competence of the valves in the communicating veins.

The soleal plexus is the most common site of origin of a deep vein thrombosis. Immobility as a result of bed rest or anaesthesia increases the stagnation of blood in the lower limb especially in the soleal plexus. The thrombus may extend from the soleal plexus to the popliteal and femoral veins, if so the risk of pulmonary embolism becomes significant. Thrombosis in the soleal plexus may also extend into the perforating veins; subsequently, after spontaneous recanalization, the protective valves in those vessels are destroyed, which allows venous blood to travel retrogradely, from the deep veins to the superficial resulting in obvious varicose veins. This results in venous hypertension in the superficial tissues of the leg as shown by soft tissue fibrosis, hyperpigmentation and, in severe cases, chronic skin ulceration. It is thought that the primary cause of varicose veins is the incompetence of the valves in the perforating veins and the retrograde flow that follows produces distension of the superficial veins. This distends the saphenous veins and renders their valves incompetent. ◆

Anaesthesia for 'Off-pump' Coronary Artery Bypass Surgery

Virin S Sidhu
Sri Varaday

Virin S Sidhu is Consultant in Anaesthesia and Intensive Care at St Mary's Hospital, London, UK. He qualified from the University Hospital of Wales, Cardiff.

Sri Varaday is Specialist Registrar at the Imperial College School of Anaesthesia, London. He graduated from Andhra University, India.

Off-pump coronary artery bypass (OPCAB) surgery is performed on a beating heart without the use of cardiopulmonary bypass. The first work relating to coronary artery bypass graft on a beating heart was carried out in 1910 by Carrel, and the first successful surgery using cardiopulmonary bypass was performed in 1953 by Gibbon. The initial morbidity and mortality on cardiopulmonary bypass was high, allowing the development of coronary artery surgery without it. In 1967, Kolessov reported a series of six cases in which the internal mammary artery was anastomosed to the left anterior descending artery on the beating heart. With the development of bubble oxygenators and cardioplegia in the late 1960s, coronary artery surgery performed on cardiopulmonary bypass became the technique of choice, though cardiopulmonary bypass is still associated with deleterious effects.

In 1996, Calafiore introduced minimally invasive direct coronary artery surgery through a left anterior short thoracotomy incision or mini-sternotomy, which renewed interest in off-pump surgery. This technique was improved by the use of stabilizers designed to imobilise a target area of the heart. However, its main limitation was that access was limited to the left anterior descending and proximal right coronary arteries. The main potential benefit of minimally invasive direct coronary artery surgery was the avoidance of cardiopulmonary bypass. This has resulted in an increase in popularity of OPCAB through a median sternotomy, allowing access to multiple vessels, and the avoidance of one-lung ventilation (mandatory for minimally invasive direct coronary artery surgery) while retaining rapid access to cardiopulmonary bypass in difficult or failed procedures. OPCAB presents new challenges for the surgeon and anaesthetist.

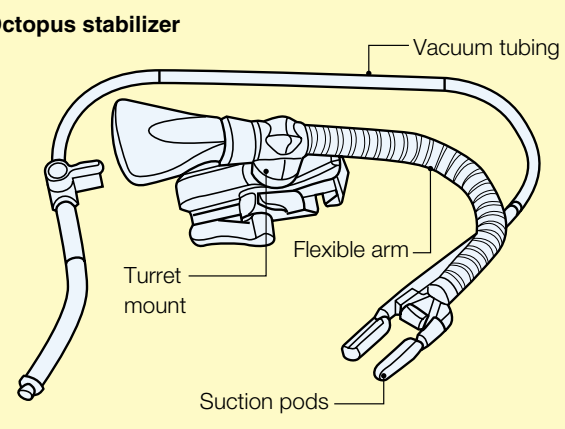
Exposure and stabilization of coronary arteries

Complete revascularization of the heart by accessing all coronary territories requires adequate exposure and stabilization of target coronary arteries. The left anterior descending and proximal right coronary arteries are exposed with minimal cardiac displacement and haemodynamic compromise using surgical packs. The circumflex, diagonal, posterior descending artery and distal right coronary artery are more difficult to expose. The application of slings, pericardial sutures and the placement of surgical packs help to displace and elevate the heart anteriorly providing adequate exposure. A Trendelenburg tilt with rotation of the operating table to the right and opening the right pleura reduces haemodynamic compromise due to compression of the heart against the right pleura, while performing anastomosis on the posterior and lateral walls. Exposure of the posterior descending artery may require a steep Trendelenburg tilt, such that the apex of the heart is almost pointing towards the ceiling! In order to prevent bleeding from the open coronary artery during anastomosis, the target vessel is occluded with slings or microvascular clamps. A humidified carbon dioxide blower is used to prevent blood obscuring the arteriotomy site. Intracoronary shunts may be used to maintain perfusion, display the suture line and reduce back-bleeding.

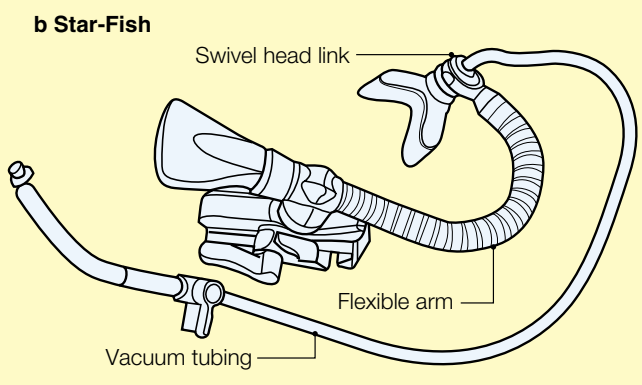
Mechanical stabilizers have greatly contributed to the feasibility of beating heart surgery, allowing good quality anastomotic suturing. Stabilization of the target site is accomplished by using stabilizers such as the Octopus Systems (Medtronic) (Figure 1a), which offer secure, stable access to all coronary arteries. Using gentle suction, the Star-Fish (Figure 1b) gently lifts, positions and holds the beating heart. Stabilization of the tissue at the grafting site is achieved by the smaller, more flexible arm and turret-mounted design of the Octopus device. The malleable suction pods assure easy application, such that the site is lifted and not depressed, thus avoiding impairment of ventricular filling.

Mechanical anastomotic stabilizer

a Octopus stabilizer



b Star-Fish



1

Anaesthetic technique

The most important anaesthetic considerations are the prevention of haemodynamic instability and ischaemia. The technique lends itself to early extubation and ambulation. Preoperative assessment should include a review of the angiogram and a discussion with the surgeon of the order of grafting. Adequate premedication is required and tachycardia avoided.

Operating room set up

Early extubation requires the maintenance of normothermia. The operating room is kept warm to avoid radiant heat loss. The head should be covered with drapes. A warming mattress and fluid warmer are used. A forced-air warming blanket is used over the lower half of the body once the saphenous vein has been harvested. The heart–lung machine and perfusionist should be available immediately, but it is usually unnecessary to have the machine primed. Facilities for defibrillation, cardiac pacing and intra-aortic balloon pump counterpulsation should also be available immediately. For multiple vessel OPCAB a cell saver reduces homologous blood transfusion.

Monitoring

Standard cardiac monitoring is used. The ECG may be distorted during cardiac displacement; in particular, the amplitude and ST segment changes may be reduced. ST segment trending is useful. Pulmonary artery pressure monitoring and transoesophageal echocardiography (TOE) may be used in high-risk patients with severe left ventricular dysfunction. TOE is useful in the detection of regional wall motion abnormalities and thus early ischaemic changes. During OPCAB, the heart is displaced or lifted and standard TOE views are lost. Furthermore, the stabilizers used may produce artefacts of regional wall motion abnormalities. However, a baseline TOE allows their assessment with particular attention to the areas supplied by the vessel to be grafted. A TOE examination following the completion of the anastomosis allows regional wall motion abnormalities to be re-checked. Continuous cardiac output monitoring is considered insensitive for routine use. The response time is too slow to detect sudden changes following manipulation and tilting of the heart; it is more useful as a trend monitor. Continuous monitoring of mixed venous oxygenation usefully detects abrupt changes in cardiac output.

Anaesthesia

Induction and maintenance of anaesthesia are determined by local extubation protocols. A balanced anaesthetic technique using limited doses of opioids, volatile agents and propofol is popular. A thoracic epidural technique provides cardiac sympathectomy, attenuates the stress response, reduces anaesthetic requirements and thus promotes early extubation and provides excellent postoperative analgesia. The risk of spinal haematoma formation can be reduced by siting the epidural catheter well before surgery. The advent of stabilizers has made the induction of pharmacological bradycardia, originally used to provide the surgeon with a relatively immobile area, less important, but tachycardia should be avoided. The serum potassium should be maintained at about 4.5 mmol/litre. Magnesium sulphate prevents and treats atrial and ventricular arrhythmias during OPCAB surgery and can be infused following induction of anaesthesia. Partial heparinization (1 mg/kg) maintaining an activated clotting time of 250–300 s and complete reversal with an appropriate dose of protamine is advocated. During proximal coronary anastomosis, arterial pressure should be reduced to 90 mm Hg to reduce the risk of aortic dissection on application of aortic side-biting clamps. Diuretics, in small doses, may be required to correct fluid balance.

Management of haemodynamic instability

The main causes of haemodynamic instability during OPCAB surgery are the impairment of venous return due to chamber compression and abnormal positioning, and pump failure due to direct ventricular compression or ischaemia during occlusion of the target arteries. Mitral valve distortion can contribute significantly to haemodynamic instability, and cardiac displacement increases the risk of intraoperative arrhythmia. The extent of the haemodynamic compromise depends on the coronary artery being anastomosed, the greatest being the circumflex artery and its branches on the posterior aspect of the heart, and the diagonal vessels on the lateral aspect. It may therefore be prudent to revascularize vessels on the anterior aspect of the heart, before any lifting or rotation occurs. Changes in arterial pressure and cardiac output may occur rapidly with cardiac manipulation and the anaesthetist must pre-empt these to maintain haemodynamic stability. The use of the Trendelenburg position, optimizing preload, the use of vasoconstrictors, inotropes, or repositioning of the heart may improve cardiac output. Occlusion of the target coronary arteries during anastomosis of grafts may result in ischaemia and arrhythmias, including ventricular fibrillation. Occlusion of the proximal right coronary artery may lead to ischaemia of the atrioventricular node and complete heart block. The application of pacing wires may be necessary before arterial occlusion. If adequate haemodynamic parameters cannot be maintained it may be necessary to convert to an on-pump technique. Good communication with the surgeon is mandatory.

Advantages and disadvantages of OPCAB

Advantages: off-pump surgery avoids the complexity and may avoid some of the deleterious effects of cardiopulmonary bypass. This includes derangements in coagulation, and multiple-organ dysfunction occurring through a combination of the systemic inflammatory response syndrome, flow abnormalities and emboli. The specific advantages of the technique are shown in Figure 2; the most important is the possible reduction of subtle neurological deficit and cognitive dysfunction. By avoiding cardio-pulmonary bypass the potential for emboli originating from the aorta and the bypass circuit is reduced, though the need for aortic manipulation is not eliminated. The renal impairment and respiratory dysfunction that may occur following cardiopulmonary bypass, have not been universally demonstrated to be reduced with an off-pump technique. The results of large randomized prospective trials are awaited.

Advantages of OPCAB

- Reduced systemic inflammatory response syndrome
- Reduced blood loss and transfusion requirements
- Short operating, intubation and ventilation times
- Possible reduced neurological and neuropsychological effects
- Shorter ICU and hospital stay
- Potential cost saving

2

Disadvantages: OPCAB surgery demands a high level of vigilance on the part of the anaesthetist and is technically demanding for the surgeon. Cardiovascular collapse or ventricular fibrillation may occur rapidly. The ability to respond quickly to such changes is essential, including conversion to an on-pump technique. Patients with severe left ventricular dysfunction requiring multiple grafts may be unsuitable for an off-pump technique as may patients with certain patterns of coronary artery disease. The long-term patency of grafts is unknown. ◆

Anaesthesia for Patients with Cardiac Disease Undergoing Non-cardiac Surgery

K Moyna Bill

K Moyna Bill is Consultant in Cardiac Anaesthesia and Intensive Care at the Royal Hospitals Trust, Belfast, UK. She qualified from the University of Edinburgh and trained in anaesthesia in Northern Ireland, and Leiden, The Netherlands.

The number of patients with cardiac disease presenting for anaesthesia to facilitate non-cardiac surgery is increasing. They present some of the greatest anaesthetic challenges because their cardiac lesions will still exist after the operation, unlike patients undergoing cardiac surgery. Perioperative cardiac morbidity (myocardial ischaemia, infarction, arrhythmias) is the most common cause of death following anaesthesia and surgery. Despite improvements in anaesthetic technique, the mortality associated with a perioperative myocardial infarction is 40–70%. The prevalence of coronary artery disease increases with increasing age and it is estimated that about 33% of patients undergoing non-cardiac surgery are at risk of having cardiovascular disease. In many patients this will not have been diagnosed, therefore preoperative assessment is important to identify it and its attendant risks. Other forms of cardiac disease (valvular and congenital heart disease or heart transplant patients) should also be considered.

Preoperative assessment

Preoperative assessment is important to:

- assess the risk to the patient
- optimize the patient's condition
- form a plan for perioperative management to minimize the risk of an adverse outcome.

Assessment of risk

The best known scoring system for estimating the risk of surgery for patients with cardiac disease was developed by Goldman in 1977, and modified by Detsky in 1986. It is a multifactorial risk analysis that combines clinical and investigation parameters and allows patients to be grouped into four risk categories, for major complications or cardiac death. The most widely used index of perioperative risk remains the ASA (American Association of Anesthesiologists) physical status system even though it is somewhat subjective and lacks specificity.

In 1996, the American College of Cardiology and American Heart Association (ACC/AHA) produced guidelines for peri-operative evaluation for non-cardiac surgery; they were updated in 2002. These guidelines differentiate clinical predictors of increased perioperative cardiac risk into three categories (major, intermediate and minor; Figure 1). Recognition of these factors, the functional capacity and the type of surgery are then used to inform the anaesthetist as to the need for further cardiac investigation.

Clinical predictors for perioperative cardiac risk

Major risk factors

- Unstable coronary syndromes
  - Acute myocardial infarction (< 6 weeks)
  - Myocardial infarction > 6 weeks or < 6 months but with myocardium at risk
  - Unstable or severe angina (CCS Class III or IV)[1]
- Decompensated congestive heart failure
- Symptomatic arrhythmias
- Severe valvular disease
- Coronary artery bypass grafting (CABG) or percutaneous transluminal coronary angioplasty (PTCA) ± stent < 6 weeks

Intermediate risk factors

- Stable angina (CCS Class I or II)
- Previous myocardial infarction by history or ECG
- Compensated or previous congestive heart failure
- Diabetes mellitus

Minor risk factors

- Age (physiological) > 70 years
- Abnormal ECG (left ventricular hypertrophy, left bundle branch block, ST abnormalities)
- Rhythm other than sinus (e.g. atrial fibrillation)
- Systemic hypertension
- History of stroke
- Hyperlipidaemia
- Low functional capacity
- Smoking
- Renal insufficiency

[1] CCS, Canadian Cardiovascular Society

1

The history, physical examination, basic haematological tests, 12-lead ECG, and chest radiograph should be carried out to identify the:

- presence of heart disease
- severity, stability and previous treatment of the disease
- functional capacity of the patient
- presence of co-morbid conditions.

More detailed cardiac investigations may be appropriate in patients who are awaiting elective or, on occasions, urgent surgery. In the emergency situation, patients with cardiac risk factors and reduced functional capacity have a high perioperative risk, but delaying surgery for detailed investigation does not benefit the patient.

Patient risk factors

Previous coronary revascularization – patients who have undergone coronary artery bypass grafting (CABG) or percutaneous transluminal coronary angioplasty (PTCA) with or without stent insertion in the previous 5 years and who have had no recurrence of symptoms with return to an active lifestyle do not need further testing. Those who have had a recent stent placement should have their surgery postponed for 6 (or preferably 12) weeks, if possible, because of the bleeding risks associated with the anti-platelet drugs (aspirin, clopidogrel) that they are obliged to take to prevent re-stenosis of the vessel and stent.

Previous coronary evaluation – those who have had cardiac evaluation in the previous 2 years should need no further investigation providing their symptoms have not changed and their activity levels have not deteriorated.

Myocardial infarction and ischaemia – advances in the treatment of myocardial infarction (thrombolysis, PTCA with or without stent) have meant that the traditional high-risk period following infarction of 6 months may be reduced, providing there is evidence that no further myocardium is at risk. This is assessed by stress testing (see later). The heart takes 4–6 weeks to remodel and heal following infarction, during which time it is more vulnerable to arrhythmias and myocardial stunning. The haemodynamic stresses and hypercoagulability associated with surgery may also lead to extension of the infarct. Patients who have unstable or severe angina (Canadian Cardiovascular Society (CCS) Class III or IV) also have a high probability of continuing plaque rupture and thrombosis. Although it is common practice to postpone truly elective surgery until 6 months after a myocardial infarction, patients who have had a myocardial infarction over 6 weeks previously and show no evidence that further myocardium is at risk can proceed with urgent surgery with perioperative cardiac risk reduction strategies. When at least 6 months have elapsed, those who have resumed normal daily activity and have no post-infarction angina should not need further testing, unless the risk of surgery or the functional capacity warrants it.

Arrhythmias – the cause should be identified and treatment instituted, especially for those that are symptomatic and cause hypotension. Indications for antiarrhythmic drugs and cardiac pacing are the same as in the nonsurgical patient.

Decompensated congestive heart failure – these patients should have their medical therapy optimized to minimize the risk of worsening their pulmonary oedema. If ischaemia is the cause, they are also at risk of developing a perioperative myocardial infarction.

Compensated congestive heart failure – patients with a left ventricular ejection fraction less than 35% are at particular risk for perioperative complications.

Diabetes mellitus – there is a high incidence of silent ischaemia associated with diabetic neuropathy, making the lack of angina with exercise a less reliable symptom. Dyspnoea, especially with minimal exertion, may be a more important symptom.

Hypertension – inclusion of hypertension as an intermediate or minor risk factor remains controversial. There is some evidence that if left ventricular hypertrophy is present and the blood pressure is not well controlled, the risk is more significant because the increase in left ventricular mass makes it more susceptible to changes in oxygen delivery and demand. Severe hypertension should be controlled before surgery if possible.

Minor risk factors – cerebrovascular disease and renal insufficiency are possibly not direct risk factors but markers of end organ damage from the same factors that cause coronary artery disease. The greater the number of minor and intermediate risk factors the greater the risk of the patient having coronary artery disease.

Functional capacity: exercise tolerance is assessed by history and is expressed as metabolic equivalents (1 MET = 3.5 ml O_2/kg/min) on a scale defined by the Duke Activity Status Index in order to estimate their maximal oxygen consumption capacity (Figure 2). Patients with moderate or excellent functional capacity and low clinical predictors of risk do not need further cardiac investigation. The functional capacity of some patients may be limited by other conditions (e.g. respiratory, peripheral vascular or joint disease). These patients and those with poor functional capacity should undergo detailed cardiac assessment.

Estimated energy requirements for various activities

Poor functional capacity (1–4 MET)

- Light housework
- Shower or dress without stopping
- Walk at 2.5 mph on level ground

Moderate functional capacity (5–7 MET)

- Climb a flight of stairs without stopping
- Walk briskly (> 4 mph) on flat
- Light gardening

Excellent functional capacity (> 7 MET)

- Digging in garden
- Carrying shopping upstairs
- More strenuous sports (e.g. cycling uphill, jogging)

2

Surgical risk factors: the type of surgery and the resultant degree of haemodynamic stress influences the risk to the patient (Figure 3). Some procedures previously counted as high risk are now categorized as intermediate risk, owing to improved perioperative management. Account must also be taken of the risk of not performing the surgery, and the experience and skill of the surgeon and anaesthetist. Peripheral vascular surgery may also be counted as high risk because the extent of the cardiac disability can be masked by the limits imposed by intermittent claudication.

Further cardiac investigations: all cardiovascular tests have limitations and risks and should be carried out only if the results will change the patient's management.

Coronary angiography and revascularization – the indications for these are the same as for those not having surgery (e.g. unstable angina unresponsive to medical treatment, deteriorating severity of symptoms).

Ambulatory ECG monitoring has been used to assess silent ischaemia, but in a significant number of patients (up to 50%) resting ECG abnormalities make the interpretation difficult.

Stress tests (e.g. exercise ECG, dipyridamole-thallium scinti-graphy (DTS) or dobutamine stress echocardiography (DSE)) are dynamic investigations that elucidate the possibility of threatened myocardium and the maximal tolerated heart rate. DSE and DTS are the only non-invasive tests that improve preoperative risk stratification.

Echocardiography and technetium-99 scanning assess myocardial function but cannot predict ischaemic events. Echocardiography is also used to assess the nature and severity of valvular heart disease.

Surgical risk factors

High risk (complication rate > 5%)
- Emergency, intermediate and major procedures
- Aortic and major vascular procedures
- Prolonged procedures
- Procedures with large fluid shifts, blood loss or which produce haemodynamic instability

Intermediate risk (complication rate 1–5%)
- Minor vascular procedures (including carotid endarterectomy)
- Prostatic surgery
- Orthopaedic surgery
- Head and neck surgery
- Intraperitoneal surgery
- Intrathoracic surgery

Low risk (complication rate < 1%)
- Endoscopic procedures
- Superficial surgery
- Breast surgery
- Ophthalmic surgery
- Plastic and reconstructive surgery

Other systems (e.g. respiratory, renal, endocrine, skeletal, airway) need assessment and possible further investigation. The results may affect the anaesthetic plan.

Preoperative therapy

The patient's condition and medication should be optimized. Most cardiac medication should be continued peroperatively. There is evidence that continuation of ACE inhibitors may increase the incidence of hypotension and some physicians have recommended withholding them for 24 hours preoperatively.

Two specific strategies have been suggested to reduce postoperative morbidity and mortality.
- In goal-directed optimization, patients with high risk factors for major surgery are admitted preoperatively to a high dependency or intensive care unit for invasive monitoring (including pulmonary artery catheter) and manipulation of fluid and inotropic therapy in order to achieve the optimal cardiac index, oxygen delivery and consumption.
- In selected patients, β-blockade has reduced perioperative cardiac events and improved 6-month survival. The optimum time from surgery for commencing and discontinuing β-blockers is less clear and it seems that achieving a target heart rate is more important.

Other studies with α_2-agonists are not so convincing. There is insufficient evidence about the effects of preoperative and intraoperative nitroglycerine.

CABG and PTCA are appropriate only in patients who would require them even if they were not awaiting surgery. The combined risk of both procedures may be greater than that of non-cardiac surgery with perioperative risk-reduction strategies.

Premedication should be adequate to allay anxiety, and oxygen therapy preoperatively may be advantageous. Warfarin therapy should be replaced with heparin and antiplatelet drugs (aspirin, clopidogrel) should be stopped at the appropriate time. This depends on the severity of the coronary artery disease and the surgical procedure.

Intraoperative management

Principles: the oxygen supply:demand ratio must be maintained to avoid ischaemia (Figure 4). In coronary artery disease, the pressure gradient across the fixed stenoses is important because the coronary arteries cannot dilate in response to increased oxygen demand. Maintenance of arterial blood pressure and reduction of heart rate should reduce the risk of ischaemia. This is also important in patients with aortic stenosis. It has been suggested that in cardiac patients, a haemoglobin level of 10 g/dl or more is needed to optimize the oxygen supply.

Factors affecting myocardial oxygen supply and demand

Supply
- Coronary perfusion pressure (aortic diastolic perfusion – left ventricular end-diastolic pressure)
- Blood oxygen content
  - Partial pressure of oxygen in arterial blood (PaO_2)
  - Haemoglobin concentration
- Coronary vascular resistance
  - Coronary artery stenosis
  - Heart rate and left ventricular end-diastolic pressure
  - Autoregulation

Demand
- Heart rate
- Contractility
- Wall tension
  - Left ventricular end-diastolic pressure
  - Arterial pressure
  - Contractility

In the preoperative plan, it is important to decide which values of preload, heart rate, systemic vascular resistance, pulmonary vascular resistance and rhythm are acceptable and to anticipate the times when the maintenance of these values will be most difficult (e.g. induction, intubation, blood loss). Strategies to deal with these situations should be considered preoperatively.

Anaesthetic agents: the choice of anaesthetic agents and techniques does not significantly affect the risks of perioperative complications, providing hypertension, tachycardia and hypotension are avoided. It should be governed by the experience and skill of the anaesthetist and their familiarity with the techniques and drugs. Etomidate has the fewest cardiovascular effects but most people are more familiar with thiopental (thiopentone) or propofol, both of which should be titrated carefully to effect. Pretreatment with a dose of opioid reduces the required dose of induction agent and may attenuate the haemodynamic response to intubation. Remifentanil is a new, potent, ultra-short-acting opioid, which has great ability to produce haemodynamic stability and suppress the stress response. It is administered by infusion and transfer to other methods for postoperative analgesia needs careful consideration. Concerns were previously raised that isoflurane might cause a 'coronary steal' situation but these have subsided. It should be remembered that N_2O is also a myocardial depressant. The role of regional blockade is keenly debated. It has many advantages, not least in reduction of the stress response and in effective analgesia. Preservation of an adequate perfusion pressure is vital and the vasodilatation produced may be better avoided in some patients. However, incomplete anaesthesia can lead to increased stress response and myocardial ischaemia.

Monitoring: a 5-lead ECG gives better detection of myocardial ischaemia. Recent studies have shown that V5 is the most sensitive single lead. ST segments should be monitored in high-risk patients. Invasive monitoring by arterial and pulmonary artery catheters may be useful in those at high risk, especially if they have had a recent myocardial infarction with cardiac failure, providing the anaesthetist has the experience to insert them and interpret the data. The pulmonary artery catheter is most useful in monitoring volume status and cardiac performance, such as cardiac output/index, mixed venous oxygen saturation, systemic and pulmonary vascular resistances. Transoesophageal echocardiography may be used to assess volume status and valvular disease and is the best way to detect ischaemia early (segmental wall motion abnormalities), but requires expertise to interpret it. Information received from the monitors (e.g. hypotension, ischaemic changes, left ventricular dysfunction, arrhythmias) needs to be acted on urgently, especially in those with severe disease.

Temperature control: there is a higher incidence of cardiac morbidity in patients who become hypothermic, therefore active warming measures are often required.

Blood glucose control: it has been shown that tighter blood glucose control (4.4–6.1 mmol/litre) leads to reduced morbidity and mortality.

Postoperative management

The period after surgery is associated with increased levels of catecholamines and hypercoagulability. Most perioperative infarcts occur in the first 3 days, therefore the preoperative plan should include the most appropriate place for postoperative care and the same management goals should be adhered to in this period. All patients should receive humidified oxygen, for at least 72 hours after major surgery. Postoperative analgesia should be adequate. Anaemia should be treated and thromboprophylaxis continued. The patient's normal cardiac medication should be restarted as soon as possible.

Specific conditions

Valvular heart disease: stenotic lesions lead to a low, fixed cardiac output, which tolerates poorly any changes in rhythm, tachycardia and decrease in preload and vascular resistance. Replacement of the valve before non-cardiac surgery may need to be considered in severe symptomatic disease, especially aortic stenosis. Patients with regurgitant valves benefit from afterload reduction, faster heart rates and maintenance of preload. Antibiotic prophylaxis is necessary for all cases and should be governed by the type of surgery and local regimens.

Congenital heart disease: anaesthesia for these patients is discussed elsewhere. It is vital to understand the pathophysiology of the particular lesion.

Cardiac transplant: all electrical stimulation in the heart is initiated from the donor sino-atrial node. The resting heart rate is generally 90–120 beats/min and there is no response to carotid sinus massage, changes in body position, light anaes-thesia or hypotension. An adequate preload should be maintained. Cardiac drugs that act directly on the myocardium or peripheral vasculature are necessary because those acting on the autonomic system have no effect on the denervated heart. Invasive monitoring should be avoided where possible and strict asepsis used at all times. Antibiotic prophylaxis depends on the type of surgery and should include anti-staphylococcal cover. It is imperative that immunosuppressive therapy is continued. ◆

Management of Cardiopulmonary Bypass

Judith Hall
Brian F Keogh

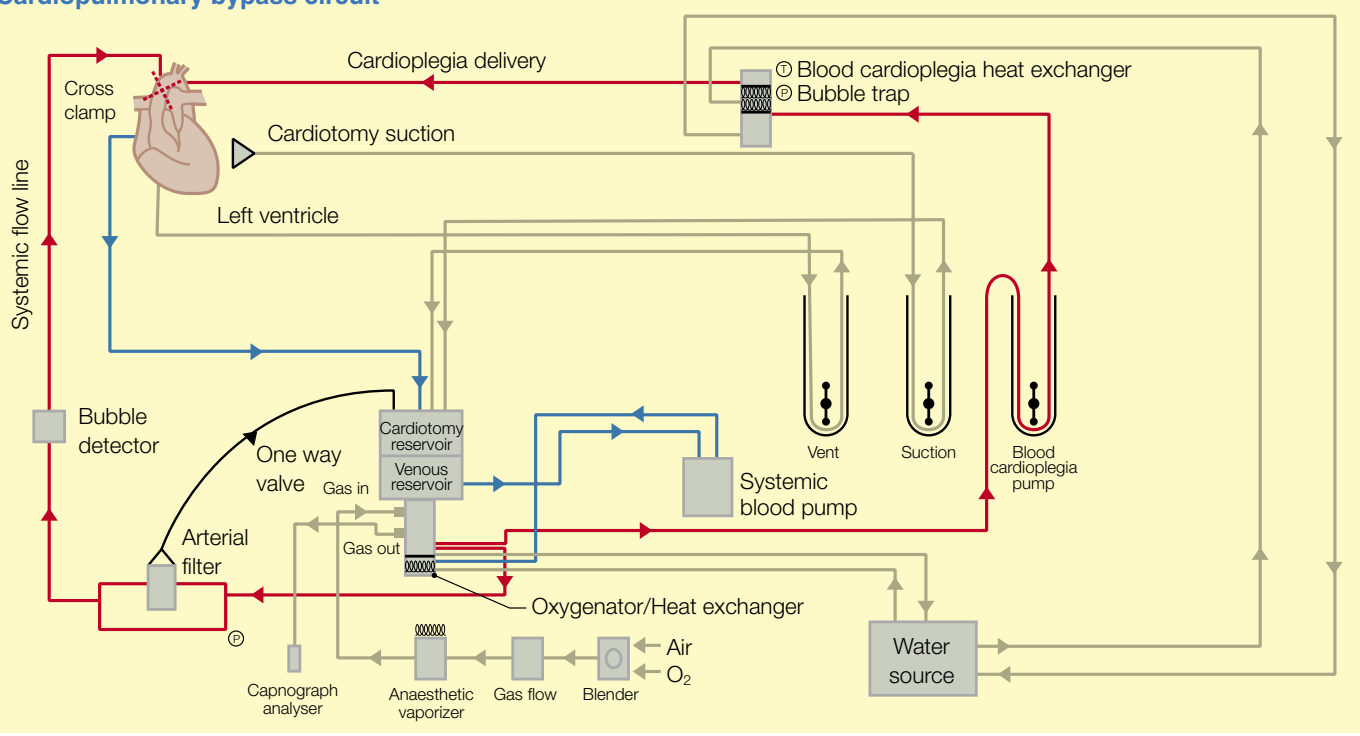
Judith Hall is Head of Perfusion at the Royal Brompton Hospital, London.

Brian F Keogh is Consultant in Cardiothoracic Anaesthesia at the Royal Brompton Hospital, London. His special interests include modes of respiratory support, particularly in acute severe pulmonary failure.

The driver for the development of cardiopulmonary bypass (CPB) was the desire to operate on a still heart in a blood-free surgical field. The concept was first applied in the animal laboratory by Gibbon in 1935. Research continued until the first clinical application of CPB by Dennis in 1951, in which the patient died due to surgical complications. In 1953, Gibbon successfully closed an atrial septal defect, using his design of heart–lung machine, and triggered the evolution of present day cardiac surgery.

The CPB circuit
The three basic functions of the CPB circuit are gas exchange, heat exchange and blood flow. The structural components of the circuit are outlined in Figure 1 and are connected with PVC tubing. The circuit requires a priming volume (usually a mixture of crystalloid and colloid) of 1.5–2 litres.

Cardiopulmonary bypass circuit



1

Venous blood drains by gravity from a single cannula placed in the right atrium when the atria are not opened, for example in coronary artery bypass graft (CABG) and aortic valve replacements, or by direct cannulation of the inferior and superior vena cava in more complex procedures. Venous blood is collected in the venous reservoir, which can be separate from, or more commonly (as in Figure 1) integrated with the cardiotomy reservoir. The blood is pumped from the reservoir through the oxygenator by a roller or centrifugal pump. The pump flow rate, reflecting oxygen delivery requirements at rest, is 2.4 litres/min/m^2. The range is 1.6–3.0 litres/min/m^2, depending on body core temperature, mean arterial pressure and mixed venous saturation. For each 1°C decrease in temperature, the required cardiac output is 7% less, and the flow can be reduced by an equivalent factor. The prolonged use of high pump flow rates is associated with destruction of red cells. In prolonged procedures, even with reduced flows, haemolysis and haemoglobinuria are common.

The oxygenator system

The oxygenator system usually includes an integrated venous reservoir, heat exchanger and oxygenator. The heat exchanger regulates blood temperature by altering the water temperature flowing through its tubing. The heat exchanger is situated proximal to the oxygenator because alterations in the temperature of blood that is 100% saturated can cause nitrogen, in the form of gaseous microemboli, to be released. The oxygenator is a series of hollow fibres bundled together and encased in a polycarbonate shell. Venous blood flows around the fibres and the inlet gas (oxygen/air) passes though the centre. Gas exchange takes place by diffusion across the oxygenator membrane. The inlet fraction of oxygen in inspired air (FiO_2) controls the resultant partial pressure of oxygen in arterial blood (PaO_2) and the $PaCO_2$ is controlled by the sweep rate of the inlet gas. Carbon dioxide is exhausted to the atmosphere and can be monitored by a capnograph attached to the gas outlet to reflect membrane gas transfer function. An anaesthetic vaporizer can be placed in the circuit before the gas inlet to provide anaesthesia during CPB.

The oxygenated blood returns to the patient via an arterial cannula, usually placed in the ascending aorta. A 40 μm filter is placed distal to the oxygenator to remove any aggregated platelets, debris from the circuit materials or large microbubbles. This filter can be coated to remove leucocytes that are activated by the non-biological surfaces of the circuit.

Heparinized blood from the pericardium and intracardiac chambers is removed through the cardiotomy suckers and filtered before it is returned to the circulation.

Conduct of perfusion

In UK practice, the perfusionist is responsible to the surgeon for the provision of safe and effective CPB. The anaesthetist's position is less formally defined, in terms of accountability, but excellent communication between the three disciplines is vital. The training and professional conduct of perfusionists is regulated by the Society of Perfusionists of Great Britain and Ireland. Perfusionists have completed a structured 2-year postgraduate training period in perfusion. Perfusionists are licensed to administer heparin and the vasoactive agents, metaraminol and phentolamine. They regularly administer volatile anaesthetic agents via the CPB circuit, corticosteroids, mannitol and potassium supplementation.

Haemofiltration in association with CPB has become commonplace and is provided and regulated by the perfusionist. This is an efficient process, the combination of a large surface area filter and an extracorporeal pump allowing rapid manipulation of body water, control of haematocrit and correction of electrolyte and metabolic abnormalities. Perfusionists have also assumed responsibility for cell salvage technology, now routinely used for cardiac surgery in many centres and which results in a substantial reduction in the number of patients requiring homologous red cell transfusion.

Anticoagulation for CPB

Heparin is used almost universally as the anticoagulant for CPB. It potentiates the activity of antithrombin III, which inhibits the activity of thrombin and other clotting factors, thus inhibiting clot formation. The elimination kinetics of heparin are variable, dose-dependent and temperature-related. Near patient testing of anticoagulation in CPB is performed with the activated clotting time (ACT), which provides an indication of heparinization, but correlates poorly with measured heparin levels. ACT levels are usually maintained above 480 seconds with supplemental heparin doses.

Monitoring of anticoagulation may be much more difficult in complex, prolonged procedures and particularly if heparinization has been reversed and re-heparinization for a further period of CPB is required. In these circumstances, heparin level assays against residual factor Xa activity, can be provided with a laboratory turn-around time of 20 minutes. Heparin levels are usually over 3 units/ml for CPB.

The introduction of the antifibrinolytic agent, aprotinin, in cardiac surgery has complicated near patient testing. In the presence of aprotinin, celite-activated ACT tubes underestimate the ACT and should be maintained at over 700 seconds. Kaolin-activated ACT tubes are much less affected by aprotinin, and should display ACT over 480 seconds.

In adults, the initial heparin dose is usually 300–500 IU/kg (100 IU = 1 mg) with a pump priming dose of 5–10,000 IU. Supplemental doses of 5–10,000 IU are administered according to ACT values. The typical heparin dose has increased in the last 5–10 years with the recognition of higher thrombin and aggregate formation with lower heparin doses, and with more sophisticated measurements of clotting activation. Baseline levels of ACT should be checked before heparin administration and prolongation of ACT must be confirmed before institution of CPB.

Reversal of heparinization

Heparin is highly charged and is reversed by the administration of protamine, which binds ionically to form a stable precipitate. Various empirical reversal regimens are used, most commonly 1–1.5 mg per 100 IU heparin administered. Heparin management systems that employ dose-response curves usually indicate lower doses are required. Protamine, derived from salmon sperm, is associated with a range of adverse effects, including direct myocardial depression. Transient systemic hypotension is often observed due to release of nitric oxide and histamine in vascular endothelium. Pulmonary vascular resistance increases, and may be catastrophic in existing pulmonary hypertension. Anaphylactoid responses, mediated by IgG or complement activation, include bronchoconstriction and acute lung injury, and are in part associated with the heparin–protamine complex. True anaphylaxis (probably IgE mediated) seldom occurs, but the consequences are catastrophic. Patients at risk include those with fish allergy and diabetics exposed to protamine-containing insulin. Many of the adverse effects relate to the rate of infusion. Large bolus doses should be avoided; the dose is usually administered over 5–10 minutes, and over longer periods and preferably by controlled infusion to patients at risk of de-stabilization (e.g. poor ventricular function, pulmonary hypertension).

Control of parameters during CBP

The different approaches to the conduct of perfusion are influenced by the nature of the planned surgery, the individual surgeon's requirements and local practice. Arterial blood pressure is controlled by a combination of flow or vasopressors or vasodilators; the normal range is 60–80 mm Hg. Venous pressure should be low, often negative. High venous pressure often indicates poor venous return or venous obstruction. If SVC pressure is high and systemic pressure is low, cerebral perfusion is impaired. The temperature range is 15–37°C depending on the operation (32–35°C for coronary artery surgery). The acid–base balance should be maintained within normal limits throughout. The optimum haematocrit level is 20–25% owing to viscosity effects at low temperature; the transfusion trigger is usually a level of haemoglobin below 6 g/dl.

Patient characteristics also influence perfusion conduct. For example, it is usual to maintain a higher mean arterial pressure in elderly patients and those with known cerebrovascular disease.

Myocardial preservation

Effective myocardial preservation is one of the main determinants of outcome in cardiac surgery. There are various methods and delivery of protection.

Electrically induced ventricular fibrillation is used for short (15–20 minutes maximum) surgery. It is used mainly in CABG surgery for distal anastomosis and the heart is re-perfused during proximal anastomosis.

Cardioplegia: potassium causes electromechanical arrest and is the main ingredient of cardioplegic solutions (concentration of 20 mmol/litre), along with magnesium and procaine. Cardioplegia is delivered either anterograde through the aortic root or by direct cannulation of the coronary ostia, or retrograde via the coronary sinus.

Crystalloid cardioplegia uses ice-cold Ringer's solution plus cardioplegia solution, at a temperature of less than 4°C. It is commercially available in 1-litre bags.

Blood cardioplegia is a combined blood and crystalloid solution, usually administered via the CPB machine, at a volume ratio from 1:1 to 8:1. The potassium concentration in crystalloid solution is adjusted to maintain a delivered concentration of 20 mmol/litre. In some instances, substrates such as tham, glucose, glutamate and aspartate may be added. Blood cardioplegia reduces the amount of fluid given to the patient and delivers an oxygenated solution, which is theoretically attractive because although the heart is quiescent, oxygen utilization still occurs.

Monitoring on CPB

Standards of monitoring during CPB have been agreed by specialist societies. In addition to basic monitoring and invasive systemic arterial and venous pressures, continuous monitoring of CPB arterial and venous oxygen saturation (or PaO_2), the integrity of gas supply to the oxygenator and CPB arterial line pressure and blood temperature is mandatory.

Anaesthesia for CPB

During CPB, ventilation is usually discontinued to allow surgical access. If pulmonary blood flow persists, and is reflected by continuing left ventricular ejection, ventilation (albeit at low tidal volume and frequency) should be continued to prevent pulmonary blood flow through collapsed lungs contributing, as true shunt, to deoxygenation of arterial blood on CPB. Ventilation is not necessary when ejection on CPB is due to aortic regurgitation (i.e. ejected blood is fully oxygenated blood regurgitated through a leaking aortic valve).

Provision of anaesthesia on CPB relates strongly to the technique used before or after CPB and to the conduct of CPB. Anaesthetic requirements are reduced with hypothermia, but drug pharmacokinetics also alter owing to haemodilution and altered clearance. Supplemental doses of muscle relaxants and/or opiates are often administered at re-warming.

Several different approaches are used. Commonly in the UK, moderate dose opiates (usually fentanyl) are supplemented by volatile administration into the CPB inlet gas (typically 0.5–1% isoflurane). Although experience indicates that this is not strictly necessary, this technique is commonly supplemented by low dose propofol infusion (100–200 mg/hour), particularly during re-warming when the risk of awareness is thought to be higher. The efficiency of volatile transfer across the oxygenator membrane is inferior to native pulmonary function so steady-state blood levels of volatile achieved are lower, and wash-in and wash-out times are prolonged compared with transpulmonary transfer. An advantage of this approach is that delivery of anaesthetic agent can be confirmed by oxygenator exhaust gas analysis (i.e. connection of the capnograph tubing to exhaust port confirms isoflurane delivery).

Total intravenous techniques are also common, combining propofol infusions with incremental fentanyl, alfentil or remifentanil infusions. Benzodiazepines may be used with either technique to guarantee amnesia. A disadvantage of a total intravenous technique is that the effective delivery of anaesthetic agents by infusion is difficult to monitor, a problem recently highlighted by unreliable delivery from syringe pumps of propofol in defective pre-filled syringes.

Separation from CPB

The following general principles are applicable to most patients. Cardiac function should be judged acceptable, either by direct visualization or transoesophageal echocardiography (TOE) assessment and an acceptable re-perfusion time should be completed to allow recovery of ventricular function. In intracardiac procedures, effective de-airing must be ensured and can be facilitated by TOE. Arrhythmias should be controlled and epicardial pacing instituted for bradycardia, with sequential a–v pacing for nodal rhythm or heart block. Electrolytes and acid–base status should be within normal limits. Core temperature should approach normothermia, skin temperature (e.g. shoulder tip) should be warm and should reflect a core-peripheral temperature gradient not more than 5–7°C. Ensure the lungs have been fully re-inflated (the left lung may be difficult to see) and are ventilated effectively.

In coronary surgery, separation is often achieved with low filling pressures (RA or LA 2–5 mm Hg), to avoid ventricular distension and functional mitral regurgitation, hence low systolic arterial pressures (e.g. 60–70 mm Hg) may be accepted initially and the heart subsequently filled slowly to achieve more normal systemic pressures. In such patients, with good or moderate ventricular function, separation is commonly achieved without inotropic support or with low doses only (dopamine, 5–7 μg/kg/min, dobutamine, 5–10 μg/kg/min).

In patients with poor ventricular function or who have had prolonged or complex surgery, more potent inotropic regimens are generally required and are usually predetermined, somewhat empirically by surgeon and anaesthetist, before separation is performed. In such patients, adrenaline (epinephrine), usual range 0.1– 0.3 μg/kg/min, is commonly used and in recent years the phosphodiesterase inhibitors milrinone, 0.3–0.7 μg/kg/min, and enoximone, 5–12 μg/kg/min, have been used increasingly. These agents, particularly milrinone, have considerable vasodilator properties and are commonly combined with noradrenaline (norepinephrine), 0.08–0.15 μg/kg/min, which, in addition to modest direct cardiac effects, modulates the reduction in systemic vascular resistance. Much higher filling pressures may be required (LA 15–18 mm Hg) in these patients and a mild degree of mitral regurgitation may need to be tolerated. If haemodynamics remain unsatisfactory, a further period of support CPB may be beneficial and inotrope regimens should be further refined. Insertion of an intra-aortic balloon pump should be considered and temporary assistance with a ventricular assist device may be appropriate in a small number of patients. Mechanical support of the failing heart is considered elsewhere. ◆

Anaesthesia for Cardiothoracic Transplantation and Ventricular Assist Devices

Andy Gaunt

Andy Gaunt is Locum Consultant Anaesthetist at Harefield Hospital, Middlesex, UK. He qualified from the University of London and trained in anaesthesia on the Imperial Rotation, West London. His main research interest is pain following cardiothoracic surgery.

The International Society for Heart/Lung Transplantation (ISHLT) maintains a database of transplants carried out worldwide. The database includes information up to 2001 of 61,533 heart transplants, 2935 heart–lung transplants and 14,588 lung transplants. In 2000, in the UK, 286 cardiothoracic transplant procedures were carried out across eight centres.

Figure 1 shows the pathologies for which patients typically receive cardiothoracic transplantation. All these conditions have implications for the conduct of general anaesthesia.

Pathologies for which patients typically receive cardiothoracic transplantation

Transplant	Patients (%)
Heart transplants	
End-stage coronary artery disease	24
Cardiomyopathies	24
Congenital heart disease	48
Single lung transplants	
Emphysema	54
Idiopathic pulmonary fibrosis	24
α_1-antitrypsin deficiency	9
Sarcoidosis	3
Primary pulmonary hypertension	1
Double lung transplants	
Cystic fibrosis	35
Emphysema	24
Idiopathic pulmonary fibrosis	10
α_1-antitrypsin deficiency	10
Primary pulmonary hypertension	9
Bronchiectasis	5
Sarcoidosis	3

1

The preoperative evaluation of transplant patients involves a variety of tests (Figure 2). Patients are evaluated for signs and symptoms of dysfunction of all major organ systems. Additional tests may be required depending on the patient and the type of transplantation proposed.

Routine tests before transplantation

- Height/weight
- Blood pressure
- Bacteriology status (swabs/samples)
- 24-hour urine collection
- Chest radiograph
- ECG and 24-hour Holter monitor
- Echocardiogram
- Full blood count, urea and electrolytes, liver function tests, thyroid function tests, viral screen, clotting profile, tissue typing, blood group
- HIV test
- Left and right heart catheter
- Lung function, VQ scan
- Arterial blood gas
- Exercise test

2

Anaesthesia

Pre-induction: anaesthesia for cardiothoracic transplant patients is hazardous. All patients are ASA III or above. Monitoring is instituted before induction of anaesthesia and includes multi-lead ECG, oxygen saturation (SpO_2) and arterial blood pressure measurement. Large-bore venous access is mandatory for all transplant patients because haemorrhage can be significant and life threatening. Central venous access to allow intraoperative and postoperative infusion of drugs is usually sited via the internal jugular or subclavian veins. In cardiac transplant patients, this is usually via the left side, because this preserves the right internal jugular, which is required for endomyocardial biopsies following the transplant. It is not mandatory to site central venous access before induction but it is the policy in many institutions.

Additionally, external adhesive defibrillator pads are attached to those undergoing a re-do sternotomy because episodes of atrial fibrillation and VT/VF may occur before cardiopulmonary bypass. Also, defibrillation via internal pads may not be possible until the adhesed heart is fully dissected. Additional ECG electrodes are often attached before induction to allow synchronization of an intra-aortic balloon pump. Pulmonary artery flotation catheters are often used to determine cardiac output, left ventricular end-diastolic pressure and pulmonary artery pressure. The position of the catheter may have to be changed several times when re-anastomosis of the right heart or pulmonary artery occurs. Left atrial pressure lines can be sited intraoperatively to facilitate more accurate estimation of left ventricle end-diastolic pressure (filling pressure).

Pre-oxygenation of the patient before induction is mandatory, particularly if using moderate doses of opiates. Chest wall rigidity can interfere with bag/mask ventilation before the onset of muscle relaxation. Hypoxaemia, of even short duration, can lead to exacerbation of pre-existing pulmonary hypertension or myocardial ischaemia.

Induction: etomidate, ketamine, propofol and thiopental (thiopentone) have all been used successfully as induction agents in transplant patients. The choice of agent depends on the experience of the anaesthetist, but may be dictated by the pre-transplant condition of the patient. For example, in patients with severely impaired left ventricular function, etomidate may be preferred to propofol because of its increased cardiostability. Thiopental (thiopentone) is not a good choice for the severely emphysematous patient undergoing lung transplantation because of its histamine-releasing properties. In these patients, the exacerbation of pre-existing airway obstruction can cause ventilation problems. Air trapping during the early stages of ventilation can prove rapidly fatal.

Moderate doses of opiates (e.g. fentanyl, 5 μg/kg) are often used in transplantation because they can obtund the hypertensive response to intubation and are cardiostable. Intraoperatively they also decrease the sympathetic stimulation caused by painful procedures. Sufentanil is commonly used in cardiac anaesthesia in the USA, but is not licensed in the UK.

Muscle relaxation is commonly achieved by pancuronium. The tachycardia it produces can offset the loss of sympathetic tone at induction. Most muscle relaxants have been used in transplant patients, but those known to exacerbate bradycardia (vecuronium) may be hazardous in patients with severely impaired ventricular function. Tachycardia is a compensatory mechanism in heart failure and the increased ventricular filling time in bradycardia can allow overdistension of the failing myocardium and lead to catastrophic cardiovascular collapse.

Maintenance of anaesthesia can be achieved by a variety of techniques. A balance of inhalational agents and opiates is often used and total intravenous anaesthesia techniques are also suitable. Isoflurane and sevoflurane are both suitable volatile agents for maintenance of anaesthesia. Nitrous oxide is often avoided because of its sympathomimetic properties, which can exacerbate pre-existing pulmonary hypertension.

Thoracic epidural analgesia can be used in lung transplant patients to limit sympathetic stimulation intraoperatively, to provide postoperative analgesia, and to facilitate early extubation. Their use is controversial because of the theoretical risk of epidural haematoma following a bloody tap. In the literature, bloody taps and epidural haematomas are uncommon. In 6000 epidurals for routine cardiac surgery, no clinically apparent epidural haematomas occurred. The incidence of bloody tap is 1.5–4.5%.

Patient management

Patient positioning of the transplant patient requires care because procedures can be prolonged. Pressure areas should be well padded to avoid nerve compression.

Maintenance of normal body temperature in single lung transplantation, and following cardiopulmonary bypass in double lung, heart–lung or heart transplantation, makes early post-operative extubation feasible. Warming mattresses, forced-air blankets and blood warmers can be used.

Haemorrhage is often significant in transplant surgery and prior planning of transfusion requirements is mandatory. Patients who have had previous surgery and required blood transfusion may have developed antibodies to non-ABO red cell antigens. The routine use of cell salvage techniques is advised and the use of antifibrinolytic agents (e.g. aprotinin) can reduce the need for blood transfusion.

Inotropic support is usually instituted during re-warming, if it is not already in place. The choice of inotropes to facilitate weaning from cardiopulmonary bypass varies according to the anaesthetist's experience. Adrenaline (epinephrine), dobutamine and dopamine have all been used successfully. Phosphodiesterase type III inhibitors (milrinone, enoximone) may offer significant advantages over more conventional inotropic support because of their beneficial effects on the pulmonary circulation, reducing right ventricular afterload and helping to offset acute right ventricular failure.

Lung transplantation can be single or double. Both procedures can be carried out without the use of cardiopulmonary bypass if the patient is able to tolerate one lung ventilation. In single lung transplantation, conventional one lung ventilation allows the procedure to be carried out through a thoracotomy.

Donor lungs have no lymphatic drainage and following reperfusion injury, interstitial pulmonary oedema may develop. It is conventional to restrict the fluids given to lung transplant recipients in the perioperative period, and this may require the use of inotropic support to maintain the circulation.

Sequential double lung transplantation, is usually carried out through a clamshell incision. One lung ventilation can be used to allow the first lung to be transplanted, before switching ventilation to the new lung to allow the second lung to be transplanted. This can be a problem because the newly transplanted lung can manifest reperfusion injury and make one lung ventilation un-feasible. Many authorities recommend carrying out the second lung transplant on cardiopulmonary bypass to avoid exposing the newly transplanted lung to the whole cardiac output, and ex-acerbating reperfusion injury. It is now becoming commonplace to transplant both lungs on cardiopulmonary bypass, thus negating the need for one lung ventilation. The use of cardiopulmonary bypass is not thought to be associated with an adverse outcome compared with off-pump transplantation.

Emergence – true fast-track transplantation anaesthesia with extubation on the operating table has proved elusive or undesirable. Most patients require at least a short period of intensive care before weaning and extubation. Early postoperative problems such as bleeding, hypothermia and organ dysfunction requiring significant inotropic support are contraindications to rapid extubation. Patients requiring inhaled nitric oxide therapy for pulmonary hypertension or right ventricular dysfunction require continuing ventilation to control the undesirable effects of hypercarbia.

Following an uncomplicated transplantation, extubation may be feasible within 2 hours, particularly in lung transplant patients with functioning epidural analgesia.

Rejection indicates an immune response to the transplanted organ. All organ recipients experience episodes of rejection. Prompt diagnosis and treatment of rejection is crucial to ensure graft survival and patient longevity. Early fulminant rejection is rapidly fatal, and can occur in the first hours following transplantation. Accurate ABO typing can avoid this. Chronic rejection refers to the changes that take place in a transplanted organ over time.

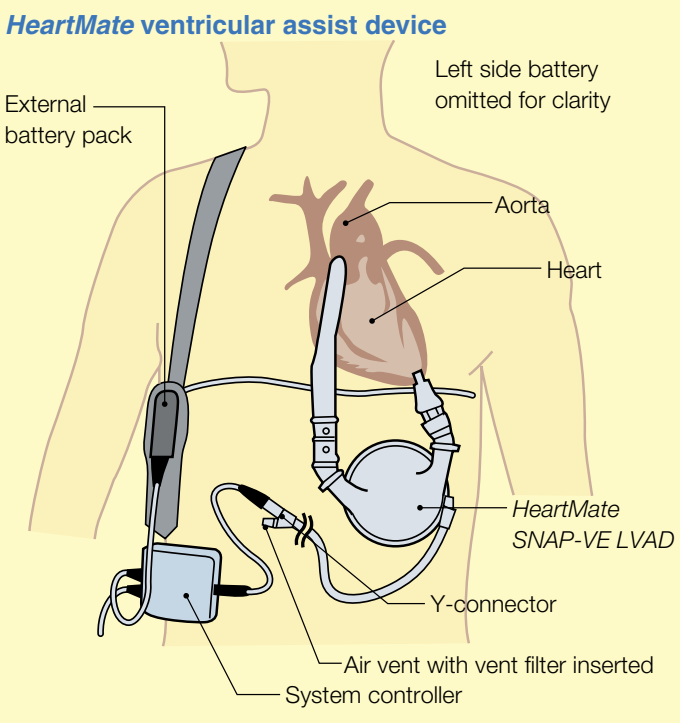
Ventricular assist devices

Ventricular assist devices (VADs) are becoming more widespread as newer devices, designed for long-term support, become available. They are used as 'bridge to recovery' support, in patients with acute cardiomyopathy (e.g. Coxsackie endocarditis), as a 'bridge to transplantation' in those with severe decompensating cardiac failure and as 'destination therapy' in those who are unsuitable for transplantation.

VADs are divided into extracorporeal and implantable types. External devices, such as the *Abiomed* VAD and the *Thoratec* pneumatic external VAD, are designed for relatively short-term support of a heart that has failed (e.g. owing to inadequate myocardial preservation during cardiopulmonary bypass). Both involve implanting pipes, to establish an extracorporeal circulation, and involve bulky machinery to drive the pumping mechanism. A portable drive apparatus for external devices is available to allow movement outside the hospital environment. Some devices (e.g. BiVAD) can support left and right hearts simultaneously.

Internal devices include the *Thoratec HeartMate* (Figure 3) and *HeartMate II*. Both are implanted under the skin but require a drive line that connects the device to its power source.

***HeartMate* ventricular assist device**



Reprinted with permission from Thoratec Corporation.

3

Newer devices such as the *Thoratec HeartMate II* and the *Jarvik 2000* are implantable impeller devices. They are pumps connected between the apex of the left ventricle and the aorta. They are designed for longer term use, require less anticoagulation and have smaller drive units, making them more portable. The newest devices (e.g. *Arrow Lionheart LVAD, Thoratec HeartMate III LVAD*) are completely implanted into the body and power is provided by transcutaneous induction. The absence of drive lines or pipes penetrating the skin should lead to lower infection rates.

Anaesthesia for VAD implantation is technically challenging. Patients for elective VAD procedures are often in severe heart failure on maximal medical treatment; typically ASA IV. Careful induction, judicious fluid management and inotropic support are required until cardiopulmonary bypass is instituted, exactly as in transplant patients. Inotropic support is often required following the procedure, to support the parts of the heart not being supported by the VAD. The interplay between the native circulation and the VAD can be complicated.

Transoesophageal echocardiography (TOE) in VAD implantation: following implantation of the devices, TOE is a useful guide to the filling status of the heart. VADs require adequate inflow in order to function, and inadequate filling can lead to collapse of the left ventricle caused by the devices drawing too much blood. It may also be desirable to have the heart ejecting slightly, rather than all the circulation being provided by the VAD. For example, one device is implanted between the left ventricular apex and the descending aorta. The machine is programmed to decrease impeller speed, and hence flow through the VAD, for 10 seconds in every 60 seconds. The idea of this is to allow the native left ventricle to fill and eject through the aortic valve, in order to flush the arch of the aorta to discourage clot formation. When these devices are implanted as a bridge to recovery, weaning of the support provided by the VAD may require the institution, or modification, of inotropic therapy. The use of TOE allows real-time estimation and measurement of heart function.

Complications of VAD therapy

Haemorrhage at the time of VAD insertion can be catastrophic and blood conservation techniques are mandatory. Use of shed red cell salvage and the routine use of antifibrinolytic agents can help to avoid excessive transfusion.

Heart failure – sudden improvements in cardiac output following VAD implantation can compromise the unsupported ventricle. For example, following left VAD support, the increase in cardiac output can cause the right ventricle to become overloaded and to fail. Not infrequently, patients with left VAD require a period of right VAD support to allow the right heart to adapt to the improved cardiac output.

Anticoagulation – the newer VAD devices require less anticoagulation (*HeartMate II* patients require aspirin only), but thrombosis and embolization remain potential problems. This can cause failure of a device or systemic embolization to a limb or organ. Careful surveillance can avoid potentially fatal problems, especially with the older devices.

Mechanism failure can be fatal, but the reliability of these devices continues to improve. Off-loading the heart can achieve significant improvements in left ventricular function. If pump failure occurs, the native heart function may have improved sufficiently to allow the patient to get to hospital to remedy the situation. ◆

Echocardiography in Cardiac Anaesthesia and Intensive Care

Marta Bird
Shane J George

Marta Bird is Clinical Fellow at Harefield Hospital. She qualified from Charles University, Czech Republic, and trained in anaesthesia in Prague and Harefield, London. Her interests lie in transoesophageal echocardiography and cardiothoracic anaesthesia.

Shane J George is Consultant in Anaesthesia and Intensive Care at Harefield Hospital, Middlesex. He qualified from St Bartholomew's Hospital, London. His research interests include transoesophageal echocardiography, 3D echocardiography and epidural anaesthesia for cardiac surgery.

Echocardiography has become an essential part of cardiac anaesthesia and intensive care. The ability to perform echocardiography via the transoesophageal route allows accurate visualization of the heart, despite the presence of drains and positive-pressure ventilation, without interfering with the surgical procedure.

Basics of ultrasound

Figure 1 shows an echocardiography machine with a transoesophageal probe. Ultrasound (sound of frequencies above 20 kHz) represents a valuable and relatively safe tool for imaging soft tissues. The frequencies can travel through tissues, but when they meet interfaces of different echodensity they reflect (echo) as well as transmit through the tissue. This 'echo' is picked up by receiving transducers and translated into an image. Ultrasound transducers use a piezoelectric crystal to generate and to receive ultrasound waves. A piezoelectric crystal is a material (e.g. quartz or a titanate ceramic) that changes its size with electric current application. Conversely, when an ultrasound wave strikes the piezoelectric crystal, an electric current is generated. The transducer emits a brief burst of ultrasound and then switches to the 'receiver mode' to await the reflected ultrasound signals from the intracardiac acoustic interfaces. This cycle is repeated temporally and spatially to generate ultrasound images. Image formation is based on the time delay between ultrasound transmission and return of the reflected signal. Ultrasound information may be displayed in a number of ways to represent an image of the structures being examined. The most common representation is a two-dimensional image that represents a slice through the heart. The transducer emitting the ultrasound may be outside the thorax (transthoracic), directly on the surface of the heart during surgery (epicardial), or within the oesophagus (transoesophageal).

1 The echocardiography machine with a transoesophageal probe. **a** Echo display screen, **b** Touch screen control panel, **c** Data input track ball and control panel, **d** Transducer scan head, **e** Dial control for rotational probe, **f** Scan head.

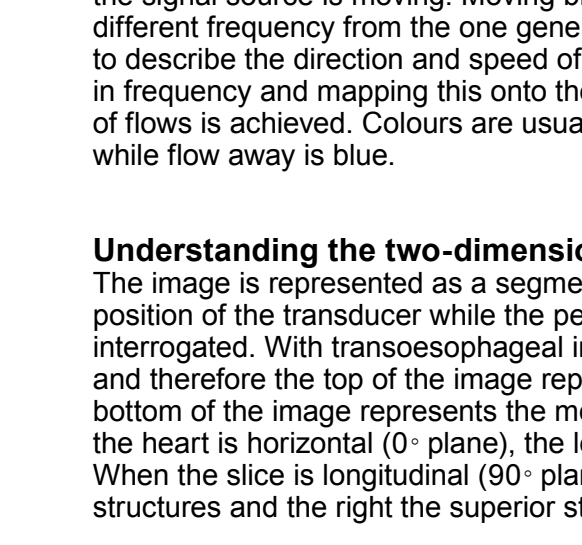
The Doppler principle is used to understand the movement of blood and tissues in the body. The Doppler effect is a change in observed frequency of a signal when the signal source is moving. Moving blood or tissue causes the transducer to 'hear' a different frequency from the one generated and the processor can use this information to describe the direction and speed of the tissue. By representing colours for changes in frequency and mapping this onto the two-dimensional image, intuitive representation of flows is achieved. Colours are usually adjusted so that flow towards the probe is red, while flow away is blue.

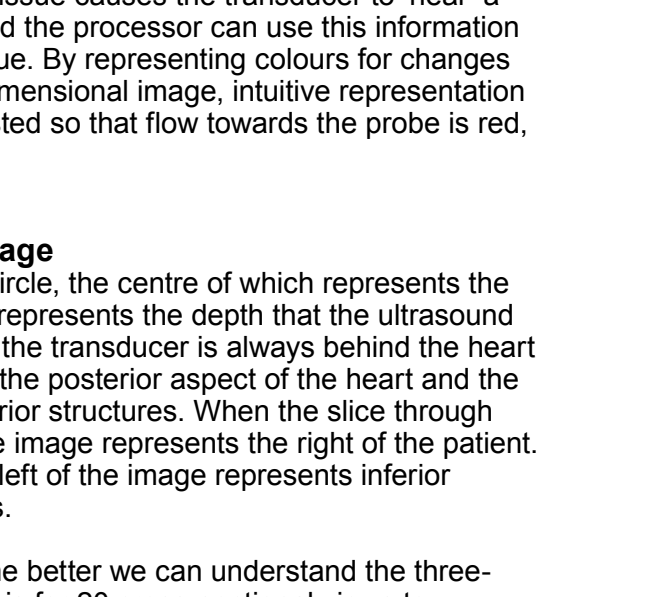
Understanding the two-dimensional image

The image is represented as a segment of a circle, the centre of which represents the position of the transducer while the periphery represents the depth that the ultrasound interrogated. With transoesophageal imaging, the transducer is always behind the heart and therefore the top of the image represents the posterior aspect of the heart and the bottom of the image represents the more anterior structures. When the slice through the heart is horizontal (0◦ plane), the left of the image represents the right of the patient. When the slice is longitudinal (90◦ plane), the left of the image represents inferior structures and the right the superior structures.

The more two-dimensional images we have the better we can understand the three-dimensional heart. A current recommendation is for 20 cross-sectional views to complete a routine examination. More recently, the two-dimensional images have been used to reconstruct a three-dimensional model. It is impossible to cover all the views in this article; we focus on three main cross-sectional views, to serve as an introduction to the main structural features of the heart, and then give examples to illustrate their utility.

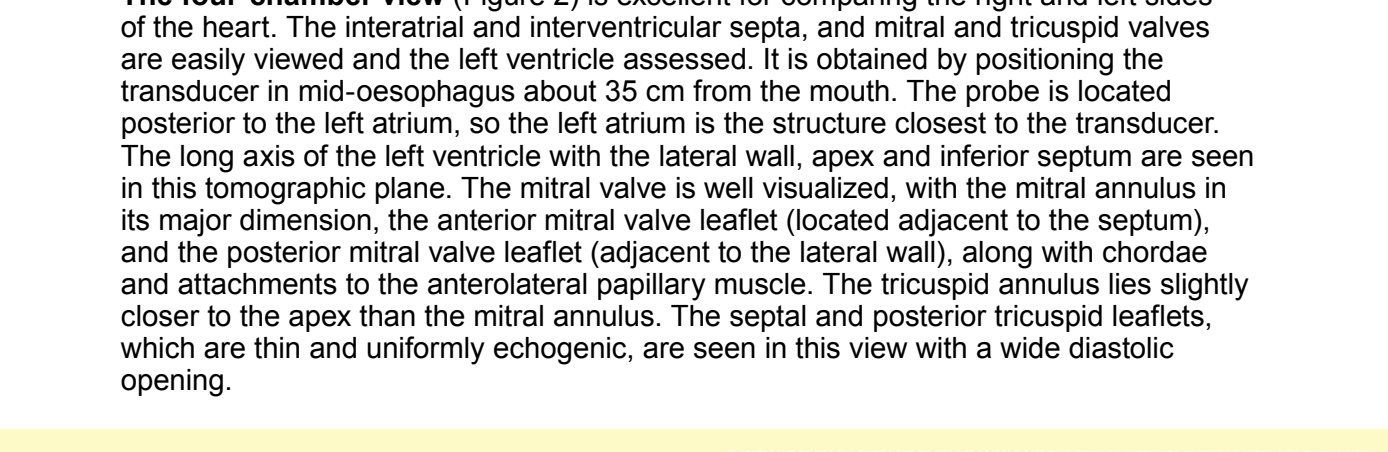
The four-chamber view (Figure 2) is excellent for comparing the right and left sides of the heart. The interatrial and interventricular septa, and mitral and tricuspid valves are easily viewed and the left ventricle assessed. It is obtained by positioning the transducer in mid-oesophagus about 35 cm from the mouth. The probe is located posterior to the left atrium, so the left atrium is the structure closest to the transducer. The long axis of the left ventricle with the lateral wall, apex and inferior septum are seen in this tomographic plane. The mitral valve is well visualized, with the mitral annulus in its major dimension, the anterior mitral valve leaflet (located adjacent to the septum), and the posterior mitral valve leaflet (adjacent to the lateral wall), along with chordae and attachments to the anterolateral papillary muscle. The tricuspid annulus lies slightly closer to the apex than the mitral annulus. The septal and posterior tricuspid leaflets, which are thin and uniformly echogenic, are seen in this view with a wide diastolic opening.





2

Long-axis view (mid-oesophageal view): (Figure 3) the angle of interrogation can be rotated electronically between 0◦ and 180◦ A long-axis view of the heart may be obtained by rotating to 130◦ from the four-chamber view. Different aspects of the heart can be seen by physically rotating the probe to the left and right. The aortic valve, left ventricular outflow tract, mitral valve, and part of the right ventricle outflow tract anterior to the aortic valve are seen in the long-axis view.



3

The transgastric midpapillary short-axis view (Figure 4) is seen by passing the probe into the stomach with anterior flexion of the probe in the 0◦ plane. This classical 'doughnut' view of the left ventricle allows evaluation of global left ventricular systolic function, left ventricular dimensions, wall thickness and regional left ventricular function. This view is particularly valuable for intraoperative monitoring because all three major coronary arteries are represented. Regional wall motion abnormalities are a sensitive indicator of myocardial ischaemia. This view also allows a good assessment of the systolic function of the heart and the volume status of the patient.

Utility of echocardiography

In the assessment of the heart and cardiovascular status, basic physiological parameters should be considered (Figure 5). The ECG assesses heart rhythm, while central venous pressure or pulmonary pressures provide pressure measurements. Echocardiography provides volume assessment, structural assessment and diastolic function assessment.

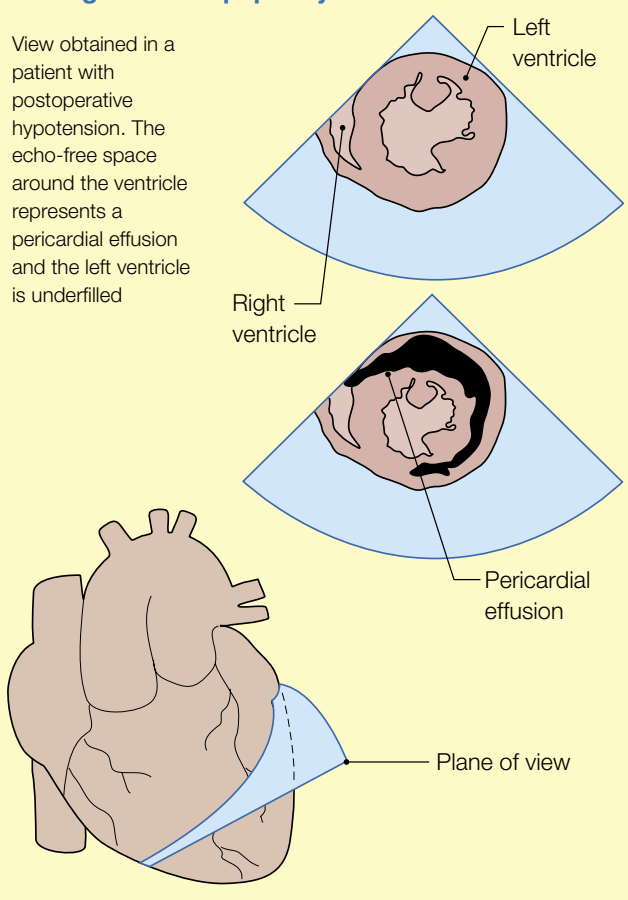
Intraoperative echocardiography is essential for mitral and aortic valve repair because of its ability to assess the results of surgery. In addition, new wall motion abnormalities can suggest areas of poor revascularization. A number of reports show the utility of echocardiography assessment for congenital heart surgery, ventricular assist device management and the management of ventricular dysfunction.

Diastolic function: there is increasing appreciation of the role of diastole in myocardial function. Diastole is not a passive process and requires energy for relaxation of the myocardial cells. Poor diastolic function of the left ventricle leads to higher left ventricular filling pressures to maintain end-diastolic volumes, with an accompanying propensity to shortness of breath and pulmonary oedema. An assessment of the compliance of the left ventricle may be made by measuring the thickness of the ventricle and comparing the peak mitral flow velocity of the early rapid filling wave (E) with the peak velocity of the late filling wave of atrial contraction (A) (the E:A ratio).

Pericardial disease: echocardiography is valuable for diagnosing pericardial effusions and cardiac tamponade and as an aid to pericardiocentesis. Two-dimensional echocardiography is especially accurate in estimating effusion size. Signs of tamponade include diastolic compression or collapse of the right atrium and right ventricle. Leftward displacement of the ventricular septum and an exaggerated increase in right ventricular size with a reciprocal decrease in left ventricular size during inspiration are also useful. Echocardiography also identifies the thick ventricle associated with aortic stenosis (Figure 6).

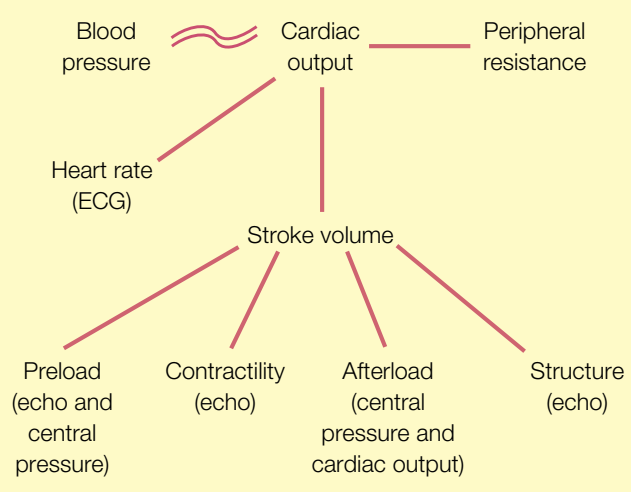
Transgastric midpapillary view

View obtained in a patient with postoperative hypotension. The echo-free space around the ventricle represents a pericardial effusion and the left ventricle is underfilled

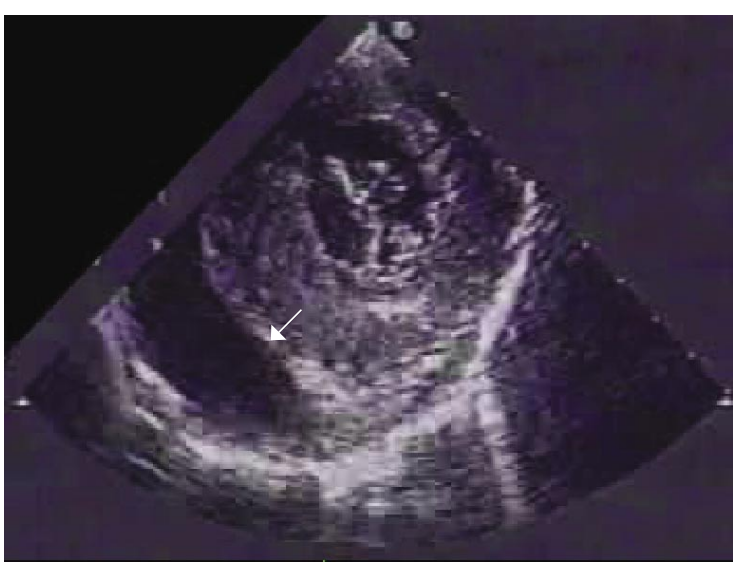


4

Assessment of hypotension

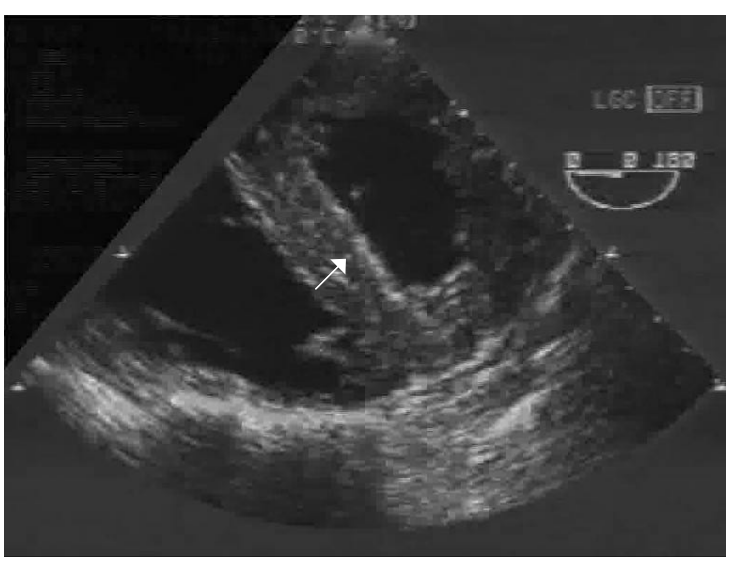


5



6 Thick ventricle (> 2 cm) (arrowed) associated with aortic stenosis, suggesting poor diastolic compliance.

Right ventricular failure is not easy to diagnose, particularly if it presents in a patient already in the ICU with organ dysfunction. Echocardiography helps to diagnose acute right ventricular failure (Figure 7), especially in an ischaemic setting, and to evaluate its severity and its response to implemented therapy. Echocardiography signs include volume and geometry of the right ventricle, the function of the free wall of the right ventricle and septum, the absence or presence of tricuspid insufficiency, and the distension and size of the inferior vena cava.

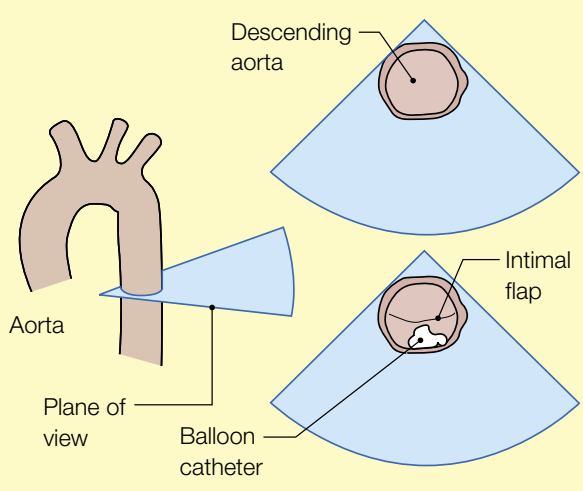


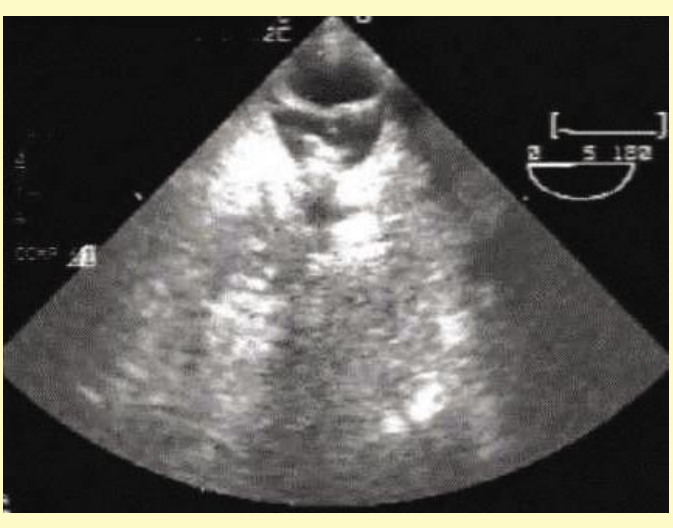
7 This transgastric image shows the normally circular left ventricle compressed on the right giving rise to a D-shaped ventricle (arrowed). This is the result of right ventricular pressures being greater than left ventricular pressures as a result of pulmonary hypertension or right ventricular failure. Hypotension management in this case may include the use of nitric oxide, phosphodiesterase inhibitors and would be different from management of left ventricular failure.

Other structures: rotating the probe to interrogate posteriorly can show the descending aorta (Figure 8). This can be useful for assessing the atheromatous state of the aorta, diagnosing dissection and confirming adequate placement of intra-aortic balloon catheters. With experience, a number of other structures can be seen, including pleural spaces, hepatic veins and renal arteries. Newer technology may allow better imaging (harmonics) or presentation in a new way (e.g. three-dimensional).

Short-axis view of the descending aorta

An intra-aortic balloon had been placed for hypotension following cardiopulmonary bypass. The catheter is seen to have created a false lumen with dissection of the aorta. The catheter was removed and the patient was eventually discharged having suffered nothing more than minor digital ischaemia





8

Risks and benefits of echocardiography

There is risk associated with oesophageal intubation, but no risk has been ascribed to the use of ultrasound alone. Many studies have looked at the risk arising from routine use of intraoperative echocardiography. The largest series to date showed a complication rate of 0.14%. Although no deaths were reported in this series, others have reported deaths at a rate of 1/10,000, mainly secondary to oesophageal perforation.

The benefits of routine use have also been quantified in specific circumstances including coronary artery surgery, mitral valve surgery, aortic valve surgery and paediatric cardiac surgery. In general, a benefit in haemodynamic or other management decisions is expected in about 20% of patients, and a major benefit resulting in a change of surgical management or return to cardiopulmonary bypass of 5%. ◆

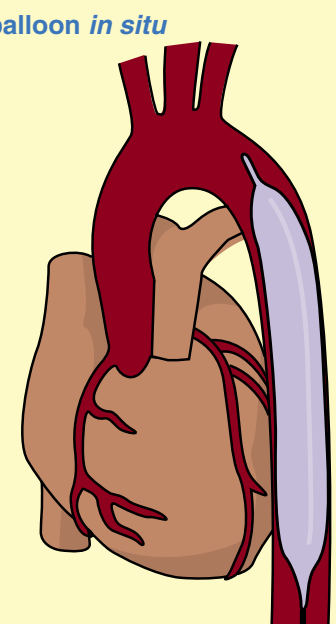
Intra-aortic Balloon Counterpulsation

Ruediger Stenz

Ruediger Stenz is Consultant Anaesthetist at the Royal Brompton Hospital, London. He qualified from the University of Freiburg, Germany, and trained in Germany, and in Boston, USA. His special interests are paediatric and adult cardiac anaesthesia.

Intra-aortic balloon counterpulsation is a simple and affordable method of mechanical circulatory support using a balloon placed in the proximal descending aorta (Figure 1). This balloon (volume 30–50 ml) is inflated during cardiac relaxation and deflated during cardiac contraction. The intra-aortic balloon pump (IABP) was first used clinically in 1968, to support patients in cardiogenic shock after acute myocardial infarction. Initially, surgical exposure of the femoral artery and a vascular prosthesis were required for insertion but percutaneous insertion techniques have encouraged a wider use of the IABP, including postoperative support and aiding weaning from cardiopulmonary bypass. The IABP is now the most commonly used mechanical cardiac assist device and about 100,000 are inserted annually worldwide.

Intra-aortic balloon *in situ*



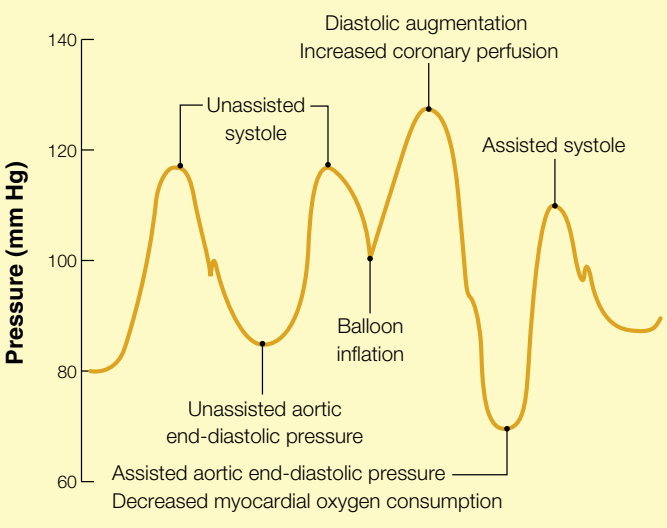
1

Theory and application

The IABP has two main effects (Figure 2):

- inflation during diastole increases coronary blood flow and thereby myocardial oxygen supply (and also generates a modest increase in aortic forward blood flow)
- deflation at the onset of systole decreases left ventricular workload and thus myocardial oxygen consumption via afterload reduction.

Aortic pressure variations during intra-aortic balloon pump therapy



2

The clinical effects of IABP include improved ejection fraction and cardiac output in conjunction with a lower left ventricular end-diastolic pressure as well as alleviating myocardial ischaemia and reducing the frequency of atrial and ventricular arrhythmias. The increase in cardiac output can be as high as 25% depending on several factors, including patient and balloon size, aortic compliance, cardiac rhythm and balloon timing.

The IABP is connected to a mobile electropneumatic console, which controls its operation. The console provides an ECG, an arterial waveform transduced from the tip of the balloon and a numeric display of heart rate and aortic blood pressure. It allows manual adjustment of timing of balloon inflation and deflation and incorporates controls for trigger selection, balloon volume and ratio of support (generally between 1:1 and 1:4 augmented beats). The balloon gas delivery system (usually using the inert gas helium) and a battery back-up power supply are also integrated in the console. Portable models for patient transfer by ground or air are available.

Indications and contraindications

Indications for the use of the IABP have expanded rapidly (Figure 3) and there has been a shift from the treatment of haemodynamic decompensation to the control of myocardial ischaemia. IABP support can be used on its own, but is often instituted in conjunction with moderate doses of vasoactive drugs and/or mechanical ventilation. In routine use, the IABP remains *in situ* for a limited period (24–72 hours) but it has been used for several weeks in heart-transplant candidates. A system for permanent implantation has also been developed. Experience with IABP treatment in children is limited, but it appears to be most effective in older children with isolated left ventricular failure.

Indications and contraindications for the use of intra-aortic balloon pumps

Indications

- Unstable angina refractory to medical treatment
- Acute ischaemia associated with coronary angioplasty
- Perioperative low cardiac output
- Cardiogenic shock after myocardial infarction
- Congestive heart failure
- Ischaemic ventricular septal defect
- Acute mitral regurgitation
- Ischaemia-related ventricular arrhythmias
- Bridge to heart transplant

Contraindications

- Severe aortic regurgitation
- Aortic dissection
- Aortic aneurysm
- Severe calcific aorto-iliac or peripheral vascular disease

3

Insertion and removal

Most IABP are inserted percutaneously via the femoral artery using a Seldinger technique under aseptic conditions. This is often done outside the operating theatre in the catheter laboratory or in the intensive care or high dependency unit. If percutaneous access proves difficult, or in cases of known anatomical problems, surgical exploration should be considered early in order to minimize vascular damage. Sheathless insertion is possible if the diameter of the artery is expected to be small. The balloon is advanced into the proximal descending aorta until the tip of the balloon is positioned 2–5 cm below the left subclavian artery (Figure 1). Correct balloon positioning must be confirmed and documented by fluoroscopy, radiography or transoesophageal echocardiography. If the femoral artery is not available for balloon insertion (in about 5% of patients) alternative routes are the axillary and subclavian arteries or the transthoracic approach via the ascending aorta, in the operating theatre.

A surgically inserted IABP must also be removed surgically and embolectomy catheters may be used proximally and distally to clear any clot or atheromatous debris. After percutaneous insertion, closed or open removal can be performed. In the case of closed removal, the artery should be allowed to bleed for several seconds while the vessel is compressed distally in order to flush out any embolic material.

Timing and weaning

Accurate timing of balloon inflation and deflation in relation to the cardiac cycle is crucial to optimal function. Balloon inflation should occur immediately after closure of the aortic valve, represented in the arterial waveform by the dicrotic notch. Balloon deflation must happen just before the onset of systole. Late inflation and early deflation lead to suboptimal augmentation of coronary blood flow. Early inflation and late deflation obstruct anterograde blood flow in the aorta and increase afterload.

In order to synchronize balloon operation with cardiac contraction, the ECG or the arterial pressure waveform can be used to trigger the IABP. Although the IABP is most effective with a regular intrinsic rhythm, continuing progress in technology has made triggering from paced rhythms and compensation for irregular rhythms, such as atrial fibrillation, more reliable.

IABP support usually begins with a ratio of 1:1 (every cardiac contraction is followed by a balloon inflation/deflation), however, an initial short period of a 1:2 support ratio (every other contraction triggers the balloon) allows for a more accurate evaluation and adjustment of balloon timing. Also, in case of heart rates beyond 100/min an assistance ratio of 1:2 may be more effective. Balloon operation must be checked and adjusted regularly throughout the course of treatment.

IABP therapy should be gradually withdrawn rather than stopped abruptly. However, it is unclear whether reduction of the assistance ratio (most common approach) or decreasing the balloon volume is superior because both approaches have advantages and disadvantages. The indication for weaning of IABP support is mainly guided by the improvement in the patient's condition and protocols will help to establish appropriate criteria (i.e. cessation of ischaemia, adequate cardiac output or arterial blood pressure) for the weaning process.

Complications

Complications can be broadly divided into vascular injuries, balloon malfunction and infection. The overall reported incidence of all complications ranges from 11% to 42% with limb ischaemia being the most common adverse event. Consistent risk factors for vascular complications are female gender, history of peripheral vascular disease and diabetes. Most complications can be controlled by balloon removal or repositioning and antibiotic cover, although surgical intervention may become necessary. Potentially life-threatening complications of IABP insertion, such as aortic or iliac dissection or perforation, occur in about 1% of cases.

Trends and outlook

A clear trend towards the early commencement of IABP therapy and the superior outcomes in ischaemic patients have led to increased use in the perioperative period. There is little evidence or consensus regarding the optimum use of IABP in this setting, but data from smaller trials indicate a survival benefit and an advantage of preoperative over intra- and postoperative insertion. The substantial variation of practice between centres reflects the lack of widely accepted guidelines as well as differing resources and attitudes towards specific indications and patient selection. There is a trend toward prophylactic use to avoid, rather than treat, ischaemia and cardiogenic shock. The use of the IABP in high-risk angioplasty and off-pump cardiac surgery is likely to increase and smaller catheter sizes will help to reduce vascular complications. A beneficial effect on right ventricular failure, particularly in the transplant population, has been suggested. The role of the IABP in relation to other cardiac support strategies still needs to be better defined. ◆

Rational Use of Inotropes

Peter Elliott

Peter Elliott is Consultant Cardiac Anaesthetist at the Royal Hospitals Trust, Belfast, UK. He qualified from Queen's University, Belfast, and trained in Northern Ireland, and Dallas, Texas. He is also Clinical Director of Anaesthetics, Theatres and Intensive Care Services at the Royal Hospitals Trust, Belfast.

Inotropes are pharmacological agents that affect the force or energy of ventricular muscle contraction, and which often have effects on other variables such as heart rate, preload and afterload, and peripheral vascular tone. The use of such agents is commonplace in the perioperative or critical care setting, and the indications for their use are multiple, and not confined to their inotropic actions. No inotrope exerts its effect purely by altering myocardial contractility, therefore the potentially useful effects on heart rate, systemic and pulmonary vascular tone and the side-effects of these agents must be taken into account when choosing an appropriate agent. The choice of inotrope is influenced by the therapeutic goal, which is seldom an elevation in systemic blood pressure alone. The purpose of manipulating a patient's haemodynamics in the acute situation is to ensure the adequate delivery of oxygen to vital tissues (to avoid or treat shock). The causes of inadequate oxygen delivery are:

- a cardiac output insufficient to meet the demands of the body or organ
- low perfusion pressure despite an adequate cardiac output.

Determinants of cardiac output

Cardiac output is determined by heart rate and stroke volume, the latter being influenced by preloading and ventricular function. Reduced preloading may be due to hypovolaemia (relative or absolute) or increased extracardiac pressure (e.g. raised intrathoracic pressure, or direct pressure on the cardiac chambers as in tamponade). Ventricular function depends on the interrelated factors of heart rate, preload, myocardial contractility and afterload, any of which can be manipulated pharmacologically. Ventricular dysfunction (systolic or diastolic, and left or right) may be caused by reduced coronary blood flow (coronary artery disease or severe systemic hypotension), myocardial infarction, drug effects, metabolic disturbances or post-cardiopulmonary bypass 'stunning'. These factors usually relate to the left ventricle, but apply to both ventricles, and there has been recent interest in the pathophysiology and treatment of right ventricular dysfunction. Left ventricular diastolic dysfunction is a separate pathophysiological entity caused by alterations in ventricular compliance and may be due to mechanical causes, left ventricular hypertrophy, ischaemia and hypertrophic cardiomyopathies. Drugs that have an effect on diastolic function (an active process) have lusitropic properties (enhanced active relaxation and improved filling characteristics in diastole resulting in a lower end-diastolic pressure for a given circulating volume). A decreased myocardial oxygen supply tends to cause systolic dysfunction, while increased demand tends to cause diastolic dysfunction.

In some instances, the cardiac output may be adequate, but the perfusion pressure, either globally (as measured by systemic blood pressure) or locally, to vital organs is low. Generally, organs attempt to maintain adequate blood flow in response to an inflammatory process by altering vasomotor tone, but at a particular minimum pressure, flow becomes proportional to perfusion pressure and the organ becomes at risk. Some organs (e.g. heart, brain) have few α-adrenergic receptors, and the flow to these organs is more closely related to the perfusion pressure. In some systemic diseases (e.g. septic shock) there may be a generalized low perfusion pressure and a normal or increased cardiac output, due to vasodilatation (mediated by nitric oxide). This type of hypotension is known as distributive shock.

Increasing the heart rate, within certain limits, increases myocardial contractility and cardiac output, although in patients with ischaemic heart disease it is important to control heart rate to minimize oxygen demand and maximize oxygen supply (longer diastole). However, in the presence of regurgitant valve lesions, ventricular overdistension (and therefore dysfunction) should be averted by avoiding bradycardia.

Afterload, determined by systemic vascular resistance for the left ventricle and pulmonary vascular resistance for the right ventricle is closely related to ventricular function. Raised systemic vascular resistance increases myocardial oxygen demand by increasing wall tension (Laplace's law) but may improve coronary artery perfusion and oxygen supply by raising the diastolic blood pressure. The right ventricle is exquisitely sensitive to variations in pulmonary vascular resistance, which has an inverse relationship with right ventricular output.

Management of impaired haemodynamics

Managing hypotension depends on diagnosing its cause and understanding the haemodynamic effects of the available drugs. To make informed decisions, adequate monitoring data should be available, including the standard measurement and analysis of the ECG and ST segments, invasive blood pressure and central venous pressure. Also useful are cardiac output and pulmonary artery pressure measurements with the derived parameters of systemic vascular resistance and pulmonary vascular resistance and, increasingly, transoesophageal echocardiography.

Often, combination therapy, using more than one inotrope, in addition to vasodilators, is indicated. Inotropes have many side-effects and Figure 1 shows the characteristics of an ideal agent.

Characteristics of an ideal inotrope

- Causes increased velocity and force of myofibril fibre shortening
- Lacks tolerance
- Does not cause vasoconstriction
- Does not cause changes in heart rate or rhythm
- Predictable and easily titratable
- Raises perfusion pressure by increasing cardiac output rather than systemic vascular resistance
- Redistributes blood flow to vital organs
- Direct acting (does not rely on release of endogenous amines)
- Compatible with other vasoactive substances
- Demonstrates lusitropy (see text)

1

Classification of inotropes

Inotropes may be classified according to Figure 2. Most of the inotropes in common use belong to Class I, but much research is being carried out into drugs of Classes II and III. Some drugs (e.g. vesnarinone, the α-adrenergic agonists) have multiple modes of action and belong to more than one class. The most commonly used drugs and drugs that are coming into routine clinical practice are described below (Figure 3). The general rules that apply to the use of inotropic agents are listed in Figure 4.

Classification of inotropes

Class I Drugs that increase intracellular calcium

- Calcium ion
- Calcium channel agonists (openers)
- Drugs that increase cardiac cAMP
  - β-agonists (adrenaline (epinephrine), noradrenaline (norepinephrine), dopamine, dobutamine, dopexamine, isoprenaline, ephedrine, xamoterol)
  - Phosphodiesterase inhibitors (milrinone, enoximone)
  - Glucagon
- Drugs that inhibit the Na-K pump (digitalis compounds)
- Drugs that prolong action potential duration (β-adrenergic agonists, vesnarinone)

Class II Drugs that increase sensitivity of actomyosin to calcium ions

- α–adrenergic agonists, vesnarinone, pimobendan, endothelin

Class III Drugs that act through metabolic or endocrine pathways

- Triiodothyronine, dichloroacetate

2

Doses and effects of commonly used inotropes

Drug	Dose/range (μg/kg/min)	Predominant receptor	Effects[1]
Adrenaline (epinephrine)	0.01–0.02	β_2	Lowered SVR, BP
	0.03–0.2	β_1	Increased contractility, HR, CO
	0.2-0.3	α	Increased SVR, BP
Noradrenaline (norepinephrine)	0.01–0.4	α_1 α_2 β_2	Raised SVR, BP, possible reflex fall in HR, possible fall in CO
Dopamine	0.01–3	Dopaminergic	Renal and splanchnic vasodilatation
	3–7	β_1	Increased contractility, HR, CO
	> 7	α	Increased SVR, BP
Dobutamine	3–20	β_1 (plus some β_2, α)	Increased contractility, decreased SVR, increased CO, ?increased HR
Dopexamine	0.5–6	β_2 (plus some β_1, α, and dopaminergic)	Increased contractility, decreased SVR, increased CO, increased HR, increased renal and ?splanchnic blood flow at low dose
Isoprenaline	0.01–0.03	β_1, β_2	Decreased SVR, increased HR
Milrinone	Bolus 50 μg/kg		Increased cAMP
	0.35–0.75		Increased contractility, coronary blood flow Decreased SVR, PVR. Arrhythmias
Phenylephrine	0.1–1.0	α	α-agonist, prolongs action potential, increased sensitivity of actinomysin to Ca Increased SVR, inotropy

[1]Abbreviations: BP, blood pressure; CO, cardiac output; HR, heart rate; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

Administration of inotropes

- Inotropic therapy should not be instituted until ventricular filling has been optimized – this may be difficult to assess and depends on the clinical circumstances
- Inotropic infusions must be administered through accurate infusion devices designed for the purpose
- Dedicated central line intravascular access must be used for infusions
- Accurate and continuous patient monitoring should be carried out by trained staff using appropriate monitoring equipment in an appropriate setting (high dependency unit or ICU)
- The effects of inotropic therapy should be regularly and frequently reviewed by appropriate staff
- Inotropic therapy should be used for short-term circulatory support

4

Calcium

The pathophysiology of heart failure includes decreased intracellular calcium, therefore it seems appropriate to treat it with calcium ions. However, there is little experimental evidence to support its routine use, and though it briefly causes a rise in arterial pressure, it does not raise cardiac output. Calcium is recommended as an inotrope in patients who have a low blood ionized calcium level, and may be of value in counteracting the effects of raised potassium (including potassium cardioplegia following cardiopulmonary bypass). It is usually administered as 10% $CaCl_2$ in a bolus dose of 5–10 mg/kg.

β-adrenoceptor agonists

Adrenaline (epinephrine) is an endogenous catecholamine that stimulates α- and β-receptors, with β_1 and β_2 effects being predominant at lower doses. Positive inotropy is the main effect and, like all inotropes, there is a possibility of myocardial ischaemia in patients with coronary artery disease as the oxygen demand increases. This is mainly a theoretical problem, and the secretion of endogenous adrenaline (epinephrine) is vital to maintaining contractility, vascular tone and modulating the stress response. Stroke volume and cardiac index increase in a dose-related manner at the lower end of the normal dose range, while α effects become significant as the dose increases. Adrenaline (epinephrine) may also cause pulmonary vasoconstriction. An increase in heart rate is apparent, but not usually clinically significant at lower doses, and adrenaline (epinephrine) causes less tachycardia than dopamine or dobutamine at equivalent inotropic doses. Side-effects include arrhythmias, but this is usually not a problem at lower infusion rates provided the patient is not hypercarbic or receiving other arrhythmogenic substances. Metabolic effects include glycolysis, causing lactic acidosis and hyperglycaemia. Most patients receiving adrenaline (epinephrine) infusions require strict control of blood sugars using insulin infusions.

The normal infusion rate is 0.02–0.3 μg/kg/min, but higher doses may be used for short periods. Its predictability, lack of serious side-effects and low cost make it a common and useful first-choice inotrope in the perioperative period and in the ICU, though chronic use (greater than 24 hours) may lead to down-regulation of the β-receptors.

Noradrenaline (norepinephrine) is an endogenous catecholamine. There has been a resurgence of interest in its use recently. It has powerful α-agonist activity, and β_1 activity similar to adrenaline (epinephrine) but with little β_2 activity. Low-dose infusions produce inotropy and an increase in heart rate, while higher doses cause vasoconstriction, a consequent rise in arterial pressure and a reflex decrease in heart rate. The increased afterload increases the myocardial oxygen demand (partially compensated for by a rise in aortic root pressure increasing coronary artery flow) and, in combination with the lowered heart rate, causes a fall in cardiac output. Mesenteric and renal arteries may be constricted, but renal blood flow may increase owing to the increased arterial pressure. It raises pulmonary vascular resistance.

Clinically, noradrenaline (norepinephrine) is used to raise the systemic vascular resistance in patients who have severe vasodilatation (e.g. in severe septicaemia, systemic inflammatory response syndrome, or following cardiac surgery). The dose, in the range 0.01–0.4 μg/kg/min is titrated in response to the desired effect; a rise in systemic vascular resistance with a concomitant rise in arterial pressure and a possible decrease in cardiac output.

Dopamine is an endogenous catecholamine, a precursor of adrenaline (epinephrine) and noradrenaline (norepinephrine), and its actions are mediated via α, β and specific postjunctional dopaminergic receptors in the renal, mesenteric and coronary arterial systems. Its effects on the circulation depend on the dose; low doses have a predominant effect on the dopaminergic receptors, intermediate doses on the myocardial β-receptors (inotropic effects) and higher doses on α-receptors (vasoconstrictor, noradrenaline-like effects). These dose-dependent effects are not highly specific and are altered by many factors including the regulation of adrenergic receptors (e.g. down-regulation in chronic congestive heart failure), the use of other inotropes or vasodilators and inter-patient and intra-patient variation in response. Dopaminergic effects may occur at higher doses, and vasoconstrictor effects at lower doses.

The pharmacodynamic effects of dopamine include inotropy, chronotropy, vasoconstriction and renal and splanchnic vasodilatation. At higher doses, arrhythmias may become a problem. Dopamine increases renal arterial blood flow by 20–40% by direct vasodilatation of the afferent arteries, and indirect vasoconstriction of the efferent arteries, which should (but has not been shown to) cause an increase in the glomerular filtration rate. There is also an inhibition of aldosterone activity.

These effects make dopamine the inotrope of choice in many situations but there are drawbacks. The renal effects have not been shown to cause a decrease in perioperative acute renal failure, length of hospital stay or mortality, though there is a possibility of converting a low output renal failure into a high output renal failure. The effect of increased inotropy and chronotropy increases myocardial oxygen demand and ischaemia may occur. The tachycardic effects may be more marked than with dobutamine or adrenaline (epinephrine) at equivalent inotropic doses. Other side-effects include an acute inhibition of prolactin secretion, with a possible detrimental effect on cell-mediated immune function. Dopamine may exaggerate the catabolic state found in critically ill patients by inhibiting growth hormone secretion and increasing basal metabolic rate at moderate doses. There may be down-regulation of the β-receptors and a consequent reduction in the effectiveness of the drug with prolonged administration or in patients with chronic heart failure.

Dobutamine is a synthetic catecholamine related to isoprenaline. It has predominantly β_1 effects with weak β_2 and α activity. It produces a dose-dependent increase in cardiac output with a reduction in filling pressures. In patients being treated with do-butamine for chronic heart failure, the heart rate has been shown to remain relatively unchanged, but in other settings it may cause a significant increase in heart rate, which is marked in some patients. It causes a reduction in the systemic vascular resistance and this effect, combined with the inotropic effect, causes a marked rise in the cardiac index, though the systemic blood pressure may not rise. It is particularly useful as an agent that increases oxygen transport, but may have to be given in combination with other agents to maintain an adequate haemodynamic response, particularly in patients with systemic sepsis. It has no specific effects on the renal vasculature, but may increase renal blood flow because of an increase in cardiac output.

Dopexamine is a relatively new synthetic catecholamine with very strong β_2 activity and less pronounced β_1, α and dopaminergic receptor activity. Its effects are positive inotropism (less than dobutamine) and peripheral and pulmonary vasodilatation, causing a marked increase in cardiac output. It causes a tachycardia, particularly at the higher end of the dose range, which may limit its use in patients with ischaemic heart disease. It also causes an increase in renal blood flow (dopaminergic effect), although, as with dopamine, its ability to prevent acute renal failure is not proven. There may be some gut-protective effect, either by increased splanchnic blood flow or by redistribution of gut blood flow to the mucosa (the main site of oxygen use in the gut). Its use in the treatment of patients with systemic sepsis is being investigated.

Isoprenaline is a potent synthetic catecholamine, with strong β_1 and β_2, but little or no α, activity. It dilates skeletal muscle, renal and mesenteric vascular beds and therefore decreases systolic and diastolic blood pressure. It is highly chronotropic, and this, in combination with the induced reduction in coronary perfusion pressure, limits its use in patients with ischaemic heart disease. Arrhythmias are common. It is a bronchodilator and may inhibit histamine liberation from mast cells. It is used mainly in the acute treatment of bradydysrhythmias associated with heart block by increasing automaticity and reducing refractoriness, in the treatment of pulmonary hypertension (and right ventricular dysfunction), and heart failure after some forms of congenital heart surgery.

Ephedrine is seldom used primarily for its positive inotropic effects. It has relatively weak α- and β-adrenergic activity and is valuable as a pressor agent, particularly in the treatment of hypotension caused by sympathetic blockade after regional anaesthesia. The weak inotropic effect may be an advantage in this situation. It is usually given as a bolus dose of 5–10 mg i.v. or i.m. repeated as necessary.

Phosphodiesterase inhibitors

The three available phosphodiesterase inhibitors are enoximone, amrinone and milrinone. Amrinone is not available in all countries and the use of enoximone has decreased with the introduction of milrinone. They do not depend on β-adrenergic receptor stimulation for their actions and therefore their effectiveness is not altered by previous β-blockade or by the down-regulation of β-receptors seen in patients with chronic heart failure or after prolonged use of catecholamines.

Phosphodiesterase inhibition in myocardium and vascular smooth muscle causes a secondary increase in cAMP, resulting in an alteration in intracellular calcium balance. There is positive inotropy and peripheral and pulmonary vasodilatation (the so-called inodilator action). When used in combination with β-agonists phosphodiesterase inhibitors have an additive effect, and they are usually administered as part of a combination therapy.

They were primarily used for the treatment of chronic heart failure and as a ‘bridge’ for patients awaiting heart transplantation. Recently, they have been used in a variety of clinical situations, such as acute left or right ventricular failure, and as part of a regimen for weaning patients from cardiopulmonary bypass.

Milrinone is a second-generation phosphodiesterase inhibitor. This bipyridine derivative was initially designed for prolonged use in patients with chronic congestive heart failure. However, in this clinical setting, its use was found to be associated with increased mortality. It is now used in the short term, in the management of heart failure and weaning from cardiopulmonary bypass. Unlike amrinone, there appears to be no thrombocytopenic effect, and it has a shorter half-life than enoximone.

Milrinone causes a rise in cardiac output without increasing myocardial oxygen consumption and this, in addition to the finding that it aids diastolic relaxation of the ventricles (lusitropy) and increases coronary artery blood flow, make it an appealing choice of inotrope in certain circumstances. It decreases systemic and pulmonary vascular resistances, thereby decreasing afterload and causing a decrease in mean systemic blood pressure and pulmonary artery pressure. Milrinone has an inotropy: vasodilatation ratio of 1:20 (compared with 1:4 for amrinone and 1:2 for enoximone). As a result, it is seldom administered alone but in combination with an appropriate inotrope or vasopressor. Despite the fact that the β-agonists and the phosphodiesterase inhibitors act through the same final pathway (increased cAMP) there is an additive effect. Milrinone is arrhythmogenic, which may limit its use in some patients.

Digoxin

Digoxin causes a rise in intracellular calcium and therefore inotropy by inhibiting the Na-K pump but it may also reduce the neuronal reuptake of catecholamines. It also reduces activation of the sympathetic nervous system, the renin–angiotensin system and the parasympathetic nervous system. Its use as an inotrope in patients with congestive heart failure is controversial and in the perioperative period other inotropes have taken precedence. Its main use is in the treatment of atrial fibrillation and flutter, and cardiac failure. Low dose digoxin increased the ejection fraction and the exercise tolerance of patients with congestive heart failure who were receiving concomitant therapy with either diuretics or ACE inhibitors.

Digoxin has a low therapeutic index, particularly in critically ill patients. The loading dose is 1 mg in divided doses over 12–24 hours given orally or intravenously, aiming for a plasma concentration of about 1.0 ng/ml. Digoxin toxicity is likely to occur with concentrations greater than 2 ng/ml, which, in the setting of the perioperative period, manifest in the form of arrhythmias and other ECG changes.

Class II drugs

Phenylephrine: the main action of the α-agonists is peripheral vasoconstriction mediated by adrenoceptors in peripheral vascular smooth muscle. They also have inotropic effects mediated by prolongation of the myocardial action potential (increasing intracellular calcium) and by increasing the sensitivity of the contractile proteins to calcium, two mechanisms that are unaffected by a down-regulation of the β-receptors. Phenylephrine may be used as an inotrope in patients in whom increasing doses of noradrenaline (norepinephrine) are required to achieve a desired effect. Under these circumstances it is best given as an infusion.

Vesnarinone is under investigation. It has effects on the action potential duration of cardiac muscle and on the sensitivity of actomyosin to calcium. Its inotropic action may be of value in the treatment of chronic congestive heart failure (the first drug to demonstrate this) but it has a narrow therapeutic ratio when used in this setting.

Triiodothyronine has been used for some time in high-risk cardiac surgical patients in whom it reduces ‘stunning’ after cardiopulmonary bypass. Its role in routine practice is not clear.

Other vasoactive agents

There are many other agents that are not inotropes, but which, by their actions, have a consequent effect on myocardial contractility and on haemodynamics. Such drugs include: nitric oxide, which, delivered through an adapted breathing system, causes pulmonary vasodilatation; prostacyclin, also a potent pulmonary vasodilator; and vasopressin, a potent systemic vasoconstrictor. Vasopressin has recently been used in the treatment of refractory ventricular fibrillation, in catecholamine-resistant hypotension caused by septicaemia, in haemodialysis-induced hypotension and after cardiopulmonary bypass. However, its use in these situations is still being investigated, and it may cause significant toxicity relating to splanchnic vasoconstriction and thrombocytopenia. ◆

Postoperative Cardiac Intensive Care

Jonathan M Handy
Jeremy Cordingley

Jonathan M Handy is Specialist Registrar in the Imperial College, London School of Anaesthesia. He qualified from University College London School of Medicine and trained in anaesthetics with a specialist interest in intensive care medicine.

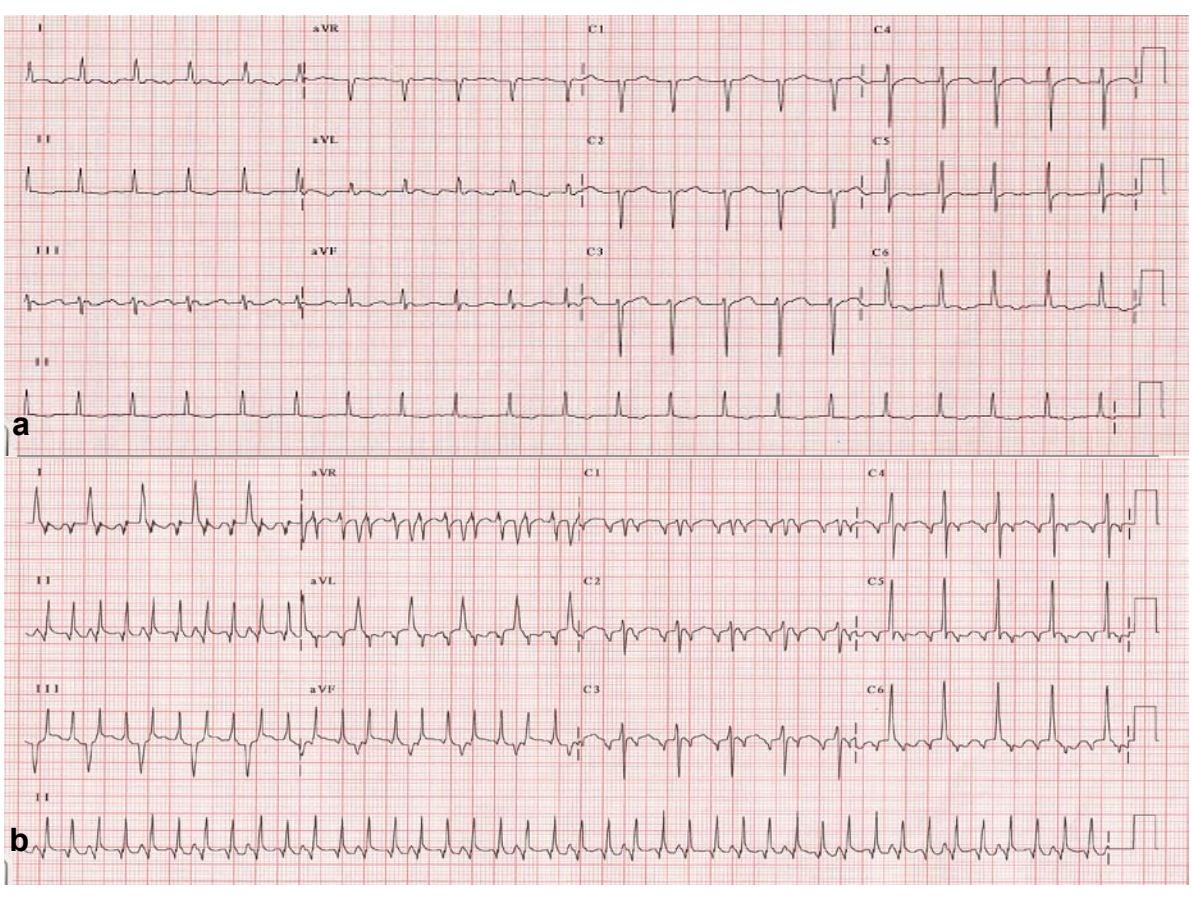
Jeremy Cordingley is Consultant in Intensive Care Medicine at the Royal Brompton Hospital, London, UK. He qualified from Charing Cross and Westminster Medical School, University of London, and trained in anaesthesia and intensive care medicine in London.

This article outlines some of the major considerations in the intensive care of patients after cardiac surgery.

Management of the cardiovascular system

Cardiac rhythm

Bradycardia and conduction block are common when the patient comes off cardiopulmonary bypass, particularly after aortic valve surgery, and may persist into the postoperative period. The usual treatment is pacing via epicardial wires, but atropine and isoprenaline infusion can be used as temporary measures. The diagnosis of supraventricular arrhythmias may be aided by the use of an 'atrial' electrocardiogram (ECG). This is performed by substituting atrial epicardial leads for the upper limb leads in a standard 12-lead ECG. The resulting ECG produces an exaggerated atrial depolarization trace making differentiation of atrial arrhythmias easier (Figure 1). Management should follow conventional lines, though causes such as electrolyte disturbances, hypoxia, hypercarbia, acidaemia, tamponade and ischaemia should be identified and corrected rapidly.



1a Surface standard 12-lead ECG demonstrating narrow complex tachycardia.
b Atrial ECG at same time showing atrial flutter with 2:1 block. The patient was subsequently cardioverted successfully.

Patients with poor left ventricular compliance benefit most from maintenance of atrioventricular synchrony and active measures should be taken to establish and maintain this. Atrial fibrillation is common in the first few postoperative days. Management includes potassium chloride (aiming for a serum potassium level of 4.5–5.0 mmol/litre) and magnesium sulphate replacement. Patients who are haemodynamically compromised should undergo DC cardioversion. Intravenous amiodarone is commonly administered to stable patients, but DC cardioversion should be carried out within 24 hours if pharmacological treatment is ineffective. Prolonged atrial fibrillation requires anticoagulation (increasing the risks of pericardial collection) and subsequent DC cardioversion preceded by transoesophageal echocardiography (TOE) to exclude intracardiac clot. Ventricular arrhythmias are uncommon after cardiac surgery and usually imply recent or continuing myocardial ischaemia.

Temporary pacing systems must be checked daily to ensure adequate pacing thresholds and to assess underlying rhythm. If the underlying rhythm remains inadequate after several days, insertion of a permanent pacemaker system is indicated. The use of two independent artificial pacing systems (usually a long-standing transvenous system and a temporary epicardial system) simultaneously is not to be recommended because of the risk of one system being inhibited by the output of the other, which may be failing to obtain mechanical capture.

Temporary pacing wires should be removed early in a normal working day in order to reduce the incidence of cardiac tamponade occurring out of hours.

Management of low cardiac output

Ideally, all patients would receive cardiac output monitoring in the perioperative and postoperative periods, but usually this is reserved for high-risk patients such as those with poor ventricular function or pulmonary hypertension. Oxygen transport related goal-directed therapy in cardiac surgical patients has been shown to decrease morbidity and length of hospital stay but has not been adopted widely. In some conditions (e.g. types of congenital heart disease, tricuspid regurgitation) the use of pulmonary artery flotation catheters is either contraindicated or would produce inaccurate cardiac output measurements. TOE is useful for guiding postoperative management in difficult cases.

Low cardiac output states (cardiac index less than 2.0–2.5 litre/min/m^2) may present insidiously postoperatively, and should be considered in patients with metabolic acidosis, core peripheral temperature gradient persistently more than 2°C, oliguria, tachycardia, obtundation or hypotension. Important causes to identify and treat rapidly are arrhythmias, decreased preload (hypovolaemia, tamponade, tension pneumothorax), pump failure (myocardial ischaemia, valve failure, myocardial stunning) and increased afterload (hypovolaemia, hypothermia and pain).

Although most hearts exhibit varying degrees of 'stunning' after cardiac surgery, inotropic support is usually weaned rapidly and any delay in weaning warrants investigation. Tamponade and left ventricular dysfunction may both be associated with hypotension and raised jugular or central venous pressure. Diagnosis may be aided by pulmonary artery catheterization and echocardiography, though transthoracic views are often inadequate in identifying posterior pericardial collections and TOE may be required. Tamponade cannot always be excluded by TOE and, if there is any doubt about the diagnosis in a patient with progressive deterioration, resternotomy should be performed urgently.

Optimization of preload is undertaken with serial fluid challenges. Patients with poor ventricular compliance may require high left atrial or pulmonary artery occlusion pressures to maintain an adequate stroke volume. There is continued uncertainty about the optimal haematocrit after cardiac surgery. For patients without cyanotic heart disease, the authors usually maintain the haemoglobin concentration above 8 g/dl.

Choice of inotropic support for impaired left ventricular function is a variable area of practice with little evidence base. For patients with mild-to-moderate ventricular impairment, dopamine, up to 5 μg/kg/min, is often used following cardiac surgery. In most patients, dopamine is weaned off within 24–48 hours. The immunomodulatory and pituitary effects of dopamine make it unsuitable for long-term use. Dopamine has no specific reno-protective effects and any improvement of glomerular filtration rate is related to increased cardiac output. However, because of its ease of use, dopamine remains a widely used inotropic agent. For patients with moderate-to-severe impairment of ventricular function a phosphodiesterase inhibitor (e.g. milrinone) is commonly used. The vasodilatory effects of milrinone usually necessitate concomitant administration of noradrenaline (norepinephrine) to maintain an adequate systemic arterial blood pressure. The half-life of milrinone is prolonged in patients with acute renal failure. Adrenaline (epinephrine) is also used for management of moderate-to-severe impairment of ventricular function. Undesirable effects include peripheral vasoconstriction and increased glucose and lactate concentrations.

Additional options for the management of impaired left ventricular function include the use of an intra-aortic balloon pump (IABP), insertion of a left ventricular assist device (LVAD) and cardiac transplantation.

Increased systemic vascular resistance is common in the postoperative period. Pain, hypothermia, hypercarbia, hypoxia and the rebound effects of discontinuing preoperative antihypertensive therapy should be considered and treated. The risks of untreated hypertension include myocardial ischaemia, and breakdown of suture lines and anastamoses. In the case of the latter (particularly aortic root replacement), strict upper limits for systolic blood pressures should be set and antihypertensive therapy commenced (e.g. sodium nitroprusside) if these limits are exceeded.

Specific problems

Right ventricular dysfunction is common in patients who have undergone cardiac surgery. Usually, it is minor and does not delay weaning from mechanical ventilation. However, some patients with elevated pulmonary vascular resistance (PVR) are at risk of acute right ventricular failure. Measures used to reduce PVR include hyperventilation, vasodilators and inhaled nitric oxide or nebulized prostacyclin. These patients should be weaned from mechanical ventilation slowly and may require tracheostomy. Endotracheal extubation should occur during daytime hours to ensure extra vigilance. Evidence of right ventricular failure (tachycardia, rising central venous pressure, oliguria, low cardiac output, respiratory distress) should prompt early re-sedation and endotracheal intubation. Severe right ventricular failure can be treated with a temporary right ventricular assist device.

Ventricular septal hypertrophy causing left ventricular outflow tract (LVOT) obstruction can be difficult to manage in the postoperative period. In addition to obstruction of ejection, because of the hypertrophied septum, the high velocity jet in the narrowed LVOT can cause systolic anterior motion of the anterior mitral valve leaflet, leading to further outflow tract obstruction. Diagnosis is made with echocardiography. Management includes maintenance of atrioventricular synchrony, controlling heart rate, ensuring optimal preload, β-blockade, and maintenance of systemic vascular resistance. Vasodilators and IABP increase ejection velocity in the LVOT and may exacerbate ventricular obstruction.

Patients with right-to-left intracardiac shunts are at risk of paradoxical veno-arterial embolization. Meticulous attention should be given to avoiding air and debris entering venous cannulae and the use of filters should be considered. Right-to-left shunt is increased if the ratio of pulmonary to systemic vascular resistances increases, resulting in increased hypoxaemia. Inhaled pulmonary vasodilators can be used to decrease PVR and vasopressors to maintain or increase systemic vascular resistance.

The systemic inflammatory response syndrome (SIRS) is common after cardiac surgery. Treatment is supportive and often includes fluid loading and maintenance of systemic vascular resistance with noradrenaline (norepinephrine). There is increasing evidence that 'relative' adrenal suppression may be important in critically ill patients. If rising doses of vasoconstrictors are required to maintain arterial blood pressure, adrenal dysfunction should be considered.

IABP are often used in the perioperative and postoperative periods. Their use is associated with a risk of limb and visceral ischaemia due to embolism, malposition and the inherent risks of anticoagulation. The management of IABP, ventricular assist devices, surgery for grown-up congenital heart disease (GUCH) and transplantation is beyond the scope of this article.

Postoperative haemorrhage

Bleeding from chest drains of more than 200 ml for 3 hours or more should prompt surgical re-exploration. However, bleeding is not always revealed and in patients with coagulopathy or in whom haemostasis was difficult, a high index of suspicion should be used with a low threshold for surgical intervention. Haemoglobin, platelet and coagulation levels should be monitored closely postoperatively. Medical management includes correction of coagulopathy with adequate heparin reversal, correction of hypocalcaemia, transfusion of platelets (platelet function may be abnormal postoperatively) and clotting products; the use of cell-saving devices to transfuse drained blood; positive end-expiratory pressure (PEEP); head-up tilt; and the administration of aprotinin and tranexamic acid. Surgical re-exploration in the ICU may be indicated.

Management of the respiratory system

Following cardiac surgery there is a decrease in vital capacity, functional residual capacity, total lung capacity, and lung and chest wall compliance. The work of breathing and the alveolar arterial gradient increase with a reduction in the ratio of partial pressure of oxygen in arterial blood to the fraction of oxygen in inspired air (PaO_2/FiO_2). Following valve surgery there may be an increase in lung compliance, due to reduction in lung water. The major determinant of prolonged postoperative ventilation is poor cardiac function emphasizing the importance of cardiac output in contributing to pulmonary dysfunction. Recent, less invasive, techniques of coronary artery bypass grafting (off-pump coronary artery bypass, OPCAB) have been used to promote early postoperative extubation and pulmonary rehabilitation, and several studies have shown no increase in mortality with significant cost savings. However, both on- and off-pump bypass surgery result in unfavourable changes to lung and chest wall mechanics and patients should be selected carefully before considering extubation in theatre.

Postoperative respiratory complications

Atelectasis and left lower lobe collapse are common, and occur more often following internal mammary artery grafting than with vein grafts alone. Treatment includes PEEP or continuous positive airway pressure, humidification of inspired gases and chest physiotherapy. Internal mammary artery grafting is also associated with a higher incidence of pleural collections, which may require drainage. The incidence of pneumonia following coronary artery bypass grafting (CABG) and valve surgery is 3–16% and 5–7%, respectively. Unless contraindicated, all intubated patients should be nursed with 30° head-up tilt to reduce the incidence of ventilator-associated pneumonia.

Phrenic nerve injury with clinically significant diaphragmatic dysfunction is more common if ice slush is used to cool the heart without a protective insulating pad.

The incidence of acute respiratory distress syndrome (ARDS) or ‘pump-lung’ following cardiopulmonary bypass has decreased with changes to techniques (e.g. the introduction of membrane oxygenators).

Ventilatory support

The incidence of prolonged postoperative mechanical ventilation is increased in patients with preoperatively decreased lung function, acute pulmonary or neurological dysfunction and those who require continued cardiovascular support. Mechanical ventilation decreases the work of breathing and reduces afterload owing to a decrease in transmural pressure gradient. However, prolonged mechanical ventilation is associated with an increased incidence of nosocomial pneumonia. In addition, positive intrathoracic pressure (especially PEEP) may increase pulmonary vascular resistance and exacerbate right ventricular failure.

Low-risk patients have similar ventilatory requirements to other postoperative patients and most are extubated within hours of arrival in ICU. Large tidal volumes (over 10 ml/kg) should be avoided in patients with internal mammary artery grafts. Standard ventilatory modes vary between units and need to be tailored according to individual patient needs. For example, patients with atelectasis may benefit from higher PEEP and mean airway pressures, but these manoeuvres can increase pulmonary vascular resistance. Weaning should follow the usual criteria. Extubation is indicated in an alert, cooperative patient who is able to protect their airway, with stable cardiovascular and respiratory function and without excessive bleeding.

Ventilatory management of patients with acute lung injury or ARDS following cardiac surgery should follow conventional lines with adjustments relevant to the individual patient’s cardiovascular physiology.

Temperature

Hypothermia is common after cardiac surgery for several reasons. Deliberately induced hypothermia is followed by core rewarming via the cardiopulmonary bypass circuit, however, on discontinuing bypass, heat redistributes to the colder fat layers. Significant heat is also lost through the surgical field. The resulting hypothermia results in shivering (with increased oxygen consumption), vasoconstriction (with increased systemic vascular resistance and hypertension), myocardial irritability and clotting abnormalities.

Rewarming should be active, using forced warm air blankets and warmed intravenous fluids, and passive by preventing further heat loss. Rapid rewarming should be avoided because it may result in sudden hypotension due to vasodilation. Hyperthermia should also be avoided because of the detrimental effects on neurological injury and the increase in oxygen consumption that may result. Shivering can be controlled with pethidine, sedation and occasionally neuromuscular blocking drugs.

Renal function and fluid balance

Acute renal dysfunction following cardiac surgery occurs in up to 10% of patients following CABG. Acute renal failure requiring mechanical renal support is less common (less than 2% of patients following CABG) but is associated with a greatly increased mortality. Risk factors for acute renal failure include increasing age, the presence of carotid artery bruit, congestive heart failure, diabetes mellitus, impaired renal function, higher body weight and duration of cardiopulmonary bypass.

Patients exposed to chronic or acute ischaemic states (e.g. renal artery stenosis, diabetes, hypovolaemia, radiocontrast agents), elderly patients and those exposed to nephrotoxic drugs are more likely to suffer acute renal failure after subsequent exposure to a surgical insult. Many patients undergoing cardiac surgery have these risk factors.

The most important factors that decrease the incidence of acute renal failure are reducing exposure to nephrotoxic agents and maintaining adequate renal perfusion by careful monitoring and management of cardiac output and systemic arterial blood pressure. No drug has been demonstrated in large randomized studies to be specifically reno-protective in the peri- or postoperative cardiac surgical patient.

There are theoretical benefits from using OPCAB instead of cardiopulmonary bypass techniques with respect to reducing renal dysfunction. However, given that postoperative renal failure is uncommon in patients without preoperative risk factors, many studies have been underpowered to show any difference and others have shown conflicting results.

Continuous veno-venous haemofiltration or haemodiafiltration is the renal replacement technique of choice in a haemodynamically unstable patient.

Sedation and neurological problems

Various mixtures of drugs provide postoperative sedation, but generally propofol/opiate combinations are used for short-term sedation and benzodiazepine/opiate combinations for long-term sedation. There is evidence that long-term sedation should be stopped daily to allow a degree of neurological recovery and to prevent the side-effects of over-sedation.

Pain management is extremely important to allow early mobilization, physiotherapy and respiratory rehabilitation. Patient-controlled analgesia is the most commonly used, with regular oral or nasogastric analgesia being used when enteral feeding begins. The use of thoracic epidural analgesia in patients undergoing procedures with full anticoagulation is controversial because of the risk of epidural haematoma formation.

The ICU is often the first place that postoperative neurological problems are diagnosed. The rate of neurological complications after cardiac surgery depends on a number of factors. Surgical risk factors include operations involving calcified valves or an atherosclerotic ascending aorta, the use of cardiopulmonary bypass, prolonged surgery, low cardiac output states and gas or debris entering the systemic circulation. Patient risk factors include previous cerebrovascular accidents or disease, diabetes and advanced age. The periods of highest risk are during aortic cannulation, onset and weaning of cardiopulmonary bypass, and removal of calcified valves.

Many complications, including postoperative confusion, associated with cardiopulmonary bypass are transient, however, some may be prolonged or permanent. CT is the most common investigation used for diagnosis, though MRI may be required. Peripheral nerve injuries can occur, as with any prolonged general anaesthetic.

Management of gastrointestinal problems

The incidence of gastrointestinal problems is about 1% after cardiac surgery. Gastrointestinal bleeding accounts for almost half of these complications, followed by hepatic dysfunction, intestinal ischaemia, acute cholecystitis and ischaemic pancreatitis. The clinical manifestations of these conditions may be atypical and may be masked by postoperative analgesia or sedation. Routine investigations should include liver function tests, serum lactate, arterial blood gas analysis and serum amylase with unexpected metabolic acidosis prompting further investigations to exclude an abdominal cause. Preservation of adequate cardiac output, routine stress ulcer prophylaxis in patients without full enteral nutrition, and early postoperative enteral feeding can reduce the risk of these complications. Treatment follows conventional lines.

Other considerations

The metabolic changes that occur after cardiac surgery are complex and multifactorial. Surgical trauma, cardiopulmonary bypass, hypothermia, drug treatments and the transfusion of blood products all contribute. The most significant changes relevant postoperatively to ICU patients are activation of the inflammatory and coagulation pathways, and increased gluconeogenesis resulting in hyperglycaemia. Systemic inflammatory and coagulation activation are multifactorial and their aetiologies and treatments are beyond the scope of this article. Altered coagulation may be deliberate (through pharmacotherapy) or pathological, but is significant because of the risk of bleeding. A fine balance exists between the commencement of anticoagulant therapy and the immediate postoperative risk of bleeding. Anticoagulation is often required after prosthetic mechanical valve insertion, treatment of intravascular or intracardiac thrombus and thromboembolic prophylaxis (particularly if there are areas of low or turbulent flow). In each case, the therapeutic range and timing of anticoagulation varies, weighing up the benefits against the risk of bleeding. For example, aortic valve prostheses pose a low risk of clot formation in the absence of anticoagulation when compared with mitral valve prostheses, owing to the high pressures associated with the former. Of note, pericardial effusions may increase in size on commencement of therapeutic anticoagulation. Should coagulopathy develop, its aetiology should be sought and treatment commenced as appropriate. Prophylaxis against thromboembolic disease should be considered in all patients. Heparin-induced thrombocytopenia should be considered if the platelet count is falling.

There is compelling evidence supporting tight glycaemic control following cardiac surgery, though the exact limits with in which blood glucose should be maintained in order to have a benefit on morbidity and mortality have yet to be established. ◆

Preoperative Assessment for Cardiac Surgery

P D Alexander
Andrea Kelleher

P D Alexander is locum Consultant Cardiothoracic Anaesthetist at the Royal Brompton Hospital, London.

Andrea Kelleher is Consultant Cardiac Anaesthetist at the Royal Brompton Hospital, London. Her special interests include paediatric cardiac anaesthesia and strategies to limit bleeding and blood transfusion during cardiac surgery.

The assessment of the patient presenting for cardiac surgery allows the anaesthetist to:
- take a history and examine the patient with particular reference to the cardiovascular disease
- plan the anaesthetic approach
- educate the patient about the anaesthesia (e.g. tracheal intubation, invasive monitoring, postoperative intensive care, and the use of intraoperative transoesophageal echocardiography or regional analgesia)
- discuss specific anaesthetic risks including damage to teeth and the potential need for transfusion of blood and blood products.

History and examination

Most patients presenting for adult cardiac surgery undergo cardiac revascularization. History taking should be directed towards assessing evidence of previous myocardial infarction, continuing cardiac ischaemia on exercise or at rest, and pulmonary oedema. The Canadian Cardiovascular Society Classification of Effort Angina is a widely accepted method of scoring the severity of anginal symptoms (Figure 1).

The Canadian Cardiovascular Society Classification of Effort Angina

- **Class 1**
Ordinary physical activity does not cause angina. Angina occurs with strenuous or rapid or prolonged exertion either at work or recreation

- **Class 2**
Slight limitation of ordinary activity. Angina occurs with walking or climbing stairs rapidly, walking up hill, walking or stair climbing after meals, or in the cold, or wind, or under emotional stress, or only during the few hours after awakening. Angina occurs when walking more than two blocks on the level or climbing more than one flight of stairs at a normal pace and in normal conditions

- **Class 3**
Marked limitation of ordinary physical activity. Angina occurs with walking one to two blocks on the level and climbing one flight of stairs in normal conditions at a normal pace

- **Class 4**
Inability to carry on any physical activity without discomfort. Angina may be present at rest

Patients presenting for valvular heart surgery range from those who are seriously ill (e.g. with infective endocarditis) to those who are relatively asymptomatic, because the decision to undergo surgery is now often based on changing ventricular dimensions rather than increasing severity of symptoms. Severe valvular heart disease may typically present with dyspnoea, syncope or angina. The New York Heart Association Functional Classification is a widely accepted system for grading dyspnoea secondary to cardiac disease (Figure 2).

New York Heart Association Functional Classification

- **Class 1**
Patients with cardiac disease but without resulting limitations of physical activity. Ordinary physical activity does not cause undue fatigue, palpitations, dyspnoea or angina

- **Class 2**
Patients with cardiac disease resulting in slight limitation of physical activity. Comfortable at rest. Ordinary physical activity results in fatigue, palpitations, dyspnoea or angina

- **Class 3**
Patients with cardiac disease resulting in marked limitation of physical activity. Comfortable at rest. Less than ordinary physical activity results in fatigue, palpitations, dyspnoea or angina

- **Class 4**
Patients with cardiac disease resulting in an inability to carry out any physical activity without discomfort. Fatigue, palpitations, dyspnoea or angina may be present at rest. If any physical activity is undertaken the symptoms of cardiac insufficiency are increased

Many patients undergoing cardiac surgery have concomitant disease, including diabetes mellitus, pulmonary disease, hypertension and peripheral vascular disease (e.g. ascending aortic and carotid atheroma). The presence and severity of associated disease should be fully evaluated preoperatively because it may have a substantial impact on the perioperative anaesthetic management, and ultimately the on outcome.

Medication

As a general principle, drugs taken to control hypertension or cardiac disease (e.g. β-blockers, calcium channel antagonists or anti-anginals) must not be stopped immediately before surgery. A possible exception to this rule is the angiotensin-converting enzyme inhibitors (e.g. lisinopril) because they may be associated with profound hypotension during cardiopulmonary bypass. They are often discontinued 24–48 hours before surgery.

Aspirin and clopidogrel both irreversibly inhibit ADP-induced platelet aggregation and should be stopped 7–10 days before surgery to allow a new population of normally functioning platelets to enter the circulation and decrease the risk of excessive postoperative bleeding. Many patients presenting for valvular surgery may be taking warfarin preoperatively which should be stopped 2–3 days before surgery to allow the international normalized ratio (INR) to fall below 2.0. If anticoagulation is essential (e.g. in the presence of a prosthetic valve) warfarin may be replaced by heparin until the time of surgery.

Risk stratification

The UK Cardiac Surgical Register data show that in 2000 the national average mortality for isolated coronary artery bypass grafting was 2.2% and for isolated valve surgery was 5.5%. The risk is not the same for all patients, so scoring systems have been developed to attempt to stratify patients according to their individual risk. These range from simple additive scores such as the Parsonnet Score, to highly complex statistical algorithms.

The Parsonnet score has been widely used for many years by cardiac surgeons attempting to predict morbidity and mortality. However, it is heavily weighted towards factors such as advan-cing age and re-do surgery, the impact of which on mortality has declined over the last decade, thus diminishing its relevance.

More recently, the Euro Score has become popular. This is a simple additive score with different weighting and risk factors, which takes into account recent advances in surgical practice. The score achieved is approximately numerically equivalent to the percentage risk of death (Figure 3).

Euro Score for Cardiac Operative Risk

Factor	Definition	Score
• Age	Per 5 years of age or part thereof from 60 years	1
• Gender	Female	1
• Chronic lung disease	Long-term use of bronchodilators or corticosteroids for lung disease	1
• Extracardiac arteriopathy	One or more of the following: claudication, carotid occlusion or > 50% stenosis, previous or planned surgery on the abdominal aorta, limb arteries or carotids	2
• Neurological dysfunction	Disease severely affecting ambulation or day-to-day functioning	2
• Previous cardiac surgery	Involving opening of the pericardium	3
• Serum creatinine	> 200 mmol/litre preoperatively	2
• Active endocarditis	Still on antibiotic treatment for endocarditis at the time of surgery	3
• Critical preoperative state	Preoperative intermittent positive-pressure ventilation, inotropic support, intra-aortic balloon pump or preoperative acute renal failure	3
• Unstable angina	Requiring intravenous nitrates until arrival in the anaesthetic room	2
• Left ventricular dysfunction	Moderate ejection fraction (30–50%)	1
	Poor ejection fraction (< 30%)	3
• Recent myocardial infarction	< 90 days	2
• Pulmonary hypertension	Systolic pulmonary artery pressure > 60 mm Hg	2
• Emergency surgery	Carried out before next available list	2
• Cardiac surgery other than isolated coronary artery bypass grafting	Cardiac surgery other than or in addition to coronary artery bypass grafting	2
• Thoracic aortic surgery	Ascending, arch or descending	4
• Postinfarction septal rupture		4

The most commonly used anaesthetic scoring systems include the American Society of Anesthesiologists (ASA) grading system and more recently the Cardiac Anaesthesia Risk Evaluation (CARE) score, which attempts to evaluate the anaesthetic risk specifically for patients undergoing cardiac surgery. It is a simple risk classification based on co-morbid disease (controlled or uncontrolled) and the complexity and urgency of the surgery (Figure 4). The anaesthetic risks must be discussed sympathetically with the patient, in the context of the need for surgery. Although it is uncommon to cancel cardiac surgery on medical grounds or on the basis of a high risk score, it may be appropriate to delay surgery to allow optimization of the patient's medical condition.

Cardiac Anaesthesia Risk Evaluation (CARE) Score

Score	Description	Predicted mortality (%)
1	Patient with stable cardiac disease and no other medical problem. Non-complex cardiac surgery planned	0.5
2	Patient with stable cardiac disease and one or more controlled medical problems (e.g. hypertension). Non-complex cardiac surgery planned	1.1
3	Patient with any non-controlled medical problem (e.g. unstable angina) or patient in whom complex cardiac surgery under-taken	2.2
3E	As 3 but with emergency surgery	4.5
4	Patient with any uncontrolled medical problem and in whom complex cardiac surgery undertaken	8.8
4E	As 4 but with emergency surgery	16.7
5	Patient with chronic or advanced cardiac disease for whom cardiac surgery is undertaken as a last resort or to save life	29.3
5E	As 5 but with emergency surgery	46.2

Investigations

In addition to routine haematological and biochemical investigations before cardiac surgery, all patients undergo an ECG and chest radiograph. Many UK centres also screen for hepatitis and multi-resistant *Staphylococcus aureus*. Patients presenting for cardiac surgery will have undergone certain specialized investigations, and it is important that the anaesthetist has an understanding of the principles behind them.

Exercise tolerance test is a non-invasive diagnostic test often used in patients with suspected ischaemic heart disease. Many different exercise-testing protocols exist, but the Bruce and modified Bruce protocols are commonly used. The modified Bruce protocol starts at a lower workload and is used in patients who have had a myocardial infarct, those whose history suggests symptoms at a low workload, or those who are elderly or sedentary. The test is conducted in 3-minute stages through which the patient's workload is progressively increased by increasing the speed and incline of the treadmill. The protocol is continued until one of several end points is reached: a true positive or negative test, hypo- or hypertension, fatigue, dyspnoea, ventricular arrhythmias or difficulty in ambulation. The test is described as positive if typical chest pain or diagnostic ST depression (at least 1 mm at 0.08 s after the end of the QRS complex) occurs. The test is negative if the patient reaches a specified heart rate (dependent on age) without chest pain or ST segment changes.

An exercise test is considered strongly positive for triple vessel or left main stem disease if the systolic blood pressure drops by 10 mm Hg or more, more than five leads show ST segment changes, and the ischaemic changes occur within 3 minutes of starting the test and take more than 9 minutes to resolve.

Perfusion imaging – patients who are unable to exercise may undergo a thallium stress test. A common protocol is to infuse dobutamine, 10–40 μg/kg/min, in conjunction with intravenous thallium-201. The dobutamine simulates exercise causing maximal dilatation of the coronary arteries. The patient is scanned with a gamma camera at peak stress and if there is a fixed coronary stenosis, the artery is unable to dilate and the blood and thallium are distributed away from the area. Hypoperfused areas appear on the scan as image defects. The patient is re-scanned 2–4 hours later, by which time the thallium will have reached the hypoperfused areas but will demonstrate very slow clearance, resulting in thallium detection in the areas of the scan where there was previously a perfusion defect. A persistent hypoperfused area indicates non-viable myocardium.

The gamma camera is also used in multiple gated acquisition (MUGA) scanning in which radiolabelled technetium-99 is injected intravenously. The image produced as it passes through the cardiac chambers can be used to quantify right and left ventricular stroke volume and therefore function. It is also useful in the assessment of intracardiac shunts and valvular regurgitation.

CT may be used to provide detailed information about the great vessels (e.g. in aortic dissection). It is particularly useful in defining cardiac anatomy in patients presenting for re-do surgery (e.g. the position of the heart in relation to the sternum).

MRI is increasingly valuable as a technique for imaging the heart and great vessels because the flowing blood produces a unique signal obviating the need for contrast media or radiographs. It is the procedure of choice in the evaluation of pericardial disease, intracardiac masses and the assessment of many forms of congenital heart disease, and is becoming increasingly recognized as a valuable tool in the preoperative and postoperative evaluation of ischaemic heart disease.

Cardiac catheterization remains the gold standard in the diagnosis of cardiac pathology, in particular coronary artery disease. A catheter is placed in turn in each of the two coronary ostia, and dye injected. A 50% reduction in vessel diameter is equivalent to a 75% reduction in cross-sectional area and represents a significant stenosis.

Left ventricular ejection fraction, cardiac output, pulmonary vascular resistance and end-diastolic pressures may be measured during cardiac catheterization. In valvular lesions, the pressure gradient or alternatively the regurgitant fraction across the valve can also be estimated.

Echocardiography and stress echocardiography – echo-cardiography (transthoracic, transoesophageal and three-dimensional) has become invaluable in the diagnosis and pre-operative assessment of many cardiac abnormalities, in particular valvular disease, allowing the measurement of gradients and the calculation of valvular areas. Echocardiography is also used to assess systolic and diastolic ventricular function and to define regional wall motion abnormalities.

Stress echocardiography, using an infusion of dobutamine incrementally increasing to 20 μg/kg/min, is also useful to identify viable myocardium in the presence of coronary artery disease and to differentiate ischaemic from non-ischaemic myocardial dysfunction. In the presence of coronary artery disease, low-dose dobutamine may be expected to increase myocardial blood flow and improve regional wall motion abnormalities. Conversely, high-dose dobutamine leads to an oxygen metabolic mismatch in areas at ischaemic risk and results in worsening regional wall motion. Thus, there is classically a biphasic response to dobutamine stress in ischaemic heart disease. Segments of the ventricle that remain akinetic or dyskinetic despite dobutamine infusion are non-viable and represent scar tissue.

Premedication

A common approach to premedication is to prescribe a short-acting benzodiazepine (e.g. temazepam) 2 hours before surgery. In most cases, this achieves anxiolysis without significant cardiac or respiratory depression, and may be supplemented if necessary in the anaesthetic room with intravenous midazolam. In addition, if the patient is to undergo beating-heart surgery, it may be appropriate to prescribe a β-blocker such as atenolol, 50 mg orally, at the time of premedication, in order to contribute to the stability of the surgical field. ◆

Principles of Cardiac Anaesthesia

John W W Gothard
Moira Wattie

John W W Gothard is Consultant Cardiothoracic Anaesthetist at the Royal Brompton Hospital, London. He qualified from St Mary's Hospital Medical School, London. He has written several textbooks on cardiac and thoracic anaesthesia and has a clinical practice encompassing all aspects of adult and paediatric cardiac anaesthesia.

Moira Wattie is Specialist Registrar at the Imperial College School of Anaesthesia, London. She qualified from University College Hospital, London.

There are a number of accepted anaesthetic techniques for cardiac surgery. New drugs continue to be introduced into clinical practice and there are differences of opinion about the optimal anaesthetic for a particular cardiac procedure. However, there is evidence that it is not the initial choice of a particular anaesthetic technique or group of drugs that is crucial to outcome but rather the manner in which they are applied in different clinical circumstances. A discussion of all anaesthetic agents and their cardiovascular effects is beyond the scope of this article but a knowledge of these agents is essential. The principles of cardiac anaesthesia are outlined below, but the anaesthetist is also involved in many other aspects of patient care during cardiac surgery, including the management of anticoagulation and clotting defects, cardiopulmonary bypass, fluid and electrolyte balance, gas exchange and acid–base status, inotropic support, pacing techniques and mechanical support of the heart.

Monitoring

The monitoring modalities used for cardiac anaesthesia are listed in Figure 1. Routine invasive monitoring for all cardiac patients includes arterial cannulation and central venous access. Pulmonary artery catheters are used routinely in many North American centres, but in the UK they are used mainly for high-risk cases. Transoesophageal echocardiography is a rapidly expanding field, which is likely to dominate perioperative monitoring in the next decade.

Monitoring for cardiac anaesthesia

Essential
ECG (5 lead)
Invasive arterial pressure
Central venous pressure
Core temperature
Urine output
Anaesthetic agent analysis
Ventilation
- Tidal volume/respiratory rate
- Airway pressure
- End-tidal carbon dioxide

Oxygenation
- Inspired/expired oxygen
- Pulse oximetry

Optional
Pulmonary artery catheter
Transoesophageal echo
Cardiac output
- As above
- Oesophageal Doppler
- Pulse contour analysis
- Lithium dilution

Cerebral function monitors

1

Arterial cannulation

Cardiac surgery is often associated with sudden changes in blood pressure, and a safe, reliable, method of measuring these acute changes is required. For this purpose, a cannula (20 or 22 G) is usually inserted percutaneously into the radial artery of the non-dominant hand. If the radial artery is to be harvested for use as a conduit during coronary artery bypass grafting, it is taken from the non-dominant arm, providing there is adequate collateral flow via the ulnar artery, and the radial artery cannula is placed in the dominant arm.

In high-risk cases, such as aortic stenosis, left main stem coronary disease and patients with poor ventricular function, it is advisable to place the arterial line under local anaesthetic before induction of anaesthesia.

The right radial artery may be preferred if aortic surgery (e.g. repair of coarctation) is to be undertaken or if an intra-aortic balloon pump (IABP) is likely to be used. This is because the right subclavian artery is unlikely to be involved in aortic surgery and in the case of an IABP it will not be occluded by the balloon and is thought to give the optimal arterial trace for timing balloon inflation. Other arteries (e.g. brachial, femoral, axillary, dorsalis pedis) can be used to measure systemic arterial pressure. Damage to the brachial artery can, rarely, result in limb ischaemia because of the poor collateral circulation at this point, and the femoral artery may be required for insertion of an intra-aortic balloon or for institution of cardiopulmonary bypass in re-do surgery.

Central venous access

Peripheral venous access will have been established before induction and a large-bore cannula can be sited in the arm for volume replacement during surgery. Central venous access is primarily required to measure the filling pressure of the right heart and for the administration of vasoactive drugs. Additional access may be required to allow the flotation of a pulmonary artery catheter. The right internal jugular vein is commonly used because:

- it can usually be ballotted in the anaesthetized patient and is easy to cannulate
- it can usually be easily located, with ultrasound if necessary
- there is a low incidence of complications
- pressure recordings are not affected if the innominate vein is stretched on opening the chest, a manoeuvre that can lead to erroneously high readings with left-sided lines
- multiple catheters can be placed in the same vessel.

A higher anatomical approach to the internal jugular vein is preferable because pneumothorax and damage to vascular structures within the chest are less likely. The Seldinger technique is safe and widely practised, though complications relating to over-zealous use of the dilator have been described. Puncture of the carotid artery with a small needle is not usually serious, but if this is undetected and a large sheath is passed into the vessel, surgical repair may be necessary. The subclavian vein is an alternative site, but is more hazardous.

The National Institute of Clinical Excellence (NICE) has recommended that ultrasound devices are made available and more widely used to aid central venous cannulation.

Pulmonary artery catheterization and cardiac output measurement

Thermodilution remains the 'gold standard' for clinical determination of cardiac output but the routine use of pulmonary artery catheters remains a subject of debate. In certain patients, such as those with poor ventricular function or valve disease, pulmonary artery catheters facilitate haemodynamic management, including choice of inotropic drugs. They may also be useful in the management of patients with significant pulmonary hypertension. The authors' practice is to insert a pulmonary artery catheter introducer sheath following induction of anaesthesia in most patients. A pulmonary artery catheter can then be introduced easily, if required, at the termination of cardiopulmonary bypass or once the patient reaches the ICU.

Pulmonary artery catheterization allows measurement of pulmonary artery pressure, pulmonary capillary wedge pressure, thermodilution cardiac output and mixed venous oxygen saturation. More sophisticated catheters can measure continuous cardiac output and/or mixed venous oxygen saturations and some have a pacing facility. A variety of haemodynamic indices can be calculated from this data (most usefully systemic and pulmonary vascular resistance) when combined with measurements of systolic/diastolic arterial pressure and central venous pressure. In difficult cases, this information may help if separation from cardiopulmonary bypass is not straightforward. Left-sided filling pressures can be measured directly with a left atrial line inserted under direct vision at surgery.

Insertion of pulmonary artery catheters is associated with the production of arrhythmias, pulmonary artery rupture, infection, catheter knotting and thromboembolism as well as complications related to central venous cannulation.

Less invasive methods of monitoring haemodynamic function and cardiac output during cardiac surgery include oesophageal Doppler, pulse contour analysis (lithium dilution) and transoesophageal echocardiography.

Transoesophageal echocardiography (TOE)

The use of intraoperative echocardiography is well established. TOE is now regarded as an essential monitor (Figure 2) during valve repair surgery and during correction of some congenital defects. It is also useful to demonstrate adequate de-airing of the heart and to monitor ventricular function when weaning a patient from cardiopulmonary bypass. Complications include dental injury, damage to the airway or oesophagus, bacteraemia and (most importantly) distraction of the operator from patient care.

Indications for transoesophageal echocardiography

Haemodynamic instability
- Evaluation of left and right ventricular disease
  - Global and regional
  - Systolic and diastolic
  - Valvular function
- Assessment of haemodynamic function
- Detection of hypovolaemia
- Cardiac tamponade
- Acute pulmonary embolism
- Dynamic left ventricular outflow tract obstruction

Cardiac surgery
- Cardiac valve reconstruction and replacement
- Myocardial revascularization (especially poor function)
- Surgical correction of congenital heart disease
- Aortic dissection
- Minimally invasive cardiac surgery
- Minimal access heart surgery
- Pulmonary embolectomy
- Resection intracardiac tumours/thrombi
- Aneurysmectomy
- Myotomy for hypertrophic cardiomyopathy
- Heart transplantation

2

Induction of anaesthesia

After appropriate monitoring has been established and pre-oxygenation completed, induction of anaesthesia is commenced, most commonly via the intravenous route in adults. The drugs used for induction (Figure 3) vary with the intended technique, but a common approach is to administer a moderate dose of opioid (e.g. fentanyl, 2.5–5 μg/kg) before a sleep dose of etomidate, thiopental (thiopentone) or propofol given by slow injection. This approach provides a smooth induction with haemodynamic stability in most cases. Pre-treatment with opioids reduces the dose of induction agent required and limits, to some extent, the myocardial depression and fall in systemic vascular resistance associated with them. It may be preferable to give propofol as an infusion in a target-controlled device, particularly in high-risk cases. Etomidate is widely used for induction because it appears to have minimal cardiovascular effects, although reductions in blood pressure occur in patients with cardiac disease or some degree of hypovolaemia. Substantial falls in arterial pressures can occur in the elderly, in whom it should be used with care. Etomidate causes pain on injection, myoclonic movements and adrenal suppression even after a single dose.

Alternative approaches include the use of benzodiazepines, which are commonly used in North America. Cardiovascular stability is well maintained with intravenous diazepam and it may be used to facilitate insertion of invasive monitoring lines under local anaesthetic. Midazolam can be used for induction, but may cause hypotension resulting from falls in systemic vascular resistance and stroke volume, particularly in combination with opioids. Ketamine produces a substantial rise in arterial pressure as a result of sympathetic stimulation. In most cardiac patients, this is not ideal but occasionally these effects may be advantageous, for example in the patient with a large pericardial effusion and/or tamponade.

Muscular relaxation

Pancuronium is widely used by cardiac anaesthetists to facilitate intubation and ventilation. Its sympathomimetic and vagolytic actions were considered advantageous when the drug was first introduced and coronary artery surgery was in its infancy but these effects produce an increase in myocardial oxygen demand, which can result in ischaemia. The improved medical treatment of angina, particularly the use of β-adrenergic receptor blockers in the treatment of ischaemic heart disease, means that tachycardia and hypertension are unlikely to be a problem if this medication is taken up to the day of surgery.

Induction agents for cardiac anaesthesia

Drug effects	Cardiovascular	Pharmacokinetics	Infusion	Special considerations
Sodium thiopental (thiopentone)	Reduction in cardiac output due to direct cardiac depression with preservation of heart rate and SVR	Slow hepatic metabolism	Rapid accumulation	
Propofol	Significant reduction in SVR and thus MAP if given in bolus dose, largely avoided with a slow infusion	Rapid metabolism largely unaffected by renal or hepatic disease	Little accumulation in short-term infusion Used to minimize awareness during cardiopulmonary bypass and for sedation post-operatively	Best avoided in outflow tract obstruction (e.g. aortic stenosis or cardiomyopathy) No evidence of neuro-protection in cardiac setting
Etomidate	Minimal cardiovascular effects in normal patients Some reduction in MAP in those with cardiac disease and particularly in the elderly	Rapid metabolism by plasma and hepatic esterases	Associated with increased mortality in the critically ill	Significant adrenal suppression with even a single dose
Midazolam	Modest decrease in MAP and SVR	Rapid hepatic metabolism and renal clearance	Accumulates in long-term infusion, particularly in the critically ill	Can be used as a premedication and to facilitate line insertion under local anaesthesia

MAP, mean arterial pressure; SVR, systemic vascular resistance

Vecuronium is used increasingly because several studies have shown that residual neuromuscular blockade is common after administration of pancuronium and may cause delayed extubation if routine reversal is not used. Vecuronium, with a shorter half-life, has a stable cardiovascular profile, but may be associated with bradycardia if given shortly after fentanyl or remifentanil. Rocuronium has a similar haemodynamic profile and has been recommended for use in cardiac anaesthetic practice. Its rapid onset facilitates early intubation and its intermediate duration of action means that residual paralysis is unlikely to be a problem.

Atracurium is not widely used in cardiac anaesthesia except as a continuous infusion. It may be useful for short non-bypass procedures, but histamine release can cause hypotension.

Tracheal intubation

Oral intubation is preferred in adults and is well tolerated post-operatively. Nasal intubation may cause mucosal trauma, resulting in severe haemorrhage following administration of heparin.

Certain procedures require use of double-lumen endobronchial tubes. These include descending aortic surgery and thoracoscopic internal mammary artery harvest. The use of a double-lumen tube allows collapse of the lung on the operative side to facilitate surgery. A left-sided tube is usually selected to circumvent problems associated with right upper lobe ventilation.

Maintenance of anaesthesia

Surgery for ischaemic heart disease represents 75% of the total UK cardiac surgical workload, with 24,000 cases in the year 2000–2001. The following description of cardiac anaesthesia is largely applicable to these patients, but the principles are relevant to all cardiac surgical patients. Specific considerations for patients with valvular heart disease (about 20% of cases) are summarized in Figure 4.

Valve surgery and anaesthesia

Aortic stenosis

Heart rate/rhythm
- Sinus rhythm essential (ventricular filling critically dependent on atrial systole)
- Avoid tachycardia (shortens diastole)
- Sequential atrioventricular pacing required if heart block presents following cardiopulmonary bypass

Preload/contractility
- Maintain preload and contractility

Systemic and pulmonary vascular resistance
- May need to maintain systemic vascular resistance temporarily with vasoconstrictors to preserve coronary blood flow (e.g. before cardiopulmonary bypass)

Aortic regurgitation

Heart rate/rhythm
- Heart rate optimal at about 90 beats/min (sinus rhythm)
- Low heart rates associated with increased diastolic time and increased regurgitation

Preload/contractility
- Maintain preload and contractility
- May benefit from inodilator therapy

Systemic and pulmonary vascular resistance
- Forward stroke volume can be augmented with vasodilators

Mitral stenosis

Heart rate/rhythm
- Ideal heart rate 70–90 beats/min
- Many patients in atrial fibrillation at time of surgery – important to control ventricular rate in this situation

Preload/contractility
- Maintain preload and contractility
- Inotropic therapy often required following surgery (avoid tachycardia)

Systemic and pulmonary vascular resistance
- Long-standing mitral stenosis can lead to pulmonary hypertension
- May require pulmonary vasodilator therapy postoperatively and prolonged weaning from ventilation
- Inhaled nitric oxide therapy has been used in the latter context

Mitral regurgitation

Heart rate/rhythm
- Low heart rates deleterious: 80–100 beats/min (sinus rhythm) ideal range
- Patients often present with atrial fibrillation

Preload/contractility
- Maintain preload and contractility

Systemic and pulmonary vascular resistance
- Decrease in left ventricular afterload (decrease in systemic vascular resistance) can reduce the degree of regurgitation through the valve
- Pulmonary hypertension may occur with chronic mitral regurgitation (often combined with mitral stenosis) and require pharmacological treatment

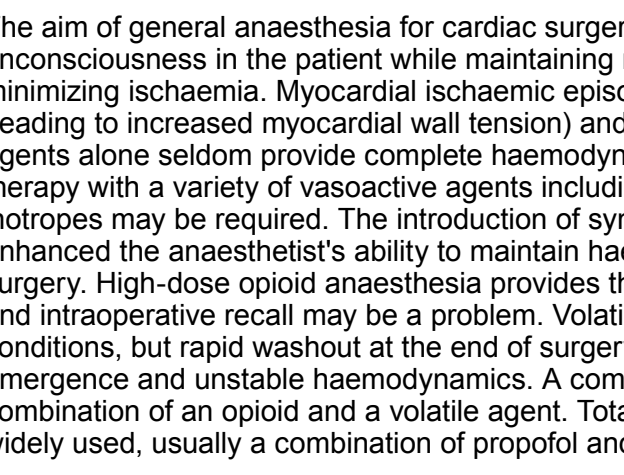
The aim of general anaesthesia for cardiac surgery is to produce a state of unconsciousness in the patient while maintaining myocardial oxygen balance and minimizing ischaemia. Myocardial ischaemic episodes are minimized if hypertension (leading to increased myocardial wall tension) and tachycardia are avoided. Anaesthetic agents alone seldom provide complete haemodynamic control, and additional drug therapy with a variety of vasoactive agents including nitrates, vasoconstrictors and inotropes may be required. The introduction of synthetic opioids 30 years ago, enhanced the anaesthetist's ability to maintain haemodynamic control during cardiac surgery. High-dose opioid anaesthesia provides this, but recovery is often prolonged and intraoperative recall may be a problem. Volatile agents provide good intraoperative conditions, but rapid washout at the end of surgery is associated with sudden emergence and unstable haemodynamics. A compromise anaesthetic technique is a combination of an opioid and a volatile agent. Total intravenous anaesthesia is also widely used, usually a combination of propofol and opioid.

The use of nitrous oxide is controversial in cardiac anaesthesia. It has myocardial depressant effects, which may be exaggerated if used in combination with opioids. To avoid this, an air/oxygen mix can be used as the carrier gas for volatile agents. This also eliminates the possibility that micro air emboli will be enlarged in the circulation by inward diffusion of nitrous oxide into the air bubbles during the period following cardiopulmonary bypass.

Inhalational agents: modern inhalational agents (e.g. isoflurane, sevoflurane, desflurane) have fewer side-effects than older agents such as halothane. On its introduction to clinical practice, isoflurane was heralded as the ideal inhalational agent for cardiac anaesthesia because it preserved cardiac output with reduced peripheral resistance and did not significantly depress myocardial contractility. A number of studies later suggested that isoflurane could cause a deleterious redistribution of coronary blood flow, increasing the flow to healthy areas of myocardium by diverting it from potentially ischaemic areas supplied by diseased coronary arteries – the ‘coronary steal effect’. These concerns have largely subsided and it is considered safe when used at moderate concentrations as part of a balanced anaesthetic technique. There is no recent evidence demonstrating any major advantage of any of the inhalational agents for cardiac anaesthesia. In practice, most units in the UK use isoflurane for adults and reserve sevoflurane for the induction of children.

During coronary artery surgery, myocardial ischaemia with subsequent reperfusion can lead to ischaemia-reperfusion injury of the myocardium with variable manifestations ranging from myocardial infarction and myocardial ‘stunning’ to reperfusion arrhythmias. Data show that inhalational agents (including isoflurane) given before an ischaemic insult confer significant protection against this injury. The mechanisms for this effect (Figure 5) include conservation of ATP levels, reduction of calcium overload and free radical scavenging, thus preserving myocardial myocyte function. This effect is not seen with intravenous agents such as propofol.

Possible mechanism for isoflurane’s myocardial protection



Activation of adenosine A1-receptors leads to a reduction in tumour necrosis factor-α (TNF-α), an increase in nitric oxide and activation of protein kinase C

Reproduced with permission from: Agnew N M, Pennefather S H, Russell G N. Isoflurane and Coronary Artery Disease. *Anaesthesia* 2002; **57:** 338–47.

Propofol is a well-established, non-cumulative intravenous anaesthetic agent, widely used in cardiac anaesthesia. It can cause significant systemic hypotension, particularly following a bolus injection. This effect is principally due to a decrease in systemic vascular resistance but there may also be an element of myocardial depression. Propofol should be used only in patients with good ventricular function and avoided in those with significant outflow tract obstruction (e.g. aortic stenosis, hypertrophic cardiomyopathy). Propofol is better tolerated if given slowly and is preferably administered as an infusion, possibly as part of a total intravenous anaesthetic (TIVA) technique. Propofol is commonly used to provide anaesthesia during the specific period of cardiopulmonary bypass and has an important role to play in the immediate postoperative period when ventilated patients can be sedated for a few hours with the non-cumulative drug.

Propofol has a neuroprotective effect in patients with severe head injuries. This effect has not been demonstrated in patients undergoing cardiopulmonary bypass.

Opioids: a range of synthetic opioids are available for use in cardiac anaesthesia. Fentanyl was first used for cardiac anaesthesia in 1978. Since then, its use has been extensively investigated along with two of its newer congeners, alfentanil and sufentanil. This group of drugs is reliable and effective for cardiac anaesthesia and is associated with minimal cardiovascular depression. In the UK, fentanyl is widely used for cardiac anaesthesia, but there has been a tendency to reduce the dose to facilitate weaning from ventilation. In this latter respect, much interest has centred around the use of the opioid remifentanil.

Remifentanil is a potent analgesic opioid agent with an ultra- short half-life (5 minutes) resulting from metabolism by plasma esterases. It is administered by infusion at a rate of 0.5–2 μg/kg/min. It has been successfully used with propofol and isoflurane to produce profound analgesia, haemodynamic stability and suppression of the stress response during cardiac surgery. Its unique properties allow patients to be weaned from ventilation within 30 minutes of stopping an infusion.

Initial enthusiasm for remifentanil has been tempered by a number of clinical observations. It has proved difficult to overlap the termination of remifentanil infusion with the commencement of an alternative analgesic (e.g. morphine or low-dose fentanyl). Proponents of TIVA consider this is only a question of attention to detail. However, if adequate analgesia is not established rapidly, the resultant pain is more resistant to treatment than if a longer-acting drug had been given throughout.

A bolus dose of remifentanil given at induction of anaesthesia can cause hypotension and bradycardia in patients with coronary artery disease. It is preferable to introduce the drug by infusion in these patients.

Neuraxial blockade

Interest in neuraxial blockade for cardiac surgery is increasing, but it is not widely used. The techniques used to provide intraoperative analgesia during cardiac surgery are intrathecal opioids and continuous epidural infusion of a low-dose local anaesthetic and opioid combination. Intrathecal opioids provide good intraoperative and early postoperative analgesia but can result in respiratory depression, which delays extubation.

In addition to excellent analgesia, thoracic epidural analgesia may beneficially affect the outcome of patients undergoing coronary artery bypass grafting through cardiac sympatholysis and attenuation of the cardiopulmonary bypass-related stress. Postoperative analgesia and respiratory function is also improved.

Thoracic epidural analgesia improves myocardial oxygen balance in several ways including selective vasodilatation of atherosclerotic coronary arteries and redistribution of blood to the subendocardium. In general, cardiac output and systemic vascular resistance are maintained. Hypertension is less likely to occur on cardiopulmonary bypass, and hypotension and bradycardia may, occasionally, be associated with thoracic epidural analgesia.

Spinal and epidural techniques have the potential to cause haematomata around the spinal cord and subsequent paralysis following the heparinization required for cardiopulmonary bypass. The incidence of major neurological complications of this nature is very small, but they are potentially devastating and may be under-reported. The optimum time for epidural catheter insertion and removal has been debated, but there is no consensus of opinion. Many practitioners recommend that several hours should elapse between insertion and heparin administration and site the epidural catheter the night before surgery in a patient first on the morning operating list. Others site the epidural just before induction of anaesthesia. Removal of epidural catheters should be carried out when coagulation is ‘at its most normal’, for example, 23 hours after the last dose of subcutaneous heparin. The timing of catheter removal is difficult because cardiac surgical patients are often treated with other anticoagulants and may also have a clotting defect following cardiopulmonary bypass. The place of thoracic epidural analgesia in cardiac anaesthesia remains uncertain with benefits demonstrated by some investigators as possibly justifying the potential complications and not by others. ◆

Respiratory Management following Cardiac Surgery

Brian F Keogh

Brian F Keogh is Consultant in Cardiothoracic Anaesthesia at the Royal Brompton Hospital, London. His special interests include modes of respiratory support, particularly in acute severe pulmonary failure.

Patients undergoing high risk, complex or re-do surgery, those with severely compromised cardiac function or those in whom unexpected perioperative difficulties have been encountered are generally referred to the intensive care team for postoperative management. Most cardiac surgical patients do not require this level of support and can be managed in postoperative cardiac care units, theatre recovery units or high dependency units as part of 'fast track' protocols. Trainee anaesthetists are often asked to direct ventilatory support and to assess suitability for extubation in this lower risk group.

Pulmonary effects of cardiac surgery

Respiratory function is subject to a variety of insults (Figure 1) even during routine cardiac surgery, though many patients suffer no adverse effects.

Effects of cardiac surgery on pulmonary function

- Reduced functional residual capacity
- Patchy atelectasis, particularly in dependent zones
- Increased V/Q mismatch and intrapulmonary shunt
- Ischaemia–reperfusion injury
- Increased pulmonary capillary permeability
- Increased extravascular lung water

1

The disturbance of lung water homeostasis associated with cardiopulmonary bypass (CPB) varies from a mild increase in extravascular lung water (EVLW) to severe acute lung injury or acute respiratory distress syndrome. It is exacerbated by any elevation in left atrial pressure. All patients undergoing CPB suffer increased EVLW and though this is less likely with non-bypass re-vascularization procedures, the risk is not eliminated. Extrapulmonary collections (blood, effusions) or pneumothoraces may combine to aggravate a reduction in functional alveolar volume.

These effects combine to decrease pulmonary compliance and increase the work of breathing. In weaning or spontaneously breathing patients, the metabolic cost of this increase may prove critical in a patient with borderline cardiac reserve. In such patients, a sudden rise in central venous pressure during weaning or following extubation is a warning sign of impending cardiopulmonary deterioration. Most cardiac surgical patients do not suffer such difficulties and proceed through respiratory weaning and extubation without notable compromise.

Approaches to respiratory support following cardiac surgery

The exact characteristics of ventilatory support in the postoperative period vary in different units. Flow-generated and pressure-generated mandatory breaths are equally applicable, though the latter may be uncomfortable for awake patients owing to the high initial inspiratory flow rate. Patient-initiated breaths should also be supported, most commonly with pressure support ventilation.

The pathophysiology outlined above results in a reduction of functional alveolar volume and ventilation–perfusion (V/Q) mismatch. Ventilatory conduct should encourage recruitment and maintenance of lung volume, while avoiding regional over-distension and the risk of barotrauma. Positive end-expiratory pressure (PEEP) is almost routinely applied to counteract atelectasis and to increase functional residual capacity, and it may have favourable effects on the redistribution of increased EVLW.

Typical initial ventilatory settings (Figure 2) allow an initial period of stabilization after surgery. It may be possible to wean some parameters (e.g. fraction of oxygen in inspired air (FiO_2), oxygen saturation (SpO_2)) rapidly. Values of 95% or above should be achieved, not because they are necessary for adequate oxygen delivery, but because lower values may reflect pulmonary pathophysiology and the need for intervention.

Typical initial ventilatory parameters following cardiac surgery

- Fraction of oxygen in inspired air (FiO_2) 0.6–0.8 (decreased if oxygen saturation in arterial blood (SaO_2) allows)
- Tidal volume 10–12 ml/kg
- Respiratory rate 10–12 breaths/min
- Inspiratory: expiratory ratio 1:2
- Positive end-expiratory pressure (PEEP) 5 cm H_2O
- Peak pressure limit 30 cm H_2O
- Pressure support ventilation setting 15 cm H_2O

2

Patients who are mildly desaturated may require an increase in PEEP or mean airway pressure (longer inspiratory:expiratory (I:E) ratio), lung volume recruitment manoeuvres (manual hyperinflation or brief increase in ventilator-delivered tidal volume) or reassessment of their haemodynamic status. Some patients require high levels of PEEP (> 10 cm H_2O) or mean airway pressure and the resultant increase in intrathoracic pressure may impair cardiac performance, particularly in the presence of hypovolaemia.

A chest radiograph is mandatory following cardiac surgery to check for fluid or air collections, to confirm the position of various tubes and catheters and to assess the state of the lung fields. It is often helpful in directing management. In addition to ventilatory manipulation (e.g. increase PEEP in bi-basal collapse) the chest radiograph may suggest the need for diuretic therapy or the introduction of an inodilator to reduce left atrial pressure.

Preoperative pulmonary function and blood gas measurements, if available, should be considered in determining target gas exchange values for an individual patient. In patients with known V/Q mismatch (e.g. those with chronic obstructive pulmonary disease (COPD)), other lung parenchymal diseases or restrictive disorders (e.g. obesity), lower levels of oxygen saturation in arterial blood (SaO_2) can be readily accepted. Bronchodilator therapy should be instituted as soon as possible after surgery in patients with COPD or airway irritability.

Weaning from mechanical ventilation

Weaning from ventilation following routine cardiac surgery does not necessarily involve a conscious decision but is usually integrated into normal clinical care. Effective analgesia must be continued throughout the weaning process. For weaning to proceed successfully, various general criteria (Figure 3) should be satisfied, of which a satisfactory haemodynamic status is paramount. An 'after-drop' in body temperature is commonly observed and temperature should approach normal levels before advanced weaning is attempted. In addition to general criteria, guidelines for acceptable respiratory parameters can be set (Figure 3) which act as alerts to initiate reassessment if they are not achieved. These are useful guidelines, which may be varied in individual patients or in unusual circumstances. For example, in a patient with known poor ventricular function, respiratory weaning and extubation may be undertaken successfully with moderate levels of inotropic support or even an intra-aortic balloon pump *in situ*.

Criteria for weaning from mechanical ventilation

General

- Stable cardiac rhythm
- Haemodynamic stability
- Low-dose or no inotrope requirement
- Acid–base status acceptable
- Haemostasis controlled (drainage < 100 ml/hour in adult)
- No residual neuromuscular blockade
- Approaching normothermia
- Adequate analgesia/controllable discomfort

Respiratory

- Partial pressure of oxygen in arterial blood (PaO_2) > 10 kPa with fraction of oxygen in inspired air (FiO_2) $\leq$ 0.5
- $PaCO_2$ < 6.5 kPa
- pH > 7.32
- Positive end-expiratory pressure (PEEP) $\leq$ 6 cm H_2O

3

Typical criteria for extubation are listed in Figure 4. As the level of respiratory support decreases, the acceptable level of partial pressure of carbon dioxide in arterial blood ($PaCO_2$) should be allowed to rise. $PaCO_2$ levels of 7.5–8 kPa are not unusual in weaning or extubated patients with acceptable cardiopulmonary parameters who are receiving adequate analgesia. The decision to extubate is clinically based and a comfortable, cooperative patient who is neither distressed nor tachypnoeic and has an acceptable respiratory pattern is likely to succeed, even if arterial blood gas values are not ideal.

Guidelines for extubation criteria

- General criteria apply (Figure 3)
- Partial pressure of oxygen in arterial blood (PaO_2) > 10 kPa with fraction of oxygen in inspired air (FiO_2) $\leq$ 0.5
- $PaCO_2$ < 8 kPa
- Respiratory rate < 20/min
- Minute volume requirement < 150 ml/kg/min
- Satisfactory respiratory pattern
- Comfortable, cooperative and neurologically intact patient

4

Post-extubation management

Patients must be encouraged to cough following extubation and it is vital that adequate analgesia is administered to allow effective propulsive coughing. Inevitably, some patients suffer areas of localized collapse, the left lower lobe being the most common, and this should be treated with intensive physiotherapy and humidified oxygen. High flow, continuous positive airway pressure (CPAP) systems are commonly used in patients with pulmonary collapse, pulmonary congestion and obesity, via face CPAP masks. This is usually well tolerated in cooperative patients, but may prove difficult or counterproductive in confused patients. Non-invasive positive pressure ventilation may also be used, via nasal or face mask, but requires patient education and compliance to be effective.

Respiratory issues in coronary re-vascularization

Internal mammary arteries are commonly harvested for conduit and ipsilateral lower lobe compression or collapse is common. Extreme care should be taken in lung hyperinflation if a left internal mammary pedicle graft has been performed because of the risk of traction disruption of the graft.

Patients may suffer myocardial stunning during surgery and may be at risk of functional mitral valve regurgitation, due to dilatation of the mitral valve ring. This may be exacerbated by respiratory weaning. A patient who becomes distressed during weaning, with a rise in right atrial pressure and relative hypotension, should be re-assessed with echocardiography. This condition requires venodilatation, usually with glyceryl trinitrate, in combination with low-dose vasoconstriction, in order to maintain coronary perfusion. It requires an index of suspicion and correct diagnosis, because fluid and inotropic therapy, both of which are commonly administered, can increase regurgitation.

Respiratory weaning – failure to progress

Unexpected failure to meet respiratory weaning targets should prompt patient reassessment. Simple factors include inadequate analgesia, sputum retention and regional pulmonary collapse. Neurological injury may also present at this time. Occult fluid or air collections should be excluded. Pericardial effusion or incipient tamponade may be associated with sudden deterioration in respiratory parameters. Similarly, deterioration in cardiovascular performance, associated with graft kinking or occlusion, or impairment of mitral valve function may initially manifest as tachypnoea and respiratory distress. Echocardiographic re-assessment of cardiac function is indicated, and may be urgently required in such patients. ◆

Airway Control

Oliver J Dyar

Oliver J Dyar is Consultant Anaesthetist and Intensivist at the John Radcliffe Hospital, Oxford, UK. He qualified from University College, Dublin and St Vincent's Hospital, Dublin, Ireland. He trained in anaesthetics and intensive care in the Nuffield Department of Anaesthetics, Oxford. His research interests include intravenous anaesthesia and the use of nitric oxide in the ARDS.

Securing control of the airway is one of the most important skills required of the anaesthetist. Whether for elective or emergency surgery, and whether the need for airway control has been predicted or not, the safety of the patient depends on the anaesthetist's ability to intervene to ensure adequate oxygenation and ventilation should the need arise. The anaesthetist must:

- develop the skills of airway assessment and management
- be familiar with the equipment and techniques available for control of the airway
- be able to choose the appropriate measures for the individual patient.

This contribution focuses on these basic principles.

Assessment of the airway

The anaesthetist must assess the airway before undertaking any anaesthesia. When general anaesthesia is contemplated, assessment facilitates a planned approach to anticipated difficulties with laryngoscopy and intubation. When a regional or local technique is contemplated, the need for airway intervention may also arise, for example, following respiratory embarrassment as a result of a high spinal or epidural blockade level, over-zealous sedation, or more rarely, following an allergic reaction to a drug.

The patient's previous anaesthetic notes should be consulted if available. It is important to realize, however, that the patient's circumstances may have changed, and a previously easy intubation may have become difficult (e.g. as a result of pregnancy). A number of anatomical factors are associated with difficulty in laryngoscopy and intubation:

- obesity, pregnancy
- large protruding incisor teeth
- short neck, especially in a heavy patient
- reduced mobility of the neck (e.g. rheumatoid arthritis)
- instability of the neck
- reduced mouth opening
- intraoral masses
- large goitre.

Anatomical assessment

Whether laryngoscopy and intubation would be possible with reasonable ease should be assessed using a reliable and reproducible bedside method of airway assessment that has minimal false-positive and false-negative rates. No single test provides this information, but the modified Mallampati test in conjunction with an assessment of thyromental distance combines ease with reasonable accuracy.

The modified Mallampati test assesses the size of the base of the tongue in relation to the size of the oropharynx. The patient sits upright with the head in the neutral position. The assessor sits in front of the patient at the patient's eye level. The patient opens their mouth as wide as possible. Without phonating, the tongue is protruded as far as possible. The assessor inspects the pharyngeal structures visible and a score is allocated according to which structures are visible (Figure 1).

Modified Mallampati test

Class	Pharyngeal structures visible
1	Fauces, faucial pillars (the palatoglossal and palatopharyngeal arches), uvula, soft palate
2	Faucial pillars are obscured leaving the fauces, uvula and soft palate visible (i.e. posterior pharyngeal wall visible below soft palate)
3	Only the soft palate and the base of the uvula seen (i.e posterior pharyngeal wall not visible below soft palate)
4	Even the soft palate obscured

1

The measurement of thyromental distance as recommended by Frerk is obtained by maximally extending the head on the neck and measuring from the prominence of the thyroid cartilage to the bony point of the chin.

A modified Mallampati grade of 3 or 4 combined with a thyromental distance of 7 cm or less gives a bedside assessment system with a sensitivity of 81% and a specificity of 98% for difficulty with intubation.

The view of the laryngeal structures obtained at direct laryngoscopy is often classified according to the system described by Cormack and Lehane (Figure 2). In this system, grades 3 and 4 constitute difficult laryngoscopies. Fairly severe difficulty with intubation may occur with grade 3, and the use of a bougie/introducer, posterior to, but held up against the epiglottis may permit blind intubation. With a grade 4 view, intubation by standard methods is virtually impossible despite optimal positioning.

Cormack and Lehane classification system

Grade	Laryngeal structures visible
1	Most of the glottis visible
2	Only the posterior part of the glottis (posterior commissure, arytenoid cartilages) visible
3	Only the epiglottis visible, no part of the glottis seen
4	Not even the epiglottis seen

2

Airway patency

Partial obstruction of the airway in the awake patient may be caused by masses in the upper airway (e.g. tonsils, adenoids, tumour), foreign bodies, or epiglottitis. In the sedated or unconscious patient, laxity of the muscles that normally keep the tongue anterior to the posterior pharyngeal wall allows the tongue to fall back and obstruct the airway. Partial obstruction is recognized by noisy inspiration (stridor), tracheal tug, and dyssynchronous movements of the thorax and abdomen on inspiration.

In normal, unobstructed breathing, the abdomen expands as the diaphragm descends in inspiration and the thorax expands as indrawn gas fills the lungs. With obstruction, the abdomen still expands, but if inspired gas cannot be inhaled at a sufficiently fast rate, the sternum is drawn inwards by the increasing, unrelieved negative intrathoracic pressure. Partial obstruction and its cause (and therefore ease of reversal) must be recognized before embarking on anaesthesia. The technique of airway management is highly modified in the presence of partial obstruction.

Aspiration risk

For elective anaesthesia, the patient is fasted. Solid food, non-clear liquids (especially those containing milk) and chewing gum should not be consumed in the 6 hours before anaesthesia. Clear liquids are permissible up to 2 hours before induction.

For emergency anaesthesia, the interval between last food or drink and the injury or onset of illness is assessed. Gastrointestinal obstruction or other abnormal motility state (e.g. ileus, diabetes mellitus, renal failure, acute pain) all increase the risk of aspiration on induction of anaesthesia.

Equipment and techniques for routine airway management

Before embarking on general anaesthesia, the equipment required should be to hand and its correct function checked. A preoperative checklist such as that proposed by the Association of Anaesthetists of Great Britain and Ireland is particularly useful (see *Anaesthesia and Intensive Care Medicine* **1:2:** 65). The minimum equipment required includes:

- source of pressurized oxygen (plus bag-valve-mask or anaesthesia circuit)
- selection of face masks
- selection of oropharyngeal and nasopharyngeal airways
- high-flow suction
- Yankauer suction catheter, and selection of narrow-bore suction catheters
- two laryngoscopes
- selection of tracheal tubes
- selection of laryngeal mask airways
- Magill's forceps
- sterile lubricating gel
- ties and padding to secure tracheal tube
- gum-elastic or other suitable bougie.

For non-emergency anaesthesia, several interventions to control the airway are available. These range from oxygen administration through a face mask, delivery of inhalational anaesthesia via an anaesthetic face mask or laryngeal mask airway, through to tracheal intubation.

Non-relaxant anaesthesia

If relaxant anaesthesia is not required (e.g. for body-surface surgery in the patient not at risk for aspiration) then inhalational anaesthesia via a face mask is appropriate. In the absence of flammable anaesthetic agents, the mask is usually clear plastic with an inflatable rim that provides a good seal in contact with the face. The size of the mask is determined by the patient's size and physical features, but a range of sizes (Figure 3) should be available. For paediatric anaesthesia, the mask should have as little dead space as possible (e.g. the Rendell-Baker–Souchet mask). Nasal masks are indicated for anaesthesia in the dental chair.

Induction in the absence of airway obstruction may be inhalational or by intravenous injection of a suitable induction agent. If there is any suggestion of airway obstruction then inhalational induction or another approach (e.g. awake fibre-optic intubation) is required.

3 Selection of face masks, including Rendell-Baker–Souchet paediatric masks (lower row).

Supporting the airway

Whatever the means of induction, once the patient is unconscious it is necessary to support the airway. There is a tendency for the airway to become partially obstructed at this stage because the tongue falls back against the posterior wall of the pharynx. Induction will normally have occurred with the patient supine, head resting on a pillow. This allows the anaesthetist to extend the head on the neck at the same time as applying a jaw thrust and opening the mouth. To achieve this triple manoeuvre, the mask is secured on to the face using one or both hands, with the thumbs on the upper part of the mask, index fingers on the lower part and the rest of the fingers effectively pulling the patient's mandible forward into the mask. It is crucial that unopposed downward pressure on the mask is not used to obtain a seal between mask and face because this will close the airway. Likewise, the third, fourth and fifth fingers must stay on the mandible and must not press on the floor of the mouth, which also tends to cause obstruction. If it is impossible to open the airway using these techniques, an artificial airway is required. Two methods are available: the oropharyngeal and the nasopharyngeal airway (Figure 4).

4a Nasopharyngeal airway.
b Selection of smaller oropharyngeal airways.

The oropharyngeal (Guedel) airway is a curved tube that has a flanged and reinforced oral end. The flange enables correct positioning at the incisor teeth, and the reinforcement prevents the patient from obstructing or severing the device by biting down. This airway is available in a range of sizes (size 3–4 is usually required for an adult, Figure 4b), and it is vital that the appropriate size is used for the patient. An easy way to determine size is to choose the airway in which the length is equal to the distance between the corner of the patient's mouth and the angle of the jaw. If the airway is too short it tends to push the tongue backwards and cause increased obstruction. If too long, the device tends to stimulate the larynx, provoking spasm, and it fails to sit securely with the flange at the front incisors. The Guedel airway is usually inserted upside-down (the pharyngeal opening facing the roof of the mouth, then rotated 180° as it passes the back of the tongue). A lightly anaesthetized patient may gag or cough with this intervention. It may also provoke laryngeal spasm.

The nasopharyngeal airway is a less stimulating intervention. It is a soft curved tube with a flanged nasal end and a bevelled pharyngeal end (Figure 4a). It is also available in a range of sizes. Sizes 6–8 mm (measured as internal diameter) are suitable for adults, the usual measure is the diameter of the patient's little finger. Before inserting the airway, a safety pin is inserted eccentrically at the flanged end, to prevent inhalation of the device. The airway should be coated with lubricating gel, and inserted into either nostril. It is advanced along the floor of the nose in a posterior direction, and should come to lie with the bevelled end in the oropharynx, behind the tongue and above the glottis. The eccentric positioning of the pin permits access of a catheter for suctioning secretions from the pharynx and airway.

Face mask: for brief procedures, anaesthesia can be maintained using a face mask, with or without airway adjuncts. For longer procedures, when it is desirable for the anaesthetist to have both hands free, the standard mask can be supported by a harness. It is now more common to insert a laryngeal mask airway for such procedures. This has the advantage of maintaining the airway without additional instrumentation, in addition to providing a more secure airway and providing hands-free operation.

The laryngeal mask airway (LMA) was designed to provide a connection between the artificial and anatomical airways in a less invasive way than with a tracheal tube, and yet with greater convenience and reliability than a conventional face mask. The standard LMA is made from silicone and is designed for multiple patient (up to 40) uses. It consists of a silicone bowl surrounded by a thin-walled elliptical ring that can be deflated to form a thin wedge shape, and which when inflated in the space posterior to the pharynx creates a seal around the laryngeal aperture. This seal permits ventilation of the airway under positive pressure. It also prevents insufflation of gas into the oesophagus and stomach, unless high inflation pressures (20–30 cm H_2O) are used. The device has a central aperture, with vertical bars, designed to prevent prolapse of the epiglottis into the tube that connects the mask to the anaesthetic circuit.

The LMA is available in a variety of sizes (Figure 5).

Correct placement is important to ensure a high-performance seal without overinflation of the cuff, and the appropriate size is chosen for the size of the patient (Figure 6).

The LMA is also available with a flexible, reinforced, non-kinking tube instead of the standard tube. This type is particularly useful for situations in which the head may be moved during surgery and for oral and ENT surgery. The intubating LMA is a development of the standard airway designed to act as a conduit permitting blind intubation of the trachea using a specially designed silicone tube.

A full description of the recommended technique for inserting the LMA is beyond the scope of this contribution. Briefly, the device is completely deflated (preferably using a cuff deflation tool, which will ensure deflation to the correct shape). The patient's head is supported on a pillow, in the classic intubating position. Extension of the head and flexion of the neck on the thorax is achieved by the non-dominant hand. The posterior surface of the LMA is lubricated with water-soluble gel. The LMA is held between index finger and thumb, with the index finger of the operator's gloved dominant hand at the junction of the mask and the tube. The aperture of the device faces caudally. An assistant holds the patient's mouth open, and the device is inserted under direct vision, with its posterior, lubricated surface firmly against the hard palate. The LMA is pushed, keeping it firmly against the palate at all times following the palate posteriorly and down into the hypopharynx. Resistance to insertion is met when the tip of the device is in the hypopharynx, with the tip resting at the upper oesophageal sphincter. It may be necessary to push the device using the non-dominant hand, if the inserting finger is not long enough. The device is released. The cuff is inflated with the recommended volume of air, at which point the tube may rise from the mouth as the device seats itself around the larynx. The tube of the LMA is connected to the anaesthetic circuit, if necessary using a swivel connector.

The LMA may be used to ventilate the anaesthetized muscle-relaxed patient, provided that the inflation pressures do not exceed about 20 cm H_2O. Above this pressure, the risk of gradual insufflation of the stomach with anaesthetic gas increases. This increases the risk of regurgitation and aspiration of gastric contents.

5a Standard laryngeal mask airways, sizes 2½, 3, 4. **b** Reinforced laryngeal mask airway, size 4.

Relaxant anaesthesia

Anaesthesia requiring a muscle-relaxant technique most commonly requires tracheal intubation. Indications for relaxant techniques and/or intubation are:

- provision of clear airway
- airway protection from blood, oral or gastric secretions
- facilitation of suctioning of airway
- prone or sitting patient, airway inaccessible
- abdominal, thoracic anaesthesia
- likelihood of postoperative respiratory support
- administration of positive end-expiratory pressure.

Tracheal intubation

Equipment: in addition to the equipment for inhalational anaesthesia using a face mask, a suitable laryngoscope, with a spare available, and a range of suitable tracheal tubes are necessary.

The laryngoscope consists of a handle (which houses the batteries) and a detachable blade, which has a screw-in bulb. Alternatively, the bulb may be in the handle, and a fibre-optic bundle transmits the light to the blade. Two basic types of laryngoscope are available (Figure 7):

- curved-blade (usually Macintosh)
- straight-blade (e.g. Wisconsin, Seward, Magill).

The curved-blade instruments are most commonly used for adults and larger children: the tip is placed in the vallecula, anterior to the epiglottis. Forward traction elevates the epiglottis without touching the posterior surface of the epiglottis. By contrast, straight-blade laryngoscopes are inserted posterior to the epiglottis and lift it from behind. These instruments are most often used for smaller children, because the epiglottis is longer and more floppy in this age group. The blades are available in a number of sizes, with the Macintosh 3 being suitable for most adults.

Tracheal tubes – an extensive range of tracheal tubes is available (Figure 8). They are most commonly made from polyvinylchloride or polyurethane and are bevel-ended. They may be plain or have a high-volume low-pressure cuff, which provides a seal enabling positive-pressure ventilation and preventing aspiration of secretions into the airway. Uncuffed (plain) tubes are used in children. This avoids the potential for ischaemic damage on the tracheal lining from high cuff pressure and maximizes tube size available. The presence of an air leak around the plain tube ensures that the fit is not too tight.

Tracheal tubes are usually inserted via the mouth, or if necessary via the nose (e.g. for intraoral surgery). Tube size is measured by the internal diameter, ranging from 2.5 mm to about 10 mm in 0.5 mm increments. The tube is usually cut to the appropriate length for the patient. Adult males usually require size 8–9 mm and adult females 7–8 mm, cut to 21–23 cm for oral intubation. For children, the tube size can be estimated from the formula (age/4 + 4 mm), and length (age/2 + 12 cm), with age being in years. This is an approximate size, and tubes 0.5 mm greater than and less than the estimated size should be available.

The tube is connected to the anaesthetic circuit at the proximal end with a tapered connector of suitable size (see *Anaesthesia and Intensive Care Medicine* **1:2:** 68). The distal end may have, in addition to the end hole, a side opening (Murphy eye) to allow passage of gas should the bevelled end be occluded by abutting on the tracheal wall.

Sizes of laryngeal mask airway

Size	Patient	Cuff volume (ml)
1	Neonates up to 6.5 kg	4
2	Patients 6.5–20 kg	10
2½	Patients 20–30 kg	14
3	Children and small adults	20
4	Normal adults	30
5	Large adults	40

8 Tracheal tubes. Nasal: **a** cuffed, **b** plain. Oral: **c** North-facing plain polar. Magill pattern oral tubes: **d** plain, **e** cuffed.

Anaesthetic management

Positioning the patient correctly before intubation is crucial. Tracheal intubation requires approximate collinearity between the axes of the mouth, oropharynx and larynx. True collinearity of these structures is impossible, but appropriate positioning can make the difference between a relatively easy laryngoscopy and intubation, and failure to visualize the larynx at laryngoscopy. The classic intubating position is the sniffing position: the head is extended on the neck (atlantoaxial extension) and the neck is flexed on the thorax. For most adults this is easily achieved by having the patient lie supine on the trolley or bed and placing a pillow under the occiput. If the pillow is too caudad (elevating the shoulders) then extension of the neck on the thorax occurs. This almost always makes laryngoscopy more difficult. In small children, the relatively large head provides the correct position without the use of a pillow.

Induction – if the patient is not at risk of aspiration of gastric content, difficulty with laryngoscopy is not anticipated, and the airway is unobstructed, induction of anaesthesia is as for the mask techniques outlined above. Following induction, it is possible, providing the patient is deeply anaesthetized, to perform laryngoscopy and intubation. This practice is relatively uncommon. More usually, the anaesthetist confirms that it is possible to ventilate the patient using the mask (with an artificial airway if needed). Then an intubating dose of a muscle relaxant is given (e.g. suxamethonium, 1–1.5mg/kg). While the advantages of the speed of onset and quality of relaxation

obtained with suxamethonium are significant, its side-effects include myalgia (which can be quite severe), occasional profound bradycardia (especially in children, and particularly likely with second doses of the drug given shortly after a first dose), hyperkalaemia, and precipitation of malignant hyperthermia in susceptible individuals. To overcome these disadvantages, an intermediate-duration non-depolarizing drug such as vecuronium, 0.1 mg/kg, atracurium, 0.5 mg/kg, or rocuronium, 0.6 mg/kg, can be used. However, they commit the anaesthetist to providing ventilation by mask for a prolonged period if intubation proves more difficult than anticipated, or is impossible. With the exception of rocuronium they also take a longer time to achieve good intubating conditions, which makes them much less suitable for the patient at risk of aspiration of gastric content. The lungs are usually manually ventilated while awaiting the onset of muscle relaxation. A mixture of oxygen and the volatile agent chosen to maintain anaesthesia is used, together with nitrous oxide, if desired. The use of nitrous oxide reduces the interval allowable for laryngoscopy and intubation. The patient will become hypoxaemic more rapidly following cessation of ventilation if this gas is used, because available oxygen stores will be reduced. A peripheral nerve stimulator may be used to confirm the presence of adequate paralysis, as demonstrated by the absence of twitch response to a supramaximal stimulus.

Laryngoscopy is then performed. The right hand opens the patient's mouth and the assistant separates the patient's lips to expose the teeth. Using a curved-blade laryngoscope, held in the left hand, the blade is inserted into the right-hand side of the mouth, and advanced as far as the tonsillar bed. Sweeping the blade into the midline at this point should displace the tongue to the left, and give a view of the tip of the epiglottis. The blade is advanced, with force applied along the shaft of the laryngoscope directed upwards and outwards (at about 30–45° to the horizontal). The patient's upper incisors or gum must not be used as a fulcrum. The tip of the blade should enter the vallecula in front of the epiglottis, and the applied force elevates the epiglottis, exposing the larynx. The tracheal tube is picked up in the right hand and advanced from the right-hand side of the mouth, using the natural curvature of the tube to place the tip in the larynx under direct vision. Once the cuff of the tube is safely past the cords, the laryngoscope is carefully removed. The anaesthetic circuit is connected to the tube using a swivel connector and a catheter mount (if desired). The lungs are ventilated and the cuff of the tube inflated with just sufficient air (or gas mixture) to abolish the audible leak of gas on inflation of the lungs. Bilateral breath sounds and absence of sounds of gastric insufflation help confirm placement, however monitoring for appropriate and continuous concentration of carbon dioxide in the exhaled gas is mandatory.

Extubation – anaesthesia is maintained with inhalational agents, and the patient is ventilated using intermittent positive-pressure ventilation throughout the operation. At the end of the operation, residual neuromuscular blockade is reversed using a combination of a cholinesterase inhibitor and a muscarinic blocking drug (to prevent bradycardia). The drugs most commonly used are neostigmine, 0.05 mg/kg, with either atropine, 0.02 mg/kg, or glycopyrrolate, 0.01 mg/kg. Secretions and occasionally gastric content will have accumulated in the pharynx during the procedure. To prevent aspiration of these secretions and severe laryngeal spasm on removal of the tracheal tube, these are removed using a Yankauer sucker or equivalent, under direct vision (with a laryngoscope). The patient is ventilated with 100% oxygen. As the patient starts to breathe, the circuit is changed to permit spontaneous ventilation, with the reservoir bag providing visible confirmation of ventilatory effort and volume.

The tracheal tube is removed when the patient is breathing adequately and has regained protective airway reflexes (the patient is actively resisting the presence of the tube). The patient may be extubated in the supine position if the anaesthetist is satisfied that a clear airway can be maintained and the patient is not at risk for aspiration. If the patient is at risk, then extubation should take place in the lateral position, with the patient as fully awake as possible. Extubation should be performed during inspiration. Having deflated the cuff of the tracheal tube, the bag on the anaesthetic circuit is squeezed to expel secretions above the cuff into the oropharynx, away from the vocal cords. The tube is removed in a smooth movement, the breathing circuit rapidly reconnected to an anaesthetic mask, and the mask closely applied to the face.

Partial obstruction of the airway may occur at this stage if the tongue falls back into the pharynx, or more often because of mild laryngeal spasm. It may respond to the application of positive end-expiratory pressure. This may be achieved by partially closing the exhaust valve on the anaesthetic circuit, but the airway pressure must be monitored. If the airway is obstructed by the tongue, then an oral or nasopharyngeal airway may be required to relieve the obstruction. When the patient is breathing adequately, he is transferred to the recovery room, ensuring that he breathes supplementary oxygen during the transfer.

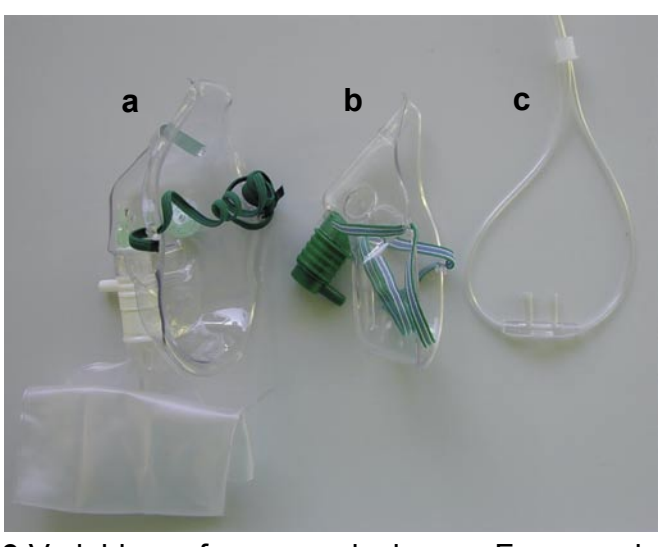
Recovery

Supplementary oxygen should be administered to all patients in the immediate recovery period. This is to prevent hypoxaemia that may otherwise occur from the ventilation–perfusion mismatch induced by surgery and anaesthesia, and the hypoventilation that may ensue from respiratory depressant drugs. Hypoxaemia may also be caused by dilutional hypoxia following cessation of nitrous oxide.

The duration of oxygen therapy may be limited to 15 minutes for young healthy patients undergoing minor day- case procedures, but extended for many hours or days for those with more serious pathology or complicated surgery. Therapy is guided by pulse oximetry or blood gas estimation, and oxygen therapy is usually titrated to achieve oxygen saturation greater than 95%.

Oxygen therapy devices may deliver either a variable or fixed concentration of supplementary oxygen to the inspired gas.

Variable performance devices include nasal prongs and simple 'Hudson'-type face masks with or without an oxygen reservoir (Figure 9). The oxygen flow delivered to the device is typically 2–4 litres/minute, which will be diluted by the air entrained during inspiration. The concentration of inspired oxygen depends on the oxygen flow rate, the patient's respiratory rate and peak inspiratory flow. Typically, 30–40% inspired oxygen is achieved when 4 litres/minute is delivered to a patient via a Hudson mask, and this concentration reduces as respiratory rate and inspiratory flows increase, due to increased air entrainment. The oxygen concentration delivered cannot be predicted accurately. This is usually of no consequence to a patient on the recovery ward, who simply needs supplemental oxygen, though the precise concentration is not critical. The inspired oxygen percentage can be increased further if an oxygen reservoir is used with the mask, and 80% inspired oxygen may then be achieved using a 12–15 litres/minute oxygen flow rate.

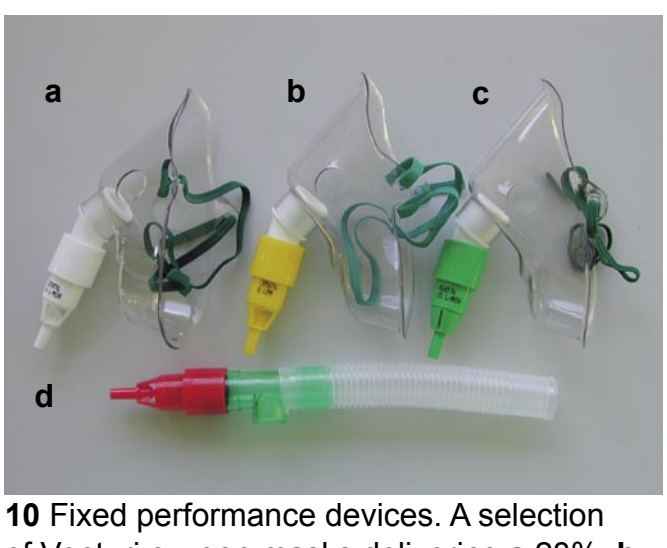


9 Variable performance devices. **a** Face mask with oxygen reservoir bag (folded); **b** simple Hudson-type oxygen face mask; **c** nasal prongs.

Fixed performance devices include face masks with Venturi-type injectors (Figure 10). They achieve a fixed inspired oxygen concentration by ensuring that a high flow rate of oxygen and entrained air is delivered, in excess of the patient's maximum peak inspiratory flow rate.

The use of a Venturi injector face mask delivers about 60 litres/minute of gas and so the inspired oxygen concentration is independent of the characteristics of inspiratory flow. Venturi devices are available to deliver fixed oxygen concentrations between 24% and 60%. The correct oxygen flow rate must be selected for the correct Venturi injector, and used with the correct mask. Details are printed on each Venturi, but typically 2 litres/minute delivers 24% oxygen, and 8 litres/minute delivers 35% oxygen. Venturi injector devices are not interchangeable with masks from different manufacturers, because the mask volume allows for adequate mixing of driving and entrained gases.

Fixed performance devices are often used in the high-dependency setting to enable accurate assessment of oxygenation, in patients with chronic lung disease who depend on a hypoxic respiratory drive, and on the general wards.



10 Fixed performance devices. A selection of Venturi oxygen masks delivering **a** 28%, **b** 35%, **c** 60% oxgen. **d** Venturi T-piece delivering 40% oxygen for use with laryngeal mask airway, tracheal tube or tracheostomy tube.

Anaesthesia for Laparoscopic Surgery

Michael W Platt

Michael W Platt is Consultant in the Department of Anaesthesia, St Mary's Hospital, London. He qualified in Western Australia. His research interests include anaesthesia and pain relief in the elderly, ethical issues at the end of life and aspects of neuropathic pain.

Laparoscopic surgery is a revolution in modern surgical techniques and has reduced postoperative pain, respiratory complications and hospital stay considerably. However, it produces extra stresses on the heart and lungs, therefore patients should be screened carefully and the risks explained fully as part of obtaining consent for the procedure. Anaesthetists should consult their surgical colleagues about the relative risks in those with cardiac and respiratory disease and should be prepared to cope with complications as they arise.

History

The earliest recorded references to endoscopy are from Hippocrates in Greece (460–375 BC), who made reference to a rectal speculum. It was only in the 1970s that the problems of transmitting light, insufflation technology and optical technology were surmounted sufficiently for gynaecologists to embrace laparoscopic surgery. Laparoscopic techniques were not supported whole-heartedly by general surgeons until after 1987, when Mouret performed the first laparoscopic cholecystectomy in France. Following this, the rapid development of solid state video camera technology has further broadened the field of laparoscopic surgery.

The advantages of minimally invasive surgery are less ileus, the greatly reduced stress response to surgery and trauma, reduced acute phase reaction, reduced pain, reduced post-operative pulmonary dysfunction and reduced hospital stay. These also have economic advantages.

More procedures are being developed for laparoscopic surgery, including extraperitoneal inguinal hernia repair and retro-peritoneal nephrectomy and adrenalectomy. Routine general surgical laparoscopic procedures now include: oesophagectomy, Nissen's fundoplication, gastric banding, oversewing of peptic ulcer, intestinal resections, including hemicolectomy and col-ectomy, rectopexy and hernia repair.

Pathophysiology and complications of laparoscopy

The complications of laparoscopy include: haemorrhage, hypotension, decreased cardiac output, acidosis, pneumothorax, pneumomediastinum, subcutaneous emphysema, retroperitoneal carbon dioxide (CO_2), venous stasis, bradycardia, increased vagal tone, cardiac arrest, fatal venous CO_2 embolism, regurgitation and aspiration. Many of these complications are the result of peritoneal insufflation (pneumoperitoneum).

Pneumoperitoneum, the insufflation of the peritoneal cavity, is required to enable a gas milieu for visualization through the laparoscope (the operating telescope). CO_2 is used for laparoscopy because it is highly soluble in blood. Blood can carry large quantities of CO_2 as bicarbonate, carboxyhaemoglobin, and in plasma proteins. Carbon dioxide is eliminated rapidly and the lethal dose as an embolus is five times that of air. Usually a CO_2 gas embolism resolves rapidly, but if it is large, it can be fatal.

Pneumoperitoneum is achieved by insufflating the peritoneal cavity with CO_2 to a pressure of 10–18 mm Hg. The intra-peritoneal insufflation of CO_2 to these pressures causes respir-atory and haemodynamic changes.

Respiratory changes that occur as a result of pneumoperitoneum consist of a reduction of chest compliance by 30–50%. Airway pressures to maintain tidal volume rise to counter the reduction of chest compliance and the elevation of the diaphragm. Functional residual capacity of the lungs decreases and there is an increase in physiological dead space and shunt because of basal compression by the diaphragm and increased ventilation/perfusion mis-matching, which may result in a reduced arterial partial pressure of oxygen. Basal atelectasis may persist into the postoperative period. If minute volume is kept constant, end-tidal CO_2 increases due to absorption of CO_2 from the peritoneal cavity. The latter changes are usually countered by increasing the tidal volume and applying positive end-expiratory pressure (PEEP).

Haemodynamic changes also occur as a result of the pneumo-peritoneum. Compression of the inferior vena cava leads to a reduction in venous return, potentially followed by a fall in cardiac output. However, a reflex tachycardia and a massive increase in peripheral vascular resistance tends to maintain cardiac output at near-normal levels, by pulling blood centrally from the periphery, but with a concomitant increase in mean arterial blood pressure. This increase in myocardial work can result in myocardial ischaemia in those at risk and can lead to infarction, which may not occur until the postoperative period. Active vasodilatation and β blockade are often required to counter these effects.

Compression of the inferior vena cava causes reduced venous flow from the legs, resulting in venous stasis and an increased risk of venous thrombosis. Prophylactic anticoagulation and elastic stockings or pneumatic calf compressors should be used, especially in the elderly.

Respiratory and haemodynamic changes are affected by the patient's position. For example, head-up tilt, used for upper abdominal operations (e.g. cholecystectomy, Nissen's fundoplication) further inhibits venous return. Head-down tilt, used for colonic and pelvic surgery, promotes venous return, but aggravates respiratory changes, further reducing chest compliance and functional residual capacity and increasing basal compression.

Other complications of pneumoperitoneum include surgical emphysema, which can affect most tissues, including the conjunctivae and the scrotal sack. Cardiac arrhythmias can be secondary to vagal stimulation (bradycardia) or to hypercarbia (tachyarrythmias). Pneumothorax (including tension pneumo-thorax) may occur, particularly with upper abdominal procedures such as Nissen's fundoplication. Gastric reflux can occur because of increased intraperitoneal pressure, although retained gas in the stomach may obstruct the surgeon's view for upper abdominal operations. Pressure on the renal veins and arteries may cause a temporary reduction in renal function, due to reduced renal blood flow. Major CO_2 gas embolus seldom occurs and is usually the result of accidental direct injection of gas into a major vessel (e.g. the inferior vena cava). This may cause an obstruction to cardiac output when it reaches the heart. The treatment is to turn the patient onto the right side immediately and position them head down, causing the gas embolus to occupy the apex of the right ventricle, relieving the obstruction to ventricular outflow.

Anaesthetic technique

Preoperative assessment

Patients should be assessed carefully preoperatively, focussing on their cardiac function and reserve, because of the amount of extra cardiac work required during pneumoperitoneum. Patients with significant cardiac disease and limited cardiac reserve should be assessed by a cardiologist. It may be that an open procedure or even cancelling the procedure would be best for the patient. Patients with added risks of venous thrombosis should be treated prophylactically with fractionated heparin, elastic stockings and calf compressors during surgery. Surgery for patients with previously untreated hypertension should be postponed until treatment has stabilized. Respiratory function should also be assessed. Pulmonary function tests should be performed in those with significant pulmonary disease. Liver and renal function need to be ascertained because these organs may also be affected by pneumoperitoneum. Intercurrent medications (especially antihypertensives) should be given as normal on the morning of operation. A light sedative, such as a short-acting benzodiazepine, may be given before surgery.

Perioperative management

A routine intravenous induction is appropriate. It is preferable to intubate and ventilate patients undergoing laparoscopic surgery. This ensures a secure airway while ventilating with higher airway pressures and reducing the inherently small risk of aspiration from gastric regurgitation. A large-bore intravenous cannula should be placed to allow ready access for the management of major complications. In upper abdominal procedures a 12–16 FG oro- or nasogastric tube is passed to allow egress of gas from the stomach to facilitate the surgeon's view.

Maintenance may be by total intravenous or inhalational anaesthesia. Intermittent positive-pressure ventilation is preferable, to ensure adequate ventilation in the presence of the reduced compliance and elevated diaphragm caused by the pneumo-peritoneum.

Opioid supplementation aids analgesia and improves post-operative analgesia. This may be as intermittent morphine and diamorphine or as an infusion of a short-acting agent such as alfentanil or remifentanil.

Monitoring should be the minimum standard of non-invasive blood pressure, electrocardiograph, end-tidal CO_2, anaesthetic gases and pulse oximetry. For patients who require laparoscopic surgery, but who have very borderline cardiac function, invasive blood pressure and central venous pressure may be necessary, to allow closer control of cardiac function, in particular myocardial work. A pulmonary artery flotation catheter may be considered if there is concern regarding left heart function.

When peritoneal insufflation begins, there is often a reflex tachycardia and significant increase in blood pressure, even at deep levels of anaesthesia. To avoid hypertensive crises, with diastolic blood pressures above 120 mm Hg, it is advisable to have a vasodilator and β blocker available. Carefully titrated doses of labetalol can be effective, with its combined α and β effects. Occasionally, vagally-mediated bradycardia, even to the point of sinus arrest, may be seen. In this case, insufflation should cease immediately, while an appropriate vagolytic (e.g. atropine) is given. Ventilation should be adjusted to increase tidal volume and PEEP applied to counter the reduced compliance, elevated diaphragm and increased CO_2 load.

At the end of the procedure, it is preferable for the surgeon to infiltrate the small port wounds with long-acting local anaesthetic to reduce postoperative pain. The raw areas of tissue that occur after cholecystectomy can contribute to pain, due to carbonic acid formation by CO_2. Spraying the peritoneal cavity with bupivacaine may be effective in these cases.

Recovery

Pain in the immediate postoperative period can be severe, presumably due mainly to stretching of the tissues. Shoulder-tip pain is common, secondary to diaphragmatic irritation. Sitting the patient up and giving systemic analgesia should help this to settle. Occasionally, large doses of intravenous opioid are required for adequate relief. However, once the pain is controlled, recovery is rapid and the patient usually goes home in 2–3 days.

Postoperative complications

Surgical emphysema is occasionally alarming because it involves much of the trunk. It is advisable to deflate the scrotal sack before recovery. More generalized emphysema settles rapidly with time, but a pneumothorax should be excluded. The main problem with surgical emphysema is pain, which should be controlled systemically. Basal atelectasis with secondary pulmonary infection may also occur. It is more common in those with pre-existing pulmonary disease, and should be treated with antibiotics and physiotherapy. Aspiration may manifest as pleural effusions or rarely as Mendelson's syndrome. These may require the input of a respiratory physician, but are not usually a major problem in fasted patients.

The most serious complications are usually haemodynamic. Postoperative myocardial infarction can occur as a result of the increase in myocardial work during the procedure.

Deep venous thrombosis may occur due to venous stasis in the legs during surgery. This occasionally presents postoperatively with pulmonary embolus. ◆

Anaesthesia for Reconstructive Free Flap Surgery

Jane Quinlan

Jane Quinlan is Consultant Anaesthetist at the Radcliffe Infirmary and the John Radcliffe Hospital, Oxford. She qualified from St Thomas' Hospital, London, and trained in anaesthesia in London and Oxford. Her interests include anaesthesia for plastic surgery and acute pain management.

Reconstructive free flap surgery is a complex method of wound closure for large wounds not amenable to linear (primary) closure. It involves the transfer of free tissue (skin, muscle, bone, bowel or a combination) to a site of tissue loss where its circulation is restored via microvascular anastomoses. A muscle flap produces a more even contour and better aesthetic appearance than that achieved by a simple skin graft and provides a better defence against infection. The defect may be caused by trauma, infection or extensive surgery (e.g. mastectomy, head and neck cancer). The site and size of the defect determines which flap is used. The most commonly used flaps are the gracilis muscle for lower leg trauma; latissimus dorsi and rectus abdominis for breast reconstruction; and pectoralis major and radial forearm flap for head and neck reconstruction.

In patients with lower third tibulofibular defects, free tissue transfer is typically required. The bony injury should be repaired and adequate debridement achieved before skin and muscle coverage begins. This should occur within the first 6 days after injury before colonization of the wound and the risk of complications increases. In patients with multiple trauma, any life-threatening injuries must be addressed first and the patient's haemodynamic status stabilized before reconstructive surgery is contemplated.

Flap transfer

The free flap is transferred with its accompanying artery and vein, which are then reattached to vessels at the donor site using microvascular techniques. The stages of flap transfer are:

- flap elevation and clamping of vessels
- primary ischaemia as blood flow ceases and intracellular metabolism becomes anaerobic (this is dependent on surgical time and lasts 60–90 minutes)
- reperfusion as the arterial and venous anastomoses are completed and the clamps released
- secondary ischaemia is subsequent to hypoperfusion of the flap (minimized by appropriate anaesthetic management).

Primary ischaemia

With cessation of blood flow, the flap becomes anoxic. In the presence of anaerobic metabolism, lactate accumulates, intra-cellular pH drops, ATP decreases, calcium levels rise and pro-inflammatory mediators accumulate. The severity of the damage caused by primary ischaemia is proportional to the duration of ischaemia. Tissues with a high metabolic rate are more susceptible to ischaemia, therefore skeletal muscle in a flap is more sensitive to ischaemic injury than skin. At the conclusion of primary ischaemia, the changes in the flap tissue include:

- narrowed capillaries due to endothelial swelling, vasoconstriction and oedema
- sequestration of leucocytes ready to release proteolytic enzymes and reactive oxygen intermediates
- diminished ability of endothelial cells to release vasodilators and degrade ambient vasoconstrictors
- end-organ cell membrane dysfunction and accumulation of intracellular and extracellular toxins
- up-regulation of enzyme systems to produce inflammatory mediators.

Reperfusion begins with the release of the vascular clamps. Normally, the re-establishment of blood flow reverses the transient physiological derangement produced by primary ischaemia. The flap recovers with minimal injury and normal cellular metabolism is restored. However, an ischaemia/reperfusion injury may result if factors in the flap are unfavourable. Prolonged ischaemia time or poor perfusion pressure make this more likely. Reperfusion injury occurs when the restored blood flow allows the influx of inflammatory substrates that may ultimately destroy the flap.

Secondary ischaemia occurs after a free flap has been transplanted and reperfused. This period of ischaemia is more damaging to the flap than primary ischaemia. Flaps affected by secondary ischaemia have massive intravascular thrombosis and significant interstitial oedema. Fibrinogen and platelet concentrations are increased in the venous effluent. Although skin flaps can tolerate 10–12 hours of ischaemia, irreversible histopathological changes in muscle can be seen after 4 hours.

Causes of flap failure: the general causes of poor flap perfusion may be classified as arterial, venous or resulting from oedema. The arterial anastomosis may be inadequate, in spasm or thrombosed. The venous anastomosis may similarly be defective, in spasm or compressed (e.g. by tight dressings or poor positioning). Oedema reduces flow to the flap and may be a result of excessive crystalloids, extreme haemodilution, trauma from handling or a prolonged ischaemia time. Flap tissue has no lymphatic drainage and is therefore susceptible to oedema.

Microcirculation: the blood flow through the microcirculation is crucial to the viability of a free flap. The microcirculation is a series of successive branchings of arterioles and venules from the central vessels. Regulation of blood flow and oxygen delivery is accomplished by three functionally distinct portions of the microcirculation: the resistance vessels, the exchange vessels and the capacitance vessels.

The resistance vessels are the muscular arterioles that control regional blood flow. Arterioles range in diameter from 20 μm to 50 μm and contain a relatively large amount of vascular smooth muscle in their walls. Alterations in vascular smooth muscle tone are responsible for active constriction and dilation in arterioles and thus control resistance to blood flow.

The capillaries constitute the network of vessels primarily responsible for the exchange function in the circulation. Small bands of vascular smooth muscle, the precapillary sphincters, are located at the arterial end of many capillaries and are responsible for the control of blood flow within the capillaries.

The venules act as the capacitance vessels, which collect blood from the capillary network and function as a reservoir for blood in the circulation.

The vascular bed of skeletal muscle has rich adrenergic in-nervation and therefore has a marked vasoconstrictor response to neural stimulation, primarily through the resistance vessels. Precapillary sphincters also constrict in response to sympathetic stimulation, but are sensitive to local factors such as hypoxia, hypercapnia, and increases in potassium, osmolality and mag-nesium, which may cause relaxation. Other vasoactive hormones (e.g. renin, vasopressin, prostaglandins, kinins) also have a role in microvascular control.

Transplanted vessels in a free flap have no sympathetic innervation but are still able to respond to local and humoral factors, including circulating catecholamines.

The flow behaviour (rheology) of blood in the microcirculation is determined by the red cell concentration, plasma viscosity, red cell aggregation and red cell deformability. Following all surgery under general anaesthesia, the changes in blood rheology include:

- increased platelet aggregation and adhesion
- an impairment of red cell deformability
- an increase in whole blood viscosity
- increased clotting factors
- increased plasma fibrinogen and red cell aggregation
- disturbance of fibrinolysis.

Normal levels of 2,3-diphosphoglycerate (2,3-DPG) are required for optimal red cell deformability. After blood transfusion, this deformability is impaired owing to the negligible amount of 2,3-DPG in stored blood.

Physiology

The physiological status of the patient has a major influence on the viability of the transferred tissues, so the conduct of anaesthesia and postoperative management have a direct effect on outcome. Surgery is long (often 6–8 hours) with multiple sites for tissue trauma, resulting in extensive blood and fluid losses as well as heat loss. The resulting hypovolaemic vasoconstriction and hypothermia, if not corrected, compromise blood flow to the flap and result in flap failure.

Even with good fluid management, blood flow to a flap may decrease by 50% for 6–12 hours postoperatively. The guiding principle of anaesthesia for free flap surgery is the maintenance of optimum blood flow. The determinants of flow are summarized by the Hagen–Poiseuille equation:

$$\text{Laminar flow} = \frac{\Delta P \times r^4 \times \pi}{8 \times \eta \times l}$$

where: ΔP is the pressure difference across the tube, r is the radius of the vessel, η is viscosity and l is the length of the tube.

From this we may deduce that the goals of anaesthesia for free flap surgery are vasodilatation, good perfusion pressure and low viscosity.

Vasodilatation

Vessel radius is the most important determinant of flow, for the vessels supplying the flap as well as those in the flap.

Temperature – the patient should be kept warm in theatre, the recovery room and the ward for the first 24–48 hours. This is best achieved by raising the ambient temperature in theatre and by using a warm air blanket. Active warming should begin before the start of anaesthesia because patient cooling occurs rapidly after induction of anaesthesia. In an awake patient, the central core temperature is higher than that of the peripheral tissue and skin temperature. After the induction of anaesthesia, vasodilatation modifies the thermal balance between compartments. The volume of the central compartment enlarges leading to a decrease in its mean temperature, while the temperature of the peripheral and skin compartments increases. At thermoregulation, the size of the central compartment becomes smaller owing to vasoconstriction, which leads to an increase in the mean temperature, although the peripheral and skin temperatures fall.

In addition to vasoconstriction, hypothermia also produces a rise in haematocrit and plasma viscosity, the aggregation of red blood cells into rouleaux, and platelet aggregation. These effects may reduce the microcirculatory blood flow in the flap.

Fluid – peripheral vasoconstriction due to an underestimation of fluid losses is common. There are two operating sites in free flap transfer: the donor site and the recipient site. Both have insensible fluid losses and both may have blood losses. A warm theatre environment also increases fluid loss. Modest hypervolaemia reduces sympathetic vascular tone and dilates the supply vessels to the flap. An increase in central venous pressure of 2 cm H_2O above the control measurement can double the cardiac output and produce skin and muscle vasodilatation. Figure 1 gives a guide to fluid management.

Guide to fluid management

Crystalloids
- 10–20 ml/kg to replace preoperative deficit
- 4–8 ml/kg/hour to replace insensible losses

Colloids
- 10–15 ml/kg for haemodilution
- To replace blood loss

Blood
- To maintain haematocrit at 30%

Dextran
- Often given postoperatively

1

Anaesthesia – isoflurane has the advantage over other volatile anaesthetics and propofol that it causes vasodilatation with minimal myocardial depression. Propofol inhibits platelet aggregation which could reduce the risk of thrombosis. This may be due to an effect of intralipid on the platelet–erythrocyte interaction, and by the increased synthesis of nitric oxide by leucocytes.

Vasospasm of the transplanted vessels may occur after surgical handling or after damage to the intima of the vessels, and can occur during surgery or postoperatively. The surgeons may use topical vasodilators such as papaverine, lidocaine (lignocaine) or verapamil during the operation to relieve the vasospasm.

Sympathetic blockade – epidural, brachial plexus or interpleural local anaesthetic infusions, used intraoperatively and postoperatively, provide sympathetic blockade to further dilate vessels. Concerns have been raised that the sympathetically-denervated transplanted vessels would be unable to dilate after lumbar epidural blockade, resulting in a 'steal' effect reducing flap blood flow. In fact, provided any hypotension due to the sympathetic block is treated appropriately, blood flow to the flap improves as a result of the increased flow through the feeding recipient artery. Other advantages of epidural analgesia include a reduction in intraoperative and postoperative blood loss and vessel spasm; a lower incidence of deep venous thrombosis; improved diaphragmatic function and more rapid post-operative recovery. Good analgesia reduces the level of circulating catecholamines and avoids the vasoconstrictor response to pain.

Perfusion pressure

The preservation of a good perfusion pressure with wide pulse pressure is essential to flap survival. Appropriate anaesthetic depth and aggressive fluid management are usually all that is needed. Most inotropes are contraindicated owing to their vasoconstrictive effects, but if required, dobutamine and low-dose dopamine could be used.

Viscosity

Isovolaemic haemodilution to a haematocrit of 30% improves flow by reducing viscosity, reducing reperfusion injury in muscle and increasing the number of patent capillaries, which decrease tissue necrosis. Further reductions in haematocrit do not provide much more advantage because the curve of viscosity versus haematocrit flattens off markedly (Figure 2). If the haematocrit falls further, the marginally improved flow characteristics from a lower viscosity may then be offset by a reduction in oxygen delivery:

$$DO_2 = CO \times [(Hb \times sat \times 1.34) + (PaO_2 \times 0.003)]$$

A low haematocrit also increases myocardial work, therefore care should be taken in patients with poor cardiac reserve.

Viscosity versus haematocrit

Practical conduct of anaesthesia

Monitoring

In addition to basic monitoring, these patients require invasive blood pressure monitoring to enable safe manipulation of the perfusion pressure. Direct measurement of arterial pressure gives a continuous record of the pressure and is more accurate than non-invasive indirect techniques. An arterial cannula also provides access to blood gas analysis and haematocrit estimations.

Central venous pressure reflects cardiac filling pressures and can be manipulated to increase cardiac output.

Core temperature measurement is essential when active warming is instituted. A nasopharyngeal or rectal probe is used intraoperatively for a continuous reading, while intermittent tympanic or axillary measurements are used in the recovery and ward areas.

Peripheral temperature is also measured because a fall in skin temperature can reflect hypovolaemia and vasoconstriction. A difference of less than 2°C between core and peripheral temp-eratures indicates a warm, well-filled patient. The temperature of the skin flap is sometimes monitored postoperatively because a drop in temperature may herald flap failure. However, this is not a sensitive test, because by the time the temperature has fallen the flap will have suffered sufficient vascular damage to render it virtually unsalvageable.

Urine output is another indicator of volume status. A urine output of 1–2 ml/kg/hour should be maintained intraoperatively and postoperatively with appropriate fluid management. Diuretics are contraindicated in these operations because volume depletion compromises flap survival.

Induction

Active warming starts before the patient is asleep. The ambient temperature in theatre is raised to about 22–24°C, a level high enough to reduce patient heat loss, but not too hot to be uncomfortable for the theatre staff. The patient is covered in a hot air blanket before induction of anaesthesia and this remains in place while the patient is prepared for theatre. Once in theatre, the blanket is moved to enable surgical access, but with as much surface area coverage as possible.

If appropriate, a regional block is inserted, preferably to cover the free flap recipient site (rather than the donor site) for the full benefit of the sympathetic block. The patient is intubated and ventilated; and a large gauge peripheral line, central line, arterial line, urinary catheter and core temperature and skin temperature probes are positioned.

Nitrous oxide diffusion into air in the stomach combined with gastric stasis results in gastric distension, with associated post-
operative nausea and vomiting. A nasogastric tube is therefore sited at intubation, left on free drainage, then aspirated and removed at the end of the operation.

Fluid, administered through a fluid warmer, is started in the anaesthetic room to compensate for preoperative dehydration.

Maintenance

Careful positioning of the patient is imperative for such a long operation. Limbs are positioned and supported to avoid neuro-logical damage or vascular compression. Eyes are taped and lightly padded to reduce the incidence of corneal abrasion and prevent drying of the cornea.

Prophylaxis against deep venous thrombosis is necessary for all patients. Subcutaneous heparin or low-molecular-weight heparin is given preoperatively, while anti-embolism (TED) stockings and compression boots are used intraoperatively.

The patient is ventilated to normocapnia. Hypocapnia increases peripheral vascular resistance and reduces cardiac output, while hypercapnia causes sympathetic stimulation. If the surgeon uses the microscope for vessel preparation or anastomosis on the chest or abdomen, the tidal volume is reduced to minimize movement in and out of the surgeon's field of vision. The respiratory rate is then increased to maintain minute ventilation.

Controlled hypotension is useful during the initial dissection and is most easily achieved using epidural local anaesthetic and/or isoflurane. An infusion of glyceryl trinitrate may be added if needed.

Crystalloids are used to replace the preoperative fluid deficit from starvation and to cover intraoperative insensible losses. The latter are high because the warm theatre increases evaporative losses from the two operating sites. Excessive use of crystalloid may precipitate oedema in the flap.

Hypervolaemic haemodilution is achieved using colloids.

Blood gas analysis and haematocrit measurement should be carried out at the start of the operation and repeated every 2 hours.

By the time the flap is reperfused, the patient should be warm, well-filled and sympathetically blocked with a high cardiac output.

Emergence and recovery

The patient should wake up pain-free. Analgesia is maintained postoperatively with local anaesthetic infusions for regional blocks, intravenous patient-controlled analgesia, or both. Coughing and vomiting increase venous pressure and reduce flap flow, so smooth emergence and extubation are needed. The principles of perioperative and postoperative care are listed in Figure 3. ◆

Principles of perioperative and postoperative care

- Maintain high cardiac output
- Normal arterial blood pressure (systolic >100 mm Hg)
- Low systemic vascular resistance
- Normothermia
- High urine output (> 1 ml/kg/hour)
- Effective analgesia
- Haematocrit 30–35%
- Monitoring of blood flow in flap (Doppler postoperatively)

The Anaesthetic Machine

Michael O'Connor
Ian Taylor

Duncan Parkhouse is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Ian Taylor is Specialist Registrar in Anaesthesia in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and is training at the Wessex School of Anaesthesia, based in Southampton, UK. His interests are vascular and obstetric anaesthesia.

Many anaesthetic machines incorporate patient monitoring; conventionally this is considered separately and will not be discussed here.

Types of anaesthetic machine

Demand and intermittent flow machines
The patient's inspiration controls the flow of fresh gases. Such machines have been used for dental anaesthesia (e.g. the McKesson anaesthetic machine) and for military field anaesthesia (the Triservice apparatus).

Continuous flow machines (Boyle's machine)
Continuous flow machines are encountered in day-to-day hospital practice in the UK. The driving force for gas flow is compressed gases. This contribution discusses continuous flow machines.

Pressures in the anaesthetic machine

Units of pressure
To understand the anaesthetic machine, it is important to be able to relate the various different units that are used to describe pressure; 1 atmosphere pressure is approximately:

- 101 kPa
- 760 mm Hg
- 1035 cm H_2O
- 1 bar
- 15 psi.

Absolute and gauge pressure

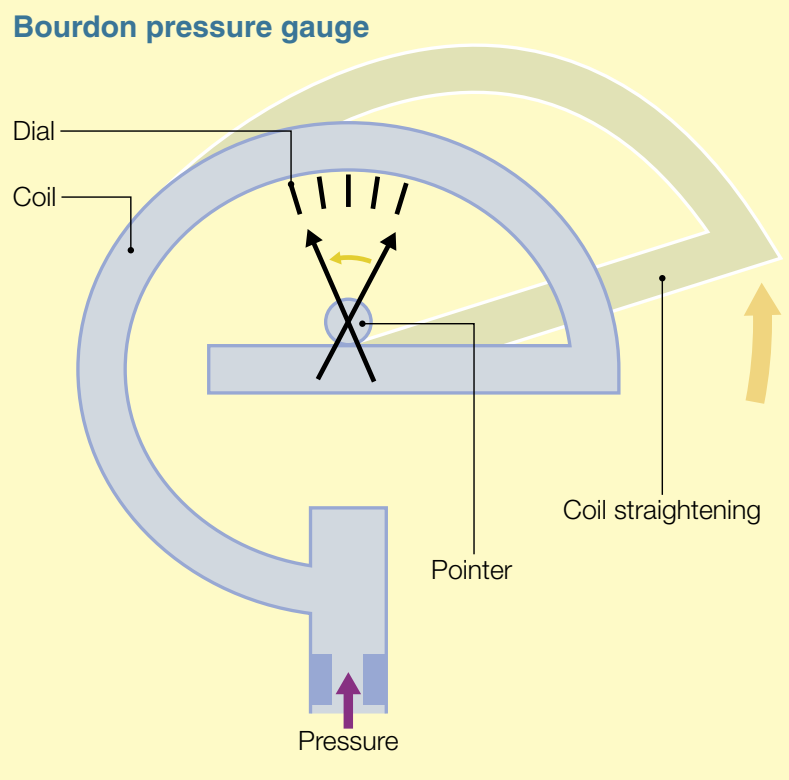
- Absolute pressure is pressure above that in a vacuum.
- Gauge pressure is pressure above atmospheric. Pressures in the anaesthetic machine are always quoted as gauge pressures.

All pipeline pressures are 400 kPa except for pressure in the air pipeline used to drive equipment such as orthopaedic drills, which is 700 kPa. Cylinder pressures are reduced to a machine working pressure of 400 kPa by pressure regulators (see below, page 66).

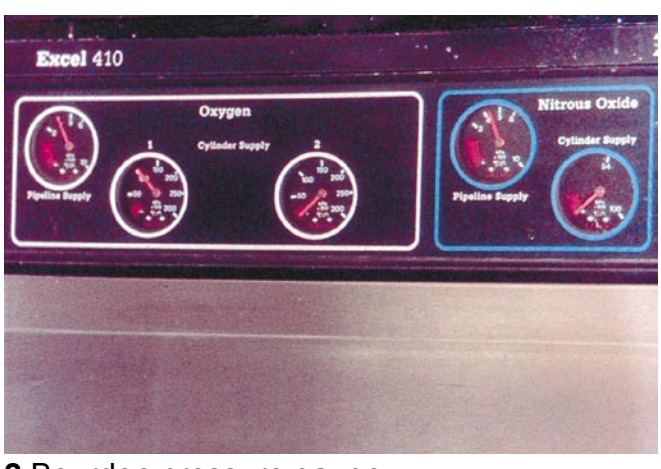
Pressure downstream of the flowmeters can range between zero (i.e. 1 atmosphere pressure), when the common gas outlet is open to the atmosphere, and about 33 kPa if the common gas outlet is completely obstructed and the safety valve in the back bar vents to the atmosphere.

Measurement of pressure
Cylinder and pipeline pressures are measured by a Bourdon pressure gauge (Figure 1). This is an aneroid (i.e. without liquid) gauge consisting of a coiled tube attached at one end to the gas supply and at the other to a pointer. The pressure of the gas causes straightening of the coil and thus movement of the pointer over the colour-coded, labelled and calibrated dial (Figure 2). The gauge is faced with heavy glass and designed such that leaks vent from the back of the valve casing and do not blow out the glass.

Bourdon pressure gauge



1

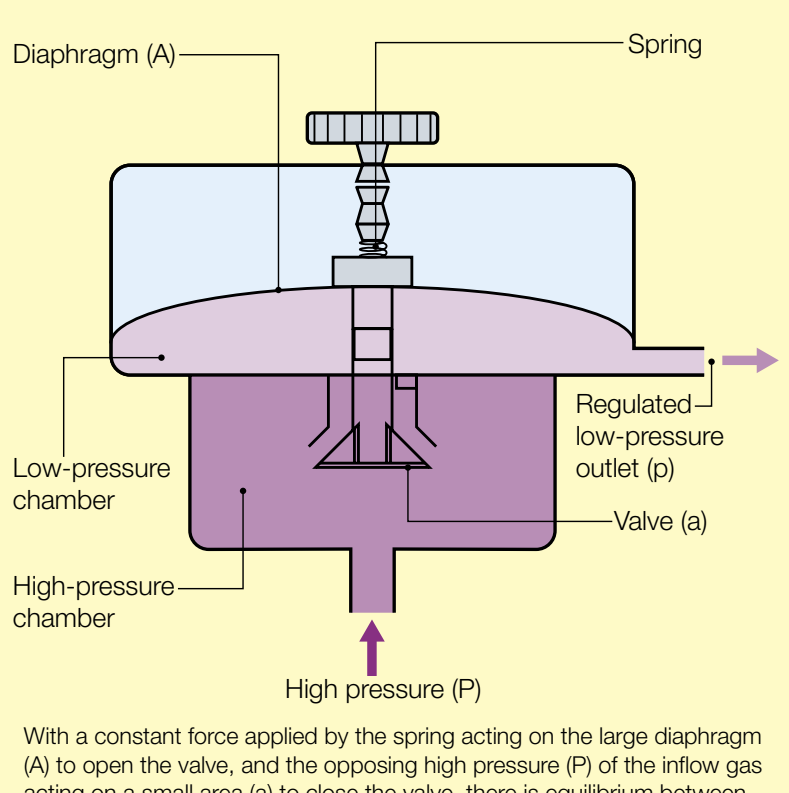


2 Bourdon pressure gauge.

Pressure regulators
Although sometimes referred to as pressure-reducing valves, the term pressure regulators is preferred because their function is not simply to reduce pressure, but in doing so to allow more accurate control of flow and to make up for the fall in cylinder pressures as they empty.

Figure 3 demonstrates the function of a pressure regulator. The principle is similar to that of the pressure-relief valve (see *Anaesthesia and Intensive Care Medicine* **1:3:** 107) except that there are two chambers, one of high pressure and the other of low, and two discs of different areas.

Pressure regulator



With a constant force applied by the spring acting on the large diaphragm (A) to open the valve, and the opposing high pressure (P) of the inflow gas acting on a small area (a) to close the valve, there is equilibrium between the high- and low-pressure chambers. To balance the equilibrium and keep the valve open, the pressure in the second chamber is thus reduced. Thus: P x a = p x A, where P = pressure in the high-pressure chamber; p = pressure in the low-pressure chamber; A = area of large diaphragm; a = area of small diaphragm.

Adjustment of the tension in the spring and thus the force it applies to the discs, regulates the pressure at the outlet to produce a constant operating pressure. As the inlet pressure falls during use of the cylinder, the force from the spring opens the valve wider, allowing more gas to flow into the second chamber and maintaining pressure at the outlet. The opposite happens if the inlet pressure rises, resulting in valve closure and thus less flow into the second chamber.

3

Flowmeters

Rotameters
Flow in most anaesthetic machines is measured by a variable orifice flowmeter known as a rotameter. A rotameter consists of a bobbin that floats in a glass tube with a diameter that increases with height up the tube. The pressure drop across the bobbin remains constant, and as flow increases it rises up the tube.

The two important properties of the gas flowing through a rotameter that influence its calibration are:

- viscosity
- density.

Gas flows in the annulus between the bobbin and the tube. At the lower end of the tube the annulus is long with respect to its cross-sectional area, and flow is laminar and dependent on the viscosity of the gas. Higher up the tube, the cross-sectional area of the annulus is greater, the gas is effectively flowing through an orifice, and flow is turbulent and dependent on the density of the gas (Figure 4).

Flowmeter

Laminar flow around the bobbin at the bottom of the tube, turbulent flow at the top. NB Pitch of the rotameter tube has been greatly exaggerated

4

Features of rotameters

- For any given gas, the flow through a rotameter depends on both its viscosity and its density. Rotameters therefore have to be calibrated individually for the gas they will be measuring.
- The bore may be varied to measure low flows accurately.
- The back plate may be luminous.
- Calibration is from the lowest accurate point, not zero.
- Accuracy is ± 2%.
- In many machines there is a constant low flow of oxygen.

Potential sources of inaccuracy in rotameters

- If the tube is not truly vertical, the annulus between the tube and the bobbin is altered.
- Static electricity can cause inaccuracies. To minimize this, glass is conductive and sprayed with antistatic material.
- Dust can collect on the bobbin or within the tube.
- Tubes may be damaged. In the UK, the oxygen rotameter tube is on the left (said to be because Boyle was left-handed). This can mean that any damage to the tubes would preferentially leak oxygen and result in the delivery of a hypoxic mixture. Many manufacturers now arrange the order in which the gases finally mix so that oxygen is the last gas added to the mixture.
- The top-sealing washer may be defective.
- The carbon dioxide bobbin may become stuck at the top of the tube.
- Back pressure from a minute volume divider such as a Manley ventilator increases the density of the gas and may cause the rotameter to under-read by about 7%.
- Atmospheric pressure affects density. Low pressure gives over-reading.
- Temperature affects density and viscosity. Increased temperature causes decreased density and increased viscosity.

Vaporizers

Vaporizers are discussed elsewhere.

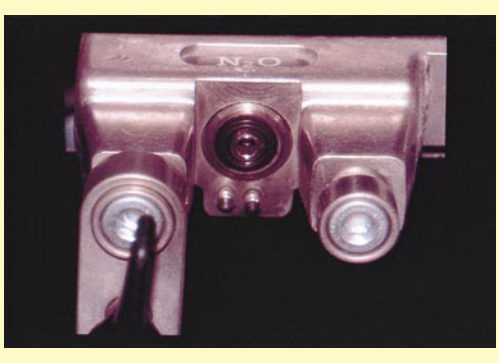
Safety

The anaesthetic machine has several in-built safety features that vary from machine to machine. The commonly found features that are of importance to anaesthetists are listed in Figure 5.

Perhaps the most important safety feature is that the machine should always be checked in a systematic fashion before use. The Association of Anaesthetists of Great Britain and Ireland has published a useful checklist, part of which is reproduced in Figure 6. These checks must be performed at the beginning of each theatre session.

Anaesthetic machine – safety features

- Non-interchangeable pipeline outlets (often referred to as Schrader connectors, though this is really a trade name)
- Pipelines are coloured and marked with the name of the gas
- Non-interchangeable screw thread connectors connect the pipeline to the anaesthetic machine
- The pin index system prevents accidental connection of the wrong cylinder to the wrong yoke
- Cylinders are coloured and marked with the name of the contents
- Grease can be flammable or explosive in contact with gases at high pressure. A Bodok seal (see below) makes a gas-tight connection between cylinder and yoke
- There are pressure gauges for pipelines and cylinders
- Rotameter knobs are identified by the oxygen knob being a distinctive colour and shape and more prominent
- The oxygen rotameter outlet may be diverted to enter the gas flow last
- Oxygen and nitrous oxide rotameters may be linked to prevent delivery of a hypoxic mixture
- The oxygen bypass can provide oxygen at high flow (> 30 litres/minute) directly to the common gas outlet
- There is an oxygen failure warning device triggered by a dropin the oxygen pressure, which also vents the flow of anaesthetic gases to the atmosphere to prevent delivery of a hypoxic mixture
- Vaporizer fillers are keyed to prevent a vaporizer being accidentally filled with the wrong agent
- Vaporizers may be arranged so that only one can be turned on at a time
- There is a machine pressure-relief valve in the back bar that prevents the pressure rising above about 33 kPa
- The machine is serviced regularly by a qualified engineer



Bodok seal.

Anaesthesic machine – safety checks

Anaesthetic machine

- Check that the anaesthetic machine and relevant ancillary equipment are connected to the mains electrical supply (where appropriate) and switched on
- Careful note should be taken of any information or labelling on the anaesthetic machine that might refer to its current status

Oxygen analyser

- The oxygen analyser should be placed where it can monitor the composition of the gases leaving the common gas outlet
- The analyser should be switched on, checked and calibrated according to the manufacturer's instructions

Medical gas supplies

- Identify and take note of the gases that are being supplied by the pipeline, confirming with a 'tug test' that each pipeline is correctly inserted into the appropriate gas supply terminal
- Check that the anaesthetic apparatus is connected to a supply of oxygen and that an adequate reserve supply of oxygen is available from a spare cylinder
- Check that adequate supplies of any other gases intended for use are available and connected as appropriate. All cylinders should be securely seated and turned ***Off*** after checking their contents. Carbon dioxide cylinders should not normally be present on the anaesthetic machine. A blanking plug should be fitted to any empty cylinder yoke
- All pressure gauges for pipelines connected to the anaesthetic machine should indicate 400 kPa
- Check the operation of flowmeters, ensuring that each control valve operates smoothly and that the bobbin moves freely through its range without sticking. With only the oxygen flow control valve open and a flow of about 5 litres/minute, check that the oxygen analyser display approaches 100%.

Turn off all flow control valves

- Operate the emergency oxygen bypass control and ensure that flow occurs without significant decrease in the pipeline supply pressure. Confirm that the oxygen analyser display approaches 100% during this test. Ensure that the emergency oxygen bypass control ceases to operate when released

Vaporizers

- Check that the vaporizer(s) for the required volatile agent(s) are fitted correctly to the anaesthetic machine, that any back bar locking mechanism is fully engaged and that the control knobs rotate fully through the full range(s). Ensure that the vaporizer is not tilted.

Turn off the vaporizers

- Check that the vaporizer(s) are adequately filled and that the filling port is tightly closed
- Set a flow of oxygen of 5 litres/minute and, with the vaporizer turned off, temporarily occlude the common gas outlet. There should be no leak from any of the vaporizer fitments and the flowmeter bobbin should dip.

Turn each vaporizer on in turn and repeat this test. There should be no leak of liquid from the filling port.

After this test, ensure that the vaporizers and flowmeters are turned off

Should it be necessary to change a vaporizer at any stage, it is essential to repeat the leak test.

Failure to do so is one of the most common causes of critical incidents

Removal of a vaporizer from a machine in order to refill it is not considered necessary

Artificial Ventilation in the Operating Theatre

Elaine M Wilson-Smith
J Duncan Young

Elaine M Wilson-Smith is Anaesthetic Specialist Registrar and Neuroanaesthesia Fellow at the Radcliffe Infirmary, Oxford, UK. She qualified from Guy's Hospital, London, and has trained in anaesthetics in Leicester, Alder Hey Hospital, Liverpool, and Oxford.

J Duncan Young is Clinical Reader in Anaesthetics at the Oxford Radcliffe Hospitals Trust. He qualified from Southampton University and trained in anaesthesia and intensive care in Southampton, Oxford and North America. His interests include artificial ventilation and techniques to improve arterial oxygenation in ICU patients.

Ventilators are used in two main settings: the operating theatre and the ICU.

- In the operating theatre, ventilators are used to maintain ventilation in anaesthetized, intubated, pharmacologically paralysed patients who have predominantly normal lungs. These ventilators are designed to interface with anaesthetic gas circuits to allow varying concentrations of oxygen, anaesthetic gases and volatile agents to be delivered to the patient. Most theatre ventilators are relatively simple, mechanical or electromechanical devices that do not have patient-sensing capabilities.
- Ventilators are often used in the ICU to ventilate patients with abnormal lungs, who require only air and oxygen as respiratory gases; these patients are seldom paralysed and often require only partial respiratory support. The ventilators used are almost all complex, computer-controlled devices with sensitive mechanisms to detect the patient's respiratory efforts.

This contribution discusses ventilators for theatre use, though many of the basic principles apply to ICU devices.

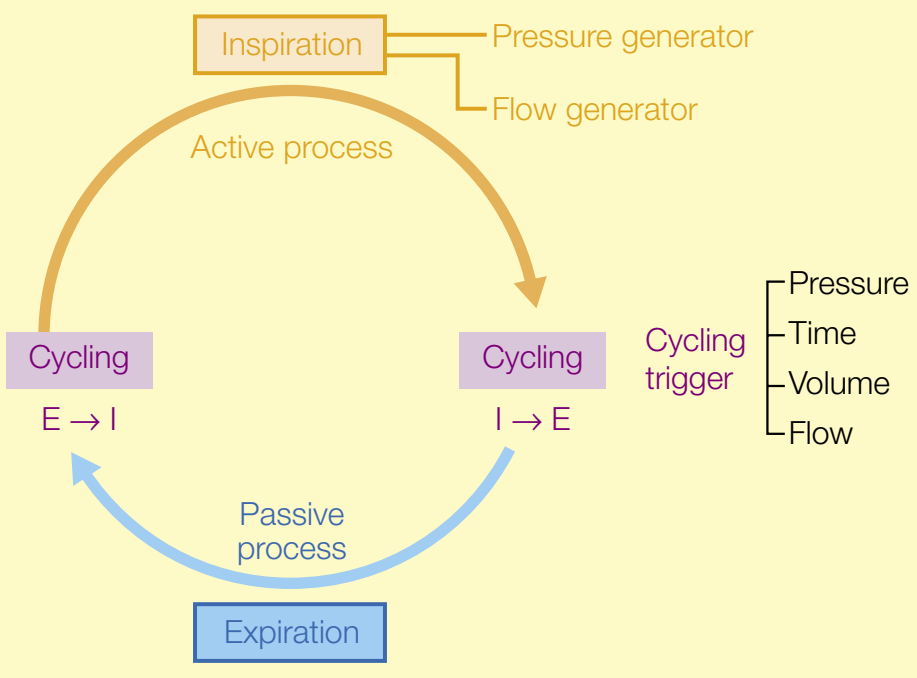
Classification of anaesthetic ventilators

Ventilators can be classified according to their function and operation.

- Functional classification is the most common and clinically useful system. It is based on the pattern of gas that the ventilator generates during inspiration, and the mechanism that cycles between inspiration and expiration (Figure 1).
- Operational classification is based on parameters such as power source or driving mechanism. Operational classification is not covered in this contribution.

Ventilator classifications were devised when most ventilators had only one mode of ventilation. Examples of such ventilators are the Manley ventilator (a time-cycled pressure generator), the Nuffield 200 ventilator (a time-cycled flow generator) and paediatric theatre ventilators (time-cycled pressure generators). Modern theatre ventilators and all ICU ventilators can operate in two or more ventilatory modes and so do not fit neatly into one single category of the traditional functional classification.

Functional classification of the respiratory cycle during intermittent positive-pressure ventilation



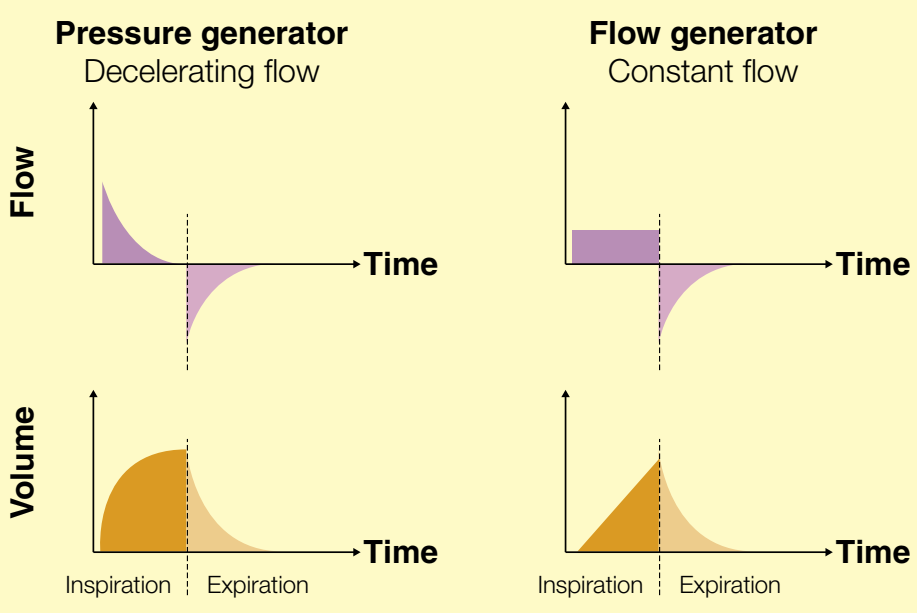
Based on Mapleson classification. I, inspiration; E, expiration

1

Functional classification of ventilators

The important difference between pressure and flow generators is the pattern of gas flow produced during inspiration. This influences the effects of changes in airway resistance, or lung and chest wall compliance, or if there is leak of delivered gases from the system. A summary of the important differences between pressure and flow generators is shown in Figure 2. Knowledge of the basic respiratory mechanics is vital to understanding ventilator–patient interactions.

Pressure generators and flow generators



2

Resistance, compliance and time constants: the pressure required to cause gas to flow into the lungs has two components:

- that required to maintain gas flow along the airways, overcoming airways resistance
- that required to overcome the elastic recoil of the respiratory system, determined by compliance.

The interaction of these components determines the time constant (TC).

TC defines the rate of a simple (first-order) exponential process. It is equivalent to the time taken for the exponential process to complete if it were to continue at the same rate as that at which it began. TC describes how fast the lungs fill with a constant applied airway pressure or how fast they empty during expiration. (TC = compliance x resistance.) It increases with increasing resistance (e.g. in asthmatics) and decreases with decreasing compliance (e.g. in pulmonary fibrosis).

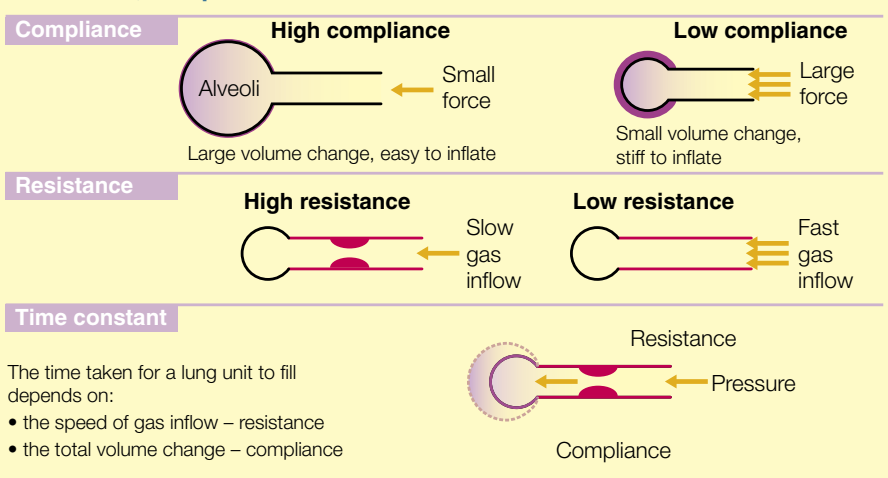
Resistance is a measure of the resistance to gas flow. The major site of respiratory resistance is in the medium-sized bronchi, but total respiratory resistance during positive-pressure ventilation also includes the contribution of the endotracheal tube and to a lesser extent the circuit. In a patient with normal lungs, this increases the total respiratory resistance from 2 to 4–6 cm H_2O/litre/second.

Compliance describes the elasticity of the respiratory system, or the ease with which it inflates, and is measured as the volume change per unit pressure. Total respiratory compliance consists of combined lung and chest wall compliance and is normally 50–70 ml/cm H_2O.

Within the normal working range of the lung compliance is constant though it decreases at extremes of volume. The contribution to compliance from the ventilator circuit is usually small. The exception is during anaesthesia in neonates and infants when the tidal volume is small compared with the circuit volume, and compression of gas within the circuit can make it difficult to ensure that accurate and adequate tidal volumes are delivered (Figure 3).

Effect on artificial ventilation − increased airways resistance and reduced lung and chest wall compliance are the most clinically significant changes in respiratory mechanics affecting artificial ventilation. Some causes are shown in Figure 4.

Resistance, compliance and time constant



3

Causes of increased airways resistance and reduced respiratory compliance

Increased airways resistance	Reduced respiratory compliance
• Bronchospasm – asthma, chronic obstructive airway disease (COAD)	• Within lung – pulmonary oedema, adult respiratory distress syndrome, fibrosis, atelectasis
• Mucosal swelling – asthma, COAD	• Around lung – pleural effusion, upward compression from abdominal contents when supine, especially if obese
• Luminal obstruction – excessive secretions	• Chest wall – surgeon compressing chest, expiration retractors, scoliosis, contractures
• Foreign body – tumour	
• Emphysema – dynamic airway compression during	
• Low lung volume	

4

Pressure and flow generators: an understanding of the different types of ventilator and how they function helps predict the behaviour and limitations of each type of machine when resistance and compliance of the lungs change (Figure 5).

Pressure generators - a pressure generator applies a preset positive-pressure waveform to the airway for the duration of inspiration. In its simplest form this pressure is constant (Figure 6).

If the inspiratory time is sufficiently long, the respiratory compliance determines the tidal volume delivered when a given airway pressure is applied. The respiratory compliance decreases linearly with lung size, therefore a pressure generator set at 15−20 cm H_2O delivers an appropriate tidal volume to a small child or an adult with normal lungs.

Pressure generators can maintain the required airway pressure, even in the presence of a leak, within reasonable limits. As a result, the main use for pressure generators in anaesthetic practice is to ventilate children. The cricoid ring is the narrowest point of the airway in children. The insertion of endotracheal tubes can lead to compression of the tracheal mucosa against the cricoid cartilage, resulting in pressure necrosis. This can be avoided by using uncuffed endotracheal tubes; the presence of an air leak during inspiration confirms that the endotracheal tube is not lodged tightly in the cricoid ring.

The pressure generator ensures that adequate tidal volumes are delivered because a consistent pressure is maintained despite the leak. Paediatric patients, particularly neonates, are prone to ventilator-induced lung damage, and constant pressure generators ensure that even when lung dynamics change, the applied pressure remains constant.

Pressure generators are designed for use with normal lungs that remain normal during surgery (delivered tidal volume = pressure x compliance.) The main disadvantage of a pressure generator is that tidal volume is determined by compliance and reductions in compliance may cause significant reductions in delivered tidal volume and minute ventilation. Therefore, pressure generators may not be appropriate when precise control of arterial carbon dioxide tension ($PaCO_2$) is important, for example, during neurosurgery.

Flow generators (Figure 7) are devices that produce a constant gas flow independent of respiratory compliance or resistance. The volume delivered per unit time remains constant even in the presence of high airway pressures. All flow generators need a high-pressure gas source. This can be delivered by compressing bellows or by using proportional control valves, which control gas flow from the pipeline supply.

The delivered tidal volume is determined by control of the inspiratory flow rate and inspiratory time. The peak and mean airway pressure generated depends on the tidal volume, inspiratory flow rate, respiratory compliance and resistance.

The main advantage of a constant flow generator is that a constant tidal volume and minute ventilation are maintained even when the mechanics of the lung are changing. The tidal volume can be set precisely and minute ventilation is predictable and consistent, giving precise control of $PaCO_2$.

The main disadvantage is the potential for high airway pressures and barotrauma if changes in lung mechanics occur. There is also no ability to compensate for leaks. Flow generators are used mainly for adults, particularly where lung mechanics are abnormal, and when precise control of $PaCO_2$ is required.

Cycling parameters - cycling is the process of stopping one phase of ventilation and changing to the next. This occurs twice within each delivered breath. For the purposes of classification, cycling marks the end of inspiration and the beginning of expiration. Ventilators may be:

- time-cycled – cycling occurs after preset time
- volume-cycled – cycling occurs after preset volume delivered
- pressure-cycled – cycling occurs after preset pressure attained
- flow-cycled – cycling occurs when flow falls below a preset value.

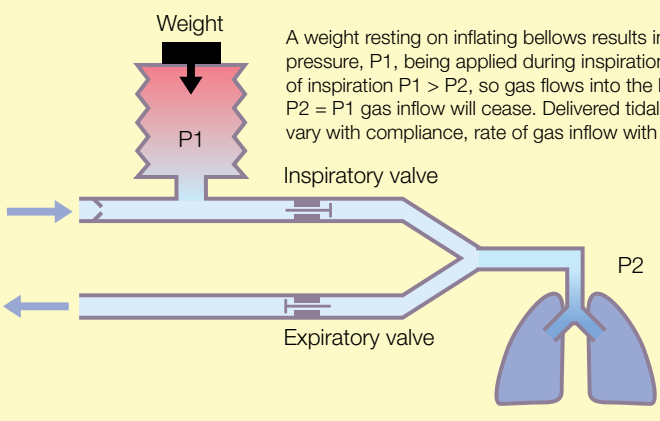
Time cycling is the most common technique. Flow cycling is used in inspiratory pressure support in the ICU but seldom in theatre. Volume and pressure cycling are used infrequently. In most ventilators, cycling from expiration to inspiration is by time.

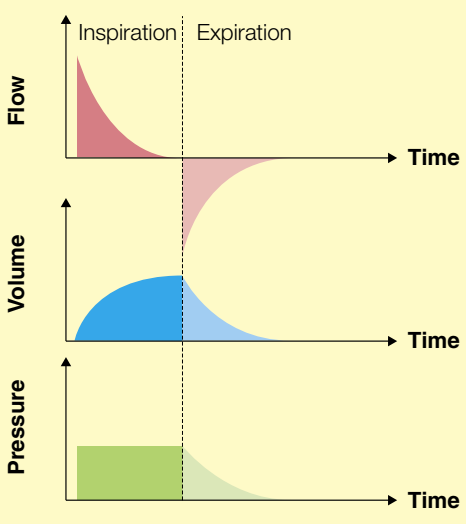
Advantages and disadvantages of pressure and flow generators

	Pressure generators	Flow generators
Advantages	• Protection from high airway pressures and barotrauma • Compensate for leaks	• Ability to maintain a constant tidal volume and minute ventilation even with significant changes in lung mechanics • Precise control of $PaCO_2$
Disadvantages	• Hypoventilation as a result of changes in lung mechanics	• Potential for high airway pressures and barotrauma • Inability to compensate for leaks

5

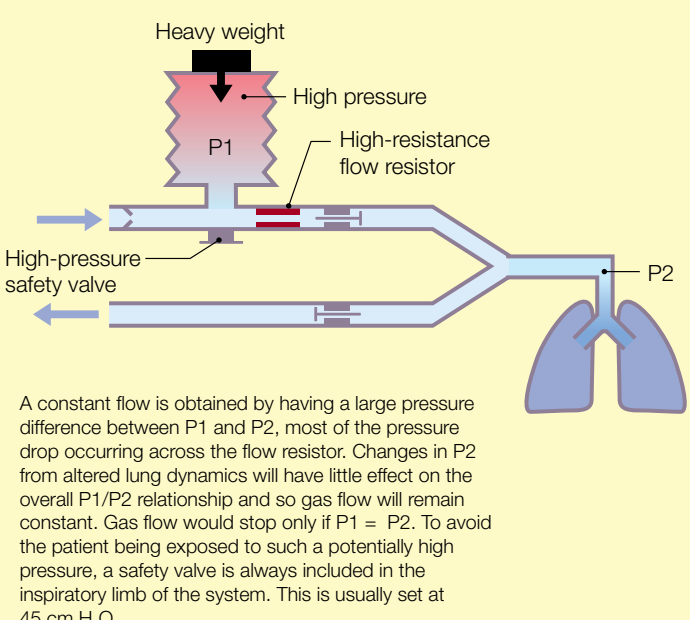
Constant pressure generator



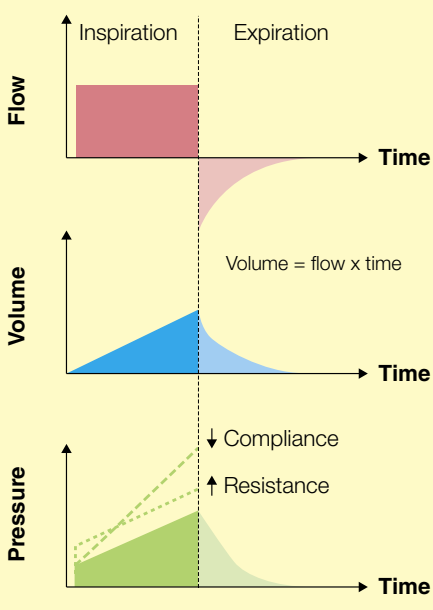


6

High-pressure, high-resistance flow generator



A constant flow is obtained by having a large pressure difference between P1 and P2, most of the pressure drop occurring across the flow resistor. Changes in P2 from altered lung dynamics will have little effect on the overall P1/P2 relationship and so gas flow will remain constant. Gas flow would stop only if P1 = P2. To avoid the patient being exposed to such a potentially high pressure, a safety valve is always included in the inspiratory limb of the system. This is usually set at 45 cm H_2O.



7

Single- and double-circuit ventilators

In a single-circuit ventilation system the anaesthetic gas is also the driving gas. A well-known example is the Manley ventilator, where the fresh gas flow set on the rotameters is divided into tidal volume (hence the term minute volume divider). The fresh gas flow powers the ventilator and is also delivered to the patient.

In a double-circuit ventilation system the anaesthetic gas and the driving gas are in separate circuits. The clearest example of this is a 'bag in bottle' or bellows ventilator. The anaesthetic gas is contained within the circuit and a set of bellows, which act as a reservoir. After delivering the tidal volume, the bellows refill during expiration. The bellows are contained within an air-tight cylinder and a separate high-pressure driving gas is used to pressurize the cylinder periodically, compressing the bellows and thereby generating inspiratory gas flow. Most modern circle/ventilator systems are double circuits.

Bellows can be of the standing or hanging variety. Standing bellows rise as they refill; hanging bellows are mounted inverted and fall as they refill. The advantage of standing bellows is that a leak of anaesthetic gases will be noticed by a failure of the bellows to rise to the full height. This is especially useful during low-flow circle anaesthesia. Hanging bellows are usually weighted at the base and entrain room air if there is a circuit leak.

The Nuffield 200 series of ventilators are functionally double circuit. Although there is no physical separation of the driving and fresh gas flow, the configuration of these ventilators ensures that fresh (anaesthetic) gases and driving gas do not mix. This is achieved by using a connector hose with an internal volume that is greater than the tidal volume.

Pulmonary physiology and the effects of intermittent positive-pressure ventilation (IPPV)

When a patient breathes spontaneously the expansion of the chest wall creates a negative pressure relative to atmospheric pressure between the visceral and parietal pleura. The transpulmonary pressure gradient created causes the lung to expand and fill. Thus, during inspiration the intrathoracic pressure is negative.

During IPPV the patient makes no respiratory effort and the transpulmonary pressure gradient required to expand the lung is generated by raising the airway pressure. With inspiration, intrathoracic pressure is positive. During artificial ventilation the mean intrathoracic pressure is increased compared with spontaneous ventilation and this has effects on the respiratory, cardiovascular, renal and endocrine systems. The effects of IPPV are wide ranging and must be viewed in the context of the position of the patient on the operating table and the effects of general anaesthesia.

Normal respiratory physiology and the effects of general anaesthesia

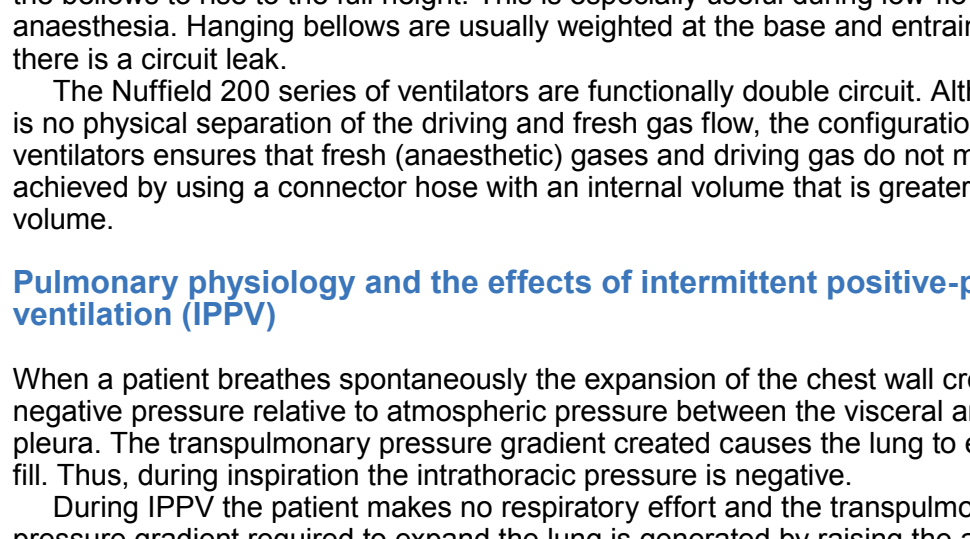
The primary function of ventilation is to move air in and out of the lungs so that carbon dioxide can be eliminated and arterial oxygenation maintained. In healthy individuals it is the requirement to eliminate carbon dioxide that is the prime determinant of minute ventilation. A normal tidal volume is about 500 ml in an adult (8 ml/kg); of this, about 150 ml (2 ml/kg) remains in the conducting airways (anatomical dead space), and the remaining 350 ml enters the alveoli and is available for gas exchange. The respiratory rate depends on the requirement for carbon dioxide elimination, but is usually 10−15 breaths per minute in adults. Effective ventilation maintains a normal arterial $PaCO_2$ of 4.5−5.5 kPa and an arterial oxygen tension (PaO_2) of 13.5 kPa in healthy young adults breathing room air.

Functional residual capacity (FRC): the various subdivisions of lung volume that can be determined by spirometry, whole-body plethysmography or helium dilution are shown in Figure 8. Of these, the most important for anaesthesia and the care of patients in the ICU is FRC. FRC is the end-expiratory volume of the lungs and is determined by the balance between:

- the elastic recoil of the lungs
- the outward recoil of the chest wall
- the respiratory muscle tone
- the position of the diaphragm.

FRC gradually reduces with age and is reduced on lying supine (by 500−800 ml) as a result of upward displacement of the diaphragm by the abdominal contents. This effect is enhanced in patients with abdominal distension or obesity. During general anaesthesia, reduction in diaphragmatic and chest wall tone and function lead to a reduction in FRC of about 20%. The effects of general anaesthesia and the supine position are additive, and can cause a significant reduction in FRC.

Lung volumes (70 kg adult)



Normal values

- Functional residual capacity 2.5 litres
- Inspiratory reserve volume 2.5–3.0 litres
- Tidal volume 0.5–0.6 litres
- Expiratory reserve volume 1.5 litres
- Residual volume 1.5–2 litres
- Vital capacity 3.5–5.5 litres
- Total lung capacity 6 litres

Minute ventilation 7.5 litres/minute
Alveolar ventilation 5 litres/minute
Vd/Vt 0.3

8

Closing capacity (CC) is the lung volume at which small airway closure begins. Closing volume is an alternative term that is equivalent to CC minus residual volume (RV). Normally CC is less than FRC, but they converge with increasing age. When FRC decreases to below CC, airway closure occurs during normal expiration and the resulting decrease in ventilation to areas of the lung distal to the closure worsens the ventilation-perfusion (V/Q) relationship. FRC usually remains greater than CC when supine until about 45 years of age but the additional reduction in FRC that occurs during general anaesthesia makes it more likely that FRC will fall below CC during anaesthesia. The resulting increase in V/Q mismatch leads to a decrease in arterial oxygenation, which is normally countered by increasing the inspired oxygen fraction.

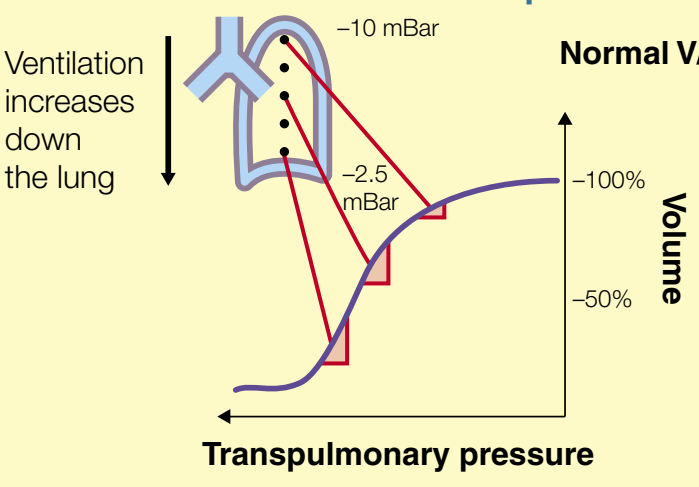
Distribution of ventilation and perfusion: during spontaneous ventilation in an upright position, distribution of ventilation and perfusion are not uniform throughout the lungs. Blood flow increases linearly from the top to the bottom of the lungs as a result of the effects of gravity on the low-pressure pulmonary circulation. The lower zones ventilate better than the upper zones because the dependent parts are on a more compliant (i.e. steeper) part of the pressure-volume curve. During normal inspiration, diaphragmatic contraction is enhanced in the parts of the diaphragm most displaced, aiding increased ventilation of the dependent parts of the lung (Figure 9).

Ideally, ventilation and perfusion at the alveolar level should be matched. Alveolar ventilation should equal perfusion and the V/Q ratio equal 1. In this situation no ventilation or perfusion is 'wasted'. However, the normal V/Q ratio is 0.8. The further the V/Q ratio deviates from 1, the more inefficient the ventilatory process becomes (Figure 10).

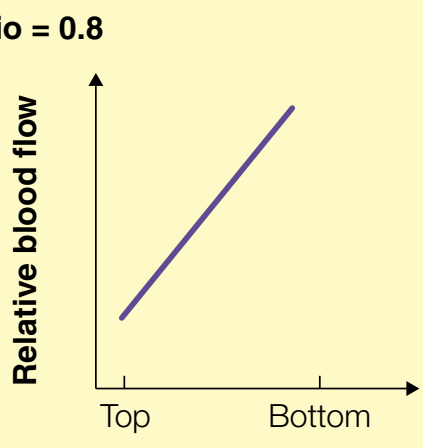
In the supine position, the gravitational effects on the lung are more limited, and perfusion is more homogeneous. However, the reduction of FRC, which is compounded by anaesthesia and the patient's position, leads to uneven ventilation because of airway closure and the tendency of the dependent portions of the lung to reduce in volume more than the superior parts (compression atelectasis).

Therefore, in the supine position (especially under anaesthesia) V/Q relationships worsen. This tends to cause hypoxaemia, which, because it is caused by a V/Q mismatch rather than a true shunt, can be reversed with added inspired oxygen.

Distribution of ventilation and perfusion in the lungs



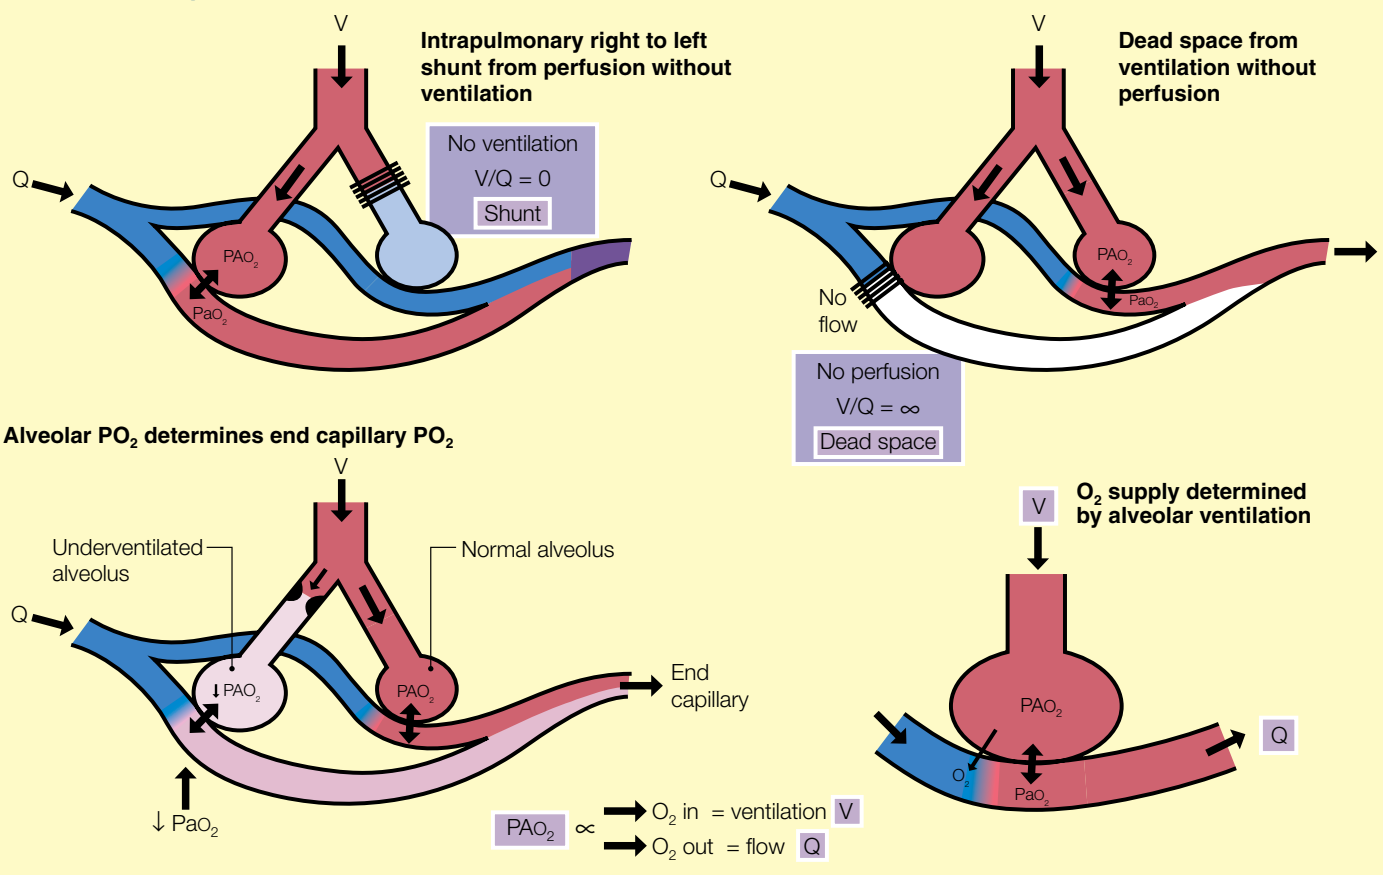
Ventilation increases from the apex to the base. Dependent parts of the lung are on a more compliant part of the pressure–volume curve



Perfusion increases on moving down the lung. The low-pressure pulmonary circulation is affected by gravity

9

Ventilation and perfusion



In an ideal alveolus capillary P_{O_2} (Pa_{O_2}) comes close to alveolar P_{O_2} (PA_{O_2}). PA_{O_2} is determined by the balance between the rate of O_2 uptake by the pulmonary capillaries (Q) and continued supply of O_2 by alveolar ventilation (V). The rate of O_2 removal is determined by the rate of O_2 consumption (metabolic rate). In an under-ventilated alveolus, the supply of O_2 is reduced. If O_2 uptake continues, the result is for PA_{O_2} to fall and so Pa_{O_2} will fall

10

Hypoxic pulmonary vasoconstriction (HPV): when the alveolar PO_2 or, to a lesser extent, the mixed venous PO_2 decreases, smooth muscle contraction occurs in small pulmonary arterioles. This diverts blood from unventilated areas to better-ventilated areas and helps minimize the effects of V/Q imbalance. Volatile anaesthetic agents as well as many vasodilators (e.g. sodium nitroprusside) inhibit HPV, worsening the effects of V/Q mismatching.

Respiratory effects of IPPV

Changes in distribution of ventilation: the preferential ventilation of the non-dependent parts of the lung in the anaesthetized, supine position is increased by IPPV. The non-dependent areas are more compliant than the dependent zones after induction of anaesthesia and muscle relaxation, and so preferentially expand in response to positive pressure. This effect is further exaggerated if the lungs have an increased density, as in the adult respiratory distress syndrome or in patients with cardiogenic pulmonary oedema. It is also compounded by compression of basal areas of the lung as a result of the upward displacement of the paralysed diaphragm.

Changes in distribution of perfusion: normal distribution of perfusion is usually maintained during IPPV. However, in the presence of high intra-alveolar pressures, compression of the alveolar capillaries occurs and flow stops. Capillary pressures are lower in the upper zones because of the effect of gravity on the low-pressure pulmonary circulation, and these zones are particularly vulnerable to increases in airway pressure. These preferentially ventilated upper zones now have much reduced flow and V/Q mismatch is further increased. This is more likely to occur when mean airway pressures are high and with the use of positive end-expiratory pressure (PEEP).

PEEP is the application of a residual positive pressure to the airway at the end of expiration instead of atmospheric pressure. This improves oxygenation by increasing FRC and thus reduces the effects of airway closure and lung volume reduction on V/Q relationships. PEEP may also reopen previously collapsed lung units and maintain their patency (alveolar recruitment).

Barotrauma is the result of excessive pressure gradients between alveoli and the interstitium, with rupture occurring. Air can spread along perivascular spaces into the mediastinum, pericardium, up into the neck, down into the abdomen or into the pleural cavity (pneumothorax). Risk factors include:

- large tidal volumes
- excessive inflation pressures, especially > 40 cm H_2O
- use of PEEP
- non-uniform lung disease
- increased airway resistance.

Recently, the term ‘volutrauma’ has been used in the ICU setting. This refers to overdistension of ‘normal’ areas of the lung by the high pressures required to inflate the diseased areas.

Other respiratory effects of IPPV: during general anaesthesia with intubation and ventilation, there is loss of the ability to cough and so secretions are retained. Inhaled anaesthetics and cold, dry gases inhibit ciliary activity in the bronchial tree, again leading to a tendency to retain secretions. In addition, if the anaesthetic gases are not warmed and humidified, the respiratory tract can be a major source of heat loss.

Cardiovascular effects of IPPV

The major effect of IPPV is to reduce cardiac output via a reduction in venous return. In most patients, this can be counteracted by fluid loading (e.g. 500−1000 ml crystalloid). There are additive effects on the pulmonary circulation and heart, but their relative contribution is thought to be minor, and significant changes occur only with high mean airway pressures.

Cardiac output: a decrease in cardiac output occurs when beginning IPPV, which can cause significant hypotension. The increase in mean intrathoracic pressure during inspiration with positive-pressure ventilation causes the low-pressure veins in the chest to be compressed. Cardiac output falls because of the reduction in venous return to the heart. The decrease in cardiac output and mean arterial blood pressure can be particularly marked in patients who are hypovolaemic or have limited cardiovascular reserve and is further worsened by PEEP. The expected fall in cardiac output can be reduced by prompt infusion of fluids to increase central venous pressure and maintain venous return.

Effects of IPPV on pulmonary vascular resistance and the heart: increased pulmonary vascular resistance occurs when airway pressures are high, from direct compression of alveolar capillaries. As pulmonary vascular resistance increases, there is an increase in right ventricular afterload and right ventricular end-diastolic volume. If end-diastolic volume becomes significantly raised, bulging of the intraventricular septum into the left ventricular cavity can occur, reducing left ventricular compliance and reducing left ventricular stroke volume. In addition, the increased wall tension in the right ventricle, coupled with a reduced arterial pressure, can compromise right ventricular perfusion in compromised patients. The final effect is right heart strain further augmenting a reduction in cardiac output. Paradoxically, in patients with existing heart failure, the increase in transpulmonary pressure transmitted to the thorax can occasionally help to off-load the left heart by reducing venous return from the pulmonary veins, thus reducing left atrial pressures. Left ventricular performance may then improve.

Other effects of IPPV

Renal: mechanical ventilation causes a reduction in urine volume, and thus sodium and water retention. A fall in renal perfusion pressure associated with the reduced cardiac output and a rise in renal venous pressure as a result of impedance of venous return, along with increased levels of antidiuretic hormone associated with IPPV, are thought to be important. An increase in sympathetic stimulation triggered by baroreceptors sensing the changes in pressure and flow may also contribute. The renal effects are persistent and are not fully reversed with fluid infusion or improvement in cardiac output.

Liver: the reduction in cardiac output and increased venous pressure leads to a fall in hepatic blood flow proportional to the drop in cardiac output. Hepatic blood flow may be reduced by up to 50% and hepatic metabolism is reduced. This can be reversed by infusion of fluid. The increased venous pressure caused by the positive intrathoracic pressure can cause hepatic venous congestion, and hypocapnia will lead to vasoconstriction.

Endocrine: antidiuretic hormone levels are increased during IPPV, with corresponding increases in renin and angiotensin levels. This contributes to salt and water retention.

Practical aspects of positive pressure ventilation

Adequate ventilation requires an adequate tidal volume and minute ventilation to be delivered, time for gas distribution and gas exchange to occur, and sufficient time for expiration to be completed. Adequate ventilation results in a normal $PaCO_2$ tension (4.5−5.0 kPa), and in anaesthetic practice this is usually estimated by the end-tidal carbon dioxide tension ($P_{E'}CO_2$). In patients with normal lungs the arterial $PaCO_2$ is about 0.5 kPa greater than the $P_{E'}CO_2$. $P_{E'}CO_2$ is measured from alveolar gases from all ventilating lung units with a spread of V/Q ratios. Units with high V/Q ratios have a reduced alveolar PCO_2 and so ‘dilute’ the gas from units with a V/Q ratio close to unity. This relationship is lost in patients with lung disease; arterial blood gas monitoring may be required in these patients. The minute volume and tidal volumes used should aim for peak airway pressures of 15−20 cm H_2O in most patients.

Arterial oxygenation is determined primarily by the inspired oxygen, which should never be below 30% (FiO_2 0.3) initially. The required inspired oxygen is determined by the saturation recorded by the pulse oximeter; 95% or greater is appropriate. After monitoring the effect of the initial settings in each patient, appropriate alterations can be made to suit the individual.

Initial IPPV settings for routine general surgical cases

Adults:

- flow generator mode of ventilation
- tidal volume 8−10 ml/kg
- respiratory rate 10−12 breaths/minute
- inspiratory/expiratory (I:E) ratio 1:2
- Fi_{O_2} 0.4 (40% oxygen)
- maximum airway pressure 30 cm H_2O.

If a circle absorber system is in use, an initial fresh gas flow of 6 litres/minute should be used.

A tidal volume of 8−10 ml/kg is appropriate for adults. An I:E ratio of 1:2 allows sufficient time for equilibration in inspiration and time for full expiration, in relation to the TC of normal lung. A starting inspired oxygen concentration of 40% helps to prevent a fall in PaO_2 and overcomes the expected increase in V/Q mismatch that occurs during IPPV. Barotrauma is avoided if peak pressures are kept below 30 cm H_2O.

Flow generators are the preferred method of ventilation in adults. A reliable and predictable tidal volume and minute ventilation can be achieved even when there are alterations in lung mechanics from pre-existing lung disease or when temporary peroperative changes occur related to the effects of patient positioning and surgery.

Children:
- pressure generator mode of ventilation
- inspiratory pressure 20 cm H_2O irrespective of weight
- respiratory rate 30−40 breaths/minute for neonates; 20−25 breaths/minute for infants; 15−20 breaths/minute for older children
- I:E ratio 1:2
- Fi_{O_2} 0.5 (50% oxygen).

Owing to their increased basal metabolic rate relative to their weight, neonates and infants have an oxygen requirement (6 ml/kg/minute) twice that of adults. As a result, they have a high carbon dioxide production, hence the need for a high respiratory rate. Young children also have a reduced FRC, high CC and relatively high airways resistance with low respiratory compliance. Their increased metabolic rate and relatively low FRC means they have limited oxygen stores and so their arterial oxygen saturation falls rapidly if ventilation is inadequate. Loss of respiratory gases as an air leak from around their uncuffed endotracheal tube is expected and indeed desirable. It provides evidence that the endotracheal tube is not so tightly fitting as to cause tracheal mucosal compression at the level of the cricoid ring. Pressure generators, which compensate for gas losses and limit peak pressures, are commonly used in paediatric anaesthesia. At puberty, differential growth of the cricoid ring and laryngeal aperture means that the larynx becomes the narrowest part of the airway as in adults, so cuffed tubes may then be used.

Safety issues

Detection of ventilator disconnection

Anaesthetized, paralysed patients are wholly dependent on the ventilator and the anaesthetist to keep them alive. In this respect, a paralysed patient is much more vulnerable than one who is breathing spontaneously. The anaesthetist should be alerted to a disconnection promptly by a disconnect alarm, which may also indicate when inadequate ventilation is occurring.

Disconnections can be sensed by:
- loss of the rhythmic increase in airway pressure
- reduction in expired gas volume
- loss of expired carbon dioxide.

Monitoring of airway pressures and exhaled CO_2 are part of minimum monitoring requirements during mechanical ventilation.

Airway pressure sensors are either aneroid gauges or, more commonly, electronic pressure transducers. The gauge the anaesthetist uses for monitoring and the alarm system are often separate devices. Airway pressure alarms detect an increase above a threshold pressure. If an increasing pressure that exceeds the threshold is not detected in the preset time, an alarm is sounded. This system does not normally detect a blocked endotracheal tube, but an alarm for the excessive inspiratory pressures generated in this scenario is usually incorporated in the same system.

Expired tidal volume or expiratory flow over time can also be measured. A minimum preset volume must be exhaled at a frequency above the preset minimum rate or the alarm will be triggered. Expired tidal volume is usually measured by integrating the expired flow signal.

Capnographs are fitted with limit alarms and often with apnoea detectors, which detect apnoea from the carbon dioxide waveform. In addition, respiratory movements are sometimes sensed via ECG leads and as a very late indicator, pulse oximeters will alarm if significant arterial desaturation occurs.

Ventilator checks

The anaesthetist is responsible for the state of the equipment he or she uses. It is expected that equipment is systematically checked before use. Although on occasion this may be delegated to trained assistants, the final responsibility lies with the anaesthetist. To this end, guidelines for machine checks have been issued by the Associaton of Anaesthetists of Great Britain and Ireland (Figure 11). With the increasing use of sophisticated, electronically controlled anaesthesic machines and ventilators, a ‘generic’ checklist must be used only with reference to the manufacturer’s suggested protocol for each machine.

Ventilator checks

- Ensure that ventilator tubing is correctly configured and securely attached
- Set the controls for use and ensure that an adequate pressure is generated during the inspiratory phase
- Check that the pressure relief valve functions
- Check that the disconnect alarm functions correctly
- Ensure that an alternative means to ventilate the patient’s lungs is available

Breathing Systems

Gordon W G French

Gordon W G French is Consultant Anaesthetist at Northampton General Hospital, UK. He qualified from Glasgow University and trained in Nottingham and Oxford. His research interests include the detection of silent myocardial ischaemia perioperatively, the use of starches for volume preloading in obstetric anaesthesia and modes of paediatric resuscitation teaching.

A 'breathing system' is the name given to apparatus that delivers and removes gas and vapour to or from a patient. The three main functions of the breathing system are:

- to supply adequate oxygen
- to remove carbon dioxide
- to supply adequate inhalational anaesthetic agent.

The perfect system has yet to be developed but the ideal breathing system should:

- be simple and safe
- deliver the intended mixture
- allow manual and intermittent positive-pressure ventilation (IPPV) in all age groups
- be efficient (able to use low gas flows)
- protect the patient from barotrauma
- be sturdy, lightweight yet compact
- be easy to scavenge
- be cheap.

Essential components of a breathing system

Tubing (hose): originally this was carbon-impregnated rubber (an antistatic design), corrugated to prevent kinking, but it was heavy and prone to perishing. Modern tubing is usually plastic, disposable or designed for single use, and often has a smooth inner bore that reduces resistance to airflow. Early systems had various means of inter-linking tubes, including tapered metal connectors that pushed into each other and screw mountings. These were manufactured in various sizes, with many systems being non-interchangeable, clearly a dangerous situation. The International Standards Organization (ISO.5356, 1987) and British Standard (BS 3849) recommend the following sizes for all breathing systems:

- 30 mm tapered connections for scavenging hose to breathing systems
- 22 mm taper for connections within breathing systems
- 15 mm connections between the breathing system and the endotracheal tube.

An upstream 'male' connector traditionally fits into a downstream 'female' part. The ISO 15 mm standard connector is cumbersome for small paediatric endotracheal tubes (2–6 mm internal diameter). Smaller, lighter 8.5 mm connectors may be used, which have adapters to connect to the 15 mm standard system. Tapered connections between plastic, metal and rubber can be 'locked' by giving them a slight twist after connecting. Systems designed for repeated use can usually be autoclaved, which does not affect their connectors. Single-use systems often distort if heated, making the connectors unsafe.

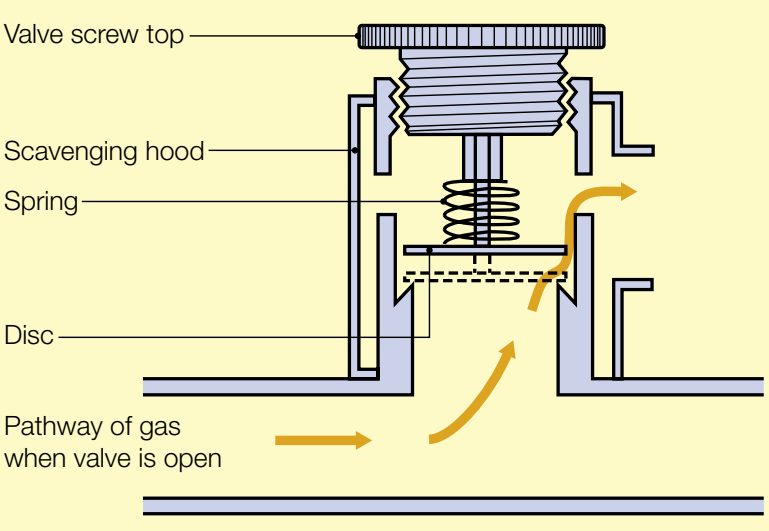
There is controversy among practising anaesthetists as to exactly what 'for single use only' means. Clearly it would be expensive to use a new breathing system for each patient, and almost certainly unnecessary. Many departments employ a cost-effective compromise by using a new disposable antibacterial filter for each patient, but only changing the actual breathing system weekly. It may be changed more often depending on clinical need (e.g. after use in a patient with known lung infection such as tuberculosis).

Reservoir bag: this stores fresh gas when the patient is exhaling and accommodates the high peak inspiratory flow rates during inspiration. Made of rubber or plastic, the common adult size is 2 litres and 0.5 litres for children, but some ventilators use other sizes up to 6 litres. The bag's motion allows observation of ventilatory patterns but does not reflect the tidal volume accurately. As the bag stretches, the pressure in its walls reaches a limit of about 40 cm H_2O (Laplace's law); further distension does not result in greatly increasing pressures. This partly protects the lungs from barotrauma should the breathing system outlet become obstructed, such as when the adjustable pressure-limiting (APL) valve is left fully screwed down. An open-ended reservoir bag is commonly used in paediatric circuits, allowing manual ventilation and assessment of the compliance of a child's lungs (e.g. Mapleson type F).

APL valve: this is a one-way, spring-loaded valve consisting of a thin, lightweight disc (made of hydrophobic material) held by an adjustable spring against knife-edged seating. This arrangement (Figure 1) reduces the area of contact between the disc and the seating, lessening any surface tension that condensed water vapour might create, causing the disc to stick. The disc prevents movement of air into the system when the patient inhales, but opens at low pressure (about 1 cm H_2O) to allow exhaled and surplus gas to be vented during expiration. When fully screwed down, modern valves open at about 60 cm H_2O positive pressure, acting as a safety feature.

Expired gases can be conveniently scavenged by surrounding the valve with a hood. If the valve is sucked open continuously by a faulty scavenging system, a huge increase in the dead space of the apparatus will result. The APL valve should be fully open during spontaneous respiration, partially closed during manual IPPV and fully closed during ventilator IPPV.

Cross-section of an adjustable pressure-limiting valve



1

Classification of breathing systems

The historical development of breathing systems was largely based on the intuition and practical experience of individual anaesthetists. As a result, there are many different systems. One classification based on function is described below.

Non-rebreathing systems

Non-rebreathing systems use one-way valves to separate inspired and expired gases. When the patient inspires, the expiratory valve closes and the inspiratory valve opens, allowing inhalation of fresh gas. There is usually a reservoir bag on the inspiratory limb, which provides enough gas for the maximum peak inspiratory flow rate (often > 30 litres/minute), and collects fresh gas when the inspiratory valve is closed in expiration. It may also allow for manual-assisted ventilation. Resuscitation devices commonly include a bag constructed of foam-lined rubber or silicone, which remains inflated in the resting state, in addition to a thin-walled reservoir bag. Manual ventilation is provided by squeezing this bag, which automatically refills from the oxygen inlet and reservoir bag when hand pressure is released. The fresh gas flow (FGF) should at least equal the patient's required minute volume. Examples are resuscitation devices such as the Ambu bag, Laerdal silicone resuscitator, drawover units and the 'Triservice' apparatus.

Rebreathing systems

In rebreathing systems, the inspiratory and expiratory gases can mix in the tubing and re-inhalation of expired gas can occur. Rebreathing refers to inhaling part or all of the previously exhaled tidal volume. In particular, it is the inhaling of previously exhaled carbon dioxide (i.e. alveolar gas) which is of most concern to the anaesthetist. A system is efficient if it can preferentially vent alveolar gas, retaining dead space (non-carbon-dioxide-containing) gas and thus use an FGF that approximates to the patient's alveolar minute ventilation. The extent of carbon dioxide rebreathing thus depends on the FGF flushing the expired gas away before the next inspiration. The normal respiratory cycle consists of an inspiration followed immediately by expiration, but there is then an expiratory pause. It is during this period that the FGF flushes the system. In 1954, Mapleson classified five commonly used systems according to their efficiency at eliminating expired carbon dioxide in spontaneously breathing patients (Mapleson systems A–E). An F system was added in 1975 (Figure 2).

The Mapleson classification of anaesthetic breathing systems and adaptations

Mapleson type		Recommended fresh gas flow	General points
System A **a** Magill **b** Lack **c** Parallel Lack		**Spontaneous** AMV (70 ml/kg/minute) **IPPV** 2–3 x AMV	**a, b, c** Efficient for spontaneous, not for IPPV Heavy, especially at patient end Unsuitable for children < 25 kg because large dead space **b** Lack: coaxial, APL and reservoir bag at machine end Inspiratory gases through outer (30 mm) tube Expiratory via inner (14 mm) **c** Parallel Lack: separate inspiratory and expiratory tubes
System B		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	FGF near patient end. Performs similarly in both modes. Seldom used
System C		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Similar arrangement to system B. The large-bore tubing to bag is shorter **a** Waters' 'to and fro' circuit: inefficient but small size and simplicity means useful for resuscitation and patient transfers **b** Waters' canister: heavy because incorporates a 1 lb soda lime container between bag and mask or ET tube Channelling occurs if incompletely packed. Nylon pot scourer compresses at bag end. Filter at patient end prevents soda lime dust movement. NB Filter to patient = dead space. Easily sterilized. Now little used. Superseded by circle absorber systems
System D **a** Bain		**Spontaneous** 2–3 x AMV **IPPV** AMV (70 ml/kg/minute)	Inefficient for spontaneous but good for IPPV Manley ventilator on spontaneous ventilation mode is a Mapleson D Safety problems include kinking of inner tube Disconnection of inner tube increases dead space. Both lead to hypoxia and hypercarbia **a** Bain: coaxial D. Length of tube does not affect properties (180–540 cm). FGF through inner tube (opposite to Lack) Ventilate with Penlon 200 replacing bag. Connecting tube long > 500 ml (usually 1 m) to prevent driving gas entering circuit. Lightweight, easy to scavenge. Ga in expiratory limb warm inspiratory gases
System E		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Used for children up to 30 kg. Low resistance, small dead space, lightweight, no valves. Inefficient but used for spontaneous and IPPV. Expiratory limb is reservoir and should be > V_T to prevent air entraining Ayre's T-piece: developed for neuro/cleft palate surgery
System F		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Jackson Rees modification. Reservoir bag allows rate and chest compliance to be monitored, ventilation by hand and continuous positive airway pressure application. Barotrauma and humidification a problem

AMV, alveolar minute volume; FGF, fresh gas flow; IPPV, intermittent positive-pressure ventilation; V_T, tidal volume

2

Mapleson A: classically describes the Magill system. The APL valve and any scavenging device make this system cumbersome at the patient's end. Lack solved this problem by creating a co-axial arrangement where the expiratory gases were carried up an inner hose to the APL and scavenging system, both of which were thus distant to the patient. However, this system is bulky, even though it is less weighty at the patient's end. In addition, if the inner tube breaks and this goes unrecognized, the system may become dangerous because carbon dioxide elimination is drastically reduced. It is also difficult to use with a ventilator. A parallel hose breathing arrangement (parallel Lack) eliminates this problem.

The Mapleson A system is an efficient system for spontaneous ventilation because it selectively vents alveolar gas through the APL valve. The first part of the exhaled tidal volume (non-carbon-dioxide-containing dead space gas) is retained in the system and is available for inhalation during the next breath. This efficiency is lost when the system is used for IPPV.

Mapleson B and C: in both systems the FGF, reservoir bag and APL are near the patient, creating a compact and portable system. However, they are both inefficient and only the Waters' 'to and fro' system is commonly used, mainly for patient transport and in postoperative recovery units.

Mapleson D: exhaled gas passes into a reservoir bag along with the fresh gas, so rebreathing occurs unless the FGF is high. The system is efficient for IPPV.

The Bain system is a coaxial version, which is particularly useful for limited-access surgery because of its light weight and the fact that the tubing can be lengthened without affecting the flow characteristics. The system can be connected to a ventilator by replacing the reservoir bag with tubing connected to a ventilator such as the Penlon Nuffield 200. The tubing should be of sufficient length to prevent the ventilator driving gas entering the breathing system (in practice > 500 ml or 1 metre of standard hose). In this system, the FGF is along a narrow internal tube (the opposite of the Lack system), and the expired gas moves along the outer tube, usefully heating up the dry FGF. It is vital that the inner tube is intact because disconnection leads to a huge increase in dead space and possible hypercarbia or hypoxia.

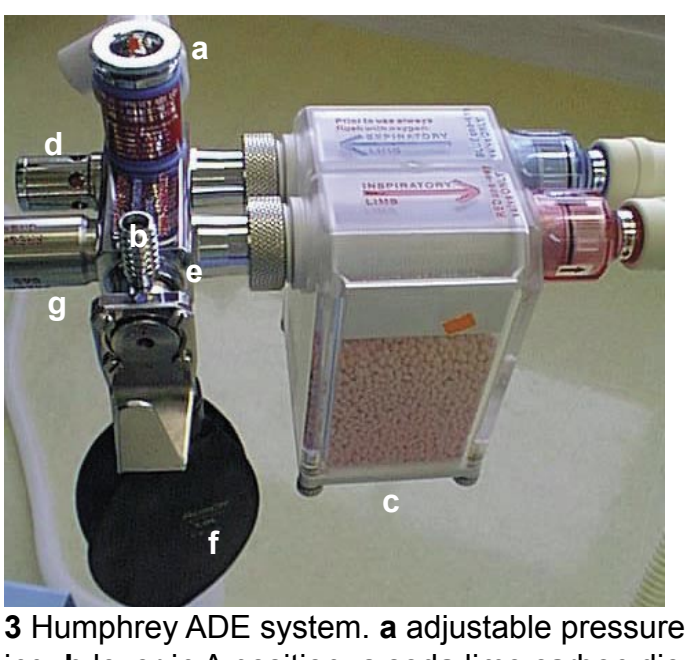
Mapleson E: the Ayre's T-piece is a valveless, lightweight system, with low internal resistance and dead space. In inspiration, gas is inhaled from both the inspiratory and expiratory limb. The volume of the expiratory limb needs to be at least equal to the tidal volume or air may be entrained. If it is too large, then rebreathing can occur because expired gas may not have vented to air before the next inhalation. Occluding the outlet intermittently allows IPPV.

Mapleson F: adding an open-ended reservoir bag to the expiratory limb of the Ayre's T-piece allows manual control of ventilation, observation of breathing and assessment of lung compliance. Some continuous positive airway pressure (CPAP) is also achieved with the system during spontaneous respiration, which, in an infant, may help to increase the functional residual capacity. Scavenging is a problem for both the Mapleson E and F systems. The routine use of capnography allows the FGF to be tailored precisely to achieve normocapnia in individual patients for all these systems.

Humphrey ADE system (Figure 3) is one of a number of hybrid systems that has become popular. It is a low-flow multipurpose system that appears to combine the best of the Magill, Lack and T-piece systems but not their disadvantages. It is cost effective in all modes, being more efficient than the Magill for spontaneous ventilation. The 15 mm, smooth-bore tubing has one-quarter of the resistance to flow of 15 mm corrugated tubing, which allows use in adults and children; 8.5 mm tubing is available for neonates. The reservoir bag, APL, scavenging shroud and a pressure-limiting valve are all located on the 'Humphrey block'. The system tubing connects to the patient via a symmetrical Y-piece, which probably accounts for much of its efficiency as it produces less turbulence than the conventional Magill–patient interface. One lever allows conversion from A mode to E mode, with only a slight increase in FGF being required to eliminate rebreathing. In E mode, the reservoir bag and APL are isolated from the system, and the expiratory tubing acts as the reservoir limb of a T-piece. This is open to the atmosphere via a port on the block to which a bag squeezer ventilator such as the Manley Servovent or Penlon Nuffield 200 or 400 can be attached. The D mode could be engaged by simply attaching a reservoir bag and APL to this port for spontaneous ventilation, but this is much less efficient than the A mode.

The APL valve provides positive end-expiratory pressure of 1 cm H_2O without increasing the airway resistance of the apparatus. The APL valve does not have to be screwed down for IPPV, except if used in the A mode. However, there is a long orange valve seat stem that can be temporarily held down instead. This also moves slightly during spontaneous respiration and gives a visual indication of respiratory movement. A separate 60 cm H_2O pressure-limiting valve lies behind the APL valve on the block. This is always in-line, whatever mode is being used. The system can be fixed on to the anaesthetic machine via a locking nut. A 500 g soda lime canister (lifespan 12 hours), which has a low resistance to flow and is autoclavable, can be fitted in front of the block. This circle system arrangement requires no other alterations in FGF for adults or children.

The entire system is MRI compatible, being made of plastic and brass. In addition, tubing lengths of over 3 m can be used without compromising its function. The main disadvantages are that it protrudes out of the anaesthetic machine, is heavy and can be knocked, which theoretically could fracture old anaesthetic machine outflow pipes.



3 Humphrey ADE system. **a** adjustable pressure limiting valve with scavenging; **b** lever in A position; **c** soda lime carbon dioxide absorber; **d** pressure relief (60 cm H_2O) valve; **e** port for ventilator; **f** reservoir bag; **g** fresh gas flow. Fresh gas flow: A mode (lever up) = 50 ml/kg/minute; E mode (lever down) = 70 ml/kg/minute. Children start at 3 litres/minute.

Systems using carbon dioxide absorbers

The circle system (Figure 4) was first described in the 1920s. It uses soda lime to absorb exhaled carbon dioxide. Partial rebreathing of other exhaled gases can thus be undertaken, depending on the arrangement of the components and the FGF.

Circle systems can be classified as follows:

- semi-open – no rebreathing, very high FGF, APL valve wide open
- semi-closed – rebreathing occurs, low flow, APL valve partly closed
- closed – FGF inflow exactly matches uptake by patient; complete rebreathing of exhaled gases after carbon dioxide uptake and APL valve fully closed.

A circle system consists of:

- FGF source
- inspiratory and expiratory unidirectional valves
- inspiratory and expiratory corrugated tubes
- a Y-piece connector
- an APL valve or pop-off valve
- a reservoir bag
- a canister containing a carbon dioxide absorbent.

Fresh gas enters the circle by a connection from the common gas outlet of the anaesthetic machine. Various arrangements of components are possible, but there are three golden rules to prevent carbon dioxide rebreathing.

- A unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs of the circuit. These valves commonly have a clear plastic cover so that their correct movement can be observed during use.
- The FGF cannot enter the circuit between the patient and the expiratory valve.
- The APL valve cannot be located between the patient and the inspiratory valve.

The most efficient circle system has the unidirectional valves near the patient and the APL valve just downstream from the expiratory valve. This arrangement conserves dead space gas and preferentially eliminates alveolar gas. The advantages and disadvantages of a circle system are listed in Figure 5.

Nitrogen washout – at the start of anaesthesia, non-nitrogen-containing gas (unless medical air is being used) is inspired and body nitrogen passes into the lungs. This effectively reduces the oxygen concentration in the alveoli and circle system, producing a potentially hypoxic mixture. The use of high flows of gas at the start of anaesthesia can 'washout' this nitrogen. Pre-oxygenation with 100% oxygen for 7–10 minutes is also effective and can theoretically then allow low circle FGF to be used from the start. Basal metabolic oxygen requirements are about 250 ml/minute, but to allow for leaks in the circle and patient variability, 500 ml/minute oxygen is the minimum recommended flow rate. 'Low flow' anaesthesia is usually regarded as less than 1 litre/minute FGF.

The uptake of volatile agents is highest initially. Fast FGF inflows and large minute volumes produce fast induction of anaesthesia as well as facilitating denitrogenation. As equilibrium is reached, the expired concentration of volatile agent begins to reflect the inspired value, and flows can be reduced. The exhaled gases are added to the fresh gas and have a dilutional effect on the concentration of oxygen and vapour, which will be proportionally greater at low flows. A potentially hypoxic alveolar concentration of oxygen can develop as the FGF reduces. Using an inspired oxygen concentration of 50% to prevent these low oxygen levels in the circle was customary before the advent of in-line gas/vapour analysers. However, this was associated with an increased chance of awareness if the inspired volatile concentration was not increased to compensate for the lower inspired nitrous oxide and volatile concentrations.

Vaporizers can be placed outside (VOC) or inside (VIC) the circle (Figure 6). Most modern vaporizers tend to be outside the circle (e.g. Back bar units such as a TEC vaporizer) and are accurate at low flows. With this set-up, the concentration of volatile gas in the circle is reduced with increased patient uptake and low FGF (due to the dilutional effect of exhaled gas), until uptake reduces and equilibration begins to occur. With a vaporizer in the circle (e.g. Goldman vaporizer), both the fresh and exhaled gas (which already contains vapour) pass through the vaporizer. When the FGF is low and alveolar ventilation high, the concentration of volatile will rise. Thus the concentration of the alveolar and circle vapour is a function of ventilation. In spontaneous ventilation, with deepening anaesthesia and depression of ventilation, the concentration of volatile gas will fall and result in the patient becoming lighter, a useful safety feature. However, low flow controlled ventilation may result in high levels of volatile gas.

Future developments in circle technology may incorporate the VIC arrangement but use a system of vapour injectors instead of the vaporizer. This would be linked to a feedback mechanism incorporating circuit vapour analysis.

Carbon dioxide absorption – closed or semi-closed circle systems require carbon dioxide absorption to make rebreathing possible. Desirable features of a carbon dioxide absorption mechanism are lack of toxicity (intrinsic or with common anaesthetics), low resistance to air flow, low cost, ease of handling and efficiency. Soda lime and baralyme are the two formulations commonly used for carbon dioxide absorption (Figure 7). Both need water but because baralyme contains water as a barium hydroxide octohydrate salt it performs better in dry climates. Soda lime (but not baralyme) is capable of some regeneration after exhaustion. Maximum absorbency of both systems is 26 litres of carbon dioxide per 100 g absorbent.

Dyes (acids or bases) are also added, which change colour as the hydrogen ion concentration changes:

- ethyl violet (colourless to violet; fluorescent light deactivates it)
- phenolphthalein (white to pink)
- Clayton yellow (red to yellow)
- ethyl orange (orange to yellow)
- mimosa z (red to white).

The chemical reaction in soda lime is:

$CO_2 + H_2O \rightleftarrows H_2CO_3$

$H_2CO_3 + 2NaOH\ [KOH] \rightleftarrows Na_2CO_3\ [K_2CO_3] + 2H_2O + heat$

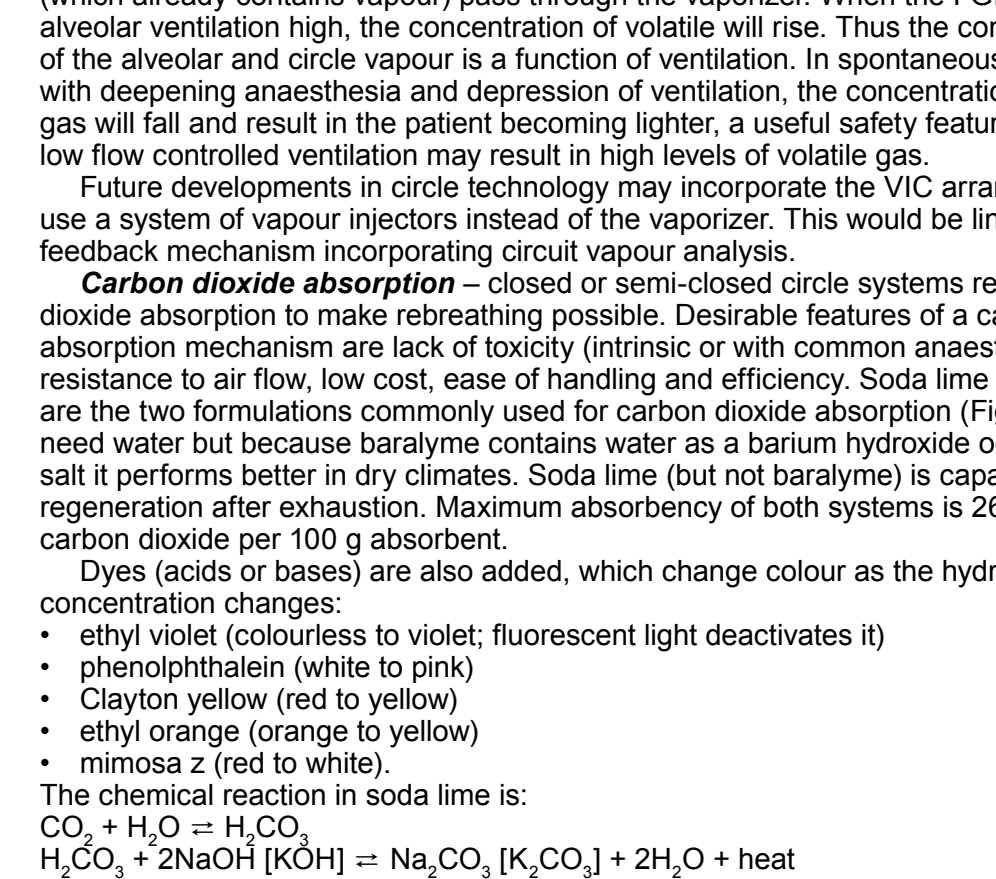
$Na_2CO_3\ [K_2CO_3] + Ca(OH)_2 \rightleftarrows CaCO_3 + 2NaOH\ [KOH]$

Some carbon dioxide reacts directly with calcium hydroxide but this is much slower. In baralyme the carbon dioxide acts directly with barium hydroxide and much more water is released. In the UK, the size of granules is 4–8 mesh (a compromise between surface area for absorption and air flow resistance). Mesh refers to the number of openings per linear inch in a sieve through which the granules pass. A 4-mesh screen indicates four quarter-inch openings per linear inch.

Soda lime and baralyme are not inherently toxic, but at low flows intrinsically produced acetone can accumulate and has been linked to nausea and vomiting. Carbon monoxide can also accumulate at low flows of dry gas (e.g. oxygen running overnight) leading to the formation of carboxyhaemoglobin.

The volatile agent trilene degrades into dichloroacetylene (a neurotoxin causing cranial nerve damage and encephalitis) and phosgene (a potent pulmonary irritant causing adult respiratory distress syndrome).

Sevoflurane and halothane are slightly unstable in soda lime, the rate of degradation increasing with temperature. Sevoflurane degrades into several compounds. Compound A (a vinylether) has been associated with lung haemorrhage and renal tubular necrosis in rats, but neither compound has been shown to cause problems in humans. Many of these problems are resolved by flushing the system regularly.



Properties of a circle system

Advantages	Disadvantages
• Heat/moisture conservation • Easy scavenging • Reduced cost • Small dead space • Good for long cases	• Multiple connections • Valves can stick • Open – leads to rebreathing • Closed – leads to asphyxia • Bulky • Inefficient for short cases • Soda lime changeover a hazard • Gas analyser necessary for accuracy • Potential for infection

5

Properties of vaporizers

Inside the circle	Outside the circle
• Low internal resistance • Low efficiency desirable • Higher concentrations at low fresh gas flow	• High internal resistance (plenum) • High efficiency desirable • Lower concentrations at low fresh gas flow (diluted)

6

Properties of soda lime and baralyme

Soda lime	Baralyme
• Calcium hydroxide (94%) • Sodium hydroxide (the catalyst) (5%) • Potassium hydroxide (1%) • Silica (calcium and sodium silicate harden it and reduce dust formation)	• Calcium hydroxide (80%) • Barium hydroxide (the catalyst) (20%) • More stable so does not contain silica • Denser and 15% less efficient than soda lime

7

System checks

All systems should be checked visually for broken parts and disconnections and a push-and-twist connector test performed. In addition, there are checks specific to individual systems.

- Occluding Mapleson types B and C causes their reservoir bags to fill, testing the air-tightness of the system. Releasing the valve causes the bag to deflate if the valve is functioning normally.
- The Bain system inner tube can be tested in two ways. Occluding the end of the inner tube causes the rotameter bobbin to dip and the pressure alarm/valve to blow if there are no leaks/disconnections up to that point. Occluding the patient end of the system will fill the reservoir bag, testing overall air- tightness. Releasing the occlusion causes the bag to deflate, then continue to empty as a result of the negative pressure caused by the Venturi-effect of the fast FGF leaving the inner tube. The connection of the inner tube can also be visually inspected because the outer corrugated tubing is often made from transparent plastic. This outer tubing may also be temporarily disconnected and a secure inner tube connection confirmed.
- To carry out the low-pressure circle leak test, the end of the system should be occluded and the APL valve closed off. The system is filled using the oxygen flush until the airway pressure gauge registers 30 cm H_2O. The pressure should remain at 30 cm H_2O if no leaks are present.

Cleaning, Disinfection and Sterilization of Equipment

Duncan Parkhouse
Jonathan Warwick

Duncan Parkhouse is a Military Anaesthetic Trainee. He joined the Royal Army Medical Corps as a medical cadet while a medical student at University College Hospital, London. During his anaesthetic training he has spent time at both military and NHS Hospitals including St Mary's Hospital, the Brompton Hospital and the National Hospital for Neurology and Neurosurgery, London.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

Hospital-acquired infections have significant implications for the morbidity and mortality of patients as well as for the economics of health care. The protection of patients and medical staff from medical equipment that has come into contact with patients or their body fluids, requires the adoption of various processes enforceable by law. Changes in these laws and guidelines, published by the Department of Health and the Medical Devices Agency, are expected in the near future. One of the reasons for the introduction of new guidelines is the development of new variant Creutzfeldt–Jakob disease, which is resistant to the standard methods of decontamination used in hospital sterile services departments.

Contamination is the soiling or pollution of an inanimate object with harmful, potentially infectious, material. In the clinical setting, this is most likely to be organic material or microorganisms. Contamination may place the patient at risk and may adversely affect equipment.

Decontamination is a method used to remove contamination and prevent microorganisms reaching a susceptible site in large enough numbers to initiate infection or other adverse effects. The three methods of decontamination routinely used are cleaning, disinfection and sterilization. The method of decontamination chosen takes into account the infection risk from the reprocessed piece of equipment. The risk is dependent on:

- the amount of contact the patient has with the piece of equipment (i.e. how invasive)
- the susceptibility of the patient (i.e. immunocompromised, potential hypersensitivity)
- the nature, extent and amount of microbial contamination on the piece of equipment (the bio burden).

The type of equipment and its intended use determine the method of decontamination used (Figure 1). The manufacturer should provide instructions for cleaning, disinfection and sterilization techniques that are effective without affecting the performance of the equipment.

It is essential that records are kept to demonstrate the number of times an item has been decontaminated and the effectiveness of each process. The documentation should allow patients to be traced in the event of any malfunction in the decontamination process.

Risk of contamination for equipment and suggested decontamination process

Risk	Application of equipment	Recommendation
High	• In close contact with a break in the skin or mucous membrane • For introduction into sterile body areas	Sterilization
Intermediate	• In contact with mucous membranes • Contaminated with particularly virulent or easily transmissible organisms • Before use on immunocompromised patients	Sterilization or disinfection (Cleaning may be acceptable in some agreed situations)
Low	• In contact with healthy skin • Not in contact with patient	Cleaning

1

'Single use' equipment

Manufacturers should state in the product literature any restrictions on the number of re-uses. Any device deemed by the manufacturer as unsuitable for reprocessing is labelled 'single use'. Devices labelled 'single patient use' may be used for an extended period of time or intermittently on the same patient. Users who disregard the manufacturer's guidelines, for example by reprocessing single use items or reprocessing more than the recommended number of times may be transferring legal liability for the safe performance of that product from the manufacturer to themselves or the organization for which they work.

Many anaesthetic departments routinely use disposable anaesthetic breathing systems marked as single use for extended periods with multiple patients. The wisdom of this practice is the subject of much controversy. The advantages of these breathing systems include safety (often pre-assembled with fewer opportunities for connection errors by the user), lightweight and low cost if used on several patients. The disadvantage is that this practice may contravene the manufacturer's recommendation for single use only and risk transmission of infection. The responsibility for use of equipment marked single use then lies with the hospital. Departments of anaesthesia should have an operational policy on the management of breathing systems marked for single use. This may include:

- the use of a new bacterial (heat and moisture exchanger type) filter for each patient
- change of all breathing systems weekly
- change of breathing system following use on a patient with known or suspected lung infection
- change of breathing system whenever there is visible contamination from blood or body fluids.

Cleaning

Cleaning physically removes contaminants without necessarily destroying microorganisms. It removes organic material and is required before disinfection or sterilization.

Manual cleaning

Manual cleaning does not disinfect. It should be used only when other mechanical methods are inappropriate or unavailable.

Immersion – wearing appropriate protective clothing, the cleaner should submerge the device in compatible water/detergent solution at the correct dilution and not exceeding 35°C. It is important to ensure that the cleaning solution reaches all surfaces of the device, including lumen surfaces. Endoscopic equipment that may be totally immersed for cleaning is marked with a blue line, usually around the eyepiece adjacent to the focussing ring. The device should be brushed or agitated to remove any visible contaminants. The device should be thoroughly drained and rinsed in clean water. This method is generally satisfactory for the routine cleaning of laryngoscopes between patients. Disinfection with an alcohol spray is then commonly used.

Non-immersion – wearing appropriate protective clothing, the cleaner should immerse a cleaning cloth into the detergent solution and wring it out. The equipment should be cleansed by wiping its surfaces. The surfaces should be hand dried using a cloth, hot air dryer or drying cabinet. This method of cleaning is often used for electrical or electronic equipment which cannot be immersed in water.

Mechanical cleaning

Mechanical cleaning uses automated washers to clean equipment and often combines cleaning with disinfection.

Thermal washer – cleaning occurs by continually spraying the equipment with water and detergent during a timed cycle. During the first process, cleaning occurs at 35°C. The second wash heats the surface of the equipment to a minimum temperature of 71°C for a minimum of 3 minutes, 80°C for 1 minute, or 90°C for 1 second to disinfect it.

Chemical washer – the first part of the cleaning process is the same as the thermal washer. Disinfection occurs by exposing the equipment to an approved disinfectant for a particular period of time at less than 60°C. The residue disinfectant is then removed by a rinse cycle.

Ultrasonic cleaners are often incorporated into washer disinfectors. These work by rapidly forming bubbles in the liquid, which immediately collapse (cavitation). This cavitation agitates the liquid, producing a highly effective cleaning system. The process does not disinfect.

Disinfection

Disinfection is used to reduce the number of viable micro-organisms, but it may not kill all microbial agents such as some viruses and bacterial spores.

Low temperature steam disinfection

Low temperature steam disinfection is also known as pasteur-ization. It kills most vegetative microorganisms and viruses by exposure to moist heat. The equipment is exposed to dry saturated steam at a temperature of 73°C for at least 10 minutes at below atmospheric pressure. The low temperature steam kills vegetative microorganisms and some heat-sensitive viruses. It cannot be used for sealed, oily or greasy pieces of equipment or those with sealed cavities due to the variation in pressure.

The advantages of this system are its broad spectrum of disinfection, it is non-toxic, non-corrosive and the equipment is relatively safe and simple to use. The disadvantages are that it requires a trained operator and that much equipment is unsuitable for disinfection in this way. The capital cost of the disinfector is high and the equipment is fixed and not portable.

Boiling water disinfection

Boiling water is an effective disinfectant against many microorganisms. Immersing a piece of equipment in soft water and boiling at 100°C for at least 5 minutes produces disinfection. Boiling inactivates most non-sporing microorganisms, fungi, viruses and some heat-sensitive spores. This method is not used if a better method is available. It is unsuitable for heat-labile pieces of equipment, hollow or porous items into which the water will not penetrate, or tubing over 1 metre in length.

The advantages are that boiling water has a broad disinfecting effect. The process is non-toxic and inexpensive. The disadvantages are that boiling water is a potential cause of injury. Following disinfection, items are wet and unfit for immediate use and must be allowed to dry and cool, which may allow recontamination. There is also no method of checking the efficacy of the process.

Washer disinfectors

Washer disinfectors are described above. They inactivate all microorganisms except bacterial spores and some heat-resistant viruses. They are unsuitable for equipment that may be heat labile or corroded by chemical disinfectant, and for hollow or porous equipment that does not allow all surfaces to come into contact with the chemical disinfectant or heat.

These methods are safe for the operator. There is minimal handling of the equipment by staff and therefore a low risk of recontamination. Another advantage is that they combine cleaning and disinfection. The disadvantages are the high cost of the equipment and the requirement for trained staff.

Liquid chemical immersion

Liquid chemical immersion relies on good contact between the chemical disinfectant and the equipment. The equipment therefore requires thorough cleaning beforehand. It is then immersed in the chemical disinfectant, ensuring that the disinfectant reaches all surfaces. The equipment is immersed for a predetermined time depending on the chemical disinfectant used. The spectrum of activity also depends on the type of chemical disinfectant used (Figure 2).

The method is unsuitable if the corrosive nature of the chemical disinfection may damage the equipment or if the equipment has areas inaccessible to liquid. It requires trained staff wearing protective clothing. It is potentially toxic, corrosive or volatile. Also, the equipment may have to be hand dried after disinfection allowing possible recontamination.

Equipment disinfectants commonly used and their spectrum of activity and physical properties

Disinfectant	Microbiological activity					Stability	Inactivation by organic matter	Corrosive/ damaging matter	Irritant
	Spores	Mycobacteria	Bacteria	Viruses[1] Enveloped	Viruses[1] Non-enveloped				
• Glutaraldehyde 2%	+++ (slow)	+++	+++	+++	+++	Moderate (fixative)	No	No	Yes
• Peracetic acid 0.2–0.35%	+++	+++	+++	+++	++	Poor (< 1 day)	No	Slight	Slight
• Alcohol (ethyl alcohol) 60–80%	None	++	+++	+++	++	High	Yes (fixative)	Slight	No Flammable
• Peroxygen compounds	None	+	+++	+++	++	Moderate (7 days)	Yes	Slight	No
• Chlorine-releasing agents >1000 ppm average Cl_2	+++	+++	+++	+++	++	Poor (< 1 day)	Yes	Yes	Yes
• Clear soluble phenolics 0.6–2%	None	+++	+++	+	None	Good	No	Slight	Yes
• Quarternary ammonium compounds	None	Variable	Moderate	+	+++	Good	Yes	No	No

[1] Activity varies with concentration of product.

Sterilization

Sterilization is used to produce an object free from viable microbial organisms including viruses and bacterial spores. There are several types of sterilizer (Figure 3).

Steam

When steam is pressurized it reaches a temperature greater than that of boiling water at atmospheric pressure and destroys or renders non-viable, bacteria, viruses and their spores. For this process to be effective, direct contact between the pure dry saturated steam and the object being sterilized is required at the specific temperature and in the absence of air. The temperature reached by the object determines the time required for sterilization. The lowest temperature recommended is 121°C for 15 minutes; the highest temperature of 134°C requires only 3 minutes.

This process is effective against all microorganisms with a significant safety factor. Problems occur with wrapped items because all air must be removed. To overcome this, porous load sterilizers are used, which incorporate a vacuum pump. Air is removed before steam is added. This is the most commonly used method for sterilization in hospitals today (Figure 4). However, it cannot be used for any material that cannot withstand the temperatures or pressures required for sterilization (e.g. thermo-labile plastics, fibre-optic endoscopes).

The advantages of this process are that steam is non-toxic, non-corrosive and a highly effective sterilizing agent. This system can be incorporated into a fully automated process on a large scale, coping with a high turnover of equipment. Disadvantages are that the operator must wear protective clothing to avoid direct contact with the steam.

Different types of hospital sterilizers

Types of sterilizer	Use	Minimum time / temperature
• Steam sterilizer		
Porous load	Wrapped instruments, dressings, utensils	134–138ºC for 3 minutes
Fluid cycle	Fluids in sealed containers	121–124ºC for 15 minutes,
	or 115ºC for 30 minutes	
Unwrapped instruments	Unwrapped instruments and utensils	134–138ºC for 3 minutes
• Hot air sterilizer	Oils, powders, heat-resistant instruments that must be kept dry	160ºC for 2 hours
• Low temperature steam formaldehyde sterilizer	Heat-sensitive equipment	73ºC for 3 hours
• Ethylene oxide	Heat-sensitive equipment	Various temperatures and times

Dry hot air

In this process, sterilization takes place by raising the ambient temperature. Typical processes consist of 160°C for 2 hours, 170°C for 1 hour, 180°C for 30 minutes. If all the items are completely clean and dry before this sterilization process starts, then all microorganisms will be killed. However, it cannot be used for materials that would be damaged by these temperatures (e.g. rubber, plastic).

Dry heat can be used to sterilize stable powders, waxes and non-aqueous liquids. It is also effective for non-stainless metals, hollow needles and glass syringes. However, the sterilization time is long compared with other methods, and items have to cool slowly afterwards. Many pieces of equipment cannot withstand these high temperatures for the allocated time.

Ethylene oxide

Ethylene oxide at ambient pressure and temperature vaporizes easily and thus has good penetrative properties. It is also non-corrosive and has a wide spectrum of activity against bacteria, spores, fungi, viruses and other living cells. Sterilization is usually carried out at 20–60°C for 2–24 hours.

Ethylene oxide is most often used under three different conditions:

- normal atmospheric pressure using undiluted ethylene oxide – the gas is very flammable, and so is often diluted to reduce explosion risk
- ethylene oxide with a diluent gas such as nitrogen at a pressure of 2 bar
- ethylene oxide diluted with carbon dioxide at a pressure of 6 bar.

This process should not be used if heat sterilization is possible. Organic material has a marked protective effect and therefore prior cleaning is essential. Ventilatory or respiratory equipment is contraindicated. Ethylene oxide does not penetrate plastic; therefore items must be wrapped in sterilization paper.

Ethylene oxide is a highly effective sterilizing agent. In particular it is used to sterilize single use medical items that would be damaged by the excessive heat used in other sterilization methods. Disadvantages of ethylene oxide are that it is toxic and long periods of aeration are required after sterilization therefore turn-around time is long. The process is expensive and there are significant health and safety issues concerning ethylene oxide and the equipment required to use it. Because of this, ethylene oxide is not often used in hospitals but is commonly used by industry.

Low temperature steam and formaldehyde

This process uses a combination of dry saturated steam and formaldehyde, which together kill vegetative bacteria, spores, fungi and most viruses. Objects are placed in the sterilizer to allow maximum contact with the steam. Air is actively removed from the container and replaced by dry saturated steam at 73°C at subatmospheric pressure. Formaldehyde is entrained as the steam enters the sterilizer.

The subatmospheric pressure may damage hollow objects. Formaldehyde may be corrosive with certain materials and some fabrics may absorb formaldehyde. This method cannot be used for items contaminated with body fluids, because the proteins in the fluids congeal and produce hard fixed deposits.

Advantages of the process are that it can provide dry, packaged items in a sterile form and the process is fully automated. Disadvantages are that the process is complex and formaldehyde is toxic, irritant and possibly mutagenic. The equipment required is also expensive, with the added problem of toxic waste products.

Irradiation

Irradiation uses γ rays or accelerated electrons. A dose greater than 25,000 Gray produces sterility. Irradiation is often used to sterilize single use items on an industrial scale. It has a broad spectrum of activity. Irradiation can cause significant degradation of materials and is unsuitable for the resterilization of hospital equipment.

The advantages are that it is reliable on an industrial scale for heat-labile pieces of equipment. However, irradiation can damage equipment particularly on re-exposure. Monitoring the process and the required safety equipment is expensive.

Special circumstances

Recent work has identified that the prion strain causing bovine spongiform encephalopathy (BSE) in cattle has infected humans, manifesting itself as a novel human prion disease, new variant Creutzfeldt–Jakob disease (vCJD). The abnormal prion protein is a new class of transmissible agent that demonstrates resistance to the standard methods of sterilization used in hospital sterile services departments.

Affected individuals accumulate prion protein in lympho-reticular tissues (e.g. appendix, tonsils), as well as in the CNS. The number of people incubating the disease is unknown, and there are concerns that prions might be transmitted iatrogenically via contamination of surgical instruments. Such risks remain unquantified, and there have been no identified cases involving vCJD transmission via surgical instruments. All neurosurgical instruments used on patients suspected of carrying vCJD are destroyed. However, there are significant implications for the safety of surgical instruments in ENT and other surgical practice.

The Spongiform Encephalopathy Advisory Committee (SEAC) has recommended that, where feasible, the move to single use instruments is appropriate. From January 2001, the Department of Health requires tonsillectomy and adenoidectomy to be performed using single use instruments in England and Wales. The recommendations are that instruments used to dissect or cut lymphoid tissue are to be disposed of. Anaesthetic equipment may also provide theoretical risk for prion disease transfer. This risk is as yet unquantified and accepted practice is continuing to evolve. It is likely that, in the near future, anaesthetic practice will change to incorporate disposable, single patient use equipment wherever possible (e.g. disposable laryngoscope blades and laryngeal mask airways).

Critical Incidents: The Cardiovascular System

Joy E R Beamer
Jonathan Warwick

Joy E R Beamer is a locum Consultant Anaesthetist at the Horton Hospital, Banbury, UK. She was recently awarded a CCST in Anaesthetics. She qualified from St George's Hospital Medical School, London, and undertook a specialist registrar training programme in the Oxford Region.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. He qualified from Birmingham University Medical School and trained in anaesthesia in the Royal Air Force. Further training as a Senior Registrar in the NHS was spent in Oxford. He now specializes in anaesthesia for plastic surgery and head and neck surgery.

Hypertension

Hypertension is a common critical incident during anaesthesia. Whether it is harmful depends on its severity, cause and duration, and on the condition of the patient. These factors also determine how actively it needs to be treated. Hypertension is difficult to define because of observer and subject variation, and the arbitrary nature of cut-off values, but definitions include:

- elevation of blood pressure at least 15% above patient's baseline
- systolic blood pressure greater than 160 mm Hg and/or a diastolic blood pressure greater than 95 mm Hg. Figure 1 lists the causes of hypertension during or persisting after anaesthesia.

Causes of hypertension during or persisting after anaesthesia

- Inadequate anaesthesia/analgesia
- Tracheal intubation/extubation
- Inadequate muscle relaxation
- Pre-existing hypertensive disease
- Hypoxaemia
- Hypercapnia
- Aortic clamping
- Raised intracranial pressure, cerebral ischaemia or cerebrovascular accident
- Drugs (e.g. ketamine, adrenaline (epinephrine))
- Metabolic disorders (e.g. malignant hyperpyrexia, thyroid crisis, phaeochromocytoma, carcinoid syndrome)
- Postoperative urinary retention, pain, anxiety

1

Complications

Cardiovascular – hypertension may precipitate myocardial ischaemia (especially subendocardial), infarction or failure.

Neurological – cerebral haemorrhage may result, especially in patients with vascular malformations. Cerebral oedema or encephalopathy are less common complications of uncontrolled hypertension.

Haemorrhage at the operation site or from pre-existing vascular malformations.

Renal – severe hypertension may precipitate acute renal failure.

Management

Management of hypertension should be directed towards the underlying cause. The usual cause is inadequate anaesthesia for the level of surgical stimulation being employed and treatment requires an increase in the inhalational or intravenous anaesthetic drug, or an increase in analgesia. Confirmation of the diagnosis may require a trial of therapy. If the cause of the hypertension cannot be diagnosed or removed, an appropriate antihypertensive drug may be used. The following are examples of drugs commonly used.

- Labetalol – combined α- and β-blockade; dose 5–20 mg i.v. over 2 minutes with increments up to 200 mg. Onset 5–30 minutes, duration 50 minutes.
- Metoprolol –β_1 (cardioselective) blockade; 2 mg increments slow i.v., maximum dose 15 mg.
- Esmolol – rapid onset; short half-life of 9 minutes; 500 µg/kg loading dose; 50–200 µg/kg/minute infusion.
- Nifedipine – calcium-channel blocker, sublingual or intranasal; onset 1–5 minutes following a 10 mg dose.
- Phentolamine – α-blockade; 0.5–2 mg i.v., repeated as necessary, rapid onset, short half-life 10–15 minutes.
- Hydralazine – direct-acting arteriolar dilator, peak action after about 20 minutes following 10–20 mg slow i.v. injection over 20 minutes. Onset occurs after 15–20 minutes; duration is 2–6 hours.
- Glyceryl trinitrate – arterial and venous dilator; use 1 mg/ml solution i.v. (preferably a central vein) via syringe driver, dose 10–200 µg/minute, maximum effect after 1–2 minutes.
- Sodium nitroprusside – arteriolar dilator; very rapid response, administered by continuous intravenous infusion via a dedicated vein, 0.5–1.5 µg/kg/minute. Direct arterial blood pressure recording is mandatory. Doses greater than 4 µg/kg/minute may cause cyanide poisoning.

Hypotension

Mild-to-moderate falls in blood pressure are common during anaesthesia, but seldom result in any harm to the patient. It is difficult to determine what is a dangerous level of hypotension; it depends on the duration of hypotension and the patient's preoperative medical condition. Two signs of inadequate myocardial perfusion are the development of ST segment depression and ectopic beats. Increased ventilation–perfusion mismatch secondary to pulmonary hypotension causes a fall in oxygen saturation (SpO_2). In awake patients receiving regional anaesthesia, nausea and dizziness are common symptoms of excessive hypotension. The lower limit of cerebral, renal and hepatic autoregulation occurs at a mean arterial pressure of about 60 mm Hg in otherwise healthy individuals.

Causes

Anaesthesia

- Volatile agents produce a dose-related fall in blood pressure (vasodilatation, myocardial depression, impaired baroreceptor response).
- Induction agents cause a dose-related fall in blood pressure owing to a complex combination of effects involving myocardial depression, vasodilatation, altered baroreceptor reflex and bradycardia (especially propofol).
- Opioids may precipitate histamine release and vasodilatation. Larger doses are associated with bradycardia.
- Non-depolarizing muscle relaxants may produce hypotension secondary to histamine release.
- Positive-pressure ventilation increases intrathoracic pressure and produces a decrease in venous return and cardiac output.
- Spinal and epidural anaesthesia produce sympathetic blockade. This results in vasodilatation, reducing venous return, cardiac output and systemic vascular resistance. Although reflex vasoconstriction occurs above the level of the block, blood pressure usually falls. Higher blocks (T4 or above) obtund the cardiac sympathetics, preventing a compensatory tachycardia.
- In obstetrics, aortocaval compression impairs venous return and in combination with spinal and epidural anaesthesia may produce profound hypotension.

Hypovolaemia, regardless of aetiology, becomes less concealed following induction of anaesthesia owing to impairment of compensatory mechanisms. Hypotension then ensues. Hypovolaemia may occur in patients with:

- trauma or burns
- gastrointestinal disease (e.g. haematemesis, melaena, small bowel obstruction, acute inflammatory bowel disease)
- dehydration from poor fluid intake, vomiting or diarrhoea
- metabolic disorders (e.g. diabetic ketoacidosis, diabetes insipidus, hypercalcaemia).

Surgical causes of hypotension include:

- haemorrhage
- head-up position
- excessive intra-abdominal pressure during laparoscopic surgery may impair venous return causing hypotension
- release of aortic cross-clamping or lower limb tourniquets causes an acute fall in systemic vascular resistance and blood pressure secondary to vasodilatation in the ischaemic tissues.

Cardiovascular disease may lead to hypotension:

- ischaemic heart disease with impaired cardiac contractility (including unstable angina and recent myocardial infarction)
- heart failure
- valvular heart disease (mitral or aortic stenosis and regurg-itation)
- dysrhythmias (fast atrial fibrillation, complete heart block)
- hypertension, especially if poorly controlled
- others (e.g. myocarditis, cardiomyopathy, constrictive pericarditis, myocardial contusion, tamponade, aortic coarctation, congenital cardiac anomalies).

Cardiovascular medication such as β-blockers, angiotensin-converting enzyme (ACE) inhibitors, calcium antagonists, nitrates, α_1-antagonists (prazosin) and centrally acting α_2-agonists (e.g. clonidine, methyldopa) may cause hypotension.

Autonomic neuropathy produces impaired baroreceptor response and may be present in a variety of disease states:

- diabetes mellitus (incidence and severity increase with the duration of the disease)
- Guillain–Barré syndrome
- spinal cord injury and following cerebrovascular accident
- Parkinson's disease
- AIDS.

Other causes

- Anaphylaxis may result in massive histamine-mediated vasodilatation, producing cardiovascular collapse.
- Pulmonary embolus from deep vein thrombosis, or emboli from air, carbon dioxide or fat may reduce cardiac output. Hypotension is accompanied by desaturation and a fall in end-tidal carbon dioxide.

Management

- Identify and remove the precipitating cause.
- Increase fraction of oxygen in inspired air (F_iO_2) to maintain SpO_2.
- Position patient supine, possibly with the legs raised to improve venous return. The head-down position is no longer recommended because it also raises cerebral venous pressure and therefore cerebral perfusion pressure may not be improved.
- Give a rapid intravenous infusion. The type and amount of fluid depends on aetiology and patient factors. A useful guide is to infuse 10 ml/kg of colloid or 20 ml/kg crystalloid initially and assess the response.
- Vasopressors may be considered, particularly if the cause of hypovolaemia is non-haemorrhagic (e.g. ephedrine, 3–6 mg i.v., metaraminol, 0.5–1.0 mg i.v., or phenylephrine, 0.5–1.0 mg i.v.).
- Consider an infusion of a positive inotrope (e.g. adrenaline (epinephrine), dobutamine) or vasoconstrictor (e.g. noradrenaline (norepinephrine)).

Massive haemorrhage

Bleeding is a significant cause of mortality and morbidity because of the loss of blood volume and its constituents and also the effects of infusions of products aimed at compensating for the loss. Massive blood transfusion can be defined as the transfusion of blood, blood products and fluids equivalent to the circulating blood volume in any 24-hour period. The most profound physiological, haematological and biochemical effects occur in those who have the most rapid loss and replacement therapy.

Causes of massive haemorrhage include:

- trauma
- major elective surgery such as orthopaedic or vascular surgery, especially rupture or dissection of the aorta
- during pregnancy and the puerperium (e.g. massive antepartum or post-partum haemorrhage)
- urgent operations and/or procedures in patients with abnormalities of haemostasis or coagulation.

Management

Measuring blood loss: the quantity of blood lost can be estimated by a number of methods.

- Weighing swabs and measurement of blood aspirated into suction apparatus. With major haemorrhage, these methods become less useful because a considerable amount of blood is spilled on to the drapes and floor. In traumatized patients, major blood loss may have occurred before arrival in hospital or may be concealed in the chest or abdomen, or in the limbs and pelvis at the site of fractures.
- Measuring packed cell volume. Blood lactate concentration gives an indication of the adequacy of organ perfusion.
- Clinical observation. The monitoring of cardiovascular variables such as heart rate, arterial pressure, capillary return, central venous pressure, and in some cases pulmonary capillary wedge pressure and cardiac output, allows a clinical impression of the adequacy of volume resuscitation to be made.

Compensatory mechanisms initially maintain the blood supply to vital organs. Unless adequate and appropriate corrective measures are taken, these mechanisms will decompensate. With increasing volumes of blood loss, there is an increase in heart rate, decrease in stroke volume, reduced pulse pressure, increased respiratory rate and a reduction in cerebral blood flow leading to a reduction in conscious level. These compensatory mechanisms are less efficacious in the elderly and very young and may be impaired by disease or medication. Figure 2 shows the relationship between the changes in vital signs and the volume loss from the circulation.

Relationship between the changes in vital signs and the volume loss from the circulation

	Blood loss (ml)			
	≤ 750	**750–1500**	**1500–2000**	**≥ 2000**
Loss as % of blood volume	≤ 15	15–30	30–40	≥ 40
Heart rate	< 100	> 100	> 120	≥ 140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Capillary return	Normal	Slowed	Slowed	Slowed
Respiratory rate (breaths/minute)	14–20	20–30	> 30	≥ 35
Urine output (ml/hour)	> 30	20–30	5–15	Negligible
Mental status	Normal	Anxious	Confused	Drowsy
Suggested volume replacement	Crystalloid	Crystalloid/colloid	Blood	Blood

Active management: the rapid and effective restoration of an adequate circulating blood volume is the primary responsibility of the anaesthetist during periods of heavy blood loss.

Establish adequate venous access by siting at least two large-bore cannulae to allow rapid fluid infusion. The most important pre-determinants of the flow rate of fluid are the diameter of the cannula and the ability to apply a continuous pressure of 2–300 mm Hg via a pressurized infusion system. Crystalloids and synthetic colloids may be used initially and should be followed by the administration of blood if bleeding continues.

Commence intravenous fluids – internationally accepted practice is to use Hartmann's solution as the initial resuscitation fluid for trauma and burns. The success of initial resuscitation in an acutely hypovolaemic patient probably depends more on adequacy of repletion than on which fluids are used. For a given blood volume expansion about twice the volume of crystalloid compared with colloid is required. In practice, combined therapy using both crystalloids and colloids is often used.

Fluids should be warmed – a transfusion system should have the ability to transfuse blood at fast flow rates (up to 500 ml/minute) and at temperatures greater than 35°C. Some systems use a constant-pressure infusion device combined with an efficient blood warmer and a purpose-designed blood-warming coil (e.g. *Level One*™). Priming or flushing blood through the system after fluid containing calcium has been used (such as *Haemaccel*) should be avoided, because this may cause blood clot formation in the tubing by reversal of the anticoagulant effect of citrate.

Blood should be taken for grouping and cross-matching, for coagulation studies and for biochemical analysis. Accurate identification of transfusion specimens and of designated units of blood, platelets and fresh frozen plasma (FFP) is particularly important in patients undergoing massive transfusion. It should be noted that most incompatible blood transfusions occur in emergency situations. For operations where significant blood loss is anticipated, replacement therapy should be available in advance of surgery.

Red cell transfusions are given to increase the haemoglobin concentration and thus improve or normalize the delivery of oxygen to the tissues. The haemoglobin concentration at which blood transfusion is commenced depends to a certain extent on the individual patient (e.g. elderly patients are at greater risk of complications from anaemia). A haemoglobin value below 8.5 g/dl would be an indication to transfuse in all apart from the younger fitter patient. A postoperative haemoglobin level of about 10 g/dl is widely accepted as a general guideline in adult surgical patients. However, it is more appropriate to base transfusion decision on a clinical assessment of the patient. If a major surgical procedure is planned, it may be possible to decrease the amount of donor blood transfusions by using an automated cell saver system.

About 80% of patients who have massive haemorrhage develop diffuse ooze from raw or cut surfaces. The causes are multifactorial but include relative hypothermia, abnormal platelet function, dilution of clotting factors, consumption of factors and enhanced fibrinolysis. It is critically important to monitor platelet numbers and the coagulation process during major bleeding and its resuscitation. The platelet count falls steadily with the transfusion of each successive unit of blood. Platelet infusion is indicated if there is:

- a platelet count less than 50 x 10^9/litre and there is impending surgery or an invasive procedure
- diffuse microvascular bleeding and transfusion greater than one blood volume and a platelet count of 50 x 10^9/litre or less, or the result is unavailable
- diffuse microvascular bleeding following cardiopulmonary bypass and the platelet count is 100 x 10^9/litre or less, or the result is unavailable
- bleeding in a patient with a qualitative platelet defect, regardless of platelet count.

Moderate deficiency of coagulation factors is common in massively transfused patients, but does not contribute to microvascular haemorrhage until levels fall below 20% of normal. These levels are reliably reflected by prolongation of the prothrombin (PT) and activated partial thromboplastin times (aPTT) to values of more than 1.5 times the control value. If the PT and aPTT are more than 1.5 times normal, 4 units of FFP should be given. If PT and aPTT are prolonged and fibrinogen is less than 0.8 g/litre, cryoprecipitate is indicated.

Arterial and central venous lines may be sited to allow rapid blood sampling, for acid–base and potassium status, and the direct measurement of arterial and central venous pressures. The central venous catheter also provides access for intermittent bolus administration of drugs or drug infusions.

A urethral catheter should be passed unless contraindicated by pelvic or urethral injury, and urine output monitored.

Core temperature should be measured continuously and every effort made to prevent heat loss. Hypothermia causes platelet dysfunction, reduced metabolism of citrate and lactate and an increased tendency to cardiac arrhythmias. This may result in bleeding diathesis, hypocalcaemia, metabolic acidosis and cardiac arrest.

Arrhythmias

Arrhythmias are one of the most commonly reported critical incidents. About 12% of patients undergoing anaesthesia develop arrhythmias; this increases to 30% in patients with cardiovascular disease. Treatment may not be required; this depends on the nature of the arrhythmia and its effect on cardiac output. Single supraventricular or ventricular ectopic beats, and slow supraventricular rhythms, do not require treatment unless cardiac output is compromised.

Management

Fluid, electrolyte and acid–base disturbances should be corrected preoperatively. Particular attention should be paid to the level of potassium ions in the plasma because they have a vital role in the generation of the resting membrane potential and thus muscle and nerve function. Patients with hypokalaemia may be prone to the development of supraventricular or ventricular extrasystoles and tachycardias. ECG changes of hypokalaemia include a long PR interval, ST depression, T wave flattening and a prominent U wave. Rapid treatment is indicated if arrhythmias are present. Intravenous administration of potassium supplements should not exceed 0.5 mmol/kg/hour.

Continuous intraoperative ECG monitoring is essential. The ECG gives no indication of cardiac output or tissue perfusion, therefore the detection of an abnormal cardiac rhythm should be followed by clinical assessment of the circulation. An absent pulse, severe hypotension or ventricular tachycardia or fibrillation should be treated as a cardiac arrest.

Correcting the precipitating factor is often the only treatment required. Hypoxaemia and inadequate anaesthesia or analgesia must be excluded. Factors associated with the development of arrhythmias are listed in Figure 3.

Intervention with a specific antiarrhythmic agent or cardioversion is indicated if there is:

- a risk of developing ventricular tachycardia or fibrillation (e.g. frequent, multifocal ectopic beats, or 'R on T' complexes)
- a significant decrease in cardiac output (causing dizziness or hypotension)
- evidence of myocardial ischaemia (causing chest pain or ST segment changes).

Factors associated with the development of arrhythmias

Preoperative conditions

- Ischaemic heart disease
- Pre-existing arrhythmias
- Congestive heart failure
- Hypertension
- Valvular heart disease
- Electrolyte disorders
- Medications (theophylline, β_2-agonists, tricyclic antidepressants)
- Others (thyrotoxicosis, myocarditis, cardiomyopathies, trauma, drug and solvent abuse)

Anaesthetic factors

- Hypoxaemia
- Hypo/hypercapnia
- Hypo/hypertension
- Laryngoscopy
- Drugs (e.g. volatile anaesthetic agents, suxamethonium, central venous pressure lines)

Surgical factors

Catecholamines

- Exogenous (e.g. infiltrated adrenaline (epinephrine))
- Endogenous (inadequate analgesia, inadequate anaesthesia)

Autonomic stimulation

- Oculocardiac reflex
- Laryngoscopy, bronchoscopy, oesophagoscopy
- Carotid artery and thyroid surgery
- Peritoneal and visceral traction
- Peritoneal insufflation

Direct stimulation of the heart

- Cardiac and thoracic surgery

Embolism

- Thrombus, fat, air, carbon dioxide, amniotic fluid

Others

- Limb reperfusion
- Aortic cross-clamping

Bradycardia can be treated with an anticholinergic agent such as atropine, 0.6 mg i.v., or glycopyrrolate, 0.2–0.4 mg i.v. If the bradycardia is refractory to treatment, cardiac pacing or an intravenous infusion of isoprenaline, 0.5–10 µg/minute, may be indicated. An anticholinergic drug may be given prophylactically if there is risk of bradycardia (e.g. strabismus surgery or following a second dose of suxamethonium).

Sinus tachycardia associated with myocardial ischaemia may be controlled by administration of a β-blocker such as metoprolol, 2 mg increments slow i.v., maximum dose 15 mg, or esmolol, 500 µg/kg, loading dose followed by 50–200 µg/kg/minute infusion.

Junctional rhythms are usually associated with the use of halothane. A reduction in concentration and/or changing the volatile agent is indicated. An anticholinergic drug may restore sinus rhythm.

Accelerated nodal rhythms may be precipitated by an increase in sympathetic tone in the presence of sensitizing volatile agents. Treatment includes adjusting the depth of anaesthesia and/or changing the anaesthetic agent.

Supraventricular tachycardia (SVT) can occur in susceptible patients, such as Wolff–Parkinson–White or other 'pre-excitation syndromes'. Treatment of SVT consists of:

- carotid sinus massage
- adenosine, 3–12 µg i.v.
- DC cardioversion if haemodynamic decompensation is present
- if there is no decompensation give verapamil, 5–10 mg slow i.v. over 30 seconds; the injection should stop when the SVT is controlled
- in sepsis-related or refractory SVT, volume loading plus amiodarone, 300 mg i.v. by infusion over 20 minutes, then 900 mg over 24 hours
- if the patient is thyrotoxic a β-blocker is useful.

Atrial fibrillation or flutter is often seen as a paroxysmal increase in the ventricular rate in patients with pre-existing atrial fibrillation or flutter. Having corrected any precipitating factors, the therapeutic options include:

- digoxin, 10 µg/kg by slow i.v. injection over 20 minutes, repeat after 4 hours according to response, maintenance dose 125–500 µg/day. Peak effect after 2 hours. Slows the ventricular rate and is a positive inotrope
- amiodarone produces a more rapid ventricular response and may re-establish sinus rhythm, give 300 mg i.v. by infusion over 20 minutes, then 900 mg over 24 hours
- β-blockers, especially in thyrotoxicosis, in combination with digoxin (e.g. propranolol 1 mg slow i.v. repeated every 2 minutes, maximum 5 mg)
- cardioversion is an option if the ventricular rate is fast with a clinically reduced cardiac output.

Premature ventricular contractions are common in healthy patients. Perioperatively they seldom progress to more serious arrhythmias unless there is underlying hypoxaemia or myocardial ischaemia. An underlying cause should be sought before antiarrhythmic agents are considered. If associated with a slow atrial rate, increasing the sinus rate with an anticholinergic drug will abolish them. Halothane lowers the threshold for catecholamine-induced ventricular arrhythmias; this is exacerbated by hypercapnia. Halothane should be used with care in patients receiving sympathomimetic drugs (including local anaesthetics containing adrenaline), and in patients taking tricyclic antidepressants and aminophylline.

Ventricular tachycardia and fibrillation should be treated as a cardiac arrest.

Malignant hyperthermia

Malignant hyperthermia is a rare inherited complication of general anaesthesia triggered by inhalational agents or suxamethonium in susceptible patients. The inheritance is complex and it is a genetically heterogeneous condition. These patients have a defect in intracellular calcium binding within the sarcoplasmic reticulum of skeletal muscle cells. Calcium ions are released on exposure to trigger agents, which initiates widespread skeletal muscle contraction and generalized membrane permeability. There is severe metabolic disturbance and catabolism runs unchecked, because raised levels of myoplasmic calcium ions result in increased production of pyruvate and heat. A successful outcome relies on making an early diagnosis, discontinuation of trigger agents, prompt treatment with intravenous dantrolene and supportive care. The mortality today has decreased to about 25% owing to increased awareness, monitoring and prompt treatment. The mode of presentation is variable and a high index of suspicion is required for early diagnosis.

Signs of malignant hyperthermia include:
- unusual muscle rigidity following suxamethonium (especially masseter spasm)
- unexplained tachycardia and arrhythmias
- rise in end-tidal carbon dioxide
- metabolic acidosis
- fall in oxygen saturation
- hyperkalaemia
- rise in core temperature (about 1–2°C/hour)
- evidence of a coagulation disorder, oozing from wound sites.

Management

Immediate actions
- Discontinue inhalational agents and inform the surgeons. Stop surgery if feasible, make the operating site safe and close wounds.
- Continue sedation or anaesthesia with a total intravenous technique. Hyperventilate with 100% oxygen using a clean breathing system. Change the circle system using fresh soda-lime, or use a non-rebreathing system.
- Immediately instruct staff to prepare dantrolene and commence as soon as available in an intravenous infusion of 1 mg/kg repeated at 10 minute intervals up to 10 mg/kg.
- Remove drapes, fully expose the patient and promote surface cooling with avoidance of vasoconstriction.
- Insert an arterial line to aid monitoring, and allow regular estimation of arterial blood gases, potassium and creatine kinase.
- Monitor the patient's core temperature.

Intermediate actions
- Control life-threatening dysrhythmias (e.g. β-blockers).
- Control hyperkalaemia with intravenous glucose or insulin.
- Control metabolic acidosis by hyperventilation, consider sodium bicarbonate (2–4 mmol/kg) if acidosis is severe (e.g. pH < 7.0).

Later actions
- Send blood for clotting screen (PT, aPTT, fibrinogen).
- Catheterize the patient. Test their urine for myoglobin. Collect samples for vanillylmandelic acid estimation to exclude phaeochromocytoma. Promote diuresis with intravenous fluids and mannitol, 0.5 g/kg over 20 minutes.
- Request a chest radiograph. Send blood for full blood count, biochemistry and thyroid function tests.
- Notify the intensive care unit.
- Repeat the creatine kinase estimation in 24 hours.
- Consider other diagnoses such as recreational drug ingestion (e.g. Ecstasy), neuroleptic malignant syndrome or myopathy.

Future care

The patient and their family should be counselled as to the likely diagnosis and the implications for future anaesthetics. Wearing a Medic-Alert bracelet should be encouraged. The patient and immediate family should be referred for further investigation and muscle biopsy to:

UK MH Investigation Unit, Academic Unit of Anaesthesia
Clinical Sciences Building
St James's University Hospital Trust
Leeds LS9 7TS
Tel: 0113 206 5274
Emergency hotline: 07947 609601

Future anaesthetic care can be provided safely with the avoidance of trigger agents – the volatile anaesthetics and depolarizing muscle relaxants. Prophylactic dantrolene is not recommended. Phenothiazines, antidepressants and haloperidol have been suggested as possible trigger agents, because of the similarity between malignant hyperthermia and the neuroleptic malignant syndrome, but this is unlikely. All other anaesthetic drugs appear to be safe.

Critical Incidents: The Respiratory System

Orlando J Warner
Jonathan Warwick

Orlando J Warner is Specialist Registrar in Anaesthetics at the Oxford Radcliffe NHS Trust Hospital, Oxford, UK. He qualified from the Royal London Hospital Medical School. For the past 2 years he has been the Advanced Trainee in Neuroanaesthesia at the Department of Neuro-surgical Critical Care and Anaesthetics, Radcliffe Infirmary, Oxford.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. He qualified from Birmingham University Medical School and trained in anaesthesia in the Royal Air Force. Further training as a Senior Registrar in the NHS was spent in Oxford. He now specializes in anaesthesia for plastic surgery and head and neck surgery.

A critical incident during anaesthesia is any event that may result in actual or potential harm to the patient if uncorrected. It may cause severe morbidity or even mortality. It is often preventable by a change in practice. Incident reporting is the key to preventing future disaster. There is observer bias concerning which incidents are recorded, and the problem for anaesthetists is to distinguish between a critical incident and the normal course of clinical practice.

This contribution deals with life-threatening problems in the management of the respiratory system including the clinical and physiological presentation of some commonly encountered critical incidents and their treatment. All may be a cause of alarming cyanosis under anaesthesia. Not all the problems discussed can be prevented and so some may not meet the precise definition of critical incidents. The recommendations aim to provide the anaesthetist with fast and effective solutions that may be used in clinical, examination or simulation situations. In all cases, the trainee anaesthetist must request senior help at the earliest opportunity.

Aetiology

The 2000 report of the National Confidential Enquiry into Perioperative Deaths (NCEPOD) cites hypotension, hypoxaemia, arrhythmia and cardiac arrest as the most common critical events that occur during or immediately following surgery. It also concludes that modern anaesthetic equipment, when properly checked, is very reliable. Human factors often play a major role in the aetiology of adverse events (Figure 1).

Factors involved in avoidable deaths

- Error of judgement
- Error of clinical expertise
- Lack of experience
- Lack of assistance
- Lack of equipment
- Equipment failure

1

Preparation is an important factor in predicting and treating these events and should involve:

- thorough preoperative patient assessment
- check of all anaesthetic equipment
- appropriate selection of drugs
- appropriate level of clinical expertise.

The Association of Anaesthetists of Great Britain and Ireland (AAGBI) has recently published new recommendations for standards of monitoring during anaesthesia and recovery. The Royal College of Anaesthetists (RCA) has a web page (http://www.rcoa.ac.uk/critincident/ciweb.html) that deals with the processing of critical incidents. The RCA is committed to setting up a national database so that even rare incidents can be reported and acted on. Critical incidents should be discussed locally at regular departmental audit meetings to complement the process of clinical governance.

Respiratory obstruction and increased peak airway pressure

Obstruction to the airway is an immediate threat to life and is the most common critical incident registered. The 'airway' can be considered as the conducting pathway responsible for the delivery of oxygen from anaesthetic machine to the alveolar/blood interface. Thus, obstruction may occur from outside or within the patient. The anaesthetic machine, breathing system and connections must be checked to ensure their patency and correct function before anaesthesia.

Obstruction of the airway within the patient may arise from the upper, supraglottic region, to the lower bronchiolar region. It may be caused by the devices used during anaesthesia or result from airway anatomy, pathology or trauma. Figure 2 shows some of the likely causes of airway obstruction in the perioperative period.

Possible causes of airway obstruction

Supraglottic

- Tongue
- Periglottic abscess, tumour, haematoma
- Regurgitation of solid material
- Blood or secretions
- Laryngeal mask airway (LMA) or tracheal tube luminal occlusion or misplacement

Laryngeal

- Laryngospasm
- Tumour or oedema
- Post-thyroidectomy (laryngeal nerve injury)
- LMA or tracheal tube luminal occlusion or misplacement

Tracheal or bronchial

- Aspiration
- Asthma
- Anaphylaxis
- Pneumothorax
- Pulmonary oedema
- Tracheal obstruction by retrosternal goitre
- LMA or tracheal tube luminal occlusion or misplacement

2

Respiratory obstruction during induction of anaesthesia

Preoperative evaluation of the airway is vital and should include mouth opening, dentition, Mallampati score, jaw movement, thyromental distance and neck movement. The aim is to predict which patients may present difficulty with direct laryngoscopy and intubation and those in whom difficulty may arise with airway maintenance following loss of consciousness, such as those with:

- obesity or a 'bull neck'
- limited mouth opening (e.g. trismus, following infection, trauma)
- restricted head and neck movement (e.g. severe ankylosing spondylitis, rheumatoid arthritis)
- stridor resulting from tumour, trauma, infection or haem-atoma
- upper airway soft tissue swelling (e.g. burns, pre-eclampsia). About 10% of reported critical incidents occur in the anaesthetic room. Patient monitoring during induction of anaesthesia should follow the guidelines established by the AAGBI. The patient must be monitored adequately during this stage of anaesthesia. If the required equipment is unavailable, induction should take place in the operating theatre.

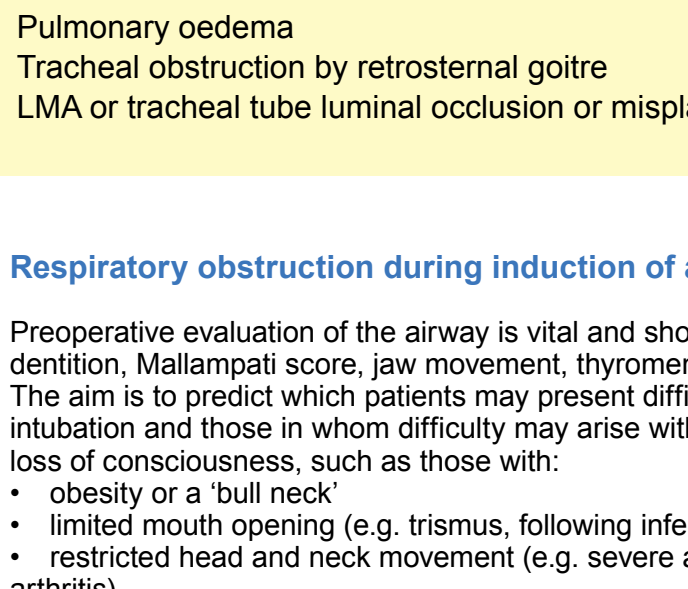
Induction of anaesthesia in patients with upper airway obstruction requires specialized expertise. Management must involve a clear plan of how to proceed in the event of total airway obstruction during induction. These patients are best managed in the operating theatre with surgeons gowned and ready to perform immediate tracheostomy under local anaesthesia if necessary.

In routine practice, airway obstruction that occurs following induction is apparent from:

- paradoxical (see-saw) chest movement (when breathing spontaneously)
- noisy airway
- absent or diminished movement of the reservoir bag
- absent or diminished capnograph trace
- increased airway pressure (when mechanically ventilated)
- progressive oxygen desaturation.

Simple airway manoeuvres such as chin lift and jaw thrust, often combined with the insertion of a correctly sized oropharyngeal or nasal airway are necessary to maintain airway patency following induction. In apnoeic patients or those requiring assisted ventilation, bag and mask ventilation by two operators is more effective than that provided by one operator (Figure 3), allowing more effective face mask application and upper airway management. Manual ventilation with bag and mask is then easier to perform. If management is difficult, it is important to switch to 100% oxygen and call for senior help early on.

Two operators providing bag and mask ventilation



3

If airway obstruction persists, a laryngeal mask airway (LMA) often corrects the situation. While tracheal intubation provides a definitive airway, it may be difficult to insert in a patient who has not received muscle relaxants. Neuromuscular blockade should never be administered unless airway patency can be assured. However, if airway maintenance is lost following the administration of muscle relaxants then swift direct laryngoscopy and tracheal intubation should be attempted. Some patients (e.g. those with adenotonsillar hypertrophy, the obese or heavy snorers) are often easy to intubate despite having a difficult airway to maintain with bag and mask. The LMA is also the technique of choice following a failed intubation if subsequent airway management is difficult. Numerous reports testify to the ability of the LMA to provide a clear airway following a failed intubation. The *Combitube* may also be useful, though it is less commonly used in the UK. Both are 'supraglottic' airway devices, therefore it is unlikely that the *Combitube* will provide a clear airway if the LMA does not.

Can't intubate, can't ventilate (CICV)

The inability to intubate or ventilate a patient is rare, with an estimated incidence of 1/10,000 anaesthetics. It occurs when alveolar ventilation cannot be maintained despite best attempts at intubation and bag-mask ventilation (Figure 4).

Analysis of closed-claims in the USA revealed that the most common predisposing factor in the development of CICV was repeated and continued attempts at intubation. With each successive period of re-oxygenation between intubation attempts, bag-mask ventilation became increasingly difficult as laryngeal oedema evolved. The anaesthetist should limit intubation attempts to a maximum of three. The decision must be made early to abandon further attempts at intubation and the anaesthetist must use an alternative airway device, or wake the patient. The main causes of CICV are:

- repeated failed attempts at intubation
- airway or neck trauma
- burns to the head and neck
- pregnancy (especially pre-eclampsia)
- tumour (e.g. larynx)
- infection.

Requirements for optimum best attempts

Optimum best bag-mask ventilation

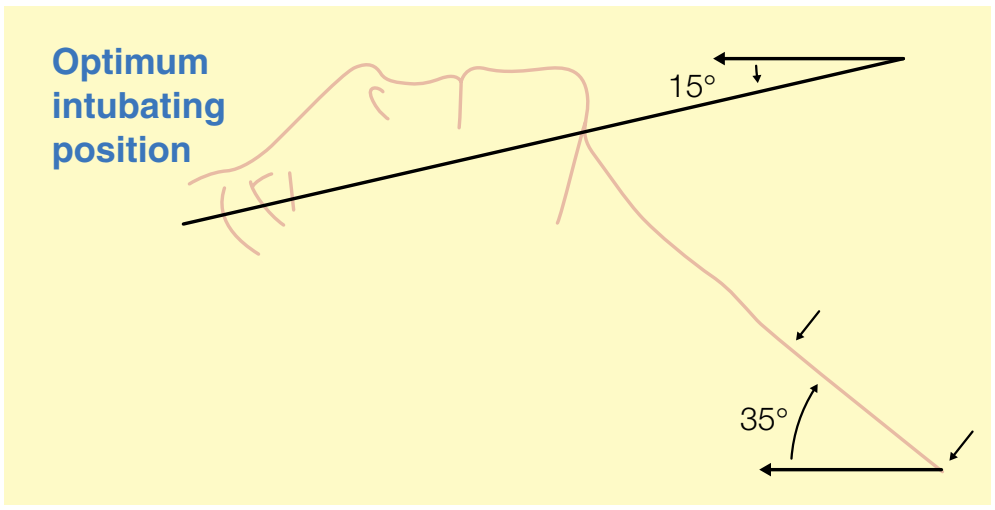
- Correctly sized oral or nasal airway
- Two-operator technique

Optimum best laryngoscopy

- Trained anaesthetist (3 years' training)
- Optimal intubating position
- Optimal external laryngeal manipulation
- Optimal laryngoscope

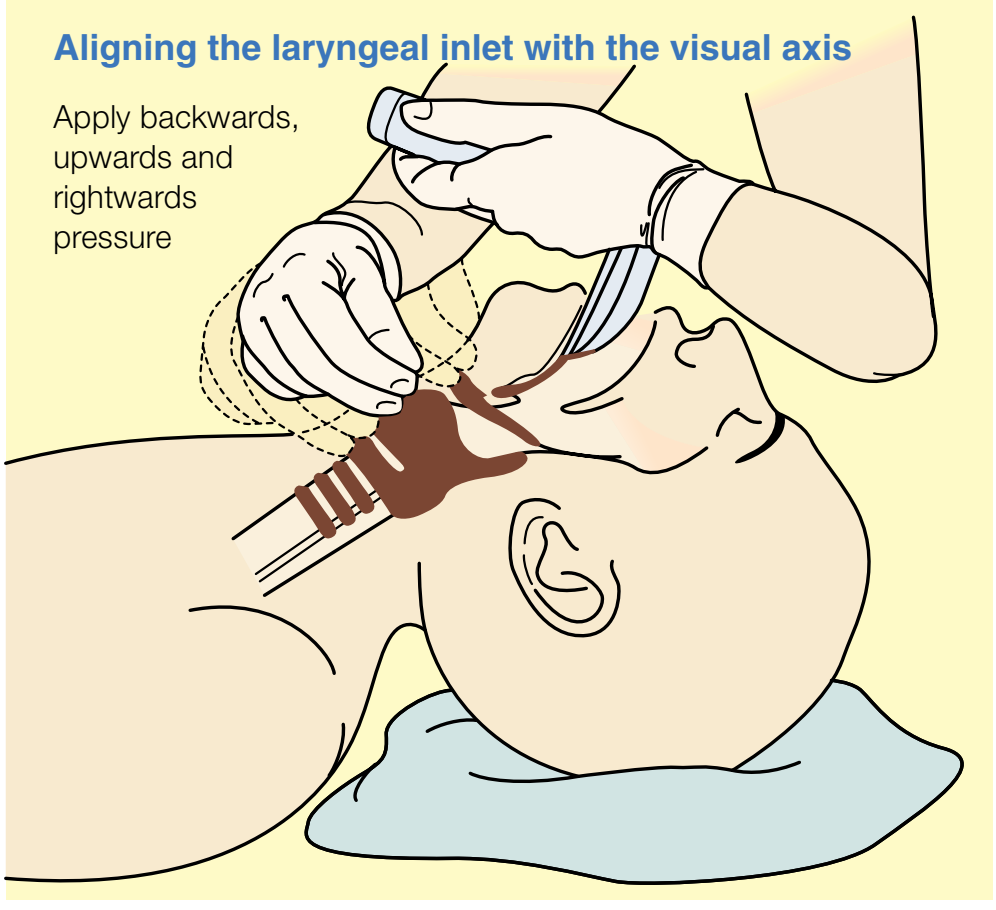
4

The optimal intubating position is shown in Figure 5. Flexion of the cervical spine, and extension of the head at the atlanto-occipital joint, aligns the glottis with the visual axis. In the obese or pregnant woman at term, this may require at least one pillow under the shoulders and two pillows beneath the head and neck. Anaesthetic induction and tracheal intubation should be avoided when patient positioning is not ideal.



5

The larynx should be manipulated from the front of the neck by the operator's free hand to help provide the best view. This position is maintained by the anaesthetic assistant while intubation is performed. Optimum external laryngeal manipulation does not mean 'cricoid pressure', which may further distort the view and make direct laryngoscopy more difficult. Optimum manipulation involves direct manipulation of the thyroid cartilage of the larynx. The application of backwards, upwards and rightwards pressure aligns the laryngeal inlet more closely with the visual axis. Correct optimum external laryngeal manipulation is shown in Figure 6.



6

The choice of laryngoscope blade is important. A useful guideline is to change the length of blade once, and the type of blade once, to achieve the best view. A variety of blades is available in clinical practice. The standard Macintosh blade (size 3) may need to be changed to a longer blade (size 4) or to a levering blade such as the McCoy. The McCoy blade can be successful in improving the laryngoscopic view by one grade (Cormack and Lehane grade 3 to 2). The Belscope blade has a 45° angle and a detachable prism, and may similarly improve a grade 3 view. The Polio blade is inclined at an angle greater than 90° to the handle, which may aid insertion into the mouth (Figure 7).

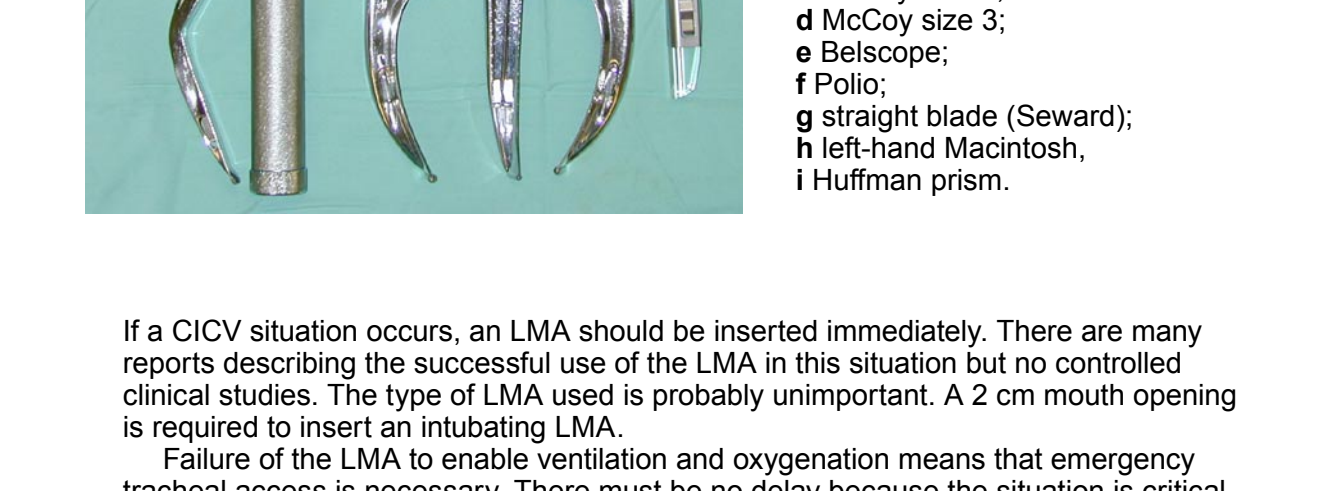
7 Laryngoscope blades:
a Macintosh size 4;
b Macintosh size 3;
c McCoy size 4;
d McCoy size 3;
e Belscope;
f Polio;
g straight blade (Seward);
h left-hand Macintosh,
i Huffman prism.

If a CICV situation occurs, an LMA should be inserted immediately. There are many reports describing the successful use of the LMA in this situation but no controlled clinical studies. The type of LMA used is probably unimportant. A 2 cm mouth opening is required to insert an intubating LMA.

Failure of the LMA to enable ventilation and oxygenation means that emergency tracheal access is necessary. There must be no delay because the situation is critical in a patient with marked hypoxia. Tracheal access is best achieved via the cricothyroid membrane by needle puncture, percutaneous cricothyrotomy or surgical cricothyrotomy. The precise technique depends on: the equipment available; the experience of the anaesthetist; and the nature of the emergency.

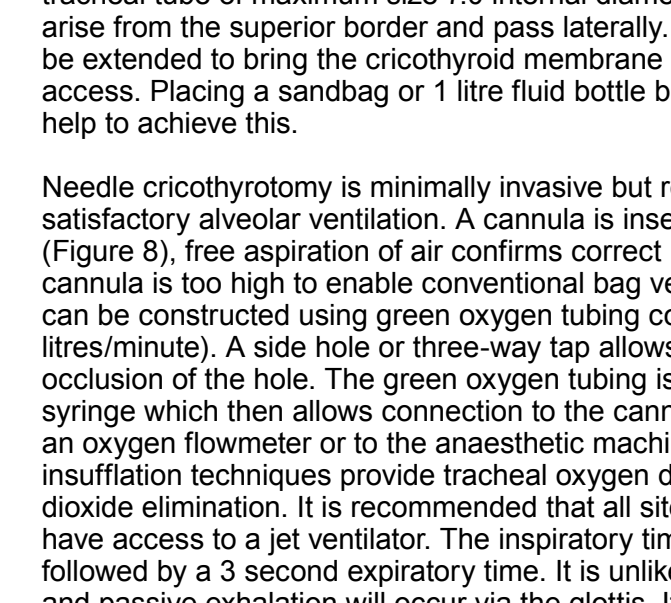
It is impossible to give firm recommendations but whatever the means used, the immediate aim is to achieve oxygen delivery to the trachea (and alveoli) via the cricothyroid membrane. This membrane lies subcutaneously between the cricoid and thyroid cartilages of the larynx and in the adult measures 1 x 3 cm. It will accept a tracheal tube of maximum size 7.0 internal diameter (ID). Paired cricothyroid arteries arise from the superior border and pass laterally. The patient's head and neck should be extended to bring the cricothyroid membrane closer to the skin surface to facilitate access. Placing a sandbag or 1 litre fluid bottle between the patient's scapulae may help to achieve this.

Needle cricothyrotomy is minimally invasive but requires a jet ventilator to achieve satisfactory alveolar ventilation. A cannula is inserted via the cricothyroid membrane (Figure 8), free aspiration of air confirms correct placement. Resistance through the cannula is too high to enable conventional bag ventilation. Simple emergency systems can be constructed using green oxygen tubing connected to a flowmeter (e.g. 10-15 litres/minute). A side hole or three-way tap allows for intermittent insufflation by finger occlusion of the hole. The green oxygen tubing is inserted into the barrel of a 2 ml syringe which then allows connection to the cannula. The free end is connected to an oxygen flowmeter or to the anaesthetic machine via a 15 mm connector. Oxygen insufflation techniques provide tracheal oxygen delivery but not satisfactory carbon dioxide elimination. It is recommended that all sites where anaesthesia is administered have access to a jet ventilator. The inspiratory time of about 1 second should be followed by a 3 second expiratory time. It is unlikely that airway obstruction is absolute and passive exhalation will occur via the glottis. If this is deemed inadequate a second cannula should be placed to allow exhalation and prevent overinflation and barotrauma. A needle cricothyrotomy is a temporary measure and preparations should be made for a formal tracheostomy.



8

Specific cricothyroid cannulae are available for emergency tracheal access (Figure 9). The Ravussin 13 G jet ventilation catheter (VBM Medical) is flanged to simplify fixation, and has both Luer-lock and 15 mm connections. The Cook 6 F emergency transtracheal catheter is spiral reinforced and kink-resistant; a standard 14 G intravenous catheter is easily kinked and difficult to fix. The main complication of the technique is incorrect needle position and subcutaneous/mediastinal emphysema.



9 Cricothyrotomy needles.
a 13 G Ravussin jet ventilation catheter (VBM Medical);
b 6 F Cook emergency transtracheal catheter;
c 14 G Venflon cannula.

Percutaneous cricothyrotomy allows emergency placement of a tracheal tube to allow more conventional ventilation via bag and mask. Several commercial kits are available, which differ in insertion technique (Seldinger or non-Seldinger), size of tube (3.5-6.0 ID), and time taken for tube placement. There are insufficient data to make recommendations concerning the optimum technique and the anaesthetist should be familiar with the equipment available in their hospital. A non-Seldinger kit (e.g. VBM Quicktrack, 4.0 mm ID) generally allows the most rapid access by direct cricothyroid puncture using a large diameter sharpened stylet. A Seldinger technique (e.g. Cook Melker kit 3.5-6.0 mm ID) may be safer to perform but requires several stages including the use of a dilator. All techniques require familiarization. Complications include bleeding, malposition and subcutaneous emphysema.

Surgical cricothyrotomy rapidly provides a definitive airway, though it requires more surgical experience and bleeding is likely to be considerable. It is ideally suited to the emergency trauma setting in the presence of severe maxillofacial, neck or laryngeal injury. Thorough training is necessary for this seldom performed but life-saving procedure. Practising on the sheep's larynx provides a realistic training model.

With finger and thumb either side, the cricothyroid membrane should be stabilized. A 22 scalpel blade is used to make a 2 cm vertical skin incision to part the skin. The scalpel should then be horizontally inserted into the cricothyroid membrane, perpendicular to the skin. This incision should be enlarged laterally. The scalpel handle should be inserted through the cricothyroid incision and rotated through 90°, then removed. A well-lubricated size 7.0 ID cuffed tracheostomy tube should be inserted. The main complications are bleeding and malposition.

Respiratory obstruction during the intraoperative period

If respiratory obstruction occurs during surgery, the following procedure will help to diagnose the cause of obstruction (Figure 2) and guide appropriate action to correct the situation. Surgery can then recommence.

- 100% oxygen should be commenced.
- The surgeons should be alerted to the problem and advised to stop surgery. The surgical stimulation may have caused the obstruction. Procedures such as dilation of the cervix or anus may precipitate severe stridor especially if anaesthesia is 'light'.
- The anaesthetic delivery circuit should be checked rapidly.

If it is patent, the obstruction must be within the patient.

- Access to the airway may be difficult, especially in head and neck surgery. Extreme circumstances of continued patient deterioration require the complete uncovering of surgical drapes and exposure of the airway.
- The upper airway should be checked for secretions, signs of regurgitation or obvious tube or LMA obstruction. The mouth and trachea should be suctioned if indicated.
- The capnograph confirms alveolar ventilation by displaying a carbon dioxide trace. Absence of a trace is a sign of complete airways obstruction. The normal capnograph trace may change in airways obstruction with a characteristic marked upslope to the alveolar plateau.
- The urgency of the situation is indicated by the oxygen saturation. If there is any doubt about the tracheal tube position, immediate replacement is needed. An LMA will need repositioning or changing to a tracheal tube. Careful observation of the chest wall during manual ventilation may show unilateral or little chest movement. Auscultation of the chest may detect unilateral air entry, wheeze or absent breath sounds. Withdrawing the tracheal tube slightly may alleviate this if the distal end has migrated to the endobronchial position, or is in contact with the carina.
- Fibre-optic bronchoscopy will confirm the position of the tracheal tube and that there is no intraluminal obstruction such as a sputum plug, blood clot or in rare circumstances, an endoluminal tumour.

Bronchospasm during anaesthesia

Bronchospasm is reversible airways obstruction most commonly associated with patients who have asthma or chronic chest disease. The incidence of asthma is 5-10% with a higher prevalence in children. Smokers and patients with upper respiratory tract infection are also at increased risk of bronchospasm. Bronchospasm occurs as a result of smooth muscle constriction within the respiratory subepithelial layers in the bronchioles. It may be accompanied by other pathological effects (e.g. mucosal oedema, cellular infiltrates, mucus secretion, desquamation of surface epithelial cells, goblet cell hyperplasia) which exacerbate smooth muscle contraction. Contraction is stimulated by neural or paracrine effects. Chemical mediators such as histamine and products of arachidonic acid, the leukotrienes, may act locally to initiate bronchoconstriction.

Bronchospasm is not the only cause of intraoperative wheeze (Figure 10). Luminal occlusion from eccentrically inflated tube cuffs (cuff herniation) used to occur with red rubber tracheal tubes, but modern disposable materials have made this complication less common, however the tracheal tube cuff should not be over-distended. The old adage 'if in doubt – take it out' remains true. A monophonic wheeze developing immediately after intubation may indicate tube occlusion, or a distal position next to the carina or within a bronchus.

Bronchospasm is suggested by:

- increased respiratory effort, tachypnoea and intercostal recession (if spontaneously breathing)
- expiratory wheeze (wheeze throughout the respiratory cycle may indicate obstruction within the breathing equipment)
- rise in inspiratory airway pressure (if mechanically ventilated). Management of wheeze while under anaesthesia is as follows.
- The surgeons should be alerted and asked to stop surgery.
- 100% oxygen should be delivered and anaesthesia deepened. Bronchospasm may result from a depth of anaesthesia that is too light for the degree of surgical stimulation. This includes stimulation of the airway by the anaesthetist. All modern inhalational agents are bronchodilators.
- The breath sounds over both lung fields and over the stomach should be listened to. Capnography confirms tracheal intubation. Tracheal tube position should be adjusted if necessary. Signs of pulmonary oedema or tension pneumothorax should be sought.• The position of the tracheal tube should be adjusted if necessary.
- The airway should be checked and the trachea should be suctioned looking for signs of aspiration.
- Full monitoring should be in place. Extreme tachycardia and cardiovascular collapse suggest anaphylaxis.

The treatment of bronchospasm includes the following.

- The inspired concentration of volatile anaesthetic agent should be increased.
- The patient should be treated with continuous inhaled salbutamol nebulizers, 5 mg, and ipratropium, 500 µg, until the wheeze settles. This is best delivered using a separate oxygen cylinder with nebulizer attachment, connected to the tracheal tube on the patient side of any heat/moisture exchange filter.
- If wheeze persists, aminophylline, 250−500 mg (5 mg/kg) i.v.in 500 ml normal saline over 20 minutes can be given (if notalready treated with theophylline or aminophylline preparations); continue with an infusion of 0.5 mg/kg/hour if needed.
- If bronchospasm is severe, salbutamol, 250 µg bolus i.v. over 5−10 minutes may be given, and continued as an infusion of 5 µg/minute, adjusted according to the heart rate and bronchospasm response.
- It may be necessary to adjust ventilator settings. A longer expiratory time may be needed to allow more complete exhalation, though a short inspiratory time will produce higher peak inspiratory pressures. An I:E ratio of 1:2 or 1:1.5 is usual.
- Hydrocortisone, 200 mg i.v., is not immediately effective but provides bronchospasm relief within 6–12 hours.
- Management of anaphylaxis will be covered in **CLINICAL ANAESTHESIA.**

Causes of intraoperative wheeze

- Endobronchial intubation
- Mechanical obstruction of the tracheal tube
- Bronchospasm
- Anaphylaxis
- Pulmonary oedema
- Tension pneumothorax
- Aspiration of gastric contents

Failure to breathe

A delay in the return of spontaneous respiration following anaesthesia is most commonly the result of an imbalance between the:

- patient requirements of anaesthesia and analgesia (differences caused by normal variation and the effects of coadministered drugs or disease)
- doses of drugs used
- timing of their administration.

In all patients, maintain ventilation to ensure satisfactory oxygenation and carbon dioxide removal. The patient is likely to be unconscious and usually all that is required is more time. If there is continued apnoea, inconsistent with the clinical picture, then a careful evaluation of the cause is needed. The patient should be reassured if they are conscious.

Assess neuromuscular block − a train-of-four ratio of 75% is usually adequate for satisfactory ventilation following anaesthesia. The presence of four good twitches with absent fade implies adequate reversal. Modern nerve stimulators (e.g. the train-of-four watch) can provide more accurate assessment of neuromuscular function by measurement of thumb acceleration (and thus force, because the mass of the thumb is constant). The standard 1 ml ampoule of glycopyrrolate, 0.5 mg/neostigmine 2.5 mg, is the correct reversal dose for a 50 kg patient. The ability to sustain a 5-second head lift from the pillow is a useful clinical indicator of neuromuscular recovery. Figure 11 shows factors that prolong the action of a non-depolarizing neuromuscular block.

Factors that may increase duration of non-depolarizing neuromuscular block

- Hypokalaemia
- Hypothermia
- Hypocarbia
- Neuromuscular disease (e.g. myasthenia gravis, Eaton-Lambert syndrome)
- Inhalational anaesthetic agents
- Aminoglycosides
- Calcium antagonists
- Magnesium
- Local anaesthetics
- Lithium
- Frusemide

Partial reversal of neuromuscular block presents as respiratory inadequacy together with jerky, uncoordinated gross muscular movement. Laryngeal muscle weakness can produce airway obstruction and stridor. The best treatment is to:

- reassure the patient (they may be distressed and feel unable to breathe, with tachycardia and hypertension) and administer 100% oxygen
- help allay anxiety by giving midazolam, 2 mg i.v. or reintroduce general anaesthesia for a short period of time
- correct any underlying cause
- administer further neostigmine (with glycopyrrolate) to a total of 70 µg/kg i.v. (maximum dose 5 mg) if necessary.

Plasma cholinesterase activity − if suxamethonium (or mivacurium) has been used and return of adequate neuro-muscular function is delayed, it is likely that plasma cholin-esterase activity is decreased. This may be an inherited abnormality of cholinesterase activity or an acquired reduction in enzyme activity (Figure 12). The genetic variants have autosomal dominant inheritance, and the prevalence of homozygotes for the atypical gene is 1:2500 of the Caucasian population. Only homozygotes display significantly prolonged apnoea. This may produce many hours of continued paralysis. The patient will come to no harm providing ventilation is supported and adequate sedation is continued (e.g. propofol, 4−6 mg/kg/hour). Neuromuscular block should be monitored with a nerve stimulator and eventually wears off. Infusion of fresh frozen plasma containing cholinesterase enzyme speeds recovery of neuro-muscular function. The benefits must be balanced against the cost and infection risk. Acquired conditions (Figure 12) that reduce plasma cholinesterase activity may slightly increase suxamethonium duration.

Factors that may cause decreased plasma cholinesterase activity

Congenital

- Autosomal dominant inheritance of abnormal enzyme Four alleles have been identified: $E1^n$ normal, $E1^a$ atypical, $E1^f$ fluoride-resistant, $E1^s$ silent

Acquired

- Infections
- Malignancy
- Chronic disease
- Liver disease
- Renal failure
- Pregnancy, oral contraceptives
- Hypothyroidism
- Drugs (monoamine oxidase inhibitors, ecothiopate eye drops, organophosphorus compounds, chemotherapy)

Doxapram is a central respiratory stimulant that may reverse the respiratory depression caused by general anaesthetic agents and potent analgesics. It does not reverse the other effects of opioids. It acts by direct stimulation on the carotid body chemoreceptors. A maximum dose of 1.5 mg/kg slow i.v. can be given.

Benzodiazepines − flumazenil can be used to reverse the central sedative effects of benzodiazepines. It has a shorter half-life than midazolam and diazepam, and therefore re-sedation is possible. Flumazenil, 200 µg i.v., should be given followed by 100 µg i.v. every minute as necessary. The maximum total dose is 1 mg. While benzodiazepines may contribute to postoperative sedation, they seldom cause apnoea unless large doses are used or the patient is elderly and frail.

Opioid drugs − if excessive narcotic is suspected, then give naloxone by titrating dose to effect. Dilute 400 µg in 10 ml normal saline and give 1−2 ml every few minutes to achieve the desired effect. It is important not to use excessive naloxone to prevent reversal of the analgesic effect. Pain, hypertension and tachycardia may result. The patient must be observed closely for the next 4−6 hours because the duration of the naloxone effect may be shorter than that of the opioid.

Check end tidal carbon dioxide tension ($P_{E'}CO_2$) – hyperventilation during anaesthesia results in reduced respiratory drive. Spontaneous ventilation is unlikely to occur until the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) and $P_{E'}CO_2$ have normalized. The addition of 5% carbon dioxide to the inspiratory gas mixture was common in older anaesthetic practice to stimulate respiratory drive. Hazards associated with carbon dioxide use, in particular the inadvertent use of carbon dioxide from incorrect flowmeter settings, have removed the use of this gas from modern practice.

The $P_{E'}CO_2$ should be allowed to rise by itself by either reducing minute volume, or adding dead space into the breathing system (e.g. disconnection of the absorber from a circle system).

Body temperature – hypothermia delays recovery from anaesthesia, prolongs the duration of neuromuscular blockade and is an important cause of postoperative hypoventilation. The fall in core temperature that occurs with anaesthesia should be anticipated and minimized using passive or active rewarming (see *Anaesthesia and Intensive Care Medicine* **1:3:** 122). Continued ventilation in the recovery area or ICU may be required until rewarming is completed and spontaneous ventilation is satisfactory.

Neurological vital signs − an intracranial bleed during surgery is a rare cause of continued unconsciousness and apnoea. It may occur as a result of an undetected head injury in patients undergoing surgery for trauma, or coincidentally in patients with cerebrovascular disease. A CT scan is required for diagnosis.

Investigations in the patient who fails to breathe following anaesthesia should include:

- blood gases, electrolytes and glucose
- body temperature
- neuromuscular function (nerve stimulator)
- ECG and chest radiograph
- CT head scan
- blood for serum cholinesterase activity if indicated.

Air embolism

If bubbles of gas enter the circulation, they may accumulate in the right ventricle. Unlike liquid, gases are compressible, and therefore adequate ejection of blood is not achieved, reducing stroke volume and cardiac output. This can present clinically as a minor fall in blood pressure, hypoxaemia or complete cardiovascular collapse with electromechanical dissociation. If a patent foramen ovale is present, or any other shunt-causing communication between the right and left sides of the heart, the air could enter the systemic circulation and cause neurological injury or coronary artery embolism and infarction (paradoxical air embolism). The effects of air embolism depend on the:

- volume of air entrained
- rate at which it enters the circulation
- general condition of the patient.

Experiments in dogs suggest that volumes greater than 20 mlare potentially fatal.

Some operations carry an increased risk of air embolus (Figure 13). Air may be entrained into an open vein when the venous pressure is subatmospheric. Air embolism occurs in 25−50% of all craniotomy operations in the sitting position and the incidence has reduced now this position is seldom used. The prone position with head tongs appears to be safer for posterior fossa surgery.

Procedures with increased risk of air embolus

- Posterior cranial fossa neurosurgery (especially in the sitting position)
- Lumbar laminectomy and head and neck surgery when the vertebral column is positioned above the level of the heart
- Hepatic surgery that carries a risk of opening the inferior vena cava
- Any patient with a central venous pressure catheter in situ that may result in accidental entrainment of air
- Varicose vein ligation
- Surgery combined with low venous pressures (e.g. in children)

13

Signs that alert the anaesthetist to the development of air embolism are usually detected by monitoring. Early diagnosis allows prompt institution of preventive measures before the situation becomes critical. The signs of air embolus include:

- sudden fall in $P_{E'}CO_2$ despite unchanged ventilatory settings (if breathing spontaneously the patient may develop respiratory distress)
- turbulent blood flow (monitored by precordial Doppler probe; conventional auscultation may reveal continuous ‘millwheel’ murmur as a late sign)
- fall in oxygen saturation
- pulmonary artery pressure increases during air embolism (it is not often monitored)
- arterial hypotension
- tachycardia, dysrhythmias or cardiac arrest.

Management (Figure 14) comprises prevention of further air entrainment, attempts to remove the air and supportive measures.

Management of air embolus

- Ventilate the patient with 100% oxygen. Stop nitrous oxide administration
- Flood the surgical site with normal saline, wet packs, and apply bone wax to any area of exposed bone cortex. Manually compress the proximal veins to stop further air entrainment
- Attempt to increase venous pressure
  - Position patient head down (or surgical site down)
  - Give rapid fluid bolus (250−500 ml) and observe effects
  - Use vasopressors if the arterial blood pressure is severely affected
  - Compression of the abdomen
  - Activation of antigravity venous compression device (G suit) if fitted
- If a central venous catheter (CVC) is in situ, try to aspirate air from all lumens. Insert a CVC (right internal jugular or subclavian) if one is not present
- The left lateral position may transfer air from the pulmonary artery to the right ventricle, thereby improving pulmonary flow (there is little evidence that this is of benefit)
- Give cardiopulmonary resuscitation if required

14

Pneumothorax

The pleural cavity usually exists only as a potential space between the parietal pleura (attached to the innermost intercostal muscle, the transversus thoracus), and the visceral pleura (continuous with the lung parenchyma). A pneumothorax occurs when this potential cavity is opened, either by breaching the chest wall structures (an open pneumothorax), or by injury to the lung parenchyma (a closed pneumothorax).

- The clinical management is concerned with releasing the accumulation of air from the cavity and correcting the chest wall injury. Understanding the anatomy of the chest cavity allows cause and effect to be identified rapidly.
- The dome of the lung protrudes superiorly above the thoracic inlet to the level of the 6th cervical vertebra. The tip of a needle inserted towards the internal jugular vein could pass more posteriorly where it may cross the pleural space and enter the apices of the lung parenchyma. This is possible even with a relatively high approach.
- The inferior part of the chest cavity extends to the costo-diaphragmatic recess. This reaches to the crura of the diaphragm at the level of the 12th thoracic vertebrae. The cavity can be entered inadvertently in this low position by surgery to the renal bed or lower thoracic and upper lumbar vertebrae.
- The mediastinal pleura lies against the vertebral bodies, oesophagus, aorta, large veins, heart and trachea. Damage to many of these mid-chest structures could allow air or blood to enter the pleural cavity. Trauma from accidents or surgical instrumentation of the oesophagus or trachea may cause this.

The signs and causes of a developing pneumothorax while under general anaesthesia are shown in Figure 15; some or all may be present depending on the nature of the pneumothorax (simple or under tension), its speed of onset, the general health of the patient and whether they are breathing spontaneously or are mechanically ventilated.

Signs and causes of pneumothorax

Signs

- Hypoxaemia
- Wheeze
- Increasing airway pressure
- Unilateral chest wall motion
- Reduced air entry
- Hyperresonance
- Distended neck veins
- Shock
- Shifted trachea away from affected side

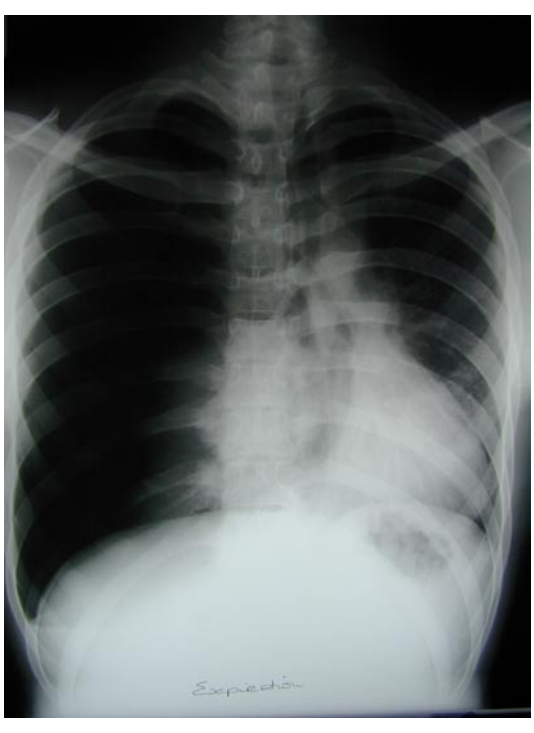
Causes

- Central venous catheter insertion
- Penetrating or blunt chest trauma
- Diaphragmatic, tracheal, oesophageal or cardiac surgery
- Chest drain clamping
- Spontaneous bullae rupture

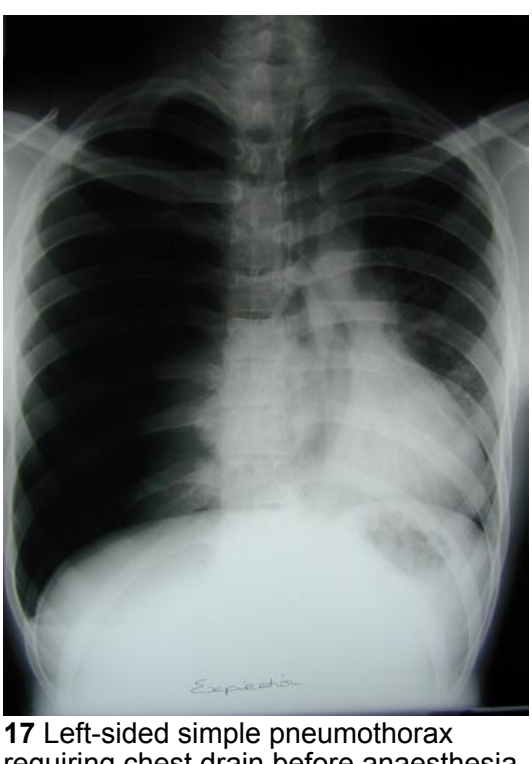
15

In trauma patients, pneumothorax should be identified and treated by chest drain insertion before anaesthesia to avoid the dangers of tension pneumothorax following the start of positive pressure ventilation (Figures 16 and 17). If there is obvious chest injury, but no clinical sign or chest radiograph appearance of pneumothorax, ‘prophylactic’ bilateral chest drains may be indicated. The risks of chest drain insertion must be balanced against the consequences of a tension pneumothorax developing during interhospital or intrahospital transfer or during the perioperative period.

Immediate management of a tension pneumothorax is chest decompression using a 14 G cannula inserted in the midclavicular line and second intercostal space. This should be followed immediately by formal chest drain insertion.



16 Right-sided tension pneumothorax requiring immediate needle decompresion followed by chest drainage. Gross mediastinal deviation is shown to the left.



17 Left-sided simple pneumothorax requiring chest drain before anaesthesia.

Electrical Hazards: Their Causes and Prevention

John Moyle

John Moyle is Consultant in Palliative Medicine in Milton Keynes and a Chartered Engineer. He trained with Philips Electrical Industries. He read medicine at St Bartholomew's Hospital, London and trained in anaesthesia and intensive care at King's College Hospital, London.

Before 1940 there was little electrical equipment in the operating theatre apart from crude radiofrequency diathermy. Since then there has been an invasion of electronic monitoring equipment and many surgical tools are electrically powered. The operating theatre and ICU are unique in electronic engineering because deliberate electrical contact is made with the human body.

The body should be protected from electric current. The body may be considered as an electrolyte solution, which is a good conductor of electricity, contained in a leather bag. Dry leather is a good electrical insulator but conducts electricity easily when damp especially with electrolyte-containing liquids such as sweat.

Electrical injury is caused primarily by the intensity of the current passing through. Current is dependent on the potential difference or 'voltage' across the body and the resistance of the tissues through which it passes (Ohm's law).

$$I = \frac{E}{R}$$

where: E, potential difference (volts); R, resistance (ohms); I, current (amperes)

Severity of injury also depends on the current pathway through the body, environmental factors and the pre-existing health of the patient.

Pathophysiological effects

The pathophysiological effects of electricity range from a mild 'tingling' feeling to ignition in extreme cases. Any electrical current passing through a resistance loses some energy by conversion to heat. The amount of heat generated depends on the current and the value of the resistance; this may be beneficial and forms the basis of coagulation by radiofrequency diathermy. Electricity may stimulate excitable tissues, both nerves and muscles. In a controlled way, this effect may be used medically (e.g. peripheral nerve stimulator, defibrillation). Direct currents, even of low intensity, may cause electrochemical effects. Very high currents, generated by high voltages, cause arcing or sparking and char the tissues. This effect may be harnessed when radiofrequency diathermy is used to cut tissues.

Complications of the inadvertent application of electric currents to the body are:

- cardiopulmonary arrest
- cardiac arrhythmia
- skin and tissue damage
- associated injuries caused by gross muscle contraction.

In the hours after an electric shock there may be further heart rhythm disturbances, hypoxia and electrolyte disturbances, and acute renal failure due to myoglobinuria. It is difficult to predict the effect of electricity on the body because of variables such as body size, proportion and general health. Pre-existing heart problems make the heart more susceptible to arrhythmias.

The current pathway through the body dictates the type of injury. Current passing through the head or across the thorax may cause loss of consciousness and respiratory arrest with or without ventricular fibrillation. Current passing from hand to hand (Figure 1) may cause ventricular fibrillation. Current passing vertically through the body is more likely to cause cardiac muscle damage and injury to other vital organs especially the spinal cord. These injuries depend on the intensity and duration of the current.

The resistance of the human body is not uniform, therefore electricity does not pass evenly through it. Skin resistance is low and allows electricity to pass easily, especially when wet with sweat. Blood has a relatively low resistance, therefore highly vascular areas or inflamed areas of skin have lower resistance. The highest skin resistance is found over heavily calloused areas such as the palm or sole.

The pathway of the current inside the body depends on the resistance of each tissue type. Tissues with the lowest resistance (the best conductance) are nervous tissue, blood, mucous membranes and muscle; the poorest conductors are tendon, bone and fat.

Direct and alternating currents have different effects on the body. Direct current of sufficient intensity causes short duration muscle spasm which may throw the victim from the source. There may be a disturbance of heart rhythm and blunt mechanical trauma. Alternating current, especially at 50 Hz (60 Hz in North America) is approximately three times more dangerous than direct current. Alternating current (40–110 Hz) causes continuous muscle spasm or tetany. As the flexor muscles are more powerful than the extensors, tetany may cause the victim to grip the offending conductor more tightly, thus prolonging the duration of current. Local diaphoresis also reduces skin resistance at the point of contact thus increasing the current.

50 Hz (or 60 Hz) is a bad choice of frequency for the public utility electricity supply because it is the frequency to which the body is most sensitive. At higher frequency the body is progressively less sensitive to the excitable effects of electricity. Radiofrequency surgical diathermy uses frequencies greater than 100 kHz at which comparatively large current may be passed, taking advantage of the heating effects of electricity without affecting excitable tissues.

Effects of hand-to-hand 50 Hz alternating current

1 mA	Tingling sensation
5 mA	Pain
15 mA	Severe pain with local muscle spasm
50 mA	Respiratory muscle spasm
80–100 mA	Dysrhythmias, pump failure, ventricular fibrillation

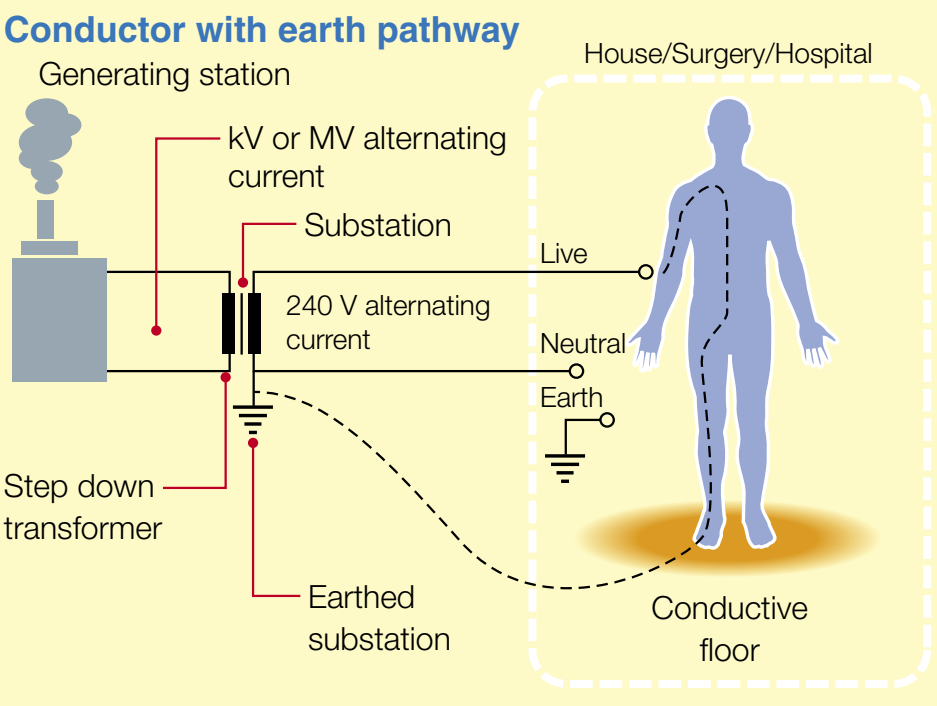
1

Electrical safety

The basic principle of electrical safety is to prevent the body becoming part of an electrical circuit. This requires good design of equipment, cables and connectors. Even with the highest quality of design, the user has the responsibility of using and handling equipment sensibly.

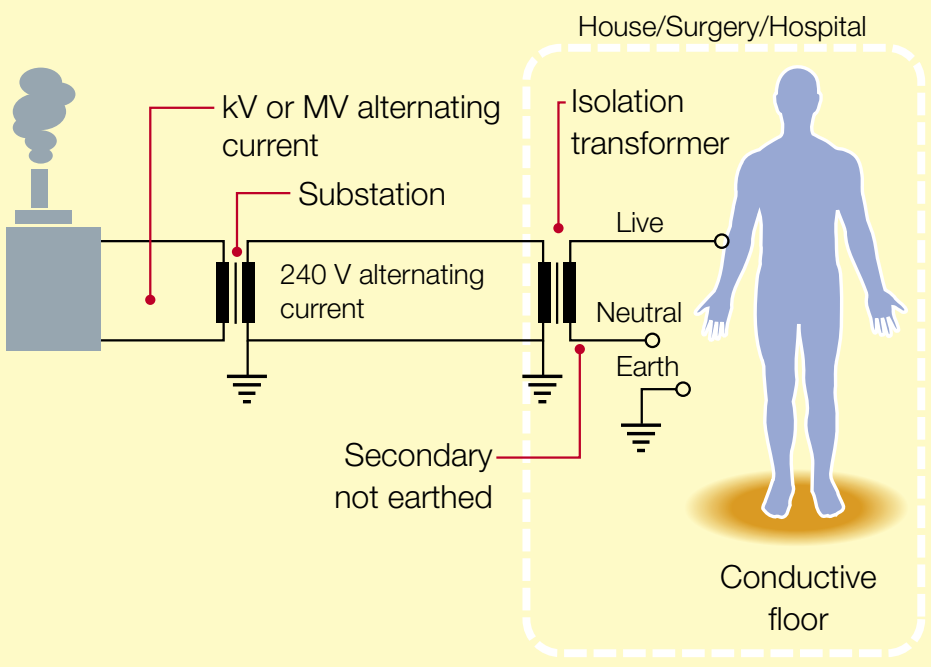
The conventional single-phase mains supply has two conductors: live and neutral. The live conductor is at a voltage dependent on the supply, normally 220–240 volts (110 volts in the USA) with respect to the neutral conductor which is 'tied' to earth at the substation. A safety or earth conductor may also be present which is connected to earth locally and therefore may be at a slightly different potential from the neutral conductor. It is unusual to get an electric shock from the neutral conductor alone but a circuit may be completed between a live conductor or component and either the neutral conductor or, more commonly, an earth pathway (Figure 2). This condition may be eased by the use of an isolation transformer (Figure 3) which will protect against electrocution via earth but not between earth and neutral. Isolation transformers are the most common form of basic protection with medical equipment and are often contained inside the equipment. (Further isolation is required when connection is made directly to the patient, this is described below.)

Conductor with earth pathway



2

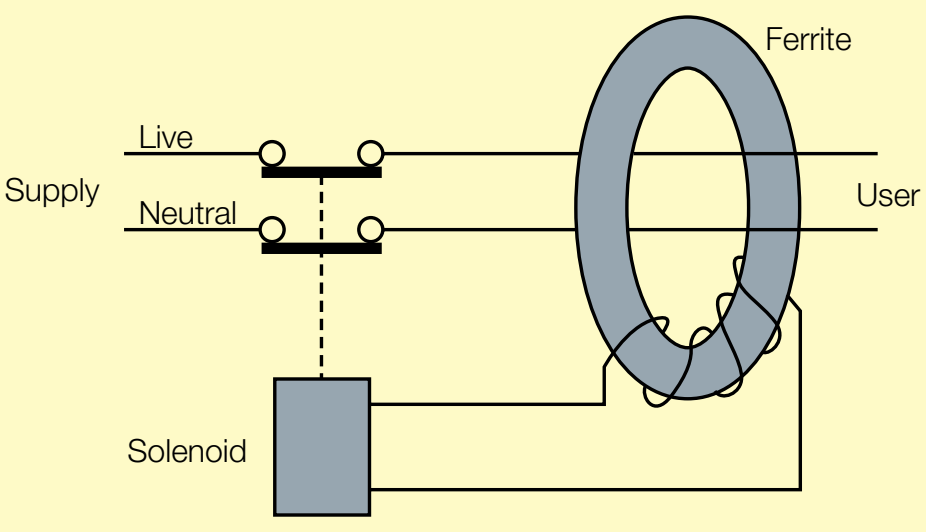
Conductor with isolation transformer



3

Electrocution depends on the duration of exposure and current. The shorter the duration, the higher the current required before damage is done. The earth leakage or residual circuit breaker stops the current passing through the body before any serious damage occurs. This phenomenon is used as the final level of protection from electrocution in the domestic situation and is commonly used commercially for power tools. The principle of the earth leakage circuit breaker (ELCB) is shown in Figure 4. The ferrite ring forms the core of an electrical transformer. The live and neutral conductors pass together through the ring, forming a single-turn primary of the transformer. The secondary of the transformer consists of many turns of much finer wire and is connected to a solenoid. When the solenoid is energized it breaks the supply. In the normal state, current passes down the live conductor, through the appliance and back through the neutral conductor. The current in the neutral is equal and opposite to that in the live and so their magnetic fields are cancelled out and no current is generated in the secondary winding. If some current leaks out of the appliance due to a fault or someone touching a live part, there is an imbalance between the live and neutral and a much amplified current is generated in the secondary, energizing the solenoid and disconnecting the supply.

Earth leakage circuit breaker



4

Microshock: electrocution of the intact human body is commonly referred to as macroshock to distinguish it from microshock in which smaller currents can lead to cardiac dysrhythmia or arrest because one of the points of contact is on or in the heart. 50 Hz mains electricity at a current as low as 50 μA by this route may have serious consequences. Contact may be made with the heart during thoracotomy but a more common and less obvious route is via electrolyte solutions in catheters in or near the heart. Therefore, any equipment that might make connection with the heart must be specially designed to protect against the unintentional passage of these very small currents. Such equipment includes ECG recorders, intravascular pressure monitoring systems, pacemakers and defibrillators.

Leakage current may be defined as electric current that has passed through insulators. It is difficult to design equipment with perfect insulation. The reduction of leakage in medical equipment requires special design features. The designer has to ensure that no electrically live parts are accessible. Any outer metal casing has to be connected to earth; an extra layer of insulation may also be used – the 'double insulation' often used on power tools. These techniques may make a piece of medical equipment safe to be in the patient environment. However, if there is any possibility of connection with the heart, special isolation techniques have to be employed by the equipment designer to ensure that any leakage current is less than 10 μA. This is a stringent limit to achieve.

Safety standards

All medical equipment manufacturers have to comply with published international standards. Each nation also has its own standards organization; in the UK it is the British Standards Institute (BSI). To make standards applicable on a worldwide basis, all national organizations cooperate to write international standards. The International Standards Organization (ISO) deals with everything excluding electricity; the International Electrotechnical Committee (IEC) deals with the standards of anything electrical. Both the ISO and the IEC are based in Geneva.

IEC-60601 is the basic standard for medical equipment. It classifies equipment in two ways; the method of electrical protection and the degree of protection.

- Class I equipment uses a 'protective' earth connection to the outer conductive casing.
- Class II protection is by double insulation. The degree of protection required is classified as B, BF or CF (C, intra cardiac or near cardiac; F, floating) as shown in Figure 5. Figure 6 shows the same symbols, with the indication that the equipment may withstand a defibrillator pulse without damage.

Three types of protection required

Type B applied part

- Maximum leakage current 0.1 mA
- Single fault condition 0.5 mA
- Allowed in patient care area but not in direct contact with patient
- Can be used in X-ray and suction equipment and operating theatre lights

Type BF applied part

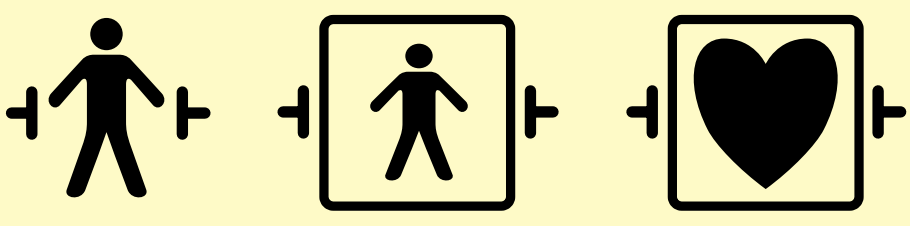
- Maximum leakage current 0.1 mA
- Single fault condition 0.5 mA
- Floating/Isolated
- May be deliberately in contact with patient but not in direct contact with heart
- Can be used in temperature measurement, non-invasive blood pressure measurement, ultrasonography, pulse oximetry, capnography

Type CF applied part

- Maximum leakage current 0.01 mA
- Single fault condition 0.05 mA
- Floating/Isolated
- Suitable for direct cardiac application
- Can be used in ECG, EEG, direct blood pressure measurement, electromagnetic blood flow

5

Symbols indicating equipment is able to withstand a defibrillator pulse



B BF CF

6

Two values of leakage current are given for each category; the lower refers to the equipment in its normal state; the higher value is the maximum allowable leakage current with a single fault condition (SFC). The Standard lists the allowable SFCs for each type of equipment. All medical equipment has to be marked with symbols to show the degree of protection. Figure 7 includes other relevant safety markings that are published in IEC 60601.

Electrical symbols

~	Alternating current
3~	3 Phase alternating current
3N~	3 Phase alternating current with neutral
⎓	Direct current
⏚	Protective earth (ground)
⏚	Earth (ground)
N	Neutral conductor (only on permanently installed equipment)
⏚	Equipotentiality

Fires and Explosions

John Moyle

John Moyle is Consultant in Palliative Medicine in Milton Keynes and a Chartered Engineer. He trained with Philips Electrical Industries. He read medicine at St Bartholomew's Hospital, London and trained in anaesthesia and intensive care at King's College Hospital, London. He teaches physics and clinical measurement to trainee anaesthetists.

Less emphasis is placed on the risk of fire and explosion in the operating theatre today than previously mainly because the use of flammable agents has decreased; for example, ether and cyclopropane are no longer used in anaesthesia. This has lead to a false sense of security and little attention to fire safety. It must not be forgotten that alcohol as an antiseptic and dry drapes are flammable and that the microenvironment around a patient may have an increased concentration of oxygen. Nitrous oxide supports combustion better than oxygen. There are also new sources of ignition, such as the intense energy at the end of fibre-optic 'light pipes' and surgical lasers as well as the dangers associated with the use of surgical diathermy.

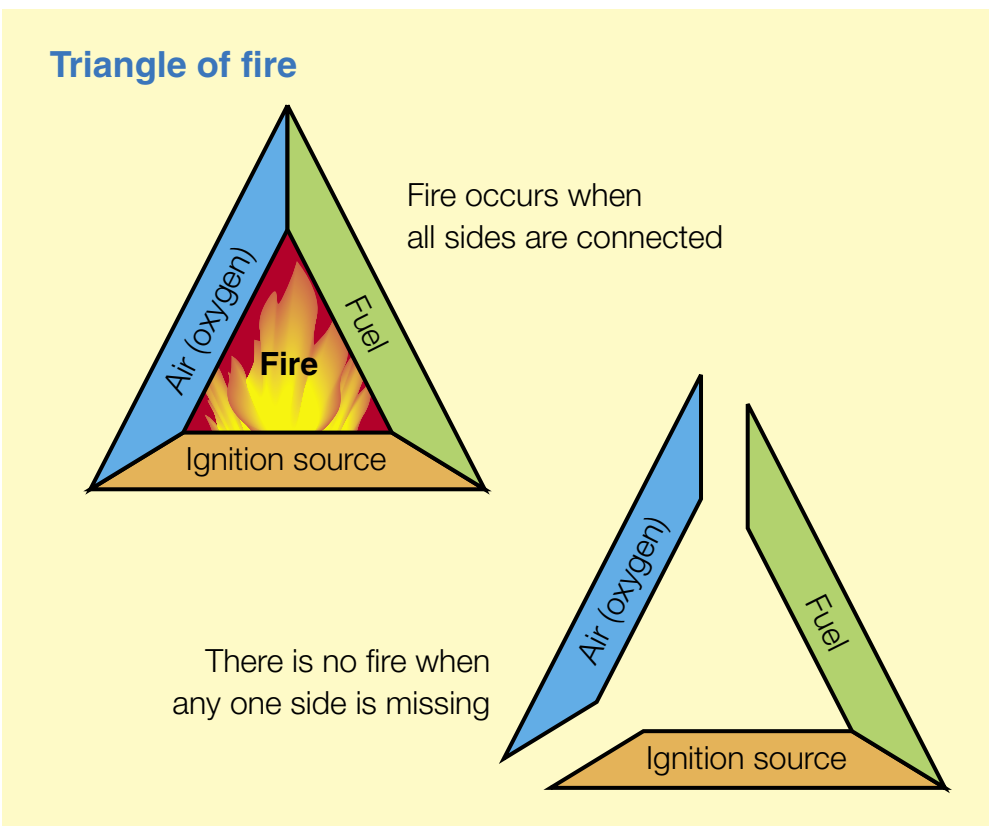
Fire and explosion

Fire or explosion occurs when a substance combines with an oxidizing agent with the release of energy. The reaction requires activation energy to trigger it (Figure 1). If the reaction occurs slowly, heat may be the only obvious evidence, though it usually leads to fire. If the reaction proceeds rapidly, large amounts of heat, light and a rapid increase in pressure occur, making sound; this is an explosion. Fire burns slowly at atmospheric pressure at a temperature of 200–500°C. An explosion is a fast, sudden increase in pressure to a high level at a much higher temperature than fire.

If the rate of liberation of heat is equal to the amount of heat required to maintain the process, the flame will stay still as long as the reactants are made available by convection. If the rate of generation of heat is larger than that required to continue activation, the flame will travel through the mixture. The greater the difference, the greater the likelihood of the reaction travelling so fast that a shock wave occurs; this is an explosion.

On a molecular basis, combustion is a chemical process. In oxidation, the intermolecular bond energy of the end products is less than the bond energy of the reactants and the excess energy is dissipated as heat. To induce the initial deformation of the molecules which allows the rearrangement of these bonds, activation energy has to be added to the system; in the case of fires and explosions this is usually in the form of heat. When the oxidation process begins, positive feedback has to occur to maintain the reaction; if not, the process would cease immediately, before the reaction was complete.

The speed of reaction is greatest for a stochiometric mixture: defined as a mixture in such proportions that none of the reactants is left at the end of the reaction.



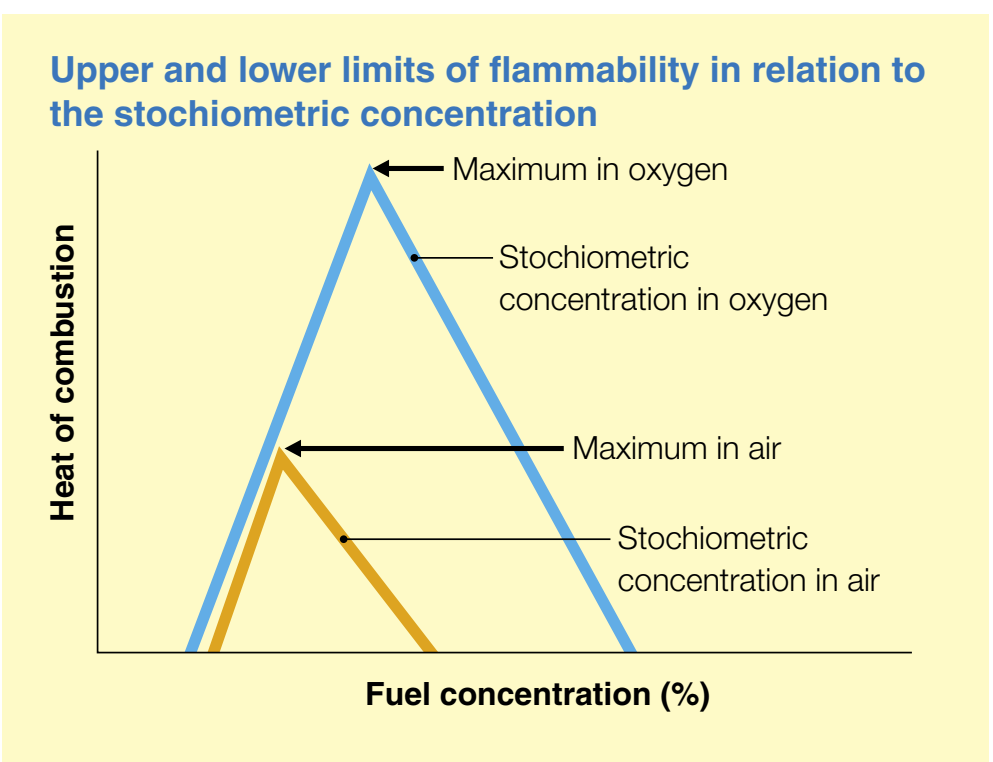
1

Fuel

A gas or vapour may be flammable over a range of concentrations with lower and upper limits of flammability. The stochiometric concentration occurs between these limits. Limits of flammability vary depending on the atmosphere in which the flammable gas or vapour is found (Figure 2).

Anaesthetic gases and vapours are not the only flammable substance that may put the patient at risk.

- Methane and hydrogen are found in bowel gas.
- Alcohol forms the basis of many skin preparation solutions and is in the exhaled gases of the inebriated. Isopropyl alcohol is commonly used to clean the skin before cannulation. Methyl alcohol is used in spirit burners and by down-and-out alcoholics.
- Drapes are often applied to the patient before the alcohol in skin preparation solution has evaporated completely. There may be a high concentration of the vapour, and even some of the liquid alcohol, beneath the drapes.
- Some surgeons use hydrogen peroxide to clean wounds. It rapidly decomposes by enzyme catalysis when poured on to open wounds, producing a froth of hydrogen and oxygen; the gas given off is highly flammable.
- Dry cotton or paper drapes are flammable.
- The plastic compounds used in the manufacture of conventional tracheal tubes may become flammable in high concen-tration of oxygen and high ignition energy levels.



2

Oxygen

Oxygen in the air is the usual source of oxygen involved in a fire. Figure 3 shows that the risk of ignition of any flammable gas or vapour is increased with increased concentration of oxygen above ambient level. Any fire burns more vigorously if the concentration of oxygen is increased.

Nitrous oxide is not combustible but it vigorously supports combustion.

Risks of fire and explosion arise from the strong oxidizing action of nitrous oxide and from its thermodynamic instability. At about 400°C, nitrous oxide breaks down to oxygen and nitrogen and if this comes into contact with combustible material, fire or explosion may result. The concentration of oxygen and nitrous oxide is increased around the mouth and upper airways if a tracheal tube or laryngeal mask does not seal perfectly. There is often an increased concentration of oxygen and nitrous oxide trapped between the patient and the surgical drapes.

Limits of flammability of gases and vapours encountered in the operating theatre[1]

Gas or vapour	Air		Oxygen		Nitrous oxide		30% oxygen 70% nitrous oxide		20% oxygen 80% nitrous oxide	
	L[2]	U	L	U	L	U	L	U	L	U
Diethyl ether	1.9	48	2.0	82	1.5	24

3

Ignition source

Sources of ignition may be sparks generated by static electricity, flames or hot surfaces. Even shaking a bottle containing an organic compound in combination with a peroxide, may cause ignition.

The flash point of a liquid is the lowest temperature at which it gives off enough vapour to form an ignitable mixture with air. At flash point, the vapour will burn, but only briefly because inadequate vapour is produced to maintain combustion. The flash point of a liquid is always quoted but is of less significance to theatre staff than the autoignition temperature.

The autoignition temperature is the minimum temperature above which a flammable mixture is capable of extracting enough energy from the environment to self-ignite. Figure 4 shows the flash points and autoignition temperatures of some compounds in the operating theatre.

If anaesthetic agents that are flammable at clinical concen-trations are used, care must be taken to keep any possible source of ignition outside the zone of risk. There are two zones of risk around the anaesthetic machine, breathing circuit and head and neck of the patient:

- 5 cm if only air is used as the source of oxygen
- 25 cm if nitrous oxide and/or oxygen are used.

Equipment must be marked as AP where air is the only source of oxygen and APG when nitrous oxide or high oxygen concentrations are used.

Possible sources of ignition

Open flames are an obvious source of ignition; they comprise spirit and gas burners, matches and cigarette lighters.

Hot surfaces may cause ignition if the temperature is above the autoignition temperature of the liquid, vapour or solid. In some cases the high temperature of a surface is obvious because it glows or is incandescent.

Hot wire filaments used for cautery may be of high enough temperature to cause ignition. Miniature filament bulbs used in old-fashioned endoscopes may have a surface temperature of 250°C; sufficient to ignite diethyl ether in air.

Light sources – powerful light sources and fibre-optic light-guides have replaced miniature light bulbs but they should always be extinguished when not in use because the energy emitted from the light-guide when not connected to an instrument is intense enough to cause a burn on a surgical drape or the skin. The likelihood of igniting a drape is higher if the concentration of oxygen or nitrous oxide is high in the atmosphere trapped beneath it.

Surgical lasers – see below.

Sparks due to current electricity, as in radiofrequency surgical diathermy and static electricity, are the most obvious sources of ignition in surgical practice. Even sparks that are so small as to be almost invisible may be of sufficient energy to cause ignition.

Sudden increase in gas pressure causes gases to heat. Therefore it is important that no oil, grease or other flammable substance comes into contact with oxygen or nitrous oxide under high pressure.

Lasers

The energy emitted from the tip of a laser applicator is extremely high. The risk of causing ignition is higher than with any other source of emission. Extreme care must be taken to ensure that a laser beam does not come into contact with anything flammable. Any drapes or swabs in the vicinity must be kept wet with water. Care must also be taken to ensure that the beam is not inadvertently reflected on to a flammable surface. If the laser is being used in the mouth, the trachael tube should be of a non-flammable type or be suitably protected. In the case of laser in the bronchi or trachea the oxygen concentration should be 21% or only slightly higher.

Precautions

- Avoid the use of flammable liquids, gases and vapours.
- Keep unsuitable equipment out of zones of risk when flammable anaesthetic agents are in use.
- Observe antistatic precautions.
- Remember bowel gases are flammable.
- Relative humidity should not be less than 50% (a dry atmosphere promotes the generation of static electrical charge).
- At least 15–20 changes of air per hour in the operating theatre will reduce the risk of build-up of flammable vapours.
- High energy light sources must not remain on dry drapes (these sources are of high enough energy to damage tissues).
- Radiofrequency surgical diathermy is a potent source of ignition energy; evaporation of flammable skin preparation solutions must be complete and the atmosphere cleared of the vapour before diathermy is used.

Flash points and autoignition temperatures of flammable liquids encountered in the operating theatre

Compound	Flash point (°C)	Autoignition temperature (°C)
Methyl alcohol	–16	385
Ethyl alcohol	12	363
Diethyl ether	–45	160
Isopropyl alcohol	11.7	455.6

Induction of Anaesthesia

James Austin

James Austin is Specialist Registrar in Anaesthesia in Oxford, UK. He qualified in Cape Town, South Africa and trained in Anaesthesia in Reading, UK.

Induction is the process that produces a state of surgical anaesthesia in a patient. The term is used only in the context of general anaesthesia and not with local anaesthesia. It is the first step in the process of anaesthesia whereby the patient is rendered unconscious, preventing both awareness of, and response to, surgical stimuli. Anaesthesia and physiological sleep are different because sleep has structured, specific EEG patterns and endocrine changes, whereas anaesthesia is associated with a diffuse damping-down of EEG function and a stress-type endocrine response.

The process of induction should ensure patient safety, produce a state of unconsciousness, ensure optimal conditions for the surgeon and prepare the patient for waking and recovery.

Before anaesthesia is induced, the anaesthetist must:

- assess the patient as completely as circumstances allow, and institute preoperative preparations (e.g. intravenous fluids, sedative drugs, analgesics)
- discuss the surgery with the surgeon, particularly in complex or unusual cases
- plan the anaesthetic technique
- ensure all necessary equipment and drugs are available, and that the equipment is working.

On arrival in the anaesthetic suite, the anaesthetist must ensure:

- the correct patient has arrived
- the correct operation is planned on the correct side
- consent has been given
- jewellery or prostheses have been removed or declared
- blood for transfusion is available if required.

Anaesthetic room

In the UK, most inductions take place in a dedicated anaesthetic room; however, in many other countries induction takes place on the operating table in theatre. The main advantage of using a dedicated induction room is the quicker change-around as the theatre is cleaned and prepared between patients. If staffing permits, induction may take place while the previous case is being completed. A separate induction room also avoids the psychological stress (for some patients) of seeing the operating theatre. The anaesthetic room must be equipped with the necessary anaesthetic and monitoring equipment for the induction to be completed safely. The duplication of equipment between anaesthetic room and operating theatre may be a financial constraint in some locations. In urgent cases, with potentially unstable patients or with the morbidly obese, theatre is the best place for induction, because it saves the time, physical hazards and period of reduced or absent monitoring associated with transfer.

Equipment checks: successful induction requires planning and attention to detail. Before the procedure begins, checks of the anaesthetic machine must have been completed and the following must be available:

- the patient must be on a tilting bed or trolley
- two working laryngoscopes (in case of bulb failure), including standard and long blades (sizes 3 and 4)
- a selection of laryngoscope blade types (e.g. the Macintosh and the McCoy levering blade)
- a selection of tracheal tube sizes, with their cuffs checked
- suction equipment
- equipment to deal with difficult or failed intubation, including oral and nasal airways, gum-elastic bougie, laryngeal mask
- standard monitoring equipment (e.g. pulse oximeter, ECG, capnometer, blood pressure monitor).

Monitoring

In addition to the clinical observations made by the anaesthetist, the Association of Anaesthetists of Great Britain and Ireland has published recommendation for standards of monitoring equipment during anaesthesia and recovery. Monitoring should be instituted before induction whenever possible and should consist of a pulse oximeter (ideally with continuous display of pulse rate and plethysmography), an ECG and non-invasive arterial blood pressure monitoring. Following unconsciousness, other variables should also be monitored, including:

- carbon dioxide (using a capnometer)
- the anaesthetic vapour concentration
- body temperature
- neuromuscular function if muscle relaxants are used (assessed using a nerve stimulator)
- invasive arterial or central venous pressures and urine output monitoring may be required.

Induction methods

Most anaesthetic inductions are performed using intravenous or inhalational (‘gas’) induction; each has advantages and disadvantages (Figure 1). Less commonly, induction may be carried out by the intramuscular route in uncooperative patients, children or those with difficult venous access. Ketamine,10 mg/kg, provides up to 30 minutes of surgical anaesthesia, but induction times are unpredictable (15–45 minutes) and recovery is slow. Rectal induction with thiopentone, methohexitone, chloral hydrate or benzodiazepines was popular for children at one time, but is seldom used now. Oral induction is effectively a heavy sedative or ‘premedicant’, rather than induction, and recovery time is prolonged.

There are several tasks to be accomplished with any form of induction:

- last-minute preliminary checks (as specified above)
- establish monitoring
- establish intravenous access
- produce unconsciousness
- secure the airway
- establish ventilation
- commence analgesia (systemic or local)
- position the patient
- establish maintenance of anaesthesia.

Intravenous and inhalational induction

Intravenous	Inhalation
Advantages	*Advantages*
• Rapid onset • Patient comfort • Airway protection in rapid-sequence induction	• Does not require IV access • Useful for children • Useful for adults with needle-phobia
Disadvantages	*Disadvantages*
• Contraindicated in patients with a ‘difficult airway’	• Slow induction • ‘Excitement’ phase • Risk of vomiting • Risk of arrhythmias • Volatile agents contraindicated in patients susceptible to malignant hyperpyrexia

1

Intravenous induction

Pulse oximetry and ECG monitoring should be established before intravenous access because occasionally a cardiovascular event (e.g. vasovagal syncope) occurs during cannulation. Intravascular access commonly consists of a simple venous cannula; however, complex cases may require an arterial line, a central venous line and/or a pulmonary artery catheter. These may be sited with local anaesthesia before induction, to provide additional monitoring if haemodynamic instability is expected.

Following intravenous access, preliminary drugs (e.g. analgesics, antibiotics, anti-emetics) may be given. These vary according to the clinical circumstances and a detailed discussion is beyond the scope of this article. A regional analgesic block, if required, may also be given at this stage. Whether to insert the block before or after the patient is anaesthetized is the subject of some controversy (Figure 2).

Advantages of regional nerve blockade performed either before or after induction

Before induction	After induction
• Patient cooperation with correct positioning • Patient may provide feedback to minimize neural damage by needle or injection • Less requirement for anaesthetic monitoring	• Patient preference • Correct positioning may be easier (e.g. patients with painful fractures or skeletal deformity)

2

Pre-oxygenation: some anaesthetists routinely pre-oxygenate their patients before induction. The correct technique is for the patient to breathe 100% oxygen via an anaesthetic circuit and close-fitting mask for about 3 minutes of tidal volume breathing. Alternatively, pre-oxygenation by three vital capacity breaths has been demonstrated to be effective. The aim is to replace nitrogen-containing air in the resting volume of the lungs (the functional residual capacity, FRC) with a high oxygen concentration. The gas within the FRC acts as an important oxygen store, and therefore pre-oxygenation lengthens the time before hypoxaemia occurs following the onset of apnoea. This may provide valuable time in which the airway can be secured if an unexpectedly difficult airway is encountered. Mask phobia and the difficulties in achieving a mask seal in non-compliant patients and children are the only significant contraindications to pre-oxygenation. Pre-oxygenation is mandatory in rapid-sequence induction.

Intravenous drugs: slow, smooth injection of an intravenous anaesthetic agent usually results in loss of consciousness in less than 1 minute. Thiopentone, for example, starts to work in a period of one ‘arm–brain circulation time’. This is the period of time taken for the drug to travel from the site of injection (the arm) to the site of action (the brain) and is about 15 seconds in a healthy patient. The dose is carefully titrated according to patient response. Typical induction doses for healthy individuals are shown in Figure 3, but dose reduction may be required in:

- patients who are less fit
- the elderly or frail
- neonates
- patients with hypotension or poor cardiac reserve
- patients with chronic renal or liver disease
- patients with raised intracranial pressure
- patients who have been premedicated.

It can be difficult to judge when enough induction agent has been given. Care and experience are needed to titrate dose to effect but some indicators include:

- loss of response to verbal command
- loss of eyelash reflex (in which brushing the eyelash produces a blink response)
- relaxation of a motor posture (e.g. a raised arm or a grip on an object)
- cooperation with bag/mask ventilation.

The eyelash reflex has conventionally been regarded as a good end-point for thiopentone induction, but it is less reliable in propofol induction, for which loss of verbal response or motor relaxation is a more useful end-point.

Induction doses of intravenous drugs

Drug	Typical adult induction dose (mg/kg)	Notes
• Propofol	1.5–2.5	Popular and widely used drug associated with rapid and ‘clear-headed' recovery. Rapid metabolism and lack of cumulative effects has made it popular for total intravenous anaesthesia
• Thiopentone	3–5 (2.5% solution)	The ‘gold-standard’ against which all other drugs are judged. Smooth induction in one arm–brain circulation time
• Methohexitone	1–1.5 (1% solution)	Lowers the convulsive threshold, mainly used in anaesthesia for electroconvulsive therapy
• Etomidate	0.2–0.3	Marked cardiovascular stability makes this drug popular for use in unstable patients
• Ketamine	0.5–2	Useful for sedation with profound analgesia. Increases pulse rate and blood pressure and useful for the induction of patients suffering from acute trauma
• Midazolam	0.15–0.5	A benzodiazepine that may provide stable induction for the elderly and frail, in combination with an opioid

3

Further procedures: the induction agent may be followed by a muscle relaxant, particularly if tracheal intubation is planned. It is important to confirm that the patient's lungs can be ventilated via a bag and mask before paralysing. A muscle relaxant should not be given until it has been confirmed that ventilation is possible. Once anaesthesia is adequate, a clear airway is established using a simple face mask (with or without an oral or nasal airway), laryngeal mask airway or tracheal intubation. If the level of anaesthesia proves to be inadequate to allow an airway or tracheal tube to be tolerated, it may be deepened either with supplementary doses of intravenous agent, or by ventilating with volatile anaesthetic. With the airway secure, ventilation can continue by the patient's own effort, by manual 'hand' ventilation, or by mechanical ventilator.

At this stage, further invasive procedures may take place, such as additional vascular access, regional blocks, bladder catheterization, passing of a nasogastric tube or insertion of a temperature probe.

Transfer to theatre: if anaesthesia has been induced in the anaesthetic room, the patient is now transferred to theatre. This is potentially hazardous because for a short time the patient is separated from monitoring equipment and the mechanical ventilator. The patient is also potentially unstable because of the effects of induction drugs and is at risk of injury during the physical transfer. It is the anaesthetist's responsibility to guarantee the patient's safety. It should be ensured that ventilation and anaesthetic maintenance are re-established in good time, that tubes and lines are not dislodged, and that changes in clinical condition are detected promptly, in particular, cardiovascular instability, desaturation or signs of waking from anaesthesia.

Once in theatre, the priorities are:

- prompt transfer on to the operating table
- prompt re-establishment of ventilation
- prompt re-establishment of anaesthetic maintenance if using volatile anaesthetic drugs
- check correct drug delivery if using intravenous maintenance technique
- prompt re-establishment of monitoring equipment
- safe positioning of the patient
- commencement of maintenance fluids and temperature control.

Rapid-sequence induction

Rapid-sequence induction is used to decrease the risk of aspiration if the patient may have a full stomach, for example in an emergency. In patients presenting for elective surgery, a period of starvation of 2 hours for clear fluids, or 6 hours for food, is considered appropriate. Bowel obstruction, incompetent lower oesophageal sphincter, pregnancy and gastroparesis caused by disease, pain or drugs such as opiate analgesics are also causes of a potentially 'full stomach'.

The incidence and severity of aspiration of gastric contents are made worse by the nature, volume and pH of the gastric solution. Mendelson's studies on aspiration pneumonitis showed that aspiration of solid particles produced more damage than purely fluid aspirates. A potential gastric aspirate greater than 25 ml in volume and/or with a pH less than 2.5 is considered dangerous, though there is little direct clinical evidence for this. In these 'at-risk' patients it is sensible to attempt to raise gastric pH, and to try to promote gastric emptying. Pre-medication with ranitidine, 50 mg i.v., to decrease gastric acidity, and metoclopramide, 10 mg i.v., to enhance gastric emptying and increase the tone of the lower oesophageal sphincter is popular with some anaesthetists; both take at least 1 hour to take effect. A non-particulate antacid, such as sodium citrate, 30 ml of 0.3 M solution orally, given on leaving the ward or arriving in the anaesthetic room, further neutralizes residual stomach acid, but at the expense of raising gastric volume further.

Some anaesthetists advise that a nasogastric tube should be passed to drain the stomach, but it is uncomfortable and may induce vomiting. The counter argument is that any vomiting is better done while the patient is fully awake with protective airway reflexes. If a nasogastric tube is already in place it should be aspirated. If the gastric contents are still acidic on litmus test, consideration should be given to instilling sodium citrate. The old practice of inducing vomiting with ipecac or apomorphine is no longer advised.

The 'rapid sequence' of drug administration aims to produce unconsciousness and intubation conditions as rapidly as possible. The airway is swiftly protected by a cuffed tracheal tube without prior inflation of the lungs via bag and mask. This is to prevent possible gastric distension with an increased risk of gastric reflux. It is performed with the help of a trained assistant, competent in the technique of cricoid pressure.

Muscle relaxants are administered before the airway is controlled, and in this way rapid-sequence induction breaks an important rule of anaesthesia. Careful preoperative assessment of potential airway difficulty is therefore vital, and rapid-sequence induction must not be performed if this assessment predicts difficulty with intubation. The trainee anaesthetist must seek further advice, because an awake intubation technique may then be indicated.

Pre-oxygenation is mandatory, though it may be difficult to achieve in children. Pre-oxygenation reduces the need to ventilate the lungs before intubation. The correct technique is described above. Oxygen must be delivered via an anaesthetic breathing system capable of delivering 100% oxygen; standard 'Hudson' type face masks are inadequate.

Drug injection: the chosen drug is rapidly adminstered (Figure 3). Thiopentone is the drug of choice because of its rapid onset of action in one arm–brain circulation time, but propofol or etomidate are alternatives, albeit slightly slower-acting. The use of rapid-acting opioids such as alfentanil, 10 μg/kg, or fentanyl, 1 μg/kg, helps to reduce the pressor response to laryngoscopy.

Cricoid pressure: or Sellick's manoeuvre, is traditionally practised in rapid-sequence induction and is applied by the anaesthetic assistant as the patient starts to lose consciousness. Pressure is applied to the cricoid cartilage to compress it against the oesophagus, preventing passive regurgitation of stomach contents.

If active vomiting occurs, it is recommended that cricoid pressure be removed to prevent oesophageal rupture – suction, head-down tilt and turning the patient's head to one side is then used instead. Otherwise, cricoid pressure is removed only on the instruction of the anaesthetist, once the airway has been secured with a cuffed tube. Occasionally, it may be removed to facilitate an intubation that is being made more difficult by its continued application.

Muscle relaxation: suxamethonium, 1.5 mg/kg, is the drug of choice. Its rapid onset produces ideal intubating conditions, with a peak effect of muscle relaxation within 50 seconds of injection. It is important to allow the drug time to work, and not to begin the intubation sequence before muscle fasciculations have subsided.

The duration of apnoea is usually about 5 minutes in healthy individuals, and thus spontaneous respiration may be re-established early in the event of a failed intubation. Suxamethonium is contraindicated in patients with:

- previous allergy
- susceptibility to malignant hyperpyrexia
- myotonia
- severe burns, muscle damage or paraplegia (of over 1 week's duration)
- known raised serum potassium.

In these patients, rocuronium, 0.6–0.9 mg/kg, may provide relaxation as rapidly as suxamethonium, but with longer duration. Rocuronium is also the drug of choice in patients with reduced or absent plasma cholinesterase activity, in whom suxamethonium has a long and unpredictable duration of action.

Intubation: the trachea is intubated with a cuffed tube following unconsciousness and muscle relaxation. Uncuffed tubes are used in children to avoid local pressure on the tracheal wall and to maximize the internal diameter of tube available. If difficulty is encountered with direct laryngoscopy, then simple steps may be taken to facilitate intubation:

- manipulate the larynx (the assistant providing the cricoid pressure may be distorting the view of the larynx)
- change to a larger blade laryngoscope
- change to a different type of blade (e.g. a McCoy levering blade)
- use the gum-elastic bougie (this thin, flexible stylet may be used to pass through the cords providing a 'track' over which the tracheal tube can be railroaded).

Before the cricoid pressure is released, the correct position of the tube must be checked carefully by auscultation and capnometry. Once the cuff has been inflated and the airway has been secured, a nasogastric tube should be passed and aspirated, if not done previously. The rest of the anaesthetic proceeds as usual; but at the end of the procedure extubation should take place with the patient awake, with their protective airway reflexes re-established, positioned on their side in a head-down tilt, and with suction available.

Failed intubation drill – if the trachea is not successfully intubated, a failed intubation drill must be followed:

- cease further attempts at intubation
- call for help
- maintain cricoid pressure
- insert an oral airway
- hand-ventilate via bag and mask using 100% oxygen
- await return of spontaneous respiration
- once spontaneous ventilation has returned, turn the patient into the lateral position with head tilted down and await return of consciousness.

A decision to abandon further attempts at intubation must be made early and certainly before arterial desaturation supervenes. The prime concern of the anaesthetist is patient safety. The safest option following failed intubation is to wake the patient. Once the effects of the intravenous induction agent and muscle relaxant have worn off, consideration must be given to how to proceed. This requires consultation with a senior anaesthetist and may involve an awake intubation technique.

Inhalational induction

Gas induction, controversially, is often used as a means of inducing anaesthesia (particularly in a child) without having to site an intravenous cannula first. However, in the event of difficulties (e.g. laryngospasm, arrhythmias) instant intravenous access should be available, because otherwise the anaesthetist controlling the airway will be unable to attempt rapid cannulation. For this reason, some anaesthetists seldom perform gas induction; others permit gas induction if a second anaesthetist is present to assist with intravenous cannulation. Gas induction of children and adults has taken place without intravenous access for over 150 years, in most cases safely and without incident.

Indications: gas induction (with intravenous access) is indicated for patients in whom airway difficulties are expected. In these cases, the patient continues to breathe spontaneously throughout and apnoea is avoided, since it may then be impossible to manually ventilate the lungs with bag and mask.

Upper airway obstruction is an important indication for inhalation induction, and in these circumstances fibre-optic techniques for intubating the trachea are contraindicated for fear of producing complete airway obstruction. However, in patients with an unobstructed 'difficult' airway, the increasing availability of fibre-optic intubation equipment and the growing skill of anaesthetists in awake intubation techniques may reduce the need for gas induction. The difficult airway may best be secured even before anaesthesia is induced.

Technique: there is controversy over whether to induce in 100% oxygen or to use nitrous oxide as well.

- Concurrent use of volatile and nitrous oxide exploits the second-gas effect for a cumulatively more rapid induction. The rapid absorption of the second gas (nitrous oxide) has the effect of increasing the alveolar concentration of the first agent. The partial pressure of anaesthetic gas in the alveolus reflects the partial pressure of anaesthetic in the brain and hence the anaesthetic effect.
- 'Pre-induction', with 33% oxygen and 66% nitrous oxide only, may render a child sleepy enough not to resist when the odour of the volatile agent is added. Clearly the more nitrous oxide is used the more anaesthetic effect is achieved; but likewise the less reserve there is against desaturation. A minimum of 30% oxygen should be given.
- Induction in 100% oxygen is least smooth, but should laryngospasm occur, it is an advantage to have as much of the lung FRC filled with oxygen as possible. This maximizes oxygen stores and thus delays the onset of hypoxaemia.

Conventional practice for inhalational induction with halothane is to start with a low inspired concentration of 0.5%, and to increase it by 0.5% every four breaths up to 4%.

Sevoflurane has greatly enhanced gas induction, because it is faster, better tolerated by patients, and is less arrhythmogenic than halothane. It has been suggested that the lower incidence of arrhythmias has contributed to a decrease in dental anaesthetic deaths in recent years. The high blood-gas solubility of sevoflurane accounts for its rapid onset and offset. Because sevoflurane is less pungent it is often used in high concentrations (maximum 8% on most vaporizers) for faster induction.

Enflurane is seldom used for gas inductions because it is slow; isoflurane and desflurane are almost never used because they are pungent and irritating to the airway.

The last-minute checks before inhalational induction are the same as those for the intravenous route. Monitoring should be established; some children make this difficult, but ECG should be the minimum monitoring instituted. Induction should ideally take place via a tight-fitting face mask (even small leaks may significantly delay induction). However, the use of a cupped hand may be less threatening to a small child in the first instance.

'Single-breath induction' has been described with halothane and sevoflurane. A Mapleson A breathing system containing a 4-litre reservoir bag is filled with a maximum concentration of volatile anaesthetic (4% halothane or 8% sevoflurane) in 66% nitrous oxide and 33% oxygen. The patient is asked to exhale to residual volume, then, via a tight-fitting mask, to inhale a full vital-capacity breath of gas, and then to hold their breath for as long as possible. This technique produces a faster induction than conventional tidal volume inhalational induction in cooperative adults. In the case of single-breath 8% sevoflurane, the speed of induction is comparable with induction with intravenous propofol. It may be a useful technique to use in cooperative needle-phobic adults, but it offers few other advantages.

Four main variables determine the speed of inhalational anaesthetic induction.

- The inspired partial pressure of the anaesthetic agent relative to its minimum alveolar concentration (MAC) alters the speed of induction. MAC is the partial pressure of the agent, expressed in volumes %, which at equilibrium prevents gross muscle movement in response to a skin incision in 50% of patients. It is thus the effective dose in 50% of patients and is a measure of anaesthetic potency.
- The faster the patient breathes, or the greater the alveolar ventilation, the faster the alveolar partial pressure of the agent approaches the inspired partial pressure. In a child, crying speeds up gas induction by increasing minute ventilation.
- The higher the cardiac output the more anaesthetic agent is removed from the alveoli and hence the slower the partial pressure rises in the alveoli. Thus, an anxious, hyperdynamic patient is slow to induce, whereas a shocked patient with a low cardiac output is quicker.
- The higher the solubility of an agent (i.e. a high blood-gas solubility coefficient), the more the agent will dissolve in blood and thus a lower partial pressure will be generated. Agents with a low solubility (e.g. sevoflurane) result in more rapid induction.

During a gas induction, most patients pass briefly through a phase of excitability during which they may be agitated and at increased risk of laryngospasm or, more rarely, arrhythmias. If a child is being induced, it is useful to warn the parents of this disinhibition in advance. The disinhibition is not remembered by the patient.

Once the patient is unconscious, anaesthesia should be deepened, assisting the ventilation by hand, using bag and mask if necessary. If not already obtained, intravenous access should be secured, which requires the help of an assistant. Muscle relaxants may then be given intravenously to assist in securing the airway. If the patient is sufficiently deeply anaesthetized, as evidenced by a regular respiratory pattern and a forward gaze in eyes with small pupils, the airway may be secured (even by intubation) purely under inhalational anaesthesia. Nevertheless, it is valuable to have intravenous access before attempting to manipulate the airway, in case any untoward airway reflexes are produced (e.g. arrhythmias, laryngospasm). With the airway secured, the remainder of the induction sequence proceeds as above.

Historical note

In 1937, Arthur Guedel published *'Inhalational Anaesthesia – a Fundamental Guide',* three chapters of which were devoted to his observations of premedicated patients' responses to gas inductions with nitrous oxide, the ethers, chloroform and cyclopropane

Guedel's stages of anaesthesia

Stage	Definition	Features
1 Analgesia	From beginning to loss of consciousness	Sedation Loss of eyelash reflex[1]
2 Delirium	Loss of consciousness to onset of rhythmic breathing	Agitation, vomiting, arrhythmias Eyes deviated
3 Surgical		
• 1st plane	Onset of rhythmic breathing to loss of eyeball movement	Loss of eyelid reflex Loss of conjunctival reflex[1]
• 2nd plane	Loss of eyeball movement to onset of intercostal paralysis	Loss of laryngeal and gag reflexes Loss of corneal reflex[1]
• 3rd plane	Onset to completion of intercostal paralysis	
• 4th plane	Complete intercostal paralysis to respiratory arrest	Dilated pupils Loss of carinal reflex[1]
4 Respiratory paralysis	Respiratory arrest to death	Loss of anal reflex

[1] Not described in Guedel's original monograph

Induction in children

Children from about 3 months of age until the teenage years are generally more anxious, or less able to control their anxiety, than adults. The preoperative visit is important in children because meeting the anaesthetist and having the procedure explained calms the fears of children and parents. If the child is old enough, address your conversation to him or her. Explain in detail what will happen, and invite the parents and child to ask questions. Where possible, bring relevant equipment, particularly a face mask for gas induction, for the child to become familiar with.

Topical local anaesthetic cream such as EMLA (a eutectic mixture of lignocaine and prilocaine) or amethocaine gel is desirable if awake intravenous access is planned. Marking visible veins in advance helps the nurse to cover the right spots. Both preparations are similarly effective in clinical practice though onset and duration of action differ (Figure 4).

It has become common for parents to accompany children to the anaesthetic room, and this is generally helpful. Smaller children may best be anaesthetized on a parent's lap – a well-positioned hug serves to comfort the child and to restrain them during intravenous cannulation or gas induction. Strapping for the cannula, and the induction drugs, should be on hand for swift application once access has been obtained.

- For gas induction, a sideways hug helps to immobilize all the limbs, while the anaesthetist's hands control the head.
- For intravenous cannulation, a 'face-to-face' hug (Figure 5), with the child's arm under the parent's arm, helps to immobilize the arm and restrict the child's view of cannulation.
- The older child may prefer or need to be anaesthetized on the trolley. If the trolley permits, it is useful to raise the back until just before (or even during) induction itself. This more upright position allows the child a better view of their surroundings, and hence a feeling of more control and less anxiety.

Children should be treated with respect at all times. They should be spoken to in non-condescending language they can understand – if something is going to be unpleasant, it should be acknowledged. The alternative is for the child to become suspicious and uncooperative for even the most innocuous procedure. There is no formula that will ensure every paediatric induction is smooth and trouble-free; some children will be understandably fractious despite all efforts to calm them.

Comparison of EMLA cream and amethocaine gel

	EMLA cream	Amethocaine gel
Constituents	Lignocaine 2.5%, prilocaine 2.5% as an oil/water emulsion	Amethocaine 4%
Presentation	White cream, 5 g per tube	Clear gel, 1.5 g per tube
Application	2 g minimum 1 hour before venepuncture, maximum 5 hours	1 g 30–45 minutes before venepuncture. Remove after 45 minutes
Duration	Efficacy declines soon after cream is removed	Efficacy remains 4–6 hours after application
Skin effects	Usually transient paleness May produce redness and oedema	Usually transient redness May produce itching and oedema
Contra-indications	Not for children < 1 year	Not for children < 1 month

4

5 Hugging the child face to face helps to immobilize the arms.

Induction of Anaesthesia in Special Circumstances

Christopher F Kearns

Christopher F Kearns is Consultant Anaesthetist in the Nuffield Department of Anaesthetics, The Radcliffe Infirmary, Oxford, UK. He qualified from Charing Cross Hospital and trained in anaesthesia and intensive care at St Bartholomew's Hospital, London, in Toronto, Canada, and at Oxford. His clinical interest is neuroanaesthesia. He organizes the Oxford Primary FRCA courses.

A full stomach

The pulmonary aspiration of acid gastric contents has long been recognized as a major risk of anaesthesia. Patients are normally asked to fast preoperatively to allow sufficient time for gastric emptying. However, induction of anaesthesia in the presence of a full stomach may be unavoidable when normal gastric emptying is impaired, or when the urgency of surgical intervention overrides the requirement for a patient to have fasted adequately. Gastric stasis, ileus and reverse peristalsis may accompany obstruction or perforation of the gastrointestinal tract. Trauma, pain and its treatment with opioids delays gastric emptying. Gastric motility may also be abnormal in the presence of diabetes mellitus or obesity and in these circumstances no period of fasting may be considered to be safe. The hazards of induction of anaesthesia in these circumstances are listed in Figure 1.

If the patient has a full stomach an attempt to reduce intragastric volume and acidity before anaesthetic induction is desirable. Gastric fluid may be removed through a gastric tube, or if there is time and no contraindications by giving a prokinetic agent (e.g. metoclopramide, 10 mg i.v.). The pH of the gastric contents may be increased by the ingestion before induction of a non-particulate alkali, usually 30 ml of a 0.3 molar solution of sodium bicarbonate.

Induction of anaesthesia in the presence of a full stomach

Hazards	Management
Pulmonary aspiration of gastric contents	Reduce gastric volume Raise intragastric pH with alkali Use of cricoid pressure Rapid sequence induction
Unanticipated failure to intubate	Preoxygenation Rapid sequence induction Failed intubation drill

1

Rapid sequence induction

Rapid sequence induction is the anaesthetic technique indicated in the presence of a full stomach (Figure 2). It aims to reduce to a minimum the period during which the airway is unprotected after induction of anaesthesia and before inflation of the cuff of a correctly placed tracheal tube.

During preparation for rapid sequence induction, a skilled assistant should carefully identify and hold the cricoid cartilage between the thumb and forefinger, ready to apply cricoid pressure as anaesthesia is induced. Cricoid pressure (Sellick's manoeuvre) correctly applied with adequate, but not excessive, force compresses and occludes the upper oesophagus between the flat posterior surface of the cricoid cartilage and the body of the sixth cervical vertebra, preventing reflux of gastric contents without distorting the view at laryngoscopy. If a gastric tube is already in place, it should not be removed but should be allowed to act as a gastric vent.

The main risk of rapid sequence induction is that there is no prior opportunity to ensure that intubation or mask ventilation will be possible after induction. Good preparation for intubation is vital and it is essential that all equipment is checked, suction equipment and aids to oxygenation are ready and the patient is in an optimum intubating position.

The patient's lungs should be preoxygenated. This is achieved by allowing the patient to breathe 100% oxygen through a tightly fitting mask and anaesthetic circuit for about 3 minutes. When apnoea occurs at induction, the lung rests at end tidal volume where there is equilibrium between the elastic recoil of the lungs and the chest wall. Arterial oxygen desaturation follows when the oxygen content within the functional residual capacity (FRC) of the lungs is exhausted. During preoxygenation, the nitrogen in the FRC will be displaced, increasing the oxygen content of this reservoir substantially and delaying the onset of cyanosis after induction of apnoea. Despite these measures, arterial oxygen desaturation is accelerated by the presence of a reduced FRC (e.g. obesity), a raised metabolic oxygen demand (e.g. sepsis) or a combination of the two (e.g. late pregnancy).

Rapid sequence induction requires the use of rapidly acting induction and paralysing agents injected intravenously in quick succession. Most intravenous induction agents cause loss of consciousness within one arm–brain circulation time in the following doses: thiopental (thiopentone), 2–4 mg/kg, etomidate 0.2–0.3 mg/kg, propofol 2–3 mg/kg. In UK practice, suxamethonium, 1.5 mg/kg, remains the neuromuscular blocking agent of choice because it provides optimum intubation conditions in the shortest time.

Once the correct position of the tracheal tube is verified clinically and by capnography and after the cuff has been inflated, cricoid pressure can be released.

In case of failure to intubate, the duration of action of the induction and paralysing agents is critical. Despite the additional time made available by preoxygenation, it may be impossible to see the larynx or intubate the patient. It is then essential to revert to a well-rehearsed failed intubation drill. The effects of the common induction agents wear off in a few minutes and the choice of suxamethonium is reinforced by its short duration of action. The temptation to give a second dose of the drugs and prolong attempts at intubation should be resisted. At this point, resumption of patient oxygenation is the priority.

Rapid sequence induction

- Selection of intubation aids and equipment for cricothyroid puncture
- Skilled assistant applying cricoid pressure
- Patient on surface that can be tipped head down
- Suction switched on with catheter under pillow
- Optimal patient intubating position
- Good quality venous access with running intravenous infusion
- Preoxygenation with 100% oxygen through close fitting face mask
- Single sleep dose of intravenous induction agent
- Single adequate intravenous dose of suxamethonium (e.g. 1.5 mg/kg)
- Failed intubation drill

2

After head injury

Induction of anaesthesia and tracheal intubation after head injury (Figure 3) is indicated when:

- the patient's airway or oxygenation is compromised
- the patient has a depressed level of consciousness (Glasgow Coma Score of 8 or less)
- in the presence of agitation
- before emergency surgery
- in preparation for safe transfer to either CT scanner or to a neurosurgical centre.

It is vital to prevent secondary brain injury due to hypoxia, hypotension, hypercapnia or uncontrolled rises in intracranial pressure. The patient is assumed to have a full stomach so a rapid sequence induction with preoxygenation and cricoid pressure is indicated. In addition, patients presenting with a severe head injury must be assumed to have suffered a cervical spine injury. Cricoid pressure is applied using a two-handed technique, the second hand supporting the back of the cervical spine. Another assistant is required to provide manual in line stabilization of the spine during induction because any cervical collar has to be temporarily removed to facilitate intubation. Coexisting facial injuries need to be assessed carefully because they may affect intubation by displacing, distorting or obstructing the airway.

Careful monitoring of cardiovascular status is required. It may not be practical to monitor blood pressure invasively before induction, but non-invasive measurements should be made frequently. Suppression of the hypertensive response to intubation requires an intravenous induction agent, though the dose may have to be reduced in the presence of depressed consciousness. Lidocaine (lignocaine), 1 mg/kg, may also be given for this purpose. After induction there should be a smooth transition to maintenance sedation, which may include opiates, to avoid fluctuations in blood pressure.

Suxamethonium is associated with a transient rise in intracranial pressure, but this potential for harm is outweighed by its advantage of rapidly producing optimal intubating con-ditions and thereby reducing the risk of hypoxia. A peripheral nerve stimulator will help to ensure adequate neuromuscular blockade before intubation, and that a non-depolarizing agent is given in time to prevent coughing and facilitate controlled ventilation as the effect of suxamethonium wears off.

Tracheal and gastric tubes should not be placed nasally, for fear of breaching a skull base fracture. Constriction or distortion of neck veins that could result in cerebral venous hypertension should be avoided when securing the tracheal tube and applying a cervical collar. Arterial hypotension must be actively investigated and treated, while moderate hypertension should be tolerated because this may be a normal response to intracranial hypertension, preserving cerebral perfusion pressure.

Induction in head injury

Hazards	Management
Full stomach	See Figure 1
Cervical spine injury assumed	In line stabilization of neck Two-handed Sellick manoeuvre
Rising intracranial pressure	Adequate dose of induction agent Adequate neuromuscular blockade Smooth transition to maintenance sedation and paralysis
Reduced cerebral perfusion pressure	Avoid hypotension
Facial injuries	Intubation facilitated or made more difficult
Skull base fracture	Avoid nasal intubation

3

Upper airway obstruction

The management of the patient with obstruction of the upper airway, including the larynx, is a vital skill for anaesthetists (Figure 4). Adequate diagnosis of the airway pathology and the derangement of normal anatomy should precede discussion of the management plan between senior anaesthetic and ENT staff. An alternative strategy must also be agreed so that there is a back-up plan before proceeding. The management plan should be explained clearly to the patient, whose cooperation will be required.

Induction in airway obstruction

Hazards	Management
Potential for airway obstruction in expert hands	Senior help present
Abnormal anatomy	Information from imaging or endoscopy
Loss of muscle tone in upper air-way at induction may precipitate complete obstruction	Inhalation induction or awake tracheostomy
Obstruction during inhalation induction	Back-up plan in place with scrubbed ENT surgeon for surgical airway

4

Assessment of the patient may elicit stridor (inspiratory noise) at rest, which suggests that the airway is more than 50% narrowed. Results of radiographs, CT or MRI scans or nasendoscopy should be available. In their absence it may be appropriate to perform endoscopic examination by fibrescope via a topicalized and vasoconstricted nasal passage. The site of obstruction must not be approached with the fibrescope because attempted fibre-optic intubation may be impossible and may be hazardous, but endoscopy may provide important reconnaissance information. If there is doubt about the feasibility of intubation, then an awake surgical tracheostomy under local anaesthesia should be considered.

If intubation is likely to be possible, an alternative strategy must be in place before embarking on induction of anaesthesia. A scrubbed ENT surgeon must be present ready for immediate intervention and opening of a surgical airway.

The usual technique for induction of anaesthesia in the presence of upper airway obstruction is an inhalation induction. Most experience has been obtained with halothane although use of sevoflurane is growing. Gradual induction of anaesthesia while maintaining spontaneous ventilation and airway muscle tone may allow adequate depth of anaesthesia for intubation without airway closure. Should there be no obstruction, no manipulation of the airway or laryngoscopy is allowed before adequate depth of anaesthesia is achieved as judged by the pupils coming to lie centrally. It is vital that no neuromuscular blockade or intravenous sedation is used before the airway is safely secured.

Obstruction of the airway during inhalation induction prevents further uptake of anaesthetic agent, therefore allowing anaesthetic depth to lighten and the patency of the upper airway to be restored. An awake surgical tracheostomy should then be performed under local anaesthesia.

Maintenance of Anaesthesia

James Austin

James Austin is Specialist Registrar in Anaesthesia in Oxford, UK. He qualified in Cape Town, and trained in Anaesthesia in Reading, UK.

This contribution is an overview of what is meant, and required, by maintenance of anaesthesia. Many of the topics are covered in greater detail in separate contributions; the aim here is to put these topics in context.

Maintenance of general anaesthesia involves four priorities:

- keeping the patient safe
- keeping the patient comfortable
- presenting the best possible operating conditions for the surgeon
- preparing the patient for the postoperative period.

Keeping the patient safe

There are several aspects involved in keeping the patient safe:

- airway, breathing and circulation
- temperature control
- monitoring
- positioning.

Airway: this will usually have been established at the time of induction. However, it should not be assumed that this remains secure. Airway disconnection or obstruction may occur and the anaesthetist must be able to detect and correct these incidents promptly, assisted by monitors such as the capnograph, pulse oximeter, disconnect alarm and airway pressure monitor. Movement of the tracheal tube (either towards the right main bronchus or withdrawal from the trachea) or dislodgement of the laryngeal mask airway (LMA) are particularly likely to occur when patients are transferred to the operating table or when changes are made to patient position. These periods require increased vigilance by the anaesthetist. The integrity of the airway should be rechecked both clinically and by monitoring after each patient movement.

Tracheostomy, rigid bronchoscopy or 'one-lung' thoracic surgery may require intraoperative changes to the airway. The anaesthetist must be prepared for such changes and, if necessary, should formulate a plan with the surgeon in advance as to how the airway will be managed.

Breathing will often depend on whether muscle relaxants are being employed as part of the anaesthetic technique. Although the use of muscle relaxants is not essential for controlled ventilation, they are usually employed for ventilated patients. Surgical factors often influence the decision to use muscle relaxants. For example, abdominal surgery is greatly facilitated by muscle relaxation. In specialized surgery, such as ophthalmic surgery or neurosurgery, where the slightest move or cough may have disastrous consequences and carbon dioxide must be controlled, paralysis is ideal. Otherwise, anaesthetists have widely differing views as to whether breathing should be controlled. Some anaesthetists use muscle relaxants almost routinely for any operation lasting longer than about 30 minutes, on the basis that carbon dioxide retention is avoided, potent short-acting opioids can be used without fear of respiratory depression, and good lung aeration with avoidance of atelectasis may be easier to achieve. Others control ventilation less often unless indicated for reasons of airway management or the requirements of surgery. Some advantages and disadvantages of paralysis and ventilation are listed in Figure 1.

The technique of 'paralysing and ventilating' may be preferred when a tracheal tube is present. It is likely that a relaxant will already have been given to enable intubation. Also, the presence of a tube within the trachea is a potent stimulus, and unless local anaesthesia has been applied to the respiratory tract, a deeper level of anaesthesia may otherwise be needed for the patient to breathe spontaneously without coughing. Lighter planes can be tolerated when a laryngeal mask or oropharyngeal airway are employed, because these devices are less stimulating to the patient. Paralysing and ventilating may also be used for longer operations, where carbon dioxide control and prevention of atelectasis is important.

However, avoiding relaxants wherever possible can reduce two important complications of general anaesthesia:

- unrecognized awareness – patient movement usually warns of light anaesthesia before the patient becomes aware
- accidental hypoxia – the spontaneously breathing patient may maintain oxygenation even in the event of circuit disconnection.

Use of muscle relaxants and controlled ventilation

Advantages	Disadvantages
• May allow 'lighter' anaesthesia because reflex activity is abolished by neuromuscular blockade	• May allow unrecognized awareness as a result of inadequate anaesthesia
• Facilitates abdominal surgery by relaxation of abdominal muscles	• Reliance on ventilation equipment and circuit integrity to maintain alveolar ventilation
• Intracranial and intraocular pressure control by regulation of $PaCO_2$	• Possible side-effects of muscle relaxant drugs (e.g. histamine release, vagal blockade, malignant hyperpyrexia)
• Allows effective ventilation during, for example, thoracic surgery, prone positioning or long procedures	• Need for reversal of neuromuscular blockade
• Allows use of potent opioids to reduce the surgical stress response in major surgery	• Possible contraindication in patients with a difficult airway. Absence of spontaneous respiration may render ventilation impossible
• May improve surgical conditions by facilitating a hypotensive technique and lowered $PaCO_2$	• When there is requirement to monitor neuromuscular function (e.g. facial nerve during surgery on the parotid gland or acoustic neuroma)
• Decreases intraoperative atelectasis	
• Decreases energy requirements and tissue carbon dioxide production	• Contraindicated in some myopathies

1

Ventilator settings – most anaesthesia ventilators are time-cycled and volume- or flow-driven. A rate, usually with a ratio of inspiratory time to expiratory time (I:E), and a tidal volume or flow need to be set. Most adults have a minute volume of 80–100 ml/kg, therefore a tidal volume of 8 ml/kg (e.g. 500–600 ml) and a rate of 10 breaths/minute is a good starting point; this can be adjusted according to the observed end-tidal partial pressure of carbon dioxide ($P_{E'CO_2}$). For routine surgery, a $P_{E'CO_2}$ of about 4.5 kPa should be aimed for. If metabolic rate and cardiac output (and hence pulmonary perfusion) are assumed to be constant, then $P_{E'CO_2}$ varies inversely with the alveolar ventilation.

In general, an I:E ratio of 1:2 is often the best compromise between maintaining low inflation pressures (e.g. 15–20 cm H_2O), satisfactory oxygenation (Sp_{O_2} > 95%) and adequate carbon dioxide removal ($P_{E'CO_2}$ 4.5 kPa). However, this can be decreased to 1:1.5 or even 1:1 to prolong inspiratory time. This may be useful in some patients to help decrease high airway pressures (e.g. > 25–30 cm H_2O) or improve oxygenation (e.g. in the obese). Some patients with asthma or chronic airway disease may benefit from a longer expiratory time to allow the lungs to empty, and an I:E ratio of 1:3 or 1:4 may be preferable.

Children have a proportionately higher minute ventilation than adults – up to 200 ml/kg in infancy, approaching adult values weight-for-weight by about age 10 years. Given that their tidal volume is slightly less weight-for-weight than adults (7 ml/kg), this increased minute volume must be provided for by an increase in rate. For example, in a 5 kg infant, a minute volume of 1000 ml might be provided by 30 breaths each of about 33 ml/minute.

However, paediatric ventilation is complicated by the obligatory leak around the uncuffed tube. Volume control is unlikely to inflate the lungs to the set volume (especially if a Newton valve is used with T-piece ventilation). This is usually overcome by increasing the tidal volume by titrating against inflation pressure and/or $P_{E'CO_2}$. Some modern anaesthesia ventilators have pressure control capabilities (e.g. the *Draeger Julian*). Specific compliance varies little with age, therefore pressure control mode can be used to deliver an inflation pressure of 15–20 cm H_2O. This provides an adequate tidal volume for any age, despite small to moderate leaks, as long as lung compliance is normal.

Regardless of the mode of ventilation, a fresh gas flow must be selected. This depends on the breathing system in use as well as the size of the patient. A high flow should be used initially (e.g. 6 litres/minute), regardless of the circuit being used. This allows time for denitrogenation and equilibration of inhaled anaesthetic agent during this early period of rapid anaesthetic uptake. After about 10 minutes, flows can be reduced considerably if the system permits. The circle system with carbon dioxide absorber is widely used, and modern lightweight valves and low-resistance tubing make it suitable for paediatric use well below the traditional lower patient weight limit of 20 kg. With appropriate monitoring of gas concentrations within the circle, this permits total fresh gas flows of 1 litre/minute or less. Higher flows are required for T-pieces such as the Bain and Jackson Rees systems. Formulae exist for each of these circuits to predict the flow of fresh gas required per kilogram patient weight to eliminate rebreathing for controlled and spontaneous respiration. However, a more practical approach is to reduce the fresh gas flow gradually, stopping when rebreathing of carbon dioxide begins to appear on the capnograph.

General anaesthesia, particularly when using volatile anaesthetic agents, causes the development of atelectasis in the dependent parts of the lung and impairs the pulmonary vascular response to hypoxia (hypoxic pulmonary vasoconstriction). These two factors produce a small but noticeable degree of shunt, usually about 10%. This can be corrected by giving anaesthetized patients higher inspired oxygen than the 21% present in air; 30% is usually given, though this can be titrated against observed oxygen saturation.

Circulation: appropriate fluid management is an important component of anaesthetic maintenance. Intravenous fluid requirements may range from none in short and relatively non-invasive procedures, to many times the circulating volume in long and traumatic procedures. Fluid requirement consists of:

- replacement of existing deficit – crystalloid or blood
- metabolic maintenance requirements – crystalloid
- replacing additional ongoing losses – crystalloid, colloid or blood.

Existing deficit – in the adult elective surgical patient, who has been starved for at least 4 hours preoperatively (and sometimes much longer), a deficit of 500 ml of crystalloid can be assumed. This deficit is generally well tolerated and does not necessarily need replacing, but it decreases the patient's margin of reserve against any further losses, or against ongoing postoperative dehydration as a result of nausea or vomiting. Many anaesthetists routinely administer 500–1000 ml of crystalloid in all patients except those at risk from fluid overload (e.g. those with renal or cardiac failure). There is evidence to suggest that this may improve the quality of early recovery and help to decrease postoperative nausea.

In the emergency patient, fluid deficit may be considerable, as a result of either trauma-related blood loss, or anorexia, vomiting and/or interstitial (third-space) fluid loss from surgical pathology. In either case, the deficit should be assessed and replaced with the appropriate fluid. The larger the deficit, the more important that it be replaced before induction, whenever circumstances permit. The exception to this rule is during major ongoing blood loss, such as a ruptured aortic aneurysm or major trauma, where the priority is stopping the bleeding rather than prolonging attempts to normalize the circulation preoperatively.

Maintenance – for many patients this is the least important component of intraoperative fluid management – the average adult requirement of about 100 ml/hour is negligible in the context of a short procedure and other fluid losses. However, in small children, maintenance requirements are proportionately larger and more significant. Paediatric maintenance fluid is usually calculated according to: 4 ml/kg/hour for the first 10 kg, plus 2 ml/kg/hour for the next 10 kg, plus 1 ml/kg/hour for the remainder. Thus, a 25 kg child would have a maintenance requirement of 40 + 20 + 5 = 65 ml/hour. The smaller the child, the less reserve there is for managing without ongoing maintenance fluids, and the greater the impact of preoperative starvation.

Infants have small glycogen reserves, and therefore need intravenous dextrose (e.g. as 5% dextrose in 0.18% saline) as maintenance to sustain their blood sugar levels. For longer procedures, careful attention must be paid to electrolyte balance, because infants have less ability to correct excessive salt loads or water loads.

Ongoing losses – the most significant aspect of intraoperative fluid management can be the most difficult to estimate.

Losses from extravascular spaces (e.g. gastrointestinal, evaporative, third-space fluid losses) are usually crystalloid losses. Evaporative losses can be large – an adult may lose in excess of 1 litre/hour from a laparotomy or thoracotomy wound, and even larger amounts from extensive open skin wounds such as burns or large graft sites. There is no way of measuring these losses directly, and measures such as blood pressure, pulse rate or central venous pressure (CVP) provide only an indirect measure of total body water. Urine output may be the most useful clinical measure. Blood tests such as plasma urea, sodium and haematocrit may provide information regarding the hydration state, and plasma electrolytes and haematocrit are now commonly available from blood gas machines.

Losses also occur from the intravascular space (i.e. blood). Losses in suction bottles may be complicated by wash, faeces, urine or amniotic fluid. Visual estimates of blood loss on swabs are often inaccurate – weighing of swabs is more precise, but still neglects losses on drapes, gloves and instruments. A dilutional technique relies on washing all swabs, instruments and gloves in a fixed volume of water, which can then be measured colorimetrically to give an accurate measure of blood loss. Such instruments are not widely available. Intravascular loss may be estimated indirectly from clinical measures such as blood pressure, pulse rate or CVP, though other anaesthetic factors such as the balance between surgical stimulation and depth of anaesthesia complicate these measures. Estimation of haemoglobin is useful only when adequate intravascular volume has been replaced. Blood losses may initially be replaced by colloid solution (e.g. a gelatin solution or hydroxyethyl starch), but larger losses (> 20% blood volume) may require replacement by packed-cell blood. Very large losses (> 1 blood volume) may require supplementation with fresh frozen plasma and/or platelets to maintain clotting function.

In practice, it is likely that fluid losses are under-replaced in many patients. This is offset by the hormonal 'stress response' to surgery: aldosterone, cortisol and antidiuretic hormone levels rise and atrial natriuretic peptide falls; all contribute to postoperative water retention.

Temperature control: there is now good evidence that the maintenance of a physiological body temperature reduces postoperative morbidity. Patients suffering from head injury or undergoing certain neurosurgical procedures are possible exceptions. Shivering increases oxygen consumption, and predisposes to myocardial ischaemia, dysrhythmias, hypotension and acidosis. Hypothermia also increases susceptibility to infection and tends to lengthen hospital stay.

Temperature control is of particular importance in patients at the extremes of age (who have less intrinsic control over body temperature and a larger surface area-to-volume ratio through which to lose heat), in operations involving open body cavities, and in all patients undergoing lengthy procedures. About 20% of trauma patients who arrive at hospital are hypothermic (core temperature < 35°C).

A change in core temperature as a result of general anaesthesia is a three-phase response.

- The first phase is a brisk fall in core temperature as a result of vasodilatation, caused by redistribution of heat to the peripheries. Core temperature may be as low as 35.5°C in some patients after transfer to the operating theatre from the anaesthetic room.
- The second phase is a slower but more sustained fall as a result of accelerated loss of heat to the environment from the warmer peripheries.
- The third phase is a stable equilibrium at a lower core temperature.

It is important to note that the anaesthetic itself brings about these changes, which are independent of the nature of the surgery, though surgery may modify the pattern. The use of spinal or epidural anaesthesia instead of general anaesthesia reduces, but does not abolish, the three-phase response described above.

Passive rewarming is the prevention of heat loss, typically by raising the temperature of the environment. Passive rewarming can serve to modify only the second phase of the heat loss response. Covering with blankets or the use of foil 'space' blankets decreases heat loss by reduced transfer of heat by convection, conduction, evaporation and radiation.

Dry inspired anaesthetic gases need to be humidified, and a heat and moisture exchange filter in the breathing system reduces heat loss by evaporation from the respiratory tract (latent heat). Low flows in a circle system (e.g. 1 litre/minute) further reduce the quantity of dry gas needing to be humidified and help retain heat and moisture within the breathing system.

A 'normal' operating room temperature of 21°C is a compromise between that which is warm enough for the patient, but cool enough for the comfort of theatre personnel. An increase in theatre temperature (e.g. to 25°C) helps to reduce the gradient for heat loss in patients at high risk (e.g. young children, patients with extensive burns).

Active rewarming is the addition of heat into the patient. It may be used to prevent or reverse the first phase of the temperature drop. The local environmental temperature can be raised so much that the transfer of heat is reversed. Warm air convection blankets (e.g. the *Bair Hugger*) are considered as active rewarming.

Intravenous fluid warmers play an increasingly important role the greater the volume of intravenous fluid given. A fluid-warming device should be used in all at-risk patients and especially when stored blood is administered. Ventilatory gases may be warmed using a heated humidifier. Overhead radiant heaters may be used when a large area of the body needs to be exposed, and neonates may undergo surgery on an open incubator such as the *Resuscitaire*.

Cardiopulmonary bypass represents the ultimate in active rewarming, but is practical only in cardiothoracic surgery or in uncommon resuscitation situations.

Care is needed not to overheat the patient and temperature monitoring is necessary when active rewarming methods are used. Monitoring probes are available for a variety of body cavities, including nasopharynx, oesophagus, rectum, bladder and tympanic membrane. In routine clinical practice, core temperature is usually measured by nasopharyngeal or rectal temperature probes. Surface temperature monitors do not reflect core temperature, but the core–peripheral gradient may provide a useful measure of peripheral vasodilatation. A gradient of less than 2°C implies good peripheral perfusion.

Monitoring: the Association of Anaesthetists has published recommendations on standards of monitoring. A summary is given in Figure 2.

Blood sugar should be monitored in infants and diabetic patients. The blood sugar of diabetic patients should be known before anaesthesia is given, and should be estimated every 1–2 hours during routine surgery.

The Association of Anaesthetists summary of standards of monitoring

- The Association of Anaesthetists of Great Britain and Ireland strongly recommends that the standard of monitoring used during general anaesthesia should be uniform in all circumstances irrespective of the duration of anaesthesia or the location of administration
- An anaesthetist must be present throughout the conduct of general anaesthesia
- Monitoring should be commenced before induction and continued until the patient has recovered from the effects of anaesthesia
- These recommendations also apply to the administration of local anaesthesia, regional analgesia or sedation where there is a risk of unconsciousness or cardiovascular or respiratory complications
- The anaesthetist should check all equipment before use. Monitoring of anaesthetic machine function during the administration of anaesthesia should include an oxygen analyser with alarms. During spontaneous ventilation, clinical observation and a capnometer should be used to detect leaks, disconnection, and rebreathing and high pressure in the breathing system. Measurement of airway pressure, expired volume and carbon dioxide concentration is strongly recommended when mechanical ventilation is employed
- A pulse oximeter and capnometer must be available for every patient
- It is strongly recommended that clinical observation of the patient should be supplemented by continuous monitoring devices displaying heart rate, pulse volume or arterial pressure, oxygen saturation, the electrocardiogram and expired carbon dioxide concentration. Devices for measuring intravascular pressures, body temperature and other parameters should be used when appropriate. It is useful to have both waveform and numerical displays
- Intermittent non-invasive arterial pressure measurement must be recorded regularly if invasive monitoring is not indicated. If neuromuscular blocking drugs are used, a means of assessing neuromuscular function should be available
- Additional monitoring may be required in certain situations. These recommendations may be extended at any time on the judgement of the anaesthetist

2

Positioning: an unconscious patient cannot move to relieve an uncomfortable position, and it is the anaesthetist's responsibility to prevent discomfort from becoming damage. The anaesthetist is also responsible for protecting the patient during movement on and off the operating table, and during changes of position. Traditionally, the anaesthetist has particular responsibility for the head and airway. It must be ensured that all members of the team are working to a common agenda and with coordinated timing. It is usually easiest and safest to disconnect as much equipment as possible before moving the patient.

Prophylaxis against venous thromboembolism – the thrombotic process often starts intraoperatively. It is difficult to identify patients at high risk, though coexisting medical illness, major surgery, malignancy, trauma (especially hip and pelvis), obesity, high-dose oestrogen therapy and age greater than 40 years are well-known risk factors. Thromboprophylaxis should commence before anaesthesia; gradated compression stockings and low-dose unfractionated heparin, 5000 IU s.c. twice daily, continued until full mobilization, is popular and effective. When positioning for surgery, raising the heels on foam pads prevents venous stasis in the calves. Intermittent pneumatic compression pumps assist venous return, but it is not known whether this reduces the incidence of postoperative pulmonary embolism.

Keeping the patient comfortable

Traditionally, the main components of anaesthetic maintenance are unconsciousness (hypnosis), analgesia and absence of movement. Some advantages and disadvantages of using muscle relaxants have been discussed. Keeping the patient unconscious and relieving the pain of surgery are now considered.

Maintenance of unconsciousness is usually achieved by anaesthetic drug delivery via the inhalational or intravenous route, or both. The intramuscular route is seldom used in hospital practice owing to the relatively slow onset of drug action, unpredictable duration and delayed recovery. Ketamine, 10 mg/kg, is the only useful intramuscular agent, with an onset of 5–10 minutes producing up to 30 minutes of anaesthesia. It has a role in the provision of emergency anaesthesia in difficult locations.

Inhalational route – this is the most widely used technique, using a volatile anaesthetic agent with or without nitrous oxide. It therefore requires a supply of compressed gas, a vaporizer and a breathing system for drug delivery. Compressed gas may not be required if a 'drawover' type vaporizer is used.

The potency of an inhaled anaesthetic agent may be described in terms of its minimum alveolar concentration (MAC). MAC is defined as the alveolar concentration of the anaesthetic agent which at equilibrium is required to prevent gross reflex muscular movement in response to a standardized skin incision in 50% of healthy, unpremedicated patients. It is therefore a measure of anaesthetic potency, and is the effective dose in 50% of the population (ED_{50}). It should be borne in mind that not all operations are 'a standardized skin incision'. The amount of anaesthetic needed to remove a foreign body from the nose is very different from that needed for an anal stretch. It is important to know the MAC of individual inhalational agents and the factors on which they depend (Figures 3 and 4).

Of any given inhalational anaesthetic, 0.7–1.3 MAC will anaesthetize 95% of the population. MACs are also additive: 0.5 MAC of nitrous oxide (52%) plus 0.5 MAC of isoflurane (0.6%) is equivalent to 1 MAC of any other inhalational agent given alone.

The principle of MAC acts as a useful guide. It allows the anaesthetist to select a vapour concentration that is likely to maintain unconsciousness. The state of anaesthesia is related to the partial pressure of anaesthetic within the brain, which is taken to be equivalent to the alveolar partial pressure. This can be measured by analysis of the end-tidal partial pressure of the anaesthetic agent. What is dialled on the vaporizer or the nitrous flowmeter is not necessarily what is in the patient's alveoli – the fresh gas flow takes time to equilibrate both with the dead space of the circuit and with the uptake by the patient. Observing how the ratio of end-tidal to inspired partial pressure varies with time can assess this rate of uptake (or 'wash-in').

MAC is useful to estimate the amount of anaesthetic required. In clinical practice this must be adjusted against indicators such as pulse rate, blood pressure, respiratory rate, patient movement, pupillary size, lacrimation and sweating. Many of these variables may be abolished by factors other than anaesthetic depth. Tachycardia may be prevented by co-administered β-blockers, hypertension masked by hypovolaemia, respiratory rate and patient movement abolished by paralysing drugs, and pupillary size altered by use of opioids or anti-muscarinic drugs. Thus, lacrimation and sweating, though crude indicators of inadequate anaesthesia, reflect the need for clinical observation in addition to monitoring.

Minimum alveolar concentration (MAC) of inhalational anaesthetic agents

Anaesthetic agent	MAC in oxygen (%)	MAC in 70% nitrous oxide
• Halothane	0.75	0.29
• Enflurane	1.68	0.57
• Isoflurane	1.15	0.50
• Sevoflurane	2.0	0.8
• Desflurane	6–9	2.5–3.5

3

Factors affecting minimum alveolar concentration

Decrease	Increase	No change
• Increasing age	• Decreasing age	• Gender
• Alcohol (acute ingestion)	• Alcohol	• Duration of anaesthesia (chronic ingestion)
• Nitrous oxide	• Hyperthermia	• Time of day
• Analgesics	• Hyperthyroidism	• Hypercarbia
• Sedatives and hypnotics	• Hypocarbia	
• Hypotension		
• Hypothermia		
• Hypothyroidism		
• Hypoxia		

4

Intravenous route – a popular alternative to inhalational anaesthesia is total intravenous anaesthesia (TIVA). Many intravenous anaesthetics have been used for TIVA, including barbiturates, ketamine, etomidate and propofol. The pharmaco-kinetic profile of propofol makes this drug the most commonly used for TIVA. It has a high clearance (1300–1900 ml/minute), short metabolic half-life (60–100 minutes) and inactive metabolites. For short procedures, propofol may be administered following initial intravenous induction by intermittent bolus with no special infusion equipment (e.g. 50 mg as required every 3–5 minutes).

For longer procedures, the advent of reliable electronic syringe pumps, and in particular the development of target-controlled infusion (TCI) software, have contributed to the widespread use of TIVA techniques. Some advantages and disadvantages of inhalational or TIVA maintenance are shown in Figure 5.

Consider a three-compartment model: vascular space, richly perfused organs, and poorly perfused organs plus clearance. A large initial bolus of propofol is needed to fill the vascular compartment, namely the induction dose. Thereafter an initially high rate of infusion is needed to keep up with losses to the richly perfused compartment until it approaches saturation. Then a slower rate is required to keep up with losses to the poorly perfused but difficult to saturate compartment, and with metabolic clearance.

The 'Bristol regimen' reflects these kinetics. This regimen aims to maintain a plasma propofol concentration of about 3 μg/ml by giving patients receiving 67% nitrous oxide an initial bolus of 1 mg/kg, followed immediately by infusion at 10 mg/kg/hour for 10 minutes, then 8 mg/kg/hour for 10 minutes, then 6 mg/kg/hour thereafter. A dose of 10 mg/kg/hour is equal to the patient's weight (in kg) as ml/ hour of 1% propofol – hence a 60 kg patient will initially receive 60 ml/hour of 1% propofol. At the end of the operation, switching off the propofol allows rapid redistribution from the vascular compartment (and therefore from the richly perfused compartment also) to the still unsaturated third compartment. It is this rapid redistribution that allows a prompt wake-up even after a long period of TIVA.

TCI microprocessor-controlled technology (e.g. as incorporated in the Graseby 3500 'Diprifusor' syringe pump) requires manual input of patient age, weight and desired plasma concentration. The pump then administers propofol according to the three-compartment pharmacokinetic model incorporated into its software. Change to a higher propofol concentration is achieved by a rapid zero-order infusion, and the plasma concentration is calculated until the new predicted value is reached. Change to a lower concentration is achieved by temporary cessation of drug infusion until the predicted plasma level falls to the required level, followed by continuation of infusion at a lower rate. The system is used in a similar fashion to adjusting the vaporizer setting during inhalational anaesthesia; the predicted plasma concentration of drug is analogous to the end-tidal concentration of the inhalational agent. Maintenance of satisfactory anaesthesia requires a plasma concentration of propofol of 2–6 mg/ml, depending on patient fitness, coexisting drug therapy and degree of surgical stimulation.

Comparison of inhalational anaesthesia and total intravenous anaesthesia (TIVA) maintenance techniques

Inhalational maintenance

Advantages
- Cost-effective (especially when used with low-flow circle systems)
- Predictable population pharmacokinetics and confidence in anaesthetic depth achieved
- Ease of measurement of end-tidal partial pressure
- Minimal metabolism of modern agents, no accumulation and clearance independent of patient hepatic and renal function

Disadvantages
- Requires conventional tidal ventilation for drug delivery
- Requires specialized equipment (e.g. vaporizer, anaesthetic machine, agent analyser)
- Concern regarding tissue and organ toxicity (especially hepatotoxicity following repeat halothane exposure)
- All volatile anaesthetics are known triggers for malignant hyperpyrexia
- Environmental pollution

TIVA

Advantages
- Independent of airway for drug delivery. May be advantage in, for example, jet ventilation techniques
- No specialized equipment is essential. More suitable technique for patient transport and difficult locations
- Rapid increase in anaesthetic depth possible by administration of intravenous bolus
- Low incidence of postoperative nausea and vomiting and better quality of early recovery (especially for propofol)
- No contraindication in malignant hyperpyrexia

Disadvantages
- Requires patent and dependable intravenous access. Undetected failure may result in awareness
- Drug accumulation with prolonged infusion
- Inability to measure plasma concentration directly has led to concerns about possibility of awareness

5

Analgesia: modern inhalational or intravenous anaesthetic drugs possess little analgesic activity, with the exception of ketamine. For all but the simplest procedures, analgesia must be provided by systemic analgesics (usually opioids) or by local anaesthetics. Analgesia has several effects.

- It reduces the required MAC (or plasma concentration) of co-administered anaesthetic drugs. Analgesia is an important component of the balanced anaesthetic technique.
- It reduces the immediate autonomic activity in response to pain. Sympathetic stimulation otherwise results in cardiovascular and respiratory responses that may lead to myocardial ischaemia and dysrhythmias.
- It reduces the neuroendocrine 'stress response' caused by surgery.

Opioid analgesics such as fentanyl, 15 μg/kg, reduce circulating concentrations of the stress hormones that increase after moderate and major surgery (e.g. noradrenaline, adrenaline, cortisol, growth hormone, glucagon, antidiuretic hormone). The stress response is largely detrimental and leads to increased catabolism, metabolic rate and oxygen consumption. This response is not significant in minor surgery.

The short-acting synthetic opioid drugs such as fentanyl and alfentanil are widely used to provide intraoperative analgesia. Fentanyl, a synthetic opioid structurally related to pethidine, is the most popular (1–2 μg/kg for minor procedures, onset 1–2 minutes, duration 30 minutes). Its potency and minimal effect on pulse and blood pressure make it commonly used for the provision of intense analgesia during surgery. These drugs are unsuitable for routine use in postoperative analgesia because of their short duration of action and their tendency to produce marked respiratory depression. They are commonly substituted by longer-acting analgesics (e.g. morphine 0.1–0.2 mg/kg i.v.) towards the end of the procedure to provide pain relief following surgery.

Pre-emptive analgesia – laboratory work suggests that noxious stimuli produce hypersensitivity in the pain pathways both centrally and peripherally. Larger doses of analgesics are then required to have an effect. If systemic analgesia or local anaesthetics are used to prevent the initial pain, this hypersensitivity is reduced. This is the basis of pre-emptive analgesia, but its clinical significance is disappointing.

Providing the best possible operating conditions

The surgeon hopes for two things from his patient during the operation: not to move, and not to bleed. If the anaesthetist has succeeded in keeping the patient safe and comfortable as described, then the patient is unlikely to move. The anaesthetist can also help to minimize bleeding.

Tourniquets are ideal for extremity surgery. Traditionally, a 90-minute time limit is imposed on upper limb tourniquets (usually at 250 mm Hg), and a 120-minute limit on lower limb tourniquets (usually at 300 mm Hg). This is arbitrary; the longer the tourniquet is on, the greater the potential for damage. The main risk is ischaemic damage to nerves directly under the tourniquet; distal ischaemia is likely to take 4–6 hours to become significant. If antibiotics are necessary, they should be given at least a few minutes before exsanguination.

Sickle-cell disease is an absolute contraindication to tourniquet use, because sickling of haemoglobin S may be induced by the local hypoxia and acidosis.

Positioning – adequate venous drainage from the operative site is ensured by careful attention to patient positioning. Raising the operative site above heart level decreases arterial and venous pressures. Arterial pressure falls by 2 mm Hg for each 2.5 cm vertical height. Head-up tilt is commonly used in head and neck surgery to decrease bleeding, but there is a risk of venous air embolism.

Hypotensive anaesthesia – moderate reduction of systolic blood pressure (e.g. to 70–80 mm Hg) in otherwise fit patients may greatly improve the operative field. It must be used with caution in patients with coronary, cerebral, renal or peripheral vascular diseases who are at risk from ischaemic events. Techniques for deliberate hypotension are outside the scope of this contribution.

Non-steroidal anti-inflammatory drugs used intraoperatively may increase blood loss during surgery.

Blood gases – carbon dioxide is a local vasodilator, and moderate hypocapnia (e.g. P_{CO_2} 4.0–4.5 kPa) contributes to a dry surgical field.

Preparing the patient for the postoperative perio

The maintenance period is often a convenient time to complete the necessary anaesthetic record and drug prescription charts. During anaesthesia, it should be considered what else may be done while the patient is unconscious to enhance his or her postoperative course. This includes the following.

Venous access must be sufficient for postoperative requirements. A central venous line should be sited if access is likely to be difficult or prolonged, or to enable central venous monitoring. A subcutaneous cannula for analgesic administration may avoid the need for injections, especially in children.

A nasogastric tube is more comfortably inserted while the patient is asleep, and its position can be checked during laparotomy.

Analgesia – ideally, the plan for postoperative pain control should be formulated before anaesthesia, and discussed with the patient. 'Balanced analgesia' is the concept of using several analgesics with differing modes of action, thus reducing dose-related side-effects and enhancing overall analgesic effect. Typically this may involve local or regional analgesia in combination with opioids, non-steroidal anti-inflammatory drugs and simple analgesics (e.g. paracetamol).

Antiemetics should be given in particular to patients receiving opioids, and those at high risk of postoperative nausea and vomiting (PONV). High risk includes patients with a history of previous PONV or motion sickness, certain operations (e.g. gynaecological, middle ear or strabismus surgery) and female gender.

Oxygen – all anaesthetics (with the exception of ketamine) induce about 10% shunt. Atelectasis, impaired hypoxic pulmonary vasoconstriction, diffusion hypoxia from nitrous oxide use, opioid-mediated hypoventilation and other factors contribute to making the postoperative patient prone to hypoxia. Added oxygen (e.g. 30–40% via a simple face mask) should be administered in the immediate recovery period to all patients for about 15 minutes, guided by pulse oximetry. Subsequently, the need for added oxygen must be determined for each patient depending on factors such as age, pre-existing disease and the nature of anaesthesia and surgery.

Fluids – there must be clear instructions for postoperative fluid intake. Elective day-surgery patients will drink when ready, but in-patients and those undergoing major procedures require intravenous fluids to replace continuing fluid losses and provide maintenance. How far in advance fluids can be prescribed depends on the accuracy of prediction of future needs.

Thromboprophylaxis – stockings for prevention of thrombo-embolic disease and/or regular heparin should be prescribed where indicated by local policy.

Antibiotics – should be prescribed at the surgeon's discretion.

Monitoring – the anaesthetist should understand the routine standard of monitoring on the postoperative ward and ensure that it meets the needs of the patient. Specific requirements must be clearly communicated, such as hourly urine output, hourly blood pressure, overnight Sp_{O_2} or any other observ-ations in an at-risk patient. Action that should be taken if the observation deviates from the desired targets should be documented.

Medical Gas Storage, Suction Devices and Humidifiers

Ian R Taylor
Michael O'Connor

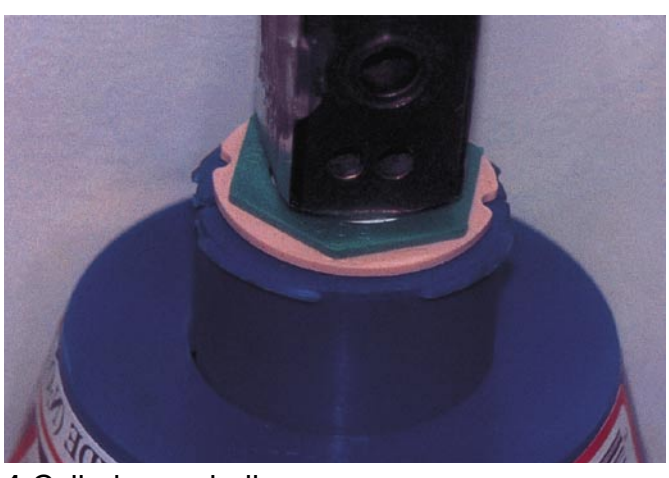
Ian R Taylor is Specialist Registrar in Anaesthesia at the Princess Margaret Hospital, Swindon, UK. He qualified from Bristol University and is training in Anaesthesia at the Wessex School of Anaesthesia, Southampton, UK. His interests are vascular and obstetric anaesthesia.

Michael O'Connor is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Cylinders

Medical gas cylinders are made of molybdenum steel to ensure they are strong and able to withstand high pressures, but are also relatively light in weight. They are constructed as a seamless tube and consist of a body, shoulder and neck. They are colour coded according to British and International Standards (BS1319C and ISO32) to identify their gas contents (see Figure 7, page 109). Cylinders are manufactured in different sizes from A, the smallest, to J, the largest. Size E cylinders are usually attached to the anaesthetic machine and size J cylinders make up manifolds.

The cylinder valve fits into the cylinder neck by a screw thread mechanism, to permit safe, controlled use of its contents. The junction between the cylinder and valve melts in the presence of intense heat, thus allowing escape of gas and minimizing the risk of explosions. Between the neck and cylinder valve is a plastic disc, the colour and shape of which denotes the year in which the cylinder was last examined (Figure 1).



1 Cylinder neck disc.

Cylinder body
The cylinder body is colour coded and engraved with:
- test pressure
- date of last test performed
- chemical symbol of contents
- tare weight (i.e. weight of empty cylinder).

It is also labelled (Figure 2) with the name and symbol of the gas it contains, its volume, pressure and minimum purity (Figure 3). The label gives additional information relating to storage, use (in conjunction with the Medical Gases Data Sheet) and safety matters. The safety points highlighted are:
- compressed gas
- flammability status
- avoidance of oil or grease because spontaneous combustion can occur with high-pressure gases.

2 Cylinder label.

Cylinder size, volume, pressure and purity of contents

Gas	Cylinder size (litres)	Volume of gas at 15°C	Pressure (kPa)	Purity (%)
Oxygen	E	680	13700	99.5
Nitrous oxide	E	1800	4400	98.0
Air	E	640	13700	21.0 (oxygen)
Carbon dioxide	C	450	5000	99.0

3

Storage
- Cylinders must be stored under cover, in a dry, clean and well-ventilated area, away from extremes of temperature.
- Smoking or the use of a naked flame in the storage area is prohibited.
- Moisture or exposure to chemicals can lead to the corrosion of the cylinder or its valve.
- Cylinders should be kept in the upright position or horizontal on shelves to avoid direct damage to the valves.
- Cylinders should be used in a sequential manner to ensure that no cylinder remains in storage for too long.
- Full and empty cylinders should be kept apart.

Testing
During manufacture, one in every 100 cylinders is cut into strips and tested for tensile strength. Cylinders in circulation are tested on a 5-yearly basis by:
- exposure to hydraulic pressure of about 22,000 kPa (far in excess of the pressures encountered in daily use)
- filling with water under pressure to assess expansion and elastic recoil
- internal endoscopic inspection.

Test date details are recorded on the plastic disc between the cylinder valve and the neck and engraved on to the cylinder body.

Filling
Medical gases are stored either in the gaseous state (oxygen and air) or as a mixture of the liquid and vapour (nitrous oxide and carbon dioxide). Cylinders that contain liquid should be used only in the upright position. Gases and vapours stored in cylinders must be free of water vapour to avoid the formation of ice (secondary to a fall in temperature on cylinder opening), which may block the exit valve. For cylinders containing gas alone, the contents can be assessed directly by measuring the pressure using a Bourdon gauge (see *Anaesthesia and Intensive Care Medicine* **1:2:** 65). In the case of cylinders containing both the liquid and vapour phases the situation is more complex. The contents of these can be determined only by subtraction of the tare weight from the cylinder weight because the pressure within will not fall until the liquid has completely vaporized, assuming the temperature stays constant.

During nitrous oxide use, the liquid within the cylinders cools owing to the uptake of latent heat of vaporization. Condensation or ice may form on the outside of the cylinder. In such circumstances, the cylinder gauge pressure may fall despite there being liquid nitrous oxide in the cylinder owing to the fall in saturated vapour pressure of nitrous oxide following the drop in temperature of the liquid. However, once the gas flow is turned off the temperature returns to that of the atmosphere and the gauge pressure returns to that at the beginning of use. Carbon dioxide is used at low flows so the chances of ice forming are low. Liquid is less compressible than gas, therefore cylinders containing nitrous oxide or carbon dioxide are only partially filled with liquid. Any change in pressure within the cylinder is minimized, thus reducing the chance of cylinder rupture should the temperature rise.

The filling ratio is that between the mass of liquid contained in the cylinder and the mass of water that it could contain if filled to the top. The filling ratios for nitrous oxide and carbon dioxide are both 0.75 in temperate climates and 0.67 in the tropics.

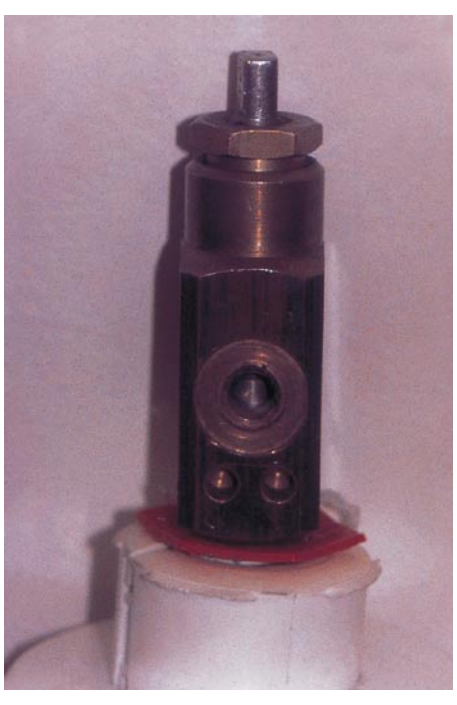
$$\text{Filling ratio} = \frac{\text{Mass of liquid}}{\text{Mass of water}}$$

Cylinder valve
Cylinder valves are made of brass and screw into the cylinder neck. There are four types of valve:
- pin-index valve block
- bull-nose valve
- hand-wheel valve
- star valve.

A pin-index valve is used on all cylinders that are to be attached to an anaesthetic machine. It is an international system (ISO2407) designed to prevent the fitting of the incorrect gas to the yoke and is fully detailed in the British Standard BS1319.

The system is made up of two components.
- Two pins projecting from the yoke, which are arranged in a gas-specific configuration in relation to the valve outlet
- Two holes within the valve block on the cylinder with a corresponding pattern for the designated gas (Figure 4).

This arrangement ensures that it is impossible to fit the incorrect cylinder to the yoke. The pin-index valve block on the cylinder is engraved with:
- tare weight
- chemical symbol for contents
- cylinder owner
- pressure of hydraulic test.



4 Pin-index valve holes on the cylinder.

Cylinder use
New or refilled cylinders are supplied from the manufacturer with a plastic dust cover over the valve to avoid dirt contamination. Before use, this cover should be removed and the valve transiently opened to expel any dirt or grease from the outlet. This reduces the chance of debris entering the anaesthetic machine and is known as 'cracking' the cylinder.

The cylinder is mounted on to the anaesthetic machine by engaging the pins on the yoke with the holes in the valve block. It is secured by tightening the wing nut.

Before use, the cylinder should be opened gently to ensure that there are no leaks, either from the cylinder valve itself or at the point of attachment to the yoke on the anaesthetic machine. A possible reason for gas leakage at the pin-index junction is the absence of the Bodok seal. This is an aluminium-rimmed neoprene washer that sits between the outlet on the valve block and the yoke on the anaesthetic machine. Gentle opening of cylinders minimizes sudden surges of high-pressure gas that may damage the pressure gauge or regulator.

Suction systems

Suction systems form part of the piped medical gases and vacuum systems (see page 107) and must comply with specifications detailed in BS4957. Portable and fixed suction systems are available to accommodate the differing circumstances of use. General operating principles are the same for both systems. Outlets from the central piped vacuum system must have the capability of maintaining a vacuum of at least 53 kPa below atmospheric pressure (101.3 kPa) and supporting a flow of 40 litres/minute.

Suction apparatus and nozzle: suction nozzles are made of either firm plastic (e.g. Yankauer) or metal. They should have a smooth tip to prevent damage to the soft tissues of the oropharynx. The tip often has more than one hole to allow continuation of suction should one hole become blocked. Suction tubing is constructed of semi-rigid plastic to minimize kinking, with a smooth internal surface to limit resistance to flow. The tubing must be of sufficient length to be practical to use, but it should be remembered that the length and width of a tube influences the laminar flow within it, according to the Hagen–Poiseuille equation:

$$\text{laminar flow} = \frac{\Delta P \pi r^4}{8 \eta L}$$

where: ΔP = pressure gradient along tube, r = tube radius, L = tube length, η = viscosity of liquid.

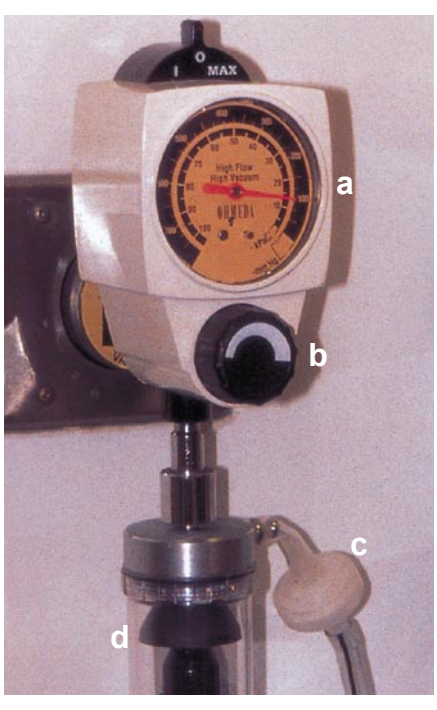
Thus, short, wide tubing maximizes laminar flow.

Reservoir: the reservoir must be of sufficient size to contain the estimated volume of suctioned material, but not so large that it increases the time taken for the vacuum to build up. Most reservoir vessels are constructed of clear material to allow the contents to be visualized and are graduated to permit accurate assessment of aspirate volume. Disposable liners are commonly used to reduce staff exposure to potentially infective material. A floating ball valve within the collection vessel prevents material from entering the control unit and the vacuum source if the container overfills.

Vacuum control regulator unit: this unit is usually situated between the reservoir and the vacuum source (Figure 5). Its function is to allow adjustment of the degree of vacuum applied to the distal suction tubing. The vacuum control adjuster acts as a variable orifice (either directly or by way of a spring acting on a diaphragm) to adjust the force of vacuum, which is indicated on a gauge. Within the unit is a filter and some form of float valve to provide protection from particulate matter.

Distribution pipeline network: between the terminal outlet and the control unit there is a colour-coded (yellow) flexible hose with a specific Schrader probe connection, as for piped medical gases.

Terminal outlet: the terminal outlet of the vacuum pipeline consists of a labelled, self-sealing valve, fronted in yellow, that accepts a probe with indexing collar to prevent misconnection.



5 Vacuum control regulation unit.
a vacuum gauge, **b** vacuum control, **c** filter, **d** float valve.

Filter unit: filters are sited within the control unit, but also in the case of piped medical gases and vacuum systems between the terminal outlet and the central vacuum source. They remove particulate matter and bacteria from the system to prevent blockage and contamination.

Central pump: the role of the pump is to generate subatmospheric pressure within the system. Pumps are commonly driven by electrical, pneumatic or manual means (Figure 6). The piston, diaphragm and rotary devices shown in Figure 6 all require some form of energy source (usually electricity) to drive mechanical pumps. In contrast to these, the gas-powered pump works on the Venturi principle and the bellows require manual input to generate subatmospheric pressure.

The type of pump is determined by the specific requirements of the suction unit. For example, most portable units use a manual pump, whereas a rotary-driven pump may be used when a large volume of aspirate is anticipated. The pump expels its exhaust gases, via a silencer, to the atmosphere at a suitable site, such that staff and patients are not exposed to the pollution.

Vacuum pumps

6

Humidification devices

Humidification strictly refers to the addition of water vapour to air. Humidification of dry, cold anaesthetic gases as they enter the patient's airway is important because dry gases result in drying of the mucosal surfaces, abnormal ciliary function and increase in the viscosity of respiratory tract secretions. Loss of these protective mechanisms can cause mucus plugging, atelectasis, reduction in gas exchange and an increased susceptibility to infection. Also, heat energy due to latent heat of vaporization is lost by the patient in warming and humidifying dry, cold anaesthetic gases.

Aims: under normal circumstances, the upper respiratory tract warms and humidifies the air to an absolute humidity (i.e. mass of water vapour in a given volume of air at specified temperature and pressure) of 34 g/m^3 at 34°C in the trachea and 44 g/m^3 at 37°C in the alveoli. These values equate to fully saturated air whereby the air contains the maximum possible water vapour at specified temperature and pressure. Achievement of these values is the 'gold standard' for humidification. The different efficiencies of various humidifiers are shown in Figure 7.

Approximate efficiency of humidifiers

The exact values depend on the model of humidifier used.

7

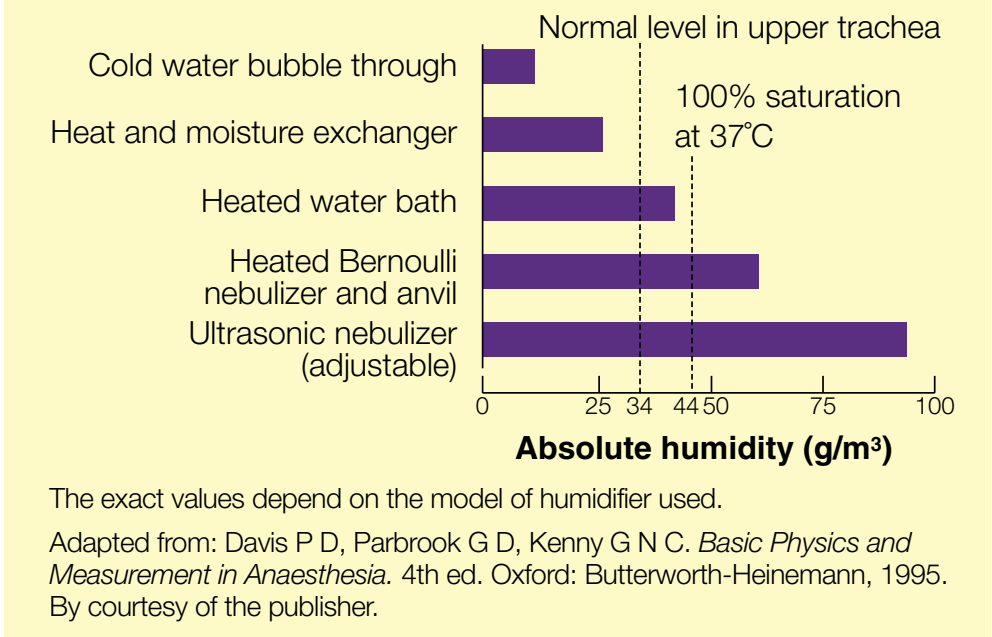
Types of humidifiers

Heat and moisture exchanger (HME) is the most commonly employed humidifier in day-to-day anaesthetic practice (Figure 8). It consists of a sealed unit that is placed within the breathing circuit. The exchanger contains a structure usually of either sponge or mesh, of large surface area, on to which water is absorbed. Absorption is maximized if the mesh is made of a hygroscopic material such as paper coated with calcium chloride or glass fibre. An additional role of some devices is to act as bacterial filters because over 99.99% of bacteria will not pass through pores of less than 0.2 microns. HMEs work on the principle that the moisture from expired gas condenses on to the mesh material within the device as it cools. The mesh is also warmed as the cooling moisture emits latent heat. As gas is inhaled it is warmed and humidified, thus exchanging heat and moisture. The advantages of the system are that it is:

- lightweight
- compact
- disposable
- efficient (60–70% relative humidity at 30–34°C, equating to absolute humidity of about 25–35 g/m^3)
- passive (requires no external power source)
- inexpensive.

The disadvantages are:

- increased dead space
- increased resistance to breathing
- single-patient use.



8 Heat and moisture exchanger.

Cold water bath humidifier (Figure 9): this operates by bubbling inspiratory gas through or over a cold water bath. The advantages are it is simple and safe. The disadvantage is that it is inefficient.

Hot water bath humidifier (Figure 10): inspiratory gases are bubbled through, or pass over, a warm water reservoir. The contact surface area is increased in some devices by the use of wicks or multiple bubble holes. The water temperature must be rigidly regulated to attain a balance between maximum humidification, bactericidal activity and heating, with the risk of thermal injury to the patient. This is achieved by the use of a thermostatic control and temperature monitoring within the circuit close to the patient. A water trap must be included on the patient side of the system and the whole apparatus must be below patient level to limit the risk of condensed water in the tubing entering the breathing circuit directly. The system is efficient but the disadvantages are:

- risk of scalding
- bacterial growth if temperature falls below 60°C
- condensation of water within tubing.

9 Cold water bath humidifier.

10 Hot water bath humidifier.

Nebulizers: the principle of nebulizers is to add tiny droplets of water to the inspired gas. Strictly speaking nebulizers are not humidifiers because they add water droplets not vapour to the gas. Nebulizers have the potential to produce water droplets of varying sizes. The result of this is that very small droplets pass into the alveoli and thus risk fluid overload, whereas large droplets risk being deposited in the breathing circuit or upper airway. Ideal droplet size is 1–5 microns. Nebulizers are highly efficient but they can be expensive and water overload may occur, especially in ultrasonic devices. There are three commonly encountered methods by which nebulizers produce water droplets.

Venturi principle – water is entrained into a jet of gas that breaks it into droplets (Figure 11). Some systems also contain a solid object (anvil) into which the droplets are propelled, thus further reducing their size. Droplet size averages 2–4 microns. Back pressure from a breathing system can affect the efficiency of the device by reducing water entrainment. Some nebulizers incorporate a heater to increase their efficiency.

Spinning disc – a rapidly rotating disc that throws off tiny water droplets.

Ultrasonic – high-frequency ultrasound waves fragment water into tiny droplets. The water may be dropped on to a vibrating surface or the device may be immersed in a water bath. Droplets 1–2 microns in size are produced.

Medical Gases and their Delivery

Ian R Taylor
Michael O'Connor

Ian R Taylor is Specialist Registrar in Anaesthesia at the Princess Margaret Hospital, Swindon, UK. He qualified from Bristol University and is training in Anaesthesia at the Wessex School of Anaesthesia, Southampton, UK. His interests are vascular and obstetric anaesthesia.

Michael O'Connor is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Medical gas

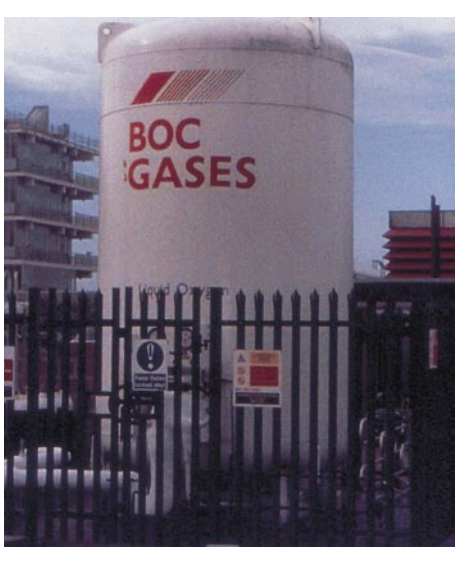
In the UK, most hospitals have piped medical gases and vacuum systems (PMGV) for convenience and economic reasons. The vacuum component of this system is discussed on page 114.

The pipeline network carries medical gases from central bulk storage sites to hose outlets in the walls of anaesthetic rooms, theatres and wards. The responsibility for this section of the PMGV is principally that of the hospital pharmacy, supplies and engineering departments. Anaesthetists have responsibility for the section of pipeline between the terminal outlet and the anaesthetic machine. The bulk store for medical gases is usually a series of cylinder manifolds (Figure 1). In the case of oxygen, the cylinder manifold is often used as a reserve because most hospitals store oxygen in a vacuum-insulated evaporator (VIE) (Figure 2). The cylinder manifold is divided into a primary unit, which is in use, and a secondary unit in reserve. As the pressure in the primary unit falls, the supply is automatically switched to the secondary unit and an alarm sounds to alert the staff to replace the empty cylinders. When there is actual or impending supply failure the alarm usually sounds in the switchboard area of the hospital.

The pipes are constructed of high-grade copper alloy to prevent degradation of gases and are de-greased to reduce the risk of combustion or explosion. They are labelled at regular intervals along their length and are separated from other pipelines within the hospital to avoid confusion. Within the network of pipes there are valves to control the supply to individual theatres or a complete department, in the event of fire or pipeline damage. These are lever-operated, non-lubricated valves housed in clearly accessible units usually behind a breakable glass cover (Figure 3).

The pressure within the pipelines is regulated at about 400 kPa.

1 Cylinder manifolds.



2 Vacuum-insulated evaporator.

3 Pipeline lever safety valve.

Terminal outlet connection

Outlet points (Figure 4) for each of the piped medical gases have specifically labelled, shaped, colour-coded and non-interchangeable Schrader sockets to prevent connection of the incorrect gas supply to the flexible hoses supplying the anaesthetic machine. These must comply with the British Standard codes (BS5682) and be labelled as such. Each terminal outlet is a self-sealing valve unit of specific size to receive the corresponding collar-indexed probe of the flexible hose.

To ensure correct connection and function of the outlet valve, the probe is firmly inserted and a sharp tug applied to ensure full engagement and opening of the valve. This simple procedure is known as the 'tug test'.

4 Terminal gas outlets.

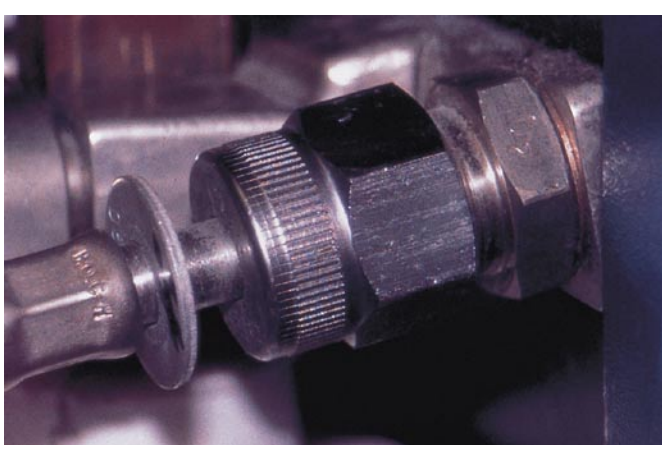
Flexible pipeline

A flexible pipeline carries medical gases from the terminal outlet to the anaesthetic machine. The terminal outlet probe (Schrader probe; Figure 5) is fitted with an indexing collar of a specific diameter for each gas, which will fit only the corresponding gas socket on the terminal outlet valve. In addition, each collar has a notch that fits over a pin within the socket to prevent rotation of the hose once installed. The entire assembly is constructed so that rapid probe insertion or withdrawal can be performed single-handedly and that once withdrawn the terminal outlet unit is self-sealing.

The flexible hose is made of a high-quality copper alloy with antistatic and bacteriostatic properties. It is colour coded and labelled in accordance with the gas it carries.

The hoses are connected to the anaesthetic machine by a non-interchangeable screw thread unit. This unit consists of a probe unique to each gas and a nut to screw the assembly on to the machine. A stainless-steel ferrule is crimped over the whole unit to seal the connection and prevent its removal (Figure 6).

5 Schrader probe.



6 Non-interchangeable screw thread.

Safety

Pipelines and flexible hoses: guidance for manufacturers, installers and maintenance engineers is in accordance with BS5682 (1987) and Health Technical Memorandum 2022 (1994). Pipelines for each of the medical gases are manufactured in different locations within the factory to prevent accidentally mixing up their unique features, for example, connection of the wrong terminal probe, non-interchangeable screw thread fitting or incorrect colour coding.

Pipelines and flexible hoses are steam cleaned, dried and sealed at both ends after internal inspection before being transported to their installation site. This is to prevent contamination and particulate matter from entering the gas supply. In the event of damage to, or technical failure of any part of the pipeline, it must be returned directly to the manufacturer for repair or replacement.

The pharmacy, supplies and engineering departments within each hospital are responsible for the pipeline supply. This includes testing of gases for purity and identity after installation of new pipelines.

The anaesthetist is responsible for ensuring that the flexible hoses are correctly engaged and that the corresponding gas passes into the anaesthetic machine. Correct engagement is checked by using the 'tug test' and the identity of the gas by using the 'single-hose test'. This is done by attaching the oxygen pipeline to the anaesthetic machine, turning on all the flowmeters and ensuring that gas flows only through the oxygen flowmeter and that it is detected by an oxygen analyser fitted at the common gas outlet.

Cylinder gas supply: cylinders and their use in conjunction with the anaesthetic machine are covered elsewhere in *Anaesthesia and intensive care medicine*.

Medical gas pressure

Working pressures within cylinder and piped medical gas supplies are outlined in Figure 7.

Pressure monitoring and display of both pipeline and cylinder gases is performed by Bourdon gauges. The Bourdon gauge is an aneroid (i.e. without liquid) gauge consisting of a coiled tube, attached at one end to the gas supply and at the other end to a pointer. The pressure of the gas causes straightening of the coil and thus causes movement of the pointer over the colour-coded, labelled and calibrated dial. The gauge is faced with heavy glass and designed such that leaks vent from the back of the valve casing and do not blow out the glass.

Cylinder and pipeline colour coding and pressures

	Body colour	Shoulder colour	Pressure (kPa) at 15°C
Cylinder			
• Oxygen	Black	White	13700
• Nitrous oxide	Blue	Blue	4400
• Carbon dioxide	Grey	Grey	5000
• Air	Grey	White/black	13700
Pipeline			
• Oxygen	White		400
• Nitrous oxide	Blue		400
• Air (clinical use)	Black		400
• Air (power tool use)	Black		700

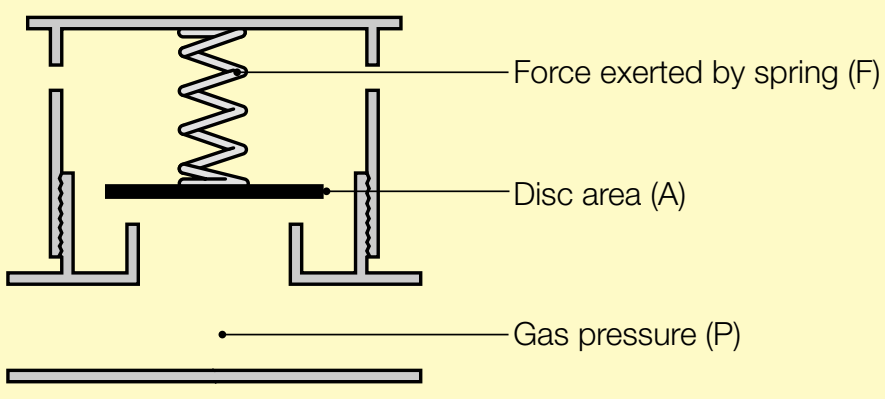
7

Pressure regulators: throughout the medical gas supply network the pressure within the system is closely regulated. This is vital for the protection of both equipment and patient. Measures to maintain a near-constant pressure are found in many sites and usually take the form of a pressure relief valve or a pressure regulator (see *Anaesthesia and Intensive Care Medicine* **1:2:** 66). Both devices are also present within the anaesthetic machine.

Pressure relief valves are designed to allow escape of gas above a certain set pressure. In the case of the VIE this protects the oxygen storage equipment from damage from pressure above 1690 kPa. Similar valves are positioned downstream of pressure regulators within the pipeline supply in case of regulator failure. These are set slightly above 400 kPa.

The principle on which the valve works relates to an equilibrium between two opposing forces: that exerted by the spring and that generated by the gas itself (Figure 8).

Pressure relief valve



$F = P \times A$

As the disc area is constant, and the force exerted by the spring to close the valve is pre-set, once the gas pressure within the system exceeds this closing force, the valve opens and gas escapes

8

Medical gases

Oxygen

Manufacture: industrial manufacture is by the fractional distillation of liquid air. This involves the removal of carbon dioxide and then the separation of oxygen and nitrogen by means of their different boiling points.

Oxygen may also be produced by oxygen concentrators, which extract oxygen from air. This process involves the passing of air through a sieve of zeolite (aluminium silicate), which absorbs the nitrogen, leaving oxygen and a trace of argon. The equipment for this process used to be bulky, but recently smaller units suitable for home use have been developed. A maximum concentration of 95% pure oxygen can be produced using these devices.

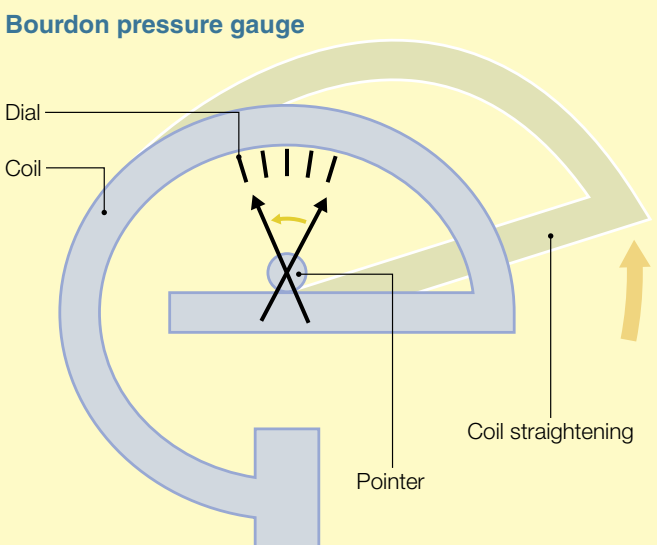
Storage: oxygen is stored either as a gas in cylinders or as a liquid in a VIE. In the UK, cylinders used for oxygen storage are black with a white shoulder (Figure 9); in the USA they are green. The oxygen is stored at a pressure of 13700 kPa at 15°C. Where piped medical gases are used, oxygen is also stored in cylinder manifolds. In cylinders, oxygen is a gas and the volume of oxygen remaining in the cylinder is directly related to the measured pressure, according to Boyle's law.

9 Cylinders. From left: oxygen, nitrous oxide, air, carbon dioxide.

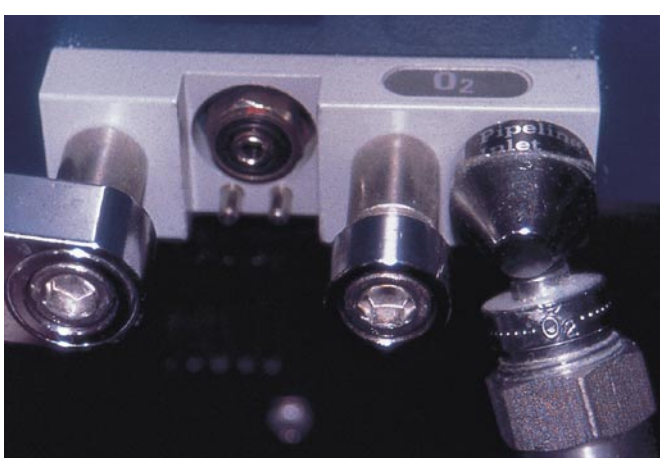
The VIE (Figure 10) is a thermally insulated device similar to a large vacuum flask. Oxygen is stored within this vessel at about –160°C and at a pressure of 5–10 atmospheres (500–1000 kPa). The low temperature is maintained by the vacuum surrounding the main chamber and by heat energy being lost from the liquid oxygen as it evaporates (latent heat of vaporization). Under normal working conditions, oxygen evaporates and passes through the pressure regulator to reduce its pressure to 400 kPa, and then enters the pipeline supply. If demand for oxygen is low, the internal pressure gradually rises until a safety valve opens at 1690 kPa to release gas to the atmosphere. When demand for oxygen is great, the control valve opens allowing liquid oxygen to pass through the pressure-raising superheater and vaporizer, evaporate and enter the pipeline supply. The superheater is a coil of uninsulated copper pipe.

The VIE (Figure 2) can be found outside all hospitals that use piped gases and may be supported by a tripod structure. Two of these legs support the weight of the evaporator, while the third is a weighing device to allow the mass of liquid contained to be measured. Modern designs stand on four legs and the contents are calculated by measuring the pressure difference between the top and bottom of the vessel.

Bourdon pressure gauge



10



11 Cylinder yoke.

Delivery: oxygen is delivered from a central supply (i.e. a manifold or VIE) or directly from cylinders. Central oxygen supply is via the pipeline system described above. Direct cylinder supply of oxygen to the anaesthetic machine involves the connection of the cylinder valve to the cylinder yoke (Figure 11) on the back of the machine.

Carbon dioxide

Manufacture: carbon dioxide is manufactured by heating calcium or magnesium carbonate in the presence of their oxides. Other sources are as a by-product of the manufacture of hydrogen, fermentation of beer or the combustion of fuel.

Storage: in the UK, carbon dioxide is stored in grey cylinders (Figure 9) at a pressure of 5000 kPa at 15°C, as a liquid in equilibrium with its vapour.

Distribution: unlike the other medical gases, carbon dioxide is not distributed via a central pipeline. The attachment of carbon dioxide cylinders to anaesthetic machines has declined in recent years to minimize the risk of accidental administration during anaesthesia. The present guidelines issued by the Association of Anaesthetists of Great Britain and Ireland state that carbon dioxide cylinders should not be routinely fitted to the anaesthetic machine.

Air

Manufacture: air for medical use is compressed, cleaned and filtered before use.

Storage: compressed air for anaesthetic use is stored in grey cylinders with black and white shoulders (Figure 9) at a pressure of 13,700 kPa at 15°C. In the USA, the cylinders are yellow.

Distribution: pipeline air is sourced from either a manifold (Figure 1) or, more economically, from an air compressor. It is important to know that air for clinical use is regulated to a pressure of 400 kPa, whereas that for the use of surgical power tools is supplied at 700 kPa. The terminal outlet for compressed air is colour coded black and white, labelled and has a non-interchangeable connection (Figure 4).

Cylinders are attached directly to the anaesthetic machine by connection of the cylinder valves to the cylinder yoke. A larger portable cylinder may be attached via a flexible hose.

Perioperative Fluids

E Anne Thornberry

E Anne Thornberry is Consultant Anaesthetist at the Gloucestershire Royal Hospital, Gloucester, UK. She qualified from King's College, London, and trained in anaesthesia in Chester, Bristol and Southampton. She has a special interest in obstetric anaesthesia.

Any surgery under anaesthesia can upset the patient's normal fluid status through preoperative restriction of oral intake of fluids. The degree of disruption depends on the patient's medical condition, the nature of the surgery and the choice of anaesthetic. Factors to consider when planning perioperative fluid management are listed in Figure 1.

Maintenance requirements: normal values for daily fluid and electrolyte requirements are shown in Figure 2. Dextrose 4% with saline 0.18% contains 30 mmol/litre of sodium and is often used for basal fluid therapy.

Determinants of perioperative fluid requirements

- Maintenance requirements
- Preoperative deficits
- Blood loss
- Third-space losses
- Transcellular fluid losses
- Effects of anaesthetic agents and technique

1

Maintenance fluid and electrolytes

Adults
- 40 ml/kg/day

Children
- 100 ml/kg/day for first 10 kg
- 50 ml/kg/day for second 10 kg
- 25 ml/kg/day for each subsequent kg

Na^+ = 1–1.5 mmol/kg/day
K^+ = 1 mmol/kg/day

2

Preoperative deficits

Preoperative assessment of the fluid status of the patient requires an appropriate history, examination and investigations.

History and examination

The following questions should be asked.
- How long has the patient been starved?
- Do they have an intravenous infusion in progress?
- Have they any reason to expect excessive losses?
- Are they taking diuretics?
- Are they pyrexic?
- Have they been vomiting or do they have a nasogastric tube *in situ*?
- Have they got diarrhoea or had a bowel preparation?
- Could they have third-space losses or occult bleeding?
- Have they any symptoms of fluid overload?

The physical examination includes evaluation of the mucous membranes and skin turgor, and measurement of the vital signs, including orthostatic changes. Ascites, pulmonary oedema and pleural effusions should be sought. Measurement of urine output may be useful.

Investigations

A normal haematocrit value may indicate that the patient has a normal fluid status or it may reflect someone with anaemia who is also dehydrated. A raised serum urea with a normal creatinine level may indicate dehydration. Raised urinary sodium levels, specific gravity and osmolality all reflect the normal homeostatic response to water depletion and can be used to monitor progress with resuscitation. The signs and symptoms of water depletion are described in Figure 3.

Estimation of total body water deficit

Deficit of body weight	For example in a 70 kg man	Signs and symptoms
Up to 5%	3.5 litres	Thirst Dry mouth
5–10%	3.5–7 litres	Decreased skin turgor Decreased intraocular pressure Tachycardia Orthostatic hypotension Tachypnoea Oliguria Skeletal muscle weakness Drowsiness
10–15%	7–10.5 litres	Severe hypotension Tachycardia Anuria Confusion/coma

3

Signs and symptoms of uncorrected acute blood loss

Volume lost	For example in a 70 kg male	Signs and symptoms
10%	490 ml	Thirst Venoconstriction
20%	980 ml	Mild increase in heart rate Systolic blood pressure normal Slight rise in diastolic pressure Decreased urine output
30%	1470 ml	Tachycardia > 120/minute Moderate hypotension Tachypnoea Cool, clammy, pale Anxious/aggressive Oliguria
40%	1960 ml	Severe hypotension and tachycardia Tachypnoea Anuria Mental confusion
50%	2450 ml	Coma

4

Fluid losses

Blood loss: the signs and symptoms of unreplaced blood loss (Figure 4) can help to estimate acute losses if accurate measurements cannot be made. Estimates of intraoperative blood losses are derived from measuring or estimating observed losses. Prediction of postoperative losses requires knowledge of the type of surgery and expected postoperative bleeding, combined with measurement of losses in the drains, vital signs, and haemoglobin and haematocrit levels.

Third-space losses are caused by sequestration of extracellular fluid into the tissues. The composition of this fluid is the same as that of interstitial fluid and losses after major bowel resection may be as great as 8 ml/kg/hour. The extent of third-space losses depends on the severity of injury to the tissues.

Transcellular fluid losses: nasogastric aspirate can be measured but pleural effusions and ascites must be estimated. Losses from evaporation occur from the surgical site and during a laparotomy these can be as much as 10 ml/kg/hour.

Effects of anaesthetic agents and techniques

Ventilation with dry anaesthetic gases increases the pulmonary losses from evaporation. General and regional anaesthesia tend to decrease the patient's blood pressure by a reduction in sympathetic tone, vasodilatation or myocardial depression. Vasopressors and intravenous fluids are used to minimize these effects, complicating the assessment of perioperative fluid status. Central venous pressure monitoring can be invaluable in helping to manage more complex cases.

Choosing perioperative fluids

Crystalloids

Dextrose solutions disperse through all the body fluid com-partments and are required to replace combined intracellular plus extracellular water depletion. Once any deficit has been replaced, dextrose is used only perioperatively as part of the basal water requirements or in a diabetic regimen.

Physiological saline disperses throughout the extracellular fluid compartments and is commonly used perioperatively to replace blood loss, transcellular losses, evaporation and third-space losses. Only one-third remains in the intravascular compartment and therefore three times the volume of the blood loss must be given if saline is used as a replacement. When large volumes of saline are administered there is a risk of developing hyperchloraemic acidosis.

Ringer's lactate (Hartmann's solution) behaves as normal saline in distribution. It is often used as the first-choice replacement fluid because the electrolyte content more accurately mimics the extracellular fluid. Its constitution varies between laboratories but in general it contains 137 mmol/litre sodium, 4 mmol/litre potassium, 3 mmol/litre calcium and 142 mmol/litre chloride. There are fewer risks of electrolyte disturbances if large volumes are administered but it is hypotonic and large volumes reduce plasma osmolality.

Colloids

The contents of the commonly used colloids are listed in Figure 5.

Properties of commonly used colloids

	Average molecular weight	Sodium (mmol/litre)	Potassium (mmol/litre)	Chloride (mmol/litre)	Calcium (mmol/litre)
Haemaccel	35,000	145	5.1	145	6.2
Gelofusine	35,000	154	0.4	154	0.4
Hetastarch	450,000	154	0	154	0
Dextran 70 in saline	70,000	150	0	150	0
Albumin 4.5%	70,000	150	2	120	0

5

Colloids used for intravenous therapy have an increased osmolality with respect to plasma and can increase plasma volume by more than the volume infused by attracting water from the interstitial fluid compartment. Consequently they are used predominantly to replace intravascular losses and are unsuitable for the treatment of dehydration. The length of time a colloid stays in the intravascular compartment depends on the shape, size and charge of the molecules suspended and the porosity of the capillary endothelium.

Gelatins are colloid solutions derived from animal gelatin. They have an average molecular weight of 35,000 but there is a wide variation in molecule size. The two commonly used gelatins are *Haemaccel*, which is urea linked, and *Gelofusine*, which is a succinylated gelatin. Their intravascular persistence is low, about 2–3 hours with *Gelofusine* and less for *Haemaccel*. Gelatins are the colloids most likely to induce an anaphylactoid reaction. Cross-matching is unaffected by the use of gelatins. *In vitro* studies suggest they interfere with clotting and platelet aggregation but in clinical practice little effect is seen.

Hydroxyethyl starches (HES) are modified natural polymers of amylopectin, which are metabolized by amylase. They are divided into high, medium and low molecular weight starches according to the range of molecular weights in the solution. *Hetastarch* is a 6% solution with an average molecular weight of 450,000 and a mean molecular weight of 70,000. The intravascular persistence of *Hetastarch* is over 24 hours. Some enters the interstitial space and is taken up by the reticulo-endothelial system where it can persist for years. Hexastarch and pentastarch are lower metabolic weight starch solutions. High molecular weight HES solutions can cause a coagulopathy by reducing factor VIII and von Willibrand factor. The lower the average molecular weight of the solution the less effect it has on coagulation. The maximum recommended dose is 33 ml/kg/day, though this has often been exceeded without any adverse effects. Anaphylactic reactions have been reported, but the incidence is low.

Dextrans are branched polysaccharides produced by the action of bacteria on a sucrose medium. Dextran solutions are divided by their average molecular weight into 10% Dextran 40 (molecular weight 40,000) and 6% Dextran 70 (molecular weight 70,000). Dextran reduces blood viscosity, reduces platelet adhesiveness and increases fibrinolysis. Doses higher than 1.5 g/kg can increase bleeding. Only Dextran 70 is used for short-term plasma expansion. Severe anaphylaxis is uncommon but has been reported.

Albumin has a molecular weight of 69,000 and is a naturally occurring plasma protein that contributes significantly to the maintenance of plasma oncotic pressure. It has been used as a colloid to treat critically ill patients with hypoalbuminaemia but there is no evidence that this improves outcome. Recent research has suggested it may worsen outcome but this is not proven. The increasing cost of production of albumin has significantly reduced its use in clinical practice.

Crystalloid–colloid controversy
It has been argued that colloids are more appropriate than crystalloids for the replacement of intravascular losses because they stay in the intravascular compartment longer, necessitating a smaller volume of replacement and a more rapid result. As stated above, the intravascular persistence varies significantly between the different colloids, while this argument holds for hydroxyethyl starches it is not so strong for the gelatins.

Opponents of colloids emphasize the incidence of ana-phylaxis with colloids, which does not exist with crystalloids. The pragmatists suggest that the normal physiological response to an acute intravascular deficit is to draw water in from the interstitial fluid compartment and therefore it makes sense to initiate resuscitation with a crystalloid and then to continue with a colloid if the loss becomes significant.

Blood and blood products
Red cell transfusions: the indication for a red cell transfusion is to increase the oxygen-carrying capacity of the blood by raising the haemoglobin concentration of patients with acute or chronic anaemia. The extent to which it should be raised depends on the balance between oxygen consumption and supply, with the aim of avoiding tissue hypoxia. Factors that affect perioperative oxygen consumption are body temperature, sympathetic activity, metabolic activity, heart rate and drug therapy.

New safety requirements are making blood products more complex and expensive to produce. Recent research suggests the traditional trigger of a haemoglobin concentration of 10 g/dl for perioperative transfusion is too high. The rate of blood loss also needs to be taken into consideration when deciding to transfuse. Suggested British Society for Haematology guidelines are summarized in Figures 6 and 7.

Need to transfuse based on an estimate of lost circulating volume

Volume lost	Indication for transfusion
15%	Only if superimposed on existing anaemia or Patient unable to compensate because of severe cardiac or respiratory disease
15–30%	As above or In the presence of continuing blood loss
30–40%	Transfusion should be considered
> 40%	Transfuse

6

Need to transfuse based on consideration of haemoglobin concentration

Haemoglobin concentration	Indication for transfusion
< 7 g/dl	Transfuse
7–10 g/dl	Transfuse patients who would tolerate anaemia poorly (e.g. those with cardiac or respiratory disease, those over 65 years of age)
> 10 g/dl	No indication

7

Concerns about the safety of transfusion have encouraged the development of alternative strategies to minimize the need for homologous transfusions. These include the use of autologous pre-donation of blood, acute normovolaemic haemodilution, intraoperative cell salvage, preoperative administration of erythropoietin and the development of blood substitutes.

Fresh frozen plasma is valuable because it contains all the clotting factors. It is used to correct a coagulopathy due to a concurrent illness, the use of anticoagulants or a dilutional coagulopathy. A coagulation screen should be requested to establish the need for fresh frozen plasma, although in the presence of a massive haemorrhage, fresh frozen plasma may be given before laboratory results are available if there are clinical signs of impaired coagulation.

Platelets should be given only if there is clinical and laboratory evidence of abnormal coagulation.

Blood substitutes
There are three different areas of research in progress: free haemoglobin solutions, encapsulated haemoglobin cells, and perfluorocarbon emulsions.

Haemoglobin-based oxygen carriers: free haemoglobin has been used as a red blood cell substitute for decades but initially there were many adverse effects including hypertension, bradycardia, renal dysfunction and a short intravascular retention time. A problem was the lack of 2,3-diphosphoglycerate (2,3-DPG) and the higher pH of plasma compared with that inside the red blood cell. There is also an increase in oncotic activity which limits the concentration of free haemoglobin that can be used to about 5–7 g/dl.

Some of the adverse effects of free haemoglobin have been reduced by a variety of modifications including polymerization and conjugation to increase the intravascular retention time and the introduction of haemoglobin into cell-like structures, using stable, porous membranes that allow molecules such as glucose to enter. Some products have reached the stage of clinical trials.

Perfluorocarbon emulsions: perfluorocarbons are synthetic carbon–fluorine compounds. They dissolve gases including oxygen and carbon dioxide. They are not metabolized *in vivo* and most are excreted unchanged via the lungs. A small amount is taken up by the reticulo-endothelial system and excreted later. They are immiscible in water and have to be emulsified. Initial emulsifiers caused numerous adverse effects. Second-generation perfluorocarbons have reduced the complications, but high doses can still interfere with coagulation, elevate liver enzymes and produce a febrile response. They are in phase III trials as a blood substitute. ◆

Positioning the Surgical Patient

Jonathan Warwick

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

The correct positioning of a patient for surgery is a balance between optimizing surgical exposure and minimizing complications for the patient. The surgeon may request a particular position and it is often the role of the anaesthetist to ensure that this is accomplished safely. The anaesthetist must consider the limits of position that may be tolerated and ensure access to the airway, monitoring and vascular devices as far as possible. In general, complications may arise from physiological consequences of the position and the effects of direct pressure on soft tissue structures.

Supine position

Indications: the supine position is the standard for most surgical procedures. The orthopaedic fracture table is a modification that enables traction to be maintained on a lower limb and provides access for an image intensifier.

Physiological consequences: when an individual is upright, ventilation per unit lung volume is greater in the lower part of the lung, because here the weight of the lung makes the intrapleural pressure–volume curve steeper (see Figure 2). The apex of the lung is on a flatter part of this curve, representing a relatively larger change in pressure for a given change in lung volume, and hence a lower compliance. The lower part of the lung is better perfused as a result of gravity.

When an individual is supine, ventilation and perfusion become more uniform and the effects of gravity less marked. The differences between base and apex are then replaced by differences between dependent and non-dependent parts of the lung. Stroke volume and cardiac output may increase as a result of the increase in central venous pressure. Baroreceptors sense an increase in arterial pressure, leading to a fall in heart rate and systemic vascular resistance.

The physiological effects of a change of posture when anaesthetized depend on additional factors:

- pharmacological effects
- circulating blood volume
- method of ventilation.

The functional residual capacity (FRC) decreases by about 20% following induction, though closing capacity remains unchanged. Anaesthetized patients are vasodilated and have diminished compensatory cardiovascular reflexes. Therefore, all positioning movements must be made slowly. The basic supine position is generally well tolerated and has no additional physiological effects in healthy patients.

Pregnant patients may suffer from the supine hypotensive syndrome, where the weight of the gravid uterus reduces venous return by compression of the inferior vena cava (IVC). This can be avoided by a lateral tilt of the operating table, usually to the left side.

Direct pressure complications: the eyes should be taped closed to prevent corneal drying or injury from scratching. Limbs must be fully supported and moved with care to prevent joint dislocation or even fracture. The arms can be secured in the drawsheet, or by the use of padded arm supports.

Skin overlying all bony points is prone to pressure damage, especially the occiput, elbows, knees, greater trochanter of the femur and sacrum. As little as 2 hours of unrelieved pressure may result in a pressure sore; the duration of pressure is considered to be more important than its intensity. The ankles should be placed in soft foam-rubber boots to avoid pressure necrosis of the heel skin.

Injury to peripheral nerves (Figure 1) is often a consequence of the way in which the patient is positioned during surgery. Nerve injury is most likely to occur with the combination of muscle relaxation, an extreme position and prolonged surgery. Peripheral nerves are damaged by local ischaemia caused by compression or stretching. This produces segmental demyelination. Complete clinical recovery usually occurs within 6–8 weeks, but may take several months. Severe damage may be associated with permanent injury. Electromyography studies may aid the prognosis.

Supine position – nerve injuries

Nerve injury	Comments
• Supraorbital	Compression by catheter mount, trachael tube connectors
• Nerves to the eye	Compression from face mask
• Facial (VIIth)	Compression by anaesthetist's fingers against ramus of mandible, face mask harness
• Brachial plexus	Stretching injury, especially when arm is abducted > 90°, externally rotated, elbow extended and forearm supinated
• Ulnar	Most common nerve injury occurring during anaesthesia. Compression between the medial epicondyle of the humerus and the edge of the operating table. Pronation of the forearm may place the nerve more at risk than supination
• Radial	Compression between the edge of the operating table or armboard and the shaft of the humerus, compression from a head-screen support
• Pudendal	Compression from the post of an orthopaedic fracture table may cause pudendal nerve injury or genital trauma
• Sciatic	Direct compression in thin patients undergoing prolonged surgery on a hard table

1

Lateral ('lateral decubitus') position

Indications:

- thoracic surgery
- lateral approach to the kidney
- surgery to the hip.

Reference to the right or left lateral position indicates the side on which the patient is lying.

Physiological consequences: when lying awake in the lateral position, ventilation to the upper and lower lungs behaves in a similar fashion to the ventilation of lung apex and base when upright. The lower lung lies on the steeper, more compliant part of the intrapleural pressure–volume curve (see Figure 2, page 12). The weight of the abdominal contents pushes the lower lung diaphragm higher than the diaphragm of the upper lung, so that it is also able to generate a higher force of contraction. The lower lung is therefore better ventilated than the upper lung. Perfusion of the lower lung is also greater as a result of gravity.

Following anaesthesia, the distribution of blood flow remains unchanged but there are significant changes to the distribution of ventilation. Muscle tone is greatly reduced or absent and the FRC of each lung falls, especially in the lower lung as a result of the weight of the mediastinum pushing down from above and the weight of the abdominal contents below. This has the effect of moving the upper lung down to a more favourable (i.e. steeper and more compliant) part of the intrapleural pressure–volume curve. The lower lung moves down to a flatter, less compliant part of the curve. Therefore the upper lung becomes the better ventilated, but because it receives less of the pulmonary blood flow, ventilation–perfusion mismatch increases.

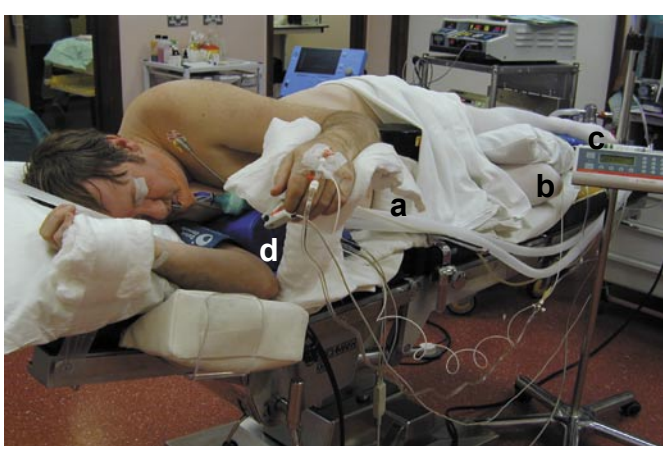
To expose the flank during the lateral approach to the kidney, the lateral flexed position over a support ('kidney position') may be necessary. Significant hypotension may result when the patient is positioned on the right side for a left kidney operation. Reduced venous return occurs as a result of partial obstruction of the IVC from the support. Hepatic encroachment on the IVC may also contribute. This problem is less common when the patient is in the left lateral position.

Direct pressure complications: the pelvis and shoulders must be well supported to prevent the patient from rolling backwards off the table, or forwards into the recovery position. The lower leg should be flexed and the upper leg extended, with a pillow between the two (Figure 2).

An axillary roll places the weight of the chest on to the ribcage and prevents direct compression injury to the shoulder and axilla, thus avoiding deltoid muscle ischaemia or neurovascular damage to the lower arm.

The lower leg is at risk from pressure damage, especially in obese patients. Compartment syndrome, myoglobinuria and acute renal failure have been reported.

Nerve injuries that may result from the lateral position are listed in Figure 3.



2 The lateral position.
a Padded supports to prevent patient rolling over – anteriorly next to iliac crests; posteriorly next to lumbar spine.
b Lower leg flexed and pillow between knees.
c Heel supported.
d An axillary roll places the weight of the chest on to the ribcage.

Lateral position – nerve injuries

Nerve injury	Comments
• Cervical spine	Lateral flexion may stretch cervical spinal nerves and make arthritic joint pain worse. May cause Horner's syndrome
• Brachial plexus	Stretching injury when the neck is extended and in lateral flexion. May occur when the arm is suspended from a bar or gutter and is inadequately supported
• Common peroneal	Compression between the operating table and the head of the fibula

3

Trendelenburg ('head-down') position

Indications:

- pelvic surgery
- insertion of central venous lines.

Friedrich Trendelenburg first described the 45° supine head-down position in 1890. This position facilitates access to the pelvis. Most head-down positions are now about 20° or less with acceptable results. The steep head-down position is now avoided because it is unnecessary and has too many disadvantages. A corrugated or non-slip mattress helps prevent patient movement.

Physiological consequences: there is a greater reduction in FRC than in the basic supine position as a result of pressure of the abdominal contents on the diaphragm. Usually ventilation is little impaired, especially in fit patients and for short periods. For longer operations and in obese patients, there is increased work of breathing against the weight of the abdominal contents, therefore controlled ventilation is preferable.

Central venous pressure rises, and cardiac output may increase. This may precipitate acute heart failure in patients with poor cardiac reserve. The position is not generally effective in improving the circulation during shock and can increase venous pooling in the upper half of the body. A prolonged head-down position will cause venous congestion and oedema in the head and neck.

Barrier pressure is the difference in intraluminal pressures either side of the gastro-oesophageal junction. The pressure within the oesophagus is normally 15–25 mm Hg higher than gastric pressure and gastro-oesophageal reflux is prevented. Barrier pressure is maintained by the action of the smooth muscle cells of the lower oesophageal sphincter and the skeletal muscle of the surrounding crural diaphragm. The head-down position may raise intragastric pressure, reduce barrier pressure and encourage reflux to occur.

There is an increase in intracranial and intraocular pressure. While inserting central venous lines in patients with head injury, care should be taken to limit the head-down tilt to the minimum necessary so as not to worsen cerebral perfusion pressure.

Direct pressure complications: injury to the brachial plexus was common when the steep 45° head-down position was used and patient movement was prevented by shoulder supports or wrist straps. Patient movement is prevented by the non-slip mattress when lesser degrees of head-down tilt are used (e.g. 20°). Brachial plexus injury is now uncommon.

Reverse Trendelenburg ('head-up') position

Indications:
- operations on the head and neck; this position reduces venous pressure and helps reduce bleeding
- surgical access to the gall bladder and proximal gastrointestinal tract, especially during laparoscopic surgery
- operations on the shoulder joint.

Usually, 15–20° head-up tilt is sufficient.

Physiological consequences: there is a small decrease in arterial pressure; but less of a decrease in FRC than in the basic supine position because less pressure is exerted on the diaphragm by the abdominal contents. There is a reduction in intraocular and intracranial pressure, mainly as a result of improved venous drainage.

Any open vein or sinus above the level of the right atrium can cause venous air embolism.

Direct pressure complications: injury to the brachial plexus may be caused by excessive rotation and lateral flexion of the neck away from the operative site.

Lithotomy position

Indications:
- urological procedures
- operations on the perineum, anus and rectum.

The patient is positioned in the supine position, with both hips and knees flexed and the thighs abducted. The ankles and feet may be supported by lithotomy poles using stirrups or calf supports, or by strapping into padded boots. The position is usually combined with some head-down tilt to aid surgical access.

Physiological consequences: the lithotomy position is generally well tolerated. There is a reduction in vital capacity and FRC as a result of diaphragmatic splinting from upward displacement of abdominal contents. This may cause difficulty with spontaneous ventilation in obese patients and controlled ventilation may be preferable. Care should be taken when the legs are lowered because this may reveal previously unrecognized hypovolaemia and cause sudden hypotension.

Direct pressure complications: backache is common and may be reduced by providing a support to maintain the normal lumbar lordosis. The sacrum must be supported and should not hang free over the end of the table. Marked flexion of the hips and knees may cause sacroiliac strain, and the legs must be moved together to avoid pelvic asymmetry. Slippage of the lithotomy poles once the legs are positioned can cause hip dislocation. Moving the thighs too far apart may strain the adductor muscles.

Compartment syndrome in the lower leg may be initiated by pressure of the calf muscles on the stirrup pole. 'Breaking' or raising the lower end of the table when the fingers have been inadvertently trapped in the gap has caused crush injury.

Anaesthesia should not be induced with the legs elevated because raised intra-abdominal pressure may predispose to regurgitation, and turning the patient will be difficult.

Nerve injuries that may occur with the lithotomy position are shown in Figure 4.

Lithotomy position – nerve injuries

Nerve injury	Comments
• Sciatic	Stretching as a result of maximum external rotation of the flexed thigh
• Common peroneal	Compression between lithotomy pole and the head of the fibula
• Tibial	Compression if the legs are supported by stirrups behind the knees
• Femoral	Compression beneath the inguinal ligament when the thighs are fully flexed on the abdomen
• Obturator	Compression at the obturator foramen when the thighs are fully flexed on the abdomen
• Saphenous	Compression between the medial condyle of the tibia and lithotomy post or stirrup

Prone position

Indications:
- operations on the spine and posterior cranial fossa
- operations on the buttocks and natal cleft
- percutaneous extraction of renal calculi.

Physiological consequences: there is often an improvement in gas exchange in the prone position. This may be as a result of the greater inspiratory pressures required to maintain the tidal volume, which decreases atelectasis, increases FRC and improves oxygenation. Pulmonary barotrauma caused by excessive inspiratory pressures should be avoided by correct positioning of the pelvis and upper chest.

The pelvis and the upper chest must be supported so that the abdomen is not compressed and the diaphragm can descend freely during respiration. This may be particularly difficult to achieve in obese patients. Patients may be positioned by using pillows, supporting the iliac crests with cushioned props, or by the use of a specialized hollowed mattress. Controlled ventilation is preferable in most patients.

There are no significant cardiovascular changes. Pulmonary blood flow is essentially unchanged from the supine position. Poor positioning and high inspiratory pressures may decrease venous return. Patients with previous coronary artery bypass grafting may be at risk from graft occlusion.

Direct pressure complications: turning the supine patient prone requires a team of four people. Great care must be taken with the head and neck to avoid twisting or hyperextension injury to the cervical spine. The face should rest on a cushioned horseshoe with the weight of the head evenly distributed. The eyes are naturally protected within their bony sockets, but exophthalmos or a flattened nasal bridge may allow transmission of pressure to the globe. Prolonged compression may result in central retinal vein thrombosis and blindness.

The tracheal tube must be securely fixed and its position checked after the turn. Some experienced anaesthetists may use the laryngeal mask for airway maintenance in prone patients, though the use of a reinforced tracheal tube is likely to be safer for the trainee. Excessive pressure on the breasts may cause ischaemic damage to the nipples, interstitial bleeding or rupture of breast implants. In men, the penis or scrotum may become trapped and compressed.

Possible nerve injuries are shown in Figure 5.

Prone position – nerve injuries

Nerve injury	Comments
• Cervical spinal cord	Stretching injury caused by overextensio plane
• Nerves to the eye	Compression from face support
• Facial (VIIth)	Compression from face support
• Brachial plexus	Stretching injury caused by extreme abduction of the arms. Limit abduction to 90°
• Ulnar	Compression between the medial epicondyle of the humerus and the mattress
• Lateral cutaneous nerve	Compression between iliac crest of the thigh and the positioning prop. If used, props should be angulated and positioned so that the patient is unable to slip sideways
• Anterior tibial	Stretching injury caused by forced plantar flexion of the foot

The sitting position

Indications:
- operations on the posterior cranial fossa and cervical spine
- dental chair anaesthesia.

The sitting position enables the surgeon to gain clear access, with optimal venous drainage, low arterial pressure and reduced bleeding. CSF drainage is good and brain swelling is minimized.

Dental chair anaesthesia in the sitting position is now uncommon.

Physiological consequences: the patient is anaesthetized in the standard supine position and the neurosurgical pins and head frame are applied. On the operating table, the patient is progressively sat upright with the neck flexed; the knees are slightly flexed and the legs are lowered. The arms rest in the lap on a pillow, with the elbows flexed.

A small fall in systolic blood pressure of 20 mm Hg usually occurs; this can be offset by prior volume loading with 500 ml of colloid solution. Occasionally, persistent instability of blood pressure can occur that may cause the position to be abandoned despite the use of vasopressors. Controlled ventilation is the method of choice, to enable control of Pa_{CO_2} and intracranial pressure. It maintains a higher mean intrathoracic pressure and reduces the likelihood of air embolus.

Air embolus is the major complication. All patients must be considered to be at risk throughout the procedure. For this reason, many neurosurgeons seldom use this position. It is still used when insufficient access is provided by the alternative prone or semi-prone positions.

Dysrhythmias, especially bradycardia, and blood pressure instability may occur following surgical manipulation in the region of the brain stem. This is a result of direct pressure effects on the autonomic control centres of the medulla.

Direct pressure complications: nerve injuries that may result from the sitting position are shown in Figure 6.

The sitting position – nerve injuries

Nerve injury	Comments
• Cervical spinal cord	Stretching injury and spinal cord ischaemia following excessive neck flexion. A two-finger breadth gap between chin and chest is recommended
• Brachial plexus	Stretching injury if the arms are unsupported
• Ulnar	Compression between the medial epicondyle of the humerus and the arm supports
• Sciatic	Stretching injury if thighs are flexed and knees extended. Maintain adequate knee flexion

Premedication

Neal Evans
Christopher F Kearns

Neal Evans is Specialist Registrar in the Oxford School of Anaesthesia. He qualified from the Royal London Hospital, and was previously a Research Fellow in ITU in Cambridge, UK.

Christopher F Kearns is Consultant Anaesthetist in the Nuffield Department of Anaesthesia at the Radcliffe Infirmary, Oxford, UK. He qualified from Charing Cross Hospital, London, and trained in anaesthesia in London, UK, Toronto, Canada, and Oxford, UK. His interests include neuroanaesthesia and medical education. He organizes the Oxford Primary FRCA courses.

Premedication involves the prescription of drugs before the induction of anaesthesia in order to alleviate the apprehension associated with surgery, to counteract the side-effects of anaesthetic agents or to reduce the risks of pre-existing pathology (Figure 1). When choosing a premedicant drug the anaesthetist must consider which of its properties are appropriate for the individual patient, the possible side-effects and its potential effect on the proposed anaesthetic technique. The ideal premedicant is:

- painless to administer
- highly reliable and specific
- of rapid onset and rapidly cleared
- free of side-effects and interactions with other drugs.

Premedicant drugs entered anaesthetic practice in the late 19th century. Early anaesthetic agents were delivered by open systems and induced unconsciousness slowly. Ether caused an increase in pharyngeal and bronchial secretions, which interfered with smooth gaseous induction. Chloroform caused marked vagal stimulation of the heart leading to bradycardia. Atropine was first used in premedication in 1890. Hyoscine, which combined anticholinergic effects with antiemesis and sedation, was often combined with an opioid (e.g. papaveretum) to produce ‘twilight sleep’. Opioids were prescribed to aid the induction of anaesthesia before the development of more potent anaesthetic induction agents.

The routine use of drugs for premedication is now in decline. There are several reasons for this.

- Modern anaesthetic agents are potent and have a rapid, smooth onset.
- The increased use of day-care surgery requires rapid patient recovery.
- In-patients are often admitted on the day of surgery and the time available between preoperative assessment and induction of anaesthesia is short.
- Pressures of high patient turnover and staffing constraints can make premedication difficult to deliver in practice.

Rationale of premedication

- Reduction of anxiety and fear
- Sedation
- Amnesia
- Antiemesis
- Reduction in volume and acidity of gastric secretions
- Attenuation of autonomic reflexes
- Maintenance of cardiovascular stability
- Reduction of airway secretions
- Provision of analgesia

1

Anxiolysis, sedation and amnesia

The preoperative visit: anxiety is common in preoperative patients. As well as being unpleasant, this anxiety is part of a stress response that may worsen coexisting pathology such as hypertension or angina. A preoperative visit by the anaesthetist is the most effective way to allay the fears and anxieties of forthcoming surgery. This visit can be used to establish rapport with the patient, to discuss the proposed anaesthetic technique in terms that they can understand and to address their worries in a sympathetic manner. Older children will benefit from inclusion in preoperative discussions and it is becoming usual for parents to stay with children during induction of anaesthesia.

For some patients, the preoperative visit alone is insufficient to allay anxiety and pharmacological methods are required. The nature of the surgical procedure, coexisting pathology or the need for a rapid recovery from anaesthesia may dictate extreme caution before the prescription of sedating premedication (Figure 2). Co-administration of an opioid and a benzodiazepine has a potent respiratory depressant effect.

Relative contraindications to sedative premedication

- Airway obstruction or airway surgery
- Poor ventilatory reserve
- Sleep apnoea
- Intracranial pathology
- Severe hepatic or renal disease
- Rapid-sequence induction
- Obstetric anaesthesia
- Day-case anaesthesia (delayed discharge)
- Extremes of age

2

Benzodiazepines
Benzodiazepines are the most commonly used premedication. They are safe and have a broad therapeutic index though they can cause unpredictable psychological effects at the extremes of age. Those that are suitable premedicants can usually be given by mouth about 1 hour before induction, have a short duration of action and produce inactive metabolites (Figure 3).

Benzodiazepines are agonists of γ-aminobutyric acid (GABA) receptors within the CNS. GABA is an important inhibitory neurotransmitter, which hyperpolarizes the neuron by causing an influx of chloride ion. Benzodiazepines also produce sedation and amnesia by their action on the limbic system. Both these effects are variable and depend on the drug used and the dose given.

Temazepam is an effective anxiolytic and is available in elixir or tablet form. It has a sufficiently short duration of action to allow its use in day-case surgery. Midazolam is presented in 2 mg/ml or 5 mg/ml glass vials. Unlike the other benzodiazepines it is water soluble at acid pH but becomes highly lipophilic at physiological pH. It can be given orally or nasally, which makes it an attractive premedicant for children in doses of 0.2–0.5 mg/kg. Lorazepam, 0.05 mg/kg (max. 4 mg), produces intense anterograde amnesia within 30 minutes, often lasting over 3 hours. Amnesia may be viewed as an advantageous property of a premedicant but some patients find the sensation unpleasant.

Benzodiazepines commonly used as premedication

Drug	Usual adult dose	Half-life of parent drug (hours)	Half-life of active metabolites (hours)
• Diazepam	5–10 mg p.o.	24–48	4–10
• Temazepam	10–30 mg p.o.	4–10	None
• Lorazepam	2–4 mg p.o.	10–20	None
• Midazolam	5–10 mg i.m. 0.5 mg/kg (maximum 20 mg) p.o. in children	1–3	None

3

Other anxiolytics and sedatives
Phenothiazines are major tranquillizers that have sedative and anticholinergic actions. They are histamine antagonists (via H_1-receptors) and have antidopaminergic and α-adrenoceptor blocking properties. They may cause pallor and restlessness in the presence of pain and hypotension. Trimeprazine elixir is sedating and is used for children in doses of 1.5–2 mg/kg, up to 2 hours before surgery. It is not licensed for use in children less than 2 years of age.

Droperidol is the only commonly used butyrophenone in current anaesthetic practice. It has antiemetic and sedating properties. Antidopaminergic side-effects such as dystonic reactions and agitation limit its routine use at sedating doses (e.g. 10 mg orally for adults).

Antiemesis

Postoperative nausea and vomiting (PONV) is a common problem, which is distressing for the patient. There are several risk factors:

- gender (incidence is three times higher in women than in men)
- patients undergoing operations on the ear, squint surgery, gynaecological procedures and laparoscopy
- previous history of PONV or motion sickness
- use of morphine
- anaesthetic technique (volatile anaesthetic maintenance is more emetic than intravenous propofol maintenance).

The vomiting reflex is coordinated by the vomiting centre within the dorsolateral reticular formation of the medulla. It receives multiple afferent pathways from peripheral and central chemoreceptors, nociceptors, the vestibular system and the cerebral cortex. The synapses in these pathways are predominantly muscarinic. The vomiting centre also receives stimuli from the chemoreceptor trigger zone in the area postrema on the floor of the fourth ventricle, but outside the blood–brain barrier. This structure is rich in dopamine (D_2) and serotonin (5-HT_3) receptors. The antiemetics commonly used in anaesthetic practice involve inhibition at one or more of these receptor sites.

Muscarinic antagonists: hyoscine (adults, 300 µg; children 4–10 years, 75–150 µg orally) is a more effective antiemetic and is more sedating than atropine. Antihistamines, including cyclizine, 50 mg orally, i.v. or i.m., and promethazine, children 2–5 years, 5–15 mg, 5–10 years, 10–25 mg orally; adults, 25–50 mg orally or intramuscularly, also have antiemetic properties, largely as a result of their antimuscarinic activity. Antimuscarinics cause dry mouth, blurred vision, and bowel and bladder dysfunction.

Dopamine antagonists are powerful antiemetics but extra-pyramidal side-effects, such as dystonia, dyskinesia, tremor and oculogyric crisis are not uncommon.

Prochlorperazine, 12.5 mg i.m., is the most widely used phenothiazine because it is less sedating and has fewer antidopaminergic and α-blockade side-effects than others of the same group.

Droperidol is an effective antiemetic at low dose, 0.625–1.25 mg, reducing the risk of unpleasant dopaminergic or psychological effects. It is usually given intravenously at induction.

Metoclopramide, 0.1 mg/kg i.v., i.m. or orally, is a dopamine antagonist with peripheral as well as central effects. Its prokinetic effects are more marked than its antiemetic properties and comparative studies have raised doubt about its effectiveness as a prophylactic antiemetic.

5-HT antagonists are powerful new antiemetics that are relatively free of side-effects. The most widely used agent is ondansetron, 4 mg i.v., given immediately before or at the end of surgery. Their relative expense has resulted in the cost-effectiveness of their prophylactic use being questioned.

Non-pharmacological measures including acupunture and acupressure have been explored. There is some evidence that these techniques are weakly effective.

Reduction in volume and acidity of gastric secretions

The potential for lung damage from the aspiration of gastric contents increases with the volume and the acidity of the aspirate. Risk of aspiration accompanies late pregnancy, emergency or trauma surgery, symptomatic oesophageal reflux, and obesity.

Acid secretion by gastric parietal cells can be reduced by the use of H_2-histamine antagonists such as ranitidine, 150 mg p.o. Proton pump inhibitors such as omeprazole, 20 mg p.o., are more powerful in reducing acid secretion but inhibit the metabolism of other drugs such as warfarin, phenytoin and diazepam.

A 0.3 molar solution of sodium citrate, 30 ml, will raise gastric pH and is less irritant to the airway should aspiration occur. The routine use of the prokinetic agent metoclopramide, 10 mg, is common practice but of no proven value in the prevention of gastric aspiration.

Attenuation of autonomic reflexes

Parasympathetic stimulation can lead to hypotension, bradycardia or even asystole mediated via the vagus nerve. Triggers include:

- traction on the extraocular muscles during squint surgery
- surgical dilatation of the cervix or of the anal sphincter
- repeated doses of suxamethonium
- laryngoscopy in children (especially on lifting the epiglottis with a straight-bladed laryngoscope)
- opioid analgesics, propofol and halothane.

Glycopyrronium, 0.2 mg i.v. at induction, provides prophylaxis without the discomfort of a dry mouth before surgery. It does not penetrate the blood–brain barrier and lacks the central side-effects of atropine.

An increase in circulating catecholamines may be caused by several factors:

- laryngoscopy and tracheal intubation
- surgical stimulation and pain
- drugs such as ketamine, cocaine and adrenaline (epinephrine) in local anaesthetics.

This increase may cause hypertension and increased myocardial oxygen demand. It may result in myocardial ischaemia in susceptible patients. A balanced anaesthetic technique reduces these risks, and β-blocker premedication (atenolol, 50 mg p.o.) may be of benefit.

There has been recent interest in the use of α_2-adrenoceptor agonists such as clonidine, 3 µg/kg p.o., as premedicants. They reduce sympathetic activity, cause sedation, a reduction in anaesthetic requirement (decreased minimum alveolar concentration) and reduce pressor responses including that of laryngoscopy. However, there appears to be a narrow therapeutic window with the potential for development of hypotension and bradycardia.

Reduction in airway secretions

Antisialogogues are occasionally prescribed as premedicants though their use in modern-day practice is uncommon. Glycopyrronium, 0.2 mg i.v. or i.m., may be used to improve conditions before fibre-optic intubation.

Analgesia

Opioids (e.g. morphine, 0.1–0.2 mg/kg i.v. or i.m.) should be used to relieve acute preoperative pain. However, in the absence of any preoperative distress and with the development of new potent opioid analgesics with a rapid onset given at induction, such as fentanyl, alfentanil and remifentanil, an opioid premedicant is seldom indicated.

Non-steroidal anti-inflammatory drugs decrease the requirement for opioid analgesia during and after a surgical procedure. Typically, ibuprofen, 400 mg p.o., or diclofenac, 50–100 mg p.o., p.r. or i.v., may be given. They should be avoided in patients with a history of peptic ulceration or renal impairment and used with caution in asthmatic patients. Other simple analgesics such as paracetamol, 1 g, can also be given p.o. or p.r.

The concept of pre-emptive analgesia is that nociception can be modulated at the level of the spinal cord by analgesia given before surgery, thereby reducing total postoperative analgesic requirements. While this concept is attractive and has been demonstrated in animal models, clinical studies have yet to prove its value.

Topical anaesthetics such as eutectic mixture of local anaesthetic (*Emla* cream) or amethocaine gel applied to the site of venepuncture, reduce the fear of intravenous anaesthetic induction in children and many adults.

Principles of Anaesthetic Vaporizers

Eileen Palayiwa

Eileen Palayiwa is a Clinical Scientist in the Clinical Measurement Department at the Oxford Radcliffe Hospital. She graduated in physics from Oxford University and obtained her PhD from Oxford Polytechnic. Her interests include evoked potential monitoring and gas analysis.

Gases, liquids and vapours

Substances can exist in the solid, liquid or gaseous state. Below a certain temperature, known as the critical temperature, it is possible to liquefy gases by compressing them. When a gas is below this critical temperature it is referred to as a vapour.

Vapours consist of molecules that have left the surface of a liquid below the critical temperature. Vapour molecules have had sufficient energy to break away from the attraction of the molecules left behind in the liquid and are therefore the more energetic molecules. Molecules leave the surface of the liquid and return to it randomly. When the vapour is in equilibrium with the liquid, the number of molecules leaving the liquid is equal to the number returning to it, and the vapour is said to be saturated. If there is insufficient liquid for there to be a reservoir from which molecules can evaporate and to which they can return, then the vapour is unsaturated and behaves as a gas.

The pressure of a vapour in equilibrium with a liquid is known as the saturated vapour pressure (SVP).

Variation of SVP with temperature

As the temperature of the liquid increases, more molecules have sufficient energy to escape from the surface and therefore the SVP rises. When the boiling point is reached, all the molecules evaporate and the SVP is equal to atmospheric pressure. Figure 1 shows the variation of SVP with temperature for halothane, enflurane and isoflurane. Unsaturated vapours behave as gases so that the pressure is inversely proportional to the volume (Boyle's law).

Cooling due to vaporization

If molecules that have left the surface of a liquid are not allowed to return to it (e.g. if they are swept away by a stream of fresh gas) then the liquid cools. This is because the evaporating molecules are more energetic than those left behind, therefore there is a net loss of energy from the liquid, which causes a drop in temperature. The latent heat of vaporization is the heat required to convert a unit mass of liquid into its vapour phase at a constant temperature. Cooling may be prevented or reduced if the liquid is in contact with a surface that can supply heat by conduction. The amount of heat that a body can supply at a given temperature depends on its specific heat and its mass, or, in other words, on its thermal capacity. Heat is also supplied by conduction from the surroundings and the rate at which this occurs is determined by the thermal conductivity of the body.

The specific heat of a substance is defined as the amount of heat (or energy) required to raise the temperature of a unit mass of the substance through 1 deg C. The units of specific heat are joules per kilogram per Kelvin change in temperature (J/(kg.K)).

The thermal capacity of a body is the heat required to raise its temperature through 1 deg C (this is also equivalent to the amount of energy the body loses when cooled by 1 deg C). The units of thermal capacity are joules per kilogram (J/kg). The thermal capacity of a body is equal to the product of its mass and specific heat.

The thermal conductivity of a material is the rate of heat transfer per unit area when a temperature difference of 1 deg C is maintained across an insulated block of the material 1 m thick. The units of thermal conductivity are Watts per metre per Kelvin (W/(m.K)).

Values of specific heat, density and thermal conductivity for copper, aluminium, glass and stainless steel are shown in Figure 2. It can be seen from this table that copper has the highest thermal conductivity of these materials so that vaporizers made of copper are the most efficient at conducting heat from the atmosphere to replace the energy that the liquid agent loses due to evaporation. Copper has the lowest specific heat of these substances; however, since it is much denser than aluminium or glass, the thermal capacity of a given volume of copper is higher than that of either of these materials. A given volume of stainless steel has the highest heat capacity of these materials. In practice, most vaporizers are made of stainless steel because it is readily available. However, copper is thermally more suitable because its much higher thermal conductivity more than compensates for the lower heat capacity.

Anaesthetic vaporizers

The SVP of most anaesthetic agents at room temperature is too high for them to be delivered to a patient without dilution (Figure 1). For example, the SVP of isoflurane at 20°C is 236.5 mm Hg (i.e. 31% v/v if atmospheric pressure is 760 mm Hg). In general, concentrations below 2% v/v are required for maintenance of anaesthesia. An anaesthetic vaporizer is a device that dilutes the vapour to give a known concentration of the agent.

Fresh gas enters the vaporizer and is split into two portions (Figure 3). One portion flows through an area known as the vaporizing chamber, where it comes into contact with the anaesthetic vapour; the remainder of the gas bypasses this chamber. The two flows then recombine and the vapour is diluted. By varying the flow rate in the two paths the resultant vapour concentration can be varied. The concentration of agent depends on the flow through the vaporizing chamber, the total fresh gas flow and the saturated vapour pressure of the anaesthetic agent. The way in which the gas flow is split between the bypass and vaporizing chamber depends on the relative resistance of each pathway. If the total fresh gas flow (F) is split into a bypass flow (F_b) and a vaporizing chamber flow (F_v) then:

$F_v + F_b = F$

The flow rate emerging from the vaporizing chamber (F_e) will be greater than that entering it, due to the volume of vapour added:

$F_e = F_v + F_e \times SVP/100$

where SVP is expressed as a percentage.

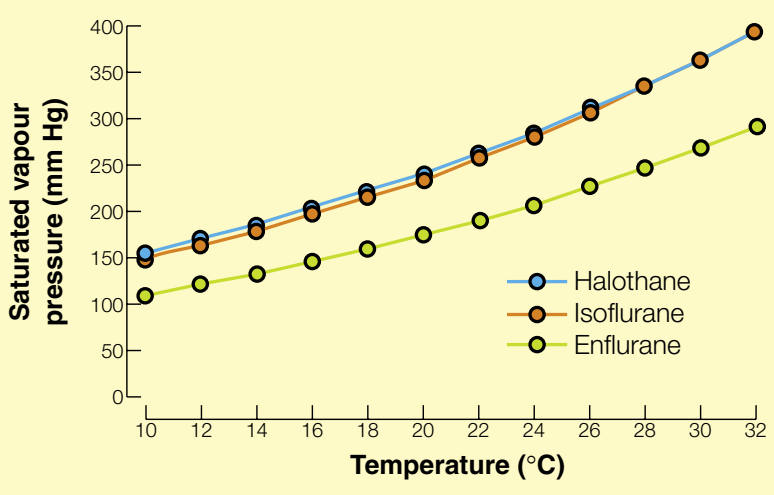
Therefore $F_e = F_v/[1-(SVP/100)]$

The concentration (C) of the vapour in the gas emerging from the vaporizer will be given by:

$C = F_e \times SVP/(F_b + F_e)$

This calculation assumes that the gas emerging from the vaporizing chamber is fully saturated with vapour. To ensure that this is the case, manufacturers increase the surface area of liquid that the gas passes over by introducing wicks made of cloth or metal into the vaporizing chamber. In many cases the gas is forced to take a long pathway through the chamber, which also helps to ensure saturation.

Variation of saturated vapour pressure with temperature



1

Physical properties of some common materials at 293K

	Specific heat (J/(kg.K))	Thermal conductivity (W/(m.K))	Density (kg/m³)
Copper	385	385	8930
Aluminium	913	201	2710
Glass	670	1	2600
Stainless steel	510	150	7930

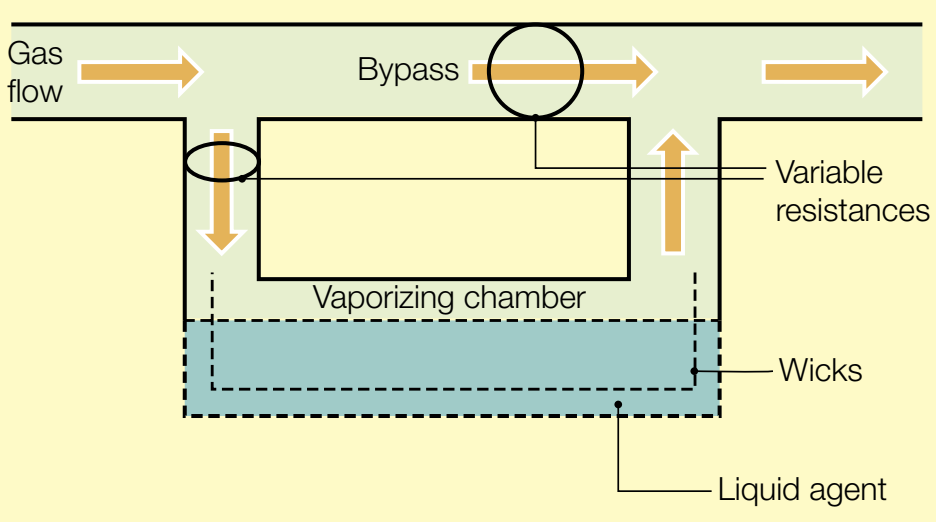
An anaesthetic vaporizer



3

Temperature compensation

As liquid evaporates from the vaporizing chamber the temperature drops, and unless there is some means of compensating for this, the output of the vaporizer also drops. The temperature drop, and hence the fall in output, is lower if the vaporizer has a large heat capacity and can therefore supply energy to the liquid to compensate for that which it has lost. For this reason most vaporizers contain a large mass of metal that can also conduct heat from the surroundings into the liquid. In addition, most vaporizers incorporate some kind of temperature compensation, which reduces the resistance of the vaporizing chamber relative to that of the bypass as the temperature drops. As a result, more gas flows through the vaporizing chamber so that the vapour concentration is maintained.

Effect of intermittent positive-pressure ventilation (IPPV)

During IPPV, the pressure at the outlet of a vaporizer is not constant. When the pressure is high, flow emerging from the vaporizer reduces and the pressure in the vaporizing chamber builds up. As the pressure drops, the excess of vapour, which has accumulated in the vaporizing chamber at this time, emerges not only from the normal outlet of the vaporizing chamber but also from the inlet. This means that the bypass gas contains vapour and therefore the concentration rises. Manufacturers have compensated for this by introducing a long inlet tube into the vaporizing chamber. When the pressure inside the vaporizing chamber drops, the vapour enters this tube, but its volume is not enough to emerge into the bypass.

Effect of flow rate on vaporizer output

The vaporizer output is dependent on the resistance of the vaporizing chamber relative to that of the bypass. With varying flows the vaporizer output remains constant only if this does not change. In practice, this is difficult to achieve over the wide range of flows used in anaesthetic practice. Only if laminar flow is maintained in each pathway throughout the flow range will this be the case. Another factor influencing the output at high flows is the increased cooling, which occurs as a result of the large amount of evaporation taking place.

Figure 4 shows the variation of output with flow for a Penlon plenum enflurane vaporizer. It can be seen that the output of this vaporizer at high settings drops as the flow rate increases. However, at the lower settings more commonly in use, the output remains reasonably constant. This indicates that the temperature compensator in the Penlon plenum vaporizer (PPV) can adjust adequately for cooling due to evaporation except at the highest dial settings and flow rates.

Effect of gas composition

The relative flow rates through the bypass and vaporizing chamber at a given dial setting remain constant only if laminar flow is maintained in both pathways. As soon as the flow in one pathway becomes turbulent, its resistance rises causing less gas to flow through it, unless it is matched by a proportional rise in the resistance of the other pathway.

Nitrous oxide has different physical characteristics from oxygen (Figure 5); in particular, the ratio of viscosity to density, which determines the flow rate at which turbulence sets in, is much lower. The effect that this has on the output of the vaporizer depends on its design. In some vaporizers, output drops when the carrier gas contains nitrous oxide whereas in others it increases.

Variation of output with flow for the Penlon plenum vaporizer

Physical properties of oxygen and nitrous oxide

Gas	Density (kg/m^3)	Viscosity ($\mu N.second/m^2$)	Kinematic viscosity ($m^2/second$)
Oxygen	1.43	18.9	10.3×10^{-5}
Nitrous oxide	1.96	13.5	6.9×10^{-5}

5

Types of vaporizer

Vaporizers fall into two broad categories.

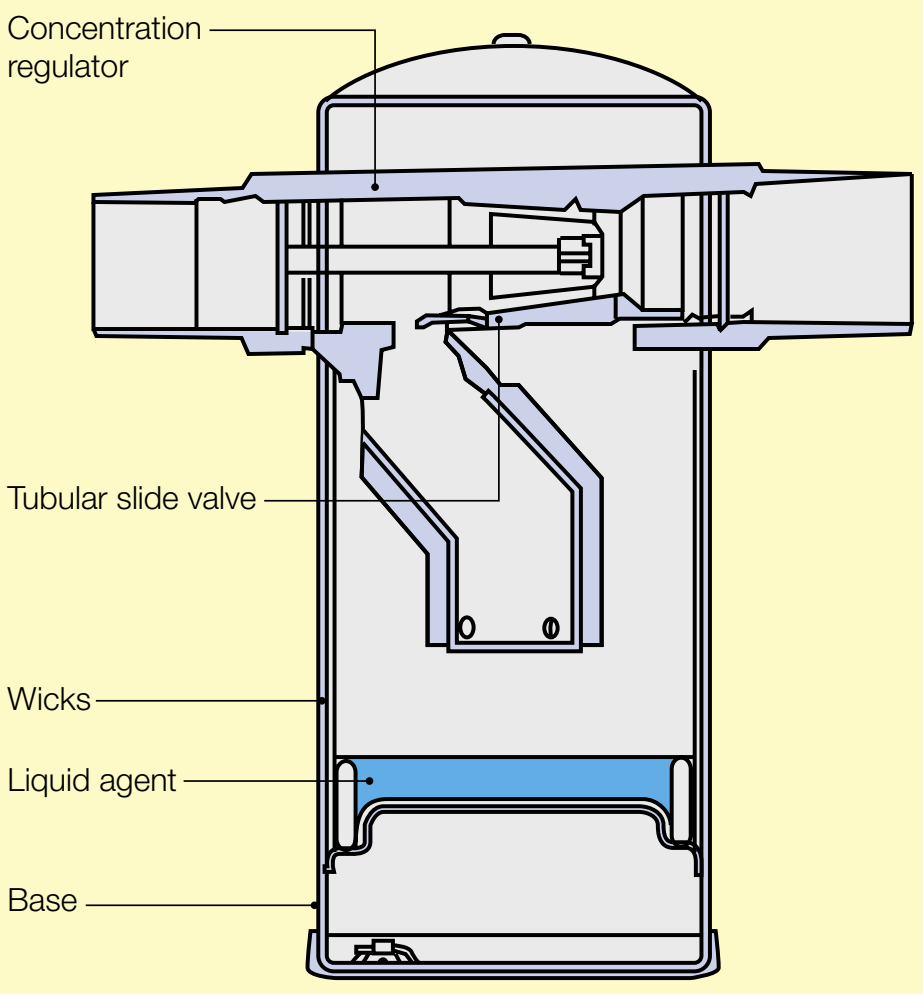
Drawover vaporizers – in a drawover vaporizer, gas is pulled through as the patient inspires (expiration is to atmosphere via a non-rebreathing valve). The flow rate of gas through the vaporizer is therefore not constant and it is necessary for the vaporizer to have a low resistance.

Plenum vaporizers – in a plenum vaporizer, gas is driven through under positive pressure. The term plenum is derived from the plenum system of ventilation where gas is forced into the system. Plenum vaporizers may have a higher resistance than drawover vaporizers though some vaporizers are designed to be used in either mode (e.g. the Oxford miniature vaporizer).

Oxford miniature vaporizer

The Oxford miniature vaporizer (Figure 6) is designed as a low resistance drawover vaporizer. It does not have any temperature compensation, but it has a water-filled jacket to increase its heat capacity.

Oxford miniature vaporizer

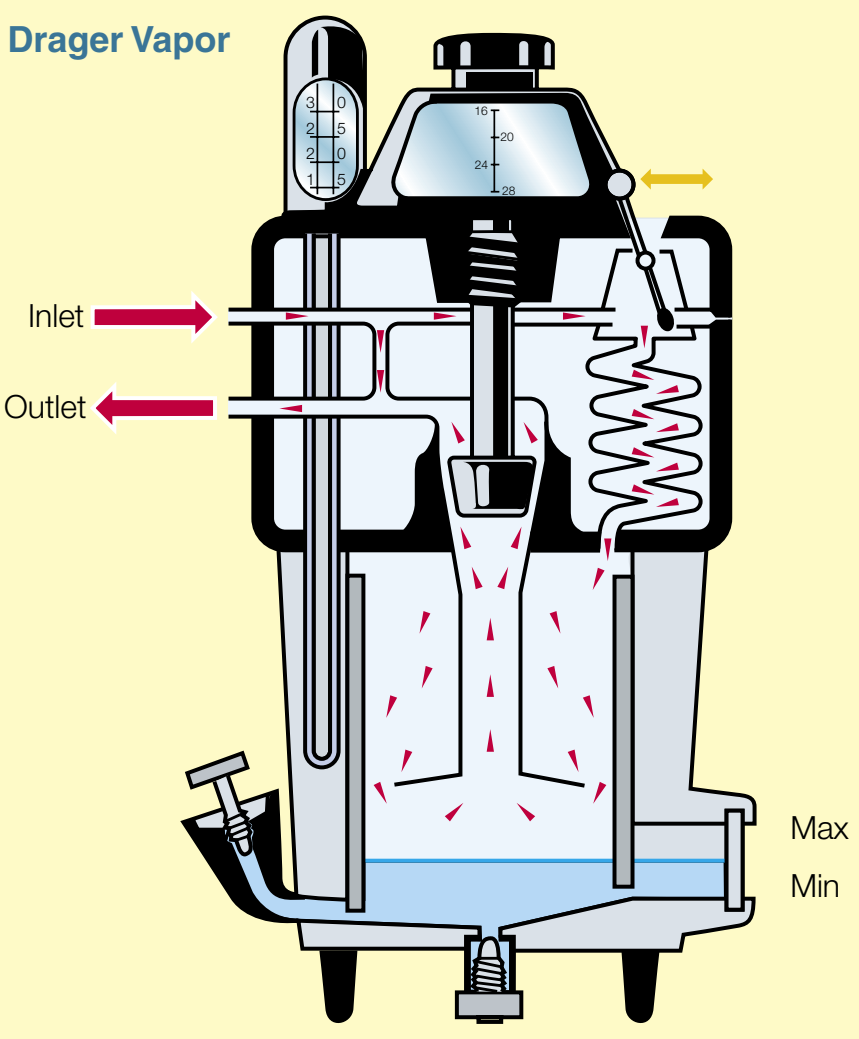


6

Drager Vapor

The Drager Vapor (Figure 7) is constructed from a large block of copper and is therefore thermally stable. It has a built-in thermometer so that the temperature of the liquid agent may be read and the position of the concentration dial is adjusted according to this temperature. In this vaporizer, the gas flow through the bypass and the vaporizing chamber is controlled by a pair of needle valves, which are carefully manufactured to ensure that gas flow is laminar in both pathways over a large range of flow rates. There is therefore little variation of output with flow rate for this vaporizer.

Drager Vapor



7

PPV

In the PPV (Figure 8), when the control dial is in the zero position the vaporizing chamber is isolated by means of a spring-loaded valve attached to the push rod, which is aligned with the control knob. When the control knob zero lock button is pressed the push rod opens the valve and as the control knob is rotated the vapour control orifice opens to allow more gas to flow through the vaporizing chamber.

Temperature compensation is achieved by a moving needle valve within the bypass orifice, which increases the bypass resistance as the temperature drops, thus forcing more gas to flow through the vaporizing chamber. The movement of the valve is controlled by a push rod attached to an ether-filled metal bellows unit. As the liquid agent changes temperature, the ether in the bellows expands or contracts causing the bellows to expand or contract linearly. Compensation for fluctuating back pressure is achieved by the inclusion of a long narrow tube in the vaporizing chamber.

Penlon plenum vaporizer

8

Tec 6 vaporizer

The Tec 6 vaporizer (Figure 9) varies from most other conventional vaporizers because it incorporates a heater element. This is necessary because desflurane concentrations up to 18% v/v may be required. The concentration knob has an interlock system, which means that it cannot be turned until the liquid agent has been heated to the correct temperature. When the control dial is turned, an electronic signal opens the shut-off valve. The pressure transducer measures the difference between the gas inlet pressure and the regulated agent pressure. The agent pressure is controlled electronically by opening or closing the pressure-regulating valve to balance the pressures. When the pressures are correctly balanced the vaporizer functions correctly.

Calibration of vaporizers

Anaesthetic vaporizers are calibrated in the factory using a refractometer (an accurate optical device) in a temperature-controlled room. In general, either oxygen or air at a medium flow rate is used for the carrier gas. The output of a vaporizer may vary under different conditions of temperature, flow or carrier gas – this is not surprising, considering the wide range of flow rates and concentrations over which a vaporizer is used. It has been said that one should expect vaporizers to produce concentrations only within 20% of their dial settings. While this is a wide margin, it is not at all unusual for concentrations to differ by 10% of the dial setting and as conditions become more extreme this difference may approach 20%. It is important that anaesthetists recognize the problems faced by manufacturers when designing vaporizers and that they do not always expect vapour concentration and dial setting to coincide.

Recognition and Management of Anaphylactic and Anaphylactoid Reactions

Andrew McIndoe

Andrew McIndoe is Consultant Anaesthetist and Senior Clinical Lecturer in the Sir Humphry Davy Department of Anaesthesia, Bristol Royal Infirmary. He is also the Director of Research and Education at the Bristol Medical Simulation Centre where he has developed a specific interest in human factors and crisis management.

The term anaphylaxis was coined by Charles Richet in 1902 to describe the reaction of dogs to a second, and often fatal, injection of foreign protein (sea anemone toxin). The term was introduced to distinguish this later injection from the first 'prophylactic' injection that induced sensitization.

Anaphylaxis is now recognized to be an immediate hypersensitivity or type I immune reaction mediated by immunoglobulin E (IgE) and resulting in mast cell degranulation and basophil activation. It is not dose related and can occur in response to minute exposure to an allergen. Typically, the severity of the response worsens on re-exposure owing to progressive sensitization of the subject. The true incidence of anaphylaxis is unknown but is estimated to be 1/6000–20,000 anaesthetics or 1/10,000 of the general population/year. Women are more likely to suffer an anaphylactic reaction than men, with a quoted increase in risk of 3–10:1. Intravenous administration of the antigen is more likely to precipitate a severe generalized reaction. Cross-sensitivities with non-steroidal anti-inflammatory drugs (NSAIDs) and muscle relaxants makes previous exposure unnecessary. Up to 80% of neuromuscular blocking agent reactions are not associated with known prior exposure.

Anaphylactoid reactions may present with a similar clinical picture, but do not result from hypersensitivity and are not mediated by IgE. Drugs such as opioids can directly stimulate mast cell degranulation with histamine release causing pruritus, rash and hypotension. They should be managed as potential anaphylactic reactions because confusion over the diagnosis merely delays effective treatment.

Pathophysiology

Primary exposure to an antigen results in the synthesis of specific IgE antibodies by lymphocytes and plasma cells. The Fc portions of these antibodies are able to fix themselves to the surface of tissue mast cells and circulating basophils. The antigen binding sites are thus presented externally. Subsequent contact with antigen causes IgE antibody:antigen cross-binding and triggers immediate degranulation of the host mast cell or basophil. Release of histamine and serotonin results in an acute inflammatory reaction, smooth muscle constriction, vasodilatation and increased capillary permeability. The clinical picture depends on the mode of exposure.

- Skin – urticaria, flare and weal reaction (hence the use of skin prick testing).
- Eyes – conjunctivitis.
- Mouth/airway – perioral and laryngeal oedema, broncho-spasm.
- Parenteral – generalized cardiovascular collapse.
- Eosinophils are mobilized by chemotaxis, attracted by histamine and other substances, they produce histaminase, helping to terminate the reaction.

History and examination

Anaphylaxis may present with a spectrum of clinical signs including hypotension, tachycardia, dysrhythmias, dyspnoea, laryngeal oedema, bronchospasm, angio-oedema, flushing, urticaria, conjunctivitis, rhinitis, abdominal pain and diarrhoea. It can therefore mimic a variety of other conditions. Diagnosis is further complicated by a variable time for exposure until symptoms develop, varying from a few seconds to several hours. 5% of patients show a biphasic response with symptoms recurring from 1–72 hours after the initial attack. Many patients do not develop all the classic signs (Figure 1).

Differential diagnoses are vasovagal faint with hypotension, bradycardia and pale, sweaty skin and panic attack with hyperventilation, tachycardia and an erythematous rash.

Percentage of patients presenting with classic signs of anaphylaxis

Signs	Patients (%)
• Cardiovascular collapse	88
• Erythema	45
• Bronchospasm	36
• Angio-oedema	24
• Rash	13
• Urticaria	8.5

1

Management

The management of anaphylaxis is summarized in Figure 2.

Management of anaphylaxis

Condition
IgE mediated immediate hypersensitivity reaction to an antigen resulting in histamine and serotonin release from mast cells and basophils

Presentation
- Cardiovascular collapse
- Erythema
- Bronchospasm
- Oedema
- Rash

Immediate action
- Remove trigger
- 100% oxygen
- Elevate legs
- Adrenaline (epinephrine) 500 μg i.m. or 50 μg increments i.v. titrated to effect
- 20 ml/kg i.v. fluid challenge

Follow-up action
- Chlorphenamine (chlorpheniramine), 10–20 mg i.v.
- Hydrocortisone, 100–300 mg i.v.
- Arterial blood gases

Investigations
- Plasma tryptase
- Urinary methylhistamine

Also consider
- Primary myocardial/cardiovascular problem
- Latex sensitivity
- Airway obstruction
- Asthma
- Tension pneumothorax
- Panic attack

2

Immediate management
- Check the airway, breathing and circulation. Stop the administration of or exposure to any potential triggers, particularly intravenous agents. Muscle relaxants, antibiotics and NSAIDs (and increasingly latex) are the most common triggers in an anaesthetic environment. Outside the operating theatre, foods (especially nuts, fish, shellfish, eggs and milk), insect venom, drugs (antibiotics, NSAIDs, contrast media, opioids) and latex are the most common precipitants.
- Call for help.
- Maintain the airway and give 100% oxygen. Reassess airway patency frequently and regularly, especially in known asthmatics and in those exposed to the allergen via the airway or mouth. If in doubt and the reaction is severe, intubate early because it may be impossible to do so later in the presence of increased oedema.
- Cardiovascular collapse is most likely following parenteral exposure to the allergen. Lay the patient flat with the legs elevated to increase central venous return.
- If the patient has a continuous ECG monitor attached, give adrenaline (epinephrine) in 50 μg i.v. increments (0.5 ml of a 1:10,000 solution) at a rate of 100 μg/minute until the blood pressure or bronchospasm improves. Alternatively, give adrenaline (epinephrine) 0.5–1 mg i.m. as 0.5–1.0 ml of a 1:1000 solution (repeated after 10 minutes if necessary). Adrenaline (epinephrine) stabilizes mast cell membranes, increases myocardial contractility, causes bronchodilatation and reverses vasodilatation; it therefore treats both cause and effect.
- Give intravenous fluid (colloid or suitable crystalloid), 20 ml/kg.
- Latex allergy may take up to 30 minutes to manifest itself. Removal of all latex triggers can then be a complex process. Allergen is more readily absorbed across mucous membranes (e.g. from surgical gloves or a urinary catheter, which should be removed immediately and hands should be re-washed to remove latex-impregnated starch granules). Inhalation of aerosolized particles within the breathing circuit is minimized by the use of an airway filter. Ensure that rubber 'corings' are not introduced intravenously (e.g. ampoule bungs and injection sets). Laryngeal mask airways are made of silicone and do not contain latex. *Diprivan* syringe bungs are also latex free.

Subsequent management
- Give an antihistamine (H_1-blocker) such as chlorphenamine (chlorpheniramine, *Piriton*), 10–20 mg by slow i.v. or i.m. injection. Consider H_2-antagonists, such as ranitidine, 50 mg slow i.v. injection.
- Give corticosteroids such as hydrocortisone, 100–300 mg by slow i.v. or i.m. injection, to inhibit later relapses.
- Give a catecholamine infusion because cardiovascular instability may last for several hours. Consider adrenaline (epinephrine) 0.05–0.1 μg/kg/minute (e.g. 4 ml/hour of 1:10,000 for a 70 kg adult) or noradrenaline (norepinephrine) 0.05–0.1 μg/kg/minute (e.g. 4 ml/hour of a solution of 4 mg made up to 40 ml in 5% dextrose for a 70 kg adult).
- Check arterial blood gases for acidosis and consider giving bicarbonate, 0.5–1.0 mmol/kg (8.4% solution = 1 mmol/ml).
- Check for the presence of airway oedema by letting down the tracheal cuff and confirming a leak before extubation.
- Consider bronchodilators for persistent bronchospasm (e.g. salbutamol, 5 mg by nebulizer or 250 μg slow i.v. injection, aminophylline 250–500 mg slow i.v. injection).

Complications

Hospital mortality to anaesthetic drug-induced anaphylaxis is 4%, despite the presence of good resuscitation facilities. Over half of those who die of anaphylaxis do so within the first hour. The deaths are related to asphyxia, from severe bronchospasm or upper airway obstruction, and from refractory hypotension.

The early use of adrenaline (epinephrine) is advisable but advice differs over the safest and most appropriate mode of administration. Adrenaline (epinephrine) is best administered by intramuscular injection (0.5 mg – usually 0.5 ml of 1:1000 solution) by first responders because it is a reliable means of achieving therapeutic plasma concentrations quickly and safely. The subcutaneous route is slow and unpredictable and is inappropriate during an acute life-threatening reaction. Anaesthetists often opt for intravenous administration of a 1:10,000 solution in incremental doses (of 50–100 μg). The intravenous route, while rapidly effective, can result in tachydysrhythmias. Cardiac complications are more common in the presence of hypoxia, hypercapnoea, and in patients taking tricyclic antidepressants or cocaine.

Patients taking β-blockers are likely to suffer more severe reactions and may be resistant to treatment with adrenaline (epinephrine). However, β-blockers are competitive antagonists and careful but continued titration of adrenaline (by sequential doubling of the initial dose in severe cases) should achieve a clinical effect.

Late diagnosis may be complicated by severe compromise of the airway and difficulty intubating the trachea.

Investigations

Investigations should be carried out when the patient has been stabilized.

Plasma tryptase: at least one 10 ml clotted blood sample should be taken 1–6 hours after the start of the reaction to perform a tryptase assay. The specimen must be spun down as soon as possible and the serum stored at –20°C, to stabilize the protein for later analysis. Tryptase is the main protein released during mast cell degranulation and is a specific marker of histamine release due to anaphylaxis or anaphylactoid reaction. Normal basal levels of serum tryptase are less than 1 ng/ml. However, unlike histamine, which is rapidly eliminated, tryptase levels remain elevated for up to 6 hours after an anaphylactic reaction. It is not a protein that is produced by RBCs or WBCs and is therefore not raised by haemolysis. Levels over 20 ng/ml may accompany an anaphylactic reaction.

Elevated metabolites in the form of urinary methylhistamine may also be measured. The value measured has to be corrected for urinary creatinine but levels in excess of 15–20 ng/ml/mmol creatinine/litre are considered higher than normal, and may indicate anaphylaxis.

Radio allergosorbent testing (RAST) is a means of searching for antigen-specific IgE in the serum. Tests are limited to specific allergens. At present only a few anaesthetic RASTs are available (e.g. suxamethonium). Fluoroimmunoassay is an alternative (*CAP System*, Pharmacia).

Follow-up and prognosis

The anaesthetist should follow up the investigation, report reactions to the Committee on Safety of Medicines via the 'yellow card' reporting scheme, and arrange skin prick testing in consultation with an immunologist. Having identified allergens, the patient should be advised to wear an alert bracelet at all times. Those who have suffered a severe reaction, especially anaphylaxis to allergens that are commonly encountered in everyday life, may be advised on how to carry and when to administer their own adrenaline (epinephrine). The *Epipen* syringe is preloaded with adrenaline (epinephrine) and will deliver a fixed intramuscular injection of 300 µg (0.3 ml of 1:1000) for adults or 150 µg for children.

Desensitization is a process that attempts to stimulate the production of IgG or IgA antibodies that competitively bind to the antigen and help block the IgE antibody–antigen hypersensitivity reaction that precipitates anaphylaxis. It is not without risk because it involves repeated inoculation with small doses of antigen.

Recognition of Correct Placement of Tracheal Tubes

Simon Berg

Simon Berg s Consultant Paediatric Anaesthetist at the Oxford Radcliffe Hospitals NHS Trust, Oxford, UK. His special interests are anaesthesia for neonatal surgery and paediatric strabismus surgery.

The technique of tracheal intubation is fundamental to anaesthetic practice. Critical incident reporting indicates that oesophageal intubation is a relatively common problem. Misplacement of a tracheal tube is not in itself harmful if the diagnosis is made promptly and corrective action taken. However, tracheal tube misplacement still accounts for a large proportion of anaesthetic deaths. It should be considered in any hypoxic intubated patient. Failure to detect incorrect tube placement is equally common for trainees and consultants. It is as likely with routine as with difficult intubation.

Methods of confirming correct tube placement

Clinical signs are often unhelpful in detecting tube misplacement and intubation should be confirmed by:

- direct visualization of the tube passing through the vocal cords
- auscultation over both axillae, lung bases and the epi-gastrium
- capnography
- oesophageal detector device or colorimetric detector if capnography is not readily available.

Visualization of larynx

The larynx is usually visualized and the tracheal tube is observed passing between the vocal cords into the trachea. However, a view of the larynx is not always possible. In routine laryngoscopy, an anaesthetist may become distracted at the moment of intubation, allowing the tube to slide past into the oesophagus. Occasionally the oesophagus may be mistakenly identified as the trachea or the tube may become displaced during fixation. Direct visualization is thus not totally reliable and may even delay a diagnosis of tube misplacement by promoting a false sense of security.

Repeat laryngoscopy is essential if a tube problem is suspected; oesophageal intubation, extubation or a kinked tube can all be identified and remedial action taken.

Chest movement

Bilateral symmetrical chest wall expansion should occur coincident with inspiration. It may be difficult to discern in the obese patient, in those with a rigid chest wall, or in chronic lung disease (e.g. emphysema). Oesophageal ventilation may imitate chest movement by expansion of the mediastinum, while gastric distension can simulate diaphragmatic and lower chest wall ventilation, especially in infants.

Auscultation

The combination of auscultation over each axilla, lung base and epigastrium achieves the most reliable results. Direct auscultation over the trachea may be of additional benefit; more obvious breath sounds can be heard, which are less likely to be confused with oesophageal ventilation.

Breath sounds over the chest wall do not always exclude oesophageal intubation. Air ventilating the oesophagus can be transmitted through the lungs to resemble convincing breath sounds. Conversely, breath sounds may be inaudible in the obese patient.

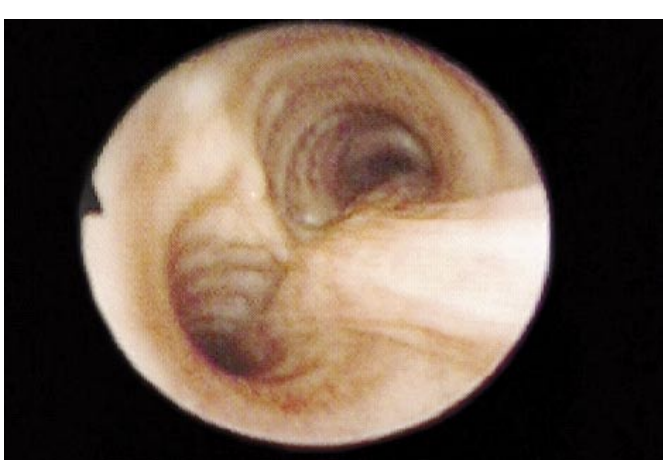
Breathing circuit

The ability to ventilate the lungs via the reservoir bag together with its typical compliance characteristics is a useful sign for the anaesthetist. In a spontaneously breathing patient the bag should empty and refill synchronously with the patient's breathing pattern. However, small movements (cardiac oscillations) can be demonstrated with oesophageal tube placement.

In contrast, it may be difficult to ventilate a morbidly obese patient via the reservoir bag or to differentiate between oesophageal intubation and partial or complete bronchospasm.

Fibre-optic laryngoscopy

The fibre-optic bronchoscope or laryngoscope can reliably confirm tracheal tube placement by identification of the tracheal rings and carina under direct vision (Figure 1). The technique requires operator experience and the equipment must be readily available.



1 View of the carina via a fibrescope, confirming the correct placement of the tracheal tube.

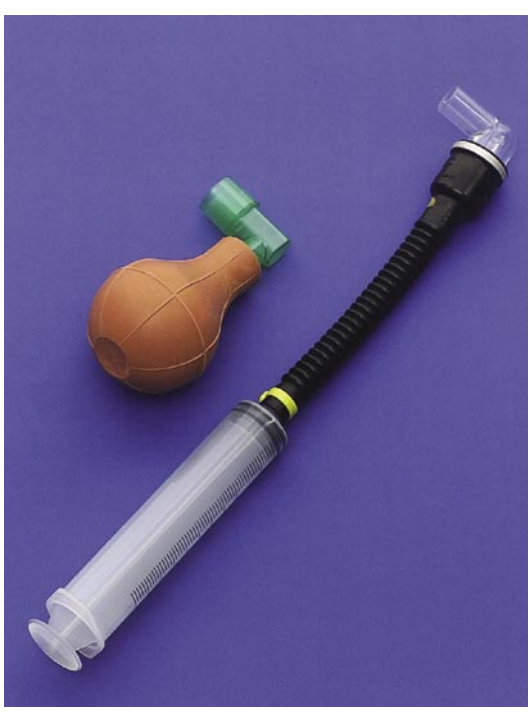
Oesophageal detector device

The Wee oesophageal detector device (ODD) consists of a 60 ml bladder syringe connected to a catheter mount. This is attached to the tracheal tube following intubation. The syringe freely aspirates gas from the patient's lungs if the tube is in the trachea (negative result). However, if this negative pressure is applied to a tube within the oesophagus, the oesophageal wall collapses and no air can be aspirated (positive result).

As a modification, the syringe has been replaced by a large rubber bulb (Ellick's evacuator) to enable the device to be used one-handed (Figure 2). In this case the bulb is first emptied and then failure to refill indicates oesophageal intubation.

The ODD is cheap, simple to construct, easy to use and reliable. It has been validated in several studies with only a small incidence of false-positive results, possibly related to endobronchial intubation or secretions blocking the lumen of the tracheal tube; there are no reported false-negative results.

It has been used successfully with uncuffed tubes in older children but is unreliable in those under 2 years of age.



2 Oesophageal detector device with Ellick's evacuator modification.

Capnography

Capnography is the real-time detection of carbon dioxide in the breathing gases and its display as a waveform that plots concentration versus time. Carbon dioxide is detected by infrared spectroscopy. It is the gold standard for verifying tracheal intubation. The guidelines of the Association of Anaesthetists state that during induction of anaesthesia, capnography is 'essential to the safe conduct of anaesthesia'.

For carbon dioxide to be detected, it must be produced in the tissues, then transported to the lungs, and finally exhaled in the expiratory gas. The capnograph is therefore an important monitor that gives information about:

- metabolic rate
- pulmonary perfusion
- alveolar ventilation.

If metabolic rate and pulmonary perfusion (or cardiac output) are constant, then changes in the capnograph trace reflect the adequacy of alveolar ventilation.

Deceptively low values may result from a large leak around the tube. Gas arising from the stomach and oesophagus usually contains only a trace of carbon dioxide, but false-positive results occur if expired alveolar gas is introduced into the stomach from mask ventilation. Significant concentrations of carbon dioxide have been reported following ingestion of carbonated drinks ('cola complication'). In these circumstances, capnography following oesophageal intubation initially resembles the normal waveform for end-tidal carbon dioxide. This initial value rapidly diminishes towards zero as the carbon dioxide is washed out. It has been suggested that the waveform should be observed for a minimum of six breaths.

Colorimetric carbon dioxide detector

This small disposable device contains a pH-sensitive indicator that displays a colour change (e.g. from purple to yellow) when exposed to carbon dioxide (Figure 3). The colour change is rapid and the detector can be left in the breathing circuit for several hours allowing continuous ventilatory monitoring. The device is about the same size and weight as a heat/moisture exchange filter and requires no power source for operation. This portability makes it useful during cardiopulmonary resuscitation or in emergency situations when capnography may not be available. Reduced carbon dioxide concentrations often present in these clinical situations, which may reduce its sensitivity.

3 Colorimetric carbon dioxide detector.

Complications of oesophageal and endobronchial tube placement

Oesophageal intubation

Undetected oesophageal intubation is a major anaesthetic cause of permanent neurological damage and death. There should be a high index of suspicion in any situation in which hypoxia develops following intubation; the onset may be delayed if preoxygenation has occurred. Difficulty in ventilation, poor or absent chest movement, inaudible breath sounds and increasing abdominal distension should all alert the anaesthetist to the possibility of tube misplacement. In practice, clinical signs are not always obvious.

Progressive gastric distension may cause regurgitation and subsequent aspiration. Splinting of the diaphragm impairs ventilation even after the patient has been correctly intubated unless the stomach is actively decompressed using a nasogastric or orogastric tube.

If there is any doubt as to correct tube placement, it is essential to remove the tube and recommence mask ventilation.

Endobronchial intubation

Endobronchial intubation is more common in children owing to the smaller length of the trachea. Flexion or extension of the neck can move the tube a significant amount within the trachea (up to 5 cm in adults), leading to endobronchial intubation or inadvertent extubation. The right main bronchus is more commonly intubated than the left side because it arises at a straighter angle from the trachea.

One-lung ventilation causes hypoxaemia due to the shunt effect that failure to ventilate the opposite lung produces. Progressive lung collapse of this unventilated side occurs. There is a reduced uptake of volatile anaesthetic agent and bronchospasm is a common occurrence, probably as a result of vagal stimulation from irritation of the carina.

The diagnosis may be obvious with asymmetric chest movement and absent breath sounds on one side of the chest, but clinical signs are often unreliable. With an uncuffed tube, breath sounds can easily be transmitted to the non-ventilated lung. A chest radiograph confirms the diagnosis and provides an estimate of the distance that the tube needs to be withdrawn. Fibre-optic bronchoscopy can also be useful.

The chances of endobronchial intubation can be lessened by cutting tracheal tubes to an appropriate size (e.g. 22–24 cm in the adult) preceding intubation. The black marker line present at the distal end of some tracheal tubes can also serve as a guide to the length of the tube to be passed through the vocal cords.

Regurgitation, Vomiting and Aspiration

Polly Davies
Jonathan Warwick

Polly Davies is Specialist Registrar in Anaesthesia rotating within the Oxford Region. She graduated from Bristol University and is currently based at Northampton General Hospital, UK.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

Regurgitation is the passive movement of gastric contents into the pharynx. The lower oesophageal sphincter normally prevents regurgitation. The sphincter is a physiological, rather than a distinct anatomical structure. Reflux is prevented because the lower oesophageal pressure is greater than the gastric pressure. This is referred to as the barrier pressure.

Vomiting is an active reflex usually occurring in the lighter planes of anaesthesia (i.e. induction and emergence). It is the forceful ejection of the contents of the upper gastrointestinal tract through the mouth. It is often secondary to stimulation from inappropriate airway manipulation.

The afferent limb of the reflex arc is composed of fibres from the gastrointestinal tract, the vestibular system, or from the chemoreceptor trigger zone in the brain stem. The vomiting centre' in the brain stem coordinates the reflex. The efferent limb involves autonomic outflow to the gastro-intestinal tract and also produces widespread effects such as pupillary dilation, sweating, salivation, vasoconstriction and tachycardia.

Pulmonary aspiration of gastric contents into the lungs is a serious, though infrequent, complication of modern anaesthesia. Mendleson first described it in detail in 1946 in 66 obstetric patients. Aspiration occurs following gastro-oesophageal regurgitation or vomiting when protective laryngeal reflexes are depressed or absent. Prevention of pulmonary aspiration is by measures aimed at reducing the incidence of regurgitation and vomiting.

Although silent regurgitation is thought to occur in up to 25% of patients under anaesthesia, the incidence of significant pulmonary aspiration in the general surgical population is much less at 1–6/10,000. For obstetric general anaesthesia the incidence is doubled. The mortality following aspiration is about 5%.

Pathophysiology

The adverse effects of pulmonary aspiration occur by three mechanisms.

Particle related – this could result in acute airway obstruction.

Acid related – the traditional view is that patients are 'at risk' if the gastric contents consist of a critical volume of more than 25 ml and have a pH of less than 2.5; there is little clinical evidence to support this. pH is the more critical factor for lung injury sustained following aspiration though there may not be an exact cut-off value. Significant morbidity can occur following inhalation of material with a very low pH even in small volumes due to chemical pneumonitis, and following large volumes of neutral fluid due to a 'near drowning' effect.

Bacterial related – aspirated fluid is not sterile and lung infection may result. Damaged lung is also more prone to secondary infection.

Risk factors

Predisposing factors for pulmonary aspiration are shown in Figure 1. Vomiting and regurgitation during induction of anaesthesia occur most often in emergency cases with acute abdominal pathology or following trauma. Pain, fear, anxiety and opioid administration all delay gastric emptying. These patients should be regarded as at high risk and appropriate precautions taken. The interval between last oral intake and time of injury in trauma patients is said to give a better guide to gastric emptying than the duration of fasting. In practice this is unreliable and it is often best to assume patients have a full stomach.

Risk factors for aspiration

Condition	Examples
Full stomach	Inadequate preoperative fasting Gastrointestinal obstruction, bleeding or ileus Trauma, burns, pain, anxiety Pregnancy Drugs (e.g. opioids)
Reduced lower oesophageal sphincter function	Hiatus hernia Drugs (e.g. opioids, atropine) Pregnancy Raised intra-abdominal pressure Obesity Lithotomy position
Material in oesophagus/ pharynx	Achalasia, scleroderma Strictures, carcinoma Pharyngeal pouch
Depressed laryngeal reflexes	Reduced consciousness (e.g. general anaesthesia, drug or alcohol intoxication, cerebrovascular accident, head injury, seizures or postictal state) Topical anaesthesia Neurological disease (e.g. myasthenia, multiple sclerosis, Parkinson's disease, Guillain–Barré syndrome) Muscular dystrophies
Others	Inexperienced anaesthetist Night-time surgery Emergency surgery Extremes of age

Obstetrics
In the third trimester, the enlarged uterus increases intra-abdominal pressure and therefore intra-gastric pressure. Before this, there is an increased risk of aspiration due to the production of:

- gastrin from the placenta, which increases gastric acid secretion
- progesterone, which relaxes smooth muscle and reduces gastrointestinal motility.

Anatomical changes in late pregnancy may increase the incidence of airway difficulties and thus of aspiration (e.g. increased body weight, large breasts, upper airway oedema). Surgery often occurs 'out of hours' as an emergency. Risks may be increased further during labour from the effects of pain, anxiety and opioid administration. Pregnant patients should be assumed to have a full stomach from the end of the first trimester until at least 18 hours post-partum. Regional anaesthesia should be used whenever possible to reduce the aspiration risks.

Prevention

Methods to prevent pulmonary aspiration are directed towards reducing the volume and increasing the pH of the stomach contents. The technique of cricoid pressure and induction of anaesthesia in the patient with a full stomach is elsewhere.

Fasting requirements
Traditionally, patients were fasted overnight before elective surgery. More recently it has been shown that the administration of clear fluids (e.g. water, non-particulate juice) up to 2–3 hours preoperatively does not increase residual gastric volume or alter pH. This increases patient comfort and reduces dehydration and hypoglycaemia in infants. An example of current fasting guidelines for elective, nonobstetric patients is shown in Figure 2.

Fasting requirements are less straightforward for emergency surgery. It is often necessary to provide anaesthesia to patients suspected of having a full stomach. Delaying urgent surgery to reduce the possibility of aspiration is usually of no benefit and may be detrimental. Patients requiring emergency surgery should be assumed to have a full stomach, irrespective of the duration of fasting, because gastric emptying is likely to be delayed. Following painful trauma, a significant gastric residue can be present after 24 hours. It is not currently recommended that emergency patients be allowed to drink clear fluids before surgery. Intravenous therapy should be used to prevent dehydration. At present there is no consensus regarding fasting during labour.

Preoperative fasting guidelines for patients undergoing elective surgery

	Length of fast (hours)
Adults	
• Solid food	6
• Clear fluid	2–3
Children	
• Solid food	6
• Formula milk	4
• Breast milk	3
• Clear fluid	2

Regional anaesthesia
Avoiding general anaesthesia reduces the risk of pulmonary aspiration. Both the proposed surgery and the patient must be amenable to the technique. The patient should be fasted because an inadequate or failed regional block, or adverse reaction, may make general anaesthesia necessary.

Gastric decompression
The insertion of a nasogastric tube to decompress the stomach may be useful. Liquid, but not solid, gastric contents can be aspirated via the tube. It is not usually possible to empty the stomach completely by this means, so the possibility of aspiration remains. If a nasogastric tube has been passed before surgery, it should be aspirated before induction. Effective cricoid pressure can be performed with the tube *in situ*.

Pharmacotherapy
Antacids: prophylactic administration of antacids to high-risk patients is recommended. These drugs neutralize gastric acid and raise gastric luminal pH. Neutral pH aspirate causes less lung damage than fluid of acidic pH. Antacids should be non-particulate to reduce the potential for lung damage if inhaled. 0.3 M sodium citrate, 30 ml, is effective in elevating the pH of gastric contents if given 15–20 minutes preoperatively; it remains effective for 1–3 hours. Antacids are used routinely in elective and emergency obstetric anaesthesia, but less often in the general surgical population.

H_2-receptor antagonists reduce the volume and acidity of gastric contents by the inhibition of hydrochloric acid secretion from gastric parietal cells. Cimetidine, 400 mg orally 90–120 minutes before induction, and ranitidine, 150 mg orally 120 minutes before induction, 50 mg intramuscularly or slow intravenous administration 45 minutes before induction, are commonly used H_2-antagonists. Ranitidine has a duration of action of at least 8 hours; about twice as long as cimetidine. It is also associated with fewer side-effects. Side-effects with cimetidine, though infrequent, include sedation and confusion, and the potentiation of other drugs through inhibition of hepatic enzymes. Hypotension, bradycardia and even cardiac arrest can follow rapid intravenous injection of cimetidine, and also of ranitidine, though ranitidine has a much lower incidence.

Prokinetics: metoclopramide, 10 mg orally 1–4 hours before surgery or intravenously shortly before induction, acts centrally and peripherally to stimulate gastric emptying, increases lower oesophageal sphincter pressure and is anti-emetic. Its central action is due to its antidopaminergic properties whereas peripherally it stimulates acetylcholine release, resulting in increased gastrointestinal motility.

Proton pump inhibitors: omeprazole, 40 mg orally at night and on the morning of surgery, inhibits the proton pump in the parietal cells of the gastric mucosa, resulting in prolonged suppression of acid secretion. It elevates gastric pH. Combining omeprazole with metoclopramide reduces gastric volume. It is seldom used in the UK despite proven effectiveness.

Anticholinergics (e.g. atropine, glycopyrollate) can decrease gastric acid secretion, but have an adverse effect on barrier pressure by decreasing lower oesophageal pressure. They are not used for aspiration prophylaxis.

Induction of anaesthesia
If general anaesthesia is chosen, a cuffed tube in the trachea should secure the patient's airway. The airway should be assessed to predict whether this is likely to be difficult. The laryngeal mask airway has become popular in modern anaesthetic practice, however, it does not protect the airway from aspiration of gastric contents as efficiently as a cuffed tube and should not be used routinely in patients at high risk.

Uncuffed tubes are used in children because the paediatric airway narrows at the cricoid ring. Uncuffed tubes prevent tracheal mucosal damage by excessive cuff pressure, and may allow passage of a slightly larger tube size permitting improved gas flow. There is no precise age or size at which cuffed tubes are chosen, but use of uncuffed tubes in children below 8–10 years is usual. The absence of a cuff may imply the theoretical risk that aspiration can still occur, although satisfactory airway protection still occurs in clinical practice.

Position:there is controversy regarding the optimum position for induction of anaesthesia in the patient at risk of pulmonary aspiration. Some anaesthetists argue in favour of a head-up (reverse Trendelenburg) or semi-sitting position, because this may reduce the incidence of reflux in patients prone to passive regurgitation. Others favour a head-down (Trendelenburg) position with the patient on their side, because this may decrease the likelihood of aspiration should regurgitation occur.

Patient safety is paramount and therefore clinicians should induce anaesthesia in the position in which they have the most experience and confidence. This will usually be a rapid sequence induction in the supine position.

Rapid sequence induction: if the anaesthetist is confident that tracheal intubation will be straightforward then an intravenous rapid sequence induction performed with cricoid pressure is indicated. Aspiration is most likely to occur in the time from loss of consciousness to intubation with a cuffed tracheal tube. Rapid sequence induction reduces this time to a minimum.

Awake intubation: if a difficult intubation is anticipated consideration should be given to securing the airway before induction. In modern practice this involves topical local anaesthesia to the airway, and intubation via a flexible fibre-optic laryngoscope. A 'blind nasal' technique used to be popular, but the arrival of modern fibre-optic instruments has allowed awake intubation to be performed under direct vision.

Inhalational (gaseous) induction may be indicated in a patient considered at risk from aspiration, in whom conventional laryngoscopy and intubation is predicted to be difficult and where awake intubation attempts may be hazardous (e.g. acute stridor, maxillofacial trauma). There is a trade-off between taking steps to prevent aspiration during induction, and maintaining and securing the airway. A senior anaesthetist should manage these cases and patient safety is paramount.

Extubation should be performed with the patient awake and following the return of upper airway protective reflexes. It is often safest to position the patient on their side with head-down tilt to facilitate clearance of the upper airway using suction, should regurgitation occur.

Diagnosis

Clinical signs and symptoms of aspiration are variable (Figure 3) and it is sometimes difficult to make a definitive diagnosis. 'Silent' aspiration may occur, and may not be diagnosed until after surgery when the patient has returned to the ward. The initial and most reliable sign of aspiration is hypoxia, which occurs following even mild cases. Wheezing is also common. In severe cases an acute respiratory distress syndrome can result. In such patients there is increased intrapulmonary shunting, ventilation–perfusion (V/Q) mismatch, increased lung water, increased airway resistance and reduced lung compliance. Although aspiration classically affects the posterior aspect of the right lower lobe, radiographic changes are variable, nonspecific and may be absent, particularly in the first few hours. The most usual findings are irregular fluffy den-sities, frequently bilaterally, collapse or pulmonary oedema (Figure 4).

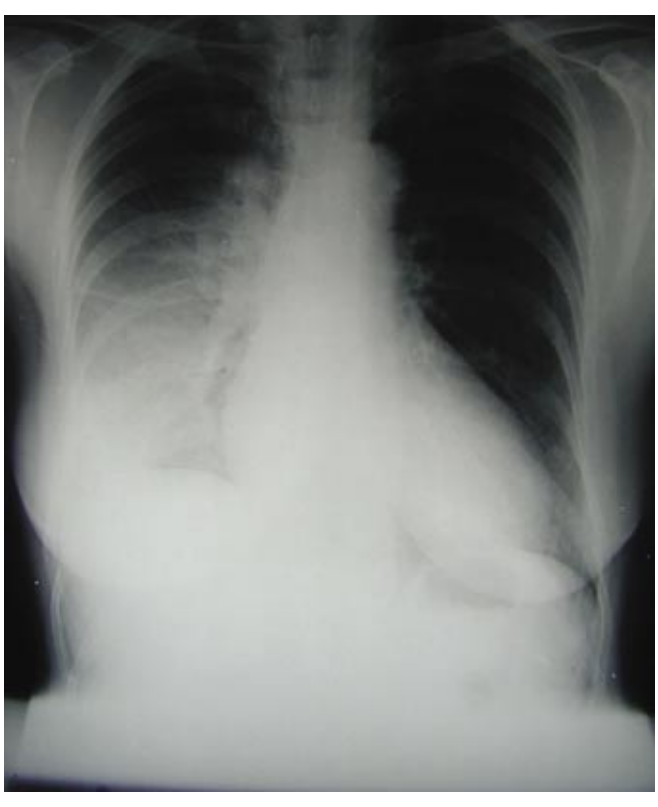
Differential diagnoses include anaphylaxis, cardiac failure, pulmonary embolism, fat embolism, sepsis and, in obstetric patients, amniotic fluid embolism.

Signs and symptoms of pulmonary aspiration

Symptoms
- Cough
- Breathlessness

Signs
- Stomach contents in oropharynx
- Tachypnoea
- Wheeze, crackles (mainly coarse)
- Cyanosis
- Tachycardia
- Pulmonary oedema
- Increased airway pressure
- Radiographic changes

3



4 Typical radiographic appearance of the chest in a patient with aspiration.

Management

If acute aspiration occurs the following procedure should be carried out.
- Place the patient in a head-down position, with head turned to one side.
- Suction material from the oropharynx.
- Administer 100% oxygen.
- Intubate the trachea if:

– adequate oxygenation cannot be maintained with spontaneous ventilation
– further tracheobronchial suction is required
– the patient is unable to protect their own airway.

The decision to continue with surgery depends on the severity of the aspiration and the urgency of surgery.

The management of established aspiration is largely supportive. Treatment is described in Figure 5.

Management of established aspiration

Oxygen therapy
- Guided by blood gas estimations or pulse oximetry

Ventilatory support
- Spontaneous ventilation may be adequate in mild cases
- Continuous positive airway pressure can be used for more severe cases, but requires alert, cooperative patient at no further risk of aspiration
- For severe cases, or those who cannot maintain a patent airway, mechanical ventilation via a tracheal tube is indicated
- Positive end-expiratory pressure is applied to increase functional residual capacity of the lung and minimize intrapulmonary shunting

Removal of aspirate
- Regular suctioning and physiotherapy are needed
- Bronchoscopy is required in more severe cases

Bronchodilators
- Given regularly by nebulizer

Antibiotics
- No proven benefit from prophylactic use
- Antibiotics often prescribed before identification of any pathogens

Fluid balance
- Shifts of fluid from the circulation to the lungs can result in pulmonary oedema
- Central venous pressure and urine output monitoring help guide fluid management
- A positive fluid balance worsens gas exchange and should be avoided

Corticosteroid therapy
- Routine use of corticosteroids is not indicated – no current evidence has shown benefit from their use

Surgical Diathermy: Mechanisms, Use and Abuse

Andrew D Farmery

Andrew D Farmery is Consultant Anaesthetist at the John Radcliffe Hospital, Oxford, UK. He trained in London, Cambridge and Oxford. His interests are in bio-mathematical modelling and clinical medical education.

The application of heat to wounds is evident in unearthed Neolithic skulls. Thermal cautery to ulcers and tumours of the breast was described in a papyrus from about 3000 BC, and later described by Hippocrates in 300 BC. Electrical diathermy is at least 250 years old, predating the practice of anaesthesia by a century.

Diathermy (*dia*, through; *thermy*, heat) strictly applies to the uniform heating of tissues by radiofrequency current or radiation. As a surgical tool, uniform heating is not required, but rather discrete and destructive heating in a specific area. This application is called 'electrosurgery' in the USA, and 'surgical diathermy' in the UK, but the term diathermy has remained.

Basic electrical principles

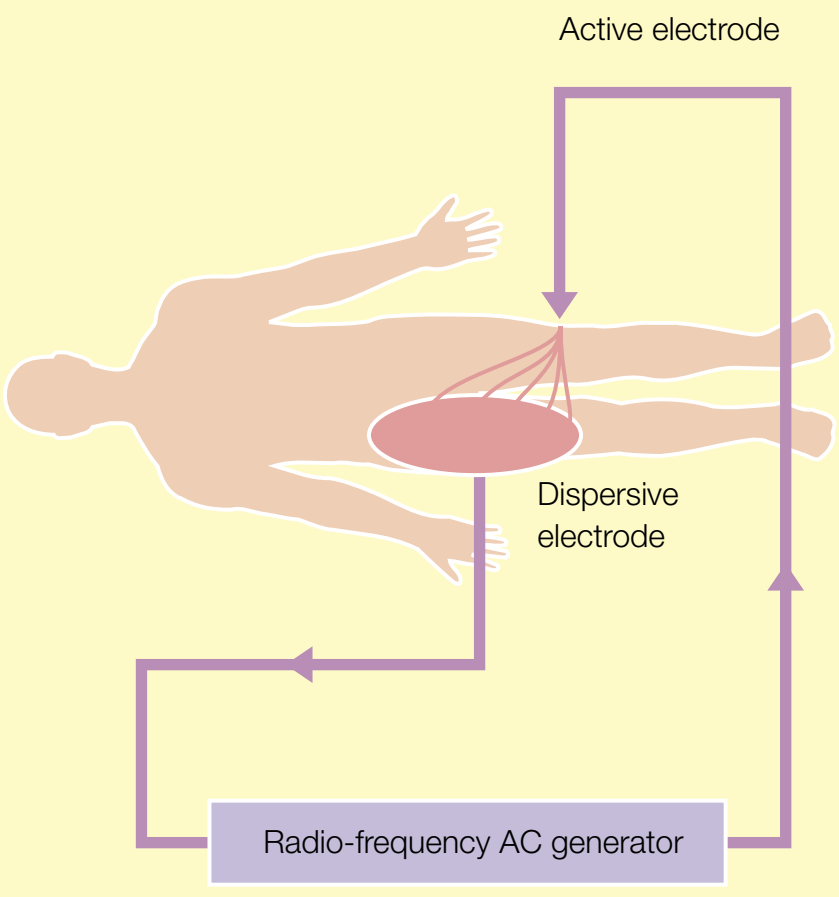
Forcing current through a resistance liberates heat

The power to heat, cut or vaporize tissues is derived from passing an electrical current through it. At any point in an electric circuit, the power dissipated is given by the formula:

$$\text{Power} = \text{Current}^2 \times \text{Resistance} \qquad (P = I^2 \times R) \quad 1$$

Current forced through regions of high resistance produces more heat than the same current passed through regions of low resistance. Figure 1 shows how the current density (and resistance) at the tip of a diathermy probe is many orders of magnitude higher than the current density elsewhere in the circuit, namely the patient's body and the large 'dispersive' electrode. This is analogous to a large crowd of people moving along a wide walkway to gain access to a football stadium. The flow is ordered and comfortable at the rear of the walkway, but when the same 'flow' is forced through a narrow turnstile, the 'power' of the crowd will be liberated (destructively) at this high resistance, high flow-density point.

Current density



The tiny active electrode/tissue contact has a high resistance, therefore a high power is liberated ($P = I^2 \times R$). Because this power is delivered to a small area, the power density, and ability to heat the tissue, is great. By contrast, the dispersive electrode, with its larger area of contact, has a low resistance and thus little power is liberated and it is distributed over a wide area, therefore the heating effect is negligible.

1

Using high-frequency alternating current prevents 'electrocution'

In Equation 1, both direct current (DC; e.g from a large battery) or alternating current (AC; e.g. from the mains supply) produce the same amount of heat for the same mean current. However, DC polarizes a tissue such that tissue connected to the anode becomes 'positive', and that connected to the cathode, 'negative'. This triggers ion channel opening and depolarizes important excitable tissues such as nerves, striated muscle and myocardium. The same is true of moderately low-frequency AC (e.g. 50 Hz), in which the tissue is alternately polarized and depolarized because the polarity of the applied voltage changes sinusoidally. This can result in convulsions, tetanic muscle twitch and ventricular fibrillation (i.e. electrocution).

High-frequency current is less prone to causing these phenomena because voltage-sensitive ion channels in excitable tissues do not respond instantly to an applied depolarizing voltage, but have a finite response time. An analogy is when the rudder of a tanker is turned suddenly, there is a delay before it slowly starts to change direction. If the rudder is turned from left to right with a low frequency, the tanker steers a course veering from left to right sinusoidally. However, if the rudder is oscillated from left to right with a high frequency, the ship steers a straight course because it does not have enough time to respond to a rudder movement in one direction before being directed to move in the opposite direction.

In the same way, a high-frequency AC voltage applied to the myocardium will neither polarize nor depolarize the membrane, because the ion channels will not have time to open or close before the polarity of the applied voltage is reversed and so the tissue will continue to function normally. Electrosurgical generators typically operate at frequencies of 0.5–4 MHz.

Surgical effects of diathermy

There are three main diathermy modes: desiccation, cutting and coagulation.

Desiccation

To cause desiccation (drying out), a low power current is passed through the tissues, as in Figure 1. The aim is to increase tissue temperature at the site of contact with the active electrode. Intracellular water is slowly driven off as steam and the tissue is dried out. This produces a blanching of tissue. Because the current is of low power, it is effective only in delicate tissues and small vessels (e.g. it is often used to blanch the fallopian tube before surgical division in laparoscopic sterilization). When tissue has been desiccated, its resistance to current flow becomes very high and current flow effectively ceases, thus terminating the heating process. It is impossible to 'cut' tissue in this mode. The current waveform is not important in this application.

Cutting

In the cutting mode, the aim is to make a discrete cut through the tissue. Initial contact with the electrode heats the tissue rapidly so that cells explode and their contents are instantly vaporized. Heat is not conducted very far from the site of contact because most of the liberated power is used to vaporize water (i.e. is consumed as latent heat of vaporization). The heating effect is therefore concentrated and neighbouring tissue is undamaged. Unlike desiccation, 'sparking' is a key feature.

The vaporized desiccated tissue is a poor electrical conductor and therefore breaks the circuit so that current flow ceases through this pathway. However, if the voltage (the driving force for current) is high enough, air around the electrode is ionized. Ionized air is a better conductor than desiccated tissue, and so current will now flow as a spark jumps to the nearest region of moist tissue. Tissue heating is produced by:

- current delivered by the spark ($I^2 \times R$)
- radiant heat from the spark
- collision of electrons bombarding the tissue.

This causes intense local heating, vaporization and thermal destruction. Cells are torn apart. The current waveform used is a continuous radiofrequency sinewave (Figure 2a).

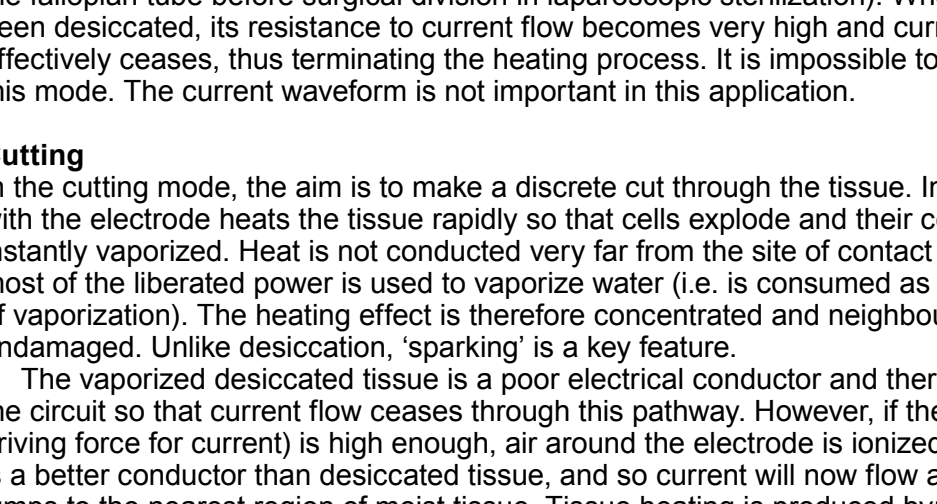
Coagulation

In coagulation mode (Figure 2b), the current waveform comprises short bursts of radiofrequency sinewaves (about 1 MHz), with bursts occurring about 20,000 times per second (burst frequency 20 kHz). The coagulation waveform can cause sparking to tissues. However, the radiofrequency current is delivered in intermittent bursts and therefore the ion cloud generated at each spark has a chance to disappear between bursts. Therefore, with each current burst, ionization occurs afresh, and because this is a random process sparking occurs more randomly and over a wider area than it does in cutting mode. This reduces the concentration of the sparking power and allows effective coagulation of vessels without tissue cutting. Peak voltages are much higher in the coagulation mode than in the cut mode because the current is zero for most of the time and so in order to deliver the same average power, the coagulation waveform generator has to deliver more power in the short periods when current is switched on.

Waveforms

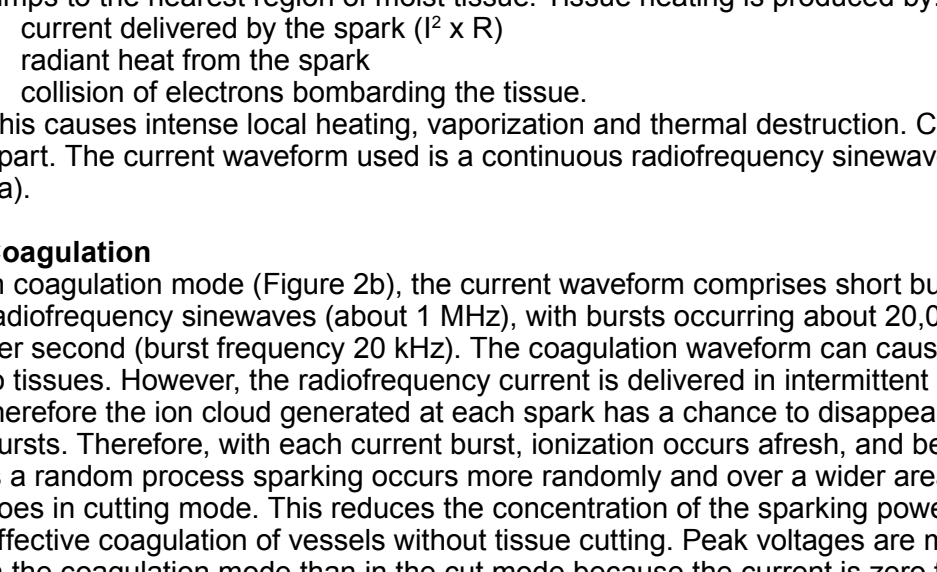
a Cutting waveform

A continuous radiofrequency sinewave of about 1 MHz



b Coagulation waveform

A 1 MHz sinewave delivered in bursts (20,000/second)



2

Monopolar and bipolar systems

Monopolar

The system described in Figure 1 is monopolar. Current is delivered via a pinpoint active electrode, which then passes through the patient (in a low-density path) to return via the dispersive electrode. This is the most widely used system because it is most effective in producing cutting as well as coagulation.

Bipolar
In a bipolar system, current is delivered via one arm of a pair of insulated forceps. It passes through any tissue grasped between the arms of the forceps and returns via the opposite arm. With a bipolar system, only desiccation can be achieved. The system is of limited power, and sparking does not occur. If the arms of the forceps are allowed to make contact with each other directly, despite there being some tissue in the path, current will be 'shorted-out', and diathermy will be less effective. Bipolar diathermy is indicated where it is undesirable to pass current through the patient's body to a distant dispersive electrode; some examples are given below.

Narrow current conduits to extremities (e.g. testicle surgery) – if a monopolar system were used, with the dispersive electrode placed on the abdominal wall, current would be forced to pass from the testicle along the vas deferens (the path of least resistance) to the trunk. Because the vas deferens is a narrow tube, current density would be high within it, and thermal injury might result.

Metal prostheses – if a metal prosthesis lies between the dispersive and active electrode, current preferentially passes through this low resistance route, producing a high current density and heating in narrow points such as a cortical screw. This may necrose bone or conduct heat to neighbouring soft tissue or vessels, sufficient to perforate an artery.

Cardiac pacemakers – the cable connecting a pacemaker generator box (implanted in the anterior chest) to the electrode in the right ventricle and/or atrium constitutes a low impedance pathway for radiofrequency current if it lies between the active and dispersive diathermy electrodes. This may result in a high current density at the point of pacemaker electrode insertion into the myocardium. Tissue desiccation may occur at this point, increasing the resistance of the contact. The 'threshold' potential may increase, such that the pacing pulse fails to trigger the heart.

More sophisticated pacemakers are capable of detecting intrinsic cardiac activity and withholding activation of the pacemaker. It is possible that stray radiofrequency current may be detected by the pacemaker, and interpreted as intrinsic cardiac activity, resulting in inappropriate inactivation of the pacemaker. For this reason, it is advisable, if possible, to have the pacemaker programmed so that this function is disabled. The safest precaution, however, is to avoid monopolar diathermy.

Patient safety

The principal issues are:
- avoidance of inadvertent thermal burns from stray diathermy current
- avoidance of inadvertent electrocution from stray 50 Hz mains current.

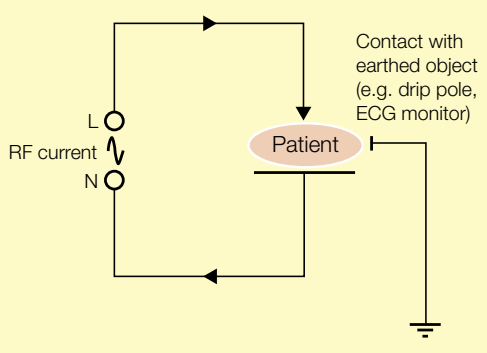
Isolated (unearthed) dispersive electrode system
Figure 3a shows a simple circuit in which neither live nor neutral terminals of the radiofrequency current generator are connected to earth.

A fundamental law of electricity is that all the current leaving the live terminal is returned to the neutral terminal. Therefore, if the patient makes contact with an earthed object (e.g. lithotomy pole, drip stand or faulty low impedance ECG electrode) none of the radiofrequency diathermy current should pass via this contact to earth because such a stray current would not be able to return to the neutral terminal. All the current should pass to the neutral terminal via the large dispersive electrode, thereby eliminating the potential for burns. This might seem a safe system but it is possible to burn patients inadvertently with isolated systems because of the phenomenon of 'capacitive coupling'. It is difficult to confine very high-frequency currents to wires, and currents tend to pass out of the cables like a radio transmitter because a wire and another conductor (e.g. earth) can behave like the two plates of a capacitor. Capacitors can conduct high-frequency current, even though insulation and a few feet of air separate the wire and earth. Radiofrequency leakage current flows only if there is a route for it to return to the neutral terminal; Figure 3b shows how this might happen. A certain amount of current from the active lead is leaked to earth via this capacitive coupling. This can return to the patient via any small, grounded contact point and potentially cause a burn at this site. From this point, the leakage current joins the main current and returns to the neutral terminal via the dispersive electrode.

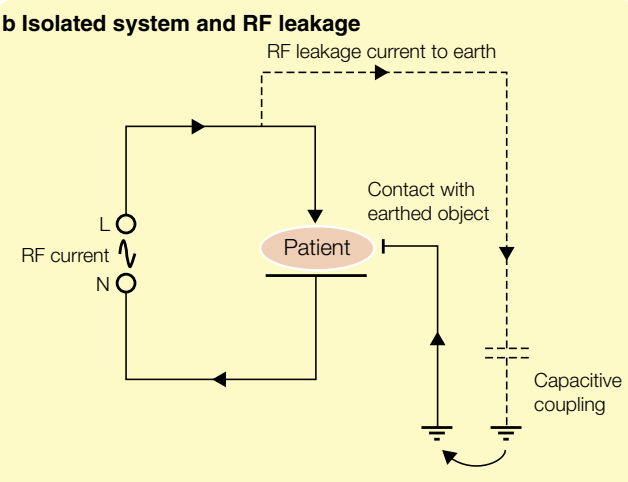
Early electrosurgical generators were not truly isolated. There was usually some connection of the neutral terminal and dispersive electrode cable to earth because of capacitive coupling between them, in a similar way to that described above. Figure 3c shows how this allows current to flow to earth through grounded contact points and complete the circuit to the neutral terminal via the 'virtual' earth connection. The amount of stray current passing through the grounded contact points depends on the relative impedance of the pathways. Given that one cannot avoid some current passing to ground, the best way to prevent this passing through unwanted pathways is to provide a route to ground via the dispersive electrode which is more 'attractive' than the alternative routes. This is done by physically earthing the dispersive plate and making the impedance of this connection as low as possible.

Isolated and earthed systems

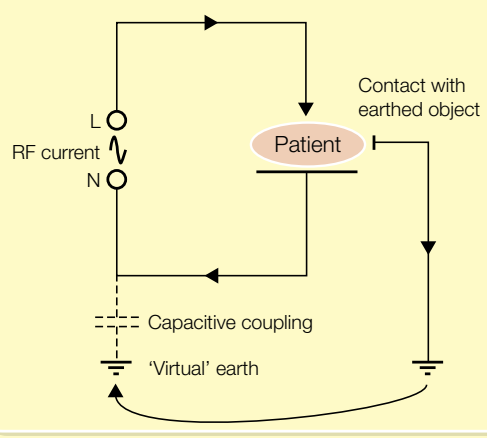
a Isolated system



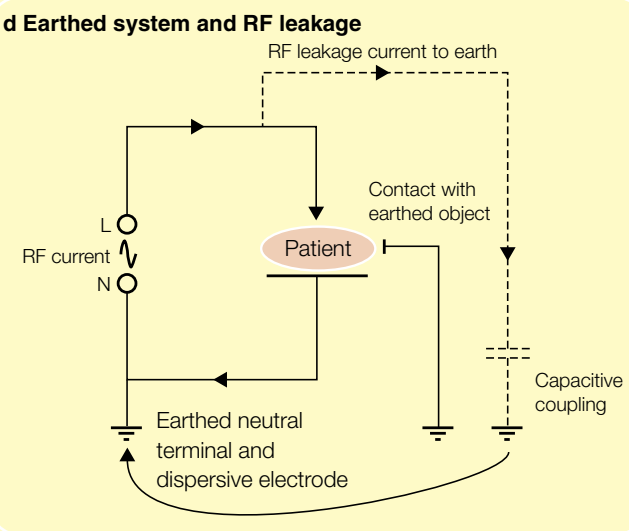
b Isolated system and RF leakage



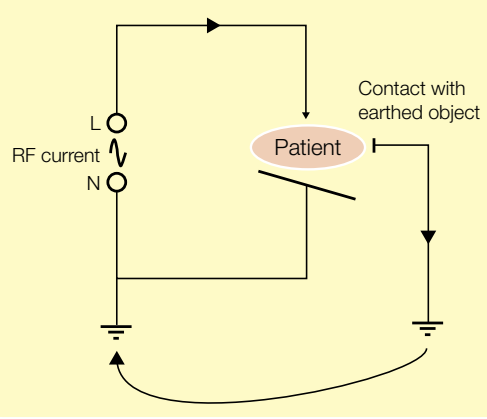
c Isolated system and 'virtual' earthing of dispersive electrode



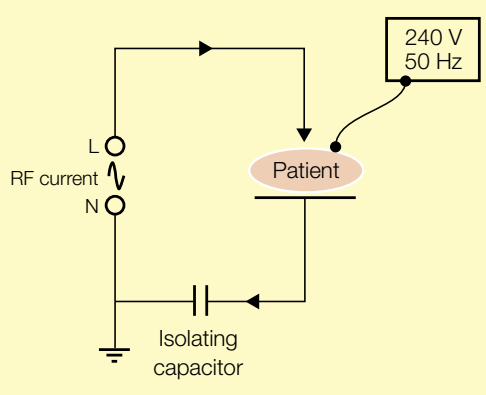
d Earthed system and RF leakage



e Earthed system and poor dispersive electrode contact



f Earthed system and isolating capacitor



L, live; N, neutral; RF, radiofrequency

Earthed dispersive electrode system
Earthing the dispersive electrode overcomes both the 'virtual' earth problem (Figure 3c) and the radiofrequency leakage problem (Figure 3b). Figure 3d shows how if the dispersive electrode and neutral terminal are earthed, any radiofrequency leakage current can return to the neutral terminal via a direct low impedance earth route that bypasses the patient. However, earthing poses other problems.

Dispersive electrode detachment: the dispersive electrode is an attractive route for ground-seeking radiofrequency current only if its impedance is many orders of magnitude lower than unwanted stray routes. If the dispersive electrode becomes detached or makes poor contact, all of the radiofrequency current can pass to earth (and hence return to the neutral terminal) via unwanted grounded contact point, as shown in Figure 3e, thus causing burns.

Mains electrocution: if the patient is exposed to a live mains voltage (e.g. via a faulty monitor lead) the earthed dispersive electrode provides a low impedance pathway for this dangerous 50 Hz current to pass through the patient to earth, thus causing electrocution. This is because mains voltage is ground seeking. This problem can be overcome by placing a capacitor in the circuit as in Figure 3f. This is capable of passing radio-frequency current, but does not conduct low frequency (50 Hz) current. Even though the patient is exposed to a live mains cable, no 50 Hz current will flow through the patient to the ground.

Techniques of Cricoid Pressure

Richard Vanner

Richard Vanner is Consultant Anaesthetist and Clinical Director in a large District General Hospital in the UK. He is a generalist with a specific interest in obstetric anaesthesia.

In 1956, the Association of Anaesthetists had collected 1000 reports of anaesthetic deaths; 110 from pulmonary aspiration of stomach contents. This often occurred during induction of general anaesthesia especially when muscle-relaxant drugs were used. Anaesthetic techniques were developed to prevent aspiration in patients at risk and included:

- emptying the stomach before induction
- intravenous induction with head-up tilt position
- inhalational induction in the lateral and head-down position.

In 1961, Sellick described cricoid pressure as a technique used to prevent regurgitation of stomach contents during the induction of general anaesthesia. It was brought into widespread practice in the UK by 1970 and largely replaced the other techniques, despite no randomized controlled trials demonstrating its benefit. It has become a routine part of anaesthetic practice for patients at risk of aspiration in combination with pre-oxygenation, an intravenous induction and tracheal intubation. All UK maternity units routinely apply cricoid pressure during induction of general anaesthesia.

Before the introduction of cricoid pressure, the incidence of aspiration pneumonitis in obstetric general anaesthetics was about 0.15%. If cricoid pressure prevents aspiration, the number needed to treat to prevent one case of aspiration would be 666. A controlled trial would be difficult because of the large numbers of patients needed and the difficulty of obtaining ethical approval.

Indications

In a patient who has been prepared for elective surgery and has not eaten for 6 hours or drunk for 2 hours, regurgitation of stomach contents during the induction of anaesthesia is unusual even when muscle-relaxant drugs are used, which relax the upper oesophageal sphincter. In these patients, cricoid pressure is unnecessary, because its benefits have to outweigh the risk of complications. However, cricoid pressure is indicated if:

- surgery is necessary before the patient is fasted
- gastric emptying is delayed
- the lower oesophageal sphincter is incompetent (e.g. in the last half of pregnancy or in reflux oesophagitis). With a full stomach from any cause, distention of the fundus causes reflex relaxation of the lower oesophageal sphincter.

Mechanism of action

Regurgitation is the flow of fluid from the oesophagus into the pharynx and is a passive process. When patients are awake the upper oesophageal sphincter prevents regurgitation. The pressure that this sphincter exerts is about 40 mm Hg and it relaxes during swallowing and during sudden distension of the oesophagus (e.g. belching, vomiting). The sphincter is mainly the cricopharyngeus muscle, a skeletal muscle, which is attached to the lateral aspects of the cricoid cartilage and is positioned behind it like a sling. The lumen of the hypopharynx within the cricopharyngeus is therefore crescent shaped. The oesophagus begins below the level of the cricoid cartilage.

The upper oesophageal sphincter relaxes during intravenous induction with thiopental (thiopentone), with heavy sedation, during deep sleep or following muscle-relaxant drugs. In all of these situations the sphincter pressure is reduced to less than 10 mm Hg, which is low enough to allow regurgitation. Following thiopental (thiopentone) the sphincter starts to relax just before loss of consciousness but is not fully relaxed until 30 seconds later. Ketamine does not relax the upper oesophageal sphincter, nor does an inhalational induction. Coughing during an inhalational induction increases upper oesophageal sphincter pressure to over 100 mm Hg.

Cricoid pressure prevents regurgitation by replacing the function of the upper oesophageal sphincter by compressing the hypopharynx against the prevertebral fascia muscles and vertebrae behind. The convex cricoid is pressed against the convex body of either the 5th or 6th cervical vertebrae. Inevitably the cricoid cartilage is deviated slightly laterally (Figures 1 and 2). Part of the crescent-shaped lumen is compressed against the vertebral body and the rest of it is less well compressed against the longus colli muscle to one side. A nasogastric tube is squeezed laterally towards the less well compressed part of the lumen and makes the occlusion of the hypopharynx more complete and therefore cricoid pressure more efficient.

A study of women undergoing emergency caesarean section under general anaesthesia with muscle relaxation showed that gastric pressure is likely to be less than 25 mm Hg in 99%. Oesophageal pressure can rise to equal gastric pressure during gastro-oesophageal reflux as the lower oesophageal sphincter relaxes to create a common cavity. A study of ten cadavers showed that 20 Newtons (N) of force applied to the cricoid cartilage prevented the regurgitation of oesophageal fluid at a pressure of 25 mm Hg in all cases and 30 N prevented regurgitation at a pressure of 40 mm Hg in all cases. Therefore, 20 N of cricoid pressure is probably sufficient and 30 N is more than enough to prevent regurgitation into the pharynx. Anaesthetic assistants can be trained to apply the correct force by practising on weighing scales and by doing this they can apply a range of forces between 5 N above or below the target force. A reasonable recommendation is to apply 30 N (3 kg).

Correct technique

Although cricoid pressure is apparently a simple technique there is growing evidence that incorrect application can cause serious problems during induction of anaesthesia. The anaesthetic assistant should practise the correct forces on weighing scales. The anaesthetist should be confident that the anaesthetic assistant knows the anatomical landmarks of the cricoid cartilage. Although Sellick suggested that the patient's head should be extended, the author recommends that it should rest on a pillow because intubation is easier and cricoid pressure is just as effective in this position. After pre-oxygenation, but before intravenous induction, lightly applied cricoid pressure should be started with a force of 10 N (1 kg), after loss of consciousness the force is increased to 30 N (3 kg). Forces of 20 N or more are not tolerated by awake patients and may cause them to retch and vomit. Normally the assistant applies cricoid pressure with their dominant hand because this can be maintained more accurately and for longer (3–5 minutes). There is no evidence that a bimanual technique, with the assistant's other hand supporting the patient's neck, improves the view at laryngoscopy when the correct forces are applied. The assistant's other hand is best kept free to assist with a difficult intubation if necessary.

Patients with small bowel obstruction should have a nasogastric tube inserted preoperatively. This should be aspirated before induction and left in place during induction. This does not make cricoid pressure less efficient and may improve it. As the tube is not compressed, it is possible, by leaving it open to atmospheric pressure, to vent liquid and gas remaining in the stomach, minimizing any increase in gastric pressure.

Sellick described the application of cricoid pressure with three fingers, thumb and middle finger on each side of the cartilage with the pressure applied with the forefinger. However, with the head on a pillow it is more comfortable to apply it with two fingers, forefinger and thumb on each side of the cartilage. This gives flexibility to apply upward and backward cricoid pressure, which improves the view at laryngoscopy if this becomes necessary. As the cricoid inevitably moves slightly laterally during cricoid pressure, it is better to ensure that it moves to the patient's right rather than to the left because this also makes intubation easier with a Macintosh laryngoscope.

Complications

Excess force applied to the awake patient has caused retching and death from aspiration and ruptured oesophagus.

Difficult intubation can be caused by cricoid pressure if the force is applied to the thyroid cartilage or if the larynx is pushed laterally to the left or if too much force is used, which compresses the airway. When cricoid pressure is applied properly with a force of 30 N (3 kg) the view at laryngoscopy is improved compared with the situation when no cricoid pressure is used. However, if only the epiglottis can be seen, then the slight lateral displacement of the larynx, which is inevitable, will make the passage of a gum elastic bougie more difficult because this is normally passed in the midline.

The so-called 'cricoid yoke', a force transducer applied to the neck, is not ideal, because it may not be applied accurately to the cricoid cartilage and may cause tracheal compression or extreme lateral displacement of the larynx, resulting in difficulty with tracheal intubation.

Difficult ventilation – cricoid pressure can obstruct the airway and prevent ventilation of the lungs with a face mask and Guedel airway. This is proportional to the force applied; 30 N causes complete obstruction in 2% of patients and 40 N does in 35%. Upward and backward cricoid pressure at a force of 30 N causes airway obstruction in 56% possibly because it tilts the cricoid cartilage and opposes the vocal cords. Following a failed intubation in a patient with a full stomach when the lungs cannot be ventilated, the force of cricoid pressure should be reduced by half. If this does not allow ventilation, cricoid pressure should be released completely to allow ventilation, with laryngoscope and suction immediately available. Further airways that may then be necessary (e.g. laryngeal mask, *Combitube*, cricothyrotomy cannula) are all better placed without cricoid pressure applied.

Tracheal Intubation: Management of Difficult and Failed Intubation

Stuart W Benham

Stuart W Benham is Consultant in Anaesthetics and Intensive Care Medicine at the John Radcliffe Hospital, Oxford, UK. He qualified from Glasgow University and trained in anaesthetics and general medicine in the west of Scotland before finishing his training in intensive care in Oxford. His research interests include acute renal failure on the ICU and difficult airway training and research.

Securing the airway with a tracheal tube is a core skill for anaesthetists. The technique may be required during anaesthesia, resuscitation or intensive care. The ability to manage patients when laryngoscopy is predicted to be difficult, or when intubation has previously failed, requires a methodical approach and a workable back-up plan. Indications for tracheal intubation are given in Figure 1.

Patients with depressed conscious levels (e.g. following head injury, self-poisoning, vascular accident, infections) need careful assessment. If there is any concern that airway reflexes are diminished, the airway must be secured with a tracheal tube. A low Glasgow Coma Score (e.g. GCS < 9) should not be relied on as the sole indication of airway compromise.

Intermittent positive-pressure ventilation can be achieved by non-invasive means without tracheal intubation. In the operating theatre this is often performed with the laryngeal mask airway (LMA), and in the ICU with a secure fitting face mask with head strapping.

Indications for tracheal intubation

Surgical indications
- Shared airway surgery
- Requirement for one lung ventilation
- Prone or sitting position for surgery
- Open abdominal or thoracic surgical procedures
- Major head and neck surgery
- Prolonged surgery

Emergency indications
- Prevention of aspiration in unfasted patients requiring general anaesthesia
- Impending airway obstruction (e.g. epiglottitis, airway burns)
- Maxillofacial trauma (blood in the airway)
- Depressed conscious level with poor airway reflexes

Ventilatory failure indications
- For intermittent positive-pressure ventilation
- Prevent aspiration of gastric contents
- Advanced ventilation strategies (e.g. partial liquid ventilation, high frequency jet ventilation)
- Prone ventilation strategies
- Ventilatory failure unresponsive to non-invasive positive- pressure ventilation

1

Management of difficult airway and failed intubation

The maintenance of alveolar ventilation is the most important aspect of difficult airway management. Patients in whom intubation is difficult or has failed, and in whom mask ventilation is also difficult are uncommon (about 1:10,000 routine anaesthetics). The anaesthetic plan must not render an awake patient who can maintain a patent airway into an unconscious patient with an unsafe and obstructed one. Preoperative assessment aims to identify patients in whom laryngoscopy and/or airway maintenance are likely to be difficult when consciousness is lost. Patients generally fall into one of three categories:
- anticipated difficult laryngoscopy
- elective unanticipated difficult laryngoscopy
- emergency unanticipated difficult laryngoscopy or failed intubation.

Anticipated difficult laryngoscopy
A comprehensive plan is required involving a primary plan and a secondary plan to be used if the primary plan fails. Two common pitfalls are:
- the operator is inexperienced in the technique chosen (e.g. flexible fibre-optic laryngoscopy – FFL)
- the back-up plan involves staff, skills and equipment that are not readily available at the time of induction (e.g. tracheostomy).

Anaesthetists have to develop plans with their own skill levels in mind, incorporating available equipment and supporting staff. Patient safety is of paramount importance. Generally, less invasive, atraumatic techniques should be preferred to surgical airway control, especially in elective patients. However, the emergency anticipated difficult airway (e.g. patients with severe maxillofacial trauma, or enlarging wound haematoma and stridor following head and neck surgery) may require a surgical airway as the primary plan.

Patients with bony abnormalities may have restricted mouth opening due to temporo-mandibular joint disease, or a cervical spine with limited neck flexion or extension (Figure 2). There is an expectation that the oropharynx and periglottic regions will be normal. In these patients, direct laryngoscopy may be impossible, but the normal oropharyngeal anatomy allows the passage of an FFL under general anaesthesia and assisted ventilation should be possible. If the primary plan fails during this elective surgery, the patient may be woken before implementing the secondary plan.

2 Restricted neck extension in ankylosing spondylitis.

Patients with obstruction in the supraglottic region include those with previous major oral surgery or radiotherapy. If there is evidence of stridor, the patient should be treated with extreme caution and one of the plans outlined below for periglottic or infraglottic obstruction should be considered. Stridor implies 50% airway narrowing. These patients may develop complete airway obstruction when anaesthetized and a surgical airway should be included in the management plan. Depending on the anaesthetist's skill, two options for the non-stridulous patient are:
- an awake fibre-optic endoscopy and intubation, before any relaxant or induction agent is given
- an inhalational induction and direct laryngoscopy to define the anatomical situation, and the feasibility of passing a tracheal tube.

Patients with obstruction in the periglottic region (including obstructing laryngeal tumours) require a thorough preoperative evaluation (e.g. CT, MRI) to assess the degree of obstruction and clinical assessment of the degree of stridor. Indirect laryngoscopy and flexible fibre-optic nasendoscopy are necessary to determine the extent of the obstruction and the feasibility of passing a tracheal tube, which should be performed by an experienced ENT surgeon. Non-stridulous lesions can be managed similarly to lesions causing supraglottic obstruction. Stridulous lesions are the most difficult to manage because neither awake fibre-optic endoscopy nor inhalational induction guarantees success. The choice of technique depends on the degree of stridor, the general condition of the patient and the experience of the anaesthetist. Severe cases may best be managed by awake tracheostomy under local anaesthesia. Depending on the level of the lesion, particularly with infraglottic obstruction, even emergency tracheostomy may not be realistic. For the most severe lesions it may be necessary to consider extracorporeal oxygenation as part of the secondary plan.

Elective unanticipated difficult laryngoscopy
Elective unanticipated difficult laryngoscopy is best managed using a stepwise approach.
- Reconfirm that assisted bag and mask ventilation is possible.
- Consider repositioning the head and neck and the use of a bougie.
- Avoid prolonged attempts at direct laryngoscopy. Change the length of laryngoscope blade once and the type of blade once to achieve the optimum view.
- Call for help and for the FFL if competent in its use.
- Consider the use of the LMA or the intubating LMA (ILMA) for ventilation.
- Consider using the LMA/ILMA as a conduit for intubation (see below).
- Consider abandoning anaesthesia, and performing an awake intubation.

Emergency unanticipated difficult laryngoscopy and failed intubation
This is a failure to secure the airway with a tracheal tube following a rapid sequence induction. Remember that it is failure of oxygenation, rather than a failure of intubation, that accounts for morbidity and mortality. The same stepwise approach as that for the elective unanticipated difficult laryngoscopy should be followed. All departments of anaesthesia should have a failed intubation drill for these circumstances, and clinicians should be familiar with their local protocols (see *Anaesthesia and Intensive Care Medicine* **2:6:** 221). It should be noted that in these situations the removal of cricoid pressure may help ventilation attempts, especially through the LMA. The risks of aspiration are small in comparison to the potential for morbidity and mortality caused by hypoxia from failed ventilation.

Techniques to overcome difficult intubation

Many devices have been developed to improve the chances of securing the airway with a tracheal tube. Some of those used by practising clinicians are described below.

Position and simple manoeuvres
Optimizing the patient's position (flexion of the cervical spine and head extension at the atlanto-occipital joint – the 'sniffing the morning air' position) is the first step to improve the view at direct laryngoscopy. Simple manoeuvres such as external laryngeal manipulation, especially backwards, upwards and rightwards pressure on the larynx can improve the view by more closely aligning the visual axis with the laryngeal inlet.

Laryngoscopes
There is a range of curved and straight blades, as well as blades with movable hinged tips (McCoy), that may improve the view at direct laryngoscopy (see *Anaesthesia and Intensive Care Medicine* **1:1** 34). Many experienced anaesthetists, however, tend to use the same type of laryngoscope blade for all their patients. Skills in the use of different blades are best acquired during routine intubations. The McCoy, or the angled Belscope laryngoscope, may be able to convert a Cormack/Lehane grade 3 view to a grade 2 view, though familiarization with the technique is required.

Simple props and aids
Gum elastic bougies should be used when:
- direct laryngoscopy allows visualization of the epiglottis but not the larynx (a grade 3 view)
- visualization of the larynx is possible but direct passage of the tracheal tube is prevented by awkward oral anatomy or teeth
- a reinforced or flexible tracheal tube cannot be directed into the visualized larynx.

Aintree intubation catheter (Cook©) (Figure 3) can be used like a gum elastic bougie, or in combination with other airway and intubating devices such as the LMA or FFL. It is sufficiently long and thin to allow a tracheal tube to be railroaded over it. It is hollow and has a detachable tube connector/adaptor that allows ventilation during the intubation process. An FFL can also be passed through it if required.

a Flexible fibre-optic laryngoscope and Aintree intubation catheter passed through the laryngeal mask airway (LMA).
b Fibre-optic endoscopy through the LMA with the Aintree exchange catheter.

3

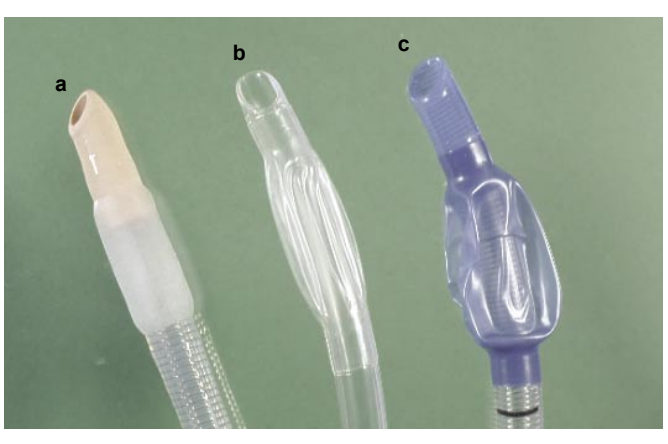
LMA and ILMA
Most anaesthetists use the LMA regularly for patients not requiring intubation. The ability to insert an LMA to allow spontaneous or assisted ventilation is a core skill for anaesthetists. It also provides a route guide for intubation, either blind or guided by an FFL. The LMA may help to achieve ventilation in patients who are otherwise difficult to intubate and ventilate.

The ILMA is modified to improve the chances of passing a tube blindly through the mask into the trachea. There is an initial short learning curve for the operator, and the clinician should practise using the ILMA in patients with normal airways before it is used in those with difficult or abnormal ones.

The main limitation on both devices is that there has to be enough mouth opening to permit inserting the device. Intubation can be blind, but both devices can be used with an FFL to visualize laryngeal anatomy and aid intubation.

Railroading the tracheal tube
The need to railroad the tracheal tube over the guide is the final step in intubation. Two manoeuvres to increase its success rate and minimize laryngeal trauma are choice of tracheal tube and bevel direction.

- The ILMA tube (softer tip) or reinforced tracheal tube (less acute bevel and softer tip) has a higher chance of passing through the vocal cords (Figure 4).
- The bevel of the standard tracheal tube is directed to lie in the right or left lateral position as it reaches the vocal cords. It is then rotated 90° as it is pushed gently through the cords. If this is unsuccessful, the tube is rotated through 360° continuously with gentle pressure to slip through the cords. If still unsuccessful, direct laryngoscopy can be performed to check the position of the route guide, and to lift the epiglottis to facilitate tube railroading.



4 Tracheal tube tips. **a** The intubating laryngeal mask airway tube, **b** standard tube, and **c** the flexometallic tube

FFL and intubation
FFL and intubation can be performed with the patient awake or anaesthetized. Awake fibre-optic intubation performed by a competent endoscopist is safe (Figure 5). The patient remains awake and self-ventilating with maintained pharyngeal muscle tone.

5 Awake fibre-optic intubation. Note the use of propofol sedation and jaw thrust.

Suggested procedure for awake fibre-optic intubation
1 Premedication of morphine, 0.1–0.15 mg/kg i.m., and hyoscine (scopolamine), 200 µg i.m., 1 hour before procedure.
2 The patient should lie semi-reclined on a trolley in the anaesthetic room, facing the anaesthetist.
3 Intravenous sedation should be administered cautiously. Target-controlled infusion with propofol (plasma concentration 0.5–1.5 µg/ml) is well tolerated.
4 Topical anaesthesia of the upper airway should be provided:

- Nasal mucosa; mixture of 5% cocaine, 2 ml, and 8.4% bicarbonate, 2 ml, as topical spray, with the patient taking deep breaths in with each spray. If the patient requires orotracheal intubation the oropharynx can be anaesthetized with lidocaine (lignocaine) spray or gel. Oropharyngeal route guides (e.g. *Ovassapian* or *Berman* airway) can be used to aid orotracheal intubation. These allow the operator to pass the FFL and tracheal tube through them. They prevent soft tissue collapse and are sized to guide the FFL through the mouth, and emerge at the epiglottis, where it can be directed into the larynx.
- Spray as you go (SAYGO) with 4% lidocaine (lignocaine) through the working channel of the FFL. Insertion of an epidural catheter through the working channel to the tip of the scope, with the catheter end trimmed to produce one end-hole, can facilitate accurate delivery of the local anaesthetic injection. Inject 1 ml solution with 4–5 ml air to help disperse the anaesthetic. Before the first attempt to pass the FFL, and before each subsequent attempt, oropharyngeal suctioning with a Yankaur sucker may be required.
- Administer supplemental oxygen. This can be delivered conveniently via a flexible suction catheter passed into the opposite nostril.

5 Allow adequate time (at least 30 seconds) after topicalization before the FFL is advanced. Avoid passing the FFL blindly. If the view ahead becomes obscured, gently withdraw the insertion cord until airway anatomy is again identified. Ask the patient to take deep breaths when advancing towards the laryngeal inlet. This opens the airway and abducts the vocal cords. If visualization of the larynx is difficult, performing a gentle jaw thrust manoeuvre on the patient can help.
6 Once the scope has been advanced through the cords it should be advanced to just proximal to the carina. A common error is to allow the FFL to withdraw, or even become displaced from the trachea while the tube is railroaded into place. This happens more often if the patient coughs at this time. The operator should attempt to keep the FFL in the centre of the airspace at all times. This minimizes trauma to the delicate tracheal mucosa and reduces the amount of blood in the airway.
7 Railroading the tracheal tube is described above. It is helpful for the assistant to hold the FFL stationary allowing the operator to railroad the tube into place using both hands.
8 A final useful check to estimate the distance from the end of the tracheal tube to carina can be performed as follows. Once intubation has been performed, the FFL is passed down just proximal to the carina. The assistant lightly pinches the FFL as it enters the proximal end of the tracheal tube. The FFL is then withdrawn slowly until the distal end of the tracheal tube comes into view. As soon as this is seen, the distance from the assistant's fingers to the tube connector of the tracheal tube is noted. This is the distance from tip of tube to carina.
9 The breathing system with capnograph is connected. The patient may then be anaesthetized and laid flat. Satisfactory ventilation is confirmed, and muscle relaxant can be given if required.

Problems with flexible fibre-optic intubation: the FFL is an intubating tool, not a ventilation device. Oxygenation and ventilation must be maintained throughout the intubation procedure.

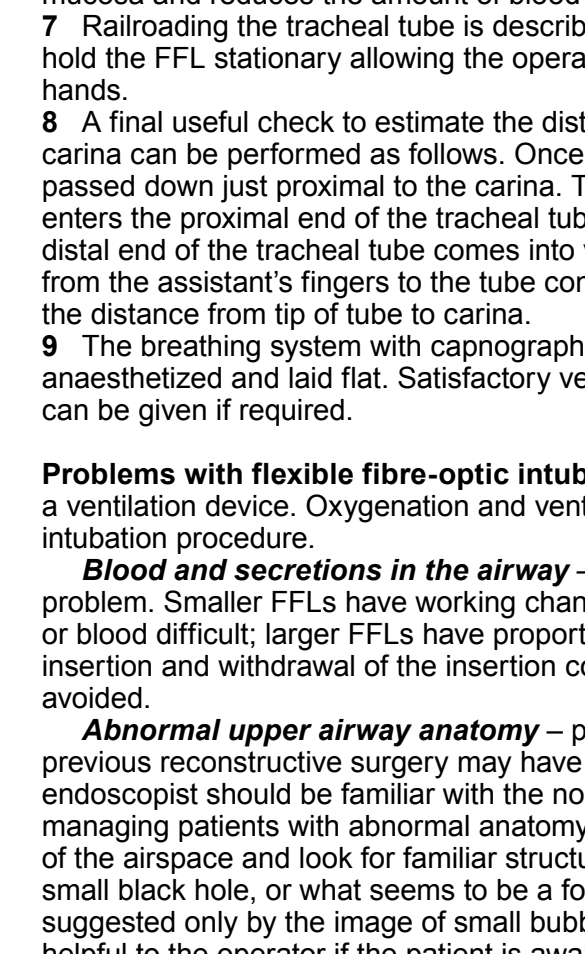
Blood and secretions in the airway – a poor view is the endoscopist's main problem. Smaller FFLs have working channels that make suctioning of sticky secretions or blood difficult; larger FFLs have proportionally larger suction channels. Repeated insertion and withdrawal of the insertion cord may precipitate bleeding and should be avoided.

Abnormal upper airway anatomy – patients with oro-pharyngeal lesions or previous reconstructive surgery may have abnormal upper airway anatomy. The endoscopist should be familiar with the normal appearances through the FFL before managing patients with abnormal anatomy. In all patients, keep the FFL in the centre of the airspace and look for familiar structures. Often the larynx is identified only as a small black hole, or what seems to be a fold in the mucosa. Identification is sometimes suggested only by the image of small bubbles appearing from a dark crevice. It is helpful to the operator if the patient is awake, semi-recumbent, and cooperating by taking deep breaths.

Equipment problems – the FFL should be checked and cleaned before use.

- The tracheal tube should be loaded on the FFL before endoscopy; forgetting to do this is a common mistake.
- Ensure that the light is on and working with white balance and focus optimal before commencing endoscopy.
- Lubricating jelly should be applied to the outside of the scope, and the tracheal tube, to facilitate easy nasal passage and tracheal intubation.
- Difficulties in railroading the tracheal tube can sometimes result from a large difference in the external diameter of the scope and internal diameter of the tracheal tube. This may be overcome by use of the Aintree intubation catheter. The intubation catheter can be railroaded over the scope, and then the tracheal tube railroaded over this.

Lack of hand–eye coordination can be remedied by practice on simulators, manikins and learning models such as an artificial bronchial tree or the Oxford 'hit-the-hole' box (Figure 6). It is indefensible to acquire these basic skills at the expense of the patient's mucosa.



6 The Oxford 'hit-the-hole' training box.

An inability to recognize anatomy is easily addressed by experience gained from instructional videos, clinical teaching and supervision. The case for using an FFL to aid routine nasal intubation is robust. In addition to the excellent learning opportunity afforded by routine use of the FFL, it assists in the selection of the best nostril and largest airspace, and identifies vulnerable nasal pathology such as polyps.

Transtracheal access

The final route for rescuing an obstructed airway is direct transtracheal access. This can be through the cricothyroid membrane, or through the upper trachea. Most anaesthetists never need to resort to this. Elective procedures, such as cricothyroid puncture used to inject local anaesthetic, or performing percutaneous tracheostomies in the ICU, provide valuable experience in tracheal access. The ability to identify the cricothyroid membrane and to insert a cricothyroid airway catheter rapidly may be a life-saving procedure. See Anaesthesia and Intensive Care Medicine issue 2:7: 268 for discussion of emergency tracheal access.

Airway Control

Oliver J Dyar

Oliver J Dyar is Consultant Anaesthetist and Intensivist at the John Radcliffe Hospital, Oxford, UK. He qualified from University College, Dublin and St Vincent's Hospital, Dublin, Ireland. He trained in anaesthetics and intensive care in the Nuffield Department of Anaesthetics, Oxford. His research interests include intravenous anaesthesia and the use of nitric oxide in the ARDS.

Securing control of the airway is one of the most important skills required of the anaesthetist. Whether for elective or emergency surgery, and whether the need for airway control has been predicted or not, the safety of the patient depends on the anaesthetist's ability to intervene to ensure adequate oxygenation and ventilation should the need arise. The anaesthetist must:

- develop the skills of airway assessment and management
- be familiar with the equipment and techniques available for control of the airway
- be able to choose the appropriate measures for the individual patient.

This contribution focuses on these basic principles.

Assessment of the airway

The anaesthetist must assess the airway before undertaking any anaesthesia. When general anaesthesia is contemplated, assessment facilitates a planned approach to anticipated difficulties with laryngoscopy and intubation. When a regional or local technique is contemplated, the need for airway intervention may also arise, for example, following respiratory embarrassment as a result of a high spinal or epidural blockade level, over-zealous sedation, or more rarely, following an allergic reaction to a drug.

The patient's previous anaesthetic notes should be consulted if available. It is important to realize, however, that the patient's circumstances may have changed, and a previously easy intubation may have become difficult (e.g. as a result of pregnancy). A number of anatomical factors are associated with difficulty in laryngoscopy and intubation:

- obesity, pregnancy
- large protruding incisor teeth
- short neck, especially in a heavy patient
- reduced mobility of the neck (e.g. rheumatoid arthritis)
- instability of the neck
- reduced mouth opening
- intraoral masses
- large goitre.

Anatomical assessment

Whether laryngoscopy and intubation would be possible with reasonable ease should be assessed using a reliable and reproducible bedside method of airway assessment that has minimal false-positive and false-negative rates. No single test provides this information, but the modified Mallampati test in conjunction with an assessment of thyromental distance combines ease with reasonable accuracy.

The modified Mallampati test assesses the size of the base of the tongue in relation to the size of the oropharynx. The patient sits upright with the head in the neutral position. The assessor sits in front of the patient at the patient's eye level. The patient opens their mouth as wide as possible. Without phonating, the tongue is protruded as far as possible. The assessor inspects the pharyngeal structures visible and a score is allocated according to which structures are visible (Figure 1).

Modified Mallampati test

Class	Pharyngeal structures visible
1	Fauces, faucial pillars (the palatoglossal and palatopharyngeal arches), uvula, soft palate
2	Faucial pillars are obscured leaving the fauces, uvula and soft palate visible (i.e. posterior pharyngeal wall visible below soft palate)
3	Only the soft palate and the base of the uvula seen (i.e posterior pharyngeal wall not visible below soft palate)
4	Even the soft palate obscured

1

The measurement of thyromental distance as recommended by Frerk is obtained by maximally extending the head on the neck and measuring from the prominence of the thyroid cartilage to the bony point of the chin.

A modified Mallampati grade of 3 or 4 combined with a thyromental distance of 7 cm or less gives a bedside assessment system with a sensitivity of 81% and a specificity of 98% for difficulty with intubation.

The view of the laryngeal structures obtained at direct laryngoscopy is often classified according to the system described by Cormack and Lehane (Figure 2). In this system, grades 3 and 4 constitute difficult laryngoscopies. Fairly severe difficulty with intubation may occur with grade 3, and the use of a bougie/introducer, posterior to, but held up against the epiglottis may permit blind intubation. With a grade 4 view, intubation by standard methods is virtually impossible despite optimal positioning.

Cormack and Lehane classification system

Grade	Laryngeal structures visible
1	Most of the glottis visible
2	Only the posterior part of the glottis (posterior commissure, arytenoid cartilages) visible
3	Only the epiglottis visible, no part of the glottis seen
4	Not even the epiglottis seen

2

Airway patency

Partial obstruction of the airway in the awake patient may be caused by masses in the upper airway (e.g. tonsils, adenoids, tumour), foreign bodies, or epiglottitis. In the sedated or unconscious patient, laxity of the muscles that normally keep the tongue anterior to the posterior pharyngeal wall allows the tongue to fall back and obstruct the airway. Partial obstruction is recognized by noisy inspiration (stridor), tracheal tug, and dyssynchronous movements of the thorax and abdomen on inspiration.

In normal, unobstructed breathing, the abdomen expands as the diaphragm descends in inspiration and the thorax expands as indrawn gas fills the lungs. With obstruction, the abdomen still expands, but if inspired gas cannot be inhaled at a sufficiently fast rate, the sternum is drawn inwards by the increasing, unrelieved negative intrathoracic pressure. Partial obstruction and its cause (and therefore ease of reversal) must be recognized before embarking on anaesthesia. The technique of airway management is highly modified in the presence of partial obstruction.

Aspiration risk

For elective anaesthesia, the patient is fasted. Solid food, non-clear liquids (especially those containing milk) and chewing gum should not be consumed in the 6 hours before anaesthesia. Clear liquids are permissible up to 2 hours before induction.

For emergency anaesthesia, the interval between last food or drink and the injury or onset of illness is assessed. Gastrointestinal obstruction or other abnormal motility state (e.g. ileus, diabetes mellitus, renal failure, acute pain) all increase the risk of aspiration on induction of anaesthesia.

Equipment and techniques for routine airway management

Before embarking on general anaesthesia, the equipment required should be to hand and its correct function checked. A preoperative checklist such as that proposed by the Association of Anaesthetists of Great Britain and Ireland is particularly useful (see *Anaesthesia and Intensive Care Medicine* **1:2:** 65). The minimum equipment required includes:

- source of pressurized oxygen (plus bag-valve-mask or anaesthesia circuit)
- selection of face masks
- selection of oropharyngeal and nasopharyngeal airways
- high-flow suction
- Yankauer suction catheter, and selection of narrow-bore suction catheters
- two laryngoscopes
- selection of tracheal tubes
- selection of laryngeal mask airways
- Magill's forceps
- sterile lubricating gel
- ties and padding to secure tracheal tube
- gum-elastic or other suitable bougie.

For non-emergency anaesthesia, several interventions to control the airway are available. These range from oxygen administration through a face mask, delivery of inhalational anaesthesia via an anaesthetic face mask or laryngeal mask airway, through to tracheal intubation.

Non-relaxant anaesthesia

If relaxant anaesthesia is not required (e.g. for body-surface surgery in the patient not at risk for aspiration) then inhalational anaesthesia via a face mask is appropriate. In the absence of flammable anaesthetic agents, the mask is usually clear plastic with an inflatable rim that provides a good seal in contact with the face. The size of the mask is determined by the patient's size and physical features, but a range of sizes (Figure 3) should be available. For paediatric anaesthesia, the mask should have as little dead space as possible (e.g. the Rendell-Baker–Souchet mask). Nasal masks are indicated for anaesthesia in the dental chair.

Induction in the absence of airway obstruction may be inhalational or by intravenous injection of a suitable induction agent. If there is any suggestion of airway obstruction then inhalational induction or another approach (e.g. awake fibre-optic intubation) is required.

3 Selection of face masks, including Rendell-Baker–Souchet paediatric masks (lower row).

Supporting the airway

Whatever the means of induction, once the patient is unconscious it is necessary to support the airway. There is a tendency for the airway to become partially obstructed at this stage because the tongue falls back against the posterior wall of the pharynx. Induction will normally have occurred with the patient supine, head resting on a pillow. This allows the anaesthetist to extend the head on the neck at the same time as applying a jaw thrust and opening the mouth. To achieve this triple manoeuvre, the mask is secured on to the face using one or both hands, with the thumbs on the upper part of the mask, index fingers on the lower part and the rest of the fingers effectively pulling the patient's mandible forward into the mask. It is crucial that unopposed downward pressure on the mask is not used to obtain a seal between mask and face because this will close the airway. Likewise, the third, fourth and fifth fingers must stay on the mandible and must not press on the floor of the mouth, which also tends to cause obstruction. If it is impossible to open the airway using these techniques, an artificial airway is required. Two methods are available: the oropharyngeal and the nasopharyngeal airway (Figure 4).

4a Nasopharyngeal airway.
b Selection of smaller oropharyngeal airways.

The oropharyngeal (Guedel) airway is a curved tube that has a flanged and reinforced oral end. The flange enables correct positioning at the incisor teeth, and the reinforcement prevents the patient from obstructing or severing the device by biting down. This airway is available in a range of sizes (size 3–4 is usually required for an adult, Figure 4b), and it is vital that the appropriate size is used for the patient. An easy way to determine size is to choose the airway in which the length is equal to the distance between the corner of the patient's mouth and the angle of the jaw. If the airway is too short it tends to push the tongue backwards and cause increased obstruction. If too long, the device tends to stimulate the larynx, provoking spasm, and it fails to sit securely with the flange at the front incisors. The Guedel airway is usually inserted upside-down (the pharyngeal opening facing the roof of the mouth, then rotated 180° as it passes the back of the tongue). A lightly anaesthetized patient may gag or cough with this intervention. It may also provoke laryngeal spasm.

The nasopharyngeal airway is a less stimulating intervention. It is a soft curved tube with a flanged nasal end and a bevelled pharyngeal end (Figure 4a). It is also available in a range of sizes. Sizes 6–8 mm (measured as internal diameter) are suitable for adults, the usual measure is the diameter of the patient's little finger. Before inserting the airway, a safety pin is inserted eccentrically at the flanged end, to prevent inhalation of the device. The airway should be coated with lubricating gel, and inserted into either nostril. It is advanced along the floor of the nose in a posterior direction, and should come to lie with the bevelled end in the oropharynx, behind the tongue and above the glottis. The eccentric positioning of the pin permits access of a catheter for suctioning secretions from the pharynx and airway.

Face mask: for brief procedures, anaesthesia can be maintained using a face mask, with or without airway adjuncts. For longer procedures, when it is desirable for the anaesthetist to have both hands free, the standard mask can be supported by a harness. It is now more common to insert a laryngeal mask airway for such procedures. This has the advantage of maintaining the airway without additional instrumentation, in addition to providing a more secure airway and providing hands-free operation.

The laryngeal mask airway (LMA) was designed to provide a connection between the artificial and anatomical airways in a less invasive way than with a tracheal tube, and yet with greater convenience and reliability than a conventional face mask. The standard LMA is made from silicone and is designed for multiple patient (up to 40) uses. It consists of a silicone bowl surrounded by a thin-walled elliptical ring that can be deflated to form a thin wedge shape, and which when inflated in the space posterior to the pharynx creates a seal around the laryngeal aperture. This seal permits ventilation of the airway under positive pressure. It also prevents insufflation of gas into the oesophagus and stomach, unless high inflation pressures (20–30 cm H_2O) are used. The device has a central aperture, with vertical bars, designed to prevent prolapse of the epiglottis into the tube that connects the mask to the anaesthetic circuit.

The LMA is available in a variety of sizes (Figure 5).

Correct placement is important to ensure a high-performance seal without overinflation of the cuff, and the appropriate size is chosen for the size of the patient (Figure 6).

The LMA is also available with a flexible, reinforced, non-kinking tube instead of the standard tube. This type is particularly useful for situations in which the head may be moved during surgery and for oral and ENT surgery. The intubating LMA is a development of the standard airway designed to act as a conduit permitting blind intubation of the trachea using a specially designed silicone tube.

A full description of the recommended technique for inserting the LMA is beyond the scope of this contribution. Briefly, the device is completely deflated (preferably using a cuff deflation tool, which will ensure deflation to the correct shape). The patient's head is supported on a pillow, in the classic intubating position. Extension of the head and flexion of the neck on the thorax is achieved by the non-dominant hand. The posterior surface of the LMA is lubricated with water-soluble gel. The LMA is held between index finger and thumb, with the index finger of the operator's gloved dominant hand at the junction of the mask and the tube. The aperture of the device faces caudally. An assistant holds the patient's mouth open, and the device is inserted under direct vision, with its posterior, lubricated surface firmly against the hard palate. The LMA is pushed, keeping it firmly against the palate at all times following the palate posteriorly and down into the hypopharynx. Resistance to insertion is met when the tip of the device is in the hypopharynx, with the tip resting at the upper oesophageal sphincter. It may be necessary to push the device using the non-dominant hand, if the inserting finger is not long enough. The device is released. The cuff is inflated with the recommended volume of air, at which point the tube may rise from the mouth as the device seats itself around the larynx. The tube of the LMA is connected to the anaesthetic circuit, if necessary using a swivel connector.

The LMA may be used to ventilate the anaesthetized muscle-relaxed patient, provided that the inflation pressures do not exceed about 20 cm H_2O. Above this pressure, the risk of gradual insufflation of the stomach with anaesthetic gas increases. This increases the risk of regurgitation and aspiration of gastric contents.

5a Standard laryngeal mask airways, sizes 2½, 3, 4. **b** Reinforced laryngeal mask airway, size 4.

Relaxant anaesthesia

Anaesthesia requiring a muscle-relaxant technique most commonly requires tracheal intubation. Indications for relaxant techniques and/or intubation are:

- provision of clear airway
- airway protection from blood, oral or gastric secretions
- facilitation of suctioning of airway
- prone or sitting patient, airway inaccessible
- abdominal, thoracic anaesthesia
- likelihood of postoperative respiratory support
- administration of positive end-expiratory pressure.

Tracheal intubation

Equipment: in addition to the equipment for inhalational anaesthesia using a face mask, a suitable laryngoscope, with a spare available, and a range of suitable tracheal tubes are necessary.

The laryngoscope consists of a handle (which houses the batteries) and a detachable blade, which has a screw-in bulb. Alternatively, the bulb may be in the handle, and a fibre-optic bundle transmits the light to the blade. Two basic types of laryngoscope are available (Figure 7):

- curved-blade (usually Macintosh)
- straight-blade (e.g. Wisconsin, Seward, Magill).

The curved-blade instruments are most commonly used for adults and larger children: the tip is placed in the vallecula, anterior to the epiglottis. Forward traction elevates the epiglottis without touching the posterior surface of the epiglottis. By contrast, straight-blade laryngoscopes are inserted posterior to the epiglottis and lift it from behind. These instruments are most often used for smaller children, because the epiglottis is longer and more floppy in this age group. The blades are available in a number of sizes, with the Macintosh 3 being suitable for most adults.

Tracheal tubes – an extensive range of tracheal tubes is available (Figure 8). They are most commonly made from polyvinylchloride or polyurethane and are bevel-ended. They may be plain or have a high-volume low-pressure cuff, which provides a seal enabling positive-pressure ventilation and preventing aspiration of secretions into the airway. Uncuffed (plain) tubes are used in children. This avoids the potential for ischaemic damage on the tracheal lining from high cuff pressure and maximizes tube size available. The presence of an air leak around the plain tube ensures that the fit is not too tight.

Tracheal tubes are usually inserted via the mouth, or if necessary via the nose (e.g. for intraoral surgery). Tube size is measured by the internal diameter, ranging from 2.5 mm to about 10 mm in 0.5 mm increments. The tube is usually cut to the appropriate length for the patient. Adult males usually require size 8–9 mm and adult females 7–8 mm, cut to 21–23 cm for oral intubation. For children, the tube size can be estimated from the formula (age/4 + 4 mm), and length (age/2 + 12 cm), with age being in years. This is an approximate size, and tubes 0.5 mm greater than and less than the estimated size should be available.

The tube is connected to the anaesthetic circuit at the proximal end with a tapered connector of suitable size (see *Anaesthesia and Intensive Care Medicine* **1:2:** 68). The distal end may have, in addition to the end hole, a side opening (Murphy eye) to allow passage of gas should the bevelled end be occluded by abutting on the tracheal wall.

Sizes of laryngeal mask airway

Size	Patient	Cuff volume (ml)
1	Neonates up to 6.5 kg	4
2	Patients 6.5–20 kg	10
2½	Patients 20–30 kg	14
3	Children and small adults	20
4	Normal adults	30
5	Large adults	40

8 Tracheal tubes. Nasal: **a** cuffed, **b** plain. Oral: **c** North-facing plain polar. Magill pattern oral tubes: **d** plain, **e** cuffed.

Anaesthetic management

Positioning the patient correctly before intubation is crucial. Tracheal intubation requires approximate collinearity between the axes of the mouth, oropharynx and larynx. True collinearity of these structures is impossible, but appropriate positioning can make the difference between a relatively easy laryngoscopy and intubation, and failure to visualize the larynx at laryngoscopy. The classic intubating position is the sniffing position: the head is extended on the neck (atlantoaxial extension) and the neck is flexed on the thorax. For most adults this is easily achieved by having the patient lie supine on the trolley or bed and placing a pillow under the occiput. If the pillow is too caudad (elevating the shoulders) then extension of the neck on the thorax occurs. This almost always makes laryngoscopy more difficult. In small children, the relatively large head provides the correct position without the use of a pillow.

Induction – if the patient is not at risk of aspiration of gastric content, difficulty with laryngoscopy is not anticipated, and the airway is unobstructed, induction of anaesthesia is as for the mask techniques outlined above. Following induction, it is possible, providing the patient is deeply anaesthetized, to perform laryngoscopy and intubation. This practice is relatively uncommon. More usually, the anaesthetist confirms that it is possible to ventilate the patient using the mask (with an artificial airway if needed). Then an intubating dose of a muscle relaxant is given (e.g. suxamethonium, 1–1.5mg/kg). While the advantages of the speed of onset and quality of relaxation

obtained with suxamethonium are significant, its side-effects include myalgia (which can be quite severe), occasional profound bradycardia (especially in children, and particularly likely with second doses of the drug given shortly after a first dose), hyperkalaemia, and precipitation of malignant hyperthermia in susceptible individuals. To overcome these disadvantages, an intermediate-duration non-depolarizing drug such as vecuronium, 0.1 mg/kg, atracurium, 0.5 mg/kg, or rocuronium, 0.6 mg/kg, can be used. However, they commit the anaesthetist to providing ventilation by mask for a prolonged period if intubation proves more difficult than anticipated, or is impossible. With the exception of rocuronium they also take a longer time to achieve good intubating conditions, which makes them much less suitable for the patient at risk of aspiration of gastric content. The lungs are usually manually ventilated while awaiting the onset of muscle relaxation. A mixture of oxygen and the volatile agent chosen to maintain anaesthesia is used, together with nitrous oxide, if desired. The use of nitrous oxide reduces the interval allowable for laryngoscopy and intubation. The patient will become hypoxaemic more rapidly following cessation of ventilation if this gas is used, because available oxygen stores will be reduced. A peripheral nerve stimulator may be used to confirm the presence of adequate paralysis, as demonstrated by the absence of twitch response to a supramaximal stimulus.

Laryngoscopy is then performed. The right hand opens the patient's mouth and the assistant separates the patient's lips to expose the teeth. Using a curved-blade laryngoscope, held in the left hand, the blade is inserted into the right-hand side of the mouth, and advanced as far as the tonsillar bed. Sweeping the blade into the midline at this point should displace the tongue to the left, and give a view of the tip of the epiglottis. The blade is advanced, with force applied along the shaft of the laryngoscope directed upwards and outwards (at about 30–45° to the horizontal). The patient's upper incisors or gum must not be used as a fulcrum. The tip of the blade should enter the vallecula in front of the epiglottis, and the applied force elevates the epiglottis, exposing the larynx. The tracheal tube is picked up in the right hand and advanced from the right-hand side of the mouth, using the natural curvature of the tube to place the tip in the larynx under direct vision. Once the cuff of the tube is safely past the cords, the laryngoscope is carefully removed. The anaesthetic circuit is connected to the tube using a swivel connector and a catheter mount (if desired). The lungs are ventilated and the cuff of the tube inflated with just sufficient air (or gas mixture) to abolish the audible leak of gas on inflation of the lungs. Bilateral breath sounds and absence of sounds of gastric insufflation help confirm placement, however monitoring for appropriate and continuous concentration of carbon dioxide in the exhaled gas is mandatory.

Extubation – anaesthesia is maintained with inhalational agents, and the patient is ventilated using intermittent positive-pressure ventilation throughout the operation. At the end of the operation, residual neuromuscular blockade is reversed using a combination of a cholinesterase inhibitor and a muscarinic blocking drug (to prevent bradycardia). The drugs most commonly used are neostigmine, 0.05 mg/kg, with either atropine, 0.02 mg/kg, or glycopyrrolate, 0.01 mg/kg. Secretions and occasionally gastric content will have accumulated in the pharynx during the procedure. To prevent aspiration of these secretions and severe laryngeal spasm on removal of the tracheal tube, these are removed using a Yankauer sucker or equivalent, under direct vision (with a laryngoscope). The patient is ventilated with 100% oxygen. As the patient starts to breathe, the circuit is changed to permit spontaneous ventilation, with the reservoir bag providing visible confirmation of ventilatory effort and volume.

The tracheal tube is removed when the patient is breathing adequately and has regained protective airway reflexes (the patient is actively resisting the presence of the tube). The patient may be extubated in the supine position if the anaesthetist is satisfied that a clear airway can be maintained and the patient is not at risk for aspiration. If the patient is at risk, then extubation should take place in the lateral position, with the patient as fully awake as possible. Extubation should be performed during inspiration. Having deflated the cuff of the tracheal tube, the bag on the anaesthetic circuit is squeezed to expel secretions above the cuff into the oropharynx, away from the vocal cords. The tube is removed in a smooth movement, the breathing circuit rapidly reconnected to an anaesthetic mask, and the mask closely applied to the face.

Partial obstruction of the airway may occur at this stage if the tongue falls back into the pharynx, or more often because of mild laryngeal spasm. It may respond to the application of positive end-expiratory pressure. This may be achieved by partially closing the exhaust valve on the anaesthetic circuit, but the airway pressure must be monitored. If the airway is obstructed by the tongue, then an oral or nasopharyngeal airway may be required to relieve the obstruction. When the patient is breathing adequately, he is transferred to the recovery room, ensuring that he breathes supplementary oxygen during the transfer.

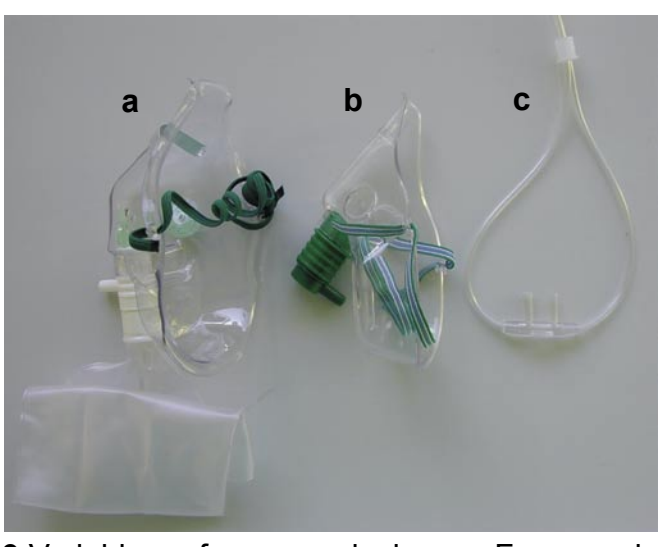
Recovery

Supplementary oxygen should be administered to all patients in the immediate recovery period. This is to prevent hypoxaemia that may otherwise occur from the ventilation–perfusion mismatch induced by surgery and anaesthesia, and the hypoventilation that may ensue from respiratory depressant drugs. Hypoxaemia may also be caused by dilutional hypoxia following cessation of nitrous oxide.

The duration of oxygen therapy may be limited to 15 minutes for young healthy patients undergoing minor day- case procedures, but extended for many hours or days for those with more serious pathology or complicated surgery. Therapy is guided by pulse oximetry or blood gas estimation, and oxygen therapy is usually titrated to achieve oxygen saturation greater than 95%.

Oxygen therapy devices may deliver either a variable or fixed concentration of supplementary oxygen to the inspired gas.

Variable performance devices include nasal prongs and simple 'Hudson'-type face masks with or without an oxygen reservoir (Figure 9). The oxygen flow delivered to the device is typically 2–4 litres/minute, which will be diluted by the air entrained during inspiration. The concentration of inspired oxygen depends on the oxygen flow rate, the patient's respiratory rate and peak inspiratory flow. Typically, 30–40% inspired oxygen is achieved when 4 litres/minute is delivered to a patient via a Hudson mask, and this concentration reduces as respiratory rate and inspiratory flows increase, due to increased air entrainment. The oxygen concentration delivered cannot be predicted accurately. This is usually of no consequence to a patient on the recovery ward, who simply needs supplemental oxygen, though the precise concentration is not critical. The inspired oxygen percentage can be increased further if an oxygen reservoir is used with the mask, and 80% inspired oxygen may then be achieved using a 12–15 litres/minute oxygen flow rate.

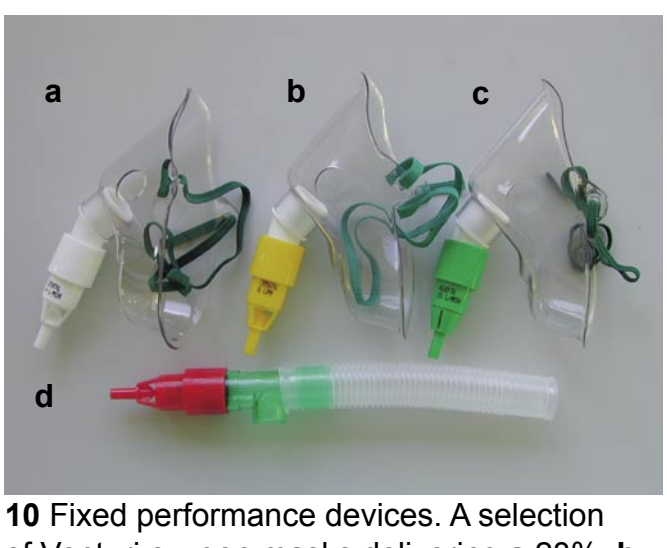


9 Variable performance devices. **a** Face mask with oxygen reservoir bag (folded); **b** simple Hudson-type oxygen face mask; **c** nasal prongs.

Fixed performance devices include face masks with Venturi-type injectors (Figure 10). They achieve a fixed inspired oxygen concentration by ensuring that a high flow rate of oxygen and entrained air is delivered, in excess of the patient's maximum peak inspiratory flow rate.

The use of a Venturi injector face mask delivers about 60 litres/minute of gas and so the inspired oxygen concentration is independent of the characteristics of inspiratory flow. Venturi devices are available to deliver fixed oxygen concentrations between 24% and 60%. The correct oxygen flow rate must be selected for the correct Venturi injector, and used with the correct mask. Details are printed on each Venturi, but typically 2 litres/minute delivers 24% oxygen, and 8 litres/minute delivers 35% oxygen. Venturi injector devices are not interchangeable with masks from different manufacturers, because the mask volume allows for adequate mixing of driving and entrained gases.

Fixed performance devices are often used in the high-dependency setting to enable accurate assessment of oxygenation, in patients with chronic lung disease who depend on a hypoxic respiratory drive, and on the general wards.



10 Fixed performance devices. A selection of Venturi oxygen masks delivering **a** 28%, **b** 35%, **c** 60% oxgen. **d** Venturi T-piece delivering 40% oxygen for use with laryngeal mask airway, tracheal tube or tracheostomy tube.

Anaesthesia for Laparoscopic Surgery

Michael W Platt

Michael W Platt is Consultant in the Department of Anaesthesia, St Mary's Hospital, London. He qualified in Western Australia. His research interests include anaesthesia and pain relief in the elderly, ethical issues at the end of life and aspects of neuropathic pain.

Laparoscopic surgery is a revolution in modern surgical techniques and has reduced postoperative pain, respiratory complications and hospital stay considerably. However, it produces extra stresses on the heart and lungs, therefore patients should be screened carefully and the risks explained fully as part of obtaining consent for the procedure. Anaesthetists should consult their surgical colleagues about the relative risks in those with cardiac and respiratory disease and should be prepared to cope with complications as they arise.

History

The earliest recorded references to endoscopy are from Hippocrates in Greece (460–375 BC), who made reference to a rectal speculum. It was only in the 1970s that the problems of transmitting light, insufflation technology and optical technology were surmounted sufficiently for gynaecologists to embrace laparoscopic surgery. Laparoscopic techniques were not supported whole-heartedly by general surgeons until after 1987, when Mouret performed the first laparoscopic cholecystectomy in France. Following this, the rapid development of solid state video camera technology has further broadened the field of laparoscopic surgery.

The advantages of minimally invasive surgery are less ileus, the greatly reduced stress response to surgery and trauma, reduced acute phase reaction, reduced pain, reduced post-operative pulmonary dysfunction and reduced hospital stay. These also have economic advantages.

More procedures are being developed for laparoscopic surgery, including extraperitoneal inguinal hernia repair and retro-peritoneal nephrectomy and adrenalectomy. Routine general surgical laparoscopic procedures now include: oesophagectomy, Nissen's fundoplication, gastric banding, oversewing of peptic ulcer, intestinal resections, including hemicolectomy and col-ectomy, rectopexy and hernia repair.

Pathophysiology and complications of laparoscopy

The complications of laparoscopy include: haemorrhage, hypotension, decreased cardiac output, acidosis, pneumothorax, pneumomediastinum, subcutaneous emphysema, retroperitoneal carbon dioxide (CO_2), venous stasis, bradycardia, increased vagal tone, cardiac arrest, fatal venous CO_2 embolism, regurgitation and aspiration. Many of these complications are the result of peritoneal insufflation (pneumoperitoneum).

Pneumoperitoneum, the insufflation of the peritoneal cavity, is required to enable a gas milieu for visualization through the laparoscope (the operating telescope). CO_2 is used for laparoscopy because it is highly soluble in blood. Blood can carry large quantities of CO_2 as bicarbonate, carboxyhaemoglobin, and in plasma proteins. Carbon dioxide is eliminated rapidly and the lethal dose as an embolus is five times that of air. Usually a CO_2 gas embolism resolves rapidly, but if it is large, it can be fatal.

Pneumoperitoneum is achieved by insufflating the peritoneal cavity with CO_2 to a pressure of 10–18 mm Hg. The intra-peritoneal insufflation of CO_2 to these pressures causes respir-atory and haemodynamic changes.

Respiratory changes that occur as a result of pneumoperitoneum consist of a reduction of chest compliance by 30–50%. Airway pressures to maintain tidal volume rise to counter the reduction of chest compliance and the elevation of the diaphragm. Functional residual capacity of the lungs decreases and there is an increase in physiological dead space and shunt because of basal compression by the diaphragm and increased ventilation/perfusion mis-matching, which may result in a reduced arterial partial pressure of oxygen. Basal atelectasis may persist into the postoperative period. If minute volume is kept constant, end-tidal CO_2 increases due to absorption of CO_2 from the peritoneal cavity. The latter changes are usually countered by increasing the tidal volume and applying positive end-expiratory pressure (PEEP).

Haemodynamic changes also occur as a result of the pneumo-peritoneum. Compression of the inferior vena cava leads to a reduction in venous return, potentially followed by a fall in cardiac output. However, a reflex tachycardia and a massive increase in peripheral vascular resistance tends to maintain cardiac output at near-normal levels, by pulling blood centrally from the periphery, but with a concomitant increase in mean arterial blood pressure. This increase in myocardial work can result in myocardial ischaemia in those at risk and can lead to infarction, which may not occur until the postoperative period. Active vasodilatation and β blockade are often required to counter these effects.

Compression of the inferior vena cava causes reduced venous flow from the legs, resulting in venous stasis and an increased risk of venous thrombosis. Prophylactic anticoagulation and elastic stockings or pneumatic calf compressors should be used, especially in the elderly.

Respiratory and haemodynamic changes are affected by the patient's position. For example, head-up tilt, used for upper abdominal operations (e.g. cholecystectomy, Nissen's fundoplication) further inhibits venous return. Head-down tilt, used for colonic and pelvic surgery, promotes venous return, but aggravates respiratory changes, further reducing chest compliance and functional residual capacity and increasing basal compression.

Other complications of pneumoperitoneum include surgical emphysema, which can affect most tissues, including the conjunctivae and the scrotal sack. Cardiac arrhythmias can be secondary to vagal stimulation (bradycardia) or to hypercarbia (tachyarrythmias). Pneumothorax (including tension pneumo-thorax) may occur, particularly with upper abdominal procedures such as Nissen's fundoplication. Gastric reflux can occur because of increased intraperitoneal pressure, although retained gas in the stomach may obstruct the surgeon's view for upper abdominal operations. Pressure on the renal veins and arteries may cause a temporary reduction in renal function, due to reduced renal blood flow. Major CO_2 gas embolus seldom occurs and is usually the result of accidental direct injection of gas into a major vessel (e.g. the inferior vena cava). This may cause an obstruction to cardiac output when it reaches the heart. The treatment is to turn the patient onto the right side immediately and position them head down, causing the gas embolus to occupy the apex of the right ventricle, relieving the obstruction to ventricular outflow.

Anaesthetic technique

Preoperative assessment

Patients should be assessed carefully preoperatively, focussing on their cardiac function and reserve, because of the amount of extra cardiac work required during pneumoperitoneum. Patients with significant cardiac disease and limited cardiac reserve should be assessed by a cardiologist. It may be that an open procedure or even cancelling the procedure would be best for the patient. Patients with added risks of venous thrombosis should be treated prophylactically with fractionated heparin, elastic stockings and calf compressors during surgery. Surgery for patients with previously untreated hypertension should be postponed until treatment has stabilized. Respiratory function should also be assessed. Pulmonary function tests should be performed in those with significant pulmonary disease. Liver and renal function need to be ascertained because these organs may also be affected by pneumoperitoneum. Intercurrent medications (especially antihypertensives) should be given as normal on the morning of operation. A light sedative, such as a short-acting benzodiazepine, may be given before surgery.

Perioperative management

A routine intravenous induction is appropriate. It is preferable to intubate and ventilate patients undergoing laparoscopic surgery. This ensures a secure airway while ventilating with higher airway pressures and reducing the inherently small risk of aspiration from gastric regurgitation. A large-bore intravenous cannula should be placed to allow ready access for the management of major complications. In upper abdominal procedures a 12–16 FG oro- or nasogastric tube is passed to allow egress of gas from the stomach to facilitate the surgeon's view.

Maintenance may be by total intravenous or inhalational anaesthesia. Intermittent positive-pressure ventilation is preferable, to ensure adequate ventilation in the presence of the reduced compliance and elevated diaphragm caused by the pneumo-peritoneum.

Opioid supplementation aids analgesia and improves post-operative analgesia. This may be as intermittent morphine and diamorphine or as an infusion of a short-acting agent such as alfentanil or remifentanil.

Monitoring should be the minimum standard of non-invasive blood pressure, electrocardiograph, end-tidal CO_2, anaesthetic gases and pulse oximetry. For patients who require laparoscopic surgery, but who have very borderline cardiac function, invasive blood pressure and central venous pressure may be necessary, to allow closer control of cardiac function, in particular myocardial work. A pulmonary artery flotation catheter may be considered if there is concern regarding left heart function.

When peritoneal insufflation begins, there is often a reflex tachycardia and significant increase in blood pressure, even at deep levels of anaesthesia. To avoid hypertensive crises, with diastolic blood pressures above 120 mm Hg, it is advisable to have a vasodilator and β blocker available. Carefully titrated doses of labetalol can be effective, with its combined α and β effects. Occasionally, vagally-mediated bradycardia, even to the point of sinus arrest, may be seen. In this case, insufflation should cease immediately, while an appropriate vagolytic (e.g. atropine) is given. Ventilation should be adjusted to increase tidal volume and PEEP applied to counter the reduced compliance, elevated diaphragm and increased CO_2 load.

At the end of the procedure, it is preferable for the surgeon to infiltrate the small port wounds with long-acting local anaesthetic to reduce postoperative pain. The raw areas of tissue that occur after cholecystectomy can contribute to pain, due to carbonic acid formation by CO_2. Spraying the peritoneal cavity with bupivacaine may be effective in these cases.

Recovery

Pain in the immediate postoperative period can be severe, presumably due mainly to stretching of the tissues. Shoulder-tip pain is common, secondary to diaphragmatic irritation. Sitting the patient up and giving systemic analgesia should help this to settle. Occasionally, large doses of intravenous opioid are required for adequate relief. However, once the pain is controlled, recovery is rapid and the patient usually goes home in 2–3 days.

Postoperative complications

Surgical emphysema is occasionally alarming because it involves much of the trunk. It is advisable to deflate the scrotal sack before recovery. More generalized emphysema settles rapidly with time, but a pneumothorax should be excluded. The main problem with surgical emphysema is pain, which should be controlled systemically. Basal atelectasis with secondary pulmonary infection may also occur. It is more common in those with pre-existing pulmonary disease, and should be treated with antibiotics and physiotherapy. Aspiration may manifest as pleural effusions or rarely as Mendelson's syndrome. These may require the input of a respiratory physician, but are not usually a major problem in fasted patients.

The most serious complications are usually haemodynamic. Postoperative myocardial infarction can occur as a result of the increase in myocardial work during the procedure.

Deep venous thrombosis may occur due to venous stasis in the legs during surgery. This occasionally presents postoperatively with pulmonary embolus. ◆

Anaesthesia for Reconstructive Free Flap Surgery

Jane Quinlan

Jane Quinlan is Consultant Anaesthetist at the Radcliffe Infirmary and the John Radcliffe Hospital, Oxford. She qualified from St Thomas' Hospital, London, and trained in anaesthesia in London and Oxford. Her interests include anaesthesia for plastic surgery and acute pain management.

Reconstructive free flap surgery is a complex method of wound closure for large wounds not amenable to linear (primary) closure. It involves the transfer of free tissue (skin, muscle, bone, bowel or a combination) to a site of tissue loss where its circulation is restored via microvascular anastomoses. A muscle flap produces a more even contour and better aesthetic appearance than that achieved by a simple skin graft and provides a better defence against infection. The defect may be caused by trauma, infection or extensive surgery (e.g. mastectomy, head and neck cancer). The site and size of the defect determines which flap is used. The most commonly used flaps are the gracilis muscle for lower leg trauma; latissimus dorsi and rectus abdominis for breast reconstruction; and pectoralis major and radial forearm flap for head and neck reconstruction.

In patients with lower third tibulofibular defects, free tissue transfer is typically required. The bony injury should be repaired and adequate debridement achieved before skin and muscle coverage begins. This should occur within the first 6 days after injury before colonization of the wound and the risk of complications increases. In patients with multiple trauma, any life-threatening injuries must be addressed first and the patient's haemodynamic status stabilized before reconstructive surgery is contemplated.

Flap transfer

The free flap is transferred with its accompanying artery and vein, which are then reattached to vessels at the donor site using microvascular techniques. The stages of flap transfer are:

- flap elevation and clamping of vessels
- primary ischaemia as blood flow ceases and intracellular metabolism becomes anaerobic (this is dependent on surgical time and lasts 60–90 minutes)
- reperfusion as the arterial and venous anastomoses are completed and the clamps released
- secondary ischaemia is subsequent to hypoperfusion of the flap (minimized by appropriate anaesthetic management).

Primary ischaemia

With cessation of blood flow, the flap becomes anoxic. In the presence of anaerobic metabolism, lactate accumulates, intra-cellular pH drops, ATP decreases, calcium levels rise and pro-inflammatory mediators accumulate. The severity of the damage caused by primary ischaemia is proportional to the duration of ischaemia. Tissues with a high metabolic rate are more susceptible to ischaemia, therefore skeletal muscle in a flap is more sensitive to ischaemic injury than skin. At the conclusion of primary ischaemia, the changes in the flap tissue include:

- narrowed capillaries due to endothelial swelling, vasoconstriction and oedema
- sequestration of leucocytes ready to release proteolytic enzymes and reactive oxygen intermediates
- diminished ability of endothelial cells to release vasodilators and degrade ambient vasoconstrictors
- end-organ cell membrane dysfunction and accumulation of intracellular and extracellular toxins
- up-regulation of enzyme systems to produce inflammatory mediators.

Reperfusion begins with the release of the vascular clamps. Normally, the re-establishment of blood flow reverses the transient physiological derangement produced by primary ischaemia. The flap recovers with minimal injury and normal cellular metabolism is restored. However, an ischaemia/reperfusion injury may result if factors in the flap are unfavourable. Prolonged ischaemia time or poor perfusion pressure make this more likely. Reperfusion injury occurs when the restored blood flow allows the influx of inflammatory substrates that may ultimately destroy the flap.

Secondary ischaemia occurs after a free flap has been transplanted and reperfused. This period of ischaemia is more damaging to the flap than primary ischaemia. Flaps affected by secondary ischaemia have massive intravascular thrombosis and significant interstitial oedema. Fibrinogen and platelet concentrations are increased in the venous effluent. Although skin flaps can tolerate 10–12 hours of ischaemia, irreversible histopathological changes in muscle can be seen after 4 hours.

Causes of flap failure: the general causes of poor flap perfusion may be classified as arterial, venous or resulting from oedema. The arterial anastomosis may be inadequate, in spasm or thrombosed. The venous anastomosis may similarly be defective, in spasm or compressed (e.g. by tight dressings or poor positioning). Oedema reduces flow to the flap and may be a result of excessive crystalloids, extreme haemodilution, trauma from handling or a prolonged ischaemia time. Flap tissue has no lymphatic drainage and is therefore susceptible to oedema.

Microcirculation: the blood flow through the microcirculation is crucial to the viability of a free flap. The microcirculation is a series of successive branchings of arterioles and venules from the central vessels. Regulation of blood flow and oxygen delivery is accomplished by three functionally distinct portions of the microcirculation: the resistance vessels, the exchange vessels and the capacitance vessels.

The resistance vessels are the muscular arterioles that control regional blood flow. Arterioles range in diameter from 20 μm to 50 μm and contain a relatively large amount of vascular smooth muscle in their walls. Alterations in vascular smooth muscle tone are responsible for active constriction and dilation in arterioles and thus control resistance to blood flow.

The capillaries constitute the network of vessels primarily responsible for the exchange function in the circulation. Small bands of vascular smooth muscle, the precapillary sphincters, are located at the arterial end of many capillaries and are responsible for the control of blood flow within the capillaries.

The venules act as the capacitance vessels, which collect blood from the capillary network and function as a reservoir for blood in the circulation.

The vascular bed of skeletal muscle has rich adrenergic in-nervation and therefore has a marked vasoconstrictor response to neural stimulation, primarily through the resistance vessels. Precapillary sphincters also constrict in response to sympathetic stimulation, but are sensitive to local factors such as hypoxia, hypercapnia, and increases in potassium, osmolality and mag-nesium, which may cause relaxation. Other vasoactive hormones (e.g. renin, vasopressin, prostaglandins, kinins) also have a role in microvascular control.

Transplanted vessels in a free flap have no sympathetic innervation but are still able to respond to local and humoral factors, including circulating catecholamines.

The flow behaviour (rheology) of blood in the microcirculation is determined by the red cell concentration, plasma viscosity, red cell aggregation and red cell deformability. Following all surgery under general anaesthesia, the changes in blood rheology include:

- increased platelet aggregation and adhesion
- an impairment of red cell deformability
- an increase in whole blood viscosity
- increased clotting factors
- increased plasma fibrinogen and red cell aggregation
- disturbance of fibrinolysis.

Normal levels of 2,3-diphosphoglycerate (2,3-DPG) are required for optimal red cell deformability. After blood transfusion, this deformability is impaired owing to the negligible amount of 2,3-DPG in stored blood.

Physiology

The physiological status of the patient has a major influence on the viability of the transferred tissues, so the conduct of anaesthesia and postoperative management have a direct effect on outcome. Surgery is long (often 6–8 hours) with multiple sites for tissue trauma, resulting in extensive blood and fluid losses as well as heat loss. The resulting hypovolaemic vasoconstriction and hypothermia, if not corrected, compromise blood flow to the flap and result in flap failure.

Even with good fluid management, blood flow to a flap may decrease by 50% for 6–12 hours postoperatively. The guiding principle of anaesthesia for free flap surgery is the maintenance of optimum blood flow. The determinants of flow are summarized by the Hagen–Poiseuille equation:

$$\text{Laminar flow} = \frac{\Delta P \times r^4 \times \pi}{8 \times \eta \times l}$$

where: ΔP is the pressure difference across the tube, r is the radius of the vessel, η is viscosity and l is the length of the tube.

From this we may deduce that the goals of anaesthesia for free flap surgery are vasodilatation, good perfusion pressure and low viscosity.

Vasodilatation

Vessel radius is the most important determinant of flow, for the vessels supplying the flap as well as those in the flap.

Temperature – the patient should be kept warm in theatre, the recovery room and the ward for the first 24–48 hours. This is best achieved by raising the ambient temperature in theatre and by using a warm air blanket. Active warming should begin before the start of anaesthesia because patient cooling occurs rapidly after induction of anaesthesia. In an awake patient, the central core temperature is higher than that of the peripheral tissue and skin temperature. After the induction of anaesthesia, vasodilatation modifies the thermal balance between compartments. The volume of the central compartment enlarges leading to a decrease in its mean temperature, while the temperature of the peripheral and skin compartments increases. At thermoregulation, the size of the central compartment becomes smaller owing to vasoconstriction, which leads to an increase in the mean temperature, although the peripheral and skin temperatures fall.

In addition to vasoconstriction, hypothermia also produces a rise in haematocrit and plasma viscosity, the aggregation of red blood cells into rouleaux, and platelet aggregation. These effects may reduce the microcirculatory blood flow in the flap.

Fluid – peripheral vasoconstriction due to an underestimation of fluid losses is common. There are two operating sites in free flap transfer: the donor site and the recipient site. Both have insensible fluid losses and both may have blood losses. A warm theatre environment also increases fluid loss. Modest hypervolaemia reduces sympathetic vascular tone and dilates the supply vessels to the flap. An increase in central venous pressure of 2 cm H_2O above the control measurement can double the cardiac output and produce skin and muscle vasodilatation. Figure 1 gives a guide to fluid management.

Guide to fluid management

Crystalloids
- 10–20 ml/kg to replace preoperative deficit
- 4–8 ml/kg/hour to replace insensible losses

Colloids
- 10–15 ml/kg for haemodilution
- To replace blood loss

Blood
- To maintain haematocrit at 30%

Dextran
- Often given postoperatively

1

Anaesthesia – isoflurane has the advantage over other volatile anaesthetics and propofol that it causes vasodilatation with minimal myocardial depression. Propofol inhibits platelet aggregation which could reduce the risk of thrombosis. This may be due to an effect of intralipid on the platelet–erythrocyte interaction, and by the increased synthesis of nitric oxide by leucocytes.

Vasospasm of the transplanted vessels may occur after surgical handling or after damage to the intima of the vessels, and can occur during surgery or postoperatively. The surgeons may use topical vasodilators such as papaverine, lidocaine (lignocaine) or verapamil during the operation to relieve the vasospasm.

Sympathetic blockade – epidural, brachial plexus or interpleural local anaesthetic infusions, used intraoperatively and postoperatively, provide sympathetic blockade to further dilate vessels. Concerns have been raised that the sympathetically-denervated transplanted vessels would be unable to dilate after lumbar epidural blockade, resulting in a 'steal' effect reducing flap blood flow. In fact, provided any hypotension due to the sympathetic block is treated appropriately, blood flow to the flap improves as a result of the increased flow through the feeding recipient artery. Other advantages of epidural analgesia include a reduction in intraoperative and postoperative blood loss and vessel spasm; a lower incidence of deep venous thrombosis; improved diaphragmatic function and more rapid post-operative recovery. Good analgesia reduces the level of circulating catecholamines and avoids the vasoconstrictor response to pain.

Perfusion pressure

The preservation of a good perfusion pressure with wide pulse pressure is essential to flap survival. Appropriate anaesthetic depth and aggressive fluid management are usually all that is needed. Most inotropes are contraindicated owing to their vasoconstrictive effects, but if required, dobutamine and low-dose dopamine could be used.

Viscosity

Isovolaemic haemodilution to a haematocrit of 30% improves flow by reducing viscosity, reducing reperfusion injury in muscle and increasing the number of patent capillaries, which decrease tissue necrosis. Further reductions in haematocrit do not provide much more advantage because the curve of viscosity versus haematocrit flattens off markedly (Figure 2). If the haematocrit falls further, the marginally improved flow characteristics from a lower viscosity may then be offset by a reduction in oxygen delivery:

$$DO_2 = CO \times [(Hb \times sat \times 1.34) + (PaO_2 \times 0.003)]$$

A low haematocrit also increases myocardial work, therefore care should be taken in patients with poor cardiac reserve.

Viscosity versus haematocrit

Practical conduct of anaesthesia

Monitoring

In addition to basic monitoring, these patients require invasive blood pressure monitoring to enable safe manipulation of the perfusion pressure. Direct measurement of arterial pressure gives a continuous record of the pressure and is more accurate than non-invasive indirect techniques. An arterial cannula also provides access to blood gas analysis and haematocrit estimations.

Central venous pressure reflects cardiac filling pressures and can be manipulated to increase cardiac output.

Core temperature measurement is essential when active warming is instituted. A nasopharyngeal or rectal probe is used intraoperatively for a continuous reading, while intermittent tympanic or axillary measurements are used in the recovery and ward areas.

Peripheral temperature is also measured because a fall in skin temperature can reflect hypovolaemia and vasoconstriction. A difference of less than 2°C between core and peripheral temp-eratures indicates a warm, well-filled patient. The temperature of the skin flap is sometimes monitored postoperatively because a drop in temperature may herald flap failure. However, this is not a sensitive test, because by the time the temperature has fallen the flap will have suffered sufficient vascular damage to render it virtually unsalvageable.

Urine output is another indicator of volume status. A urine output of 1–2 ml/kg/hour should be maintained intraoperatively and postoperatively with appropriate fluid management. Diuretics are contraindicated in these operations because volume depletion compromises flap survival.

Induction

Active warming starts before the patient is asleep. The ambient temperature in theatre is raised to about 22–24°C, a level high enough to reduce patient heat loss, but not too hot to be uncomfortable for the theatre staff. The patient is covered in a hot air blanket before induction of anaesthesia and this remains in place while the patient is prepared for theatre. Once in theatre, the blanket is moved to enable surgical access, but with as much surface area coverage as possible.

If appropriate, a regional block is inserted, preferably to cover the free flap recipient site (rather than the donor site) for the full benefit of the sympathetic block. The patient is intubated and ventilated; and a large gauge peripheral line, central line, arterial line, urinary catheter and core temperature and skin temperature probes are positioned.

Nitrous oxide diffusion into air in the stomach combined with gastric stasis results in gastric distension, with associated post-
operative nausea and vomiting. A nasogastric tube is therefore sited at intubation, left on free drainage, then aspirated and removed at the end of the operation.

Fluid, administered through a fluid warmer, is started in the anaesthetic room to compensate for preoperative dehydration.

Maintenance

Careful positioning of the patient is imperative for such a long operation. Limbs are positioned and supported to avoid neuro-logical damage or vascular compression. Eyes are taped and lightly padded to reduce the incidence of corneal abrasion and prevent drying of the cornea.

Prophylaxis against deep venous thrombosis is necessary for all patients. Subcutaneous heparin or low-molecular-weight heparin is given preoperatively, while anti-embolism (TED) stockings and compression boots are used intraoperatively.

The patient is ventilated to normocapnia. Hypocapnia increases peripheral vascular resistance and reduces cardiac output, while hypercapnia causes sympathetic stimulation. If the surgeon uses the microscope for vessel preparation or anastomosis on the chest or abdomen, the tidal volume is reduced to minimize movement in and out of the surgeon's field of vision. The respiratory rate is then increased to maintain minute ventilation.

Controlled hypotension is useful during the initial dissection and is most easily achieved using epidural local anaesthetic and/or isoflurane. An infusion of glyceryl trinitrate may be added if needed.

Crystalloids are used to replace the preoperative fluid deficit from starvation and to cover intraoperative insensible losses. The latter are high because the warm theatre increases evaporative losses from the two operating sites. Excessive use of crystalloid may precipitate oedema in the flap.

Hypervolaemic haemodilution is achieved using colloids.

Blood gas analysis and haematocrit measurement should be carried out at the start of the operation and repeated every 2 hours.

By the time the flap is reperfused, the patient should be warm, well-filled and sympathetically blocked with a high cardiac output.

Emergence and recovery

The patient should wake up pain-free. Analgesia is maintained postoperatively with local anaesthetic infusions for regional blocks, intravenous patient-controlled analgesia, or both. Coughing and vomiting increase venous pressure and reduce flap flow, so smooth emergence and extubation are needed. The principles of perioperative and postoperative care are listed in Figure 3. ◆

Principles of perioperative and postoperative care

- Maintain high cardiac output
- Normal arterial blood pressure (systolic >100 mm Hg)
- Low systemic vascular resistance
- Normothermia
- High urine output (> 1 ml/kg/hour)
- Effective analgesia
- Haematocrit 30–35%
- Monitoring of blood flow in flap (Doppler postoperatively)

The Anaesthetic Machine

Michael O'Connor
Ian Taylor

Duncan Parkhouse is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Ian Taylor is Specialist Registrar in Anaesthesia in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and is training at the Wessex School of Anaesthesia, based in Southampton, UK. His interests are vascular and obstetric anaesthesia.

Many anaesthetic machines incorporate patient monitoring; conventionally this is considered separately and will not be discussed here.

Types of anaesthetic machine

Demand and intermittent flow machines
The patient's inspiration controls the flow of fresh gases. Such machines have been used for dental anaesthesia (e.g. the McKesson anaesthetic machine) and for military field anaesthesia (the Triservice apparatus).

Continuous flow machines (Boyle's machine)
Continuous flow machines are encountered in day-to-day hospital practice in the UK. The driving force for gas flow is compressed gases. This contribution discusses continuous flow machines.

Pressures in the anaesthetic machine

Units of pressure
To understand the anaesthetic machine, it is important to be able to relate the various different units that are used to describe pressure; 1 atmosphere pressure is approximately:

- 101 kPa
- 760 mm Hg
- 1035 cm H_2O
- 1 bar
- 15 psi.

Absolute and gauge pressure

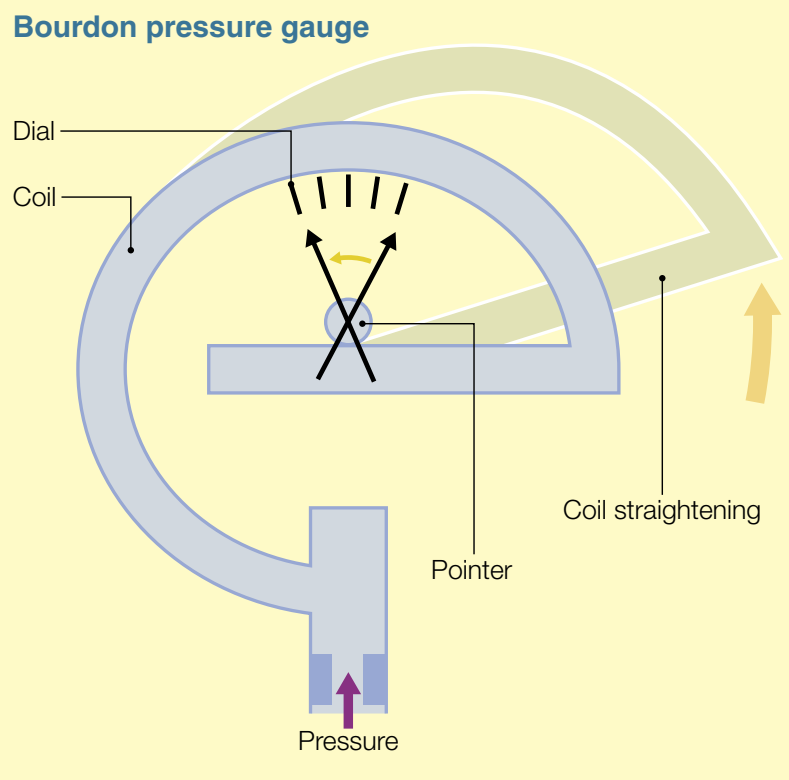
- Absolute pressure is pressure above that in a vacuum.
- Gauge pressure is pressure above atmospheric. Pressures in the anaesthetic machine are always quoted as gauge pressures.

All pipeline pressures are 400 kPa except for pressure in the air pipeline used to drive equipment such as orthopaedic drills, which is 700 kPa. Cylinder pressures are reduced to a machine working pressure of 400 kPa by pressure regulators (see below, page 66).

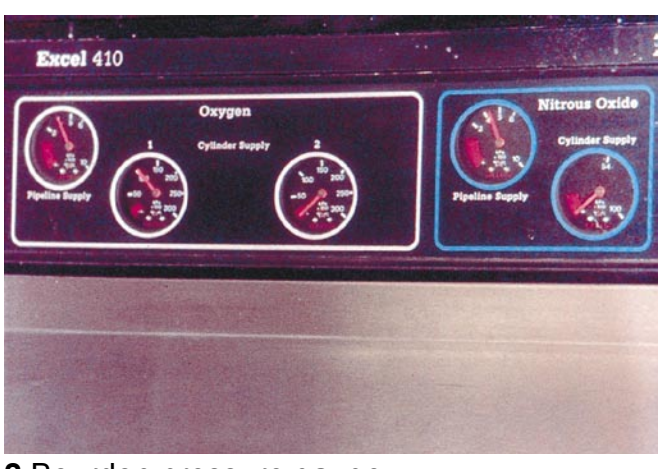
Pressure downstream of the flowmeters can range between zero (i.e. 1 atmosphere pressure), when the common gas outlet is open to the atmosphere, and about 33 kPa if the common gas outlet is completely obstructed and the safety valve in the back bar vents to the atmosphere.

Measurement of pressure
Cylinder and pipeline pressures are measured by a Bourdon pressure gauge (Figure 1). This is an aneroid (i.e. without liquid) gauge consisting of a coiled tube attached at one end to the gas supply and at the other to a pointer. The pressure of the gas causes straightening of the coil and thus movement of the pointer over the colour-coded, labelled and calibrated dial (Figure 2). The gauge is faced with heavy glass and designed such that leaks vent from the back of the valve casing and do not blow out the glass.

Bourdon pressure gauge



1

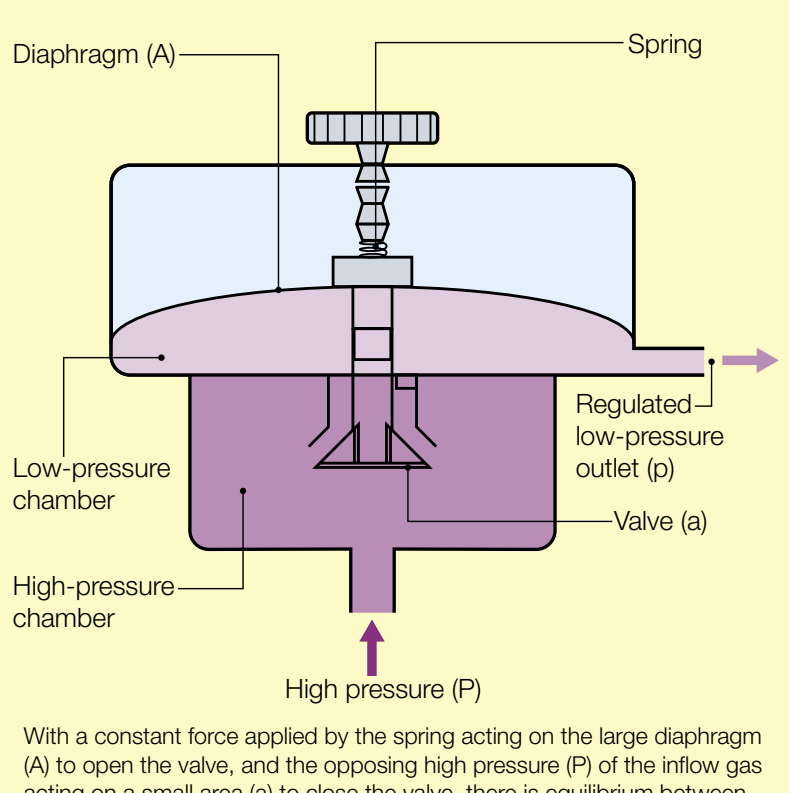


2 Bourdon pressure gauge.

Pressure regulators
Although sometimes referred to as pressure-reducing valves, the term pressure regulators is preferred because their function is not simply to reduce pressure, but in doing so to allow more accurate control of flow and to make up for the fall in cylinder pressures as they empty.

Figure 3 demonstrates the function of a pressure regulator. The principle is similar to that of the pressure-relief valve (see *Anaesthesia and Intensive Care Medicine* **1:3:** 107) except that there are two chambers, one of high pressure and the other of low, and two discs of different areas.

Pressure regulator



With a constant force applied by the spring acting on the large diaphragm (A) to open the valve, and the opposing high pressure (P) of the inflow gas acting on a small area (a) to close the valve, there is equilibrium between the high- and low-pressure chambers. To balance the equilibrium and keep the valve open, the pressure in the second chamber is thus reduced. Thus: P x a = p x A, where P = pressure in the high-pressure chamber; p = pressure in the low-pressure chamber; A = area of large diaphragm; a = area of small diaphragm.

Adjustment of the tension in the spring and thus the force it applies to the discs, regulates the pressure at the outlet to produce a constant operating pressure. As the inlet pressure falls during use of the cylinder, the force from the spring opens the valve wider, allowing more gas to flow into the second chamber and maintaining pressure at the outlet. The opposite happens if the inlet pressure rises, resulting in valve closure and thus less flow into the second chamber.

3

Flowmeters

Rotameters
Flow in most anaesthetic machines is measured by a variable orifice flowmeter known as a rotameter. A rotameter consists of a bobbin that floats in a glass tube with a diameter that increases with height up the tube. The pressure drop across the bobbin remains constant, and as flow increases it rises up the tube.

The two important properties of the gas flowing through a rotameter that influence its calibration are:

- viscosity
- density.

Gas flows in the annulus between the bobbin and the tube. At the lower end of the tube the annulus is long with respect to its cross-sectional area, and flow is laminar and dependent on the viscosity of the gas. Higher up the tube, the cross-sectional area of the annulus is greater, the gas is effectively flowing through an orifice, and flow is turbulent and dependent on the density of the gas (Figure 4).

Flowmeter

Laminar flow around the bobbin at the bottom of the tube, turbulent flow at the top. NB Pitch of the rotameter tube has been greatly exaggerated

4

Features of rotameters

- For any given gas, the flow through a rotameter depends on both its viscosity and its density. Rotameters therefore have to be calibrated individually for the gas they will be measuring.
- The bore may be varied to measure low flows accurately.
- The back plate may be luminous.
- Calibration is from the lowest accurate point, not zero.
- Accuracy is ± 2%.
- In many machines there is a constant low flow of oxygen.

Potential sources of inaccuracy in rotameters

- If the tube is not truly vertical, the annulus between the tube and the bobbin is altered.
- Static electricity can cause inaccuracies. To minimize this, glass is conductive and sprayed with antistatic material.
- Dust can collect on the bobbin or within the tube.
- Tubes may be damaged. In the UK, the oxygen rotameter tube is on the left (said to be because Boyle was left-handed). This can mean that any damage to the tubes would preferentially leak oxygen and result in the delivery of a hypoxic mixture. Many manufacturers now arrange the order in which the gases finally mix so that oxygen is the last gas added to the mixture.
- The top-sealing washer may be defective.
- The carbon dioxide bobbin may become stuck at the top of the tube.
- Back pressure from a minute volume divider such as a Manley ventilator increases the density of the gas and may cause the rotameter to under-read by about 7%.
- Atmospheric pressure affects density. Low pressure gives over-reading.
- Temperature affects density and viscosity. Increased temperature causes decreased density and increased viscosity.

Vaporizers

Vaporizers are discussed elsewhere.

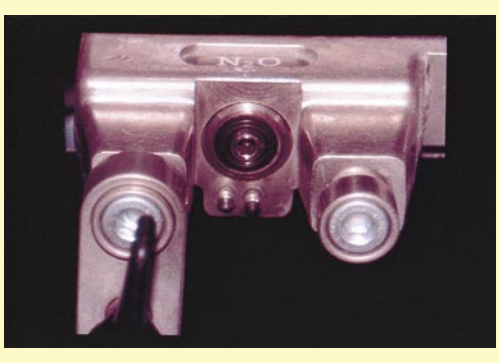
Safety

The anaesthetic machine has several in-built safety features that vary from machine to machine. The commonly found features that are of importance to anaesthetists are listed in Figure 5.

Perhaps the most important safety feature is that the machine should always be checked in a systematic fashion before use. The Association of Anaesthetists of Great Britain and Ireland has published a useful checklist, part of which is reproduced in Figure 6. These checks must be performed at the beginning of each theatre session.

Anaesthetic machine – safety features

- Non-interchangeable pipeline outlets (often referred to as Schrader connectors, though this is really a trade name)
- Pipelines are coloured and marked with the name of the gas
- Non-interchangeable screw thread connectors connect the pipeline to the anaesthetic machine
- The pin index system prevents accidental connection of the wrong cylinder to the wrong yoke
- Cylinders are coloured and marked with the name of the contents
- Grease can be flammable or explosive in contact with gases at high pressure. A Bodok seal (see below) makes a gas-tight connection between cylinder and yoke
- There are pressure gauges for pipelines and cylinders
- Rotameter knobs are identified by the oxygen knob being a distinctive colour and shape and more prominent
- The oxygen rotameter outlet may be diverted to enter the gas flow last
- Oxygen and nitrous oxide rotameters may be linked to prevent delivery of a hypoxic mixture
- The oxygen bypass can provide oxygen at high flow (> 30 litres/minute) directly to the common gas outlet
- There is an oxygen failure warning device triggered by a dropin the oxygen pressure, which also vents the flow of anaesthetic gases to the atmosphere to prevent delivery of a hypoxic mixture
- Vaporizer fillers are keyed to prevent a vaporizer being accidentally filled with the wrong agent
- Vaporizers may be arranged so that only one can be turned on at a time
- There is a machine pressure-relief valve in the back bar that prevents the pressure rising above about 33 kPa
- The machine is serviced regularly by a qualified engineer



Bodok seal.

Anaesthesic machine – safety checks

Anaesthetic machine

- Check that the anaesthetic machine and relevant ancillary equipment are connected to the mains electrical supply (where appropriate) and switched on
- Careful note should be taken of any information or labelling on the anaesthetic machine that might refer to its current status

Oxygen analyser

- The oxygen analyser should be placed where it can monitor the composition of the gases leaving the common gas outlet
- The analyser should be switched on, checked and calibrated according to the manufacturer's instructions

Medical gas supplies

- Identify and take note of the gases that are being supplied by the pipeline, confirming with a 'tug test' that each pipeline is correctly inserted into the appropriate gas supply terminal
- Check that the anaesthetic apparatus is connected to a supply of oxygen and that an adequate reserve supply of oxygen is available from a spare cylinder
- Check that adequate supplies of any other gases intended for use are available and connected as appropriate. All cylinders should be securely seated and turned ***Off*** after checking their contents. Carbon dioxide cylinders should not normally be present on the anaesthetic machine. A blanking plug should be fitted to any empty cylinder yoke
- All pressure gauges for pipelines connected to the anaesthetic machine should indicate 400 kPa
- Check the operation of flowmeters, ensuring that each control valve operates smoothly and that the bobbin moves freely through its range without sticking. With only the oxygen flow control valve open and a flow of about 5 litres/minute, check that the oxygen analyser display approaches 100%.

Turn off all flow control valves

- Operate the emergency oxygen bypass control and ensure that flow occurs without significant decrease in the pipeline supply pressure. Confirm that the oxygen analyser display approaches 100% during this test. Ensure that the emergency oxygen bypass control ceases to operate when released

Vaporizers

- Check that the vaporizer(s) for the required volatile agent(s) are fitted correctly to the anaesthetic machine, that any back bar locking mechanism is fully engaged and that the control knobs rotate fully through the full range(s). Ensure that the vaporizer is not tilted.

Turn off the vaporizers

- Check that the vaporizer(s) are adequately filled and that the filling port is tightly closed
- Set a flow of oxygen of 5 litres/minute and, with the vaporizer turned off, temporarily occlude the common gas outlet. There should be no leak from any of the vaporizer fitments and the flowmeter bobbin should dip.

Turn each vaporizer on in turn and repeat this test. There should be no leak of liquid from the filling port.

After this test, ensure that the vaporizers and flowmeters are turned off

Should it be necessary to change a vaporizer at any stage, it is essential to repeat the leak test.

Failure to do so is one of the most common causes of critical incidents

Removal of a vaporizer from a machine in order to refill it is not considered necessary

Artificial Ventilation in the Operating Theatre

Elaine M Wilson-Smith
J Duncan Young

Elaine M Wilson-Smith is Anaesthetic Specialist Registrar and Neuroanaesthesia Fellow at the Radcliffe Infirmary, Oxford, UK. She qualified from Guy's Hospital, London, and has trained in anaesthetics in Leicester, Alder Hey Hospital, Liverpool, and Oxford.

J Duncan Young is Clinical Reader in Anaesthetics at the Oxford Radcliffe Hospitals Trust. He qualified from Southampton University and trained in anaesthesia and intensive care in Southampton, Oxford and North America. His interests include artificial ventilation and techniques to improve arterial oxygenation in ICU patients.

Ventilators are used in two main settings: the operating theatre and the ICU.

- In the operating theatre, ventilators are used to maintain ventilation in anaesthetized, intubated, pharmacologically paralysed patients who have predominantly normal lungs. These ventilators are designed to interface with anaesthetic gas circuits to allow varying concentrations of oxygen, anaesthetic gases and volatile agents to be delivered to the patient. Most theatre ventilators are relatively simple, mechanical or electromechanical devices that do not have patient-sensing capabilities.
- Ventilators are often used in the ICU to ventilate patients with abnormal lungs, who require only air and oxygen as respiratory gases; these patients are seldom paralysed and often require only partial respiratory support. The ventilators used are almost all complex, computer-controlled devices with sensitive mechanisms to detect the patient's respiratory efforts.

This contribution discusses ventilators for theatre use, though many of the basic principles apply to ICU devices.

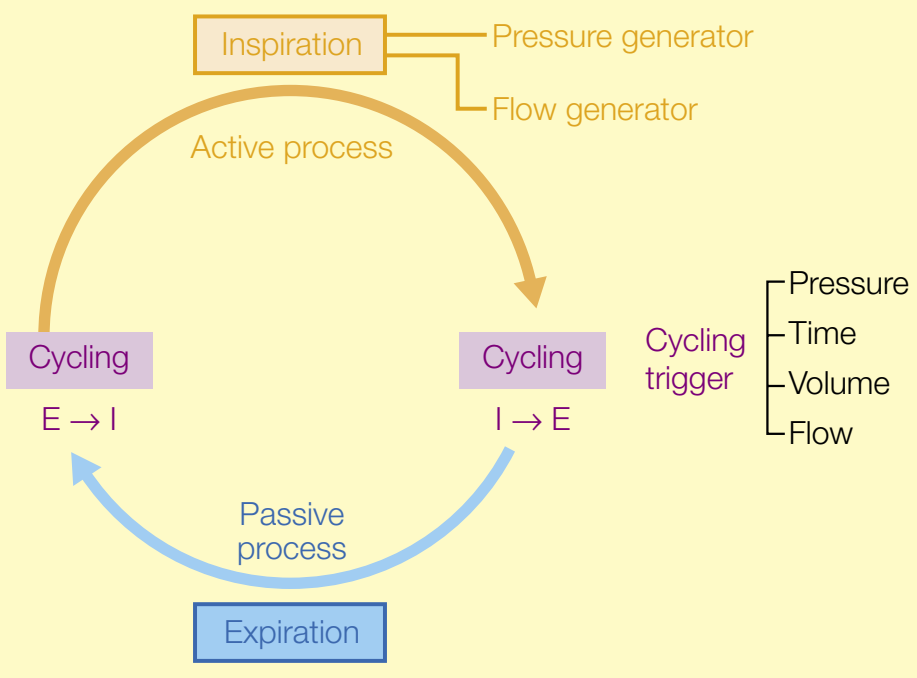
Classification of anaesthetic ventilators

Ventilators can be classified according to their function and operation.

- Functional classification is the most common and clinically useful system. It is based on the pattern of gas that the ventilator generates during inspiration, and the mechanism that cycles between inspiration and expiration (Figure 1).
- Operational classification is based on parameters such as power source or driving mechanism. Operational classification is not covered in this contribution.

Ventilator classifications were devised when most ventilators had only one mode of ventilation. Examples of such ventilators are the Manley ventilator (a time-cycled pressure generator), the Nuffield 200 ventilator (a time-cycled flow generator) and paediatric theatre ventilators (time-cycled pressure generators). Modern theatre ventilators and all ICU ventilators can operate in two or more ventilatory modes and so do not fit neatly into one single category of the traditional functional classification.

Functional classification of the respiratory cycle during intermittent positive-pressure ventilation



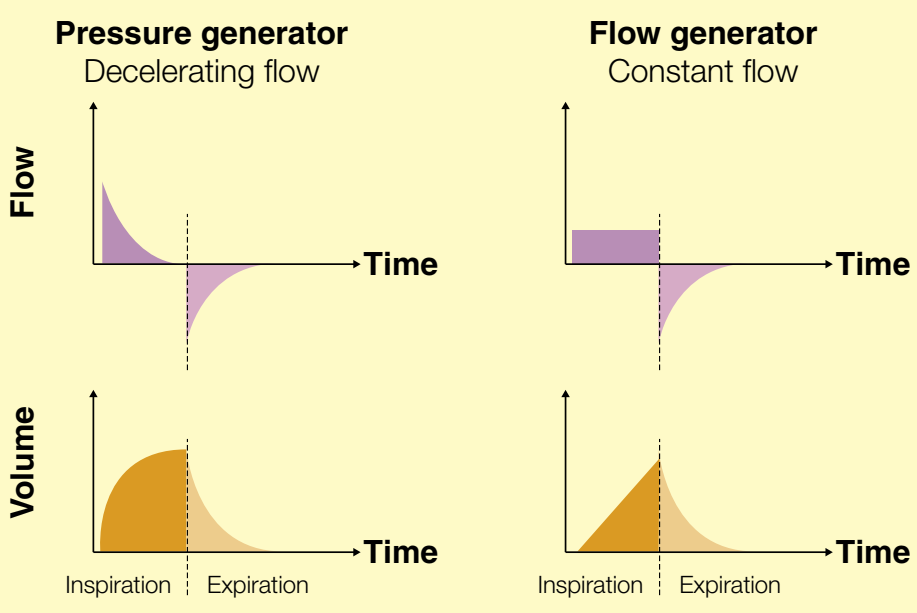
Based on Mapleson classification. I, inspiration; E, expiration

1

Functional classification of ventilators

The important difference between pressure and flow generators is the pattern of gas flow produced during inspiration. This influences the effects of changes in airway resistance, or lung and chest wall compliance, or if there is leak of delivered gases from the system. A summary of the important differences between pressure and flow generators is shown in Figure 2. Knowledge of the basic respiratory mechanics is vital to understanding ventilator–patient interactions.

Pressure generators and flow generators



2

Resistance, compliance and time constants: the pressure required to cause gas to flow into the lungs has two components:

- that required to maintain gas flow along the airways, overcoming airways resistance
- that required to overcome the elastic recoil of the respiratory system, determined by compliance.

The interaction of these components determines the time constant (TC).

TC defines the rate of a simple (first-order) exponential process. It is equivalent to the time taken for the exponential process to complete if it were to continue at the same rate as that at which it began. TC describes how fast the lungs fill with a constant applied airway pressure or how fast they empty during expiration. (TC = compliance x resistance.) It increases with increasing resistance (e.g. in asthmatics) and decreases with decreasing compliance (e.g. in pulmonary fibrosis).

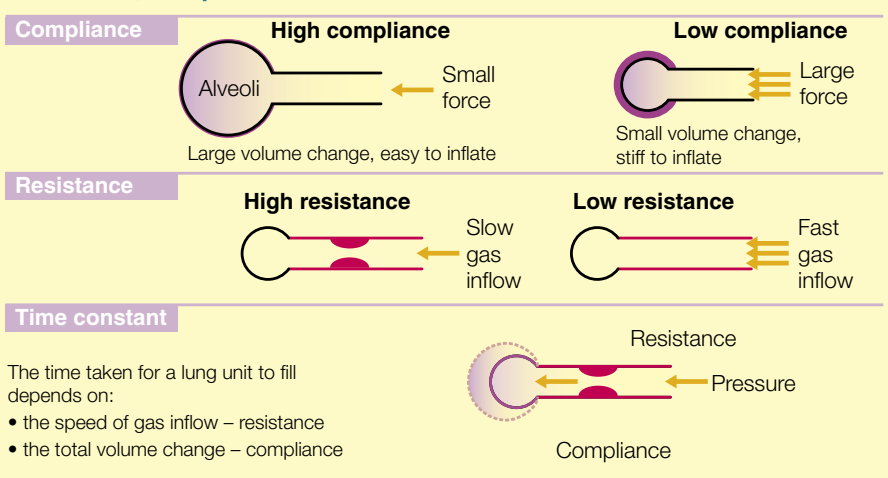
Resistance is a measure of the resistance to gas flow. The major site of respiratory resistance is in the medium-sized bronchi, but total respiratory resistance during positive-pressure ventilation also includes the contribution of the endotracheal tube and to a lesser extent the circuit. In a patient with normal lungs, this increases the total respiratory resistance from 2 to 4–6 cm H_2O/litre/second.

Compliance describes the elasticity of the respiratory system, or the ease with which it inflates, and is measured as the volume change per unit pressure. Total respiratory compliance consists of combined lung and chest wall compliance and is normally 50–70 ml/cm H_2O.

Within the normal working range of the lung compliance is constant though it decreases at extremes of volume. The contribution to compliance from the ventilator circuit is usually small. The exception is during anaesthesia in neonates and infants when the tidal volume is small compared with the circuit volume, and compression of gas within the circuit can make it difficult to ensure that accurate and adequate tidal volumes are delivered (Figure 3).

Effect on artificial ventilation − increased airways resistance and reduced lung and chest wall compliance are the most clinically significant changes in respiratory mechanics affecting artificial ventilation. Some causes are shown in Figure 4.

Resistance, compliance and time constant



3

Causes of increased airways resistance and reduced respiratory compliance

Increased airways resistance	Reduced respiratory compliance
• Bronchospasm – asthma, chronic obstructive airway disease (COAD)	• Within lung – pulmonary oedema, adult respiratory distress syndrome, fibrosis, atelectasis
• Mucosal swelling – asthma, COAD	• Around lung – pleural effusion, upward compression from abdominal contents when supine, especially if obese
• Luminal obstruction – excessive secretions	• Chest wall – surgeon compressing chest, expiration retractors, scoliosis, contractures
• Foreign body – tumour	
• Emphysema – dynamic airway compression during	
• Low lung volume	

4

Pressure and flow generators: an understanding of the different types of ventilator and how they function helps predict the behaviour and limitations of each type of machine when resistance and compliance of the lungs change (Figure 5).

Pressure generators - a pressure generator applies a preset positive-pressure waveform to the airway for the duration of inspiration. In its simplest form this pressure is constant (Figure 6).

If the inspiratory time is sufficiently long, the respiratory compliance determines the tidal volume delivered when a given airway pressure is applied. The respiratory compliance decreases linearly with lung size, therefore a pressure generator set at 15−20 cm H_2O delivers an appropriate tidal volume to a small child or an adult with normal lungs.

Pressure generators can maintain the required airway pressure, even in the presence of a leak, within reasonable limits. As a result, the main use for pressure generators in anaesthetic practice is to ventilate children. The cricoid ring is the narrowest point of the airway in children. The insertion of endotracheal tubes can lead to compression of the tracheal mucosa against the cricoid cartilage, resulting in pressure necrosis. This can be avoided by using uncuffed endotracheal tubes; the presence of an air leak during inspiration confirms that the endotracheal tube is not lodged tightly in the cricoid ring.

The pressure generator ensures that adequate tidal volumes are delivered because a consistent pressure is maintained despite the leak. Paediatric patients, particularly neonates, are prone to ventilator-induced lung damage, and constant pressure generators ensure that even when lung dynamics change, the applied pressure remains constant.

Pressure generators are designed for use with normal lungs that remain normal during surgery (delivered tidal volume = pressure x compliance.) The main disadvantage of a pressure generator is that tidal volume is determined by compliance and reductions in compliance may cause significant reductions in delivered tidal volume and minute ventilation. Therefore, pressure generators may not be appropriate when precise control of arterial carbon dioxide tension ($PaCO_2$) is important, for example, during neurosurgery.

Flow generators (Figure 7) are devices that produce a constant gas flow independent of respiratory compliance or resistance. The volume delivered per unit time remains constant even in the presence of high airway pressures. All flow generators need a high-pressure gas source. This can be delivered by compressing bellows or by using proportional control valves, which control gas flow from the pipeline supply.

The delivered tidal volume is determined by control of the inspiratory flow rate and inspiratory time. The peak and mean airway pressure generated depends on the tidal volume, inspiratory flow rate, respiratory compliance and resistance.

The main advantage of a constant flow generator is that a constant tidal volume and minute ventilation are maintained even when the mechanics of the lung are changing. The tidal volume can be set precisely and minute ventilation is predictable and consistent, giving precise control of $PaCO_2$.

The main disadvantage is the potential for high airway pressures and barotrauma if changes in lung mechanics occur. There is also no ability to compensate for leaks. Flow generators are used mainly for adults, particularly where lung mechanics are abnormal, and when precise control of $PaCO_2$ is required.

Cycling parameters - cycling is the process of stopping one phase of ventilation and changing to the next. This occurs twice within each delivered breath. For the purposes of classification, cycling marks the end of inspiration and the beginning of expiration. Ventilators may be:

- time-cycled – cycling occurs after preset time
- volume-cycled – cycling occurs after preset volume delivered
- pressure-cycled – cycling occurs after preset pressure attained
- flow-cycled – cycling occurs when flow falls below a preset value.

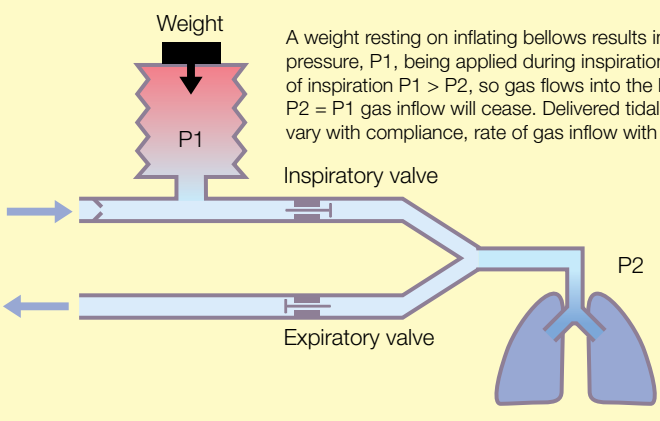
Time cycling is the most common technique. Flow cycling is used in inspiratory pressure support in the ICU but seldom in theatre. Volume and pressure cycling are used infrequently. In most ventilators, cycling from expiration to inspiration is by time.

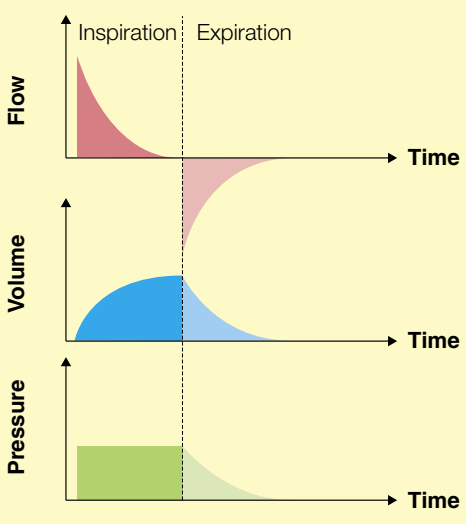
Advantages and disadvantages of pressure and flow generators

	Pressure generators	Flow generators
Advantages	• Protection from high airway pressures and barotrauma • Compensate for leaks	• Ability to maintain a constant tidal volume and minute ventilation even with significant changes in lung mechanics • Precise control of $PaCO_2$
Disadvantages	• Hypoventilation as a result of changes in lung mechanics	• Potential for high airway pressures and barotrauma • Inability to compensate for leaks

5

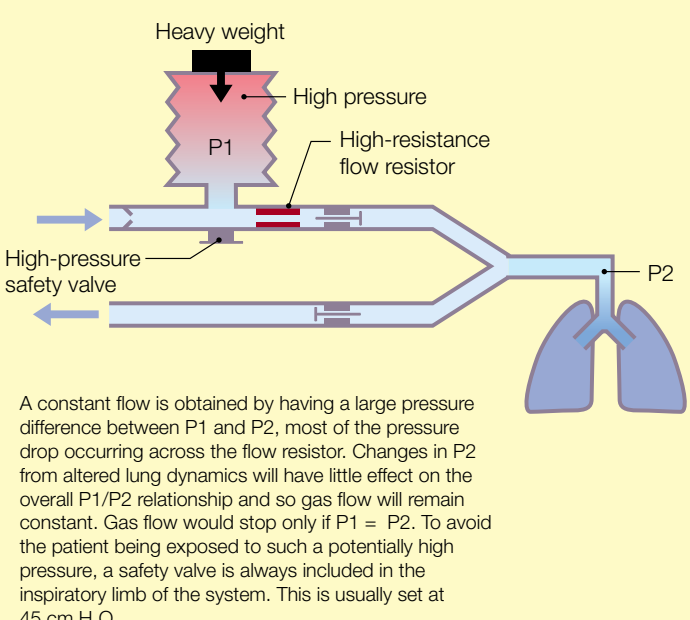
Constant pressure generator



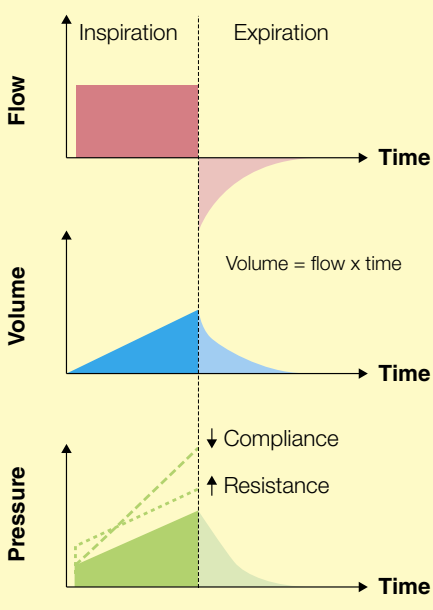


6

High-pressure, high-resistance flow generator



A constant flow is obtained by having a large pressure difference between P1 and P2, most of the pressure drop occurring across the flow resistor. Changes in P2 from altered lung dynamics will have little effect on the overall P1/P2 relationship and so gas flow will remain constant. Gas flow would stop only if P1 = P2. To avoid the patient being exposed to such a potentially high pressure, a safety valve is always included in the inspiratory limb of the system. This is usually set at 45 cm H_2O.



7

Single- and double-circuit ventilators

In a single-circuit ventilation system the anaesthetic gas is also the driving gas. A well-known example is the Manley ventilator, where the fresh gas flow set on the rotameters is divided into tidal volume (hence the term minute volume divider). The fresh gas flow powers the ventilator and is also delivered to the patient.

In a double-circuit ventilation system the anaesthetic gas and the driving gas are in separate circuits. The clearest example of this is a 'bag in bottle' or bellows ventilator. The anaesthetic gas is contained within the circuit and a set of bellows, which act as a reservoir. After delivering the tidal volume, the bellows refill during expiration. The bellows are contained within an air-tight cylinder and a separate high-pressure driving gas is used to pressurize the cylinder periodically, compressing the bellows and thereby generating inspiratory gas flow. Most modern circle/ventilator systems are double circuits.

Bellows can be of the standing or hanging variety. Standing bellows rise as they refill; hanging bellows are mounted inverted and fall as they refill. The advantage of standing bellows is that a leak of anaesthetic gases will be noticed by a failure of the bellows to rise to the full height. This is especially useful during low-flow circle anaesthesia. Hanging bellows are usually weighted at the base and entrain room air if there is a circuit leak.

The Nuffield 200 series of ventilators are functionally double circuit. Although there is no physical separation of the driving and fresh gas flow, the configuration of these ventilators ensures that fresh (anaesthetic) gases and driving gas do not mix. This is achieved by using a connector hose with an internal volume that is greater than the tidal volume.

Pulmonary physiology and the effects of intermittent positive-pressure ventilation (IPPV)

When a patient breathes spontaneously the expansion of the chest wall creates a negative pressure relative to atmospheric pressure between the visceral and parietal pleura. The transpulmonary pressure gradient created causes the lung to expand and fill. Thus, during inspiration the intrathoracic pressure is negative.

During IPPV the patient makes no respiratory effort and the transpulmonary pressure gradient required to expand the lung is generated by raising the airway pressure. With inspiration, intrathoracic pressure is positive. During artificial ventilation the mean intrathoracic pressure is increased compared with spontaneous ventilation and this has effects on the respiratory, cardiovascular, renal and endocrine systems. The effects of IPPV are wide ranging and must be viewed in the context of the position of the patient on the operating table and the effects of general anaesthesia.

Normal respiratory physiology and the effects of general anaesthesia

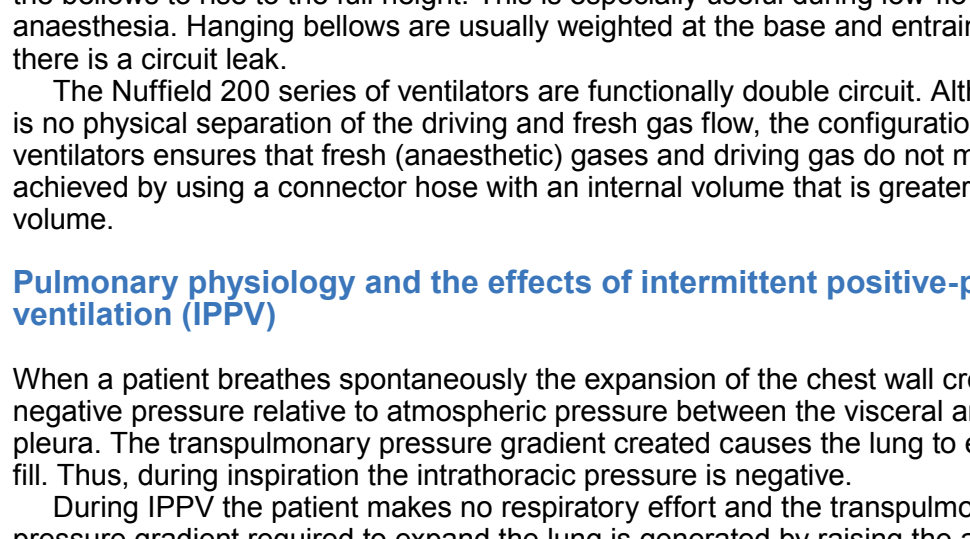
The primary function of ventilation is to move air in and out of the lungs so that carbon dioxide can be eliminated and arterial oxygenation maintained. In healthy individuals it is the requirement to eliminate carbon dioxide that is the prime determinant of minute ventilation. A normal tidal volume is about 500 ml in an adult (8 ml/kg); of this, about 150 ml (2 ml/kg) remains in the conducting airways (anatomical dead space), and the remaining 350 ml enters the alveoli and is available for gas exchange. The respiratory rate depends on the requirement for carbon dioxide elimination, but is usually 10−15 breaths per minute in adults. Effective ventilation maintains a normal arterial $PaCO_2$ of 4.5−5.5 kPa and an arterial oxygen tension (PaO_2) of 13.5 kPa in healthy young adults breathing room air.

Functional residual capacity (FRC): the various subdivisions of lung volume that can be determined by spirometry, whole-body plethysmography or helium dilution are shown in Figure 8. Of these, the most important for anaesthesia and the care of patients in the ICU is FRC. FRC is the end-expiratory volume of the lungs and is determined by the balance between:

- the elastic recoil of the lungs
- the outward recoil of the chest wall
- the respiratory muscle tone
- the position of the diaphragm.

FRC gradually reduces with age and is reduced on lying supine (by 500−800 ml) as a result of upward displacement of the diaphragm by the abdominal contents. This effect is enhanced in patients with abdominal distension or obesity. During general anaesthesia, reduction in diaphragmatic and chest wall tone and function lead to a reduction in FRC of about 20%. The effects of general anaesthesia and the supine position are additive, and can cause a significant reduction in FRC.

Lung volumes (70 kg adult)



Normal values

- Functional residual capacity 2.5 litres
- Inspiratory reserve volume 2.5–3.0 litres
- Tidal volume 0.5–0.6 litres
- Expiratory reserve volume 1.5 litres
- Residual volume 1.5–2 litres
- Vital capacity 3.5–5.5 litres
- Total lung capacity 6 litres

Minute ventilation 7.5 litres/minute
Alveolar ventilation 5 litres/minute
Vd/Vt 0.3

8

Closing capacity (CC) is the lung volume at which small airway closure begins. Closing volume is an alternative term that is equivalent to CC minus residual volume (RV). Normally CC is less than FRC, but they converge with increasing age. When FRC decreases to below CC, airway closure occurs during normal expiration and the resulting decrease in ventilation to areas of the lung distal to the closure worsens the ventilation-perfusion (V/Q) relationship. FRC usually remains greater than CC when supine until about 45 years of age but the additional reduction in FRC that occurs during general anaesthesia makes it more likely that FRC will fall below CC during anaesthesia. The resulting increase in V/Q mismatch leads to a decrease in arterial oxygenation, which is normally countered by increasing the inspired oxygen fraction.

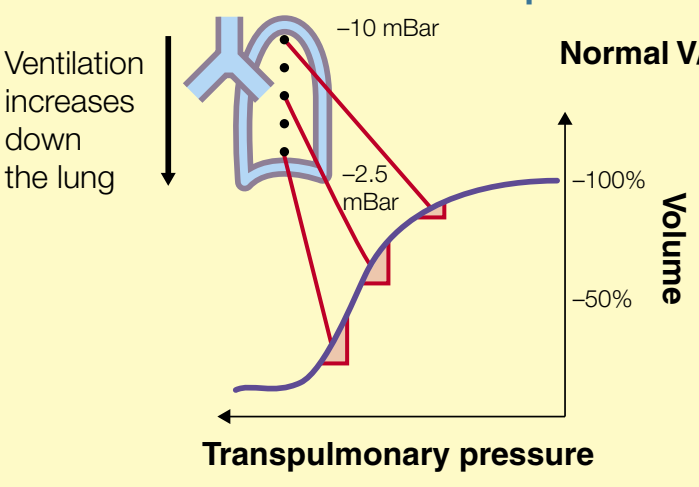
Distribution of ventilation and perfusion: during spontaneous ventilation in an upright position, distribution of ventilation and perfusion are not uniform throughout the lungs. Blood flow increases linearly from the top to the bottom of the lungs as a result of the effects of gravity on the low-pressure pulmonary circulation. The lower zones ventilate better than the upper zones because the dependent parts are on a more compliant (i.e. steeper) part of the pressure-volume curve. During normal inspiration, diaphragmatic contraction is enhanced in the parts of the diaphragm most displaced, aiding increased ventilation of the dependent parts of the lung (Figure 9).

Ideally, ventilation and perfusion at the alveolar level should be matched. Alveolar ventilation should equal perfusion and the V/Q ratio equal 1. In this situation no ventilation or perfusion is 'wasted'. However, the normal V/Q ratio is 0.8. The further the V/Q ratio deviates from 1, the more inefficient the ventilatory process becomes (Figure 10).

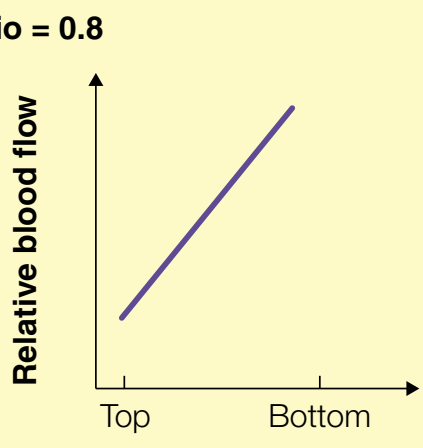
In the supine position, the gravitational effects on the lung are more limited, and perfusion is more homogeneous. However, the reduction of FRC, which is compounded by anaesthesia and the patient's position, leads to uneven ventilation because of airway closure and the tendency of the dependent portions of the lung to reduce in volume more than the superior parts (compression atelectasis).

Therefore, in the supine position (especially under anaesthesia) V/Q relationships worsen. This tends to cause hypoxaemia, which, because it is caused by a V/Q mismatch rather than a true shunt, can be reversed with added inspired oxygen.

Distribution of ventilation and perfusion in the lungs



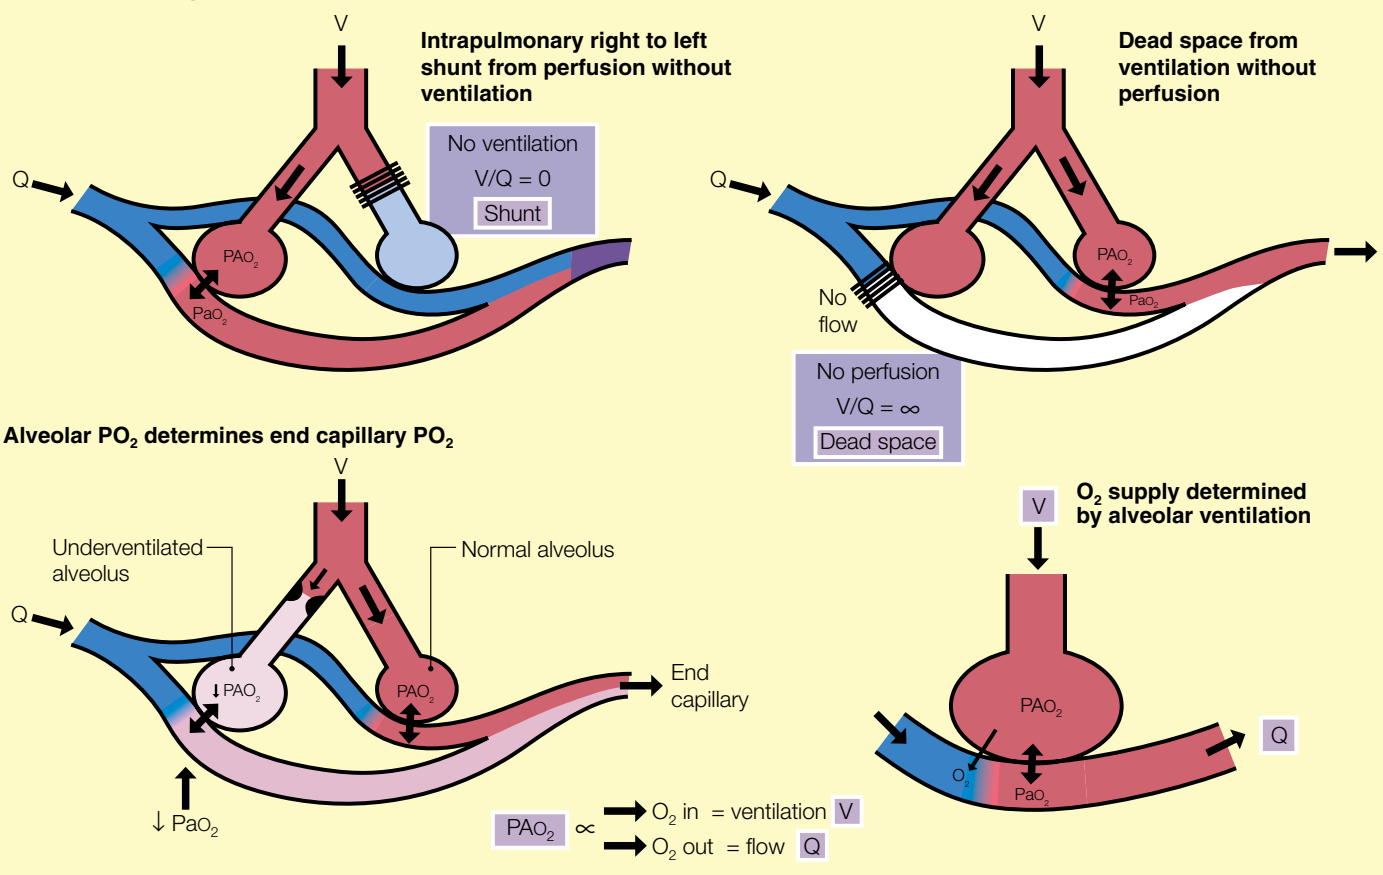
Ventilation increases from the apex to the base. Dependent parts of the lung are on a more compliant part of the pressure–volume curve



Perfusion increases on moving down the lung. The low-pressure pulmonary circulation is affected by gravity

9

Ventilation and perfusion



In an ideal alveolus capillary P_{O_2} (Pa_{O_2}) comes close to alveolar P_{O_2} (PA_{O_2}). PA_{O_2} is determined by the balance between the rate of O_2 uptake by the pulmonary capillaries (Q) and continued supply of O_2 by alveolar ventilation (V). The rate of O_2 removal is determined by the rate of O_2 consumption (metabolic rate). In an under-ventilated alveolus, the supply of O_2 is reduced. If O_2 uptake continues, the result is for PA_{O_2} to fall and so Pa_{O_2} will fall

10

Hypoxic pulmonary vasoconstriction (HPV): when the alveolar PO_2 or, to a lesser extent, the mixed venous PO_2 decreases, smooth muscle contraction occurs in small pulmonary arterioles. This diverts blood from unventilated areas to better-ventilated areas and helps minimize the effects of V/Q imbalance. Volatile anaesthetic agents as well as many vasodilators (e.g. sodium nitroprusside) inhibit HPV, worsening the effects of V/Q mismatching.

Respiratory effects of IPPV

Changes in distribution of ventilation: the preferential ventilation of the non-dependent parts of the lung in the anaesthetized, supine position is increased by IPPV. The non-dependent areas are more compliant than the dependent zones after induction of anaesthesia and muscle relaxation, and so preferentially expand in response to positive pressure. This effect is further exaggerated if the lungs have an increased density, as in the adult respiratory distress syndrome or in patients with cardiogenic pulmonary oedema. It is also compounded by compression of basal areas of the lung as a result of the upward displacement of the paralysed diaphragm.

Changes in distribution of perfusion: normal distribution of perfusion is usually maintained during IPPV. However, in the presence of high intra-alveolar pressures, compression of the alveolar capillaries occurs and flow stops. Capillary pressures are lower in the upper zones because of the effect of gravity on the low-pressure pulmonary circulation, and these zones are particularly vulnerable to increases in airway pressure. These preferentially ventilated upper zones now have much reduced flow and V/Q mismatch is further increased. This is more likely to occur when mean airway pressures are high and with the use of positive end-expiratory pressure (PEEP).

PEEP is the application of a residual positive pressure to the airway at the end of expiration instead of atmospheric pressure. This improves oxygenation by increasing FRC and thus reduces the effects of airway closure and lung volume reduction on V/Q relationships. PEEP may also reopen previously collapsed lung units and maintain their patency (alveolar recruitment).

Barotrauma is the result of excessive pressure gradients between alveoli and the interstitium, with rupture occurring. Air can spread along perivascular spaces into the mediastinum, pericardium, up into the neck, down into the abdomen or into the pleural cavity (pneumothorax). Risk factors include:

- large tidal volumes
- excessive inflation pressures, especially > 40 cm H_2O
- use of PEEP
- non-uniform lung disease
- increased airway resistance.

Recently, the term ‘volutrauma’ has been used in the ICU setting. This refers to overdistension of ‘normal’ areas of the lung by the high pressures required to inflate the diseased areas.

Other respiratory effects of IPPV: during general anaesthesia with intubation and ventilation, there is loss of the ability to cough and so secretions are retained. Inhaled anaesthetics and cold, dry gases inhibit ciliary activity in the bronchial tree, again leading to a tendency to retain secretions. In addition, if the anaesthetic gases are not warmed and humidified, the respiratory tract can be a major source of heat loss.

Cardiovascular effects of IPPV

The major effect of IPPV is to reduce cardiac output via a reduction in venous return. In most patients, this can be counteracted by fluid loading (e.g. 500−1000 ml crystalloid). There are additive effects on the pulmonary circulation and heart, but their relative contribution is thought to be minor, and significant changes occur only with high mean airway pressures.

Cardiac output: a decrease in cardiac output occurs when beginning IPPV, which can cause significant hypotension. The increase in mean intrathoracic pressure during inspiration with positive-pressure ventilation causes the low-pressure veins in the chest to be compressed. Cardiac output falls because of the reduction in venous return to the heart. The decrease in cardiac output and mean arterial blood pressure can be particularly marked in patients who are hypovolaemic or have limited cardiovascular reserve and is further worsened by PEEP. The expected fall in cardiac output can be reduced by prompt infusion of fluids to increase central venous pressure and maintain venous return.

Effects of IPPV on pulmonary vascular resistance and the heart: increased pulmonary vascular resistance occurs when airway pressures are high, from direct compression of alveolar capillaries. As pulmonary vascular resistance increases, there is an increase in right ventricular afterload and right ventricular end-diastolic volume. If end-diastolic volume becomes significantly raised, bulging of the intraventricular septum into the left ventricular cavity can occur, reducing left ventricular compliance and reducing left ventricular stroke volume. In addition, the increased wall tension in the right ventricle, coupled with a reduced arterial pressure, can compromise right ventricular perfusion in compromised patients. The final effect is right heart strain further augmenting a reduction in cardiac output. Paradoxically, in patients with existing heart failure, the increase in transpulmonary pressure transmitted to the thorax can occasionally help to off-load the left heart by reducing venous return from the pulmonary veins, thus reducing left atrial pressures. Left ventricular performance may then improve.

Other effects of IPPV

Renal: mechanical ventilation causes a reduction in urine volume, and thus sodium and water retention. A fall in renal perfusion pressure associated with the reduced cardiac output and a rise in renal venous pressure as a result of impedance of venous return, along with increased levels of antidiuretic hormone associated with IPPV, are thought to be important. An increase in sympathetic stimulation triggered by baroreceptors sensing the changes in pressure and flow may also contribute. The renal effects are persistent and are not fully reversed with fluid infusion or improvement in cardiac output.

Liver: the reduction in cardiac output and increased venous pressure leads to a fall in hepatic blood flow proportional to the drop in cardiac output. Hepatic blood flow may be reduced by up to 50% and hepatic metabolism is reduced. This can be reversed by infusion of fluid. The increased venous pressure caused by the positive intrathoracic pressure can cause hepatic venous congestion, and hypocapnia will lead to vasoconstriction.

Endocrine: antidiuretic hormone levels are increased during IPPV, with corresponding increases in renin and angiotensin levels. This contributes to salt and water retention.

Practical aspects of positive pressure ventilation

Adequate ventilation requires an adequate tidal volume and minute ventilation to be delivered, time for gas distribution and gas exchange to occur, and sufficient time for expiration to be completed. Adequate ventilation results in a normal $PaCO_2$ tension (4.5−5.0 kPa), and in anaesthetic practice this is usually estimated by the end-tidal carbon dioxide tension ($P_{E'}CO_2$). In patients with normal lungs the arterial $PaCO_2$ is about 0.5 kPa greater than the $P_{E'}CO_2$. $P_{E'}CO_2$ is measured from alveolar gases from all ventilating lung units with a spread of V/Q ratios. Units with high V/Q ratios have a reduced alveolar PCO_2 and so ‘dilute’ the gas from units with a V/Q ratio close to unity. This relationship is lost in patients with lung disease; arterial blood gas monitoring may be required in these patients. The minute volume and tidal volumes used should aim for peak airway pressures of 15−20 cm H_2O in most patients.

Arterial oxygenation is determined primarily by the inspired oxygen, which should never be below 30% (FiO_2 0.3) initially. The required inspired oxygen is determined by the saturation recorded by the pulse oximeter; 95% or greater is appropriate. After monitoring the effect of the initial settings in each patient, appropriate alterations can be made to suit the individual.

Initial IPPV settings for routine general surgical cases

Adults:

- flow generator mode of ventilation
- tidal volume 8−10 ml/kg
- respiratory rate 10−12 breaths/minute
- inspiratory/expiratory (I:E) ratio 1:2
- Fi_{O_2} 0.4 (40% oxygen)
- maximum airway pressure 30 cm H_2O.

If a circle absorber system is in use, an initial fresh gas flow of 6 litres/minute should be used.

A tidal volume of 8−10 ml/kg is appropriate for adults. An I:E ratio of 1:2 allows sufficient time for equilibration in inspiration and time for full expiration, in relation to the TC of normal lung. A starting inspired oxygen concentration of 40% helps to prevent a fall in PaO_2 and overcomes the expected increase in V/Q mismatch that occurs during IPPV. Barotrauma is avoided if peak pressures are kept below 30 cm H_2O.

Flow generators are the preferred method of ventilation in adults. A reliable and predictable tidal volume and minute ventilation can be achieved even when there are alterations in lung mechanics from pre-existing lung disease or when temporary peroperative changes occur related to the effects of patient positioning and surgery.

Children:
- pressure generator mode of ventilation
- inspiratory pressure 20 cm H_2O irrespective of weight
- respiratory rate 30−40 breaths/minute for neonates; 20−25 breaths/minute for infants; 15−20 breaths/minute for older children
- I:E ratio 1:2
- Fi_{O_2} 0.5 (50% oxygen).

Owing to their increased basal metabolic rate relative to their weight, neonates and infants have an oxygen requirement (6 ml/kg/minute) twice that of adults. As a result, they have a high carbon dioxide production, hence the need for a high respiratory rate. Young children also have a reduced FRC, high CC and relatively high airways resistance with low respiratory compliance. Their increased metabolic rate and relatively low FRC means they have limited oxygen stores and so their arterial oxygen saturation falls rapidly if ventilation is inadequate. Loss of respiratory gases as an air leak from around their uncuffed endotracheal tube is expected and indeed desirable. It provides evidence that the endotracheal tube is not so tightly fitting as to cause tracheal mucosal compression at the level of the cricoid ring. Pressure generators, which compensate for gas losses and limit peak pressures, are commonly used in paediatric anaesthesia. At puberty, differential growth of the cricoid ring and laryngeal aperture means that the larynx becomes the narrowest part of the airway as in adults, so cuffed tubes may then be used.

Safety issues

Detection of ventilator disconnection

Anaesthetized, paralysed patients are wholly dependent on the ventilator and the anaesthetist to keep them alive. In this respect, a paralysed patient is much more vulnerable than one who is breathing spontaneously. The anaesthetist should be alerted to a disconnection promptly by a disconnect alarm, which may also indicate when inadequate ventilation is occurring.

Disconnections can be sensed by:
- loss of the rhythmic increase in airway pressure
- reduction in expired gas volume
- loss of expired carbon dioxide.

Monitoring of airway pressures and exhaled CO_2 are part of minimum monitoring requirements during mechanical ventilation.

Airway pressure sensors are either aneroid gauges or, more commonly, electronic pressure transducers. The gauge the anaesthetist uses for monitoring and the alarm system are often separate devices. Airway pressure alarms detect an increase above a threshold pressure. If an increasing pressure that exceeds the threshold is not detected in the preset time, an alarm is sounded. This system does not normally detect a blocked endotracheal tube, but an alarm for the excessive inspiratory pressures generated in this scenario is usually incorporated in the same system.

Expired tidal volume or expiratory flow over time can also be measured. A minimum preset volume must be exhaled at a frequency above the preset minimum rate or the alarm will be triggered. Expired tidal volume is usually measured by integrating the expired flow signal.

Capnographs are fitted with limit alarms and often with apnoea detectors, which detect apnoea from the carbon dioxide waveform. In addition, respiratory movements are sometimes sensed via ECG leads and as a very late indicator, pulse oximeters will alarm if significant arterial desaturation occurs.

Ventilator checks

The anaesthetist is responsible for the state of the equipment he or she uses. It is expected that equipment is systematically checked before use. Although on occasion this may be delegated to trained assistants, the final responsibility lies with the anaesthetist. To this end, guidelines for machine checks have been issued by the Associaton of Anaesthetists of Great Britain and Ireland (Figure 11). With the increasing use of sophisticated, electronically controlled anaesthesic machines and ventilators, a ‘generic’ checklist must be used only with reference to the manufacturer’s suggested protocol for each machine.

Ventilator checks

- Ensure that ventilator tubing is correctly configured and securely attached
- Set the controls for use and ensure that an adequate pressure is generated during the inspiratory phase
- Check that the pressure relief valve functions
- Check that the disconnect alarm functions correctly
- Ensure that an alternative means to ventilate the patient’s lungs is available

Breathing Systems

Gordon W G French

Gordon W G French is Consultant Anaesthetist at Northampton General Hospital, UK. He qualified from Glasgow University and trained in Nottingham and Oxford. His research interests include the detection of silent myocardial ischaemia perioperatively, the use of starches for volume preloading in obstetric anaesthesia and modes of paediatric resuscitation teaching.

A 'breathing system' is the name given to apparatus that delivers and removes gas and vapour to or from a patient. The three main functions of the breathing system are:

- to supply adequate oxygen
- to remove carbon dioxide
- to supply adequate inhalational anaesthetic agent.

The perfect system has yet to be developed but the ideal breathing system should:

- be simple and safe
- deliver the intended mixture
- allow manual and intermittent positive-pressure ventilation (IPPV) in all age groups
- be efficient (able to use low gas flows)
- protect the patient from barotrauma
- be sturdy, lightweight yet compact
- be easy to scavenge
- be cheap.

Essential components of a breathing system

Tubing (hose): originally this was carbon-impregnated rubber (an antistatic design), corrugated to prevent kinking, but it was heavy and prone to perishing. Modern tubing is usually plastic, disposable or designed for single use, and often has a smooth inner bore that reduces resistance to airflow. Early systems had various means of inter-linking tubes, including tapered metal connectors that pushed into each other and screw mountings. These were manufactured in various sizes, with many systems being non-interchangeable, clearly a dangerous situation. The International Standards Organization (ISO.5356, 1987) and British Standard (BS 3849) recommend the following sizes for all breathing systems:

- 30 mm tapered connections for scavenging hose to breathing systems
- 22 mm taper for connections within breathing systems
- 15 mm connections between the breathing system and the endotracheal tube.

An upstream 'male' connector traditionally fits into a downstream 'female' part. The ISO 15 mm standard connector is cumbersome for small paediatric endotracheal tubes (2–6 mm internal diameter). Smaller, lighter 8.5 mm connectors may be used, which have adapters to connect to the 15 mm standard system. Tapered connections between plastic, metal and rubber can be 'locked' by giving them a slight twist after connecting. Systems designed for repeated use can usually be autoclaved, which does not affect their connectors. Single-use systems often distort if heated, making the connectors unsafe.

There is controversy among practising anaesthetists as to exactly what 'for single use only' means. Clearly it would be expensive to use a new breathing system for each patient, and almost certainly unnecessary. Many departments employ a cost-effective compromise by using a new disposable antibacterial filter for each patient, but only changing the actual breathing system weekly. It may be changed more often depending on clinical need (e.g. after use in a patient with known lung infection such as tuberculosis).

Reservoir bag: this stores fresh gas when the patient is exhaling and accommodates the high peak inspiratory flow rates during inspiration. Made of rubber or plastic, the common adult size is 2 litres and 0.5 litres for children, but some ventilators use other sizes up to 6 litres. The bag's motion allows observation of ventilatory patterns but does not reflect the tidal volume accurately. As the bag stretches, the pressure in its walls reaches a limit of about 40 cm H_2O (Laplace's law); further distension does not result in greatly increasing pressures. This partly protects the lungs from barotrauma should the breathing system outlet become obstructed, such as when the adjustable pressure-limiting (APL) valve is left fully screwed down. An open-ended reservoir bag is commonly used in paediatric circuits, allowing manual ventilation and assessment of the compliance of a child's lungs (e.g. Mapleson type F).

APL valve: this is a one-way, spring-loaded valve consisting of a thin, lightweight disc (made of hydrophobic material) held by an adjustable spring against knife-edged seating. This arrangement (Figure 1) reduces the area of contact between the disc and the seating, lessening any surface tension that condensed water vapour might create, causing the disc to stick. The disc prevents movement of air into the system when the patient inhales, but opens at low pressure (about 1 cm H_2O) to allow exhaled and surplus gas to be vented during expiration. When fully screwed down, modern valves open at about 60 cm H_2O positive pressure, acting as a safety feature.

Expired gases can be conveniently scavenged by surrounding the valve with a hood. If the valve is sucked open continuously by a faulty scavenging system, a huge increase in the dead space of the apparatus will result. The APL valve should be fully open during spontaneous respiration, partially closed during manual IPPV and fully closed during ventilator IPPV.

Cross-section of an adjustable pressure-limiting valve

1

Classification of breathing systems

The historical development of breathing systems was largely based on the intuition and practical experience of individual anaesthetists. As a result, there are many different systems. One classification based on function is described below.

Non-rebreathing systems

Non-rebreathing systems use one-way valves to separate inspired and expired gases. When the patient inspires, the expiratory valve closes and the inspiratory valve opens, allowing inhalation of fresh gas. There is usually a reservoir bag on the inspiratory limb, which provides enough gas for the maximum peak inspiratory flow rate (often > 30 litres/minute), and collects fresh gas when the inspiratory valve is closed in expiration. It may also allow for manual-assisted ventilation. Resuscitation devices commonly include a bag constructed of foam-lined rubber or silicone, which remains inflated in the resting state, in addition to a thin-walled reservoir bag. Manual ventilation is provided by squeezing this bag, which automatically refills from the oxygen inlet and reservoir bag when hand pressure is released. The fresh gas flow (FGF) should at least equal the patient's required minute volume. Examples are resuscitation devices such as the Ambu bag, Laerdal silicone resuscitator, drawover units and the 'Triservice' apparatus.

Rebreathing systems

In rebreathing systems, the inspiratory and expiratory gases can mix in the tubing and re-inhalation of expired gas can occur. Rebreathing refers to inhaling part or all of the previously exhaled tidal volume. In particular, it is the inhaling of previously exhaled carbon dioxide (i.e. alveolar gas) which is of most concern to the anaesthetist. A system is efficient if it can preferentially vent alveolar gas, retaining dead space (non-carbon-dioxide-containing) gas and thus use an FGF that approximates to the patient's alveolar minute ventilation. The extent of carbon dioxide rebreathing thus depends on the FGF flushing the expired gas away before the next inspiration. The normal respiratory cycle consists of an inspiration followed immediately by expiration, but there is then an expiratory pause. It is during this period that the FGF flushes the system. In 1954, Mapleson classified five commonly used systems according to their efficiency at eliminating expired carbon dioxide in spontaneously breathing patients (Mapleson systems A–E). An F system was added in 1975 (Figure 2).

The Mapleson classification of anaesthetic breathing systems and adaptations

Mapleson type		Recommended fresh gas flow	General points
System A **a** Magill **b** Lack **c** Parallel Lack		**Spontaneous** AMV (70 ml/kg/minute) **IPPV** 2–3 x AMV	**a, b, c** Efficient for spontaneous, not for IPPV Heavy, especially at patient end Unsuitable for children < 25 kg because large dead space **b** Lack: coaxial, APL and reservoir bag at machine end Inspiratory gases through outer (30 mm) tube Expiratory via inner (14 mm) **c** Parallel Lack: separate inspiratory and expiratory tubes
System B		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	FGF near patient end. Performs similarly in both modes. Seldom used
System C		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Similar arrangement to system B. The large-bore tubing to bag is shorter **a** Waters' 'to and fro' circuit: inefficient but small size and simplicity means useful for resuscitation and patient transfers **b** Waters' canister: heavy because incorporates a 1 lb soda lime container between bag and mask or ET tube Channelling occurs if incompletely packed. Nylon pot scourer compresses at bag end. Filter at patient end prevents soda lime dust movement. NB Filter to patient = dead space. Easily sterilized. Now little used. Superseded by circle absorber systems
System D **a** Bain		**Spontaneous** 2–3 x AMV **IPPV** AMV (70 ml/kg/minute)	Inefficient for spontaneous but good for IPPV Manley ventilator on spontaneous ventilation mode is a Mapleson D Safety problems include kinking of inner tube Disconnection of inner tube increases dead space. Both lead to hypoxia and hypercarbia **a** Bain: coaxial D. Length of tube does not affect properties (180–540 cm). FGF through inner tube (opposite to Lack) Ventilate with Penlon 200 replacing bag. Connecting tube long > 500 ml (usually 1 m) to prevent driving gas entering circuit. Lightweight, easy to scavenge. Ga in expiratory limb warm inspiratory gases
System E		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Used for children up to 30 kg. Low resistance, small dead space, lightweight, no valves. Inefficient but used for spontaneous and IPPV. Expiratory limb is reservoir and should be > V_T to prevent air entraining Ayre's T-piece: developed for neuro/cleft palate surgery
System F		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Jackson Rees modification. Reservoir bag allows rate and chest compliance to be monitored, ventilation by hand and continuous positive airway pressure application. Barotrauma and humidification a problem

AMV, alveolar minute volume; FGF, fresh gas flow; IPPV, intermittent positive-pressure ventilation; V_T, tidal volume

2

Mapleson A: classically describes the Magill system. The APL valve and any scavenging device make this system cumbersome at the patient's end. Lack solved this problem by creating a co-axial arrangement where the expiratory gases were carried up an inner hose to the APL and scavenging system, both of which were thus distant to the patient. However, this system is bulky, even though it is less weighty at the patient's end. In addition, if the inner tube breaks and this goes unrecognized, the system may become dangerous because carbon dioxide elimination is drastically reduced. It is also difficult to use with a ventilator. A parallel hose breathing arrangement (parallel Lack) eliminates this problem.

The Mapleson A system is an efficient system for spontaneous ventilation because it selectively vents alveolar gas through the APL valve. The first part of the exhaled tidal volume (non-carbon-dioxide-containing dead space gas) is retained in the system and is available for inhalation during the next breath. This efficiency is lost when the system is used for IPPV.

Mapleson B and C: in both systems the FGF, reservoir bag and APL are near the patient, creating a compact and portable system. However, they are both inefficient and only the Waters' 'to and fro' system is commonly used, mainly for patient transport and in postoperative recovery units.

Mapleson D: exhaled gas passes into a reservoir bag along with the fresh gas, so rebreathing occurs unless the FGF is high. The system is efficient for IPPV.

The Bain system is a coaxial version, which is particularly useful for limited-access surgery because of its light weight and the fact that the tubing can be lengthened without affecting the flow characteristics. The system can be connected to a ventilator by replacing the reservoir bag with tubing connected to a ventilator such as the Penlon Nuffield 200. The tubing should be of sufficient length to prevent the ventilator driving gas entering the breathing system (in practice > 500 ml or 1 metre of standard hose). In this system, the FGF is along a narrow internal tube (the opposite of the Lack system), and the expired gas moves along the outer tube, usefully heating up the dry FGF. It is vital that the inner tube is intact because disconnection leads to a huge increase in dead space and possible hypercarbia or hypoxia.

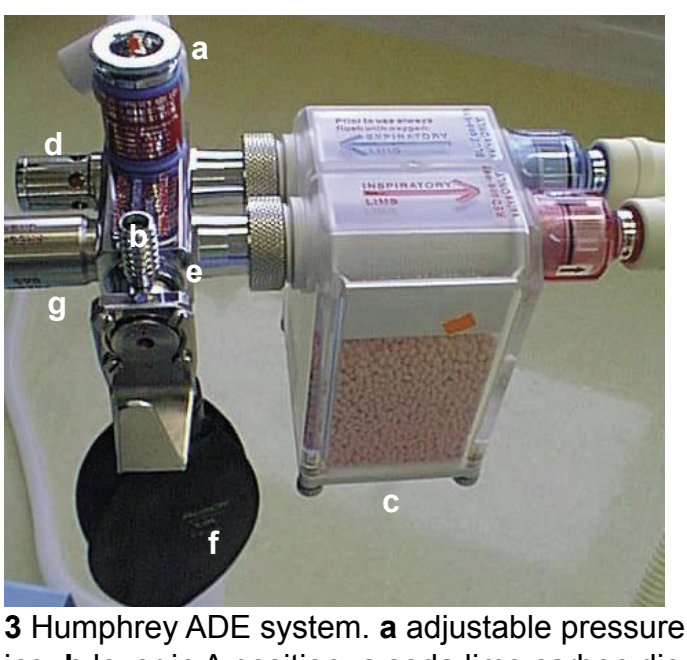
Mapleson E: the Ayre's T-piece is a valveless, lightweight system, with low internal resistance and dead space. In inspiration, gas is inhaled from both the inspiratory and expiratory limb. The volume of the expiratory limb needs to be at least equal to the tidal volume or air may be entrained. If it is too large, then rebreathing can occur because expired gas may not have vented to air before the next inhalation. Occluding the outlet intermittently allows IPPV.

Mapleson F: adding an open-ended reservoir bag to the expiratory limb of the Ayre's T-piece allows manual control of ventilation, observation of breathing and assessment of lung compliance. Some continuous positive airway pressure (CPAP) is also achieved with the system during spontaneous respiration, which, in an infant, may help to increase the functional residual capacity. Scavenging is a problem for both the Mapleson E and F systems. The routine use of capnography allows the FGF to be tailored precisely to achieve normocapnia in individual patients for all these systems.

Humphrey ADE system (Figure 3) is one of a number of hybrid systems that has become popular. It is a low-flow multipurpose system that appears to combine the best of the Magill, Lack and T-piece systems but not their disadvantages. It is cost effective in all modes, being more efficient than the Magill for spontaneous ventilation. The 15 mm, smooth-bore tubing has one-quarter of the resistance to flow of 15 mm corrugated tubing, which allows use in adults and children; 8.5 mm tubing is available for neonates. The reservoir bag, APL, scavenging shroud and a pressure-limiting valve are all located on the 'Humphrey block'. The system tubing connects to the patient via a symmetrical Y-piece, which probably accounts for much of its efficiency as it produces less turbulence than the conventional Magill–patient interface. One lever allows conversion from A mode to E mode, with only a slight increase in FGF being required to eliminate rebreathing. In E mode, the reservoir bag and APL are isolated from the system, and the expiratory tubing acts as the reservoir limb of a T-piece. This is open to the atmosphere via a port on the block to which a bag squeezer ventilator such as the Manley Servovent or Penlon Nuffield 200 or 400 can be attached. The D mode could be engaged by simply attaching a reservoir bag and APL to this port for spontaneous ventilation, but this is much less efficient than the A mode.

The APL valve provides positive end-expiratory pressure of 1 cm H_2O without increasing the airway resistance of the apparatus. The APL valve does not have to be screwed down for IPPV, except if used in the A mode. However, there is a long orange valve seat stem that can be temporarily held down instead. This also moves slightly during spontaneous respiration and gives a visual indication of respiratory movement. A separate 60 cm H_2O pressure-limiting valve lies behind the APL valve on the block. This is always in-line, whatever mode is being used. The system can be fixed on to the anaesthetic machine via a locking nut. A 500 g soda lime canister (lifespan 12 hours), which has a low resistance to flow and is autoclavable, can be fitted in front of the block. This circle system arrangement requires no other alterations in FGF for adults or children.

The entire system is MRI compatible, being made of plastic and brass. In addition, tubing lengths of over 3 m can be used without compromising its function. The main disadvantages are that it protrudes out of the anaesthetic machine, is heavy and can be knocked, which theoretically could fracture old anaesthetic machine outflow pipes.



3 Humphrey ADE system. **a** adjustable pressure limiting valve with scavenging; **b** lever in A position; **c** soda lime carbon dioxide absorber; **d** pressure relief (60 cm H_2O) valve; **e** port for ventilator; **f** reservoir bag; **g** fresh gas flow. Fresh gas flow: A mode (lever up) = 50 ml/kg/minute; E mode (lever down) = 70 ml/kg/minute. Children start at 3 litres/minute.

Systems using carbon dioxide absorbers

The circle system (Figure 4) was first described in the 1920s. It uses soda lime to absorb exhaled carbon dioxide. Partial rebreathing of other exhaled gases can thus be undertaken, depending on the arrangement of the components and the FGF.

Circle systems can be classified as follows:

- semi-open – no rebreathing, very high FGF, APL valve wide open
- semi-closed – rebreathing occurs, low flow, APL valve partly closed
- closed – FGF inflow exactly matches uptake by patient; complete rebreathing of exhaled gases after carbon dioxide uptake and APL valve fully closed.

A circle system consists of:

- FGF source
- inspiratory and expiratory unidirectional valves
- inspiratory and expiratory corrugated tubes
- a Y-piece connector
- an APL valve or pop-off valve
- a reservoir bag
- a canister containing a carbon dioxide absorbent.

Fresh gas enters the circle by a connection from the common gas outlet of the anaesthetic machine. Various arrangements of components are possible, but there are three golden rules to prevent carbon dioxide rebreathing.

- A unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs of the circuit. These valves commonly have a clear plastic cover so that their correct movement can be observed during use.
- The FGF cannot enter the circuit between the patient and the expiratory valve.
- The APL valve cannot be located between the patient and the inspiratory valve.

The most efficient circle system has the unidirectional valves near the patient and the APL valve just downstream from the expiratory valve. This arrangement conserves dead space gas and preferentially eliminates alveolar gas. The advantages and disadvantages of a circle system are listed in Figure 5.

Nitrogen washout – at the start of anaesthesia, non-nitrogen-containing gas (unless medical air is being used) is inspired and body nitrogen passes into the lungs. This effectively reduces the oxygen concentration in the alveoli and circle system, producing a potentially hypoxic mixture. The use of high flows of gas at the start of anaesthesia can 'washout' this nitrogen. Pre-oxygenation with 100% oxygen for 7–10 minutes is also effective and can theoretically then allow low circle FGF to be used from the start. Basal metabolic oxygen requirements are about 250 ml/minute, but to allow for leaks in the circle and patient variability, 500 ml/minute oxygen is the minimum recommended flow rate. 'Low flow' anaesthesia is usually regarded as less than 1 litre/minute FGF.

The uptake of volatile agents is highest initially. Fast FGF inflows and large minute volumes produce fast induction of anaesthesia as well as facilitating denitrogenation. As equilibrium is reached, the expired concentration of volatile agent begins to reflect the inspired value, and flows can be reduced. The exhaled gases are added to the fresh gas and have a dilutional effect on the concentration of oxygen and vapour, which will be proportionally greater at low flows. A potentially hypoxic alveolar concentration of oxygen can develop as the FGF reduces. Using an inspired oxygen concentration of 50% to prevent these low oxygen levels in the circle was customary before the advent of in-line gas/vapour analysers. However, this was associated with an increased chance of awareness if the inspired volatile concentration was not increased to compensate for the lower inspired nitrous oxide and volatile concentrations.

Vaporizers can be placed outside (VOC) or inside (VIC) the circle (Figure 6). Most modern vaporizers tend to be outside the circle (e.g. Back bar units such as a TEC vaporizer) and are accurate at low flows. With this set-up, the concentration of volatile gas in the circle is reduced with increased patient uptake and low FGF (due to the dilutional effect of exhaled gas), until uptake reduces and equilibration begins to occur. With a vaporizer in the circle (e.g. Goldman vaporizer), both the fresh and exhaled gas (which already contains vapour) pass through the vaporizer. When the FGF is low and alveolar ventilation high, the concentration of volatile will rise. Thus the concentration of the alveolar and circle vapour is a function of ventilation. In spontaneous ventilation, with deepening anaesthesia and depression of ventilation, the concentration of volatile gas will fall and result in the patient becoming lighter, a useful safety feature. However, low flow controlled ventilation may result in high levels of volatile gas.

Future developments in circle technology may incorporate the VIC arrangement but use a system of vapour injectors instead of the vaporizer. This would be linked to a feedback mechanism incorporating circuit vapour analysis.

Carbon dioxide absorption – closed or semi-closed circle systems require carbon dioxide absorption to make rebreathing possible. Desirable features of a carbon dioxide absorption mechanism are lack of toxicity (intrinsic or with common anaesthetics), low resistance to air flow, low cost, ease of handling and efficiency. Soda lime and baralyme are the two formulations commonly used for carbon dioxide absorption (Figure 7). Both need water but because baralyme contains water as a barium hydroxide octohydrate salt it performs better in dry climates. Soda lime (but not baralyme) is capable of some regeneration after exhaustion. Maximum absorbency of both systems is 26 litres of carbon dioxide per 100 g absorbent.

Dyes (acids or bases) are also added, which change colour as the hydrogen ion concentration changes:

- ethyl violet (colourless to violet; fluorescent light deactivates it)
- phenolphthalein (white to pink)
- Clayton yellow (red to yellow)
- ethyl orange (orange to yellow)
- mimosa z (red to white).

The chemical reaction in soda lime is:

$CO_2 + H_2O \rightleftarrows H_2CO_3$

$H_2CO_3 + 2NaOH\ [KOH] \rightleftarrows Na_2CO_3\ [K_2CO_3] + 2H_2O + heat$

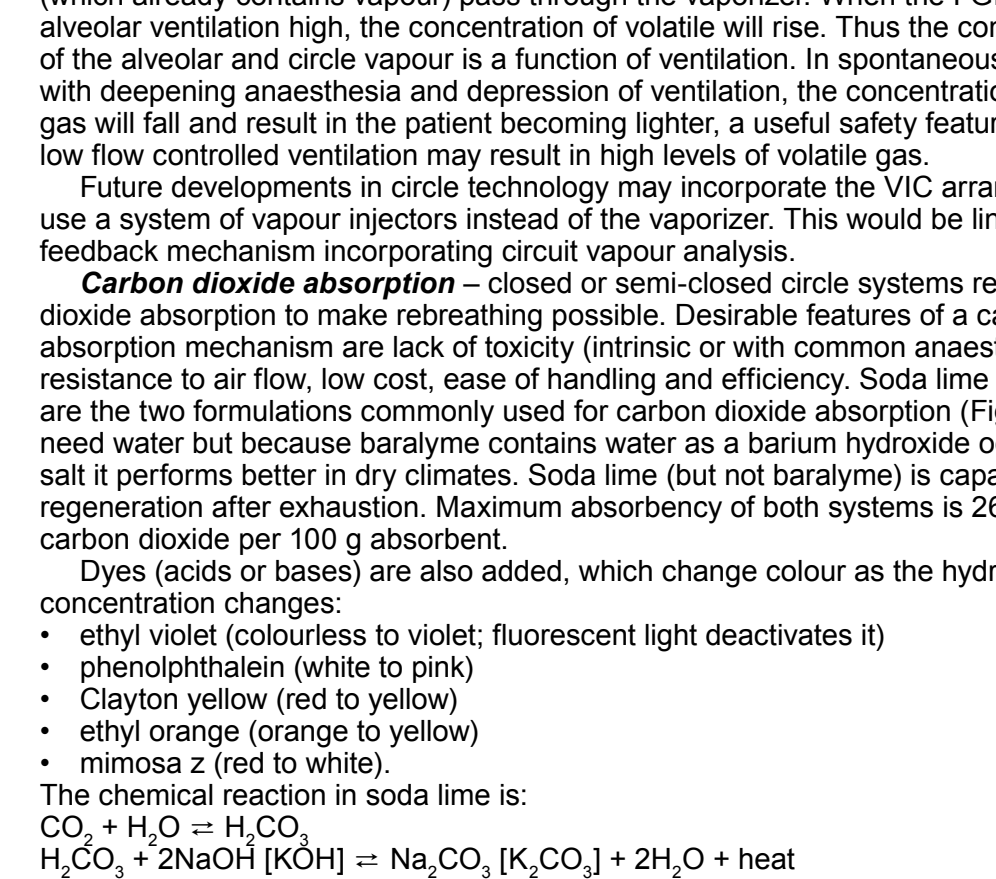
$Na_2CO_3\ [K_2CO_3] + Ca(OH)_2 \rightleftarrows CaCO_3 + 2NaOH\ [KOH]$

Some carbon dioxide reacts directly with calcium hydroxide but this is much slower. In baralyme the carbon dioxide acts directly with barium hydroxide and much more water is released. In the UK, the size of granules is 4–8 mesh (a compromise between surface area for absorption and air flow resistance). Mesh refers to the number of openings per linear inch in a sieve through which the granules pass. A 4-mesh screen indicates four quarter-inch openings per linear inch.

Soda lime and baralyme are not inherently toxic, but at low flows intrinsically produced acetone can accumulate and has been linked to nausea and vomiting. Carbon monoxide can also accumulate at low flows of dry gas (e.g. oxygen running overnight) leading to the formation of carboxyhaemoglobin.

The volatile agent trilene degrades into dichloroacetylene (a neurotoxin causing cranial nerve damage and encephalitis) and phosgene (a potent pulmonary irritant causing adult respiratory distress syndrome).

Sevoflurane and halothane are slightly unstable in soda lime, the rate of degradation increasing with temperature. Sevoflurane degrades into several compounds. Compound A (a vinylether) has been associated with lung haemorrhage and renal tubular necrosis in rats, but neither compound has been shown to cause problems in humans. Many of these problems are resolved by flushing the system regularly.



Properties of a circle system

Advantages	Disadvantages
• Heat/moisture conservation • Easy scavenging • Reduced cost • Small dead space • Good for long cases	• Multiple connections • Valves can stick • Open – leads to rebreathing • Closed – leads to asphyxia • Bulky • Inefficient for short cases • Soda lime changeover a hazard • Gas analyser necessary for accuracy • Potential for infection

5

Properties of vaporizers

Inside the circle	Outside the circle
• Low internal resistance • Low efficiency desirable • Higher concentrations at low fresh gas flow	• High internal resistance (plenum) • High efficiency desirable • Lower concentrations at low fresh gas flow (diluted)

6

Properties of soda lime and baralyme

Soda lime	Baralyme
• Calcium hydroxide (94%) • Sodium hydroxide (the catalyst) (5%) • Potassium hydroxide (1%) • Silica (calcium and sodium silicate harden it and reduce dust formation)	• Calcium hydroxide (80%) • Barium hydroxide (the catalyst) (20%) • More stable so does not contain silica • Denser and 15% less efficient than soda lime

7

System checks

All systems should be checked visually for broken parts and disconnections and a push-and-twist connector test performed. In addition, there are checks specific to individual systems.

- Occluding Mapleson types B and C causes their reservoir bags to fill, testing the air-tightness of the system. Releasing the valve causes the bag to deflate if the valve is functioning normally.
- The Bain system inner tube can be tested in two ways. Occluding the end of the inner tube causes the rotameter bobbin to dip and the pressure alarm/valve to blow if there are no leaks/disconnections up to that point. Occluding the patient end of the system will fill the reservoir bag, testing overall air- tightness. Releasing the occlusion causes the bag to deflate, then continue to empty as a result of the negative pressure caused by the Venturi-effect of the fast FGF leaving the inner tube. The connection of the inner tube can also be visually inspected because the outer corrugated tubing is often made from transparent plastic. This outer tubing may also be temporarily disconnected and a secure inner tube connection confirmed.
- To carry out the low-pressure circle leak test, the end of the system should be occluded and the APL valve closed off. The system is filled using the oxygen flush until the airway pressure gauge registers 30 cm H_2O. The pressure should remain at 30 cm H_2O if no leaks are present.

Cleaning, Disinfection and Sterilization of Equipment

Duncan Parkhouse
Jonathan Warwick

Duncan Parkhouse is a Military Anaesthetic Trainee. He joined the Royal Army Medical Corps as a medical cadet while a medical student at University College Hospital, London. During his anaesthetic training he has spent time at both military and NHS Hospitals including St Mary's Hospital, the Brompton Hospital and the National Hospital for Neurology and Neurosurgery, London.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

Hospital-acquired infections have significant implications for the morbidity and mortality of patients as well as for the economics of health care. The protection of patients and medical staff from medical equipment that has come into contact with patients or their body fluids, requires the adoption of various processes enforceable by law. Changes in these laws and guidelines, published by the Department of Health and the Medical Devices Agency, are expected in the near future. One of the reasons for the introduction of new guidelines is the development of new variant Creutzfeldt–Jakob disease, which is resistant to the standard methods of decontamination used in hospital sterile services departments.

Contamination is the soiling or pollution of an inanimate object with harmful, potentially infectious, material. In the clinical setting, this is most likely to be organic material or microorganisms. Contamination may place the patient at risk and may adversely affect equipment.

Decontamination is a method used to remove contamination and prevent microorganisms reaching a susceptible site in large enough numbers to initiate infection or other adverse effects. The three methods of decontamination routinely used are cleaning, disinfection and sterilization. The method of decontamination chosen takes into account the infection risk from the reprocessed piece of equipment. The risk is dependent on:

- the amount of contact the patient has with the piece of equipment (i.e. how invasive)
- the susceptibility of the patient (i.e. immunocompromised, potential hypersensitivity)
- the nature, extent and amount of microbial contamination on the piece of equipment (the bio burden).

The type of equipment and its intended use determine the method of decontamination used (Figure 1). The manufacturer should provide instructions for cleaning, disinfection and sterilization techniques that are effective without affecting the performance of the equipment.

It is essential that records are kept to demonstrate the number of times an item has been decontaminated and the effectiveness of each process. The documentation should allow patients to be traced in the event of any malfunction in the decontamination process.

Risk of contamination for equipment and suggested decontamination process

Risk	Application of equipment	Recommendation
High	• In close contact with a break in the skin or mucous membrane • For introduction into sterile body areas	Sterilization
Intermediate	• In contact with mucous membranes • Contaminated with particularly virulent or easily transmissible organisms • Before use on immunocompromised patients	Sterilization or disinfection (Cleaning may be acceptable in some agreed situations)
Low	• In contact with healthy skin • Not in contact with patient	Cleaning

1

'Single use' equipment

Manufacturers should state in the product literature any restrictions on the number of re-uses. Any device deemed by the manufacturer as unsuitable for reprocessing is labelled 'single use'. Devices labelled 'single patient use' may be used for an extended period of time or intermittently on the same patient. Users who disregard the manufacturer's guidelines, for example by reprocessing single use items or reprocessing more than the recommended number of times may be transferring legal liability for the safe performance of that product from the manufacturer to themselves or the organization for which they work.

Many anaesthetic departments routinely use disposable anaesthetic breathing systems marked as single use for extended periods with multiple patients. The wisdom of this practice is the subject of much controversy. The advantages of these breathing systems include safety (often pre-assembled with fewer opportunities for connection errors by the user), lightweight and low cost if used on several patients. The disadvantage is that this practice may contravene the manufacturer's recommendation for single use only and risk transmission of infection. The responsibility for use of equipment marked single use then lies with the hospital. Departments of anaesthesia should have an operational policy on the management of breathing systems marked for single use. This may include:

- the use of a new bacterial (heat and moisture exchanger type) filter for each patient
- change of all breathing systems weekly
- change of breathing system following use on a patient with known or suspected lung infection
- change of breathing system whenever there is visible contamination from blood or body fluids.

Cleaning

Cleaning physically removes contaminants without necessarily destroying microorganisms. It removes organic material and is required before disinfection or sterilization.

Manual cleaning

Manual cleaning does not disinfect. It should be used only when other mechanical methods are inappropriate or unavailable.

Immersion – wearing appropriate protective clothing, the cleaner should submerge the device in compatible water/detergent solution at the correct dilution and not exceeding 35°C. It is important to ensure that the cleaning solution reaches all surfaces of the device, including lumen surfaces. Endoscopic equipment that may be totally immersed for cleaning is marked with a blue line, usually around the eyepiece adjacent to the focussing ring. The device should be brushed or agitated to remove any visible contaminants. The device should be thoroughly drained and rinsed in clean water. This method is generally satisfactory for the routine cleaning of laryngoscopes between patients. Disinfection with an alcohol spray is then commonly used.

Non-immersion – wearing appropriate protective clothing, the cleaner should immerse a cleaning cloth into the detergent solution and wring it out. The equipment should be cleansed by wiping its surfaces. The surfaces should be hand dried using a cloth, hot air dryer or drying cabinet. This method of cleaning is often used for electrical or electronic equipment which cannot be immersed in water.

Mechanical cleaning

Mechanical cleaning uses automated washers to clean equipment and often combines cleaning with disinfection.

Thermal washer – cleaning occurs by continually spraying the equipment with water and detergent during a timed cycle. During the first process, cleaning occurs at 35°C. The second wash heats the surface of the equipment to a minimum temperature of 71°C for a minimum of 3 minutes, 80°C for 1 minute, or 90°C for 1 second to disinfect it.

Chemical washer – the first part of the cleaning process is the same as the thermal washer. Disinfection occurs by exposing the equipment to an approved disinfectant for a particular period of time at less than 60°C. The residue disinfectant is then removed by a rinse cycle.

Ultrasonic cleaners are often incorporated into washer disinfectors. These work by rapidly forming bubbles in the liquid, which immediately collapse (cavitation). This cavitation agitates the liquid, producing a highly effective cleaning system. The process does not disinfect.

Disinfection

Disinfection is used to reduce the number of viable micro-organisms, but it may not kill all microbial agents such as some viruses and bacterial spores.

Low temperature steam disinfection

Low temperature steam disinfection is also known as pasteur-ization. It kills most vegetative microorganisms and viruses by exposure to moist heat. The equipment is exposed to dry saturated steam at a temperature of 73°C for at least 10 minutes at below atmospheric pressure. The low temperature steam kills vegetative microorganisms and some heat-sensitive viruses. It cannot be used for sealed, oily or greasy pieces of equipment or those with sealed cavities due to the variation in pressure.

The advantages of this system are its broad spectrum of disinfection, it is non-toxic, non-corrosive and the equipment is relatively safe and simple to use. The disadvantages are that it requires a trained operator and that much equipment is unsuitable for disinfection in this way. The capital cost of the disinfector is high and the equipment is fixed and not portable.

Boiling water disinfection

Boiling water is an effective disinfectant against many microorganisms. Immersing a piece of equipment in soft water and boiling at 100°C for at least 5 minutes produces disinfection. Boiling inactivates most non-sporing microorganisms, fungi, viruses and some heat-sensitive spores. This method is not used if a better method is available. It is unsuitable for heat-labile pieces of equipment, hollow or porous items into which the water will not penetrate, or tubing over 1 metre in length.

The advantages are that boiling water has a broad disinfecting effect. The process is non-toxic and inexpensive. The disadvantages are that boiling water is a potential cause of injury. Following disinfection, items are wet and unfit for immediate use and must be allowed to dry and cool, which may allow recontamination. There is also no method of checking the efficacy of the process.

Washer disinfectors

Washer disinfectors are described above. They inactivate all microorganisms except bacterial spores and some heat-resistant viruses. They are unsuitable for equipment that may be heat labile or corroded by chemical disinfectant, and for hollow or porous equipment that does not allow all surfaces to come into contact with the chemical disinfectant or heat.

These methods are safe for the operator. There is minimal handling of the equipment by staff and therefore a low risk of recontamination. Another advantage is that they combine cleaning and disinfection. The disadvantages are the high cost of the equipment and the requirement for trained staff.

Liquid chemical immersion

Liquid chemical immersion relies on good contact between the chemical disinfectant and the equipment. The equipment therefore requires thorough cleaning beforehand. It is then immersed in the chemical disinfectant, ensuring that the disinfectant reaches all surfaces. The equipment is immersed for a predetermined time depending on the chemical disinfectant used. The spectrum of activity also depends on the type of chemical disinfectant used (Figure 2).

The method is unsuitable if the corrosive nature of the chemical disinfection may damage the equipment or if the equipment has areas inaccessible to liquid. It requires trained staff wearing protective clothing. It is potentially toxic, corrosive or volatile. Also, the equipment may have to be hand dried after disinfection allowing possible recontamination.

Equipment disinfectants commonly used and their spectrum of activity and physical properties

Disinfectant	Microbiological activity					Stability	Inactivation by organic matter	Corrosive/ damaging matter	Irritant
	Spores	Mycobacteria	Bacteria	Viruses[1] Enveloped	Viruses[1] Non-enveloped				
• Glutaraldehyde 2%	+++ (slow)	+++	+++	+++	+++	Moderate (fixative)	No	No	Yes
• Peracetic acid 0.2–0.35%	+++	+++	+++	+++	++	Poor (< 1 day)	No	Slight	Slight
• Alcohol (ethyl alcohol) 60–80%	None	++	+++	+++	++	High	Yes (fixative)	Slight	No Flammable
• Peroxygen compounds	None	+	+++	+++	++	Moderate (7 days)	Yes	Slight	No
• Chlorine-releasing agents >1000 ppm average Cl_2	+++	+++	+++	+++	++	Poor (< 1 day)	Yes	Yes	Yes
• Clear soluble phenolics 0.6–2%	None	+++	+++	+	None	Good	No	Slight	Yes
• Quarternary ammonium compounds	None	Variable	Moderate	+	+++	Good	Yes	No	No

[1] Activity varies with concentration of product.

Sterilization

Sterilization is used to produce an object free from viable microbial organisms including viruses and bacterial spores. There are several types of sterilizer (Figure 3).

Steam

When steam is pressurized it reaches a temperature greater than that of boiling water at atmospheric pressure and destroys or renders non-viable, bacteria, viruses and their spores. For this process to be effective, direct contact between the pure dry saturated steam and the object being sterilized is required at the specific temperature and in the absence of air. The temperature reached by the object determines the time required for sterilization. The lowest temperature recommended is 121°C for 15 minutes; the highest temperature of 134°C requires only 3 minutes.

This process is effective against all microorganisms with a significant safety factor. Problems occur with wrapped items because all air must be removed. To overcome this, porous load sterilizers are used, which incorporate a vacuum pump. Air is removed before steam is added. This is the most commonly used method for sterilization in hospitals today (Figure 4). However, it cannot be used for any material that cannot withstand the temperatures or pressures required for sterilization (e.g. thermo-labile plastics, fibre-optic endoscopes).

The advantages of this process are that steam is non-toxic, non-corrosive and a highly effective sterilizing agent. This system can be incorporated into a fully automated process on a large scale, coping with a high turnover of equipment. Disadvantages are that the operator must wear protective clothing to avoid direct contact with the steam.

Different types of hospital sterilizers

Types of sterilizer	Use	Minimum time / temperature
• Steam sterilizer		
Porous load	Wrapped instruments, dressings, utensils	134–138ºC for 3 minutes
Fluid cycle	Fluids in sealed containers	121–124ºC for 15 minutes,
	or 115ºC for 30 minutes	
Unwrapped instruments	Unwrapped instruments and utensils	134–138ºC for 3 minutes
• Hot air sterilizer	Oils, powders, heat-resistant instruments that must be kept dry	160ºC for 2 hours
• Low temperature steam formaldehyde sterilizer	Heat-sensitive equipment	73ºC for 3 hours
• Ethylene oxide	Heat-sensitive equipment	Various temperatures and times

Dry hot air

In this process, sterilization takes place by raising the ambient temperature. Typical processes consist of 160°C for 2 hours, 170°C for 1 hour, 180°C for 30 minutes. If all the items are completely clean and dry before this sterilization process starts, then all microorganisms will be killed. However, it cannot be used for materials that would be damaged by these temperatures (e.g. rubber, plastic).

Dry heat can be used to sterilize stable powders, waxes and non-aqueous liquids. It is also effective for non-stainless metals, hollow needles and glass syringes. However, the sterilization time is long compared with other methods, and items have to cool slowly afterwards. Many pieces of equipment cannot withstand these high temperatures for the allocated time.

Ethylene oxide

Ethylene oxide at ambient pressure and temperature vaporizes easily and thus has good penetrative properties. It is also non-corrosive and has a wide spectrum of activity against bacteria, spores, fungi, viruses and other living cells. Sterilization is usually carried out at 20–60°C for 2–24 hours.

Ethylene oxide is most often used under three different conditions:

- normal atmospheric pressure using undiluted ethylene oxide – the gas is very flammable, and so is often diluted to reduce explosion risk
- ethylene oxide with a diluent gas such as nitrogen at a pressure of 2 bar
- ethylene oxide diluted with carbon dioxide at a pressure of 6 bar.

This process should not be used if heat sterilization is possible. Organic material has a marked protective effect and therefore prior cleaning is essential. Ventilatory or respiratory equipment is contraindicated. Ethylene oxide does not penetrate plastic; therefore items must be wrapped in sterilization paper.

Ethylene oxide is a highly effective sterilizing agent. In particular it is used to sterilize single use medical items that would be damaged by the excessive heat used in other sterilization methods. Disadvantages of ethylene oxide are that it is toxic and long periods of aeration are required after sterilization therefore turn-around time is long. The process is expensive and there are significant health and safety issues concerning ethylene oxide and the equipment required to use it. Because of this, ethylene oxide is not often used in hospitals but is commonly used by industry.

Low temperature steam and formaldehyde

This process uses a combination of dry saturated steam and formaldehyde, which together kill vegetative bacteria, spores, fungi and most viruses. Objects are placed in the sterilizer to allow maximum contact with the steam. Air is actively removed from the container and replaced by dry saturated steam at 73°C at subatmospheric pressure. Formaldehyde is entrained as the steam enters the sterilizer.

The subatmospheric pressure may damage hollow objects. Formaldehyde may be corrosive with certain materials and some fabrics may absorb formaldehyde. This method cannot be used for items contaminated with body fluids, because the proteins in the fluids congeal and produce hard fixed deposits.

Advantages of the process are that it can provide dry, packaged items in a sterile form and the process is fully automated. Disadvantages are that the process is complex and formaldehyde is toxic, irritant and possibly mutagenic. The equipment required is also expensive, with the added problem of toxic waste products.

Irradiation

Irradiation uses γ rays or accelerated electrons. A dose greater than 25,000 Gray produces sterility. Irradiation is often used to sterilize single use items on an industrial scale. It has a broad spectrum of activity. Irradiation can cause significant degradation of materials and is unsuitable for the resterilization of hospital equipment.

The advantages are that it is reliable on an industrial scale for heat-labile pieces of equipment. However, irradiation can damage equipment particularly on re-exposure. Monitoring the process and the required safety equipment is expensive.

Special circumstances

Recent work has identified that the prion strain causing bovine spongiform encephalopathy (BSE) in cattle has infected humans, manifesting itself as a novel human prion disease, new variant Creutzfeldt–Jakob disease (vCJD). The abnormal prion protein is a new class of transmissible agent that demonstrates resistance to the standard methods of sterilization used in hospital sterile services departments.

Affected individuals accumulate prion protein in lympho-reticular tissues (e.g. appendix, tonsils), as well as in the CNS. The number of people incubating the disease is unknown, and there are concerns that prions might be transmitted iatrogenically via contamination of surgical instruments. Such risks remain unquantified, and there have been no identified cases involving vCJD transmission via surgical instruments. All neurosurgical instruments used on patients suspected of carrying vCJD are destroyed. However, there are significant implications for the safety of surgical instruments in ENT and other surgical practice.

The Spongiform Encephalopathy Advisory Committee (SEAC) has recommended that, where feasible, the move to single use instruments is appropriate. From January 2001, the Department of Health requires tonsillectomy and adenoidectomy to be performed using single use instruments in England and Wales. The recommendations are that instruments used to dissect or cut lymphoid tissue are to be disposed of. Anaesthetic equipment may also provide theoretical risk for prion disease transfer. This risk is as yet unquantified and accepted practice is continuing to evolve. It is likely that, in the near future, anaesthetic practice will change to incorporate disposable, single patient use equipment wherever possible (e.g. disposable laryngoscope blades and laryngeal mask airways).

Critical Incidents: The Cardiovascular System

Joy E R Beamer
Jonathan Warwick

Joy E R Beamer is a locum Consultant Anaesthetist at the Horton Hospital, Banbury, UK. She was recently awarded a CCST in Anaesthetics. She qualified from St George's Hospital Medical School, London, and undertook a specialist registrar training programme in the Oxford Region.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. He qualified from Birmingham University Medical School and trained in anaesthesia in the Royal Air Force. Further training as a Senior Registrar in the NHS was spent in Oxford. He now specializes in anaesthesia for plastic surgery and head and neck surgery.

Hypertension

Hypertension is a common critical incident during anaesthesia. Whether it is harmful depends on its severity, cause and duration, and on the condition of the patient. These factors also determine how actively it needs to be treated. Hypertension is difficult to define because of observer and subject variation, and the arbitrary nature of cut-off values, but definitions include:

- elevation of blood pressure at least 15% above patient's baseline
- systolic blood pressure greater than 160 mm Hg and/or a diastolic blood pressure greater than 95 mm Hg. Figure 1 lists the causes of hypertension during or persisting after anaesthesia.

Causes of hypertension during or persisting after anaesthesia

- Inadequate anaesthesia/analgesia
- Tracheal intubation/extubation
- Inadequate muscle relaxation
- Pre-existing hypertensive disease
- Hypoxaemia
- Hypercapnia
- Aortic clamping
- Raised intracranial pressure, cerebral ischaemia or cerebrovascular accident
- Drugs (e.g. ketamine, adrenaline (epinephrine))
- Metabolic disorders (e.g. malignant hyperpyrexia, thyroid crisis, phaeochromocytoma, carcinoid syndrome)
- Postoperative urinary retention, pain, anxiety

1

Complications

Cardiovascular – hypertension may precipitate myocardial ischaemia (especially subendocardial), infarction or failure.

Neurological – cerebral haemorrhage may result, especially in patients with vascular malformations. Cerebral oedema or encephalopathy are less common complications of uncontrolled hypertension.

Haemorrhage at the operation site or from pre-existing vascular malformations.

Renal – severe hypertension may precipitate acute renal failure.

Management

Management of hypertension should be directed towards the underlying cause. The usual cause is inadequate anaesthesia for the level of surgical stimulation being employed and treatment requires an increase in the inhalational or intravenous anaesthetic drug, or an increase in analgesia. Confirmation of the diagnosis may require a trial of therapy. If the cause of the hypertension cannot be diagnosed or removed, an appropriate antihypertensive drug may be used. The following are examples of drugs commonly used.

- Labetalol – combined α- and β-blockade; dose 5–20 mg i.v. over 2 minutes with increments up to 200 mg. Onset 5–30 minutes, duration 50 minutes.
- Metoprolol –β_1 (cardioselective) blockade; 2 mg increments slow i.v., maximum dose 15 mg.
- Esmolol – rapid onset; short half-life of 9 minutes; 500 µg/kg loading dose; 50–200 µg/kg/minute infusion.
- Nifedipine – calcium-channel blocker, sublingual or intranasal; onset 1–5 minutes following a 10 mg dose.
- Phentolamine – α-blockade; 0.5–2 mg i.v., repeated as necessary, rapid onset, short half-life 10–15 minutes.
- Hydralazine – direct-acting arteriolar dilator, peak action after about 20 minutes following 10–20 mg slow i.v. injection over 20 minutes. Onset occurs after 15–20 minutes; duration is 2–6 hours.
- Glyceryl trinitrate – arterial and venous dilator; use 1 mg/ml solution i.v. (preferably a central vein) via syringe driver, dose 10–200 µg/minute, maximum effect after 1–2 minutes.
- Sodium nitroprusside – arteriolar dilator; very rapid response, administered by continuous intravenous infusion via a dedicated vein, 0.5–1.5 µg/kg/minute. Direct arterial blood pressure recording is mandatory. Doses greater than 4 µg/kg/minute may cause cyanide poisoning.

Hypotension

Mild-to-moderate falls in blood pressure are common during anaesthesia, but seldom result in any harm to the patient. It is difficult to determine what is a dangerous level of hypotension; it depends on the duration of hypotension and the patient's preoperative medical condition. Two signs of inadequate myocardial perfusion are the development of ST segment depression and ectopic beats. Increased ventilation–perfusion mismatch secondary to pulmonary hypotension causes a fall in oxygen saturation (SpO_2). In awake patients receiving regional anaesthesia, nausea and dizziness are common symptoms of excessive hypotension. The lower limit of cerebral, renal and hepatic autoregulation occurs at a mean arterial pressure of about 60 mm Hg in otherwise healthy individuals.

Causes

Anaesthesia

- Volatile agents produce a dose-related fall in blood pressure (vasodilatation, myocardial depression, impaired baroreceptor response).
- Induction agents cause a dose-related fall in blood pressure owing to a complex combination of effects involving myocardial depression, vasodilatation, altered baroreceptor reflex and bradycardia (especially propofol).
- Opioids may precipitate histamine release and vasodilatation. Larger doses are associated with bradycardia.
- Non-depolarizing muscle relaxants may produce hypotension secondary to histamine release.
- Positive-pressure ventilation increases intrathoracic pressure and produces a decrease in venous return and cardiac output.
- Spinal and epidural anaesthesia produce sympathetic blockade. This results in vasodilatation, reducing venous return, cardiac output and systemic vascular resistance. Although reflex vasoconstriction occurs above the level of the block, blood pressure usually falls. Higher blocks (T4 or above) obtund the cardiac sympathetics, preventing a compensatory tachycardia.
- In obstetrics, aortocaval compression impairs venous return and in combination with spinal and epidural anaesthesia may produce profound hypotension.

Hypovolaemia, regardless of aetiology, becomes less concealed following induction of anaesthesia owing to impairment of compensatory mechanisms. Hypotension then ensues. Hypovolaemia may occur in patients with:

- trauma or burns
- gastrointestinal disease (e.g. haematemesis, melaena, small bowel obstruction, acute inflammatory bowel disease)
- dehydration from poor fluid intake, vomiting or diarrhoea
- metabolic disorders (e.g. diabetic ketoacidosis, diabetes insipidus, hypercalcaemia).

Surgical causes of hypotension include:

- haemorrhage
- head-up position
- excessive intra-abdominal pressure during laparoscopic surgery may impair venous return causing hypotension
- release of aortic cross-clamping or lower limb tourniquets causes an acute fall in systemic vascular resistance and blood pressure secondary to vasodilatation in the ischaemic tissues.

Cardiovascular disease may lead to hypotension:

- ischaemic heart disease with impaired cardiac contractility (including unstable angina and recent myocardial infarction)
- heart failure
- valvular heart disease (mitral or aortic stenosis and regurg-itation)
- dysrhythmias (fast atrial fibrillation, complete heart block)
- hypertension, especially if poorly controlled
- others (e.g. myocarditis, cardiomyopathy, constrictive pericarditis, myocardial contusion, tamponade, aortic coarctation, congenital cardiac anomalies).

Cardiovascular medication such as β-blockers, angiotensin-converting enzyme (ACE) inhibitors, calcium antagonists, nitrates, α_1-antagonists (prazosin) and centrally acting α_2-agonists (e.g. clonidine, methyldopa) may cause hypotension.

Autonomic neuropathy produces impaired baroreceptor response and may be present in a variety of disease states:

- diabetes mellitus (incidence and severity increase with the duration of the disease)
- Guillain–Barré syndrome
- spinal cord injury and following cerebrovascular accident
- Parkinson's disease
- AIDS.

Other causes

- Anaphylaxis may result in massive histamine-mediated vasodilatation, producing cardiovascular collapse.
- Pulmonary embolus from deep vein thrombosis, or emboli from air, carbon dioxide or fat may reduce cardiac output. Hypotension is accompanied by desaturation and a fall in end-tidal carbon dioxide.

Management

- Identify and remove the precipitating cause.
- Increase fraction of oxygen in inspired air (F_iO_2) to maintain SpO_2.
- Position patient supine, possibly with the legs raised to improve venous return. The head-down position is no longer recommended because it also raises cerebral venous pressure and therefore cerebral perfusion pressure may not be improved.
- Give a rapid intravenous infusion. The type and amount of fluid depends on aetiology and patient factors. A useful guide is to infuse 10 ml/kg of colloid or 20 ml/kg crystalloid initially and assess the response.
- Vasopressors may be considered, particularly if the cause of hypovolaemia is non-haemorrhagic (e.g. ephedrine, 3–6 mg i.v., metaraminol, 0.5–1.0 mg i.v., or phenylephrine, 0.5–1.0 mg i.v.).
- Consider an infusion of a positive inotrope (e.g. adrenaline (epinephrine), dobutamine) or vasoconstrictor (e.g. noradrenaline (norepinephrine)).

Massive haemorrhage

Bleeding is a significant cause of mortality and morbidity because of the loss of blood volume and its constituents and also the effects of infusions of products aimed at compensating for the loss. Massive blood transfusion can be defined as the transfusion of blood, blood products and fluids equivalent to the circulating blood volume in any 24-hour period. The most profound physiological, haematological and biochemical effects occur in those who have the most rapid loss and replacement therapy.

Causes of massive haemorrhage include:

- trauma
- major elective surgery such as orthopaedic or vascular surgery, especially rupture or dissection of the aorta
- during pregnancy and the puerperium (e.g. massive antepartum or post-partum haemorrhage)
- urgent operations and/or procedures in patients with abnormalities of haemostasis or coagulation.

Management

Measuring blood loss: the quantity of blood lost can be estimated by a number of methods.

- Weighing swabs and measurement of blood aspirated into suction apparatus. With major haemorrhage, these methods become less useful because a considerable amount of blood is spilled on to the drapes and floor. In traumatized patients, major blood loss may have occurred before arrival in hospital or may be concealed in the chest or abdomen, or in the limbs and pelvis at the site of fractures.
- Measuring packed cell volume. Blood lactate concentration gives an indication of the adequacy of organ perfusion.
- Clinical observation. The monitoring of cardiovascular variables such as heart rate, arterial pressure, capillary return, central venous pressure, and in some cases pulmonary capillary wedge pressure and cardiac output, allows a clinical impression of the adequacy of volume resuscitation to be made.

Compensatory mechanisms initially maintain the blood supply to vital organs. Unless adequate and appropriate corrective measures are taken, these mechanisms will decompensate. With increasing volumes of blood loss, there is an increase in heart rate, decrease in stroke volume, reduced pulse pressure, increased respiratory rate and a reduction in cerebral blood flow leading to a reduction in conscious level. These compensatory mechanisms are less efficacious in the elderly and very young and may be impaired by disease or medication. Figure 2 shows the relationship between the changes in vital signs and the volume loss from the circulation.

Relationship between the changes in vital signs and the volume loss from the circulation

	Blood loss (ml)			
	≤ 750	**750–1500**	**1500–2000**	**≥ 2000**
Loss as % of blood volume	≤ 15	15–30	30–40	≥ 40
Heart rate	< 100	> 100	> 120	≥ 140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Capillary return	Normal	Slowed	Slowed	Slowed
Respiratory rate (breaths/minute)	14–20	20–30	> 30	≥ 35
Urine output (ml/hour)	> 30	20–30	5–15	Negligible
Mental status	Normal	Anxious	Confused	Drowsy
Suggested volume replacement	Crystalloid	Crystalloid/colloid	Blood	Blood

Active management: the rapid and effective restoration of an adequate circulating blood volume is the primary responsibility of the anaesthetist during periods of heavy blood loss.

Establish adequate venous access by siting at least two large-bore cannulae to allow rapid fluid infusion. The most important pre-determinants of the flow rate of fluid are the diameter of the cannula and the ability to apply a continuous pressure of 2–300 mm Hg via a pressurized infusion system. Crystalloids and synthetic colloids may be used initially and should be followed by the administration of blood if bleeding continues.

Commence intravenous fluids – internationally accepted practice is to use Hartmann's solution as the initial resuscitation fluid for trauma and burns. The success of initial resuscitation in an acutely hypovolaemic patient probably depends more on adequacy of repletion than on which fluids are used. For a given blood volume expansion about twice the volume of crystalloid compared with colloid is required. In practice, combined therapy using both crystalloids and colloids is often used.

Fluids should be warmed – a transfusion system should have the ability to transfuse blood at fast flow rates (up to 500 ml/minute) and at temperatures greater than 35°C. Some systems use a constant-pressure infusion device combined with an efficient blood warmer and a purpose-designed blood-warming coil (e.g. *Level One*™). Priming or flushing blood through the system after fluid containing calcium has been used (such as *Haemaccel*) should be avoided, because this may cause blood clot formation in the tubing by reversal of the anticoagulant effect of citrate.

Blood should be taken for grouping and cross-matching, for coagulation studies and for biochemical analysis. Accurate identification of transfusion specimens and of designated units of blood, platelets and fresh frozen plasma (FFP) is particularly important in patients undergoing massive transfusion. It should be noted that most incompatible blood transfusions occur in emergency situations. For operations where significant blood loss is anticipated, replacement therapy should be available in advance of surgery.

Red cell transfusions are given to increase the haemoglobin concentration and thus improve or normalize the delivery of oxygen to the tissues. The haemoglobin concentration at which blood transfusion is commenced depends to a certain extent on the individual patient (e.g. elderly patients are at greater risk of complications from anaemia). A haemoglobin value below 8.5 g/dl would be an indication to transfuse in all apart from the younger fitter patient. A postoperative haemoglobin level of about 10 g/dl is widely accepted as a general guideline in adult surgical patients. However, it is more appropriate to base transfusion decision on a clinical assessment of the patient. If a major surgical procedure is planned, it may be possible to decrease the amount of donor blood transfusions by using an automated cell saver system.

About 80% of patients who have massive haemorrhage develop diffuse ooze from raw or cut surfaces. The causes are multifactorial but include relative hypothermia, abnormal platelet function, dilution of clotting factors, consumption of factors and enhanced fibrinolysis. It is critically important to monitor platelet numbers and the coagulation process during major bleeding and its resuscitation. The platelet count falls steadily with the transfusion of each successive unit of blood. Platelet infusion is indicated if there is:

- a platelet count less than 50 x 10^9/litre and there is impending surgery or an invasive procedure
- diffuse microvascular bleeding and transfusion greater than one blood volume and a platelet count of 50 x 10^9/litre or less, or the result is unavailable
- diffuse microvascular bleeding following cardiopulmonary bypass and the platelet count is 100 x 10^9/litre or less, or the result is unavailable
- bleeding in a patient with a qualitative platelet defect, regardless of platelet count.

Moderate deficiency of coagulation factors is common in massively transfused patients, but does not contribute to microvascular haemorrhage until levels fall below 20% of normal. These levels are reliably reflected by prolongation of the prothrombin (PT) and activated partial thromboplastin times (aPTT) to values of more than 1.5 times the control value. If the PT and aPTT are more than 1.5 times normal, 4 units of FFP should be given. If PT and aPTT are prolonged and fibrinogen is less than 0.8 g/litre, cryoprecipitate is indicated.

Arterial and central venous lines may be sited to allow rapid blood sampling, for acid–base and potassium status, and the direct measurement of arterial and central venous pressures. The central venous catheter also provides access for intermittent bolus administration of drugs or drug infusions.

A urethral catheter should be passed unless contraindicated by pelvic or urethral injury, and urine output monitored.

Core temperature should be measured continuously and every effort made to prevent heat loss. Hypothermia causes platelet dysfunction, reduced metabolism of citrate and lactate and an increased tendency to cardiac arrhythmias. This may result in bleeding diathesis, hypocalcaemia, metabolic acidosis and cardiac arrest.

Arrhythmias

Arrhythmias are one of the most commonly reported critical incidents. About 12% of patients undergoing anaesthesia develop arrhythmias; this increases to 30% in patients with cardiovascular disease. Treatment may not be required; this depends on the nature of the arrhythmia and its effect on cardiac output. Single supraventricular or ventricular ectopic beats, and slow supraventricular rhythms, do not require treatment unless cardiac output is compromised.

Management

Fluid, electrolyte and acid–base disturbances should be corrected preoperatively. Particular attention should be paid to the level of potassium ions in the plasma because they have a vital role in the generation of the resting membrane potential and thus muscle and nerve function. Patients with hypokalaemia may be prone to the development of supraventricular or ventricular extrasystoles and tachycardias. ECG changes of hypokalaemia include a long PR interval, ST depression, T wave flattening and a prominent U wave. Rapid treatment is indicated if arrhythmias are present. Intravenous administration of potassium supplements should not exceed 0.5 mmol/kg/hour.

Continuous intraoperative ECG monitoring is essential. The ECG gives no indication of cardiac output or tissue perfusion, therefore the detection of an abnormal cardiac rhythm should be followed by clinical assessment of the circulation. An absent pulse, severe hypotension or ventricular tachycardia or fibrillation should be treated as a cardiac arrest.

Correcting the precipitating factor is often the only treatment required. Hypoxaemia and inadequate anaesthesia or analgesia must be excluded. Factors associated with the development of arrhythmias are listed in Figure 3.

Intervention with a specific antiarrhythmic agent or cardioversion is indicated if there is:

- a risk of developing ventricular tachycardia or fibrillation (e.g. frequent, multifocal ectopic beats, or 'R on T' complexes)
- a significant decrease in cardiac output (causing dizziness or hypotension)
- evidence of myocardial ischaemia (causing chest pain or ST segment changes).

Factors associated with the development of arrhythmias

Preoperative conditions

- Ischaemic heart disease
- Pre-existing arrhythmias
- Congestive heart failure
- Hypertension
- Valvular heart disease
- Electrolyte disorders
- Medications (theophylline, β_2-agonists, tricyclic antidepressants)
- Others (thyrotoxicosis, myocarditis, cardiomyopathies, trauma, drug and solvent abuse)

Anaesthetic factors

- Hypoxaemia
- Hypo/hypercapnia
- Hypo/hypertension
- Laryngoscopy
- Drugs (e.g. volatile anaesthetic agents, suxamethonium, central venous pressure lines)

Surgical factors

Catecholamines

- Exogenous (e.g. infiltrated adrenaline (epinephrine))
- Endogenous (inadequate analgesia, inadequate anaesthesia)

Autonomic stimulation

- Oculocardiac reflex
- Laryngoscopy, bronchoscopy, oesophagoscopy
- Carotid artery and thyroid surgery
- Peritoneal and visceral traction
- Peritoneal insufflation

Direct stimulation of the heart

- Cardiac and thoracic surgery

Embolism

- Thrombus, fat, air, carbon dioxide, amniotic fluid

Others

- Limb reperfusion
- Aortic cross-clamping

Bradycardia can be treated with an anticholinergic agent such as atropine, 0.6 mg i.v., or glycopyrrolate, 0.2–0.4 mg i.v. If the bradycardia is refractory to treatment, cardiac pacing or an intravenous infusion of isoprenaline, 0.5–10 µg/minute, may be indicated. An anticholinergic drug may be given prophylactically if there is risk of bradycardia (e.g. strabismus surgery or following a second dose of suxamethonium).

Sinus tachycardia associated with myocardial ischaemia may be controlled by administration of a β-blocker such as metoprolol, 2 mg increments slow i.v., maximum dose 15 mg, or esmolol, 500 µg/kg, loading dose followed by 50–200 µg/kg/minute infusion.

Junctional rhythms are usually associated with the use of halothane. A reduction in concentration and/or changing the volatile agent is indicated. An anticholinergic drug may restore sinus rhythm.

Accelerated nodal rhythms may be precipitated by an increase in sympathetic tone in the presence of sensitizing volatile agents. Treatment includes adjusting the depth of anaesthesia and/or changing the anaesthetic agent.

Supraventricular tachycardia (SVT) can occur in susceptible patients, such as Wolff–Parkinson–White or other 'pre-excitation syndromes'. Treatment of SVT consists of:

- carotid sinus massage
- adenosine, 3–12 µg i.v.
- DC cardioversion if haemodynamic decompensation is present
- if there is no decompensation give verapamil, 5–10 mg slow i.v. over 30 seconds; the injection should stop when the SVT is controlled
- in sepsis-related or refractory SVT, volume loading plus amiodarone, 300 mg i.v. by infusion over 20 minutes, then 900 mg over 24 hours
- if the patient is thyrotoxic a β-blocker is useful.

Atrial fibrillation or flutter is often seen as a paroxysmal increase in the ventricular rate in patients with pre-existing atrial fibrillation or flutter. Having corrected any precipitating factors, the therapeutic options include:

- digoxin, 10 µg/kg by slow i.v. injection over 20 minutes, repeat after 4 hours according to response, maintenance dose 125–500 µg/day. Peak effect after 2 hours. Slows the ventricular rate and is a positive inotrope
- amiodarone produces a more rapid ventricular response and may re-establish sinus rhythm, give 300 mg i.v. by infusion over 20 minutes, then 900 mg over 24 hours
- β-blockers, especially in thyrotoxicosis, in combination with digoxin (e.g. propranolol 1 mg slow i.v. repeated every 2 minutes, maximum 5 mg)
- cardioversion is an option if the ventricular rate is fast with a clinically reduced cardiac output.

Premature ventricular contractions are common in healthy patients. Perioperatively they seldom progress to more serious arrhythmias unless there is underlying hypoxaemia or myocardial ischaemia. An underlying cause should be sought before antiarrhythmic agents are considered. If associated with a slow atrial rate, increasing the sinus rate with an anticholinergic drug will abolish them. Halothane lowers the threshold for catecholamine-induced ventricular arrhythmias; this is exacerbated by hypercapnia. Halothane should be used with care in patients receiving sympathomimetic drugs (including local anaesthetics containing adrenaline), and in patients taking tricyclic antidepressants and aminophylline.

Ventricular tachycardia and fibrillation should be treated as a cardiac arrest.

Malignant hyperthermia

Malignant hyperthermia is a rare inherited complication of general anaesthesia triggered by inhalational agents or suxamethonium in susceptible patients. The inheritance is complex and it is a genetically heterogeneous condition. These patients have a defect in intracellular calcium binding within the sarcoplasmic reticulum of skeletal muscle cells. Calcium ions are released on exposure to trigger agents, which initiates widespread skeletal muscle contraction and generalized membrane permeability. There is severe metabolic disturbance and catabolism runs unchecked, because raised levels of myoplasmic calcium ions result in increased production of pyruvate and heat. A successful outcome relies on making an early diagnosis, discontinuation of trigger agents, prompt treatment with intravenous dantrolene and supportive care. The mortality today has decreased to about 25% owing to increased awareness, monitoring and prompt treatment. The mode of presentation is variable and a high index of suspicion is required for early diagnosis.

Signs of malignant hyperthermia include:
- unusual muscle rigidity following suxamethonium (especially masseter spasm)
- unexplained tachycardia and arrhythmias
- rise in end-tidal carbon dioxide
- metabolic acidosis
- fall in oxygen saturation
- hyperkalaemia
- rise in core temperature (about 1–2°C/hour)
- evidence of a coagulation disorder, oozing from wound sites.

Management

Immediate actions
- Discontinue inhalational agents and inform the surgeons. Stop surgery if feasible, make the operating site safe and close wounds.
- Continue sedation or anaesthesia with a total intravenous technique. Hyperventilate with 100% oxygen using a clean breathing system. Change the circle system using fresh soda-lime, or use a non-rebreathing system.
- Immediately instruct staff to prepare dantrolene and commence as soon as available in an intravenous infusion of 1 mg/kg repeated at 10 minute intervals up to 10 mg/kg.
- Remove drapes, fully expose the patient and promote surface cooling with avoidance of vasoconstriction.
- Insert an arterial line to aid monitoring, and allow regular estimation of arterial blood gases, potassium and creatine kinase.
- Monitor the patient's core temperature.

Intermediate actions
- Control life-threatening dysrhythmias (e.g. β-blockers).
- Control hyperkalaemia with intravenous glucose or insulin.
- Control metabolic acidosis by hyperventilation, consider sodium bicarbonate (2–4 mmol/kg) if acidosis is severe (e.g. pH < 7.0).

Later actions
- Send blood for clotting screen (PT, aPTT, fibrinogen).
- Catheterize the patient. Test their urine for myoglobin. Collect samples for vanillylmandelic acid estimation to exclude phaeochromocytoma. Promote diuresis with intravenous fluids and mannitol, 0.5 g/kg over 20 minutes.
- Request a chest radiograph. Send blood for full blood count, biochemistry and thyroid function tests.
- Notify the intensive care unit.
- Repeat the creatine kinase estimation in 24 hours.
- Consider other diagnoses such as recreational drug ingestion (e.g. Ecstasy), neuroleptic malignant syndrome or myopathy.

Future care

The patient and their family should be counselled as to the likely diagnosis and the implications for future anaesthetics. Wearing a Medic-Alert bracelet should be encouraged. The patient and immediate family should be referred for further investigation and muscle biopsy to:

UK MH Investigation Unit, Academic Unit of Anaesthesia
Clinical Sciences Building
St James's University Hospital Trust
Leeds LS9 7TS
Tel: 0113 206 5274
Emergency hotline: 07947 609601

Future anaesthetic care can be provided safely with the avoidance of trigger agents – the volatile anaesthetics and depolarizing muscle relaxants. Prophylactic dantrolene is not recommended. Phenothiazines, antidepressants and haloperidol have been suggested as possible trigger agents, because of the similarity between malignant hyperthermia and the neuroleptic malignant syndrome, but this is unlikely. All other anaesthetic drugs appear to be safe.

Critical Incidents: The Respiratory System

Orlando J Warner
Jonathan Warwick

Orlando J Warner is Specialist Registrar in Anaesthetics at the Oxford Radcliffe NHS Trust Hospital, Oxford, UK. He qualified from the Royal London Hospital Medical School. For the past 2 years he has been the Advanced Trainee in Neuroanaesthesia at the Department of Neuro-surgical Critical Care and Anaesthetics, Radcliffe Infirmary, Oxford.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. He qualified from Birmingham University Medical School and trained in anaesthesia in the Royal Air Force. Further training as a Senior Registrar in the NHS was spent in Oxford. He now specializes in anaesthesia for plastic surgery and head and neck surgery.

A critical incident during anaesthesia is any event that may result in actual or potential harm to the patient if uncorrected. It may cause severe morbidity or even mortality. It is often preventable by a change in practice. Incident reporting is the key to preventing future disaster. There is observer bias concerning which incidents are recorded, and the problem for anaesthetists is to distinguish between a critical incident and the normal course of clinical practice.

This contribution deals with life-threatening problems in the management of the respiratory system including the clinical and physiological presentation of some commonly encountered critical incidents and their treatment. All may be a cause of alarming cyanosis under anaesthesia. Not all the problems discussed can be prevented and so some may not meet the precise definition of critical incidents. The recommendations aim to provide the anaesthetist with fast and effective solutions that may be used in clinical, examination or simulation situations. In all cases, the trainee anaesthetist must request senior help at the earliest opportunity.

Aetiology

The 2000 report of the National Confidential Enquiry into Perioperative Deaths (NCEPOD) cites hypotension, hypoxaemia, arrhythmia and cardiac arrest as the most common critical events that occur during or immediately following surgery. It also concludes that modern anaesthetic equipment, when properly checked, is very reliable. Human factors often play a major role in the aetiology of adverse events (Figure 1).

Factors involved in avoidable deaths

- Error of judgement
- Error of clinical expertise
- Lack of experience
- Lack of assistance
- Lack of equipment
- Equipment failure

1

Preparation is an important factor in predicting and treating these events and should involve:

- thorough preoperative patient assessment
- check of all anaesthetic equipment
- appropriate selection of drugs
- appropriate level of clinical expertise.

The Association of Anaesthetists of Great Britain and Ireland (AAGBI) has recently published new recommendations for standards of monitoring during anaesthesia and recovery. The Royal College of Anaesthetists (RCA) has a web page (http://www.rcoa.ac.uk/critincident/ciweb.html) that deals with the processing of critical incidents. The RCA is committed to setting up a national database so that even rare incidents can be reported and acted on. Critical incidents should be discussed locally at regular departmental audit meetings to complement the process of clinical governance.

Respiratory obstruction and increased peak airway pressure

Obstruction to the airway is an immediate threat to life and is the most common critical incident registered. The 'airway' can be considered as the conducting pathway responsible for the delivery of oxygen from anaesthetic machine to the alveolar/blood interface. Thus, obstruction may occur from outside or within the patient. The anaesthetic machine, breathing system and connections must be checked to ensure their patency and correct function before anaesthesia.

Obstruction of the airway within the patient may arise from the upper, supraglottic region, to the lower bronchiolar region. It may be caused by the devices used during anaesthesia or result from airway anatomy, pathology or trauma. Figure 2 shows some of the likely causes of airway obstruction in the perioperative period.

Possible causes of airway obstruction

Supraglottic

- Tongue
- Periglottic abscess, tumour, haematoma
- Regurgitation of solid material
- Blood or secretions
- Laryngeal mask airway (LMA) or tracheal tube luminal occlusion or misplacement

Laryngeal

- Laryngospasm
- Tumour or oedema
- Post-thyroidectomy (laryngeal nerve injury)
- LMA or tracheal tube luminal occlusion or misplacement

Tracheal or bronchial

- Aspiration
- Asthma
- Anaphylaxis
- Pneumothorax
- Pulmonary oedema
- Tracheal obstruction by retrosternal goitre
- LMA or tracheal tube luminal occlusion or misplacement

2

Respiratory obstruction during induction of anaesthesia

Preoperative evaluation of the airway is vital and should include mouth opening, dentition, Mallampati score, jaw movement, thyromental distance and neck movement. The aim is to predict which patients may present difficulty with direct laryngoscopy and intubation and those in whom difficulty may arise with airway maintenance following loss of consciousness, such as those with:

- obesity or a 'bull neck'
- limited mouth opening (e.g. trismus, following infection, trauma)
- restricted head and neck movement (e.g. severe ankylosing spondylitis, rheumatoid arthritis)
- stridor resulting from tumour, trauma, infection or haem-atoma
- upper airway soft tissue swelling (e.g. burns, pre-eclampsia). About 10% of reported critical incidents occur in the anaesthetic room. Patient monitoring during induction of anaesthesia should follow the guidelines established by the AAGBI. The patient must be monitored adequately during this stage of anaesthesia. If the required equipment is unavailable, induction should take place in the operating theatre.

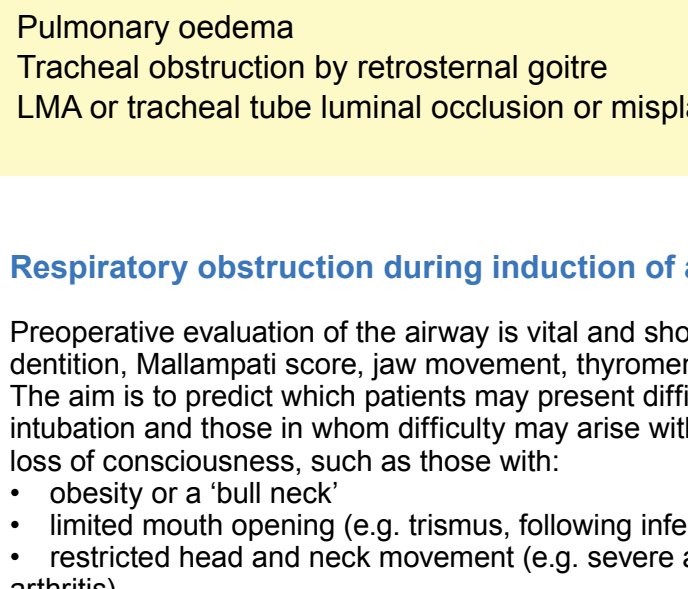
Induction of anaesthesia in patients with upper airway obstruction requires specialized expertise. Management must involve a clear plan of how to proceed in the event of total airway obstruction during induction. These patients are best managed in the operating theatre with surgeons gowned and ready to perform immediate tracheostomy under local anaesthesia if necessary.

In routine practice, airway obstruction that occurs following induction is apparent from:

- paradoxical (see-saw) chest movement (when breathing spontaneously)
- noisy airway
- absent or diminished movement of the reservoir bag
- absent or diminished capnograph trace
- increased airway pressure (when mechanically ventilated)
- progressive oxygen desaturation.

Simple airway manoeuvres such as chin lift and jaw thrust, often combined with the insertion of a correctly sized oropharyngeal or nasal airway are necessary to maintain airway patency following induction. In apnoeic patients or those requiring assisted ventilation, bag and mask ventilation by two operators is more effective than that provided by one operator (Figure 3), allowing more effective face mask application and upper airway management. Manual ventilation with bag and mask is then easier to perform. If management is difficult, it is important to switch to 100% oxygen and call for senior help early on.

Two operators providing bag and mask ventilation



3

If airway obstruction persists, a laryngeal mask airway (LMA) often corrects the situation. While tracheal intubation provides a definitive airway, it may be difficult to insert in a patient who has not received muscle relaxants. Neuromuscular blockade should never be administered unless airway patency can be assured. However, if airway maintenance is lost following the administration of muscle relaxants then swift direct laryngoscopy and tracheal intubation should be attempted. Some patients (e.g. those with adenotonsillar hypertrophy, the obese or heavy snorers) are often easy to intubate despite having a difficult airway to maintain with bag and mask. The LMA is also the technique of choice following a failed intubation if subsequent airway management is difficult. Numerous reports testify to the ability of the LMA to provide a clear airway following a failed intubation. The *Combitube* may also be useful, though it is less commonly used in the UK. Both are 'supraglottic' airway devices, therefore it is unlikely that the *Combitube* will provide a clear airway if the LMA does not.

Can't intubate, can't ventilate (CICV)

The inability to intubate or ventilate a patient is rare, with an estimated incidence of 1/10,000 anaesthetics. It occurs when alveolar ventilation cannot be maintained despite best attempts at intubation and bag-mask ventilation (Figure 4).

Analysis of closed-claims in the USA revealed that the most common predisposing factor in the development of CICV was repeated and continued attempts at intubation. With each successive period of re-oxygenation between intubation attempts, bag-mask ventilation became increasingly difficult as laryngeal oedema evolved. The anaesthetist should limit intubation attempts to a maximum of three. The decision must be made early to abandon further attempts at intubation and the anaesthetist must use an alternative airway device, or wake the patient. The main causes of CICV are:

- repeated failed attempts at intubation
- airway or neck trauma
- burns to the head and neck
- pregnancy (especially pre-eclampsia)
- tumour (e.g. larynx)
- infection.

Requirements for optimum best attempts

Optimum best bag-mask ventilation

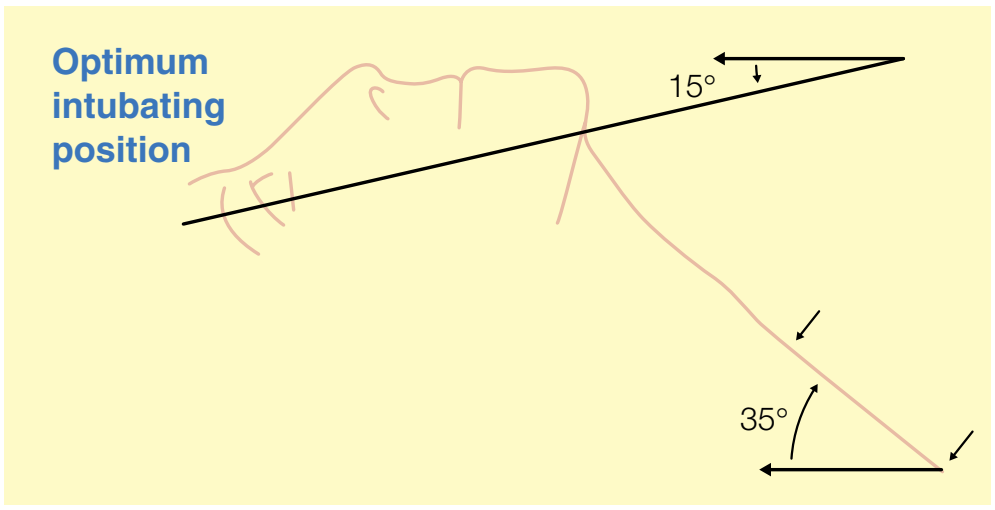
- Correctly sized oral or nasal airway
- Two-operator technique

Optimum best laryngoscopy

- Trained anaesthetist (3 years' training)
- Optimal intubating position
- Optimal external laryngeal manipulation
- Optimal laryngoscope

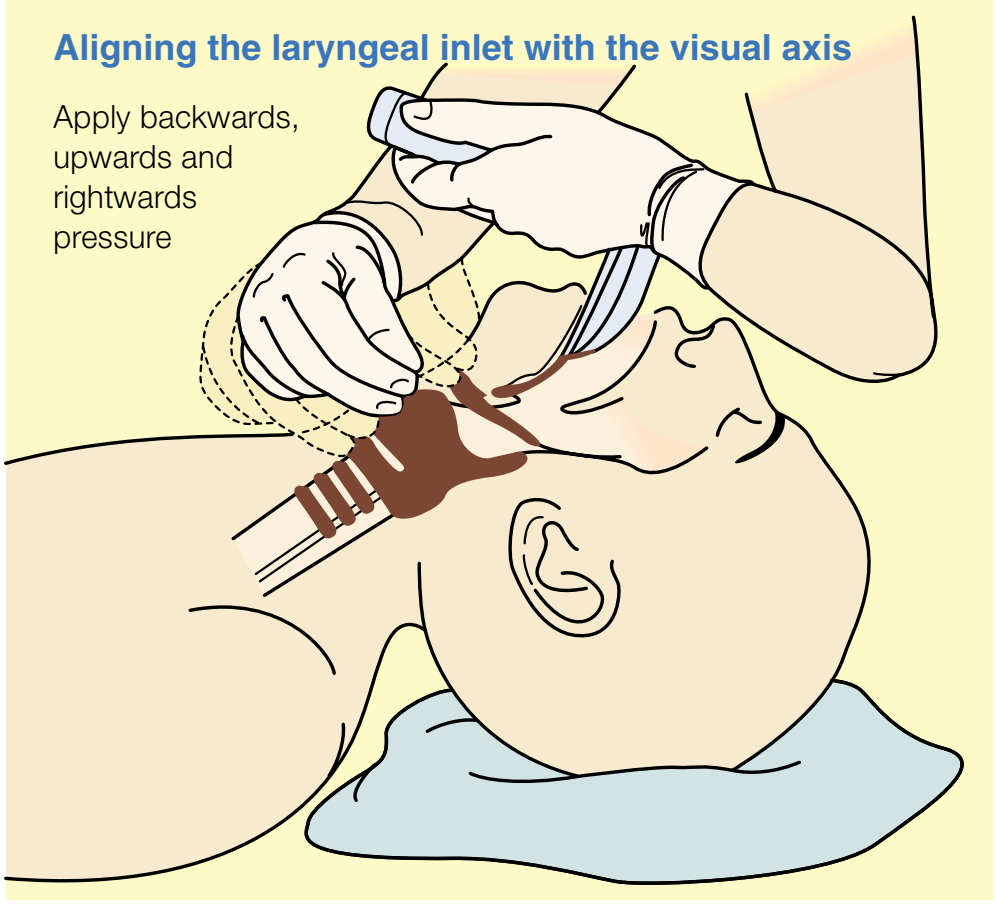
4

The optimal intubating position is shown in Figure 5. Flexion of the cervical spine, and extension of the head at the atlanto-occipital joint, aligns the glottis with the visual axis. In the obese or pregnant woman at term, this may require at least one pillow under the shoulders and two pillows beneath the head and neck. Anaesthetic induction and tracheal intubation should be avoided when patient positioning is not ideal.



5

The larynx should be manipulated from the front of the neck by the operator's free hand to help provide the best view. This position is maintained by the anaesthetic assistant while intubation is performed. Optimum external laryngeal manipulation does not mean 'cricoid pressure', which may further distort the view and make direct laryngoscopy more difficult. Optimum manipulation involves direct manipulation of the thyroid cartilage of the larynx. The application of backwards, upwards and rightwards pressure aligns the laryngeal inlet more closely with the visual axis. Correct optimum external laryngeal manipulation is shown in Figure 6.



6

The choice of laryngoscope blade is important. A useful guideline is to change the length of blade once, and the type of blade once, to achieve the best view. A variety of blades is available in clinical practice. The standard Macintosh blade (size 3) may need to be changed to a longer blade (size 4) or to a levering blade such as the McCoy. The McCoy blade can be successful in improving the laryngoscopic view by one grade (Cormack and Lehane grade 3 to 2). The Belscope blade has a 45° angle and a detachable prism, and may similarly improve a grade 3 view. The Polio blade is inclined at an angle greater than 90° to the handle, which may aid insertion into the mouth (Figure 7).

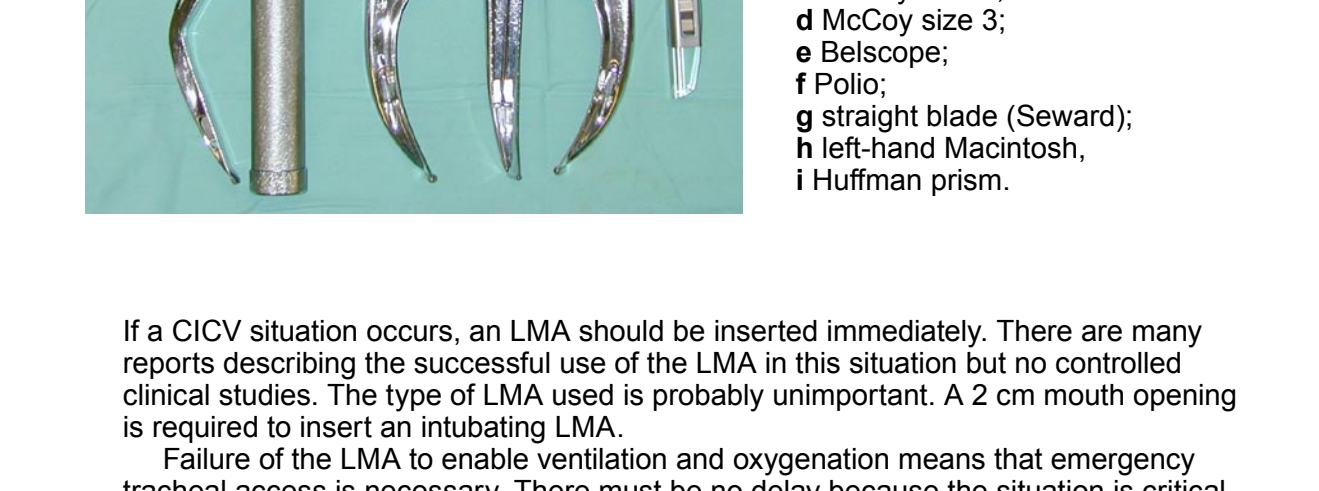
7 Laryngoscope blades:
a Macintosh size 4;
b Macintosh size 3;
c McCoy size 4;
d McCoy size 3;
e Belscope;
f Polio;
g straight blade (Seward);
h left-hand Macintosh,
i Huffman prism.

If a CICV situation occurs, an LMA should be inserted immediately. There are many reports describing the successful use of the LMA in this situation but no controlled clinical studies. The type of LMA used is probably unimportant. A 2 cm mouth opening is required to insert an intubating LMA.

Failure of the LMA to enable ventilation and oxygenation means that emergency tracheal access is necessary. There must be no delay because the situation is critical in a patient with marked hypoxia. Tracheal access is best achieved via the cricothyroid membrane by needle puncture, percutaneous cricothyrotomy or surgical cricothyrotomy. The precise technique depends on: the equipment available; the experience of the anaesthetist; and the nature of the emergency.

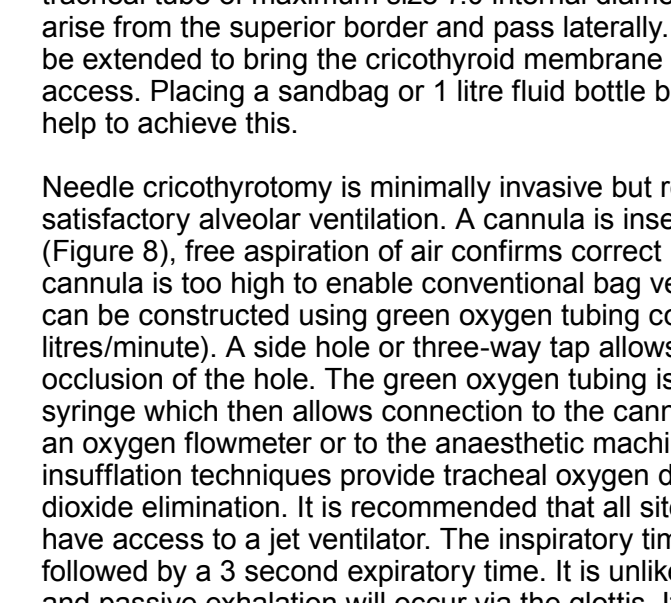
It is impossible to give firm recommendations but whatever the means used, the immediate aim is to achieve oxygen delivery to the trachea (and alveoli) via the cricothyroid membrane. This membrane lies subcutaneously between the cricoid and thyroid cartilages of the larynx and in the adult measures 1 x 3 cm. It will accept a tracheal tube of maximum size 7.0 internal diameter (ID). Paired cricothyroid arteries arise from the superior border and pass laterally. The patient's head and neck should be extended to bring the cricothyroid membrane closer to the skin surface to facilitate access. Placing a sandbag or 1 litre fluid bottle between the patient's scapulae may help to achieve this.

Needle cricothyrotomy is minimally invasive but requires a jet ventilator to achieve satisfactory alveolar ventilation. A cannula is inserted via the cricothyroid membrane (Figure 8), free aspiration of air confirms correct placement. Resistance through the cannula is too high to enable conventional bag ventilation. Simple emergency systems can be constructed using green oxygen tubing connected to a flowmeter (e.g. 10-15 litres/minute). A side hole or three-way tap allows for intermittent insufflation by finger occlusion of the hole. The green oxygen tubing is inserted into the barrel of a 2 ml syringe which then allows connection to the cannula. The free end is connected to an oxygen flowmeter or to the anaesthetic machine via a 15 mm connector. Oxygen insufflation techniques provide tracheal oxygen delivery but not satisfactory carbon dioxide elimination. It is recommended that all sites where anaesthesia is administered have access to a jet ventilator. The inspiratory time of about 1 second should be followed by a 3 second expiratory time. It is unlikely that airway obstruction is absolute and passive exhalation will occur via the glottis. If this is deemed inadequate a second cannula should be placed to allow exhalation and prevent overinflation and barotrauma. A needle cricothyrotomy is a temporary measure and preparations should be made for a formal tracheostomy.



8

Specific cricothyroid cannulae are available for emergency tracheal access (Figure 9). The Ravussin 13 G jet ventilation catheter (VBM Medical) is flanged to simplify fixation, and has both Luer-lock and 15 mm connections. The Cook 6 F emergency transtracheal catheter is spiral reinforced and kink-resistant; a standard 14 G intravenous catheter is easily kinked and difficult to fix. The main complication of the technique is incorrect needle position and subcutaneous/mediastinal emphysema.



9 Cricothyrotomy needles.
a 13 G Ravussin jet ventilation catheter (VBM Medical);
b 6 F Cook emergency transtracheal catheter;
c 14 G Venflon cannula.

Percutaneous cricothyrotomy allows emergency placement of a tracheal tube to allow more conventional ventilation via bag and mask. Several commercial kits are available, which differ in insertion technique (Seldinger or non-Seldinger), size of tube (3.5-6.0 ID), and time taken for tube placement. There are insufficient data to make recommendations concerning the optimum technique and the anaesthetist should be familiar with the equipment available in their hospital. A non-Seldinger kit (e.g. VBM Quicktrack, 4.0 mm ID) generally allows the most rapid access by direct cricothyroid puncture using a large diameter sharpened stylet. A Seldinger technique (e.g. Cook Melker kit 3.5-6.0 mm ID) may be safer to perform but requires several stages including the use of a dilator. All techniques require familiarization. Complications include bleeding, malposition and subcutaneous emphysema.

Surgical cricothyrotomy rapidly provides a definitive airway, though it requires more surgical experience and bleeding is likely to be considerable. It is ideally suited to the emergency trauma setting in the presence of severe maxillofacial, neck or laryngeal injury. Thorough training is necessary for this seldom performed but life-saving procedure. Practising on the sheep's larynx provides a realistic training model.

With finger and thumb either side, the cricothyroid membrane should be stabilized. A 22 scalpel blade is used to make a 2 cm vertical skin incision to part the skin. The scalpel should then be horizontally inserted into the cricothyroid membrane, perpendicular to the skin. This incision should be enlarged laterally. The scalpel handle should be inserted through the cricothyroid incision and rotated through 90°, then removed. A well-lubricated size 7.0 ID cuffed tracheostomy tube should be inserted. The main complications are bleeding and malposition.

Respiratory obstruction during the intraoperative period

If respiratory obstruction occurs during surgery, the following procedure will help to diagnose the cause of obstruction (Figure 2) and guide appropriate action to correct the situation. Surgery can then recommence.

- 100% oxygen should be commenced.
- The surgeons should be alerted to the problem and advised to stop surgery. The surgical stimulation may have caused the obstruction. Procedures such as dilation of the cervix or anus may precipitate severe stridor especially if anaesthesia is 'light'.
- The anaesthetic delivery circuit should be checked rapidly.

If it is patent, the obstruction must be within the patient.

- Access to the airway may be difficult, especially in head and neck surgery. Extreme circumstances of continued patient deterioration require the complete uncovering of surgical drapes and exposure of the airway.
- The upper airway should be checked for secretions, signs of regurgitation or obvious tube or LMA obstruction. The mouth and trachea should be suctioned if indicated.
- The capnograph confirms alveolar ventilation by displaying a carbon dioxide trace. Absence of a trace is a sign of complete airways obstruction. The normal capnograph trace may change in airways obstruction with a characteristic marked upslope to the alveolar plateau.
- The urgency of the situation is indicated by the oxygen saturation. If there is any doubt about the tracheal tube position, immediate replacement is needed. An LMA will need repositioning or changing to a tracheal tube. Careful observation of the chest wall during manual ventilation may show unilateral or little chest movement. Auscultation of the chest may detect unilateral air entry, wheeze or absent breath sounds. Withdrawing the tracheal tube slightly may alleviate this if the distal end has migrated to the endobronchial position, or is in contact with the carina.
- Fibre-optic bronchoscopy will confirm the position of the tracheal tube and that there is no intraluminal obstruction such as a sputum plug, blood clot or in rare circumstances, an endoluminal tumour.

Bronchospasm during anaesthesia

Bronchospasm is reversible airways obstruction most commonly associated with patients who have asthma or chronic chest disease. The incidence of asthma is 5-10% with a higher prevalence in children. Smokers and patients with upper respiratory tract infection are also at increased risk of bronchospasm. Bronchospasm occurs as a result of smooth muscle constriction within the respiratory subepithelial layers in the bronchioles. It may be accompanied by other pathological effects (e.g. mucosal oedema, cellular infiltrates, mucus secretion, desquamation of surface epithelial cells, goblet cell hyperplasia) which exacerbate smooth muscle contraction. Contraction is stimulated by neural or paracrine effects. Chemical mediators such as histamine and products of arachidonic acid, the leukotrienes, may act locally to initiate bronchoconstriction.

Bronchospasm is not the only cause of intraoperative wheeze (Figure 10). Luminal occlusion from eccentrically inflated tube cuffs (cuff herniation) used to occur with red rubber tracheal tubes, but modern disposable materials have made this complication less common, however the tracheal tube cuff should not be over-distended. The old adage 'if in doubt – take it out' remains true. A monophonic wheeze developing immediately after intubation may indicate tube occlusion, or a distal position next to the carina or within a bronchus.

Bronchospasm is suggested by:

- increased respiratory effort, tachypnoea and intercostal recession (if spontaneously breathing)
- expiratory wheeze (wheeze throughout the respiratory cycle may indicate obstruction within the breathing equipment)
- rise in inspiratory airway pressure (if mechanically ventilated). Management of wheeze while under anaesthesia is as follows.
- The surgeons should be alerted and asked to stop surgery.
- 100% oxygen should be delivered and anaesthesia deepened. Bronchospasm may result from a depth of anaesthesia that is too light for the degree of surgical stimulation. This includes stimulation of the airway by the anaesthetist. All modern inhalational agents are bronchodilators.
- The breath sounds over both lung fields and over the stomach should be listened to. Capnography confirms tracheal intubation. Tracheal tube position should be adjusted if necessary. Signs of pulmonary oedema or tension pneumothorax should be sought.• The position of the tracheal tube should be adjusted if necessary.
- The airway should be checked and the trachea should be suctioned looking for signs of aspiration.
- Full monitoring should be in place. Extreme tachycardia and cardiovascular collapse suggest anaphylaxis.

The treatment of bronchospasm includes the following.

- The inspired concentration of volatile anaesthetic agent should be increased.
- The patient should be treated with continuous inhaled salbutamol nebulizers, 5 mg, and ipratropium, 500 µg, until the wheeze settles. This is best delivered using a separate oxygen cylinder with nebulizer attachment, connected to the tracheal tube on the patient side of any heat/moisture exchange filter.
- If wheeze persists, aminophylline, 250−500 mg (5 mg/kg) i.v.in 500 ml normal saline over 20 minutes can be given (if notalready treated with theophylline or aminophylline preparations); continue with an infusion of 0.5 mg/kg/hour if needed.
- If bronchospasm is severe, salbutamol, 250 µg bolus i.v. over 5−10 minutes may be given, and continued as an infusion of 5 µg/minute, adjusted according to the heart rate and bronchospasm response.
- It may be necessary to adjust ventilator settings. A longer expiratory time may be needed to allow more complete exhalation, though a short inspiratory time will produce higher peak inspiratory pressures. An I:E ratio of 1:2 or 1:1.5 is usual.
- Hydrocortisone, 200 mg i.v., is not immediately effective but provides bronchospasm relief within 6–12 hours.
- Management of anaphylaxis will be covered in **CLINICAL ANAESTHESIA.**

Causes of intraoperative wheeze

- Endobronchial intubation
- Mechanical obstruction of the tracheal tube
- Bronchospasm
- Anaphylaxis
- Pulmonary oedema
- Tension pneumothorax
- Aspiration of gastric contents

Failure to breathe

A delay in the return of spontaneous respiration following anaesthesia is most commonly the result of an imbalance between the:

- patient requirements of anaesthesia and analgesia (differences caused by normal variation and the effects of coadministered drugs or disease)
- doses of drugs used
- timing of their administration.

In all patients, maintain ventilation to ensure satisfactory oxygenation and carbon dioxide removal. The patient is likely to be unconscious and usually all that is required is more time. If there is continued apnoea, inconsistent with the clinical picture, then a careful evaluation of the cause is needed. The patient should be reassured if they are conscious.

Assess neuromuscular block − a train-of-four ratio of 75% is usually adequate for satisfactory ventilation following anaesthesia. The presence of four good twitches with absent fade implies adequate reversal. Modern nerve stimulators (e.g. the train-of-four watch) can provide more accurate assessment of neuromuscular function by measurement of thumb acceleration (and thus force, because the mass of the thumb is constant). The standard 1 ml ampoule of glycopyrrolate, 0.5 mg/neostigmine 2.5 mg, is the correct reversal dose for a 50 kg patient. The ability to sustain a 5-second head lift from the pillow is a useful clinical indicator of neuromuscular recovery. Figure 11 shows factors that prolong the action of a non-depolarizing neuromuscular block.

Factors that may increase duration of non-depolarizing neuromuscular block

- Hypokalaemia
- Hypothermia
- Hypocarbia
- Neuromuscular disease (e.g. myasthenia gravis, Eaton-Lambert syndrome)
- Inhalational anaesthetic agents
- Aminoglycosides
- Calcium antagonists
- Magnesium
- Local anaesthetics
- Lithium
- Frusemide

Partial reversal of neuromuscular block presents as respiratory inadequacy together with jerky, uncoordinated gross muscular movement. Laryngeal muscle weakness can produce airway obstruction and stridor. The best treatment is to:

- reassure the patient (they may be distressed and feel unable to breathe, with tachycardia and hypertension) and administer 100% oxygen
- help allay anxiety by giving midazolam, 2 mg i.v. or reintroduce general anaesthesia for a short period of time
- correct any underlying cause
- administer further neostigmine (with glycopyrrolate) to a total of 70 µg/kg i.v. (maximum dose 5 mg) if necessary.

Plasma cholinesterase activity − if suxamethonium (or mivacurium) has been used and return of adequate neuro-muscular function is delayed, it is likely that plasma cholin-esterase activity is decreased. This may be an inherited abnormality of cholinesterase activity or an acquired reduction in enzyme activity (Figure 12). The genetic variants have autosomal dominant inheritance, and the prevalence of homozygotes for the atypical gene is 1:2500 of the Caucasian population. Only homozygotes display significantly prolonged apnoea. This may produce many hours of continued paralysis. The patient will come to no harm providing ventilation is supported and adequate sedation is continued (e.g. propofol, 4−6 mg/kg/hour). Neuromuscular block should be monitored with a nerve stimulator and eventually wears off. Infusion of fresh frozen plasma containing cholinesterase enzyme speeds recovery of neuro-muscular function. The benefits must be balanced against the cost and infection risk. Acquired conditions (Figure 12) that reduce plasma cholinesterase activity may slightly increase suxamethonium duration.

Factors that may cause decreased plasma cholinesterase activity

Congenital

- Autosomal dominant inheritance of abnormal enzyme Four alleles have been identified: $E1^n$ normal, $E1^a$ atypical, $E1^f$ fluoride-resistant, $E1^s$ silent

Acquired

- Infections
- Malignancy
- Chronic disease
- Liver disease
- Renal failure
- Pregnancy, oral contraceptives
- Hypothyroidism
- Drugs (monoamine oxidase inhibitors, ecothiopate eye drops, organophosphorus compounds, chemotherapy)

Doxapram is a central respiratory stimulant that may reverse the respiratory depression caused by general anaesthetic agents and potent analgesics. It does not reverse the other effects of opioids. It acts by direct stimulation on the carotid body chemoreceptors. A maximum dose of 1.5 mg/kg slow i.v. can be given.

Benzodiazepines − flumazenil can be used to reverse the central sedative effects of benzodiazepines. It has a shorter half-life than midazolam and diazepam, and therefore re-sedation is possible. Flumazenil, 200 µg i.v., should be given followed by 100 µg i.v. every minute as necessary. The maximum total dose is 1 mg. While benzodiazepines may contribute to postoperative sedation, they seldom cause apnoea unless large doses are used or the patient is elderly and frail.

Opioid drugs − if excessive narcotic is suspected, then give naloxone by titrating dose to effect. Dilute 400 µg in 10 ml normal saline and give 1−2 ml every few minutes to achieve the desired effect. It is important not to use excessive naloxone to prevent reversal of the analgesic effect. Pain, hypertension and tachycardia may result. The patient must be observed closely for the next 4−6 hours because the duration of the naloxone effect may be shorter than that of the opioid.

Check end tidal carbon dioxide tension ($P_{E'}CO_2$) – hyperventilation during anaesthesia results in reduced respiratory drive. Spontaneous ventilation is unlikely to occur until the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) and $P_{E'}CO_2$ have normalized. The addition of 5% carbon dioxide to the inspiratory gas mixture was common in older anaesthetic practice to stimulate respiratory drive. Hazards associated with carbon dioxide use, in particular the inadvertent use of carbon dioxide from incorrect flowmeter settings, have removed the use of this gas from modern practice.

The $P_{E'}CO_2$ should be allowed to rise by itself by either reducing minute volume, or adding dead space into the breathing system (e.g. disconnection of the absorber from a circle system).

Body temperature – hypothermia delays recovery from anaesthesia, prolongs the duration of neuromuscular blockade and is an important cause of postoperative hypoventilation. The fall in core temperature that occurs with anaesthesia should be anticipated and minimized using passive or active rewarming (see *Anaesthesia and Intensive Care Medicine* **1:3:** 122). Continued ventilation in the recovery area or ICU may be required until rewarming is completed and spontaneous ventilation is satisfactory.

Neurological vital signs − an intracranial bleed during surgery is a rare cause of continued unconsciousness and apnoea. It may occur as a result of an undetected head injury in patients undergoing surgery for trauma, or coincidentally in patients with cerebrovascular disease. A CT scan is required for diagnosis.

Investigations in the patient who fails to breathe following anaesthesia should include:

- blood gases, electrolytes and glucose
- body temperature
- neuromuscular function (nerve stimulator)
- ECG and chest radiograph
- CT head scan
- blood for serum cholinesterase activity if indicated.

Air embolism

If bubbles of gas enter the circulation, they may accumulate in the right ventricle. Unlike liquid, gases are compressible, and therefore adequate ejection of blood is not achieved, reducing stroke volume and cardiac output. This can present clinically as a minor fall in blood pressure, hypoxaemia or complete cardiovascular collapse with electromechanical dissociation. If a patent foramen ovale is present, or any other shunt-causing communication between the right and left sides of the heart, the air could enter the systemic circulation and cause neurological injury or coronary artery embolism and infarction (paradoxical air embolism). The effects of air embolism depend on the:

- volume of air entrained
- rate at which it enters the circulation
- general condition of the patient.

Experiments in dogs suggest that volumes greater than 20 mlare potentially fatal.

Some operations carry an increased risk of air embolus (Figure 13). Air may be entrained into an open vein when the venous pressure is subatmospheric. Air embolism occurs in 25−50% of all craniotomy operations in the sitting position and the incidence has reduced now this position is seldom used. The prone position with head tongs appears to be safer for posterior fossa surgery.

Procedures with increased risk of air embolus

- Posterior cranial fossa neurosurgery (especially in the sitting position)
- Lumbar laminectomy and head and neck surgery when the vertebral column is positioned above the level of the heart
- Hepatic surgery that carries a risk of opening the inferior vena cava
- Any patient with a central venous pressure catheter in situ that may result in accidental entrainment of air
- Varicose vein ligation
- Surgery combined with low venous pressures (e.g. in children)

13

Signs that alert the anaesthetist to the development of air embolism are usually detected by monitoring. Early diagnosis allows prompt institution of preventive measures before the situation becomes critical. The signs of air embolus include:

- sudden fall in $P_{E'}CO_2$ despite unchanged ventilatory settings (if breathing spontaneously the patient may develop respiratory distress)
- turbulent blood flow (monitored by precordial Doppler probe; conventional auscultation may reveal continuous ‘millwheel’ murmur as a late sign)
- fall in oxygen saturation
- pulmonary artery pressure increases during air embolism (it is not often monitored)
- arterial hypotension
- tachycardia, dysrhythmias or cardiac arrest.

Management (Figure 14) comprises prevention of further air entrainment, attempts to remove the air and supportive measures.

Management of air embolus

- Ventilate the patient with 100% oxygen. Stop nitrous oxide administration
- Flood the surgical site with normal saline, wet packs, and apply bone wax to any area of exposed bone cortex. Manually compress the proximal veins to stop further air entrainment
- Attempt to increase venous pressure
  - Position patient head down (or surgical site down)
  - Give rapid fluid bolus (250−500 ml) and observe effects
  - Use vasopressors if the arterial blood pressure is severely affected
  - Compression of the abdomen
  - Activation of antigravity venous compression device (G suit) if fitted
- If a central venous catheter (CVC) is in situ, try to aspirate air from all lumens. Insert a CVC (right internal jugular or subclavian) if one is not present
- The left lateral position may transfer air from the pulmonary artery to the right ventricle, thereby improving pulmonary flow (there is little evidence that this is of benefit)
- Give cardiopulmonary resuscitation if required

14

Pneumothorax

The pleural cavity usually exists only as a potential space between the parietal pleura (attached to the innermost intercostal muscle, the transversus thoracus), and the visceral pleura (continuous with the lung parenchyma). A pneumothorax occurs when this potential cavity is opened, either by breaching the chest wall structures (an open pneumothorax), or by injury to the lung parenchyma (a closed pneumothorax).

- The clinical management is concerned with releasing the accumulation of air from the cavity and correcting the chest wall injury. Understanding the anatomy of the chest cavity allows cause and effect to be identified rapidly.
- The dome of the lung protrudes superiorly above the thoracic inlet to the level of the 6th cervical vertebra. The tip of a needle inserted towards the internal jugular vein could pass more posteriorly where it may cross the pleural space and enter the apices of the lung parenchyma. This is possible even with a relatively high approach.
- The inferior part of the chest cavity extends to the costo-diaphragmatic recess. This reaches to the crura of the diaphragm at the level of the 12th thoracic vertebrae. The cavity can be entered inadvertently in this low position by surgery to the renal bed or lower thoracic and upper lumbar vertebrae.
- The mediastinal pleura lies against the vertebral bodies, oesophagus, aorta, large veins, heart and trachea. Damage to many of these mid-chest structures could allow air or blood to enter the pleural cavity. Trauma from accidents or surgical instrumentation of the oesophagus or trachea may cause this.

The signs and causes of a developing pneumothorax while under general anaesthesia are shown in Figure 15; some or all may be present depending on the nature of the pneumothorax (simple or under tension), its speed of onset, the general health of the patient and whether they are breathing spontaneously or are mechanically ventilated.

Signs and causes of pneumothorax

Signs

- Hypoxaemia
- Wheeze
- Increasing airway pressure
- Unilateral chest wall motion
- Reduced air entry
- Hyperresonance
- Distended neck veins
- Shock
- Shifted trachea away from affected side

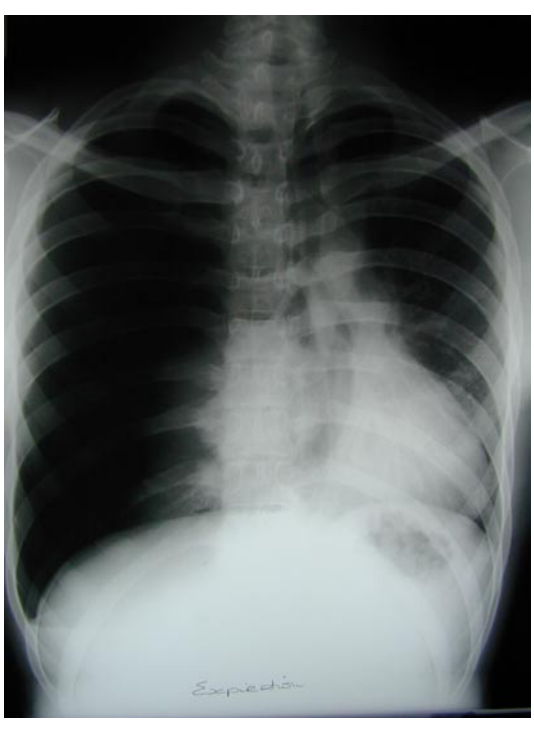
Causes

- Central venous catheter insertion
- Penetrating or blunt chest trauma
- Diaphragmatic, tracheal, oesophageal or cardiac surgery
- Chest drain clamping
- Spontaneous bullae rupture

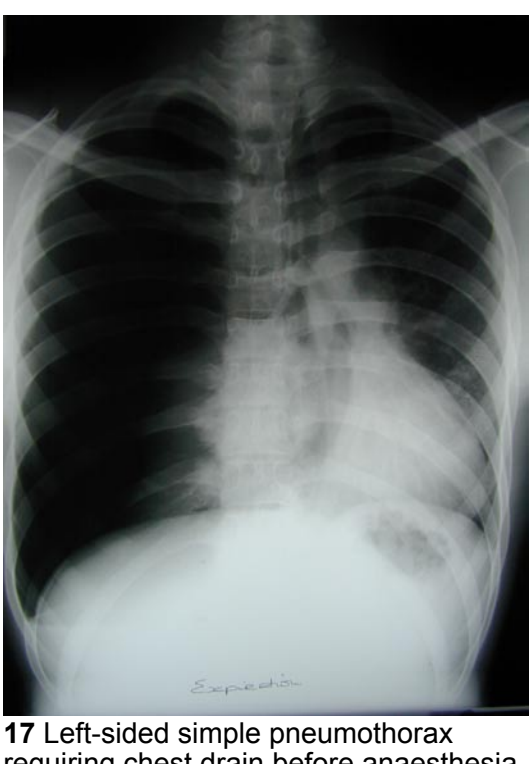
15

In trauma patients, pneumothorax should be identified and treated by chest drain insertion before anaesthesia to avoid the dangers of tension pneumothorax following the start of positive pressure ventilation (Figures 16 and 17). If there is obvious chest injury, but no clinical sign or chest radiograph appearance of pneumothorax, ‘prophylactic’ bilateral chest drains may be indicated. The risks of chest drain insertion must be balanced against the consequences of a tension pneumothorax developing during interhospital or intrahospital transfer or during the perioperative period.

Immediate management of a tension pneumothorax is chest decompression using a 14 G cannula inserted in the midclavicular line and second intercostal space. This should be followed immediately by formal chest drain insertion.



16 Right-sided tension pneumothorax requiring immediate needle decompresion followed by chest drainage. Gross mediastinal deviation is shown to the left.



17 Left-sided simple pneumothorax requiring chest drain before anaesthesia.

Electrical Hazards: Their Causes and Prevention

John Moyle

John Moyle is Consultant in Palliative Medicine in Milton Keynes and a Chartered Engineer. He trained with Philips Electrical Industries. He read medicine at St Bartholomew's Hospital, London and trained in anaesthesia and intensive care at King's College Hospital, London.

Before 1940 there was little electrical equipment in the operating theatre apart from crude radiofrequency diathermy. Since then there has been an invasion of electronic monitoring equipment and many surgical tools are electrically powered. The operating theatre and ICU are unique in electronic engineering because deliberate electrical contact is made with the human body.

The body should be protected from electric current. The body may be considered as an electrolyte solution, which is a good conductor of electricity, contained in a leather bag. Dry leather is a good electrical insulator but conducts electricity easily when damp especially with electrolyte-containing liquids such as sweat.

Electrical injury is caused primarily by the intensity of the current passing through. Current is dependent on the potential difference or 'voltage' across the body and the resistance of the tissues through which it passes (Ohm's law).

$$I = \frac{E}{R}$$

where: E, potential difference (volts); R, resistance (ohms); I, current (amperes)

Severity of injury also depends on the current pathway through the body, environmental factors and the pre-existing health of the patient.

Pathophysiological effects

The pathophysiological effects of electricity range from a mild 'tingling' feeling to ignition in extreme cases. Any electrical current passing through a resistance loses some energy by conversion to heat. The amount of heat generated depends on the current and the value of the resistance; this may be beneficial and forms the basis of coagulation by radiofrequency diathermy. Electricity may stimulate excitable tissues, both nerves and muscles. In a controlled way, this effect may be used medically (e.g. peripheral nerve stimulator, defibrillation). Direct currents, even of low intensity, may cause electrochemical effects. Very high currents, generated by high voltages, cause arcing or sparking and char the tissues. This effect may be harnessed when radiofrequency diathermy is used to cut tissues.

Complications of the inadvertent application of electric currents to the body are:

- cardiopulmonary arrest
- cardiac arrhythmia
- skin and tissue damage
- associated injuries caused by gross muscle contraction.

In the hours after an electric shock there may be further heart rhythm disturbances, hypoxia and electrolyte disturbances, and acute renal failure due to myoglobinuria. It is difficult to predict the effect of electricity on the body because of variables such as body size, proportion and general health. Pre-existing heart problems make the heart more susceptible to arrhythmias.

The current pathway through the body dictates the type of injury. Current passing through the head or across the thorax may cause loss of consciousness and respiratory arrest with or without ventricular fibrillation. Current passing from hand to hand (Figure 1) may cause ventricular fibrillation. Current passing vertically through the body is more likely to cause cardiac muscle damage and injury to other vital organs especially the spinal cord. These injuries depend on the intensity and duration of the current.

The resistance of the human body is not uniform, therefore electricity does not pass evenly through it. Skin resistance is low and allows electricity to pass easily, especially when wet with sweat. Blood has a relatively low resistance, therefore highly vascular areas or inflamed areas of skin have lower resistance. The highest skin resistance is found over heavily calloused areas such as the palm or sole.

The pathway of the current inside the body depends on the resistance of each tissue type. Tissues with the lowest resistance (the best conductance) are nervous tissue, blood, mucous membranes and muscle; the poorest conductors are tendon, bone and fat.

Direct and alternating currents have different effects on the body. Direct current of sufficient intensity causes short duration muscle spasm which may throw the victim from the source. There may be a disturbance of heart rhythm and blunt mechanical trauma. Alternating current, especially at 50 Hz (60 Hz in North America) is approximately three times more dangerous than direct current. Alternating current (40–110 Hz) causes continuous muscle spasm or tetany. As the flexor muscles are more powerful than the extensors, tetany may cause the victim to grip the offending conductor more tightly, thus prolonging the duration of current. Local diaphoresis also reduces skin resistance at the point of contact thus increasing the current.

50 Hz (or 60 Hz) is a bad choice of frequency for the public utility electricity supply because it is the frequency to which the body is most sensitive. At higher frequency the body is progressively less sensitive to the excitable effects of electricity. Radiofrequency surgical diathermy uses frequencies greater than 100 kHz at which comparatively large current may be passed, taking advantage of the heating effects of electricity without affecting excitable tissues.

Effects of hand-to-hand 50 Hz alternating current

1 mA	Tingling sensation
5 mA	Pain
15 mA	Severe pain with local muscle spasm
50 mA	Respiratory muscle spasm
80–100 mA	Dysrhythmias, pump failure, ventricular fibrillation

1

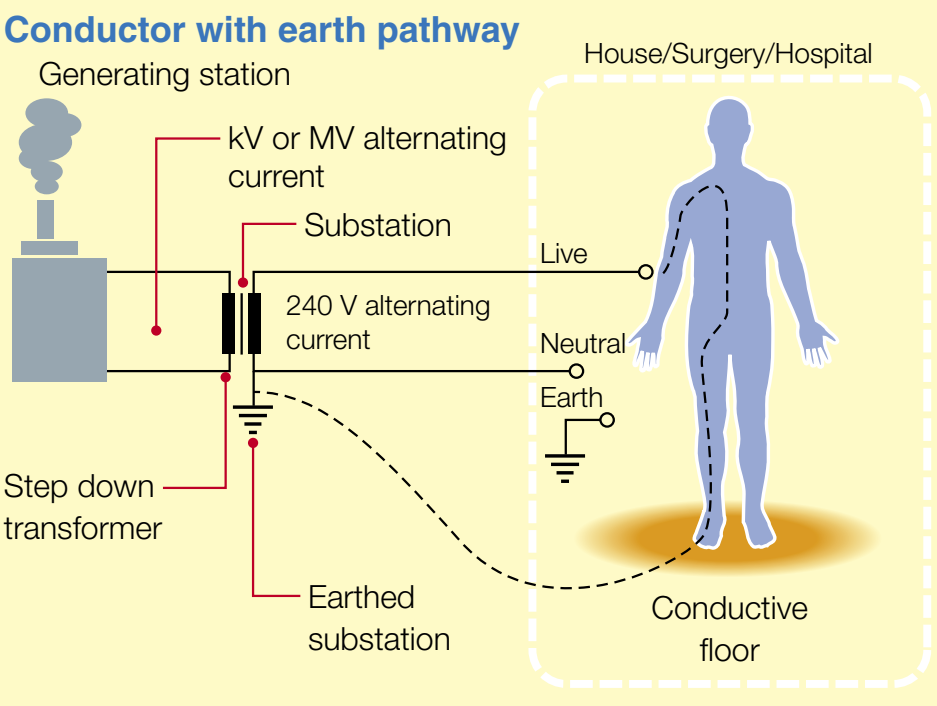
Electrical safety

The basic principle of electrical safety is to prevent the body becoming part of an electrical circuit. This requires good design of equipment, cables and connectors. Even with the highest quality of design, the user has the responsibility of using and handling equipment sensibly.

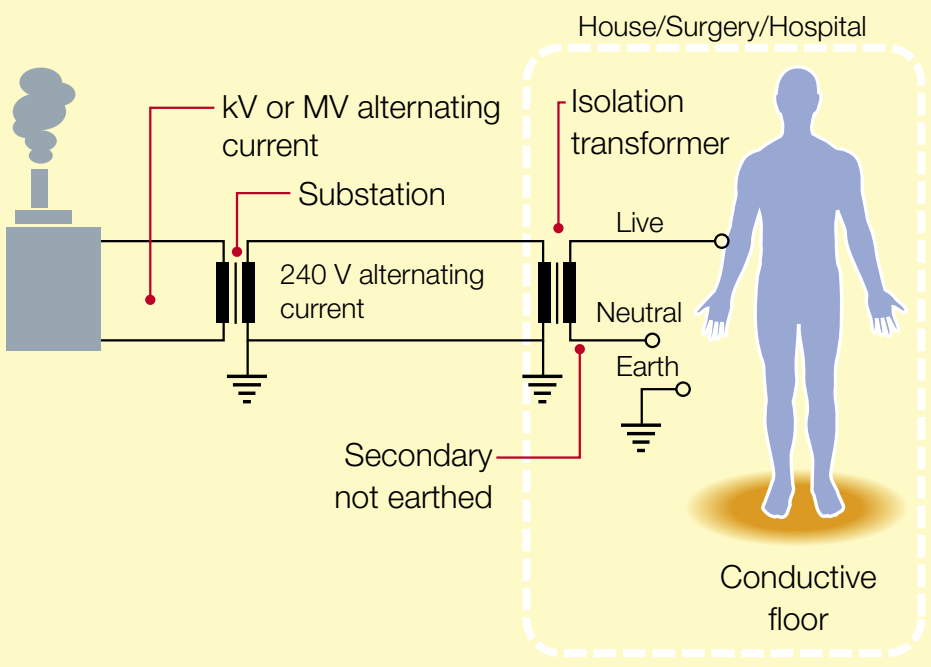
The conventional single-phase mains supply has two conductors: live and neutral. The live conductor is at a voltage dependent on the supply, normally 220–240 volts (110 volts in the USA) with respect to the neutral conductor which is 'tied' to earth at the substation. A safety or earth conductor may also be present which is connected to earth locally and therefore may be at a slightly different potential from the neutral conductor. It is unusual to get an electric shock from the neutral conductor alone but a circuit may be completed between a live conductor or component and either the neutral conductor or, more commonly, an earth pathway (Figure 2). This condition may be eased by the use of an isolation transformer (Figure 3) which will protect against electrocution via earth but not between earth and neutral. Isolation transformers are the most common form of basic protection with medical equipment and are often contained inside the equipment. (Further isolation is required when connection is made directly to the patient, this is described below.)

Conductor with earth pathway



2

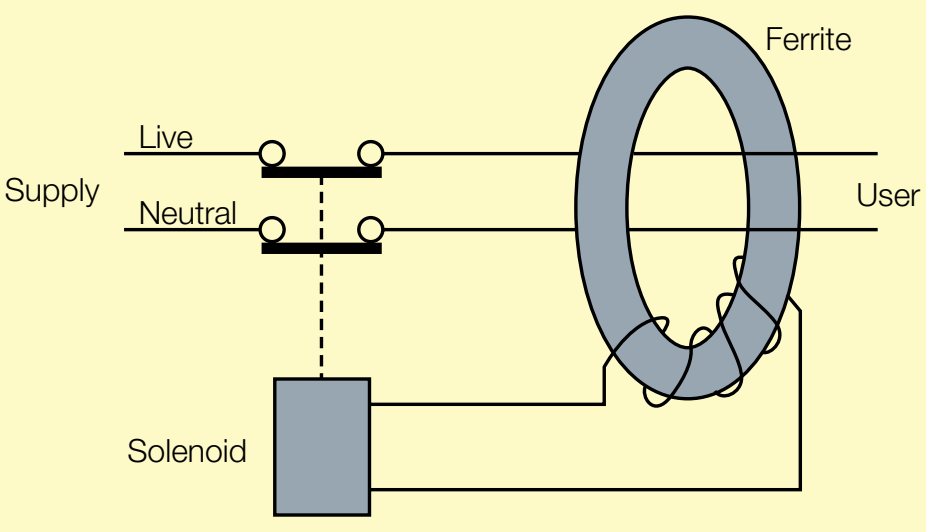
Conductor with isolation transformer



3

Electrocution depends on the duration of exposure and current. The shorter the duration, the higher the current required before damage is done. The earth leakage or residual circuit breaker stops the current passing through the body before any serious damage occurs. This phenomenon is used as the final level of protection from electrocution in the domestic situation and is commonly used commercially for power tools. The principle of the earth leakage circuit breaker (ELCB) is shown in Figure 4. The ferrite ring forms the core of an electrical transformer. The live and neutral conductors pass together through the ring, forming a single-turn primary of the transformer. The secondary of the transformer consists of many turns of much finer wire and is connected to a solenoid. When the solenoid is energized it breaks the supply. In the normal state, current passes down the live conductor, through the appliance and back through the neutral conductor. The current in the neutral is equal and opposite to that in the live and so their magnetic fields are cancelled out and no current is generated in the secondary winding. If some current leaks out of the appliance due to a fault or someone touching a live part, there is an imbalance between the live and neutral and a much amplified current is generated in the secondary, energizing the solenoid and disconnecting the supply.

Earth leakage circuit breaker



4

Microshock: electrocution of the intact human body is commonly referred to as macroshock to distinguish it from microshock in which smaller currents can lead to cardiac dysrhythmia or arrest because one of the points of contact is on or in the heart. 50 Hz mains electricity at a current as low as 50 μA by this route may have serious consequences. Contact may be made with the heart during thoracotomy but a more common and less obvious route is via electrolyte solutions in catheters in or near the heart. Therefore, any equipment that might make connection with the heart must be specially designed to protect against the unintentional passage of these very small currents. Such equipment includes ECG recorders, intravascular pressure monitoring systems, pacemakers and defibrillators.

Leakage current may be defined as electric current that has passed through insulators. It is difficult to design equipment with perfect insulation. The reduction of leakage in medical equipment requires special design features. The designer has to ensure that no electrically live parts are accessible. Any outer metal casing has to be connected to earth; an extra layer of insulation may also be used – the 'double insulation' often used on power tools. These techniques may make a piece of medical equipment safe to be in the patient environment. However, if there is any possibility of connection with the heart, special isolation techniques have to be employed by the equipment designer to ensure that any leakage current is less than 10 μA. This is a stringent limit to achieve.

Safety standards

All medical equipment manufacturers have to comply with published international standards. Each nation also has its own standards organization; in the UK it is the British Standards Institute (BSI). To make standards applicable on a worldwide basis, all national organizations cooperate to write international standards. The International Standards Organization (ISO) deals with everything excluding electricity; the International Electrotechnical Committee (IEC) deals with the standards of anything electrical. Both the ISO and the IEC are based in Geneva.

IEC-60601 is the basic standard for medical equipment. It classifies equipment in two ways; the method of electrical protection and the degree of protection.

- Class I equipment uses a 'protective' earth connection to the outer conductive casing.
- Class II protection is by double insulation. The degree of protection required is classified as B, BF or CF (C, intra cardiac or near cardiac; F, floating) as shown in Figure 5. Figure 6 shows the same symbols, with the indication that the equipment may withstand a defibrillator pulse without damage.

Three types of protection required

Type B applied part

- Maximum leakage current 0.1 mA
- Single fault condition 0.5 mA
- Allowed in patient care area but not in direct contact with patient
- Can be used in X-ray and suction equipment and operating theatre lights

Type BF applied part

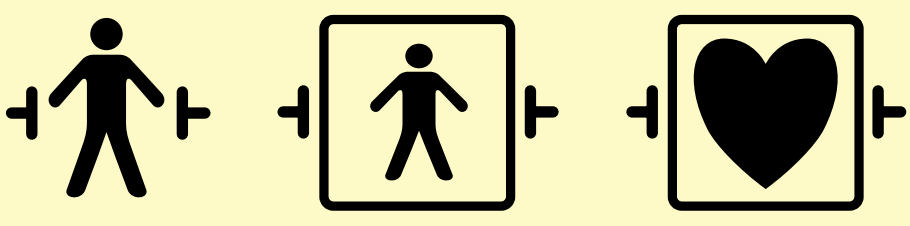
- Maximum leakage current 0.1 mA
- Single fault condition 0.5 mA
- Floating/Isolated
- May be deliberately in contact with patient but not in direct contact with heart
- Can be used in temperature measurement, non-invasive blood pressure measurement, ultrasonography, pulse oximetry, capnography

Type CF applied part

- Maximum leakage current 0.01 mA
- Single fault condition 0.05 mA
- Floating/Isolated
- Suitable for direct cardiac application
- Can be used in ECG, EEG, direct blood pressure measurement, electromagnetic blood flow

5

Symbols indicating equipment is able to withstand a defibrillator pulse



B BF CF

6

Two values of leakage current are given for each category; the lower refers to the equipment in its normal state; the higher value is the maximum allowable leakage current with a single fault condition (SFC). The Standard lists the allowable SFCs for each type of equipment. All medical equipment has to be marked with symbols to show the degree of protection. Figure 7 includes other relevant safety markings that are published in IEC 60601.

Electrical symbols

~	Alternating current
3~	3 Phase alternating current
3N~	3 Phase alternating current with neutral
⎓	Direct current
⏚	Protective earth (ground)
⏚	Earth (ground)
N	Neutral conductor (only on permanently installed equipment)
⏚	Equipotentiality

Fires and Explosions

John Moyle

John Moyle is Consultant in Palliative Medicine in Milton Keynes and a Chartered Engineer. He trained with Philips Electrical Industries. He read medicine at St Bartholomew's Hospital, London and trained in anaesthesia and intensive care at King's College Hospital, London. He teaches physics and clinical measurement to trainee anaesthetists.

Less emphasis is placed on the risk of fire and explosion in the operating theatre today than previously mainly because the use of flammable agents has decreased; for example, ether and cyclopropane are no longer used in anaesthesia. This has lead to a false sense of security and little attention to fire safety. It must not be forgotten that alcohol as an antiseptic and dry drapes are flammable and that the microenvironment around a patient may have an increased concentration of oxygen. Nitrous oxide supports combustion better than oxygen. There are also new sources of ignition, such as the intense energy at the end of fibre-optic 'light pipes' and surgical lasers as well as the dangers associated with the use of surgical diathermy.

Fire and explosion

Fire or explosion occurs when a substance combines with an oxidizing agent with the release of energy. The reaction requires activation energy to trigger it (Figure 1). If the reaction occurs slowly, heat may be the only obvious evidence, though it usually leads to fire. If the reaction proceeds rapidly, large amounts of heat, light and a rapid increase in pressure occur, making sound; this is an explosion. Fire burns slowly at atmospheric pressure at a temperature of 200–500°C. An explosion is a fast, sudden increase in pressure to a high level at a much higher temperature than fire.

If the rate of liberation of heat is equal to the amount of heat required to maintain the process, the flame will stay still as long as the reactants are made available by convection. If the rate of generation of heat is larger than that required to continue activation, the flame will travel through the mixture. The greater the difference, the greater the likelihood of the reaction travelling so fast that a shock wave occurs; this is an explosion.

On a molecular basis, combustion is a chemical process. In oxidation, the intermolecular bond energy of the end products is less than the bond energy of the reactants and the excess energy is dissipated as heat. To induce the initial deformation of the molecules which allows the rearrangement of these bonds, activation energy has to be added to the system; in the case of fires and explosions this is usually in the form of heat. When the oxidation process begins, positive feedback has to occur to maintain the reaction; if not, the process would cease immediately, before the reaction was complete.

The speed of reaction is greatest for a stochiometric mixture: defined as a mixture in such proportions that none of the reactants is left at the end of the reaction.

1

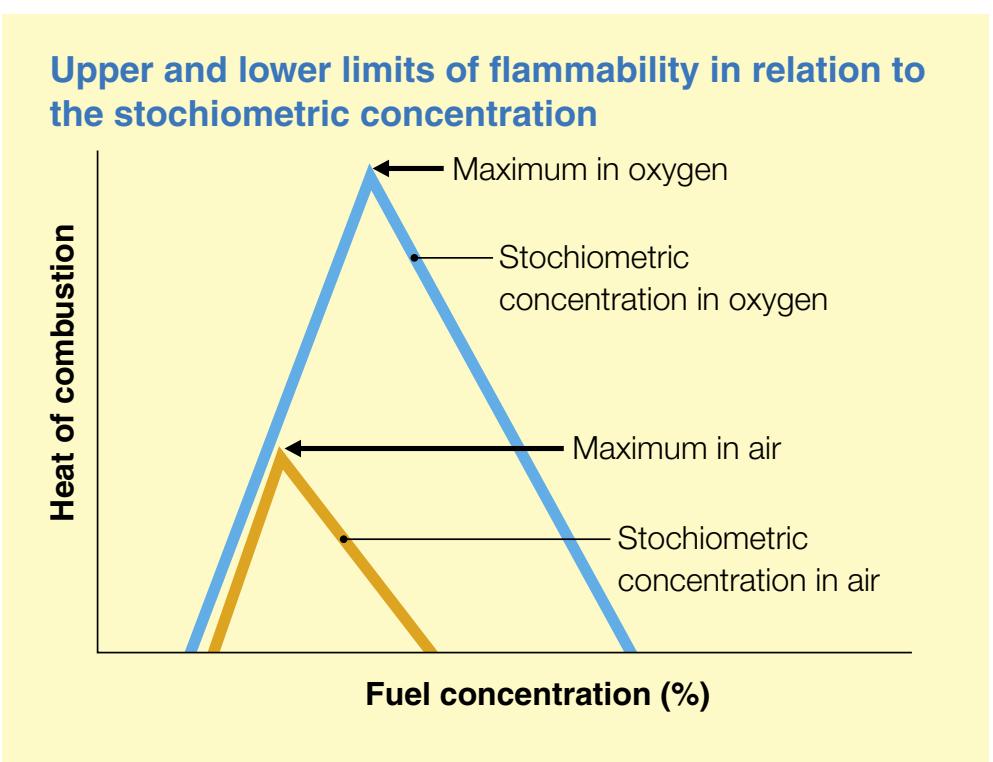
Fuel

A gas or vapour may be flammable over a range of concentrations with lower and upper limits of flammability. The stochiometric concentration occurs between these limits. Limits of flammability vary depending on the atmosphere in which the flammable gas or vapour is found (Figure 2).

Anaesthetic gases and vapours are not the only flammable substance that may put the patient at risk.

- Methane and hydrogen are found in bowel gas.
- Alcohol forms the basis of many skin preparation solutions and is in the exhaled gases of the inebriated. Isopropyl alcohol is commonly used to clean the skin before cannulation. Methyl alcohol is used in spirit burners and by down-and-out alcoholics.
- Drapes are often applied to the patient before the alcohol in skin preparation solution has evaporated completely. There may be a high concentration of the vapour, and even some of the liquid alcohol, beneath the drapes.
- Some surgeons use hydrogen peroxide to clean wounds. It rapidly decomposes by enzyme catalysis when poured on to open wounds, producing a froth of hydrogen and oxygen; the gas given off is highly flammable.
- Dry cotton or paper drapes are flammable.
- The plastic compounds used in the manufacture of conventional tracheal tubes may become flammable in high concen-tration of oxygen and high ignition energy levels.



2

Oxygen

Oxygen in the air is the usual source of oxygen involved in a fire. Figure 3 shows that the risk of ignition of any flammable gas or vapour is increased with increased concentration of oxygen above ambient level. Any fire burns more vigorously if the concentration of oxygen is increased.

Nitrous oxide is not combustible but it vigorously supports combustion.

Risks of fire and explosion arise from the strong oxidizing action of nitrous oxide and from its thermodynamic instability. At about 400°C, nitrous oxide breaks down to oxygen and nitrogen and if this comes into contact with combustible material, fire or explosion may result. The concentration of oxygen and nitrous oxide is increased around the mouth and upper airways if a tracheal tube or laryngeal mask does not seal perfectly. There is often an increased concentration of oxygen and nitrous oxide trapped between the patient and the surgical drapes.

Limits of flammability of gases and vapours encountered in the operating theatre[1]

Gas or vapour	Air		Oxygen		Nitrous oxide		30% oxygen 70% nitrous oxide		20% oxygen 80% nitrous oxide	
	L[2]	U	L	U	L	U	L	U	L	U
Diethyl ether	1.9	48	2.0	82	1.5	24				
Cyclopropane	2.4	10	2.5	60	1.6	30

All values are percentages.

3

Ignition source

Sources of ignition may be sparks generated by static electricity, flames or hot surfaces. Even shaking a bottle containing an organic compound in combination with a peroxide, may cause ignition.

The flash point of a liquid is the lowest temperature at which it gives off enough vapour to form an ignitable mixture with air. At flash point, the vapour will burn, but only briefly because inadequate vapour is produced to maintain combustion. The flash point of a liquid is always quoted but is of less significance to theatre staff than the autoignition temperature.

The autoignition temperature is the minimum temperature above which a flammable mixture is capable of extracting enough energy from the environment to self-ignite. Figure 4 shows the flash points and autoignition temperatures of some compounds in the operating theatre.

If anaesthetic agents that are flammable at clinical concen-trations are used, care must be taken to keep any possible source of ignition outside the zone of risk. There are two zones of risk around the anaesthetic machine, breathing circuit and head and neck of the patient:

- 5 cm if only air is used as the source of oxygen
- 25 cm if nitrous oxide and/or oxygen are used.

Equipment must be marked as AP where air is the only source of oxygen and APG when nitrous oxide or high oxygen concentrations are used.

Possible sources of ignition

Open flames are an obvious source of ignition; they comprise spirit and gas burners, matches and cigarette lighters.

Hot surfaces may cause ignition if the temperature is above the autoignition temperature of the liquid, vapour or solid. In some cases the high temperature of a surface is obvious because it glows or is incandescent.

Hot wire filaments used for cautery may be of high enough temperature to cause ignition. Miniature filament bulbs used in old-fashioned endoscopes may have a surface temperature of 250°C; sufficient to ignite diethyl ether in air.

Light sources – powerful light sources and fibre-optic light-guides have replaced miniature light bulbs but they should always be extinguished when not in use because the energy emitted from the light-guide when not connected to an instrument is intense enough to cause a burn on a surgical drape or the skin. The likelihood of igniting a drape is higher if the concentration of oxygen or nitrous oxide is high in the atmosphere trapped beneath it.

Surgical lasers – see below.

Sparks due to current electricity, as in radiofrequency surgical diathermy and static electricity, are the most obvious sources of ignition in surgical practice. Even sparks that are so small as to be almost invisible may be of sufficient energy to cause ignition.

Sudden increase in gas pressure causes gases to heat. Therefore it is important that no oil, grease or other flammable substance comes into contact with oxygen or nitrous oxide under high pressure.

Lasers

The energy emitted from the tip of a laser applicator is extremely high. The risk of causing ignition is higher than with any other source of emission. Extreme care must be taken to ensure that a laser beam does not come into contact with anything flammable. Any drapes or swabs in the vicinity must be kept wet with water. Care must also be taken to ensure that the beam is not inadvertently reflected on to a flammable surface. If the laser is being used in the mouth, the trachael tube should be of a non-flammable type or be suitably protected. In the case of laser in the bronchi or trachea the oxygen concentration should be 21% or only slightly higher.

Precautions

- Avoid the use of flammable liquids, gases and vapours.
- Keep unsuitable equipment out of zones of risk when flammable anaesthetic agents are in use.
- Observe antistatic precautions.
- Remember bowel gases are flammable.
- Relative humidity should not be less than 50% (a dry atmosphere promotes the generation of static electrical charge).
- At least 15–20 changes of air per hour in the operating theatre will reduce the risk of build-up of flammable vapours.
- High energy light sources must not remain on dry drapes (these sources are of high enough energy to damage tissues).
- Radiofrequency surgical diathermy is a potent source of ignition energy; evaporation of flammable skin preparation solutions must be complete and the atmosphere cleared of the vapour before diathermy is used.

Flash points and autoignition temperatures of flammable liquids encountered in the operating theatre

Compound	Flash point (°C)	Autoignition temperature (°C)
Methyl alcohol	–16	385
Ethyl alcohol	12	363
Diethyl ether	–45	160
Isopropyl alcohol	11.7	455.6

Induction of Anaesthesia

James Austin

James Austin is Specialist Registrar in Anaesthesia in Oxford, UK. He qualified in Cape Town, South Africa and trained in Anaesthesia in Reading, UK.

Induction is the process that produces a state of surgical anaesthesia in a patient. The term is used only in the context of general anaesthesia and not with local anaesthesia. It is the first step in the process of anaesthesia whereby the patient is rendered unconscious, preventing both awareness of, and response to, surgical stimuli. Anaesthesia and physiological sleep are different because sleep has structured, specific EEG patterns and endocrine changes, whereas anaesthesia is associated with a diffuse damping-down of EEG function and a stress-type endocrine response.

The process of induction should ensure patient safety, produce a state of unconsciousness, ensure optimal conditions for the surgeon and prepare the patient for waking and recovery.

Before anaesthesia is induced, the anaesthetist must:

- assess the patient as completely as circumstances allow, and institute preoperative preparations (e.g. intravenous fluids, sedative drugs, analgesics)
- discuss the surgery with the surgeon, particularly in complex or unusual cases
- plan the anaesthetic technique
- ensure all necessary equipment and drugs are available, and that the equipment is working.

On arrival in the anaesthetic suite, the anaesthetist must ensure:

- the correct patient has arrived
- the correct operation is planned on the correct side
- consent has been given
- jewellery or prostheses have been removed or declared
- blood for transfusion is available if required.

Anaesthetic room

In the UK, most inductions take place in a dedicated anaesthetic room; however, in many other countries induction takes place on the operating table in theatre. The main advantage of using a dedicated induction room is the quicker change-around as the theatre is cleaned and prepared between patients. If staffing permits, induction may take place while the previous case is being completed. A separate induction room also avoids the psychological stress (for some patients) of seeing the operating theatre. The anaesthetic room must be equipped with the necessary anaesthetic and monitoring equipment for the induction to be completed safely. The duplication of equipment between anaesthetic room and operating theatre may be a financial constraint in some locations. In urgent cases, with potentially unstable patients or with the morbidly obese, theatre is the best place for induction, because it saves the time, physical hazards and period of reduced or absent monitoring associated with transfer.

Equipment checks: successful induction requires planning and attention to detail. Before the procedure begins, checks of the anaesthetic machine must have been completed and the following must be available:

- the patient must be on a tilting bed or trolley
- two working laryngoscopes (in case of bulb failure), including standard and long blades (sizes 3 and 4)
- a selection of laryngoscope blade types (e.g. the Macintosh and the McCoy levering blade)
- a selection of tracheal tube sizes, with their cuffs checked
- suction equipment
- equipment to deal with difficult or failed intubation, including oral and nasal airways, gum-elastic bougie, laryngeal mask
- standard monitoring equipment (e.g. pulse oximeter, ECG, capnometer, blood pressure monitor).

Monitoring

In addition to the clinical observations made by the anaesthetist, the Association of Anaesthetists of Great Britain and Ireland has published recommendation for standards of monitoring equipment during anaesthesia and recovery. Monitoring should be instituted before induction whenever possible and should consist of a pulse oximeter (ideally with continuous display of pulse rate and plethysmography), an ECG and non-invasive arterial blood pressure monitoring. Following unconsciousness, other variables should also be monitored, including:

- carbon dioxide (using a capnometer)
- the anaesthetic vapour concentration
- body temperature
- neuromuscular function if muscle relaxants are used (assessed using a nerve stimulator)
- invasive arterial or central venous pressures and urine output monitoring may be required.

Induction methods

Most anaesthetic inductions are performed using intravenous or inhalational (‘gas’) induction; each has advantages and disadvantages (Figure 1). Less commonly, induction may be carried out by the intramuscular route in uncooperative patients, children or those with difficult venous access. Ketamine,10 mg/kg, provides up to 30 minutes of surgical anaesthesia, but induction times are unpredictable (15–45 minutes) and recovery is slow. Rectal induction with thiopentone, methohexitone, chloral hydrate or benzodiazepines was popular for children at one time, but is seldom used now. Oral induction is effectively a heavy sedative or ‘premedicant’, rather than induction, and recovery time is prolonged.

There are several tasks to be accomplished with any form of induction:

- last-minute preliminary checks (as specified above)
- establish monitoring
- establish intravenous access
- produce unconsciousness
- secure the airway
- establish ventilation
- commence analgesia (systemic or local)
- position the patient
- establish maintenance of anaesthesia.

Intravenous and inhalational induction

Intravenous	Inhalation
Advantages	*Advantages*
• Rapid onset • Patient comfort • Airway protection in rapid-sequence induction	• Does not require IV access • Useful for children • Useful for adults with needle-phobia
Disadvantages	*Disadvantages*
• Contraindicated in patients with a ‘difficult airway’	• Slow induction • ‘Excitement’ phase • Risk of vomiting • Risk of arrhythmias • Volatile agents contraindicated in patients susceptible to malignant hyperpyrexia

1

Intravenous induction

Pulse oximetry and ECG monitoring should be established before intravenous access because occasionally a cardiovascular event (e.g. vasovagal syncope) occurs during cannulation. Intravascular access commonly consists of a simple venous cannula; however, complex cases may require an arterial line, a central venous line and/or a pulmonary artery catheter. These may be sited with local anaesthesia before induction, to provide additional monitoring if haemodynamic instability is expected.

Following intravenous access, preliminary drugs (e.g. analgesics, antibiotics, anti-emetics) may be given. These vary according to the clinical circumstances and a detailed discussion is beyond the scope of this article. A regional analgesic block, if required, may also be given at this stage. Whether to insert the block before or after the patient is anaesthetized is the subject of some controversy (Figure 2).

Advantages of regional nerve blockade performed either before or after induction

Before induction	After induction
• Patient cooperation with correct positioning • Patient may provide feedback to minimize neural damage by needle or injection • Less requirement for anaesthetic monitoring	• Patient preference • Correct positioning may be easier (e.g. patients with painful fractures or skeletal deformity)

2

Pre-oxygenation: some anaesthetists routinely pre-oxygenate their patients before induction. The correct technique is for the patient to breathe 100% oxygen via an anaesthetic circuit and close-fitting mask for about 3 minutes of tidal volume breathing. Alternatively, pre-oxygenation by three vital capacity breaths has been demonstrated to be effective. The aim is to replace nitrogen-containing air in the resting volume of the lungs (the functional residual capacity, FRC) with a high oxygen concentration. The gas within the FRC acts as an important oxygen store, and therefore pre-oxygenation lengthens the time before hypoxaemia occurs following the onset of apnoea. This may provide valuable time in which the airway can be secured if an unexpectedly difficult airway is encountered. Mask phobia and the difficulties in achieving a mask seal in non-compliant patients and children are the only significant contraindications to pre-oxygenation. Pre-oxygenation is mandatory in rapid-sequence induction.

Intravenous drugs: slow, smooth injection of an intravenous anaesthetic agent usually results in loss of consciousness in less than 1 minute. Thiopentone, for example, starts to work in a period of one ‘arm–brain circulation time’. This is the period of time taken for the drug to travel from the site of injection (the arm) to the site of action (the brain) and is about 15 seconds in a healthy patient. The dose is carefully titrated according to patient response. Typical induction doses for healthy individuals are shown in Figure 3, but dose reduction may be required in:

- patients who are less fit
- the elderly or frail
- neonates
- patients with hypotension or poor cardiac reserve
- patients with chronic renal or liver disease
- patients with raised intracranial pressure
- patients who have been premedicated.

It can be difficult to judge when enough induction agent has been given. Care and experience are needed to titrate dose to effect but some indicators include:

- loss of response to verbal command
- loss of eyelash reflex (in which brushing the eyelash produces a blink response)
- relaxation of a motor posture (e.g. a raised arm or a grip on an object)
- cooperation with bag/mask ventilation.

The eyelash reflex has conventionally been regarded as a good end-point for thiopentone induction, but it is less reliable in propofol induction, for which loss of verbal response or motor relaxation is a more useful end-point.

Induction doses of intravenous drugs

Drug	Typical adult induction dose (mg/kg)	Notes
• Propofol	1.5–2.5	Popular and widely used drug associated with rapid and ‘clear-headed' recovery. Rapid metabolism and lack of cumulative effects has made it popular for total intravenous anaesthesia
• Thiopentone	3–5 (2.5% solution)	The ‘gold-standard’ against which all other drugs are judged. Smooth induction in one arm–brain circulation time
• Methohexitone	1–1.5 (1% solution)	Lowers the convulsive threshold, mainly used in anaesthesia for electroconvulsive therapy
• Etomidate	0.2–0.3	Marked cardiovascular stability makes this drug popular for use in unstable patients
• Ketamine	0.5–2	Useful for sedation with profound analgesia. Increases pulse rate and blood pressure and useful for the induction of patients suffering from acute trauma
• Midazolam	0.15–0.5	A benzodiazepine that may provide stable induction for the elderly and frail, in combination with an opioid

3

Further procedures: the induction agent may be followed by a muscle relaxant, particularly if tracheal intubation is planned. It is important to confirm that the patient's lungs can be ventilated via a bag and mask before paralysing. A muscle relaxant should not be given until it has been confirmed that ventilation is possible. Once anaesthesia is adequate, a clear airway is established using a simple face mask (with or without an oral or nasal airway), laryngeal mask airway or tracheal intubation. If the level of anaesthesia proves to be inadequate to allow an airway or tracheal tube to be tolerated, it may be deepened either with supplementary doses of intravenous agent, or by ventilating with volatile anaesthetic. With the airway secure, ventilation can continue by the patient's own effort, by manual 'hand' ventilation, or by mechanical ventilator.

At this stage, further invasive procedures may take place, such as additional vascular access, regional blocks, bladder catheterization, passing of a nasogastric tube or insertion of a temperature probe.

Transfer to theatre: if anaesthesia has been induced in the anaesthetic room, the patient is now transferred to theatre. This is potentially hazardous because for a short time the patient is separated from monitoring equipment and the mechanical ventilator. The patient is also potentially unstable because of the effects of induction drugs and is at risk of injury during the physical transfer. It is the anaesthetist's responsibility to guarantee the patient's safety. It should be ensured that ventilation and anaesthetic maintenance are re-established in good time, that tubes and lines are not dislodged, and that changes in clinical condition are detected promptly, in particular, cardiovascular instability, desaturation or signs of waking from anaesthesia.

Once in theatre, the priorities are:

- prompt transfer on to the operating table
- prompt re-establishment of ventilation
- prompt re-establishment of anaesthetic maintenance if using volatile anaesthetic drugs
- check correct drug delivery if using intravenous maintenance technique
- prompt re-establishment of monitoring equipment
- safe positioning of the patient
- commencement of maintenance fluids and temperature control.

Rapid-sequence induction

Rapid-sequence induction is used to decrease the risk of aspiration if the patient may have a full stomach, for example in an emergency. In patients presenting for elective surgery, a period of starvation of 2 hours for clear fluids, or 6 hours for food, is considered appropriate. Bowel obstruction, incompetent lower oesophageal sphincter, pregnancy and gastroparesis caused by disease, pain or drugs such as opiate analgesics are also causes of a potentially 'full stomach'.

The incidence and severity of aspiration of gastric contents are made worse by the nature, volume and pH of the gastric solution. Mendelson's studies on aspiration pneumonitis showed that aspiration of solid particles produced more damage than purely fluid aspirates. A potential gastric aspirate greater than 25 ml in volume and/or with a pH less than 2.5 is considered dangerous, though there is little direct clinical evidence for this. In these 'at-risk' patients it is sensible to attempt to raise gastric pH, and to try to promote gastric emptying. Pre-medication with ranitidine, 50 mg i.v., to decrease gastric acidity, and metoclopramide, 10 mg i.v., to enhance gastric emptying and increase the tone of the lower oesophageal sphincter is popular with some anaesthetists; both take at least 1 hour to take effect. A non-particulate antacid, such as sodium citrate, 30 ml of 0.3 M solution orally, given on leaving the ward or arriving in the anaesthetic room, further neutralizes residual stomach acid, but at the expense of raising gastric volume further.

Some anaesthetists advise that a nasogastric tube should be passed to drain the stomach, but it is uncomfortable and may induce vomiting. The counter argument is that any vomiting is better done while the patient is fully awake with protective airway reflexes. If a nasogastric tube is already in place it should be aspirated. If the gastric contents are still acidic on litmus test, consideration should be given to instilling sodium citrate. The old practice of inducing vomiting with ipecac or apomorphine is no longer advised.

The 'rapid sequence' of drug administration aims to produce unconsciousness and intubation conditions as rapidly as possible. The airway is swiftly protected by a cuffed tracheal tube without prior inflation of the lungs via bag and mask. This is to prevent possible gastric distension with an increased risk of gastric reflux. It is performed with the help of a trained assistant, competent in the technique of cricoid pressure.

Muscle relaxants are administered before the airway is controlled, and in this way rapid-sequence induction breaks an important rule of anaesthesia. Careful preoperative assessment of potential airway difficulty is therefore vital, and rapid-sequence induction must not be performed if this assessment predicts difficulty with intubation. The trainee anaesthetist must seek further advice, because an awake intubation technique may then be indicated.

Pre-oxygenation is mandatory, though it may be difficult to achieve in children. Pre-oxygenation reduces the need to ventilate the lungs before intubation. The correct technique is described above. Oxygen must be delivered via an anaesthetic breathing system capable of delivering 100% oxygen; standard 'Hudson' type face masks are inadequate.

Drug injection: the chosen drug is rapidly adminstered (Figure 3). Thiopentone is the drug of choice because of its rapid onset of action in one arm–brain circulation time, but propofol or etomidate are alternatives, albeit slightly slower-acting. The use of rapid-acting opioids such as alfentanil, 10 μg/kg, or fentanyl, 1 μg/kg, helps to reduce the pressor response to laryngoscopy.

Cricoid pressure: or Sellick's manoeuvre, is traditionally practised in rapid-sequence induction and is applied by the anaesthetic assistant as the patient starts to lose consciousness. Pressure is applied to the cricoid cartilage to compress it against the oesophagus, preventing passive regurgitation of stomach contents.

If active vomiting occurs, it is recommended that cricoid pressure be removed to prevent oesophageal rupture – suction, head-down tilt and turning the patient's head to one side is then used instead. Otherwise, cricoid pressure is removed only on the instruction of the anaesthetist, once the airway has been secured with a cuffed tube. Occasionally, it may be removed to facilitate an intubation that is being made more difficult by its continued application.

Muscle relaxation: suxamethonium, 1.5 mg/kg, is the drug of choice. Its rapid onset produces ideal intubating conditions, with a peak effect of muscle relaxation within 50 seconds of injection. It is important to allow the drug time to work, and not to begin the intubation sequence before muscle fasciculations have subsided.

The duration of apnoea is usually about 5 minutes in healthy individuals, and thus spontaneous respiration may be re-established early in the event of a failed intubation. Suxamethonium is contraindicated in patients with:

- previous allergy
- susceptibility to malignant hyperpyrexia
- myotonia
- severe burns, muscle damage or paraplegia (of over 1 week's duration)
- known raised serum potassium.

In these patients, rocuronium, 0.6–0.9 mg/kg, may provide relaxation as rapidly as suxamethonium, but with longer duration. Rocuronium is also the drug of choice in patients with reduced or absent plasma cholinesterase activity, in whom suxamethonium has a long and unpredictable duration of action.

Intubation: the trachea is intubated with a cuffed tube following unconsciousness and muscle relaxation. Uncuffed tubes are used in children to avoid local pressure on the tracheal wall and to maximize the internal diameter of tube available. If difficulty is encountered with direct laryngoscopy, then simple steps may be taken to facilitate intubation:

- manipulate the larynx (the assistant providing the cricoid pressure may be distorting the view of the larynx)
- change to a larger blade laryngoscope
- change to a different type of blade (e.g. a McCoy levering blade)
- use the gum-elastic bougie (this thin, flexible stylet may be used to pass through the cords providing a 'track' over which the tracheal tube can be railroaded).

Before the cricoid pressure is released, the correct position of the tube must be checked carefully by auscultation and capnometry. Once the cuff has been inflated and the airway has been secured, a nasogastric tube should be passed and aspirated, if not done previously. The rest of the anaesthetic proceeds as usual; but at the end of the procedure extubation should take place with the patient awake, with their protective airway reflexes re-established, positioned on their side in a head-down tilt, and with suction available.

Failed intubation drill – if the trachea is not successfully intubated, a failed intubation drill must be followed:

- cease further attempts at intubation
- call for help
- maintain cricoid pressure
- insert an oral airway
- hand-ventilate via bag and mask using 100% oxygen
- await return of spontaneous respiration
- once spontaneous ventilation has returned, turn the patient into the lateral position with head tilted down and await return of consciousness.

A decision to abandon further attempts at intubation must be made early and certainly before arterial desaturation supervenes. The prime concern of the anaesthetist is patient safety. The safest option following failed intubation is to wake the patient. Once the effects of the intravenous induction agent and muscle relaxant have worn off, consideration must be given to how to proceed. This requires consultation with a senior anaesthetist and may involve an awake intubation technique.

Inhalational induction

Gas induction, controversially, is often used as a means of inducing anaesthesia (particularly in a child) without having to site an intravenous cannula first. However, in the event of difficulties (e.g. laryngospasm, arrhythmias) instant intravenous access should be available, because otherwise the anaesthetist controlling the airway will be unable to attempt rapid cannulation. For this reason, some anaesthetists seldom perform gas induction; others permit gas induction if a second anaesthetist is present to assist with intravenous cannulation. Gas induction of children and adults has taken place without intravenous access for over 150 years, in most cases safely and without incident.

Indications: gas induction (with intravenous access) is indicated for patients in whom airway difficulties are expected. In these cases, the patient continues to breathe spontaneously throughout and apnoea is avoided, since it may then be impossible to manually ventilate the lungs with bag and mask.

Upper airway obstruction is an important indication for inhalation induction, and in these circumstances fibre-optic techniques for intubating the trachea are contraindicated for fear of producing complete airway obstruction. However, in patients with an unobstructed 'difficult' airway, the increasing availability of fibre-optic intubation equipment and the growing skill of anaesthetists in awake intubation techniques may reduce the need for gas induction. The difficult airway may best be secured even before anaesthesia is induced.

Technique: there is controversy over whether to induce in 100% oxygen or to use nitrous oxide as well.

- Concurrent use of volatile and nitrous oxide exploits the second-gas effect for a cumulatively more rapid induction. The rapid absorption of the second gas (nitrous oxide) has the effect of increasing the alveolar concentration of the first agent. The partial pressure of anaesthetic gas in the alveolus reflects the partial pressure of anaesthetic in the brain and hence the anaesthetic effect.
- 'Pre-induction', with 33% oxygen and 66% nitrous oxide only, may render a child sleepy enough not to resist when the odour of the volatile agent is added. Clearly the more nitrous oxide is used the more anaesthetic effect is achieved; but likewise the less reserve there is against desaturation. A minimum of 30% oxygen should be given.
- Induction in 100% oxygen is least smooth, but should laryngospasm occur, it is an advantage to have as much of the lung FRC filled with oxygen as possible. This maximizes oxygen stores and thus delays the onset of hypoxaemia.

Conventional practice for inhalational induction with halothane is to start with a low inspired concentration of 0.5%, and to increase it by 0.5% every four breaths up to 4%.

Sevoflurane has greatly enhanced gas induction, because it is faster, better tolerated by patients, and is less arrhythmogenic than halothane. It has been suggested that the lower incidence of arrhythmias has contributed to a decrease in dental anaesthetic deaths in recent years. The high blood-gas solubility of sevoflurane accounts for its rapid onset and offset. Because sevoflurane is less pungent it is often used in high concentrations (maximum 8% on most vaporizers) for faster induction.

Enflurane is seldom used for gas inductions because it is slow; isoflurane and desflurane are almost never used because they are pungent and irritating to the airway.

The last-minute checks before inhalational induction are the same as those for the intravenous route. Monitoring should be established; some children make this difficult, but ECG should be the minimum monitoring instituted. Induction should ideally take place via a tight-fitting face mask (even small leaks may significantly delay induction). However, the use of a cupped hand may be less threatening to a small child in the first instance.

'Single-breath induction' has been described with halothane and sevoflurane. A Mapleson A breathing system containing a 4-litre reservoir bag is filled with a maximum concentration of volatile anaesthetic (4% halothane or 8% sevoflurane) in 66% nitrous oxide and 33% oxygen. The patient is asked to exhale to residual volume, then, via a tight-fitting mask, to inhale a full vital-capacity breath of gas, and then to hold their breath for as long as possible. This technique produces a faster induction than conventional tidal volume inhalational induction in cooperative adults. In the case of single-breath 8% sevoflurane, the speed of induction is comparable with induction with intravenous propofol. It may be a useful technique to use in cooperative needle-phobic adults, but it offers few other advantages.

Four main variables determine the speed of inhalational anaesthetic induction.

- The inspired partial pressure of the anaesthetic agent relative to its minimum alveolar concentration (MAC) alters the speed of induction. MAC is the partial pressure of the agent, expressed in volumes %, which at equilibrium prevents gross muscle movement in response to a skin incision in 50% of patients. It is thus the effective dose in 50% of patients and is a measure of anaesthetic potency.
- The faster the patient breathes, or the greater the alveolar ventilation, the faster the alveolar partial pressure of the agent approaches the inspired partial pressure. In a child, crying speeds up gas induction by increasing minute ventilation.
- The higher the cardiac output the more anaesthetic agent is removed from the alveoli and hence the slower the partial pressure rises in the alveoli. Thus, an anxious, hyperdynamic patient is slow to induce, whereas a shocked patient with a low cardiac output is quicker.
- The higher the solubility of an agent (i.e. a high blood-gas solubility coefficient), the more the agent will dissolve in blood and thus a lower partial pressure will be generated. Agents with a low solubility (e.g. sevoflurane) result in more rapid induction.

During a gas induction, most patients pass briefly through a phase of excitability during which they may be agitated and at increased risk of laryngospasm or, more rarely, arrhythmias. If a child is being induced, it is useful to warn the parents of this disinhibition in advance. The disinhibition is not remembered by the patient.

Once the patient is unconscious, anaesthesia should be deepened, assisting the ventilation by hand, using bag and mask if necessary. If not already obtained, intravenous access should be secured, which requires the help of an assistant. Muscle relaxants may then be given intravenously to assist in securing the airway. If the patient is sufficiently deeply anaesthetized, as evidenced by a regular respiratory pattern and a forward gaze in eyes with small pupils, the airway may be secured (even by intubation) purely under inhalational anaesthesia. Nevertheless, it is valuable to have intravenous access before attempting to manipulate the airway, in case any untoward airway reflexes are produced (e.g. arrhythmias, laryngospasm). With the airway secured, the remainder of the induction sequence proceeds as above.

Historical note

In 1937, Arthur Guedel published *'Inhalational Anaesthesia – a Fundamental Guide',* three chapters of which were devoted to his observations of premedicated patients' responses to gas inductions with nitrous oxide, the ethers, chloroform and cyclopropane

Guedel's stages of anaesthesia

Stage	Definition	Features
1 Analgesia	From beginning to loss of consciousness	Sedation Loss of eyelash reflex[1]
2 Delirium	Loss of consciousness to onset of rhythmic breathing	Agitation, vomiting, arrhythmias Eyes deviated
3 Surgical		
• 1st plane	Onset of rhythmic breathing to loss of eyeball movement	Loss of eyelid reflex Loss of conjunctival reflex[1]
• 2nd plane	Loss of eyeball movement to onset of intercostal paralysis	Loss of laryngeal and gag reflexes Loss of corneal reflex[1]
• 3rd plane	Onset to completion of intercostal paralysis	
• 4th plane	Complete intercostal paralysis to respiratory arrest	Dilated pupils Loss of carinal reflex[1]
4 Respiratory paralysis	Respiratory arrest to death	Loss of anal reflex

[1] Not described in Guedel's original monograph

Induction in children

Children from about 3 months of age until the teenage years are generally more anxious, or less able to control their anxiety, than adults. The preoperative visit is important in children because meeting the anaesthetist and having the procedure explained calms the fears of children and parents. If the child is old enough, address your conversation to him or her. Explain in detail what will happen, and invite the parents and child to ask questions. Where possible, bring relevant equipment, particularly a face mask for gas induction, for the child to become familiar with.

Topical local anaesthetic cream such as EMLA (a eutectic mixture of lignocaine and prilocaine) or amethocaine gel is desirable if awake intravenous access is planned. Marking visible veins in advance helps the nurse to cover the right spots. Both preparations are similarly effective in clinical practice though onset and duration of action differ (Figure 4).

It has become common for parents to accompany children to the anaesthetic room, and this is generally helpful. Smaller children may best be anaesthetized on a parent's lap – a well-positioned hug serves to comfort the child and to restrain them during intravenous cannulation or gas induction. Strapping for the cannula, and the induction drugs, should be on hand for swift application once access has been obtained.

- For gas induction, a sideways hug helps to immobilize all the limbs, while the anaesthetist's hands control the head.
- For intravenous cannulation, a 'face-to-face' hug (Figure 5), with the child's arm under the parent's arm, helps to immobilize the arm and restrict the child's view of cannulation.
- The older child may prefer or need to be anaesthetized on the trolley. If the trolley permits, it is useful to raise the back until just before (or even during) induction itself. This more upright position allows the child a better view of their surroundings, and hence a feeling of more control and less anxiety.

Children should be treated with respect at all times. They should be spoken to in non-condescending language they can understand – if something is going to be unpleasant, it should be acknowledged. The alternative is for the child to become suspicious and uncooperative for even the most innocuous procedure. There is no formula that will ensure every paediatric induction is smooth and trouble-free; some children will be understandably fractious despite all efforts to calm them.

Comparison of EMLA cream and amethocaine gel

	EMLA cream	Amethocaine gel
Constituents	Lignocaine 2.5%, prilocaine 2.5% as an oil/water emulsion	Amethocaine 4%
Presentation	White cream, 5 g per tube	Clear gel, 1.5 g per tube
Application	2 g minimum 1 hour before venepuncture, maximum 5 hours	1 g 30–45 minutes before venepuncture. Remove after 45 minutes
Duration	Efficacy declines soon after cream is removed	Efficacy remains 4–6 hours after application
Skin effects	Usually transient paleness May produce redness and oedema	Usually transient redness May produce itching and oedema
Contra-indications	Not for children < 1 year	Not for children < 1 month

4

5 Hugging the child face to face helps to immobilize the arms.

Induction of Anaesthesia in Special Circumstances

Christopher F Kearns

Christopher F Kearns is Consultant Anaesthetist in the Nuffield Department of Anaesthetics, The Radcliffe Infirmary, Oxford, UK. He qualified from Charing Cross Hospital and trained in anaesthesia and intensive care at St Bartholomew's Hospital, London, in Toronto, Canada, and at Oxford. His clinical interest is neuroanaesthesia. He organizes the Oxford Primary FRCA courses.

A full stomach

The pulmonary aspiration of acid gastric contents has long been recognized as a major risk of anaesthesia. Patients are normally asked to fast preoperatively to allow sufficient time for gastric emptying. However, induction of anaesthesia in the presence of a full stomach may be unavoidable when normal gastric emptying is impaired, or when the urgency of surgical intervention overrides the requirement for a patient to have fasted adequately. Gastric stasis, ileus and reverse peristalsis may accompany obstruction or perforation of the gastrointestinal tract. Trauma, pain and its treatment with opioids delays gastric emptying. Gastric motility may also be abnormal in the presence of diabetes mellitus or obesity and in these circumstances no period of fasting may be considered to be safe. The hazards of induction of anaesthesia in these circumstances are listed in Figure 1.

If the patient has a full stomach an attempt to reduce intragastric volume and acidity before anaesthetic induction is desirable. Gastric fluid may be removed through a gastric tube, or if there is time and no contraindications by giving a prokinetic agent (e.g. metoclopramide, 10 mg i.v.). The pH of the gastric contents may be increased by the ingestion before induction of a non-particulate alkali, usually 30 ml of a 0.3 molar solution of sodium bicarbonate.

Induction of anaesthesia in the presence of a full stomach

Hazards	Management
Pulmonary aspiration of gastric contents	Reduce gastric volume Raise intragastric pH with alkali Use of cricoid pressure Rapid sequence induction
Unanticipated failure to intubate	Preoxygenation Rapid sequence induction Failed intubation drill

1

Rapid sequence induction

Rapid sequence induction is the anaesthetic technique indicated in the presence of a full stomach (Figure 2). It aims to reduce to a minimum the period during which the airway is unprotected after induction of anaesthesia and before inflation of the cuff of a correctly placed tracheal tube.

During preparation for rapid sequence induction, a skilled assistant should carefully identify and hold the cricoid cartilage between the thumb and forefinger, ready to apply cricoid pressure as anaesthesia is induced. Cricoid pressure (Sellick's manoeuvre) correctly applied with adequate, but not excessive, force compresses and occludes the upper oesophagus between the flat posterior surface of the cricoid cartilage and the body of the sixth cervical vertebra, preventing reflux of gastric contents without distorting the view at laryngoscopy. If a gastric tube is already in place, it should not be removed but should be allowed to act as a gastric vent.

The main risk of rapid sequence induction is that there is no prior opportunity to ensure that intubation or mask ventilation will be possible after induction. Good preparation for intubation is vital and it is essential that all equipment is checked, suction equipment and aids to oxygenation are ready and the patient is in an optimum intubating position.

The patient's lungs should be preoxygenated. This is achieved by allowing the patient to breathe 100% oxygen through a tightly fitting mask and anaesthetic circuit for about 3 minutes. When apnoea occurs at induction, the lung rests at end tidal volume where there is equilibrium between the elastic recoil of the lungs and the chest wall. Arterial oxygen desaturation follows when the oxygen content within the functional residual capacity (FRC) of the lungs is exhausted. During preoxygenation, the nitrogen in the FRC will be displaced, increasing the oxygen content of this reservoir substantially and delaying the onset of cyanosis after induction of apnoea. Despite these measures, arterial oxygen desaturation is accelerated by the presence of a reduced FRC (e.g. obesity), a raised metabolic oxygen demand (e.g. sepsis) or a combination of the two (e.g. late pregnancy).

Rapid sequence induction requires the use of rapidly acting induction and paralysing agents injected intravenously in quick succession. Most intravenous induction agents cause loss of consciousness within one arm–brain circulation time in the following doses: thiopental (thiopentone), 2–4 mg/kg, etomidate 0.2–0.3 mg/kg, propofol 2–3 mg/kg. In UK practice, suxamethonium, 1.5 mg/kg, remains the neuromuscular blocking agent of choice because it provides optimum intubation conditions in the shortest time.

Once the correct position of the tracheal tube is verified clinically and by capnography and after the cuff has been inflated, cricoid pressure can be released.

In case of failure to intubate, the duration of action of the induction and paralysing agents is critical. Despite the additional time made available by preoxygenation, it may be impossible to see the larynx or intubate the patient. It is then essential to revert to a well-rehearsed failed intubation drill. The effects of the common induction agents wear off in a few minutes and the choice of suxamethonium is reinforced by its short duration of action. The temptation to give a second dose of the drugs and prolong attempts at intubation should be resisted. At this point, resumption of patient oxygenation is the priority.

Rapid sequence induction

- Selection of intubation aids and equipment for cricothyroid puncture
- Skilled assistant applying cricoid pressure
- Patient on surface that can be tipped head down
- Suction switched on with catheter under pillow
- Optimal patient intubating position
- Good quality venous access with running intravenous infusion
- Preoxygenation with 100% oxygen through close fitting face mask
- Single sleep dose of intravenous induction agent
- Single adequate intravenous dose of suxamethonium (e.g. 1.5 mg/kg)
- Failed intubation drill

2

After head injury

Induction of anaesthesia and tracheal intubation after head injury (Figure 3) is indicated when:

- the patient's airway or oxygenation is compromised
- the patient has a depressed level of consciousness (Glasgow Coma Score of 8 or less)
- in the presence of agitation
- before emergency surgery
- in preparation for safe transfer to either CT scanner or to a neurosurgical centre.

It is vital to prevent secondary brain injury due to hypoxia, hypotension, hypercapnia or uncontrolled rises in intracranial pressure. The patient is assumed to have a full stomach so a rapid sequence induction with preoxygenation and cricoid pressure is indicated. In addition, patients presenting with a severe head injury must be assumed to have suffered a cervical spine injury. Cricoid pressure is applied using a two-handed technique, the second hand supporting the back of the cervical spine. Another assistant is required to provide manual in line stabilization of the spine during induction because any cervical collar has to be temporarily removed to facilitate intubation. Coexisting facial injuries need to be assessed carefully because they may affect intubation by displacing, distorting or obstructing the airway.

Careful monitoring of cardiovascular status is required. It may not be practical to monitor blood pressure invasively before induction, but non-invasive measurements should be made frequently. Suppression of the hypertensive response to intubation requires an intravenous induction agent, though the dose may have to be reduced in the presence of depressed consciousness. Lidocaine (lignocaine), 1 mg/kg, may also be given for this purpose. After induction there should be a smooth transition to maintenance sedation, which may include opiates, to avoid fluctuations in blood pressure.

Suxamethonium is associated with a transient rise in intracranial pressure, but this potential for harm is outweighed by its advantage of rapidly producing optimal intubating con-ditions and thereby reducing the risk of hypoxia. A peripheral nerve stimulator will help to ensure adequate neuromuscular blockade before intubation, and that a non-depolarizing agent is given in time to prevent coughing and facilitate controlled ventilation as the effect of suxamethonium wears off.

Tracheal and gastric tubes should not be placed nasally, for fear of breaching a skull base fracture. Constriction or distortion of neck veins that could result in cerebral venous hypertension should be avoided when securing the tracheal tube and applying a cervical collar. Arterial hypotension must be actively investigated and treated, while moderate hypertension should be tolerated because this may be a normal response to intracranial hypertension, preserving cerebral perfusion pressure.

Induction in head injury

Hazards	Management
Full stomach	See Figure 1
Cervical spine injury assumed	In line stabilization of neck Two-handed Sellick manoeuvre
Rising intracranial pressure	Adequate dose of induction agent Adequate neuromuscular blockade Smooth transition to maintenance sedation and paralysis
Reduced cerebral perfusion pressure	Avoid hypotension
Facial injuries	Intubation facilitated or made more difficult
Skull base fracture	Avoid nasal intubation

3

Upper airway obstruction

The management of the patient with obstruction of the upper airway, including the larynx, is a vital skill for anaesthetists (Figure 4). Adequate diagnosis of the airway pathology and the derangement of normal anatomy should precede discussion of the management plan between senior anaesthetic and ENT staff. An alternative strategy must also be agreed so that there is a back-up plan before proceeding. The management plan should be explained clearly to the patient, whose cooperation will be required.

Induction in airway obstruction

Hazards	Management
Potential for airway obstruction in expert hands	Senior help present
Abnormal anatomy	Information from imaging or endoscopy
Loss of muscle tone in upper air-way at induction may precipitate complete obstruction	Inhalation induction or awake tracheostomy
Obstruction during inhalation induction	Back-up plan in place with scrubbed ENT surgeon for surgical airway

4

Assessment of the patient may elicit stridor (inspiratory noise) at rest, which suggests that the airway is more than 50% narrowed. Results of radiographs, CT or MRI scans or nasendoscopy should be available. In their absence it may be appropriate to perform endoscopic examination by fibrescope via a topicalized and vasoconstricted nasal passage. The site of obstruction must not be approached with the fibrescope because attempted fibre-optic intubation may be impossible and may be hazardous, but endoscopy may provide important reconnaissance information. If there is doubt about the feasibility of intubation, then an awake surgical tracheostomy under local anaesthesia should be considered.

If intubation is likely to be possible, an alternative strategy must be in place before embarking on induction of anaesthesia. A scrubbed ENT surgeon must be present ready for immediate intervention and opening of a surgical airway.

The usual technique for induction of anaesthesia in the presence of upper airway obstruction is an inhalation induction. Most experience has been obtained with halothane although use of sevoflurane is growing. Gradual induction of anaesthesia while maintaining spontaneous ventilation and airway muscle tone may allow adequate depth of anaesthesia for intubation without airway closure. Should there be no obstruction, no manipulation of the airway or laryngoscopy is allowed before adequate depth of anaesthesia is achieved as judged by the pupils coming to lie centrally. It is vital that no neuromuscular blockade or intravenous sedation is used before the airway is safely secured.

Obstruction of the airway during inhalation induction prevents further uptake of anaesthetic agent, therefore allowing anaesthetic depth to lighten and the patency of the upper airway to be restored. An awake surgical tracheostomy should then be performed under local anaesthesia.

Maintenance of Anaesthesia

James Austin

James Austin is Specialist Registrar in Anaesthesia in Oxford, UK. He qualified in Cape Town, and trained in Anaesthesia in Reading, UK.

This contribution is an overview of what is meant, and required, by maintenance of anaesthesia. Many of the topics are covered in greater detail in separate contributions; the aim here is to put these topics in context.

Maintenance of general anaesthesia involves four priorities:

- keeping the patient safe
- keeping the patient comfortable
- presenting the best possible operating conditions for the surgeon
- preparing the patient for the postoperative period.

Keeping the patient safe

There are several aspects involved in keeping the patient safe:

- airway, breathing and circulation
- temperature control
- monitoring
- positioning.

Airway: this will usually have been established at the time of induction. However, it should not be assumed that this remains secure. Airway disconnection or obstruction may occur and the anaesthetist must be able to detect and correct these incidents promptly, assisted by monitors such as the capnograph, pulse oximeter, disconnect alarm and airway pressure monitor. Movement of the tracheal tube (either towards the right main bronchus or withdrawal from the trachea) or dislodgement of the laryngeal mask airway (LMA) are particularly likely to occur when patients are transferred to the operating table or when changes are made to patient position. These periods require increased vigilance by the anaesthetist. The integrity of the airway should be rechecked both clinically and by monitoring after each patient movement.

Tracheostomy, rigid bronchoscopy or 'one-lung' thoracic surgery may require intraoperative changes to the airway. The anaesthetist must be prepared for such changes and, if necessary, should formulate a plan with the surgeon in advance as to how the airway will be managed.

Breathing will often depend on whether muscle relaxants are being employed as part of the anaesthetic technique. Although the use of muscle relaxants is not essential for controlled ventilation, they are usually employed for ventilated patients. Surgical factors often influence the decision to use muscle relaxants. For example, abdominal surgery is greatly facilitated by muscle relaxation. In specialized surgery, such as ophthalmic surgery or neurosurgery, where the slightest move or cough may have disastrous consequences and carbon dioxide must be controlled, paralysis is ideal. Otherwise, anaesthetists have widely differing views as to whether breathing should be controlled. Some anaesthetists use muscle relaxants almost routinely for any operation lasting longer than about 30 minutes, on the basis that carbon dioxide retention is avoided, potent short-acting opioids can be used without fear of respiratory depression, and good lung aeration with avoidance of atelectasis may be easier to achieve. Others control ventilation less often unless indicated for reasons of airway management or the requirements of surgery. Some advantages and disadvantages of paralysis and ventilation are listed in Figure 1.

The technique of 'paralysing and ventilating' may be preferred when a tracheal tube is present. It is likely that a relaxant will already have been given to enable intubation. Also, the presence of a tube within the trachea is a potent stimulus, and unless local anaesthesia has been applied to the respiratory tract, a deeper level of anaesthesia may otherwise be needed for the patient to breathe spontaneously without coughing. Lighter planes can be tolerated when a laryngeal mask or oropharyngeal airway are employed, because these devices are less stimulating to the patient. Paralysing and ventilating may also be used for longer operations, where carbon dioxide control and prevention of atelectasis is important.

However, avoiding relaxants wherever possible can reduce two important complications of general anaesthesia:

- unrecognized awareness – patient movement usually warns of light anaesthesia before the patient becomes aware
- accidental hypoxia – the spontaneously breathing patient may maintain oxygenation even in the event of circuit disconnection.

Use of muscle relaxants and controlled ventilation

Advantages	Disadvantages
• May allow 'lighter' anaesthesia because reflex activity is abolished by neuromuscular blockade	• May allow unrecognized awareness as a result of inadequate anaesthesia
• Facilitates abdominal surgery by relaxation of abdominal muscles	• Reliance on ventilation equipment and circuit integrity to maintain alveolar ventilation
• Intracranial and intraocular pressure control by regulation of $PaCO_2$	• Possible side-effects of muscle relaxant drugs (e.g. histamine release, vagal blockade, malignant hyperpyrexia)
• Allows effective ventilation during, for example, thoracic surgery, prone positioning or long procedures	• Need for reversal of neuromuscular blockade
• Allows use of potent opioids to reduce the surgical stress response in major surgery	• Possible contraindication in patients with a difficult airway. Absence of spontaneous respiration may render ventilation impossible
• May improve surgical conditions by facilitating a hypotensive technique and lowered $PaCO_2$	• When there is requirement to monitor neuromuscular function (e.g. facial nerve during surgery on the parotid gland or acoustic neuroma)
• Decreases intraoperative atelectasis	
• Decreases energy requirements and tissue carbon dioxide production	• Contraindicated in some myopathies

1

Ventilator settings – most anaesthesia ventilators are time-cycled and volume- or flow-driven. A rate, usually with a ratio of inspiratory time to expiratory time (I:E), and a tidal volume or flow need to be set. Most adults have a minute volume of 80–100 ml/kg, therefore a tidal volume of 8 ml/kg (e.g. 500–600 ml) and a rate of 10 breaths/minute is a good starting point; this can be adjusted according to the observed end-tidal partial pressure of carbon dioxide ($P_{E'CO_2}$). For routine surgery, a $P_{E'CO_2}$ of about 4.5 kPa should be aimed for. If metabolic rate and cardiac output (and hence pulmonary perfusion) are assumed to be constant, then $P_{E'CO_2}$ varies inversely with the alveolar ventilation.

In general, an I:E ratio of 1:2 is often the best compromise between maintaining low inflation pressures (e.g. 15–20 cm H_2O), satisfactory oxygenation (Sp_{O_2} > 95%) and adequate carbon dioxide removal ($P_{E'CO_2}$ 4.5 kPa). However, this can be decreased to 1:1.5 or even 1:1 to prolong inspiratory time. This may be useful in some patients to help decrease high airway pressures (e.g. > 25–30 cm H_2O) or improve oxygenation (e.g. in the obese). Some patients with asthma or chronic airway disease may benefit from a longer expiratory time to allow the lungs to empty, and an I:E ratio of 1:3 or 1:4 may be preferable.

Children have a proportionately higher minute ventilation than adults – up to 200 ml/kg in infancy, approaching adult values weight-for-weight by about age 10 years. Given that their tidal volume is slightly less weight-for-weight than adults (7 ml/kg), this increased minute volume must be provided for by an increase in rate. For example, in a 5 kg infant, a minute volume of 1000 ml might be provided by 30 breaths each of about 33 ml/minute.

However, paediatric ventilation is complicated by the obligatory leak around the uncuffed tube. Volume control is unlikely to inflate the lungs to the set volume (especially if a Newton valve is used with T-piece ventilation). This is usually overcome by increasing the tidal volume by titrating against inflation pressure and/or $P_{E'CO_2}$. Some modern anaesthesia ventilators have pressure control capabilities (e.g. the *Draeger Julian*). Specific compliance varies little with age, therefore pressure control mode can be used to deliver an inflation pressure of 15–20 cm H_2O. This provides an adequate tidal volume for any age, despite small to moderate leaks, as long as lung compliance is normal.

Regardless of the mode of ventilation, a fresh gas flow must be selected. This depends on the breathing system in use as well as the size of the patient. A high flow should be used initially (e.g. 6 litres/minute), regardless of the circuit being used. This allows time for denitrogenation and equilibration of inhaled anaesthetic agent during this early period of rapid anaesthetic uptake. After about 10 minutes, flows can be reduced considerably if the system permits. The circle system with carbon dioxide absorber is widely used, and modern lightweight valves and low-resistance tubing make it suitable for paediatric use well below the traditional lower patient weight limit of 20 kg. With appropriate monitoring of gas concentrations within the circle, this permits total fresh gas flows of 1 litre/minute or less. Higher flows are required for T-pieces such as the Bain and Jackson Rees systems. Formulae exist for each of these circuits to predict the flow of fresh gas required per kilogram patient weight to eliminate rebreathing for controlled and spontaneous respiration. However, a more practical approach is to reduce the fresh gas flow gradually, stopping when rebreathing of carbon dioxide begins to appear on the capnograph.

General anaesthesia, particularly when using volatile anaesthetic agents, causes the development of atelectasis in the dependent parts of the lung and impairs the pulmonary vascular response to hypoxia (hypoxic pulmonary vasoconstriction). These two factors produce a small but noticeable degree of shunt, usually about 10%. This can be corrected by giving anaesthetized patients higher inspired oxygen than the 21% present in air; 30% is usually given, though this can be titrated against observed oxygen saturation.

Circulation: appropriate fluid management is an important component of anaesthetic maintenance. Intravenous fluid requirements may range from none in short and relatively non-invasive procedures, to many times the circulating volume in long and traumatic procedures. Fluid requirement consists of:

- replacement of existing deficit – crystalloid or blood
- metabolic maintenance requirements – crystalloid
- replacing additional ongoing losses – crystalloid, colloid or blood.

Existing deficit – in the adult elective surgical patient, who has been starved for at least 4 hours preoperatively (and sometimes much longer), a deficit of 500 ml of crystalloid can be assumed. This deficit is generally well tolerated and does not necessarily need replacing, but it decreases the patient's margin of reserve against any further losses, or against ongoing postoperative dehydration as a result of nausea or vomiting. Many anaesthetists routinely administer 500–1000 ml of crystalloid in all patients except those at risk from fluid overload (e.g. those with renal or cardiac failure). There is evidence to suggest that this may improve the quality of early recovery and help to decrease postoperative nausea.

In the emergency patient, fluid deficit may be considerable, as a result of either trauma-related blood loss, or anorexia, vomiting and/or interstitial (third-space) fluid loss from surgical pathology. In either case, the deficit should be assessed and replaced with the appropriate fluid. The larger the deficit, the more important that it be replaced before induction, whenever circumstances permit. The exception to this rule is during major ongoing blood loss, such as a ruptured aortic aneurysm or major trauma, where the priority is stopping the bleeding rather than prolonging attempts to normalize the circulation preoperatively.

Maintenance – for many patients this is the least important component of intraoperative fluid management – the average adult requirement of about 100 ml/hour is negligible in the context of a short procedure and other fluid losses. However, in small children, maintenance requirements are proportionately larger and more significant. Paediatric maintenance fluid is usually calculated according to: 4 ml/kg/hour for the first 10 kg, plus 2 ml/kg/hour for the next 10 kg, plus 1 ml/kg/hour for the remainder. Thus, a 25 kg child would have a maintenance requirement of 40 + 20 + 5 = 65 ml/hour. The smaller the child, the less reserve there is for managing without ongoing maintenance fluids, and the greater the impact of preoperative starvation.

Infants have small glycogen reserves, and therefore need intravenous dextrose (e.g. as 5% dextrose in 0.18% saline) as maintenance to sustain their blood sugar levels. For longer procedures, careful attention must be paid to electrolyte balance, because infants have less ability to correct excessive salt loads or water loads.

Ongoing losses – the most significant aspect of intraoperative fluid management can be the most difficult to estimate.

Losses from extravascular spaces (e.g. gastrointestinal, evaporative, third-space fluid losses) are usually crystalloid losses. Evaporative losses can be large – an adult may lose in excess of 1 litre/hour from a laparotomy or thoracotomy wound, and even larger amounts from extensive open skin wounds such as burns or large graft sites. There is no way of measuring these losses directly, and measures such as blood pressure, pulse rate or central venous pressure (CVP) provide only an indirect measure of total body water. Urine output may be the most useful clinical measure. Blood tests such as plasma urea, sodium and haematocrit may provide information regarding the hydration state, and plasma electrolytes and haematocrit are now commonly available from blood gas machines.

Losses also occur from the intravascular space (i.e. blood). Losses in suction bottles may be complicated by wash, faeces, urine or amniotic fluid. Visual estimates of blood loss on swabs are often inaccurate – weighing of swabs is more precise, but still neglects losses on drapes, gloves and instruments. A dilutional technique relies on washing all swabs, instruments and gloves in a fixed volume of water, which can then be measured colorimetrically to give an accurate measure of blood loss. Such instruments are not widely available. Intravascular loss may be estimated indirectly from clinical measures such as blood pressure, pulse rate or CVP, though other anaesthetic factors such as the balance between surgical stimulation and depth of anaesthesia complicate these measures. Estimation of haemoglobin is useful only when adequate intravascular volume has been replaced. Blood losses may initially be replaced by colloid solution (e.g. a gelatin solution or hydroxyethyl starch), but larger losses (> 20% blood volume) may require replacement by packed-cell blood. Very large losses (> 1 blood volume) may require supplementation with fresh frozen plasma and/or platelets to maintain clotting function.

In practice, it is likely that fluid losses are under-replaced in many patients. This is offset by the hormonal 'stress response' to surgery: aldosterone, cortisol and antidiuretic hormone levels rise and atrial natriuretic peptide falls; all contribute to postoperative water retention.

Temperature control: there is now good evidence that the maintenance of a physiological body temperature reduces postoperative morbidity. Patients suffering from head injury or undergoing certain neurosurgical procedures are possible exceptions. Shivering increases oxygen consumption, and predisposes to myocardial ischaemia, dysrhythmias, hypotension and acidosis. Hypothermia also increases susceptibility to infection and tends to lengthen hospital stay.

Temperature control is of particular importance in patients at the extremes of age (who have less intrinsic control over body temperature and a larger surface area-to-volume ratio through which to lose heat), in operations involving open body cavities, and in all patients undergoing lengthy procedures. About 20% of trauma patients who arrive at hospital are hypothermic (core temperature < 35°C).

A change in core temperature as a result of general anaesthesia is a three-phase response.

- The first phase is a brisk fall in core temperature as a result of vasodilatation, caused by redistribution of heat to the peripheries. Core temperature may be as low as 35.5°C in some patients after transfer to the operating theatre from the anaesthetic room.
- The second phase is a slower but more sustained fall as a result of accelerated loss of heat to the environment from the warmer peripheries.
- The third phase is a stable equilibrium at a lower core temperature.

It is important to note that the anaesthetic itself brings about these changes, which are independent of the nature of the surgery, though surgery may modify the pattern. The use of spinal or epidural anaesthesia instead of general anaesthesia reduces, but does not abolish, the three-phase response described above.

Passive rewarming is the prevention of heat loss, typically by raising the temperature of the environment. Passive rewarming can serve to modify only the second phase of the heat loss response. Covering with blankets or the use of foil 'space' blankets decreases heat loss by reduced transfer of heat by convection, conduction, evaporation and radiation.

Dry inspired anaesthetic gases need to be humidified, and a heat and moisture exchange filter in the breathing system reduces heat loss by evaporation from the respiratory tract (latent heat). Low flows in a circle system (e.g. 1 litre/minute) further reduce the quantity of dry gas needing to be humidified and help retain heat and moisture within the breathing system.

A 'normal' operating room temperature of 21°C is a compromise between that which is warm enough for the patient, but cool enough for the comfort of theatre personnel. An increase in theatre temperature (e.g. to 25°C) helps to reduce the gradient for heat loss in patients at high risk (e.g. young children, patients with extensive burns).

Active rewarming is the addition of heat into the patient. It may be used to prevent or reverse the first phase of the temperature drop. The local environmental temperature can be raised so much that the transfer of heat is reversed. Warm air convection blankets (e.g. the *Bair Hugger*) are considered as active rewarming.

Intravenous fluid warmers play an increasingly important role the greater the volume of intravenous fluid given. A fluid-warming device should be used in all at-risk patients and especially when stored blood is administered. Ventilatory gases may be warmed using a heated humidifier. Overhead radiant heaters may be used when a large area of the body needs to be exposed, and neonates may undergo surgery on an open incubator such as the *Resuscitaire*.

Cardiopulmonary bypass represents the ultimate in active rewarming, but is practical only in cardiothoracic surgery or in uncommon resuscitation situations.

Care is needed not to overheat the patient and temperature monitoring is necessary when active rewarming methods are used. Monitoring probes are available for a variety of body cavities, including nasopharynx, oesophagus, rectum, bladder and tympanic membrane. In routine clinical practice, core temperature is usually measured by nasopharyngeal or rectal temperature probes. Surface temperature monitors do not reflect core temperature, but the core–peripheral gradient may provide a useful measure of peripheral vasodilatation. A gradient of less than 2°C implies good peripheral perfusion.

Monitoring: the Association of Anaesthetists has published recommendations on standards of monitoring. A summary is given in Figure 2.

Blood sugar should be monitored in infants and diabetic patients. The blood sugar of diabetic patients should be known before anaesthesia is given, and should be estimated every 1–2 hours during routine surgery.

The Association of Anaesthetists summary of standards of monitoring

- The Association of Anaesthetists of Great Britain and Ireland strongly recommends that the standard of monitoring used during general anaesthesia should be uniform in all circumstances irrespective of the duration of anaesthesia or the location of administration
- An anaesthetist must be present throughout the conduct of general anaesthesia
- Monitoring should be commenced before induction and continued until the patient has recovered from the effects of anaesthesia
- These recommendations also apply to the administration of local anaesthesia, regional analgesia or sedation where there is a risk of unconsciousness or cardiovascular or respiratory complications
- The anaesthetist should check all equipment before use. Monitoring of anaesthetic machine function during the administration of anaesthesia should include an oxygen analyser with alarms. During spontaneous ventilation, clinical observation and a capnometer should be used to detect leaks, disconnection, and rebreathing and high pressure in the breathing system. Measurement of airway pressure, expired volume and carbon dioxide concentration is strongly recommended when mechanical ventilation is employed
- A pulse oximeter and capnometer must be available for every patient
- It is strongly recommended that clinical observation of the patient should be supplemented by continuous monitoring devices displaying heart rate, pulse volume or arterial pressure, oxygen saturation, the electrocardiogram and expired carbon dioxide concentration. Devices for measuring intravascular pressures, body temperature and other parameters should be used when appropriate. It is useful to have both waveform and numerical displays
- Intermittent non-invasive arterial pressure measurement must be recorded regularly if invasive monitoring is not indicated. If neuromuscular blocking drugs are used, a means of assessing neuromuscular function should be available
- Additional monitoring may be required in certain situations. These recommendations may be extended at any time on the judgement of the anaesthetist

2

Positioning: an unconscious patient cannot move to relieve an uncomfortable position, and it is the anaesthetist's responsibility to prevent discomfort from becoming damage. The anaesthetist is also responsible for protecting the patient during movement on and off the operating table, and during changes of position. Traditionally, the anaesthetist has particular responsibility for the head and airway. It must be ensured that all members of the team are working to a common agenda and with coordinated timing. It is usually easiest and safest to disconnect as much equipment as possible before moving the patient.

Prophylaxis against venous thromboembolism – the thrombotic process often starts intraoperatively. It is difficult to identify patients at high risk, though coexisting medical illness, major surgery, malignancy, trauma (especially hip and pelvis), obesity, high-dose oestrogen therapy and age greater than 40 years are well-known risk factors. Thromboprophylaxis should commence before anaesthesia; gradated compression stockings and low-dose unfractionated heparin, 5000 IU s.c. twice daily, continued until full mobilization, is popular and effective. When positioning for surgery, raising the heels on foam pads prevents venous stasis in the calves. Intermittent pneumatic compression pumps assist venous return, but it is not known whether this reduces the incidence of postoperative pulmonary embolism.

Keeping the patient comfortable

Traditionally, the main components of anaesthetic maintenance are unconsciousness (hypnosis), analgesia and absence of movement. Some advantages and disadvantages of using muscle relaxants have been discussed. Keeping the patient unconscious and relieving the pain of surgery are now considered.

Maintenance of unconsciousness is usually achieved by anaesthetic drug delivery via the inhalational or intravenous route, or both. The intramuscular route is seldom used in hospital practice owing to the relatively slow onset of drug action, unpredictable duration and delayed recovery. Ketamine, 10 mg/kg, is the only useful intramuscular agent, with an onset of 5–10 minutes producing up to 30 minutes of anaesthesia. It has a role in the provision of emergency anaesthesia in difficult locations.

Inhalational route – this is the most widely used technique, using a volatile anaesthetic agent with or without nitrous oxide. It therefore requires a supply of compressed gas, a vaporizer and a breathing system for drug delivery. Compressed gas may not be required if a 'drawover' type vaporizer is used.

The potency of an inhaled anaesthetic agent may be described in terms of its minimum alveolar concentration (MAC). MAC is defined as the alveolar concentration of the anaesthetic agent which at equilibrium is required to prevent gross reflex muscular movement in response to a standardized skin incision in 50% of healthy, unpremedicated patients. It is therefore a measure of anaesthetic potency, and is the effective dose in 50% of the population (ED_{50}). It should be borne in mind that not all operations are 'a standardized skin incision'. The amount of anaesthetic needed to remove a foreign body from the nose is very different from that needed for an anal stretch. It is important to know the MAC of individual inhalational agents and the factors on which they depend (Figures 3 and 4).

Of any given inhalational anaesthetic, 0.7–1.3 MAC will anaesthetize 95% of the population. MACs are also additive: 0.5 MAC of nitrous oxide (52%) plus 0.5 MAC of isoflurane (0.6%) is equivalent to 1 MAC of any other inhalational agent given alone.

The principle of MAC acts as a useful guide. It allows the anaesthetist to select a vapour concentration that is likely to maintain unconsciousness. The state of anaesthesia is related to the partial pressure of anaesthetic within the brain, which is taken to be equivalent to the alveolar partial pressure. This can be measured by analysis of the end-tidal partial pressure of the anaesthetic agent. What is dialled on the vaporizer or the nitrous flowmeter is not necessarily what is in the patient's alveoli – the fresh gas flow takes time to equilibrate both with the dead space of the circuit and with the uptake by the patient. Observing how the ratio of end-tidal to inspired partial pressure varies with time can assess this rate of uptake (or 'wash-in').

MAC is useful to estimate the amount of anaesthetic required. In clinical practice this must be adjusted against indicators such as pulse rate, blood pressure, respiratory rate, patient movement, pupillary size, lacrimation and sweating. Many of these variables may be abolished by factors other than anaesthetic depth. Tachycardia may be prevented by co-administered β-blockers, hypertension masked by hypovolaemia, respiratory rate and patient movement abolished by paralysing drugs, and pupillary size altered by use of opioids or anti-muscarinic drugs. Thus, lacrimation and sweating, though crude indicators of inadequate anaesthesia, reflect the need for clinical observation in addition to monitoring.

Minimum alveolar concentration (MAC) of inhalational anaesthetic agents

Anaesthetic agent	MAC in oxygen (%)	MAC in 70% nitrous oxide
• Halothane	0.75	0.29
• Enflurane	1.68	0.57
• Isoflurane	1.15	0.50
• Sevoflurane	2.0	0.8
• Desflurane	6–9	2.5–3.5

3

Factors affecting minimum alveolar concentration

Decrease	Increase	No change
• Increasing age	• Decreasing age	• Gender
• Alcohol (acute ingestion)	• Alcohol	• Duration of anaesthesia (chronic ingestion)
• Nitrous oxide	• Hyperthermia	• Time of day
• Analgesics	• Hyperthyroidism	• Hypercarbia
• Sedatives and hypnotics	• Hypocarbia	
• Hypotension		
• Hypothermia		
• Hypothyroidism		
• Hypoxia		

4

Intravenous route – a popular alternative to inhalational anaesthesia is total intravenous anaesthesia (TIVA). Many intravenous anaesthetics have been used for TIVA, including barbiturates, ketamine, etomidate and propofol. The pharmaco-kinetic profile of propofol makes this drug the most commonly used for TIVA. It has a high clearance (1300–1900 ml/minute), short metabolic half-life (60–100 minutes) and inactive metabolites. For short procedures, propofol may be administered following initial intravenous induction by intermittent bolus with no special infusion equipment (e.g. 50 mg as required every 3–5 minutes).

For longer procedures, the advent of reliable electronic syringe pumps, and in particular the development of target-controlled infusion (TCI) software, have contributed to the widespread use of TIVA techniques. Some advantages and disadvantages of inhalational or TIVA maintenance are shown in Figure 5.

Consider a three-compartment model: vascular space, richly perfused organs, and poorly perfused organs plus clearance. A large initial bolus of propofol is needed to fill the vascular compartment, namely the induction dose. Thereafter an initially high rate of infusion is needed to keep up with losses to the richly perfused compartment until it approaches saturation. Then a slower rate is required to keep up with losses to the poorly perfused but difficult to saturate compartment, and with metabolic clearance.

The 'Bristol regimen' reflects these kinetics. This regimen aims to maintain a plasma propofol concentration of about 3 μg/ml by giving patients receiving 67% nitrous oxide an initial bolus of 1 mg/kg, followed immediately by infusion at 10 mg/kg/hour for 10 minutes, then 8 mg/kg/hour for 10 minutes, then 6 mg/kg/hour thereafter. A dose of 10 mg/kg/hour is equal to the patient's weight (in kg) as ml/ hour of 1% propofol – hence a 60 kg patient will initially receive 60 ml/hour of 1% propofol. At the end of the operation, switching off the propofol allows rapid redistribution from the vascular compartment (and therefore from the richly perfused compartment also) to the still unsaturated third compartment. It is this rapid redistribution that allows a prompt wake-up even after a long period of TIVA.

TCI microprocessor-controlled technology (e.g. as incorporated in the Graseby 3500 'Diprifusor' syringe pump) requires manual input of patient age, weight and desired plasma concentration. The pump then administers propofol according to the three-compartment pharmacokinetic model incorporated into its software. Change to a higher propofol concentration is achieved by a rapid zero-order infusion, and the plasma concentration is calculated until the new predicted value is reached. Change to a lower concentration is achieved by temporary cessation of drug infusion until the predicted plasma level falls to the required level, followed by continuation of infusion at a lower rate. The system is used in a similar fashion to adjusting the vaporizer setting during inhalational anaesthesia; the predicted plasma concentration of drug is analogous to the end-tidal concentration of the inhalational agent. Maintenance of satisfactory anaesthesia requires a plasma concentration of propofol of 2–6 mg/ml, depending on patient fitness, coexisting drug therapy and degree of surgical stimulation.

Comparison of inhalational anaesthesia and total intravenous anaesthesia (TIVA) maintenance techniques

Inhalational maintenance

Advantages
- Cost-effective (especially when used with low-flow circle systems)
- Predictable population pharmacokinetics and confidence in anaesthetic depth achieved
- Ease of measurement of end-tidal partial pressure
- Minimal metabolism of modern agents, no accumulation and clearance independent of patient hepatic and renal function

Disadvantages
- Requires conventional tidal ventilation for drug delivery
- Requires specialized equipment (e.g. vaporizer, anaesthetic machine, agent analyser)
- Concern regarding tissue and organ toxicity (especially hepatotoxicity following repeat halothane exposure)
- All volatile anaesthetics are known triggers for malignant hyperpyrexia
- Environmental pollution

TIVA

Advantages
- Independent of airway for drug delivery. May be advantage in, for example, jet ventilation techniques
- No specialized equipment is essential. More suitable technique for patient transport and difficult locations
- Rapid increase in anaesthetic depth possible by administration of intravenous bolus
- Low incidence of postoperative nausea and vomiting and better quality of early recovery (especially for propofol)
- No contraindication in malignant hyperpyrexia

Disadvantages
- Requires patent and dependable intravenous access. Undetected failure may result in awareness
- Drug accumulation with prolonged infusion
- Inability to measure plasma concentration directly has led to concerns about possibility of awareness

5

Analgesia: modern inhalational or intravenous anaesthetic drugs possess little analgesic activity, with the exception of ketamine. For all but the simplest procedures, analgesia must be provided by systemic analgesics (usually opioids) or by local anaesthetics. Analgesia has several effects.

- It reduces the required MAC (or plasma concentration) of co-administered anaesthetic drugs. Analgesia is an important component of the balanced anaesthetic technique.
- It reduces the immediate autonomic activity in response to pain. Sympathetic stimulation otherwise results in cardiovascular and respiratory responses that may lead to myocardial ischaemia and dysrhythmias.
- It reduces the neuroendocrine 'stress response' caused by surgery.

Opioid analgesics such as fentanyl, 15 μg/kg, reduce circulating concentrations of the stress hormones that increase after moderate and major surgery (e.g. noradrenaline, adrenaline, cortisol, growth hormone, glucagon, antidiuretic hormone). The stress response is largely detrimental and leads to increased catabolism, metabolic rate and oxygen consumption. This response is not significant in minor surgery.

The short-acting synthetic opioid drugs such as fentanyl and alfentanil are widely used to provide intraoperative analgesia. Fentanyl, a synthetic opioid structurally related to pethidine, is the most popular (1–2 μg/kg for minor procedures, onset 1–2 minutes, duration 30 minutes). Its potency and minimal effect on pulse and blood pressure make it commonly used for the provision of intense analgesia during surgery. These drugs are unsuitable for routine use in postoperative analgesia because of their short duration of action and their tendency to produce marked respiratory depression. They are commonly substituted by longer-acting analgesics (e.g. morphine 0.1–0.2 mg/kg i.v.) towards the end of the procedure to provide pain relief following surgery.

Pre-emptive analgesia – laboratory work suggests that noxious stimuli produce hypersensitivity in the pain pathways both centrally and peripherally. Larger doses of analgesics are then required to have an effect. If systemic analgesia or local anaesthetics are used to prevent the initial pain, this hypersensitivity is reduced. This is the basis of pre-emptive analgesia, but its clinical significance is disappointing.

Providing the best possible operating conditions

The surgeon hopes for two things from his patient during the operation: not to move, and not to bleed. If the anaesthetist has succeeded in keeping the patient safe and comfortable as described, then the patient is unlikely to move. The anaesthetist can also help to minimize bleeding.

Tourniquets are ideal for extremity surgery. Traditionally, a 90-minute time limit is imposed on upper limb tourniquets (usually at 250 mm Hg), and a 120-minute limit on lower limb tourniquets (usually at 300 mm Hg). This is arbitrary; the longer the tourniquet is on, the greater the potential for damage. The main risk is ischaemic damage to nerves directly under the tourniquet; distal ischaemia is likely to take 4–6 hours to become significant. If antibiotics are necessary, they should be given at least a few minutes before exsanguination.

Sickle-cell disease is an absolute contraindication to tourniquet use, because sickling of haemoglobin S may be induced by the local hypoxia and acidosis.

Positioning – adequate venous drainage from the operative site is ensured by careful attention to patient positioning. Raising the operative site above heart level decreases arterial and venous pressures. Arterial pressure falls by 2 mm Hg for each 2.5 cm vertical height. Head-up tilt is commonly used in head and neck surgery to decrease bleeding, but there is a risk of venous air embolism.

Hypotensive anaesthesia – moderate reduction of systolic blood pressure (e.g. to 70–80 mm Hg) in otherwise fit patients may greatly improve the operative field. It must be used with caution in patients with coronary, cerebral, renal or peripheral vascular diseases who are at risk from ischaemic events. Techniques for deliberate hypotension are outside the scope of this contribution.

Non-steroidal anti-inflammatory drugs used intraoperatively may increase blood loss during surgery.

Blood gases – carbon dioxide is a local vasodilator, and moderate hypocapnia (e.g. P_{CO_2} 4.0–4.5 kPa) contributes to a dry surgical field.

Preparing the patient for the postoperative perio

The maintenance period is often a convenient time to complete the necessary anaesthetic record and drug prescription charts. During anaesthesia, it should be considered what else may be done while the patient is unconscious to enhance his or her postoperative course. This includes the following.

Venous access must be sufficient for postoperative requirements. A central venous line should be sited if access is likely to be difficult or prolonged, or to enable central venous monitoring. A subcutaneous cannula for analgesic administration may avoid the need for injections, especially in children.

A nasogastric tube is more comfortably inserted while the patient is asleep, and its position can be checked during laparotomy.

Analgesia – ideally, the plan for postoperative pain control should be formulated before anaesthesia, and discussed with the patient. 'Balanced analgesia' is the concept of using several analgesics with differing modes of action, thus reducing dose-related side-effects and enhancing overall analgesic effect. Typically this may involve local or regional analgesia in combination with opioids, non-steroidal anti-inflammatory drugs and simple analgesics (e.g. paracetamol).

Antiemetics should be given in particular to patients receiving opioids, and those at high risk of postoperative nausea and vomiting (PONV). High risk includes patients with a history of previous PONV or motion sickness, certain operations (e.g. gynaecological, middle ear or strabismus surgery) and female gender.

Oxygen – all anaesthetics (with the exception of ketamine) induce about 10% shunt. Atelectasis, impaired hypoxic pulmonary vasoconstriction, diffusion hypoxia from nitrous oxide use, opioid-mediated hypoventilation and other factors contribute to making the postoperative patient prone to hypoxia. Added oxygen (e.g. 30–40% via a simple face mask) should be administered in the immediate recovery period to all patients for about 15 minutes, guided by pulse oximetry. Subsequently, the need for added oxygen must be determined for each patient depending on factors such as age, pre-existing disease and the nature of anaesthesia and surgery.

Fluids – there must be clear instructions for postoperative fluid intake. Elective day-surgery patients will drink when ready, but in-patients and those undergoing major procedures require intravenous fluids to replace continuing fluid losses and provide maintenance. How far in advance fluids can be prescribed depends on the accuracy of prediction of future needs.

Thromboprophylaxis – stockings for prevention of thrombo-embolic disease and/or regular heparin should be prescribed where indicated by local policy.

Antibiotics – should be prescribed at the surgeon's discretion.

Monitoring – the anaesthetist should understand the routine standard of monitoring on the postoperative ward and ensure that it meets the needs of the patient. Specific requirements must be clearly communicated, such as hourly urine output, hourly blood pressure, overnight Sp_{O_2} or any other observ-ations in an at-risk patient. Action that should be taken if the observation deviates from the desired targets should be documented.

Medical Gas Storage, Suction Devices and Humidifiers

Ian R Taylor
Michael O'Connor

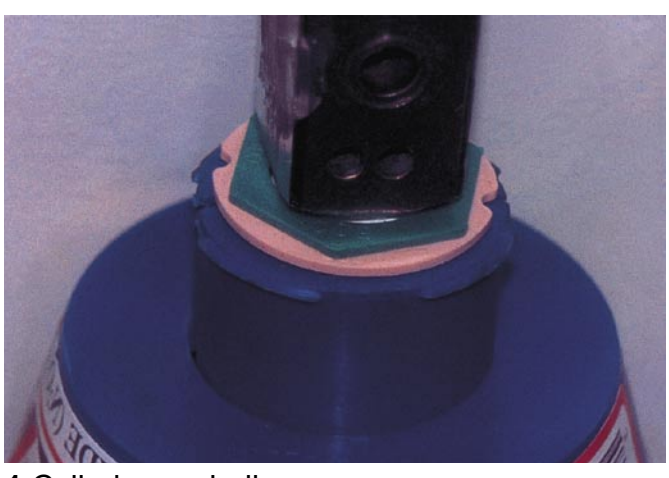
Ian R Taylor is Specialist Registrar in Anaesthesia at the Princess Margaret Hospital, Swindon, UK. He qualified from Bristol University and is training in Anaesthesia at the Wessex School of Anaesthesia, Southampton, UK. His interests are vascular and obstetric anaesthesia.

Michael O'Connor is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Cylinders

Medical gas cylinders are made of molybdenum steel to ensure they are strong and able to withstand high pressures, but are also relatively light in weight. They are constructed as a seamless tube and consist of a body, shoulder and neck. They are colour coded according to British and International Standards (BS1319C and ISO32) to identify their gas contents (see Figure 7, page 109). Cylinders are manufactured in different sizes from A, the smallest, to J, the largest. Size E cylinders are usually attached to the anaesthetic machine and size J cylinders make up manifolds.

The cylinder valve fits into the cylinder neck by a screw thread mechanism, to permit safe, controlled use of its contents. The junction between the cylinder and valve melts in the presence of intense heat, thus allowing escape of gas and minimizing the risk of explosions. Between the neck and cylinder valve is a plastic disc, the colour and shape of which denotes the year in which the cylinder was last examined (Figure 1).



1 Cylinder neck disc.

Cylinder body
The cylinder body is colour coded and engraved with:
- test pressure
- date of last test performed
- chemical symbol of contents
- tare weight (i.e. weight of empty cylinder).

It is also labelled (Figure 2) with the name and symbol of the gas it contains, its volume, pressure and minimum purity (Figure 3). The label gives additional information relating to storage, use (in conjunction with the Medical Gases Data Sheet) and safety matters. The safety points highlighted are:
- compressed gas
- flammability status
- avoidance of oil or grease because spontaneous combustion can occur with high-pressure gases.

2 Cylinder label.

Cylinder size, volume, pressure and purity of contents

Gas	Cylinder size (litres)	Volume of gas at 15°C	Pressure (kPa)	Purity (%)
Oxygen	E	680	13700	99.5
Nitrous oxide	E	1800	4400	98.0
Air	E	640	13700	21.0 (oxygen)
Carbon dioxide	C	450	5000	99.0

3

Storage
- Cylinders must be stored under cover, in a dry, clean and well-ventilated area, away from extremes of temperature.
- Smoking or the use of a naked flame in the storage area is prohibited.
- Moisture or exposure to chemicals can lead to the corrosion of the cylinder or its valve.
- Cylinders should be kept in the upright position or horizontal on shelves to avoid direct damage to the valves.
- Cylinders should be used in a sequential manner to ensure that no cylinder remains in storage for too long.
- Full and empty cylinders should be kept apart.

Testing
During manufacture, one in every 100 cylinders is cut into strips and tested for tensile strength. Cylinders in circulation are tested on a 5-yearly basis by:
- exposure to hydraulic pressure of about 22,000 kPa (far in excess of the pressures encountered in daily use)
- filling with water under pressure to assess expansion and elastic recoil
- internal endoscopic inspection.

Test date details are recorded on the plastic disc between the cylinder valve and the neck and engraved on to the cylinder body.

Filling
Medical gases are stored either in the gaseous state (oxygen and air) or as a mixture of the liquid and vapour (nitrous oxide and carbon dioxide). Cylinders that contain liquid should be used only in the upright position. Gases and vapours stored in cylinders must be free of water vapour to avoid the formation of ice (secondary to a fall in temperature on cylinder opening), which may block the exit valve. For cylinders containing gas alone, the contents can be assessed directly by measuring the pressure using a Bourdon gauge (see *Anaesthesia and Intensive Care Medicine* **1:2:** 65). In the case of cylinders containing both the liquid and vapour phases the situation is more complex. The contents of these can be determined only by subtraction of the tare weight from the cylinder weight because the pressure within will not fall until the liquid has completely vaporized, assuming the temperature stays constant.

During nitrous oxide use, the liquid within the cylinders cools owing to the uptake of latent heat of vaporization. Condensation or ice may form on the outside of the cylinder. In such circumstances, the cylinder gauge pressure may fall despite there being liquid nitrous oxide in the cylinder owing to the fall in saturated vapour pressure of nitrous oxide following the drop in temperature of the liquid. However, once the gas flow is turned off the temperature returns to that of the atmosphere and the gauge pressure returns to that at the beginning of use. Carbon dioxide is used at low flows so the chances of ice forming are low. Liquid is less compressible than gas, therefore cylinders containing nitrous oxide or carbon dioxide are only partially filled with liquid. Any change in pressure within the cylinder is minimized, thus reducing the chance of cylinder rupture should the temperature rise.

The filling ratio is that between the mass of liquid contained in the cylinder and the mass of water that it could contain if filled to the top. The filling ratios for nitrous oxide and carbon dioxide are both 0.75 in temperate climates and 0.67 in the tropics.

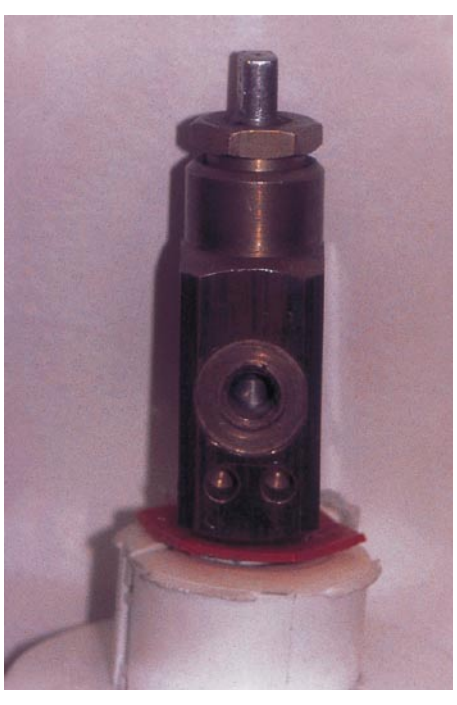
$$\text{Filling ratio} = \frac{\text{Mass of liquid}}{\text{Mass of water}}$$

Cylinder valve
Cylinder valves are made of brass and screw into the cylinder neck. There are four types of valve:
- pin-index valve block
- bull-nose valve
- hand-wheel valve
- star valve.

A pin-index valve is used on all cylinders that are to be attached to an anaesthetic machine. It is an international system (ISO2407) designed to prevent the fitting of the incorrect gas to the yoke and is fully detailed in the British Standard BS1319.

The system is made up of two components.
- Two pins projecting from the yoke, which are arranged in a gas-specific configuration in relation to the valve outlet
- Two holes within the valve block on the cylinder with a corresponding pattern for the designated gas (Figure 4).

This arrangement ensures that it is impossible to fit the incorrect cylinder to the yoke. The pin-index valve block on the cylinder is engraved with:
- tare weight
- chemical symbol for contents
- cylinder owner
- pressure of hydraulic test.



4 Pin-index valve holes on the cylinder.

Cylinder use
New or refilled cylinders are supplied from the manufacturer with a plastic dust cover over the valve to avoid dirt contamination. Before use, this cover should be removed and the valve transiently opened to expel any dirt or grease from the outlet. This reduces the chance of debris entering the anaesthetic machine and is known as 'cracking' the cylinder.

The cylinder is mounted on to the anaesthetic machine by engaging the pins on the yoke with the holes in the valve block. It is secured by tightening the wing nut.

Before use, the cylinder should be opened gently to ensure that there are no leaks, either from the cylinder valve itself or at the point of attachment to the yoke on the anaesthetic machine. A possible reason for gas leakage at the pin-index junction is the absence of the Bodok seal. This is an aluminium-rimmed neoprene washer that sits between the outlet on the valve block and the yoke on the anaesthetic machine. Gentle opening of cylinders minimizes sudden surges of high-pressure gas that may damage the pressure gauge or regulator.

Suction systems

Suction systems form part of the piped medical gases and vacuum systems (see page 107) and must comply with specifications detailed in BS4957. Portable and fixed suction systems are available to accommodate the differing circumstances of use. General operating principles are the same for both systems. Outlets from the central piped vacuum system must have the capability of maintaining a vacuum of at least 53 kPa below atmospheric pressure (101.3 kPa) and supporting a flow of 40 litres/minute.

Suction apparatus and nozzle: suction nozzles are made of either firm plastic (e.g. Yankauer) or metal. They should have a smooth tip to prevent damage to the soft tissues of the oropharynx. The tip often has more than one hole to allow continuation of suction should one hole become blocked. Suction tubing is constructed of semi-rigid plastic to minimize kinking, with a smooth internal surface to limit resistance to flow. The tubing must be of sufficient length to be practical to use, but it should be remembered that the length and width of a tube influences the laminar flow within it, according to the Hagen–Poiseuille equation:

$$\text{laminar flow} = \frac{\Delta P \pi r^4}{8 \eta L}$$

where: ΔP = pressure gradient along tube, r = tube radius, L = tube length, η = viscosity of liquid.

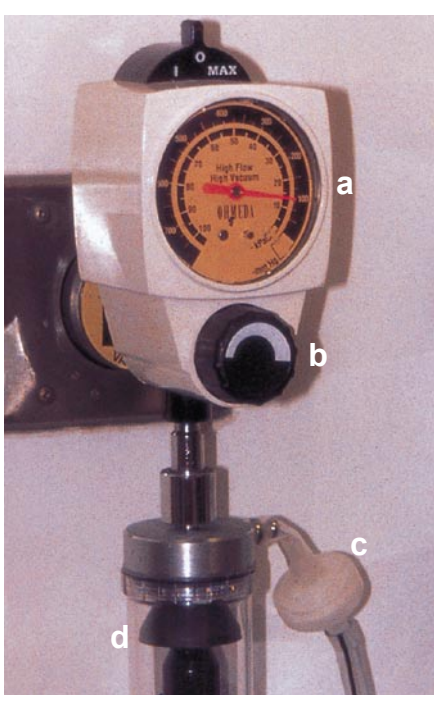
Thus, short, wide tubing maximizes laminar flow.

Reservoir: the reservoir must be of sufficient size to contain the estimated volume of suctioned material, but not so large that it increases the time taken for the vacuum to build up. Most reservoir vessels are constructed of clear material to allow the contents to be visualized and are graduated to permit accurate assessment of aspirate volume. Disposable liners are commonly used to reduce staff exposure to potentially infective material. A floating ball valve within the collection vessel prevents material from entering the control unit and the vacuum source if the container overfills.

Vacuum control regulator unit: this unit is usually situated between the reservoir and the vacuum source (Figure 5). Its function is to allow adjustment of the degree of vacuum applied to the distal suction tubing. The vacuum control adjuster acts as a variable orifice (either directly or by way of a spring acting on a diaphragm) to adjust the force of vacuum, which is indicated on a gauge. Within the unit is a filter and some form of float valve to provide protection from particulate matter.

Distribution pipeline network: between the terminal outlet and the control unit there is a colour-coded (yellow) flexible hose with a specific Schrader probe connection, as for piped medical gases.

Terminal outlet: the terminal outlet of the vacuum pipeline consists of a labelled, self-sealing valve, fronted in yellow, that accepts a probe with indexing collar to prevent misconnection.



5 Vacuum control regulation unit.
a vacuum gauge, **b** vacuum control, **c** filter, **d** float valve.

Filter unit: filters are sited within the control unit, but also in the case of piped medical gases and vacuum systems between the terminal outlet and the central vacuum source. They remove particulate matter and bacteria from the system to prevent blockage and contamination.

Central pump: the role of the pump is to generate subatmospheric pressure within the system. Pumps are commonly driven by electrical, pneumatic or manual means (Figure 6). The piston, diaphragm and rotary devices shown in Figure 6 all require some form of energy source (usually electricity) to drive mechanical pumps. In contrast to these, the gas-powered pump works on the Venturi principle and the bellows require manual input to generate subatmospheric pressure.

The type of pump is determined by the specific requirements of the suction unit. For example, most portable units use a manual pump, whereas a rotary-driven pump may be used when a large volume of aspirate is anticipated. The pump expels its exhaust gases, via a silencer, to the atmosphere at a suitable site, such that staff and patients are not exposed to the pollution.

Vacuum pumps

6

Humidification devices

Humidification strictly refers to the addition of water vapour to air. Humidification of dry, cold anaesthetic gases as they enter the patient's airway is important because dry gases result in drying of the mucosal surfaces, abnormal ciliary function and increase in the viscosity of respiratory tract secretions. Loss of these protective mechanisms can cause mucus plugging, atelectasis, reduction in gas exchange and an increased susceptibility to infection. Also, heat energy due to latent heat of vaporization is lost by the patient in warming and humidifying dry, cold anaesthetic gases.

Aims: under normal circumstances, the upper respiratory tract warms and humidifies the air to an absolute humidity (i.e. mass of water vapour in a given volume of air at specified temperature and pressure) of 34 g/m^3 at 34°C in the trachea and 44 g/m^3 at 37°C in the alveoli. These values equate to fully saturated air whereby the air contains the maximum possible water vapour at specified temperature and pressure. Achievement of these values is the 'gold standard' for humidification. The different efficiencies of various humidifiers are shown in Figure 7.

Approximate efficiency of humidifiers

The exact values depend on the model of humidifier used.

7

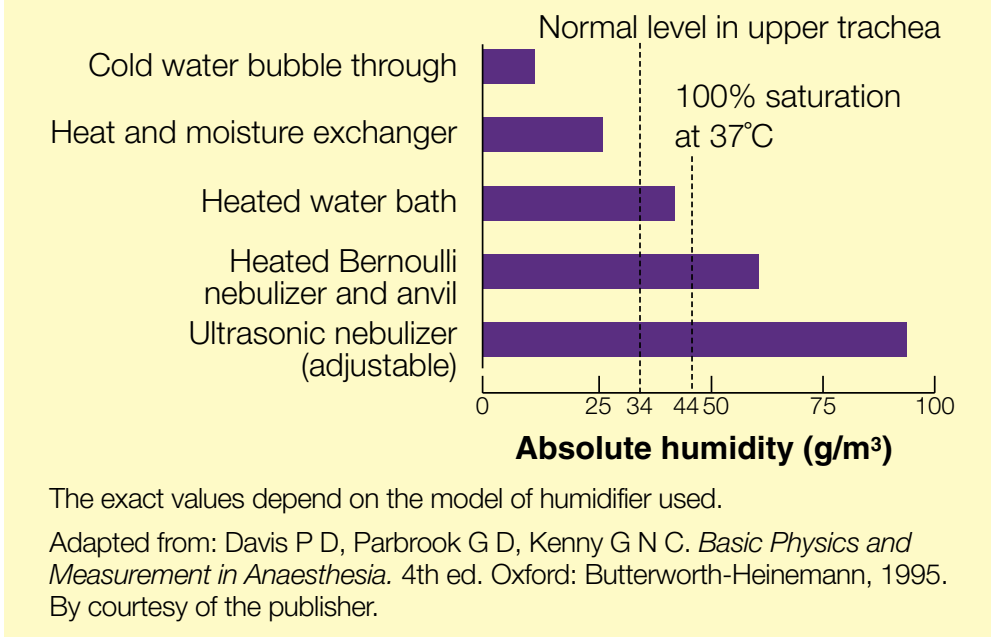
Types of humidifiers

Heat and moisture exchanger (HME) is the most commonly employed humidifier in day-to-day anaesthetic practice (Figure 8). It consists of a sealed unit that is placed within the breathing circuit. The exchanger contains a structure usually of either sponge or mesh, of large surface area, on to which water is absorbed. Absorption is maximized if the mesh is made of a hygroscopic material such as paper coated with calcium chloride or glass fibre. An additional role of some devices is to act as bacterial filters because over 99.99% of bacteria will not pass through pores of less than 0.2 microns. HMEs work on the principle that the moisture from expired gas condenses on to the mesh material within the device as it cools. The mesh is also warmed as the cooling moisture emits latent heat. As gas is inhaled it is warmed and humidified, thus exchanging heat and moisture. The advantages of the system are that it is:

- lightweight
- compact
- disposable
- efficient (60–70% relative humidity at 30–34°C, equating to absolute humidity of about 25–35 g/m^3)
- passive (requires no external power source)
- inexpensive.

The disadvantages are:

- increased dead space
- increased resistance to breathing
- single-patient use.



8 Heat and moisture exchanger.

Cold water bath humidifier (Figure 9): this operates by bubbling inspiratory gas through or over a cold water bath. The advantages are it is simple and safe. The disadvantage is that it is inefficient.

Hot water bath humidifier (Figure 10): inspiratory gases are bubbled through, or pass over, a warm water reservoir. The contact surface area is increased in some devices by the use of wicks or multiple bubble holes. The water temperature must be rigidly regulated to attain a balance between maximum humidification, bactericidal activity and heating, with the risk of thermal injury to the patient. This is achieved by the use of a thermostatic control and temperature monitoring within the circuit close to the patient. A water trap must be included on the patient side of the system and the whole apparatus must be below patient level to limit the risk of condensed water in the tubing entering the breathing circuit directly. The system is efficient but the disadvantages are:

- risk of scalding
- bacterial growth if temperature falls below 60°C
- condensation of water within tubing.

9 Cold water bath humidifier.

10 Hot water bath humidifier.

Nebulizers: the principle of nebulizers is to add tiny droplets of water to the inspired gas. Strictly speaking nebulizers are not humidifiers because they add water droplets not vapour to the gas. Nebulizers have the potential to produce water droplets of varying sizes. The result of this is that very small droplets pass into the alveoli and thus risk fluid overload, whereas large droplets risk being deposited in the breathing circuit or upper airway. Ideal droplet size is 1–5 microns. Nebulizers are highly efficient but they can be expensive and water overload may occur, especially in ultrasonic devices. There are three commonly encountered methods by which nebulizers produce water droplets.

Venturi principle – water is entrained into a jet of gas that breaks it into droplets (Figure 11). Some systems also contain a solid object (anvil) into which the droplets are propelled, thus further reducing their size. Droplet size averages 2–4 microns. Back pressure from a breathing system can affect the efficiency of the device by reducing water entrainment. Some nebulizers incorporate a heater to increase their efficiency.

Spinning disc – a rapidly rotating disc that throws off tiny water droplets.

Ultrasonic – high-frequency ultrasound waves fragment water into tiny droplets. The water may be dropped on to a vibrating surface or the device may be immersed in a water bath. Droplets 1–2 microns in size are produced.

Medical Gases and their Delivery

Ian R Taylor
Michael O'Connor

Ian R Taylor is Specialist Registrar in Anaesthesia at the Princess Margaret Hospital, Swindon, UK. He qualified from Bristol University and is training in Anaesthesia at the Wessex School of Anaesthesia, Southampton, UK. His interests are vascular and obstetric anaesthesia.

Michael O'Connor is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Medical gas

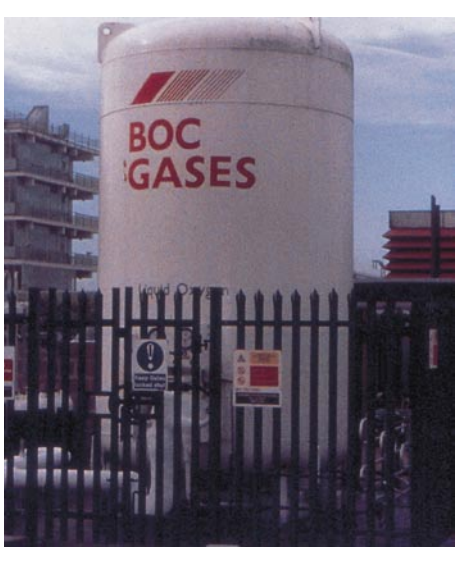
In the UK, most hospitals have piped medical gases and vacuum systems (PMGV) for convenience and economic reasons. The vacuum component of this system is discussed on page 114.

The pipeline network carries medical gases from central bulk storage sites to hose outlets in the walls of anaesthetic rooms, theatres and wards. The responsibility for this section of the PMGV is principally that of the hospital pharmacy, supplies and engineering departments. Anaesthetists have responsibility for the section of pipeline between the terminal outlet and the anaesthetic machine. The bulk store for medical gases is usually a series of cylinder manifolds (Figure 1). In the case of oxygen, the cylinder manifold is often used as a reserve because most hospitals store oxygen in a vacuum-insulated evaporator (VIE) (Figure 2). The cylinder manifold is divided into a primary unit, which is in use, and a secondary unit in reserve. As the pressure in the primary unit falls, the supply is automatically switched to the secondary unit and an alarm sounds to alert the staff to replace the empty cylinders. When there is actual or impending supply failure the alarm usually sounds in the switchboard area of the hospital.

The pipes are constructed of high-grade copper alloy to prevent degradation of gases and are de-greased to reduce the risk of combustion or explosion. They are labelled at regular intervals along their length and are separated from other pipelines within the hospital to avoid confusion. Within the network of pipes there are valves to control the supply to individual theatres or a complete department, in the event of fire or pipeline damage. These are lever-operated, non-lubricated valves housed in clearly accessible units usually behind a breakable glass cover (Figure 3).

The pressure within the pipelines is regulated at about 400 kPa.

1 Cylinder manifolds.



2 Vacuum-insulated evaporator.

3 Pipeline lever safety valve.

Terminal outlet connection

Outlet points (Figure 4) for each of the piped medical gases have specifically labelled, shaped, colour-coded and non-interchangeable Schrader sockets to prevent connection of the incorrect gas supply to the flexible hoses supplying the anaesthetic machine. These must comply with the British Standard codes (BS5682) and be labelled as such. Each terminal outlet is a self-sealing valve unit of specific size to receive the corresponding collar-indexed probe of the flexible hose.

To ensure correct connection and function of the outlet valve, the probe is firmly inserted and a sharp tug applied to ensure full engagement and opening of the valve. This simple procedure is known as the 'tug test'.

4 Terminal gas outlets.

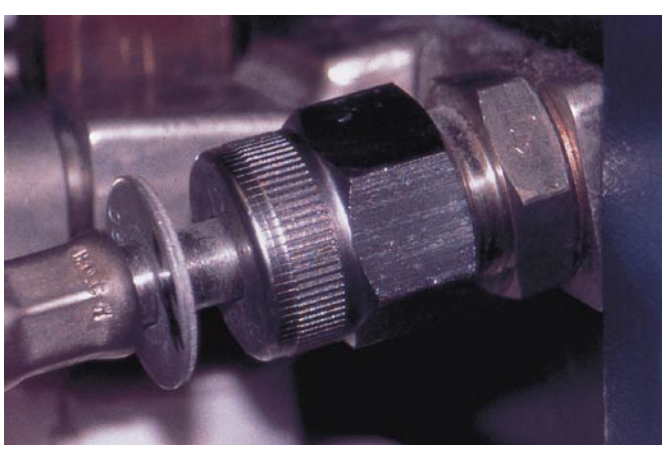
Flexible pipeline

A flexible pipeline carries medical gases from the terminal outlet to the anaesthetic machine. The terminal outlet probe (Schrader probe; Figure 5) is fitted with an indexing collar of a specific diameter for each gas, which will fit only the corresponding gas socket on the terminal outlet valve. In addition, each collar has a notch that fits over a pin within the socket to prevent rotation of the hose once installed. The entire assembly is constructed so that rapid probe insertion or withdrawal can be performed single-handedly and that once withdrawn the terminal outlet unit is self-sealing.

The flexible hose is made of a high-quality copper alloy with antistatic and bacteriostatic properties. It is colour coded and labelled in accordance with the gas it carries.

The hoses are connected to the anaesthetic machine by a non-interchangeable screw thread unit. This unit consists of a probe unique to each gas and a nut to screw the assembly on to the machine. A stainless-steel ferrule is crimped over the whole unit to seal the connection and prevent its removal (Figure 6).

5 Schrader probe.



6 Non-interchangeable screw thread.

Safety

Pipelines and flexible hoses: guidance for manufacturers, installers and maintenance engineers is in accordance with BS5682 (1987) and Health Technical Memorandum 2022 (1994). Pipelines for each of the medical gases are manufactured in different locations within the factory to prevent accidentally mixing up their unique features, for example, connection of the wrong terminal probe, non-interchangeable screw thread fitting or incorrect colour coding.

Pipelines and flexible hoses are steam cleaned, dried and sealed at both ends after internal inspection before being transported to their installation site. This is to prevent contamination and particulate matter from entering the gas supply. In the event of damage to, or technical failure of any part of the pipeline, it must be returned directly to the manufacturer for repair or replacement.

The pharmacy, supplies and engineering departments within each hospital are responsible for the pipeline supply. This includes testing of gases for purity and identity after installation of new pipelines.

The anaesthetist is responsible for ensuring that the flexible hoses are correctly engaged and that the corresponding gas passes into the anaesthetic machine. Correct engagement is checked by using the 'tug test' and the identity of the gas by using the 'single-hose test'. This is done by attaching the oxygen pipeline to the anaesthetic machine, turning on all the flowmeters and ensuring that gas flows only through the oxygen flowmeter and that it is detected by an oxygen analyser fitted at the common gas outlet.

Cylinder gas supply: cylinders and their use in conjunction with the anaesthetic machine are covered elsewhere in *Anaesthesia and intensive care medicine*.

Medical gas pressure

Working pressures within cylinder and piped medical gas supplies are outlined in Figure 7.

Pressure monitoring and display of both pipeline and cylinder gases is performed by Bourdon gauges. The Bourdon gauge is an aneroid (i.e. without liquid) gauge consisting of a coiled tube, attached at one end to the gas supply and at the other end to a pointer. The pressure of the gas causes straightening of the coil and thus causes movement of the pointer over the colour-coded, labelled and calibrated dial. The gauge is faced with heavy glass and designed such that leaks vent from the back of the valve casing and do not blow out the glass.

Cylinder and pipeline colour coding and pressures

	Body colour	Shoulder colour	Pressure (kPa) at 15°C
Cylinder			
• Oxygen	Black	White	13700
• Nitrous oxide	Blue	Blue	4400
• Carbon dioxide	Grey	Grey	5000
• Air	Grey	White/black	13700
Pipeline			
• Oxygen	White		400
• Nitrous oxide	Blue		400
• Air (clinical use)	Black		400
• Air (power tool use)	Black		700

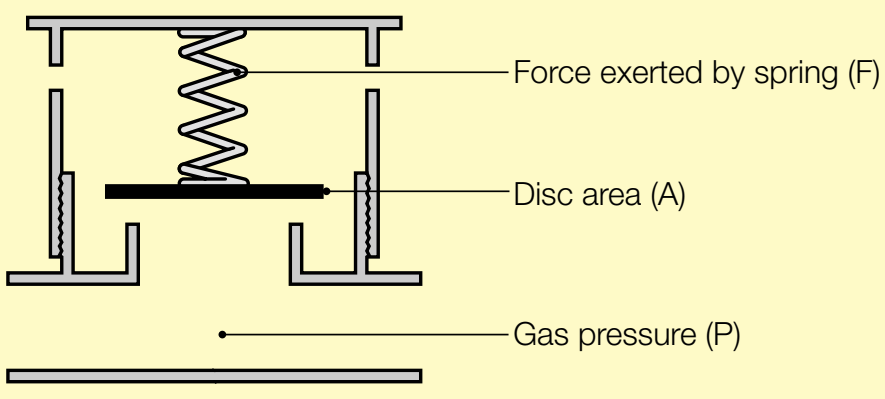
7

Pressure regulators: throughout the medical gas supply network the pressure within the system is closely regulated. This is vital for the protection of both equipment and patient. Measures to maintain a near-constant pressure are found in many sites and usually take the form of a pressure relief valve or a pressure regulator (see *Anaesthesia and Intensive Care Medicine* **1:2:** 66). Both devices are also present within the anaesthetic machine.

Pressure relief valves are designed to allow escape of gas above a certain set pressure. In the case of the VIE this protects the oxygen storage equipment from damage from pressure above 1690 kPa. Similar valves are positioned downstream of pressure regulators within the pipeline supply in case of regulator failure. These are set slightly above 400 kPa.

The principle on which the valve works relates to an equilibrium between two opposing forces: that exerted by the spring and that generated by the gas itself (Figure 8).

Pressure relief valve



$F = P \times A$

As the disc area is constant, and the force exerted by the spring to close the valve is pre-set, once the gas pressure within the system exceeds this closing force, the valve opens and gas escapes

8

Medical gases

Oxygen

Manufacture: industrial manufacture is by the fractional distillation of liquid air. This involves the removal of carbon dioxide and then the separation of oxygen and nitrogen by means of their different boiling points.

Oxygen may also be produced by oxygen concentrators, which extract oxygen from air. This process involves the passing of air through a sieve of zeolite (aluminium silicate), which absorbs the nitrogen, leaving oxygen and a trace of argon. The equipment for this process used to be bulky, but recently smaller units suitable for home use have been developed. A maximum concentration of 95% pure oxygen can be produced using these devices.

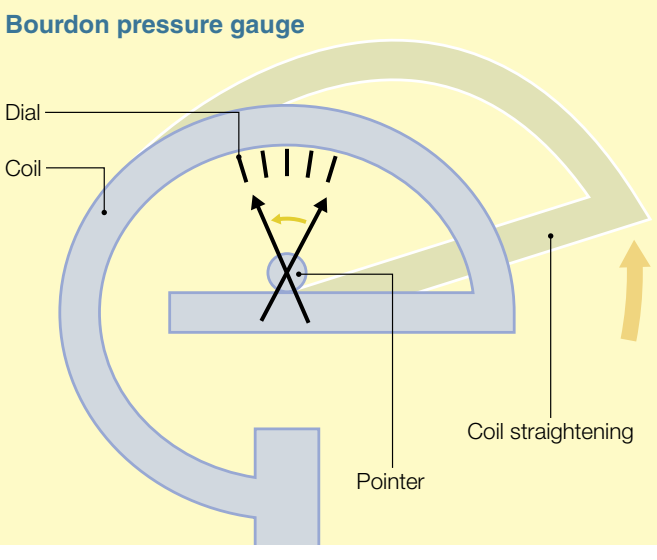
Storage: oxygen is stored either as a gas in cylinders or as a liquid in a VIE. In the UK, cylinders used for oxygen storage are black with a white shoulder (Figure 9); in the USA they are green. The oxygen is stored at a pressure of 13700 kPa at 15°C. Where piped medical gases are used, oxygen is also stored in cylinder manifolds. In cylinders, oxygen is a gas and the volume of oxygen remaining in the cylinder is directly related to the measured pressure, according to Boyle's law.

9 Cylinders. From left: oxygen, nitrous oxide, air, carbon dioxide.

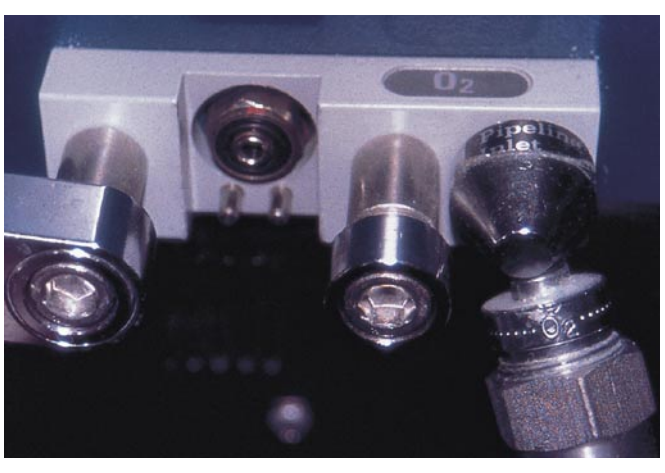
The VIE (Figure 10) is a thermally insulated device similar to a large vacuum flask. Oxygen is stored within this vessel at about –160°C and at a pressure of 5–10 atmospheres (500–1000 kPa). The low temperature is maintained by the vacuum surrounding the main chamber and by heat energy being lost from the liquid oxygen as it evaporates (latent heat of vaporization). Under normal working conditions, oxygen evaporates and passes through the pressure regulator to reduce its pressure to 400 kPa, and then enters the pipeline supply. If demand for oxygen is low, the internal pressure gradually rises until a safety valve opens at 1690 kPa to release gas to the atmosphere. When demand for oxygen is great, the control valve opens allowing liquid oxygen to pass through the pressure-raising superheater and vaporizer, evaporate and enter the pipeline supply. The superheater is a coil of uninsulated copper pipe.

The VIE (Figure 2) can be found outside all hospitals that use piped gases and may be supported by a tripod structure. Two of these legs support the weight of the evaporator, while the third is a weighing device to allow the mass of liquid contained to be measured. Modern designs stand on four legs and the contents are calculated by measuring the pressure difference between the top and bottom of the vessel.

Bourdon pressure gauge



10



11 Cylinder yoke.

Delivery: oxygen is delivered from a central supply (i.e. a manifold or VIE) or directly from cylinders. Central oxygen supply is via the pipeline system described above. Direct cylinder supply of oxygen to the anaesthetic machine involves the connection of the cylinder valve to the cylinder yoke (Figure 11) on the back of the machine.

Carbon dioxide

Manufacture: carbon dioxide is manufactured by heating calcium or magnesium carbonate in the presence of their oxides. Other sources are as a by-product of the manufacture of hydrogen, fermentation of beer or the combustion of fuel.

Storage: in the UK, carbon dioxide is stored in grey cylinders (Figure 9) at a pressure of 5000 kPa at 15°C, as a liquid in equilibrium with its vapour.

Distribution: unlike the other medical gases, carbon dioxide is not distributed via a central pipeline. The attachment of carbon dioxide cylinders to anaesthetic machines has declined in recent years to minimize the risk of accidental administration during anaesthesia. The present guidelines issued by the Association of Anaesthetists of Great Britain and Ireland state that carbon dioxide cylinders should not be routinely fitted to the anaesthetic machine.

Air

Manufacture: air for medical use is compressed, cleaned and filtered before use.

Storage: compressed air for anaesthetic use is stored in grey cylinders with black and white shoulders (Figure 9) at a pressure of 13,700 kPa at 15°C. In the USA, the cylinders are yellow.

Distribution: pipeline air is sourced from either a manifold (Figure 1) or, more economically, from an air compressor. It is important to know that air for clinical use is regulated to a pressure of 400 kPa, whereas that for the use of surgical power tools is supplied at 700 kPa. The terminal outlet for compressed air is colour coded black and white, labelled and has a non-interchangeable connection (Figure 4).

Cylinders are attached directly to the anaesthetic machine by connection of the cylinder valves to the cylinder yoke. A larger portable cylinder may be attached via a flexible hose.

Perioperative Fluids

E Anne Thornberry

E Anne Thornberry is Consultant Anaesthetist at the Gloucestershire Royal Hospital, Gloucester, UK. She qualified from King's College, London, and trained in anaesthesia in Chester, Bristol and Southampton. She has a special interest in obstetric anaesthesia.

Any surgery under anaesthesia can upset the patient's normal fluid status through preoperative restriction of oral intake of fluids. The degree of disruption depends on the patient's medical condition, the nature of the surgery and the choice of anaesthetic. Factors to consider when planning perioperative fluid management are listed in Figure 1.

Maintenance requirements: normal values for daily fluid and electrolyte requirements are shown in Figure 2. Dextrose 4% with saline 0.18% contains 30 mmol/litre of sodium and is often used for basal fluid therapy.

Determinants of perioperative fluid requirements

- Maintenance requirements
- Preoperative deficits
- Blood loss
- Third-space losses
- Transcellular fluid losses
- Effects of anaesthetic agents and technique

1

Maintenance fluid and electrolytes

Adults
- 40 ml/kg/day

Children
- 100 ml/kg/day for first 10 kg
- 50 ml/kg/day for second 10 kg
- 25 ml/kg/day for each subsequent kg

Na^+ = 1–1.5 mmol/kg/day
K^+ = 1 mmol/kg/day

2

Preoperative deficits

Preoperative assessment of the fluid status of the patient requires an appropriate history, examination and investigations.

History and examination

The following questions should be asked.
- How long has the patient been starved?
- Do they have an intravenous infusion in progress?
- Have they any reason to expect excessive losses?
- Are they taking diuretics?
- Are they pyrexic?
- Have they been vomiting or do they have a nasogastric tube *in situ*?
- Have they got diarrhoea or had a bowel preparation?
- Could they have third-space losses or occult bleeding?
- Have they any symptoms of fluid overload?

The physical examination includes evaluation of the mucous membranes and skin turgor, and measurement of the vital signs, including orthostatic changes. Ascites, pulmonary oedema and pleural effusions should be sought. Measurement of urine output may be useful.

Investigations

A normal haematocrit value may indicate that the patient has a normal fluid status or it may reflect someone with anaemia who is also dehydrated. A raised serum urea with a normal creatinine level may indicate dehydration. Raised urinary sodium levels, specific gravity and osmolality all reflect the normal homeostatic response to water depletion and can be used to monitor progress with resuscitation. The signs and symptoms of water depletion are described in Figure 3.

Estimation of total body water deficit

Deficit of body weight	For example in a 70 kg man	Signs and symptoms
Up to 5%	3.5 litres	Thirst Dry mouth
5–10%	3.5–7 litres	Decreased skin turgor Decreased intraocular pressure Tachycardia Orthostatic hypotension Tachypnoea Oliguria Skeletal muscle weakness Drowsiness
10–15%	7–10.5 litres	Severe hypotension Tachycardia Anuria Confusion/coma

3

Signs and symptoms of uncorrected acute blood loss

Volume lost	For example in a 70 kg male	Signs and symptoms
10%	490 ml	Thirst Venoconstriction
20%	980 ml	Mild increase in heart rate Systolic blood pressure normal Slight rise in diastolic pressure Decreased urine output
30%	1470 ml	Tachycardia > 120/minute Moderate hypotension Tachypnoea Cool, clammy, pale Anxious/aggressive Oliguria
40%	1960 ml	Severe hypotension and tachycardia Tachypnoea Anuria Mental confusion
50%	2450 ml	Coma

4

Fluid losses

Blood loss: the signs and symptoms of unreplaced blood loss (Figure 4) can help to estimate acute losses if accurate measurements cannot be made. Estimates of intraoperative blood losses are derived from measuring or estimating observed losses. Prediction of postoperative losses requires knowledge of the type of surgery and expected postoperative bleeding, combined with measurement of losses in the drains, vital signs, and haemoglobin and haematocrit levels.

Third-space losses are caused by sequestration of extracellular fluid into the tissues. The composition of this fluid is the same as that of interstitial fluid and losses after major bowel resection may be as great as 8 ml/kg/hour. The extent of third-space losses depends on the severity of injury to the tissues.

Transcellular fluid losses: nasogastric aspirate can be measured but pleural effusions and ascites must be estimated. Losses from evaporation occur from the surgical site and during a laparotomy these can be as much as 10 ml/kg/hour.

Effects of anaesthetic agents and techniques

Ventilation with dry anaesthetic gases increases the pulmonary losses from evaporation. General and regional anaesthesia tend to decrease the patient's blood pressure by a reduction in sympathetic tone, vasodilatation or myocardial depression. Vasopressors and intravenous fluids are used to minimize these effects, complicating the assessment of perioperative fluid status. Central venous pressure monitoring can be invaluable in helping to manage more complex cases.

Choosing perioperative fluids

Crystalloids

Dextrose solutions disperse through all the body fluid com-partments and are required to replace combined intracellular plus extracellular water depletion. Once any deficit has been replaced, dextrose is used only perioperatively as part of the basal water requirements or in a diabetic regimen.

Physiological saline disperses throughout the extracellular fluid compartments and is commonly used perioperatively to replace blood loss, transcellular losses, evaporation and third-space losses. Only one-third remains in the intravascular compartment and therefore three times the volume of the blood loss must be given if saline is used as a replacement. When large volumes of saline are administered there is a risk of developing hyperchloraemic acidosis.

Ringer's lactate (Hartmann's solution) behaves as normal saline in distribution. It is often used as the first-choice replacement fluid because the electrolyte content more accurately mimics the extracellular fluid. Its constitution varies between laboratories but in general it contains 137 mmol/litre sodium, 4 mmol/litre potassium, 3 mmol/litre calcium and 142 mmol/litre chloride. There are fewer risks of electrolyte disturbances if large volumes are administered but it is hypotonic and large volumes reduce plasma osmolality.

Colloids

The contents of the commonly used colloids are listed in Figure 5.

Properties of commonly used colloids

	Average molecular weight	Sodium (mmol/litre)	Potassium (mmol/litre)	Chloride (mmol/litre)	Calcium (mmol/litre)
Haemaccel	35,000	145	5.1	145	6.2
Gelofusine	35,000	154	0.4	154	0.4
Hetastarch	450,000	154	0	154	0
Dextran 70 in saline	70,000	150	0	150	0
Albumin 4.5%	70,000	150	2	120	0

5

Colloids used for intravenous therapy have an increased osmolality with respect to plasma and can increase plasma volume by more than the volume infused by attracting water from the interstitial fluid compartment. Consequently they are used predominantly to replace intravascular losses and are unsuitable for the treatment of dehydration. The length of time a colloid stays in the intravascular compartment depends on the shape, size and charge of the molecules suspended and the porosity of the capillary endothelium.

Gelatins are colloid solutions derived from animal gelatin. They have an average molecular weight of 35,000 but there is a wide variation in molecule size. The two commonly used gelatins are *Haemaccel*, which is urea linked, and *Gelofusine*, which is a succinylated gelatin. Their intravascular persistence is low, about 2–3 hours with *Gelofusine* and less for *Haemaccel*. Gelatins are the colloids most likely to induce an anaphylactoid reaction. Cross-matching is unaffected by the use of gelatins. *In vitro* studies suggest they interfere with clotting and platelet aggregation but in clinical practice little effect is seen.

Hydroxyethyl starches (HES) are modified natural polymers of amylopectin, which are metabolized by amylase. They are divided into high, medium and low molecular weight starches according to the range of molecular weights in the solution. *Hetastarch* is a 6% solution with an average molecular weight of 450,000 and a mean molecular weight of 70,000. The intravascular persistence of *Hetastarch* is over 24 hours. Some enters the interstitial space and is taken up by the reticulo-endothelial system where it can persist for years. Hexastarch and pentastarch are lower metabolic weight starch solutions. High molecular weight HES solutions can cause a coagulopathy by reducing factor VIII and von Willibrand factor. The lower the average molecular weight of the solution the less effect it has on coagulation. The maximum recommended dose is 33 ml/kg/day, though this has often been exceeded without any adverse effects. Anaphylactic reactions have been reported, but the incidence is low.

Dextrans are branched polysaccharides produced by the action of bacteria on a sucrose medium. Dextran solutions are divided by their average molecular weight into 10% Dextran 40 (molecular weight 40,000) and 6% Dextran 70 (molecular weight 70,000). Dextran reduces blood viscosity, reduces platelet adhesiveness and increases fibrinolysis. Doses higher than 1.5 g/kg can increase bleeding. Only Dextran 70 is used for short-term plasma expansion. Severe anaphylaxis is uncommon but has been reported.

Albumin has a molecular weight of 69,000 and is a naturally occurring plasma protein that contributes significantly to the maintenance of plasma oncotic pressure. It has been used as a colloid to treat critically ill patients with hypoalbuminaemia but there is no evidence that this improves outcome. Recent research has suggested it may worsen outcome but this is not proven. The increasing cost of production of albumin has significantly reduced its use in clinical practice.

Crystalloid–colloid controversy
It has been argued that colloids are more appropriate than crystalloids for the replacement of intravascular losses because they stay in the intravascular compartment longer, necessitating a smaller volume of replacement and a more rapid result. As stated above, the intravascular persistence varies significantly between the different colloids, while this argument holds for hydroxyethyl starches it is not so strong for the gelatins.

Opponents of colloids emphasize the incidence of ana-phylaxis with colloids, which does not exist with crystalloids. The pragmatists suggest that the normal physiological response to an acute intravascular deficit is to draw water in from the interstitial fluid compartment and therefore it makes sense to initiate resuscitation with a crystalloid and then to continue with a colloid if the loss becomes significant.

Blood and blood products
Red cell transfusions: the indication for a red cell transfusion is to increase the oxygen-carrying capacity of the blood by raising the haemoglobin concentration of patients with acute or chronic anaemia. The extent to which it should be raised depends on the balance between oxygen consumption and supply, with the aim of avoiding tissue hypoxia. Factors that affect perioperative oxygen consumption are body temperature, sympathetic activity, metabolic activity, heart rate and drug therapy.

New safety requirements are making blood products more complex and expensive to produce. Recent research suggests the traditional trigger of a haemoglobin concentration of 10 g/dl for perioperative transfusion is too high. The rate of blood loss also needs to be taken into consideration when deciding to transfuse. Suggested British Society for Haematology guidelines are summarized in Figures 6 and 7.

Need to transfuse based on an estimate of lost circulating volume

Volume lost	Indication for transfusion
15%	Only if superimposed on existing anaemia or Patient unable to compensate because of severe cardiac or respiratory disease
15–30%	As above or In the presence of continuing blood loss
30–40%	Transfusion should be considered
> 40%	Transfuse

6

Need to transfuse based on consideration of haemoglobin concentration

Haemoglobin concentration	Indication for transfusion
< 7 g/dl	Transfuse
7–10 g/dl	Transfuse patients who would tolerate anaemia poorly (e.g. those with cardiac or respiratory disease, those over 65 years of age)
> 10 g/dl	No indication

7

Concerns about the safety of transfusion have encouraged the development of alternative strategies to minimize the need for homologous transfusions. These include the use of autologous pre-donation of blood, acute normovolaemic haemodilution, intraoperative cell salvage, preoperative administration of erythropoietin and the development of blood substitutes.

Fresh frozen plasma is valuable because it contains all the clotting factors. It is used to correct a coagulopathy due to a concurrent illness, the use of anticoagulants or a dilutional coagulopathy. A coagulation screen should be requested to establish the need for fresh frozen plasma, although in the presence of a massive haemorrhage, fresh frozen plasma may be given before laboratory results are available if there are clinical signs of impaired coagulation.

Platelets should be given only if there is clinical and laboratory evidence of abnormal coagulation.

Blood substitutes
There are three different areas of research in progress: free haemoglobin solutions, encapsulated haemoglobin cells, and perfluorocarbon emulsions.

Haemoglobin-based oxygen carriers: free haemoglobin has been used as a red blood cell substitute for decades but initially there were many adverse effects including hypertension, bradycardia, renal dysfunction and a short intravascular retention time. A problem was the lack of 2,3-diphosphoglycerate (2,3-DPG) and the higher pH of plasma compared with that inside the red blood cell. There is also an increase in oncotic activity which limits the concentration of free haemoglobin that can be used to about 5–7 g/dl.

Some of the adverse effects of free haemoglobin have been reduced by a variety of modifications including polymerization and conjugation to increase the intravascular retention time and the introduction of haemoglobin into cell-like structures, using stable, porous membranes that allow molecules such as glucose to enter. Some products have reached the stage of clinical trials.

Perfluorocarbon emulsions: perfluorocarbons are synthetic carbon–fluorine compounds. They dissolve gases including oxygen and carbon dioxide. They are not metabolized *in vivo* and most are excreted unchanged via the lungs. A small amount is taken up by the reticulo-endothelial system and excreted later. They are immiscible in water and have to be emulsified. Initial emulsifiers caused numerous adverse effects. Second-generation perfluorocarbons have reduced the complications, but high doses can still interfere with coagulation, elevate liver enzymes and produce a febrile response. They are in phase III trials as a blood substitute. ◆

Positioning the Surgical Patient

Jonathan Warwick

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

The correct positioning of a patient for surgery is a balance between optimizing surgical exposure and minimizing complications for the patient. The surgeon may request a particular position and it is often the role of the anaesthetist to ensure that this is accomplished safely. The anaesthetist must consider the limits of position that may be tolerated and ensure access to the airway, monitoring and vascular devices as far as possible. In general, complications may arise from physiological consequences of the position and the effects of direct pressure on soft tissue structures.

Supine position

Indications: the supine position is the standard for most surgical procedures. The orthopaedic fracture table is a modification that enables traction to be maintained on a lower limb and provides access for an image intensifier.

Physiological consequences: when an individual is upright, ventilation per unit lung volume is greater in the lower part of the lung, because here the weight of the lung makes the intrapleural pressure–volume curve steeper (see Figure 2). The apex of the lung is on a flatter part of this curve, representing a relatively larger change in pressure for a given change in lung volume, and hence a lower compliance. The lower part of the lung is better perfused as a result of gravity.

When an individual is supine, ventilation and perfusion become more uniform and the effects of gravity less marked. The differences between base and apex are then replaced by differences between dependent and non-dependent parts of the lung. Stroke volume and cardiac output may increase as a result of the increase in central venous pressure. Baroreceptors sense an increase in arterial pressure, leading to a fall in heart rate and systemic vascular resistance.

The physiological effects of a change of posture when anaesthetized depend on additional factors:

- pharmacological effects
- circulating blood volume
- method of ventilation.

The functional residual capacity (FRC) decreases by about 20% following induction, though closing capacity remains unchanged. Anaesthetized patients are vasodilated and have diminished compensatory cardiovascular reflexes. Therefore, all positioning movements must be made slowly. The basic supine position is generally well tolerated and has no additional physiological effects in healthy patients.

Pregnant patients may suffer from the supine hypotensive syndrome, where the weight of the gravid uterus reduces venous return by compression of the inferior vena cava (IVC). This can be avoided by a lateral tilt of the operating table, usually to the left side.

Direct pressure complications: the eyes should be taped closed to prevent corneal drying or injury from scratching. Limbs must be fully supported and moved with care to prevent joint dislocation or even fracture. The arms can be secured in the drawsheet, or by the use of padded arm supports.

Skin overlying all bony points is prone to pressure damage, especially the occiput, elbows, knees, greater trochanter of the femur and sacrum. As little as 2 hours of unrelieved pressure may result in a pressure sore; the duration of pressure is considered to be more important than its intensity. The ankles should be placed in soft foam-rubber boots to avoid pressure necrosis of the heel skin.

Injury to peripheral nerves (Figure 1) is often a consequence of the way in which the patient is positioned during surgery. Nerve injury is most likely to occur with the combination of muscle relaxation, an extreme position and prolonged surgery. Peripheral nerves are damaged by local ischaemia caused by compression or stretching. This produces segmental demyelination. Complete clinical recovery usually occurs within 6–8 weeks, but may take several months. Severe damage may be associated with permanent injury. Electromyography studies may aid the prognosis.

Supine position – nerve injuries

Nerve injury	Comments
• Supraorbital	Compression by catheter mount, trachael tube connectors
• Nerves to the eye	Compression from face mask
• Facial (VIIth)	Compression by anaesthetist's fingers against ramus of mandible, face mask harness
• Brachial plexus	Stretching injury, especially when arm is abducted > 90°, externally rotated, elbow extended and forearm supinated
• Ulnar	Most common nerve injury occurring during anaesthesia. Compression between the medial epicondyle of the humerus and the edge of the operating table. Pronation of the forearm may place the nerve more at risk than supination
• Radial	Compression between the edge of the operating table or armboard and the shaft of the humerus, compression from a head-screen support
• Pudendal	Compression from the post of an orthopaedic fracture table may cause pudendal nerve injury or genital trauma
• Sciatic	Direct compression in thin patients undergoing prolonged surgery on a hard table

1

Lateral ('lateral decubitus') position

Indications:

- thoracic surgery
- lateral approach to the kidney
- surgery to the hip.

Reference to the right or left lateral position indicates the side on which the patient is lying.

Physiological consequences: when lying awake in the lateral position, ventilation to the upper and lower lungs behaves in a similar fashion to the ventilation of lung apex and base when upright. The lower lung lies on the steeper, more compliant part of the intrapleural pressure–volume curve (see Figure 2, page 12). The weight of the abdominal contents pushes the lower lung diaphragm higher than the diaphragm of the upper lung, so that it is also able to generate a higher force of contraction. The lower lung is therefore better ventilated than the upper lung. Perfusion of the lower lung is also greater as a result of gravity.

Following anaesthesia, the distribution of blood flow remains unchanged but there are significant changes to the distribution of ventilation. Muscle tone is greatly reduced or absent and the FRC of each lung falls, especially in the lower lung as a result of the weight of the mediastinum pushing down from above and the weight of the abdominal contents below. This has the effect of moving the upper lung down to a more favourable (i.e. steeper and more compliant) part of the intrapleural pressure–volume curve. The lower lung moves down to a flatter, less compliant part of the curve. Therefore the upper lung becomes the better ventilated, but because it receives less of the pulmonary blood flow, ventilation–perfusion mismatch increases.

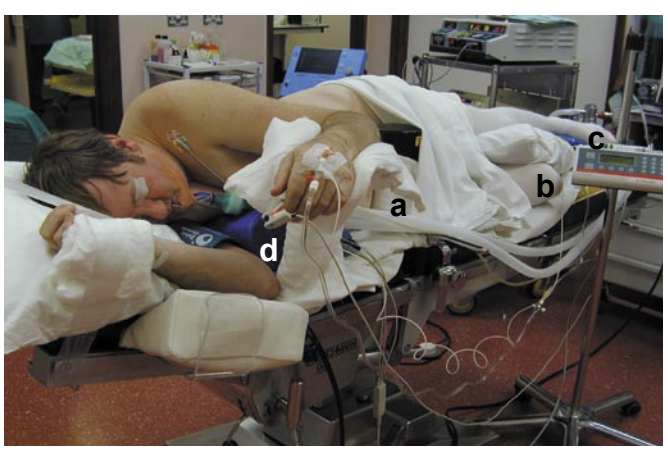
To expose the flank during the lateral approach to the kidney, the lateral flexed position over a support ('kidney position') may be necessary. Significant hypotension may result when the patient is positioned on the right side for a left kidney operation. Reduced venous return occurs as a result of partial obstruction of the IVC from the support. Hepatic encroachment on the IVC may also contribute. This problem is less common when the patient is in the left lateral position.

Direct pressure complications: the pelvis and shoulders must be well supported to prevent the patient from rolling backwards off the table, or forwards into the recovery position. The lower leg should be flexed and the upper leg extended, with a pillow between the two (Figure 2).

An axillary roll places the weight of the chest on to the ribcage and prevents direct compression injury to the shoulder and axilla, thus avoiding deltoid muscle ischaemia or neurovascular damage to the lower arm.

The lower leg is at risk from pressure damage, especially in obese patients. Compartment syndrome, myoglobinuria and acute renal failure have been reported.

Nerve injuries that may result from the lateral position are listed in Figure 3.



2 The lateral position.
a Padded supports to prevent patient rolling over – anteriorly next to iliac crests; posteriorly next to lumbar spine.
b Lower leg flexed and pillow between knees.
c Heel supported.
d An axillary roll places the weight of the chest on to the ribcage.

Lateral position – nerve injuries

Nerve injury	Comments
• Cervical spine	Lateral flexion may stretch cervical spinal nerves and make arthritic joint pain worse. May cause Horner's syndrome
• Brachial plexus	Stretching injury when the neck is extended and in lateral flexion. May occur when the arm is suspended from a bar or gutter and is inadequately supported
• Common peroneal	Compression between the operating table and the head of the fibula

3

Trendelenburg ('head-down') position

Indications:

- pelvic surgery
- insertion of central venous lines.

Friedrich Trendelenburg first described the 45° supine head-down position in 1890. This position facilitates access to the pelvis. Most head-down positions are now about 20° or less with acceptable results. The steep head-down position is now avoided because it is unnecessary and has too many disadvantages. A corrugated or non-slip mattress helps prevent patient movement.

Physiological consequences: there is a greater reduction in FRC than in the basic supine position as a result of pressure of the abdominal contents on the diaphragm. Usually ventilation is little impaired, especially in fit patients and for short periods. For longer operations and in obese patients, there is increased work of breathing against the weight of the abdominal contents, therefore controlled ventilation is preferable.

Central venous pressure rises, and cardiac output may increase. This may precipitate acute heart failure in patients with poor cardiac reserve. The position is not generally effective in improving the circulation during shock and can increase venous pooling in the upper half of the body. A prolonged head-down position will cause venous congestion and oedema in the head and neck.

Barrier pressure is the difference in intraluminal pressures either side of the gastro-oesophageal junction. The pressure within the oesophagus is normally 15–25 mm Hg higher than gastric pressure and gastro-oesophageal reflux is prevented. Barrier pressure is maintained by the action of the smooth muscle cells of the lower oesophageal sphincter and the skeletal muscle of the surrounding crural diaphragm. The head-down position may raise intragastric pressure, reduce barrier pressure and encourage reflux to occur.

There is an increase in intracranial and intraocular pressure. While inserting central venous lines in patients with head injury, care should be taken to limit the head-down tilt to the minimum necessary so as not to worsen cerebral perfusion pressure.

Direct pressure complications: injury to the brachial plexus was common when the steep 45° head-down position was used and patient movement was prevented by shoulder supports or wrist straps. Patient movement is prevented by the non-slip mattress when lesser degrees of head-down tilt are used (e.g. 20°). Brachial plexus injury is now uncommon.

Reverse Trendelenburg ('head-up') position

Indications:
- operations on the head and neck; this position reduces venous pressure and helps reduce bleeding
- surgical access to the gall bladder and proximal gastrointestinal tract, especially during laparoscopic surgery
- operations on the shoulder joint.

Usually, 15–20° head-up tilt is sufficient.

Physiological consequences: there is a small decrease in arterial pressure; but less of a decrease in FRC than in the basic supine position because less pressure is exerted on the diaphragm by the abdominal contents. There is a reduction in intraocular and intracranial pressure, mainly as a result of improved venous drainage.

Any open vein or sinus above the level of the right atrium can cause venous air embolism.

Direct pressure complications: injury to the brachial plexus may be caused by excessive rotation and lateral flexion of the neck away from the operative site.

Lithotomy position

Indications:
- urological procedures
- operations on the perineum, anus and rectum.

The patient is positioned in the supine position, with both hips and knees flexed and the thighs abducted. The ankles and feet may be supported by lithotomy poles using stirrups or calf supports, or by strapping into padded boots. The position is usually combined with some head-down tilt to aid surgical access.

Physiological consequences: the lithotomy position is generally well tolerated. There is a reduction in vital capacity and FRC as a result of diaphragmatic splinting from upward displacement of abdominal contents. This may cause difficulty with spontaneous ventilation in obese patients and controlled ventilation may be preferable. Care should be taken when the legs are lowered because this may reveal previously unrecognized hypovolaemia and cause sudden hypotension.

Direct pressure complications: backache is common and may be reduced by providing a support to maintain the normal lumbar lordosis. The sacrum must be supported and should not hang free over the end of the table. Marked flexion of the hips and knees may cause sacroiliac strain, and the legs must be moved together to avoid pelvic asymmetry. Slippage of the lithotomy poles once the legs are positioned can cause hip dislocation. Moving the thighs too far apart may strain the adductor muscles.

Compartment syndrome in the lower leg may be initiated by pressure of the calf muscles on the stirrup pole. 'Breaking' or raising the lower end of the table when the fingers have been inadvertently trapped in the gap has caused crush injury.

Anaesthesia should not be induced with the legs elevated because raised intra-abdominal pressure may predispose to regurgitation, and turning the patient will be difficult.

Nerve injuries that may occur with the lithotomy position are shown in Figure 4.

Lithotomy position – nerve injuries

Nerve injury	Comments
• Sciatic	Stretching as a result of maximum external rotation of the flexed thigh
• Common peroneal	Compression between lithotomy pole and the head of the fibula
• Tibial	Compression if the legs are supported by stirrups behind the knees
• Femoral	Compression beneath the inguinal ligament when the thighs are fully flexed on the abdomen
• Obturator	Compression at the obturator foramen when the thighs are fully flexed on the abdomen
• Saphenous	Compression between the medial condyle of the tibia and lithotomy post or stirrup

Prone position

Indications:
- operations on the spine and posterior cranial fossa
- operations on the buttocks and natal cleft
- percutaneous extraction of renal calculi.

Physiological consequences: there is often an improvement in gas exchange in the prone position. This may be as a result of the greater inspiratory pressures required to maintain the tidal volume, which decreases atelectasis, increases FRC and improves oxygenation. Pulmonary barotrauma caused by excessive inspiratory pressures should be avoided by correct positioning of the pelvis and upper chest.

The pelvis and the upper chest must be supported so that the abdomen is not compressed and the diaphragm can descend freely during respiration. This may be particularly difficult to achieve in obese patients. Patients may be positioned by using pillows, supporting the iliac crests with cushioned props, or by the use of a specialized hollowed mattress. Controlled ventilation is preferable in most patients.

There are no significant cardiovascular changes. Pulmonary blood flow is essentially unchanged from the supine position. Poor positioning and high inspiratory pressures may decrease venous return. Patients with previous coronary artery bypass grafting may be at risk from graft occlusion.

Direct pressure complications: turning the supine patient prone requires a team of four people. Great care must be taken with the head and neck to avoid twisting or hyperextension injury to the cervical spine. The face should rest on a cushioned horseshoe with the weight of the head evenly distributed. The eyes are naturally protected within their bony sockets, but exophthalmos or a flattened nasal bridge may allow transmission of pressure to the globe. Prolonged compression may result in central retinal vein thrombosis and blindness.

The tracheal tube must be securely fixed and its position checked after the turn. Some experienced anaesthetists may use the laryngeal mask for airway maintenance in prone patients, though the use of a reinforced tracheal tube is likely to be safer for the trainee. Excessive pressure on the breasts may cause ischaemic damage to the nipples, interstitial bleeding or rupture of breast implants. In men, the penis or scrotum may become trapped and compressed.

Possible nerve injuries are shown in Figure 5.

Prone position – nerve injuries

Nerve injury	Comments
• Cervical spinal cord	Stretching injury caused by overextensio plane
• Nerves to the eye	Compression from face support
• Facial (VIIth)	Compression from face support
• Brachial plexus	Stretching injury caused by extreme abduction of the arms. Limit abduction to 90°
• Ulnar	Compression between the medial epicondyle of the humerus and the mattress
• Lateral cutaneous nerve	Compression between iliac crest of the thigh and the positioning prop. If used, props should be angulated and positioned so that the patient is unable to slip sideways
• Anterior tibial	Stretching injury caused by forced plantar flexion of the foot

The sitting position

Indications:
- operations on the posterior cranial fossa and cervical spine
- dental chair anaesthesia.

The sitting position enables the surgeon to gain clear access, with optimal venous drainage, low arterial pressure and reduced bleeding. CSF drainage is good and brain swelling is minimized.

Dental chair anaesthesia in the sitting position is now uncommon.

Physiological consequences: the patient is anaesthetized in the standard supine position and the neurosurgical pins and head frame are applied. On the operating table, the patient is progressively sat upright with the neck flexed; the knees are slightly flexed and the legs are lowered. The arms rest in the lap on a pillow, with the elbows flexed.

A small fall in systolic blood pressure of 20 mm Hg usually occurs; this can be offset by prior volume loading with 500 ml of colloid solution. Occasionally, persistent instability of blood pressure can occur that may cause the position to be abandoned despite the use of vasopressors. Controlled ventilation is the method of choice, to enable control of Pa_{CO_2} and intracranial pressure. It maintains a higher mean intrathoracic pressure and reduces the likelihood of air embolus.

Air embolus is the major complication. All patients must be considered to be at risk throughout the procedure. For this reason, many neurosurgeons seldom use this position. It is still used when insufficient access is provided by the alternative prone or semi-prone positions.

Dysrhythmias, especially bradycardia, and blood pressure instability may occur following surgical manipulation in the region of the brain stem. This is a result of direct pressure effects on the autonomic control centres of the medulla.

Direct pressure complications: nerve injuries that may result from the sitting position are shown in Figure 6.

The sitting position – nerve injuries

Nerve injury	Comments
• Cervical spinal cord	Stretching injury and spinal cord ischaemia following excessive neck flexion. A two-finger breadth gap between chin and chest is recommended
• Brachial plexus	Stretching injury if the arms are unsupported
• Ulnar	Compression between the medial epicondyle of the humerus and the arm supports
• Sciatic	Stretching injury if thighs are flexed and knees extended. Maintain adequate knee flexion

Premedication

Neal Evans
Christopher F Kearns

Neal Evans is Specialist Registrar in the Oxford School of Anaesthesia. He qualified from the Royal London Hospital, and was previously a Research Fellow in ITU in Cambridge, UK.

Christopher F Kearns is Consultant Anaesthetist in the Nuffield Department of Anaesthesia at the Radcliffe Infirmary, Oxford, UK. He qualified from Charing Cross Hospital, London, and trained in anaesthesia in London, UK, Toronto, Canada, and Oxford, UK. His interests include neuroanaesthesia and medical education. He organizes the Oxford Primary FRCA courses.

Premedication involves the prescription of drugs before the induction of anaesthesia in order to alleviate the apprehension associated with surgery, to counteract the side-effects of anaesthetic agents or to reduce the risks of pre-existing pathology (Figure 1). When choosing a premedicant drug the anaesthetist must consider which of its properties are appropriate for the individual patient, the possible side-effects and its potential effect on the proposed anaesthetic technique. The ideal premedicant is:

- painless to administer
- highly reliable and specific
- of rapid onset and rapidly cleared
- free of side-effects and interactions with other drugs.

Premedicant drugs entered anaesthetic practice in the late 19th century. Early anaesthetic agents were delivered by open systems and induced unconsciousness slowly. Ether caused an increase in pharyngeal and bronchial secretions, which interfered with smooth gaseous induction. Chloroform caused marked vagal stimulation of the heart leading to bradycardia. Atropine was first used in premedication in 1890. Hyoscine, which combined anticholinergic effects with antiemesis and sedation, was often combined with an opioid (e.g. papaveretum) to produce ‘twilight sleep’. Opioids were prescribed to aid the induction of anaesthesia before the development of more potent anaesthetic induction agents.

The routine use of drugs for premedication is now in decline. There are several reasons for this.

- Modern anaesthetic agents are potent and have a rapid, smooth onset.
- The increased use of day-care surgery requires rapid patient recovery.
- In-patients are often admitted on the day of surgery and the time available between preoperative assessment and induction of anaesthesia is short.
- Pressures of high patient turnover and staffing constraints can make premedication difficult to deliver in practice.

Rationale of premedication

- Reduction of anxiety and fear
- Sedation
- Amnesia
- Antiemesis
- Reduction in volume and acidity of gastric secretions
- Attenuation of autonomic reflexes
- Maintenance of cardiovascular stability
- Reduction of airway secretions
- Provision of analgesia

1

Anxiolysis, sedation and amnesia

The preoperative visit: anxiety is common in preoperative patients. As well as being unpleasant, this anxiety is part of a stress response that may worsen coexisting pathology such as hypertension or angina. A preoperative visit by the anaesthetist is the most effective way to allay the fears and anxieties of forthcoming surgery. This visit can be used to establish rapport with the patient, to discuss the proposed anaesthetic technique in terms that they can understand and to address their worries in a sympathetic manner. Older children will benefit from inclusion in preoperative discussions and it is becoming usual for parents to stay with children during induction of anaesthesia.

For some patients, the preoperative visit alone is insufficient to allay anxiety and pharmacological methods are required. The nature of the surgical procedure, coexisting pathology or the need for a rapid recovery from anaesthesia may dictate extreme caution before the prescription of sedating premedication (Figure 2). Co-administration of an opioid and a benzodiazepine has a potent respiratory depressant effect.

Relative contraindications to sedative premedication

- Airway obstruction or airway surgery
- Poor ventilatory reserve
- Sleep apnoea
- Intracranial pathology
- Severe hepatic or renal disease
- Rapid-sequence induction
- Obstetric anaesthesia
- Day-case anaesthesia (delayed discharge)
- Extremes of age

2

Benzodiazepines
Benzodiazepines are the most commonly used premedication. They are safe and have a broad therapeutic index though they can cause unpredictable psychological effects at the extremes of age. Those that are suitable premedicants can usually be given by mouth about 1 hour before induction, have a short duration of action and produce inactive metabolites (Figure 3).

Benzodiazepines are agonists of γ-aminobutyric acid (GABA) receptors within the CNS. GABA is an important inhibitory neurotransmitter, which hyperpolarizes the neuron by causing an influx of chloride ion. Benzodiazepines also produce sedation and amnesia by their action on the limbic system. Both these effects are variable and depend on the drug used and the dose given.

Temazepam is an effective anxiolytic and is available in elixir or tablet form. It has a sufficiently short duration of action to allow its use in day-case surgery. Midazolam is presented in 2 mg/ml or 5 mg/ml glass vials. Unlike the other benzodiazepines it is water soluble at acid pH but becomes highly lipophilic at physiological pH. It can be given orally or nasally, which makes it an attractive premedicant for children in doses of 0.2–0.5 mg/kg. Lorazepam, 0.05 mg/kg (max. 4 mg), produces intense anterograde amnesia within 30 minutes, often lasting over 3 hours. Amnesia may be viewed as an advantageous property of a premedicant but some patients find the sensation unpleasant.

Benzodiazepines commonly used as premedication

Drug	Usual adult dose	Half-life of parent drug (hours)	Half-life of active metabolites (hours)
• Diazepam	5–10 mg p.o.	24–48	4–10
• Temazepam	10–30 mg p.o.	4–10	None
• Lorazepam	2–4 mg p.o.	10–20	None
• Midazolam	5–10 mg i.m. 0.5 mg/kg (maximum 20 mg) p.o. in children	1–3	None

3

Other anxiolytics and sedatives
Phenothiazines are major tranquillizers that have sedative and anticholinergic actions. They are histamine antagonists (via H_1-receptors) and have antidopaminergic and α-adrenoceptor blocking properties. They may cause pallor and restlessness in the presence of pain and hypotension. Trimeprazine elixir is sedating and is used for children in doses of 1.5–2 mg/kg, up to 2 hours before surgery. It is not licensed for use in children less than 2 years of age.

Droperidol is the only commonly used butyrophenone in current anaesthetic practice. It has antiemetic and sedating properties. Antidopaminergic side-effects such as dystonic reactions and agitation limit its routine use at sedating doses (e.g. 10 mg orally for adults).

Antiemesis

Postoperative nausea and vomiting (PONV) is a common problem, which is distressing for the patient. There are several risk factors:

- gender (incidence is three times higher in women than in men)
- patients undergoing operations on the ear, squint surgery, gynaecological procedures and laparoscopy
- previous history of PONV or motion sickness
- use of morphine
- anaesthetic technique (volatile anaesthetic maintenance is more emetic than intravenous propofol maintenance).

The vomiting reflex is coordinated by the vomiting centre within the dorsolateral reticular formation of the medulla. It receives multiple afferent pathways from peripheral and central chemoreceptors, nociceptors, the vestibular system and the cerebral cortex. The synapses in these pathways are predominantly muscarinic. The vomiting centre also receives stimuli from the chemoreceptor trigger zone in the area postrema on the floor of the fourth ventricle, but outside the blood–brain barrier. This structure is rich in dopamine (D_2) and serotonin (5-HT_3) receptors. The antiemetics commonly used in anaesthetic practice involve inhibition at one or more of these receptor sites.

Muscarinic antagonists: hyoscine (adults, 300 µg; children 4–10 years, 75–150 µg orally) is a more effective antiemetic and is more sedating than atropine. Antihistamines, including cyclizine, 50 mg orally, i.v. or i.m., and promethazine, children 2–5 years, 5–15 mg, 5–10 years, 10–25 mg orally; adults, 25–50 mg orally or intramuscularly, also have antiemetic properties, largely as a result of their antimuscarinic activity. Antimuscarinics cause dry mouth, blurred vision, and bowel and bladder dysfunction.

Dopamine antagonists are powerful antiemetics but extra-pyramidal side-effects, such as dystonia, dyskinesia, tremor and oculogyric crisis are not uncommon.

Prochlorperazine, 12.5 mg i.m., is the most widely used phenothiazine because it is less sedating and has fewer antidopaminergic and α-blockade side-effects than others of the same group.

Droperidol is an effective antiemetic at low dose, 0.625–1.25 mg, reducing the risk of unpleasant dopaminergic or psychological effects. It is usually given intravenously at induction.

Metoclopramide, 0.1 mg/kg i.v., i.m. or orally, is a dopamine antagonist with peripheral as well as central effects. Its prokinetic effects are more marked than its antiemetic properties and comparative studies have raised doubt about its effectiveness as a prophylactic antiemetic.

5-HT antagonists are powerful new antiemetics that are relatively free of side-effects. The most widely used agent is ondansetron, 4 mg i.v., given immediately before or at the end of surgery. Their relative expense has resulted in the cost-effectiveness of their prophylactic use being questioned.

Non-pharmacological measures including acupunture and acupressure have been explored. There is some evidence that these techniques are weakly effective.

Reduction in volume and acidity of gastric secretions

The potential for lung damage from the aspiration of gastric contents increases with the volume and the acidity of the aspirate. Risk of aspiration accompanies late pregnancy, emergency or trauma surgery, symptomatic oesophageal reflux, and obesity.

Acid secretion by gastric parietal cells can be reduced by the use of H_2-histamine antagonists such as ranitidine, 150 mg p.o. Proton pump inhibitors such as omeprazole, 20 mg p.o., are more powerful in reducing acid secretion but inhibit the metabolism of other drugs such as warfarin, phenytoin and diazepam.

A 0.3 molar solution of sodium citrate, 30 ml, will raise gastric pH and is less irritant to the airway should aspiration occur. The routine use of the prokinetic agent metoclopramide, 10 mg, is common practice but of no proven value in the prevention of gastric aspiration.

Attenuation of autonomic reflexes

Parasympathetic stimulation can lead to hypotension, bradycardia or even asystole mediated via the vagus nerve. Triggers include:

- traction on the extraocular muscles during squint surgery
- surgical dilatation of the cervix or of the anal sphincter
- repeated doses of suxamethonium
- laryngoscopy in children (especially on lifting the epiglottis with a straight-bladed laryngoscope)
- opioid analgesics, propofol and halothane.

Glycopyrronium, 0.2 mg i.v. at induction, provides prophylaxis without the discomfort of a dry mouth before surgery. It does not penetrate the blood–brain barrier and lacks the central side-effects of atropine.

An increase in circulating catecholamines may be caused by several factors:

- laryngoscopy and tracheal intubation
- surgical stimulation and pain
- drugs such as ketamine, cocaine and adrenaline (epinephrine) in local anaesthetics.

This increase may cause hypertension and increased myocardial oxygen demand. It may result in myocardial ischaemia in susceptible patients. A balanced anaesthetic technique reduces these risks, and β-blocker premedication (atenolol, 50 mg p.o.) may be of benefit.

There has been recent interest in the use of α_2-adrenoceptor agonists such as clonidine, 3 µg/kg p.o., as premedicants. They reduce sympathetic activity, cause sedation, a reduction in anaesthetic requirement (decreased minimum alveolar concentration) and reduce pressor responses including that of laryngoscopy. However, there appears to be a narrow therapeutic window with the potential for development of hypotension and bradycardia.

Reduction in airway secretions

Antisialogogues are occasionally prescribed as premedicants though their use in modern-day practice is uncommon. Glycopyrronium, 0.2 mg i.v. or i.m., may be used to improve conditions before fibre-optic intubation.

Analgesia

Opioids (e.g. morphine, 0.1–0.2 mg/kg i.v. or i.m.) should be used to relieve acute preoperative pain. However, in the absence of any preoperative distress and with the development of new potent opioid analgesics with a rapid onset given at induction, such as fentanyl, alfentanil and remifentanil, an opioid premedicant is seldom indicated.

Non-steroidal anti-inflammatory drugs decrease the requirement for opioid analgesia during and after a surgical procedure. Typically, ibuprofen, 400 mg p.o., or diclofenac, 50–100 mg p.o., p.r. or i.v., may be given. They should be avoided in patients with a history of peptic ulceration or renal impairment and used with caution in asthmatic patients. Other simple analgesics such as paracetamol, 1 g, can also be given p.o. or p.r.

The concept of pre-emptive analgesia is that nociception can be modulated at the level of the spinal cord by analgesia given before surgery, thereby reducing total postoperative analgesic requirements. While this concept is attractive and has been demonstrated in animal models, clinical studies have yet to prove its value.

Topical anaesthetics such as eutectic mixture of local anaesthetic (*Emla* cream) or amethocaine gel applied to the site of venepuncture, reduce the fear of intravenous anaesthetic induction in children and many adults.

Principles of Anaesthetic Vaporizers

Eileen Palayiwa

Eileen Palayiwa is a Clinical Scientist in the Clinical Measurement Department at the Oxford Radcliffe Hospital. She graduated in physics from Oxford University and obtained her PhD from Oxford Polytechnic. Her interests include evoked potential monitoring and gas analysis.

Gases, liquids and vapours

Substances can exist in the solid, liquid or gaseous state. Below a certain temperature, known as the critical temperature, it is possible to liquefy gases by compressing them. When a gas is below this critical temperature it is referred to as a vapour.

Vapours consist of molecules that have left the surface of a liquid below the critical temperature. Vapour molecules have had sufficient energy to break away from the attraction of the molecules left behind in the liquid and are therefore the more energetic molecules. Molecules leave the surface of the liquid and return to it randomly. When the vapour is in equilibrium with the liquid, the number of molecules leaving the liquid is equal to the number returning to it, and the vapour is said to be saturated. If there is insufficient liquid for there to be a reservoir from which molecules can evaporate and to which they can return, then the vapour is unsaturated and behaves as a gas.

The pressure of a vapour in equilibrium with a liquid is known as the saturated vapour pressure (SVP).

Variation of SVP with temperature

As the temperature of the liquid increases, more molecules have sufficient energy to escape from the surface and therefore the SVP rises. When the boiling point is reached, all the molecules evaporate and the SVP is equal to atmospheric pressure. Figure 1 shows the variation of SVP with temperature for halothane, enflurane and isoflurane. Unsaturated vapours behave as gases so that the pressure is inversely proportional to the volume (Boyle's law).

Cooling due to vaporization

If molecules that have left the surface of a liquid are not allowed to return to it (e.g. if they are swept away by a stream of fresh gas) then the liquid cools. This is because the evaporating molecules are more energetic than those left behind, therefore there is a net loss of energy from the liquid, which causes a drop in temperature. The latent heat of vaporization is the heat required to convert a unit mass of liquid into its vapour phase at a constant temperature. Cooling may be prevented or reduced if the liquid is in contact with a surface that can supply heat by conduction. The amount of heat that a body can supply at a given temperature depends on its specific heat and its mass, or, in other words, on its thermal capacity. Heat is also supplied by conduction from the surroundings and the rate at which this occurs is determined by the thermal conductivity of the body.

The specific heat of a substance is defined as the amount of heat (or energy) required to raise the temperature of a unit mass of the substance through 1 deg C. The units of specific heat are joules per kilogram per Kelvin change in temperature (J/(kg.K)).

The thermal capacity of a body is the heat required to raise its temperature through 1 deg C (this is also equivalent to the amount of energy the body loses when cooled by 1 deg C). The units of thermal capacity are joules per kilogram (J/kg). The thermal capacity of a body is equal to the product of its mass and specific heat.

The thermal conductivity of a material is the rate of heat transfer per unit area when a temperature difference of 1 deg C is maintained across an insulated block of the material 1 m thick. The units of thermal conductivity are Watts per metre per Kelvin (W/(m.K)).

Values of specific heat, density and thermal conductivity for copper, aluminium, glass and stainless steel are shown in Figure 2. It can be seen from this table that copper has the highest thermal conductivity of these materials so that vaporizers made of copper are the most efficient at conducting heat from the atmosphere to replace the energy that the liquid agent loses due to evaporation. Copper has the lowest specific heat of these substances; however, since it is much denser than aluminium or glass, the thermal capacity of a given volume of copper is higher than that of either of these materials. A given volume of stainless steel has the highest heat capacity of these materials. In practice, most vaporizers are made of stainless steel because it is readily available. However, copper is thermally more suitable because its much higher thermal conductivity more than compensates for the lower heat capacity.

Anaesthetic vaporizers

The SVP of most anaesthetic agents at room temperature is too high for them to be delivered to a patient without dilution (Figure 1). For example, the SVP of isoflurane at 20°C is 236.5 mm Hg (i.e. 31% v/v if atmospheric pressure is 760 mm Hg). In general, concentrations below 2% v/v are required for maintenance of anaesthesia. An anaesthetic vaporizer is a device that dilutes the vapour to give a known concentration of the agent.

Fresh gas enters the vaporizer and is split into two portions (Figure 3). One portion flows through an area known as the vaporizing chamber, where it comes into contact with the anaesthetic vapour; the remainder of the gas bypasses this chamber. The two flows then recombine and the vapour is diluted. By varying the flow rate in the two paths the resultant vapour concentration can be varied. The concentration of agent depends on the flow through the vaporizing chamber, the total fresh gas flow and the saturated vapour pressure of the anaesthetic agent. The way in which the gas flow is split between the bypass and vaporizing chamber depends on the relative resistance of each pathway. If the total fresh gas flow (F) is split into a bypass flow (F_b) and a vaporizing chamber flow (F_v) then:

$F_v + F_b = F$

The flow rate emerging from the vaporizing chamber (F_e) will be greater than that entering it, due to the volume of vapour added:

$F_e = F_v + F_e \times SVP/100$

where SVP is expressed as a percentage.

Therefore $F_e = F_v/[1-(SVP/100)]$

The concentration (C) of the vapour in the gas emerging from the vaporizer will be given by:

$C = F_e \times SVP/(F_b + F_e)$

This calculation assumes that the gas emerging from the vaporizing chamber is fully saturated with vapour. To ensure that this is the case, manufacturers increase the surface area of liquid that the gas passes over by introducing wicks made of cloth or metal into the vaporizing chamber. In many cases the gas is forced to take a long pathway through the chamber, which also helps to ensure saturation.

Variation of saturated vapour pressure with temperature

An anaesthetic vaporizer

3

Temperature compensation

As liquid evaporates from the vaporizing chamber the temperature drops, and unless there is some means of compensating for this, the output of the vaporizer also drops. The temperature drop, and hence the fall in output, is lower if the vaporizer has a large heat capacity and can therefore supply energy to the liquid to compensate for that which it has lost. For this reason most vaporizers contain a large mass of metal that can also conduct heat from the surroundings into the liquid. In addition, most vaporizers incorporate some kind of temperature compensation, which reduces the resistance of the vaporizing chamber relative to that of the bypass as the temperature drops. As a result, more gas flows through the vaporizing chamber so that the vapour concentration is maintained.

Effect of intermittent positive-pressure ventilation (IPPV)

During IPPV, the pressure at the outlet of a vaporizer is not constant. When the pressure is high, flow emerging from the vaporizer reduces and the pressure in the vaporizing chamber builds up. As the pressure drops, the excess of vapour, which has accumulated in the vaporizing chamber at this time, emerges not only from the normal outlet of the vaporizing chamber but also from the inlet. This means that the bypass gas contains vapour and therefore the concentration rises. Manufacturers have compensated for this by introducing a long inlet tube into the vaporizing chamber. When the pressure inside the vaporizing chamber drops, the vapour enters this tube, but its volume is not enough to emerge into the bypass.

Effect of flow rate on vaporizer output

The vaporizer output is dependent on the resistance of the vaporizing chamber relative to that of the bypass. With varying flows the vaporizer output remains constant only if this does not change. In practice, this is difficult to achieve over the wide range of flows used in anaesthetic practice. Only if laminar flow is maintained in each pathway throughout the flow range will this be the case. Another factor influencing the output at high flows is the increased cooling, which occurs as a result of the large amount of evaporation taking place.

Figure 4 shows the variation of output with flow for a Penlon plenum enflurane vaporizer. It can be seen that the output of this vaporizer at high settings drops as the flow rate increases. However, at the lower settings more commonly in use, the output remains reasonably constant. This indicates that the temperature compensator in the Penlon plenum vaporizer (PPV) can adjust adequately for cooling due to evaporation except at the highest dial settings and flow rates.

Effect of gas composition

The relative flow rates through the bypass and vaporizing chamber at a given dial setting remain constant only if laminar flow is maintained in both pathways. As soon as the flow in one pathway becomes turbulent, its resistance rises causing less gas to flow through it, unless it is matched by a proportional rise in the resistance of the other pathway.

Nitrous oxide has different physical characteristics from oxygen (Figure 5); in particular, the ratio of viscosity to density, which determines the flow rate at which turbulence sets in, is much lower. The effect that this has on the output of the vaporizer depends on its design. In some vaporizers, output drops when the carrier gas contains nitrous oxide whereas in others it increases.

Variation of output with flow for the Penlon plenum vaporizer

Physical properties of oxygen and nitrous oxide

Gas	Density (kg/m^3)	Viscosity ($\mu N.second/m^2$)	Kinematic viscosity ($m^2/second$)
Oxygen	1.43	18.9	10.3×10^{-5}
Nitrous oxide	1.96	13.5	6.9×10^{-5}

5

Types of vaporizer

Vaporizers fall into two broad categories.

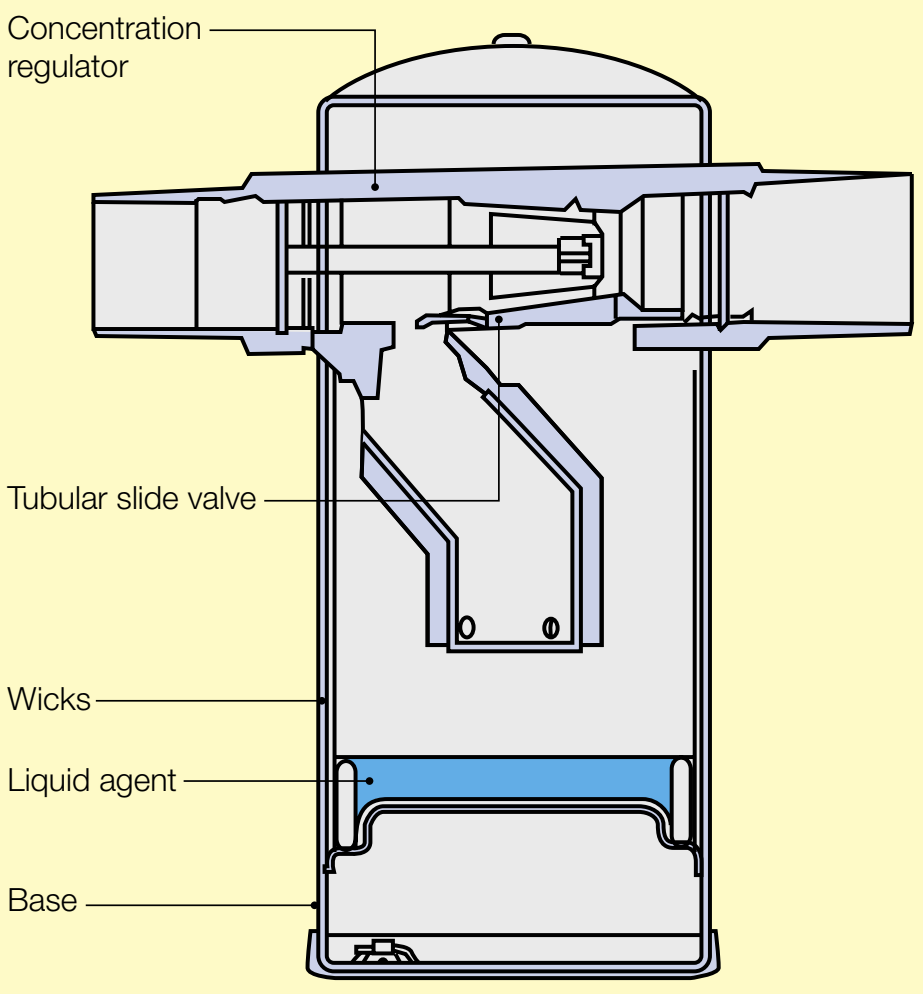
Drawover vaporizers – in a drawover vaporizer, gas is pulled through as the patient inspires (expiration is to atmosphere via a non-rebreathing valve). The flow rate of gas through the vaporizer is therefore not constant and it is necessary for the vaporizer to have a low resistance.

Plenum vaporizers – in a plenum vaporizer, gas is driven through under positive pressure. The term plenum is derived from the plenum system of ventilation where gas is forced into the system. Plenum vaporizers may have a higher resistance than drawover vaporizers though some vaporizers are designed to be used in either mode (e.g. the Oxford miniature vaporizer).

Oxford miniature vaporizer

The Oxford miniature vaporizer (Figure 6) is designed as a low resistance drawover vaporizer. It does not have any temperature compensation, but it has a water-filled jacket to increase its heat capacity.

Oxford miniature vaporizer

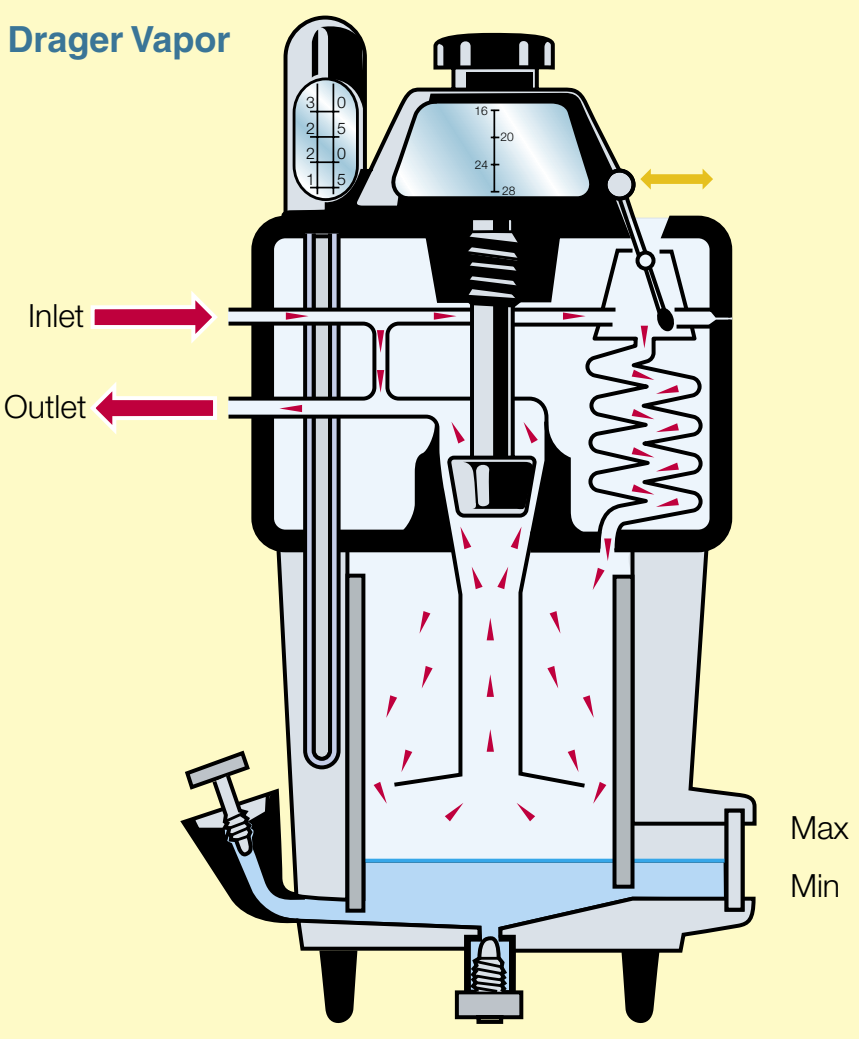


6

Drager Vapor

The Drager Vapor (Figure 7) is constructed from a large block of copper and is therefore thermally stable. It has a built-in thermometer so that the temperature of the liquid agent may be read and the position of the concentration dial is adjusted according to this temperature. In this vaporizer, the gas flow through the bypass and the vaporizing chamber is controlled by a pair of needle valves, which are carefully manufactured to ensure that gas flow is laminar in both pathways over a large range of flow rates. There is therefore little variation of output with flow rate for this vaporizer.

Drager Vapor



7

PPV

In the PPV (Figure 8), when the control dial is in the zero position the vaporizing chamber is isolated by means of a spring-loaded valve attached to the push rod, which is aligned with the control knob. When the control knob zero lock button is pressed the push rod opens the valve and as the control knob is rotated the vapour control orifice opens to allow more gas to flow through the vaporizing chamber.

Temperature compensation is achieved by a moving needle valve within the bypass orifice, which increases the bypass resistance as the temperature drops, thus forcing more gas to flow through the vaporizing chamber. The movement of the valve is controlled by a push rod attached to an ether-filled metal bellows unit. As the liquid agent changes temperature, the ether in the bellows expands or contracts causing the bellows to expand or contract linearly. Compensation for fluctuating back pressure is achieved by the inclusion of a long narrow tube in the vaporizing chamber.

Penlon plenum vaporizer

8

Tec 6 vaporizer

The Tec 6 vaporizer (Figure 9) varies from most other conventional vaporizers because it incorporates a heater element. This is necessary because desflurane concentrations up to 18% v/v may be required. The concentration knob has an interlock system, which means that it cannot be turned until the liquid agent has been heated to the correct temperature. When the control dial is turned, an electronic signal opens the shut-off valve. The pressure transducer measures the difference between the gas inlet pressure and the regulated agent pressure. The agent pressure is controlled electronically by opening or closing the pressure-regulating valve to balance the pressures. When the pressures are correctly balanced the vaporizer functions correctly.

Calibration of vaporizers

Anaesthetic vaporizers are calibrated in the factory using a refractometer (an accurate optical device) in a temperature-controlled room. In general, either oxygen or air at a medium flow rate is used for the carrier gas. The output of a vaporizer may vary under different conditions of temperature, flow or carrier gas – this is not surprising, considering the wide range of flow rates and concentrations over which a vaporizer is used. It has been said that one should expect vaporizers to produce concentrations only within 20% of their dial settings. While this is a wide margin, it is not at all unusual for concentrations to differ by 10% of the dial setting and as conditions become more extreme this difference may approach 20%. It is important that anaesthetists recognize the problems faced by manufacturers when designing vaporizers and that they do not always expect vapour concentration and dial setting to coincide.

Recognition and Management of Anaphylactic and Anaphylactoid Reactions

Andrew McIndoe

Andrew McIndoe is Consultant Anaesthetist and Senior Clinical Lecturer in the Sir Humphry Davy Department of Anaesthesia, Bristol Royal Infirmary. He is also the Director of Research and Education at the Bristol Medical Simulation Centre where he has developed a specific interest in human factors and crisis management.

The term anaphylaxis was coined by Charles Richet in 1902 to describe the reaction of dogs to a second, and often fatal, injection of foreign protein (sea anemone toxin). The term was introduced to distinguish this later injection from the first 'prophylactic' injection that induced sensitization.

Anaphylaxis is now recognized to be an immediate hypersensitivity or type I immune reaction mediated by immunoglobulin E (IgE) and resulting in mast cell degranulation and basophil activation. It is not dose related and can occur in response to minute exposure to an allergen. Typically, the severity of the response worsens on re-exposure owing to progressive sensitization of the subject. The true incidence of anaphylaxis is unknown but is estimated to be 1/6000–20,000 anaesthetics or 1/10,000 of the general population/year. Women are more likely to suffer an anaphylactic reaction than men, with a quoted increase in risk of 3–10:1. Intravenous administration of the antigen is more likely to precipitate a severe generalized reaction. Cross-sensitivities with non-steroidal anti-inflammatory drugs (NSAIDs) and muscle relaxants makes previous exposure unnecessary. Up to 80% of neuromuscular blocking agent reactions are not associated with known prior exposure.

Anaphylactoid reactions may present with a similar clinical picture, but do not result from hypersensitivity and are not mediated by IgE. Drugs such as opioids can directly stimulate mast cell degranulation with histamine release causing pruritus, rash and hypotension. They should be managed as potential anaphylactic reactions because confusion over the diagnosis merely delays effective treatment.

Pathophysiology

Primary exposure to an antigen results in the synthesis of specific IgE antibodies by lymphocytes and plasma cells. The Fc portions of these antibodies are able to fix themselves to the surface of tissue mast cells and circulating basophils. The antigen binding sites are thus presented externally. Subsequent contact with antigen causes IgE antibody:antigen cross-binding and triggers immediate degranulation of the host mast cell or basophil. Release of histamine and serotonin results in an acute inflammatory reaction, smooth muscle constriction, vasodilatation and increased capillary permeability. The clinical picture depends on the mode of exposure.

- Skin – urticaria, flare and weal reaction (hence the use of skin prick testing).
- Eyes – conjunctivitis.
- Mouth/airway – perioral and laryngeal oedema, broncho-spasm.
- Parenteral – generalized cardiovascular collapse.
- Eosinophils are mobilized by chemotaxis, attracted by histamine and other substances, they produce histaminase, helping to terminate the reaction.

History and examination

Anaphylaxis may present with a spectrum of clinical signs including hypotension, tachycardia, dysrhythmias, dyspnoea, laryngeal oedema, bronchospasm, angio-oedema, flushing, urticaria, conjunctivitis, rhinitis, abdominal pain and diarrhoea. It can therefore mimic a variety of other conditions. Diagnosis is further complicated by a variable time for exposure until symptoms develop, varying from a few seconds to several hours. 5% of patients show a biphasic response with symptoms recurring from 1–72 hours after the initial attack. Many patients do not develop all the classic signs (Figure 1).

Differential diagnoses are vasovagal faint with hypotension, bradycardia and pale, sweaty skin and panic attack with hyperventilation, tachycardia and an erythematous rash.

Percentage of patients presenting with classic signs of anaphylaxis

Signs	Patients (%)
• Cardiovascular collapse	88
• Erythema	45
• Bronchospasm	36
• Angio-oedema	24
• Rash	13
• Urticaria	8.5

1

Management

The management of anaphylaxis is summarized in Figure 2.

Management of anaphylaxis

Condition
IgE mediated immediate hypersensitivity reaction to an antigen resulting in histamine and serotonin release from mast cells and basophils

Presentation
- Cardiovascular collapse
- Erythema
- Bronchospasm
- Oedema
- Rash

Immediate action
- Remove trigger
- 100% oxygen
- Elevate legs
- Adrenaline (epinephrine) 500 μg i.m. or 50 μg increments i.v. titrated to effect
- 20 ml/kg i.v. fluid challenge

Follow-up action
- Chlorphenamine (chlorpheniramine), 10–20 mg i.v.
- Hydrocortisone, 100–300 mg i.v.
- Arterial blood gases

Investigations
- Plasma tryptase
- Urinary methylhistamine

Also consider
- Primary myocardial/cardiovascular problem
- Latex sensitivity
- Airway obstruction
- Asthma
- Tension pneumothorax
- Panic attack

2

Immediate management
- Check the airway, breathing and circulation. Stop the administration of or exposure to any potential triggers, particularly intravenous agents. Muscle relaxants, antibiotics and NSAIDs (and increasingly latex) are the most common triggers in an anaesthetic environment. Outside the operating theatre, foods (especially nuts, fish, shellfish, eggs and milk), insect venom, drugs (antibiotics, NSAIDs, contrast media, opioids) and latex are the most common precipitants.
- Call for help.
- Maintain the airway and give 100% oxygen. Reassess airway patency frequently and regularly, especially in known asthmatics and in those exposed to the allergen via the airway or mouth. If in doubt and the reaction is severe, intubate early because it may be impossible to do so later in the presence of increased oedema.
- Cardiovascular collapse is most likely following parenteral exposure to the allergen. Lay the patient flat with the legs elevated to increase central venous return.
- If the patient has a continuous ECG monitor attached, give adrenaline (epinephrine) in 50 μg i.v. increments (0.5 ml of a 1:10,000 solution) at a rate of 100 μg/minute until the blood pressure or bronchospasm improves. Alternatively, give adrenaline (epinephrine) 0.5–1 mg i.m. as 0.5–1.0 ml of a 1:1000 solution (repeated after 10 minutes if necessary). Adrenaline (epinephrine) stabilizes mast cell membranes, increases myocardial contractility, causes bronchodilatation and reverses vasodilatation; it therefore treats both cause and effect.
- Give intravenous fluid (colloid or suitable crystalloid), 20 ml/kg.
- Latex allergy may take up to 30 minutes to manifest itself. Removal of all latex triggers can then be a complex process. Allergen is more readily absorbed across mucous membranes (e.g. from surgical gloves or a urinary catheter, which should be removed immediately and hands should be re-washed to remove latex-impregnated starch granules). Inhalation of aerosolized particles within the breathing circuit is minimized by the use of an airway filter. Ensure that rubber 'corings' are not introduced intravenously (e.g. ampoule bungs and injection sets). Laryngeal mask airways are made of silicone and do not contain latex. *Diprivan* syringe bungs are also latex free.

Subsequent management
- Give an antihistamine (H_1-blocker) such as chlorphenamine (chlorpheniramine, *Piriton*), 10–20 mg by slow i.v. or i.m. injection. Consider H_2-antagonists, such as ranitidine, 50 mg slow i.v. injection.
- Give corticosteroids such as hydrocortisone, 100–300 mg by slow i.v. or i.m. injection, to inhibit later relapses.
- Give a catecholamine infusion because cardiovascular instability may last for several hours. Consider adrenaline (epinephrine) 0.05–0.1 μg/kg/minute (e.g. 4 ml/hour of 1:10,000 for a 70 kg adult) or noradrenaline (norepinephrine) 0.05–0.1 μg/kg/minute (e.g. 4 ml/hour of a solution of 4 mg made up to 40 ml in 5% dextrose for a 70 kg adult).
- Check arterial blood gases for acidosis and consider giving bicarbonate, 0.5–1.0 mmol/kg (8.4% solution = 1 mmol/ml).
- Check for the presence of airway oedema by letting down the tracheal cuff and confirming a leak before extubation.
- Consider bronchodilators for persistent bronchospasm (e.g. salbutamol, 5 mg by nebulizer or 250 μg slow i.v. injection, aminophylline 250–500 mg slow i.v. injection).

Complications

Hospital mortality to anaesthetic drug-induced anaphylaxis is 4%, despite the presence of good resuscitation facilities. Over half of those who die of anaphylaxis do so within the first hour. The deaths are related to asphyxia, from severe bronchospasm or upper airway obstruction, and from refractory hypotension.

The early use of adrenaline (epinephrine) is advisable but advice differs over the safest and most appropriate mode of administration. Adrenaline (epinephrine) is best administered by intramuscular injection (0.5 mg – usually 0.5 ml of 1:1000 solution) by first responders because it is a reliable means of achieving therapeutic plasma concentrations quickly and safely. The subcutaneous route is slow and unpredictable and is inappropriate during an acute life-threatening reaction. Anaesthetists often opt for intravenous administration of a 1:10,000 solution in incremental doses (of 50–100 μg). The intravenous route, while rapidly effective, can result in tachydysrhythmias. Cardiac complications are more common in the presence of hypoxia, hypercapnoea, and in patients taking tricyclic antidepressants or cocaine.

Patients taking β-blockers are likely to suffer more severe reactions and may be resistant to treatment with adrenaline (epinephrine). However, β-blockers are competitive antagonists and careful but continued titration of adrenaline (by sequential doubling of the initial dose in severe cases) should achieve a clinical effect.

Late diagnosis may be complicated by severe compromise of the airway and difficulty intubating the trachea.

Investigations

Investigations should be carried out when the patient has been stabilized.

Plasma tryptase: at least one 10 ml clotted blood sample should be taken 1–6 hours after the start of the reaction to perform a tryptase assay. The specimen must be spun down as soon as possible and the serum stored at –20°C, to stabilize the protein for later analysis. Tryptase is the main protein released during mast cell degranulation and is a specific marker of histamine release due to anaphylaxis or anaphylactoid reaction. Normal basal levels of serum tryptase are less than 1 ng/ml. However, unlike histamine, which is rapidly eliminated, tryptase levels remain elevated for up to 6 hours after an anaphylactic reaction. It is not a protein that is produced by RBCs or WBCs and is therefore not raised by haemolysis. Levels over 20 ng/ml may accompany an anaphylactic reaction.

Elevated metabolites in the form of urinary methylhistamine may also be measured. The value measured has to be corrected for urinary creatinine but levels in excess of 15–20 ng/ml/mmol creatinine/litre are considered higher than normal, and may indicate anaphylaxis.

Radio allergosorbent testing (RAST) is a means of searching for antigen-specific IgE in the serum. Tests are limited to specific allergens. At present only a few anaesthetic RASTs are available (e.g. suxamethonium). Fluoroimmunoassay is an alternative (*CAP System*, Pharmacia).

Follow-up and prognosis

The anaesthetist should follow up the investigation, report reactions to the Committee on Safety of Medicines via the 'yellow card' reporting scheme, and arrange skin prick testing in consultation with an immunologist. Having identified allergens, the patient should be advised to wear an alert bracelet at all times. Those who have suffered a severe reaction, especially anaphylaxis to allergens that are commonly encountered in everyday life, may be advised on how to carry and when to administer their own adrenaline (epinephrine). The *Epipen* syringe is preloaded with adrenaline (epinephrine) and will deliver a fixed intramuscular injection of 300 µg (0.3 ml of 1:1000) for adults or 150 µg for children.

Desensitization is a process that attempts to stimulate the production of IgG or IgA antibodies that competitively bind to the antigen and help block the IgE antibody–antigen hypersensitivity reaction that precipitates anaphylaxis. It is not without risk because it involves repeated inoculation with small doses of antigen.

Recognition of Correct Placement of Tracheal Tubes

Simon Berg

Simon Berg s Consultant Paediatric Anaesthetist at the Oxford Radcliffe Hospitals NHS Trust, Oxford, UK. His special interests are anaesthesia for neonatal surgery and paediatric strabismus surgery.

The technique of tracheal intubation is fundamental to anaesthetic practice. Critical incident reporting indicates that oesophageal intubation is a relatively common problem. Misplacement of a tracheal tube is not in itself harmful if the diagnosis is made promptly and corrective action taken. However, tracheal tube misplacement still accounts for a large proportion of anaesthetic deaths. It should be considered in any hypoxic intubated patient. Failure to detect incorrect tube placement is equally common for trainees and consultants. It is as likely with routine as with difficult intubation.

Methods of confirming correct tube placement

Clinical signs are often unhelpful in detecting tube misplacement and intubation should be confirmed by:

- direct visualization of the tube passing through the vocal cords
- auscultation over both axillae, lung bases and the epi-gastrium
- capnography
- oesophageal detector device or colorimetric detector if capnography is not readily available.

Visualization of larynx

The larynx is usually visualized and the tracheal tube is observed passing between the vocal cords into the trachea. However, a view of the larynx is not always possible. In routine laryngoscopy, an anaesthetist may become distracted at the moment of intubation, allowing the tube to slide past into the oesophagus. Occasionally the oesophagus may be mistakenly identified as the trachea or the tube may become displaced during fixation. Direct visualization is thus not totally reliable and may even delay a diagnosis of tube misplacement by promoting a false sense of security.

Repeat laryngoscopy is essential if a tube problem is suspected; oesophageal intubation, extubation or a kinked tube can all be identified and remedial action taken.

Chest movement

Bilateral symmetrical chest wall expansion should occur coincident with inspiration. It may be difficult to discern in the obese patient, in those with a rigid chest wall, or in chronic lung disease (e.g. emphysema). Oesophageal ventilation may imitate chest movement by expansion of the mediastinum, while gastric distension can simulate diaphragmatic and lower chest wall ventilation, especially in infants.

Auscultation

The combination of auscultation over each axilla, lung base and epigastrium achieves the most reliable results. Direct auscultation over the trachea may be of additional benefit; more obvious breath sounds can be heard, which are less likely to be confused with oesophageal ventilation.

Breath sounds over the chest wall do not always exclude oesophageal intubation. Air ventilating the oesophagus can be transmitted through the lungs to resemble convincing breath sounds. Conversely, breath sounds may be inaudible in the obese patient.

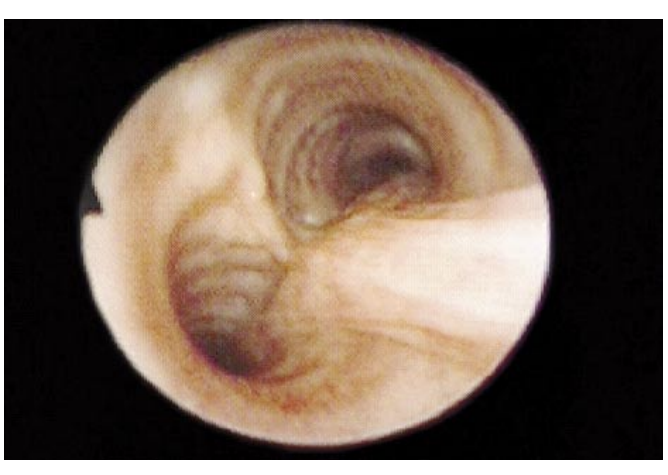
Breathing circuit

The ability to ventilate the lungs via the reservoir bag together with its typical compliance characteristics is a useful sign for the anaesthetist. In a spontaneously breathing patient the bag should empty and refill synchronously with the patient's breathing pattern. However, small movements (cardiac oscillations) can be demonstrated with oesophageal tube placement.

In contrast, it may be difficult to ventilate a morbidly obese patient via the reservoir bag or to differentiate between oesophageal intubation and partial or complete bronchospasm.

Fibre-optic laryngoscopy

The fibre-optic bronchoscope or laryngoscope can reliably confirm tracheal tube placement by identification of the tracheal rings and carina under direct vision (Figure 1). The technique requires operator experience and the equipment must be readily available.



1 View of the carina via a fibrescope, confirming the correct placement of the tracheal tube.

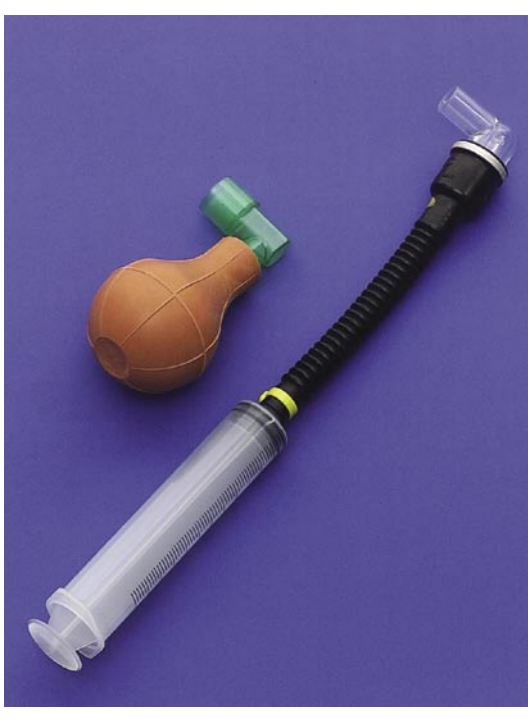
Oesophageal detector device

The Wee oesophageal detector device (ODD) consists of a 60 ml bladder syringe connected to a catheter mount. This is attached to the tracheal tube following intubation. The syringe freely aspirates gas from the patient's lungs if the tube is in the trachea (negative result). However, if this negative pressure is applied to a tube within the oesophagus, the oesophageal wall collapses and no air can be aspirated (positive result).

As a modification, the syringe has been replaced by a large rubber bulb (Ellick's evacuator) to enable the device to be used one-handed (Figure 2). In this case the bulb is first emptied and then failure to refill indicates oesophageal intubation.

The ODD is cheap, simple to construct, easy to use and reliable. It has been validated in several studies with only a small incidence of false-positive results, possibly related to endobronchial intubation or secretions blocking the lumen of the tracheal tube; there are no reported false-negative results.

It has been used successfully with uncuffed tubes in older children but is unreliable in those under 2 years of age.



2 Oesophageal detector device with Ellick's evacuator modification.

Capnography

Capnography is the real-time detection of carbon dioxide in the breathing gases and its display as a waveform that plots concentration versus time. Carbon dioxide is detected by infrared spectroscopy. It is the gold standard for verifying tracheal intubation. The guidelines of the Association of Anaesthetists state that during induction of anaesthesia, capnography is 'essential to the safe conduct of anaesthesia'.

For carbon dioxide to be detected, it must be produced in the tissues, then transported to the lungs, and finally exhaled in the expiratory gas. The capnograph is therefore an important monitor that gives information about:

- metabolic rate
- pulmonary perfusion
- alveolar ventilation.

If metabolic rate and pulmonary perfusion (or cardiac output) are constant, then changes in the capnograph trace reflect the adequacy of alveolar ventilation.

Deceptively low values may result from a large leak around the tube. Gas arising from the stomach and oesophagus usually contains only a trace of carbon dioxide, but false-positive results occur if expired alveolar gas is introduced into the stomach from mask ventilation. Significant concentrations of carbon dioxide have been reported following ingestion of carbonated drinks ('cola complication'). In these circumstances, capnography following oesophageal intubation initially resembles the normal waveform for end-tidal carbon dioxide. This initial value rapidly diminishes towards zero as the carbon dioxide is washed out. It has been suggested that the waveform should be observed for a minimum of six breaths.

Colorimetric carbon dioxide detector

This small disposable device contains a pH-sensitive indicator that displays a colour change (e.g. from purple to yellow) when exposed to carbon dioxide (Figure 3). The colour change is rapid and the detector can be left in the breathing circuit for several hours allowing continuous ventilatory monitoring. The device is about the same size and weight as a heat/moisture exchange filter and requires no power source for operation. This portability makes it useful during cardiopulmonary resuscitation or in emergency situations when capnography may not be available. Reduced carbon dioxide concentrations often present in these clinical situations, which may reduce its sensitivity.

3 Colorimetric carbon dioxide detector.

Complications of oesophageal and endobronchial tube placement

Oesophageal intubation

Undetected oesophageal intubation is a major anaesthetic cause of permanent neurological damage and death. There should be a high index of suspicion in any situation in which hypoxia develops following intubation; the onset may be delayed if preoxygenation has occurred. Difficulty in ventilation, poor or absent chest movement, inaudible breath sounds and increasing abdominal distension should all alert the anaesthetist to the possibility of tube misplacement. In practice, clinical signs are not always obvious.

Progressive gastric distension may cause regurgitation and subsequent aspiration. Splinting of the diaphragm impairs ventilation even after the patient has been correctly intubated unless the stomach is actively decompressed using a nasogastric or orogastric tube.

If there is any doubt as to correct tube placement, it is essential to remove the tube and recommence mask ventilation.

Endobronchial intubation

Endobronchial intubation is more common in children owing to the smaller length of the trachea. Flexion or extension of the neck can move the tube a significant amount within the trachea (up to 5 cm in adults), leading to endobronchial intubation or inadvertent extubation. The right main bronchus is more commonly intubated than the left side because it arises at a straighter angle from the trachea.

One-lung ventilation causes hypoxaemia due to the shunt effect that failure to ventilate the opposite lung produces. Progressive lung collapse of this unventilated side occurs. There is a reduced uptake of volatile anaesthetic agent and bronchospasm is a common occurrence, probably as a result of vagal stimulation from irritation of the carina.

The diagnosis may be obvious with asymmetric chest movement and absent breath sounds on one side of the chest, but clinical signs are often unreliable. With an uncuffed tube, breath sounds can easily be transmitted to the non-ventilated lung. A chest radiograph confirms the diagnosis and provides an estimate of the distance that the tube needs to be withdrawn. Fibre-optic bronchoscopy can also be useful.

The chances of endobronchial intubation can be lessened by cutting tracheal tubes to an appropriate size (e.g. 22–24 cm in the adult) preceding intubation. The black marker line present at the distal end of some tracheal tubes can also serve as a guide to the length of the tube to be passed through the vocal cords.

Regurgitation, Vomiting and Aspiration

Polly Davies
Jonathan Warwick

Polly Davies is Specialist Registrar in Anaesthesia rotating within the Oxford Region. She graduated from Bristol University and is currently based at Northampton General Hospital, UK.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

Regurgitation is the passive movement of gastric contents into the pharynx. The lower oesophageal sphincter normally prevents regurgitation. The sphincter is a physiological, rather than a distinct anatomical structure. Reflux is prevented because the lower oesophageal pressure is greater than the gastric pressure. This is referred to as the barrier pressure.

Vomiting is an active reflex usually occurring in the lighter planes of anaesthesia (i.e. induction and emergence). It is the forceful ejection of the contents of the upper gastrointestinal tract through the mouth. It is often secondary to stimulation from inappropriate airway manipulation.

The afferent limb of the reflex arc is composed of fibres from the gastrointestinal tract, the vestibular system, or from the chemoreceptor trigger zone in the brain stem. The vomiting centre' in the brain stem coordinates the reflex. The efferent limb involves autonomic outflow to the gastro-intestinal tract and also produces widespread effects such as pupillary dilation, sweating, salivation, vasoconstriction and tachycardia.

Pulmonary aspiration of gastric contents into the lungs is a serious, though infrequent, complication of modern anaesthesia. Mendleson first described it in detail in 1946 in 66 obstetric patients. Aspiration occurs following gastro-oesophageal regurgitation or vomiting when protective laryngeal reflexes are depressed or absent. Prevention of pulmonary aspiration is by measures aimed at reducing the incidence of regurgitation and vomiting.

Although silent regurgitation is thought to occur in up to 25% of patients under anaesthesia, the incidence of significant pulmonary aspiration in the general surgical population is much less at 1–6/10,000. For obstetric general anaesthesia the incidence is doubled. The mortality following aspiration is about 5%.

Pathophysiology

The adverse effects of pulmonary aspiration occur by three mechanisms.

Particle related – this could result in acute airway obstruction.

Acid related – the traditional view is that patients are 'at risk' if the gastric contents consist of a critical volume of more than 25 ml and have a pH of less than 2.5; there is little clinical evidence to support this. pH is the more critical factor for lung injury sustained following aspiration though there may not be an exact cut-off value. Significant morbidity can occur following inhalation of material with a very low pH even in small volumes due to chemical pneumonitis, and following large volumes of neutral fluid due to a 'near drowning' effect.

Bacterial related – aspirated fluid is not sterile and lung infection may result. Damaged lung is also more prone to secondary infection.

Risk factors

Predisposing factors for pulmonary aspiration are shown in Figure 1. Vomiting and regurgitation during induction of anaesthesia occur most often in emergency cases with acute abdominal pathology or following trauma. Pain, fear, anxiety and opioid administration all delay gastric emptying. These patients should be regarded as at high risk and appropriate precautions taken. The interval between last oral intake and time of injury in trauma patients is said to give a better guide to gastric emptying than the duration of fasting. In practice this is unreliable and it is often best to assume patients have a full stomach.

Risk factors for aspiration

Condition	Examples
Full stomach	Inadequate preoperative fasting Gastrointestinal obstruction, bleeding or ileus Trauma, burns, pain, anxiety Pregnancy Drugs (e.g. opioids)
Reduced lower oesophageal sphincter function	Hiatus hernia Drugs (e.g. opioids, atropine) Pregnancy Raised intra-abdominal pressure Obesity Lithotomy position
Material in oesophagus/ pharynx	Achalasia, scleroderma Strictures, carcinoma Pharyngeal pouch
Depressed laryngeal reflexes	Reduced consciousness (e.g. general anaesthesia, drug or alcohol intoxication, cerebrovascular accident, head injury, seizures or postictal state) Topical anaesthesia Neurological disease (e.g. myasthenia, multiple sclerosis, Parkinson's disease, Guillain–Barré syndrome) Muscular dystrophies
Others	Inexperienced anaesthetist Night-time surgery Emergency surgery Extremes of age

Obstetrics
In the third trimester, the enlarged uterus increases intra-abdominal pressure and therefore intra-gastric pressure. Before this, there is an increased risk of aspiration due to the production of:

- gastrin from the placenta, which increases gastric acid secretion
- progesterone, which relaxes smooth muscle and reduces gastrointestinal motility.

Anatomical changes in late pregnancy may increase the incidence of airway difficulties and thus of aspiration (e.g. increased body weight, large breasts, upper airway oedema). Surgery often occurs 'out of hours' as an emergency. Risks may be increased further during labour from the effects of pain, anxiety and opioid administration. Pregnant patients should be assumed to have a full stomach from the end of the first trimester until at least 18 hours post-partum. Regional anaesthesia should be used whenever possible to reduce the aspiration risks.

Prevention

Methods to prevent pulmonary aspiration are directed towards reducing the volume and increasing the pH of the stomach contents. The technique of cricoid pressure and induction of anaesthesia in the patient with a full stomach is elsewhere.

Fasting requirements
Traditionally, patients were fasted overnight before elective surgery. More recently it has been shown that the administration of clear fluids (e.g. water, non-particulate juice) up to 2–3 hours preoperatively does not increase residual gastric volume or alter pH. This increases patient comfort and reduces dehydration and hypoglycaemia in infants. An example of current fasting guidelines for elective, nonobstetric patients is shown in Figure 2.

Fasting requirements are less straightforward for emergency surgery. It is often necessary to provide anaesthesia to patients suspected of having a full stomach. Delaying urgent surgery to reduce the possibility of aspiration is usually of no benefit and may be detrimental. Patients requiring emergency surgery should be assumed to have a full stomach, irrespective of the duration of fasting, because gastric emptying is likely to be delayed. Following painful trauma, a significant gastric residue can be present after 24 hours. It is not currently recommended that emergency patients be allowed to drink clear fluids before surgery. Intravenous therapy should be used to prevent dehydration. At present there is no consensus regarding fasting during labour.

Preoperative fasting guidelines for patients undergoing elective surgery

	Length of fast (hours)
Adults	
• Solid food	6
• Clear fluid	2–3
Children	
• Solid food	6
• Formula milk	4
• Breast milk	3
• Clear fluid	2

Regional anaesthesia
Avoiding general anaesthesia reduces the risk of pulmonary aspiration. Both the proposed surgery and the patient must be amenable to the technique. The patient should be fasted because an inadequate or failed regional block, or adverse reaction, may make general anaesthesia necessary.

Gastric decompression
The insertion of a nasogastric tube to decompress the stomach may be useful. Liquid, but not solid, gastric contents can be aspirated via the tube. It is not usually possible to empty the stomach completely by this means, so the possibility of aspiration remains. If a nasogastric tube has been passed before surgery, it should be aspirated before induction. Effective cricoid pressure can be performed with the tube *in situ*.

Pharmacotherapy
Antacids: prophylactic administration of antacids to high-risk patients is recommended. These drugs neutralize gastric acid and raise gastric luminal pH. Neutral pH aspirate causes less lung damage than fluid of acidic pH. Antacids should be non-particulate to reduce the potential for lung damage if inhaled. 0.3 M sodium citrate, 30 ml, is effective in elevating the pH of gastric contents if given 15–20 minutes preoperatively; it remains effective for 1–3 hours. Antacids are used routinely in elective and emergency obstetric anaesthesia, but less often in the general surgical population.

H_2-receptor antagonists reduce the volume and acidity of gastric contents by the inhibition of hydrochloric acid secretion from gastric parietal cells. Cimetidine, 400 mg orally 90–120 minutes before induction, and ranitidine, 150 mg orally 120 minutes before induction, 50 mg intramuscularly or slow intravenous administration 45 minutes before induction, are commonly used H_2-antagonists. Ranitidine has a duration of action of at least 8 hours; about twice as long as cimetidine. It is also associated with fewer side-effects. Side-effects with cimetidine, though infrequent, include sedation and confusion, and the potentiation of other drugs through inhibition of hepatic enzymes. Hypotension, bradycardia and even cardiac arrest can follow rapid intravenous injection of cimetidine, and also of ranitidine, though ranitidine has a much lower incidence.

Prokinetics: metoclopramide, 10 mg orally 1–4 hours before surgery or intravenously shortly before induction, acts centrally and peripherally to stimulate gastric emptying, increases lower oesophageal sphincter pressure and is anti-emetic. Its central action is due to its antidopaminergic properties whereas peripherally it stimulates acetylcholine release, resulting in increased gastrointestinal motility.

Proton pump inhibitors: omeprazole, 40 mg orally at night and on the morning of surgery, inhibits the proton pump in the parietal cells of the gastric mucosa, resulting in prolonged suppression of acid secretion. It elevates gastric pH. Combining omeprazole with metoclopramide reduces gastric volume. It is seldom used in the UK despite proven effectiveness.

Anticholinergics (e.g. atropine, glycopyrollate) can decrease gastric acid secretion, but have an adverse effect on barrier pressure by decreasing lower oesophageal pressure. They are not used for aspiration prophylaxis.

Induction of anaesthesia
If general anaesthesia is chosen, a cuffed tube in the trachea should secure the patient's airway. The airway should be assessed to predict whether this is likely to be difficult. The laryngeal mask airway has become popular in modern anaesthetic practice, however, it does not protect the airway from aspiration of gastric contents as efficiently as a cuffed tube and should not be used routinely in patients at high risk.

Uncuffed tubes are used in children because the paediatric airway narrows at the cricoid ring. Uncuffed tubes prevent tracheal mucosal damage by excessive cuff pressure, and may allow passage of a slightly larger tube size permitting improved gas flow. There is no precise age or size at which cuffed tubes are chosen, but use of uncuffed tubes in children below 8–10 years is usual. The absence of a cuff may imply the theoretical risk that aspiration can still occur, although satisfactory airway protection still occurs in clinical practice.

Position:there is controversy regarding the optimum position for induction of anaesthesia in the patient at risk of pulmonary aspiration. Some anaesthetists argue in favour of a head-up (reverse Trendelenburg) or semi-sitting position, because this may reduce the incidence of reflux in patients prone to passive regurgitation. Others favour a head-down (Trendelenburg) position with the patient on their side, because this may decrease the likelihood of aspiration should regurgitation occur.

Patient safety is paramount and therefore clinicians should induce anaesthesia in the position in which they have the most experience and confidence. This will usually be a rapid sequence induction in the supine position.

Rapid sequence induction: if the anaesthetist is confident that tracheal intubation will be straightforward then an intravenous rapid sequence induction performed with cricoid pressure is indicated. Aspiration is most likely to occur in the time from loss of consciousness to intubation with a cuffed tracheal tube. Rapid sequence induction reduces this time to a minimum.

Awake intubation: if a difficult intubation is anticipated consideration should be given to securing the airway before induction. In modern practice this involves topical local anaesthesia to the airway, and intubation via a flexible fibre-optic laryngoscope. A 'blind nasal' technique used to be popular, but the arrival of modern fibre-optic instruments has allowed awake intubation to be performed under direct vision.

Inhalational (gaseous) induction may be indicated in a patient considered at risk from aspiration, in whom conventional laryngoscopy and intubation is predicted to be difficult and where awake intubation attempts may be hazardous (e.g. acute stridor, maxillofacial trauma). There is a trade-off between taking steps to prevent aspiration during induction, and maintaining and securing the airway. A senior anaesthetist should manage these cases and patient safety is paramount.

Extubation should be performed with the patient awake and following the return of upper airway protective reflexes. It is often safest to position the patient on their side with head-down tilt to facilitate clearance of the upper airway using suction, should regurgitation occur.

Diagnosis

Clinical signs and symptoms of aspiration are variable (Figure 3) and it is sometimes difficult to make a definitive diagnosis. 'Silent' aspiration may occur, and may not be diagnosed until after surgery when the patient has returned to the ward. The initial and most reliable sign of aspiration is hypoxia, which occurs following even mild cases. Wheezing is also common. In severe cases an acute respiratory distress syndrome can result. In such patients there is increased intrapulmonary shunting, ventilation–perfusion (V/Q) mismatch, increased lung water, increased airway resistance and reduced lung compliance. Although aspiration classically affects the posterior aspect of the right lower lobe, radiographic changes are variable, nonspecific and may be absent, particularly in the first few hours. The most usual findings are irregular fluffy den-sities, frequently bilaterally, collapse or pulmonary oedema (Figure 4).

Differential diagnoses include anaphylaxis, cardiac failure, pulmonary embolism, fat embolism, sepsis and, in obstetric patients, amniotic fluid embolism.

Signs and symptoms of pulmonary aspiration

Symptoms
- Cough
- Breathlessness

Signs
- Stomach contents in oropharynx
- Tachypnoea
- Wheeze, crackles (mainly coarse)
- Cyanosis
- Tachycardia
- Pulmonary oedema
- Increased airway pressure
- Radiographic changes

3

4 Typical radiographic appearance of the chest in a patient with aspiration.

Management

If acute aspiration occurs the following procedure should be carried out.
- Place the patient in a head-down position, with head turned to one side.
- Suction material from the oropharynx.
- Administer 100% oxygen.
- Intubate the trachea if:

– adequate oxygenation cannot be maintained with spontaneous ventilation
– further tracheobronchial suction is required
– the patient is unable to protect their own airway.

The decision to continue with surgery depends on the severity of the aspiration and the urgency of surgery.

The management of established aspiration is largely supportive. Treatment is described in Figure 5.

Management of established aspiration

Oxygen therapy
- Guided by blood gas estimations or pulse oximetry

Ventilatory support
- Spontaneous ventilation may be adequate in mild cases
- Continuous positive airway pressure can be used for more severe cases, but requires alert, cooperative patient at no further risk of aspiration
- For severe cases, or those who cannot maintain a patent airway, mechanical ventilation via a tracheal tube is indicated
- Positive end-expiratory pressure is applied to increase functional residual capacity of the lung and minimize intrapulmonary shunting

Removal of aspirate
- Regular suctioning and physiotherapy are needed
- Bronchoscopy is required in more severe cases

Bronchodilators
- Given regularly by nebulizer

Antibiotics
- No proven benefit from prophylactic use
- Antibiotics often prescribed before identification of any pathogens

Fluid balance
- Shifts of fluid from the circulation to the lungs can result in pulmonary oedema
- Central venous pressure and urine output monitoring help guide fluid management
- A positive fluid balance worsens gas exchange and should be avoided

Corticosteroid therapy
- Routine use of corticosteroids is not indicated – no current evidence has shown benefit from their use

Surgical Diathermy: Mechanisms, Use and Abuse

Andrew D Farmery

Andrew D Farmery is Consultant Anaesthetist at the John Radcliffe Hospital, Oxford, UK. He trained in London, Cambridge and Oxford. His interests are in bio-mathematical modelling and clinical medical education.

The application of heat to wounds is evident in unearthed Neolithic skulls. Thermal cautery to ulcers and tumours of the breast was described in a papyrus from about 3000 BC, and later described by Hippocrates in 300 BC. Electrical diathermy is at least 250 years old, predating the practice of anaesthesia by a century.

Diathermy (*dia*, through; *thermy*, heat) strictly applies to the uniform heating of tissues by radiofrequency current or radiation. As a surgical tool, uniform heating is not required, but rather discrete and destructive heating in a specific area. This application is called 'electrosurgery' in the USA, and 'surgical diathermy' in the UK, but the term diathermy has remained.

Basic electrical principles

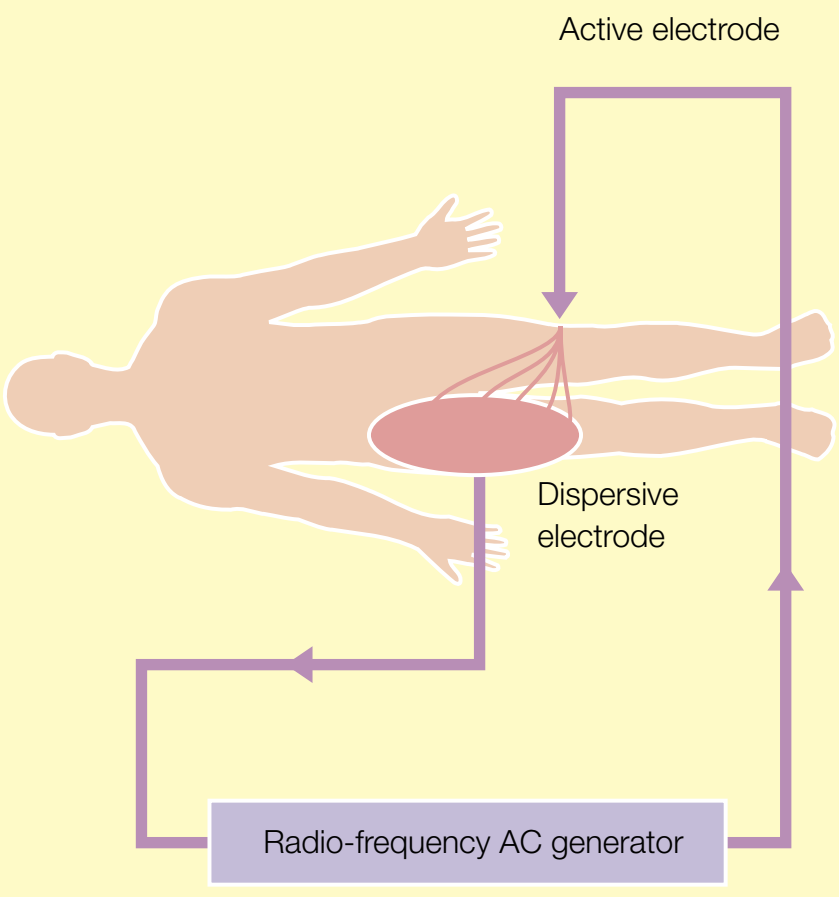
Forcing current through a resistance liberates heat

The power to heat, cut or vaporize tissues is derived from passing an electrical current through it. At any point in an electric circuit, the power dissipated is given by the formula:

$$\text{Power} = \text{Current}^2 \times \text{Resistance} \qquad (P = I^2 \times R) \quad 1$$

Current forced through regions of high resistance produces more heat than the same current passed through regions of low resistance. Figure 1 shows how the current density (and resistance) at the tip of a diathermy probe is many orders of magnitude higher than the current density elsewhere in the circuit, namely the patient's body and the large 'dispersive' electrode. This is analogous to a large crowd of people moving along a wide walkway to gain access to a football stadium. The flow is ordered and comfortable at the rear of the walkway, but when the same 'flow' is forced through a narrow turnstile, the 'power' of the crowd will be liberated (destructively) at this high resistance, high flow-density point.

Current density



The tiny active electrode/tissue contact has a high resistance, therefore a high power is liberated ($P = I^2 \times R$). Because this power is delivered to a small area, the power density, and ability to heat the tissue, is great. By contrast, the dispersive electrode, with its larger area of contact, has a low resistance and thus little power is liberated and it is distributed over a wide area, therefore the heating effect is negligible.

1

Using high-frequency alternating current prevents 'electrocution'

In Equation 1, both direct current (DC; e.g from a large battery) or alternating current (AC; e.g. from the mains supply) produce the same amount of heat for the same mean current. However, DC polarizes a tissue such that tissue connected to the anode becomes 'positive', and that connected to the cathode, 'negative'. This triggers ion channel opening and depolarizes important excitable tissues such as nerves, striated muscle and myocardium. The same is true of moderately low-frequency AC (e.g. 50 Hz), in which the tissue is alternately polarized and depolarized because the polarity of the applied voltage changes sinusoidally. This can result in convulsions, tetanic muscle twitch and ventricular fibrillation (i.e. electrocution).

High-frequency current is less prone to causing these phenomena because voltage-sensitive ion channels in excitable tissues do not respond instantly to an applied depolarizing voltage, but have a finite response time. An analogy is when the rudder of a tanker is turned suddenly, there is a delay before it slowly starts to change direction. If the rudder is turned from left to right with a low frequency, the tanker steers a course veering from left to right sinusoidally. However, if the rudder is oscillated from left to right with a high frequency, the ship steers a straight course because it does not have enough time to respond to a rudder movement in one direction before being directed to move in the opposite direction.

In the same way, a high-frequency AC voltage applied to the myocardium will neither polarize nor depolarize the membrane, because the ion channels will not have time to open or close before the polarity of the applied voltage is reversed and so the tissue will continue to function normally. Electrosurgical generators typically operate at frequencies of 0.5–4 MHz.

Surgical effects of diathermy

There are three main diathermy modes: desiccation, cutting and coagulation.

Desiccation

To cause desiccation (drying out), a low power current is passed through the tissues, as in Figure 1. The aim is to increase tissue temperature at the site of contact with the active electrode. Intracellular water is slowly driven off as steam and the tissue is dried out. This produces a blanching of tissue. Because the current is of low power, it is effective only in delicate tissues and small vessels (e.g. it is often used to blanch the fallopian tube before surgical division in laparoscopic sterilization). When tissue has been desiccated, its resistance to current flow becomes very high and current flow effectively ceases, thus terminating the heating process. It is impossible to 'cut' tissue in this mode. The current waveform is not important in this application.

Cutting

In the cutting mode, the aim is to make a discrete cut through the tissue. Initial contact with the electrode heats the tissue rapidly so that cells explode and their contents are instantly vaporized. Heat is not conducted very far from the site of contact because most of the liberated power is used to vaporize water (i.e. is consumed as latent heat of vaporization). The heating effect is therefore concentrated and neighbouring tissue is undamaged. Unlike desiccation, 'sparking' is a key feature.

The vaporized desiccated tissue is a poor electrical conductor and therefore breaks the circuit so that current flow ceases through this pathway. However, if the voltage (the driving force for current) is high enough, air around the electrode is ionized. Ionized air is a better conductor than desiccated tissue, and so current will now flow as a spark jumps to the nearest region of moist tissue. Tissue heating is produced by:

- current delivered by the spark ($I^2 \times R$)
- radiant heat from the spark
- collision of electrons bombarding the tissue.

This causes intense local heating, vaporization and thermal destruction. Cells are torn apart. The current waveform used is a continuous radiofrequency sinewave (Figure 2a).

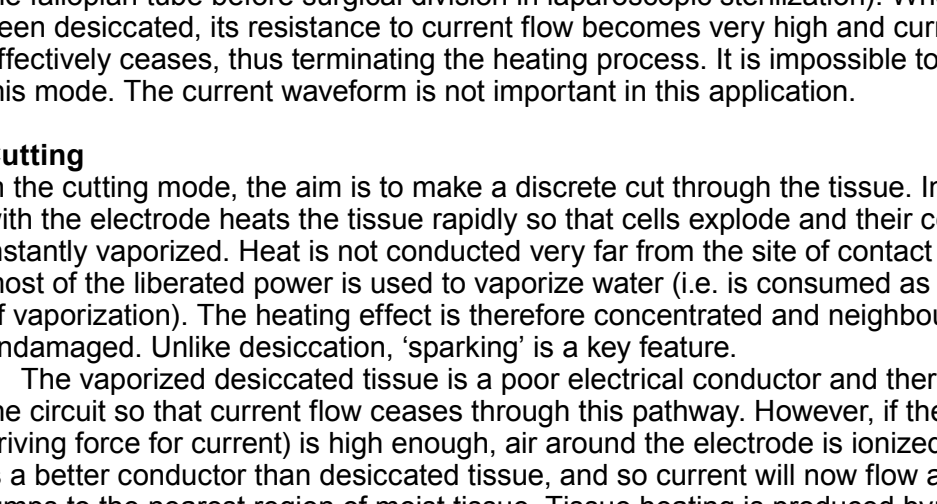
Coagulation

In coagulation mode (Figure 2b), the current waveform comprises short bursts of radiofrequency sinewaves (about 1 MHz), with bursts occurring about 20,000 times per second (burst frequency 20 kHz). The coagulation waveform can cause sparking to tissues. However, the radiofrequency current is delivered in intermittent bursts and therefore the ion cloud generated at each spark has a chance to disappear between bursts. Therefore, with each current burst, ionization occurs afresh, and because this is a random process sparking occurs more randomly and over a wider area than it does in cutting mode. This reduces the concentration of the sparking power and allows effective coagulation of vessels without tissue cutting. Peak voltages are much higher in the coagulation mode than in the cut mode because the current is zero for most of the time and so in order to deliver the same average power, the coagulation waveform generator has to deliver more power in the short periods when current is switched on.

Waveforms

a Cutting waveform

A continuous radiofrequency sinewave of about 1 MHz



b Coagulation waveform

A 1 MHz sinewave delivered in bursts (20,000/second)

2

Monopolar and bipolar systems

Monopolar

The system described in Figure 1 is monopolar. Current is delivered via a pinpoint active electrode, which then passes through the patient (in a low-density path) to return via the dispersive electrode. This is the most widely used system because it is most effective in producing cutting as well as coagulation.

Bipolar
In a bipolar system, current is delivered via one arm of a pair of insulated forceps. It passes through any tissue grasped between the arms of the forceps and returns via the opposite arm. With a bipolar system, only desiccation can be achieved. The system is of limited power, and sparking does not occur. If the arms of the forceps are allowed to make contact with each other directly, despite there being some tissue in the path, current will be 'shorted-out', and diathermy will be less effective. Bipolar diathermy is indicated where it is undesirable to pass current through the patient's body to a distant dispersive electrode; some examples are given below.

Narrow current conduits to extremities (e.g. testicle surgery) – if a monopolar system were used, with the dispersive electrode placed on the abdominal wall, current would be forced to pass from the testicle along the vas deferens (the path of least resistance) to the trunk. Because the vas deferens is a narrow tube, current density would be high within it, and thermal injury might result.

Metal prostheses – if a metal prosthesis lies between the dispersive and active electrode, current preferentially passes through this low resistance route, producing a high current density and heating in narrow points such as a cortical screw. This may necrose bone or conduct heat to neighbouring soft tissue or vessels, sufficient to perforate an artery.

Cardiac pacemakers – the cable connecting a pacemaker generator box (implanted in the anterior chest) to the electrode in the right ventricle and/or atrium constitutes a low impedance pathway for radiofrequency current if it lies between the active and dispersive diathermy electrodes. This may result in a high current density at the point of pacemaker electrode insertion into the myocardium. Tissue desiccation may occur at this point, increasing the resistance of the contact. The 'threshold' potential may increase, such that the pacing pulse fails to trigger the heart.

More sophisticated pacemakers are capable of detecting intrinsic cardiac activity and withholding activation of the pacemaker. It is possible that stray radiofrequency current may be detected by the pacemaker, and interpreted as intrinsic cardiac activity, resulting in inappropriate inactivation of the pacemaker. For this reason, it is advisable, if possible, to have the pacemaker programmed so that this function is disabled. The safest precaution, however, is to avoid monopolar diathermy.

Patient safety

The principal issues are:
- avoidance of inadvertent thermal burns from stray diathermy current
- avoidance of inadvertent electrocution from stray 50 Hz mains current.

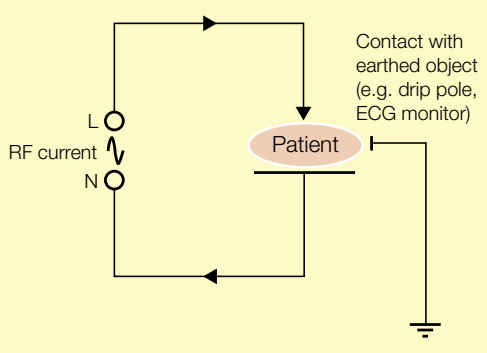
Isolated (unearthed) dispersive electrode system
Figure 3a shows a simple circuit in which neither live nor neutral terminals of the radiofrequency current generator are connected to earth.

A fundamental law of electricity is that all the current leaving the live terminal is returned to the neutral terminal. Therefore, if the patient makes contact with an earthed object (e.g. lithotomy pole, drip stand or faulty low impedance ECG electrode) none of the radiofrequency diathermy current should pass via this contact to earth because such a stray current would not be able to return to the neutral terminal. All the current should pass to the neutral terminal via the large dispersive electrode, thereby eliminating the potential for burns. This might seem a safe system but it is possible to burn patients inadvertently with isolated systems because of the phenomenon of 'capacitive coupling'. It is difficult to confine very high-frequency currents to wires, and currents tend to pass out of the cables like a radio transmitter because a wire and another conductor (e.g. earth) can behave like the two plates of a capacitor. Capacitors can conduct high-frequency current, even though insulation and a few feet of air separate the wire and earth. Radiofrequency leakage current flows only if there is a route for it to return to the neutral terminal; Figure 3b shows how this might happen. A certain amount of current from the active lead is leaked to earth via this capacitive coupling. This can return to the patient via any small, grounded contact point and potentially cause a burn at this site. From this point, the leakage current joins the main current and returns to the neutral terminal via the dispersive electrode.

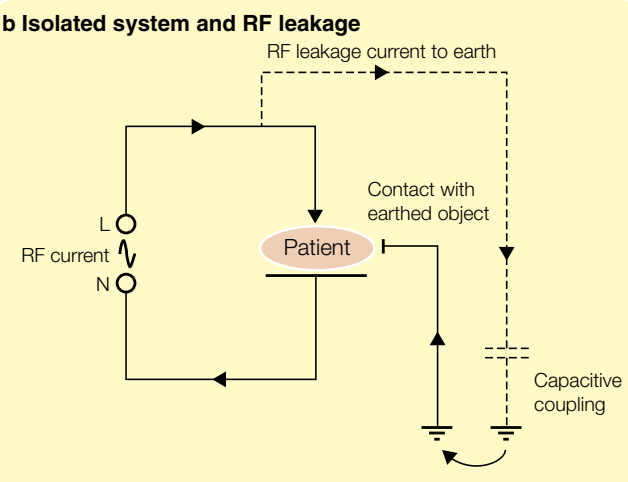
Early electrosurgical generators were not truly isolated. There was usually some connection of the neutral terminal and dispersive electrode cable to earth because of capacitive coupling between them, in a similar way to that described above. Figure 3c shows how this allows current to flow to earth through grounded contact points and complete the circuit to the neutral terminal via the 'virtual' earth connection. The amount of stray current passing through the grounded contact points depends on the relative impedance of the pathways. Given that one cannot avoid some current passing to ground, the best way to prevent this passing through unwanted pathways is to provide a route to ground via the dispersive electrode which is more 'attractive' than the alternative routes. This is done by physically earthing the dispersive plate and making the impedance of this connection as low as possible.

Isolated and earthed systems

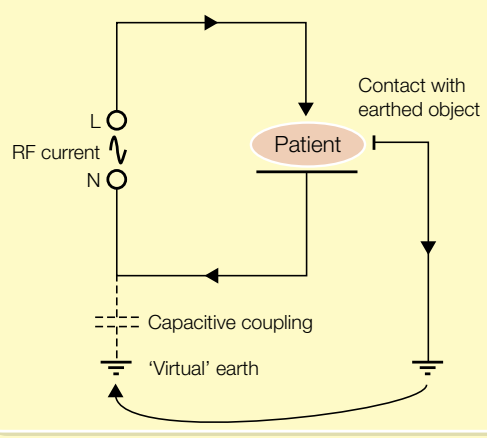
a Isolated system



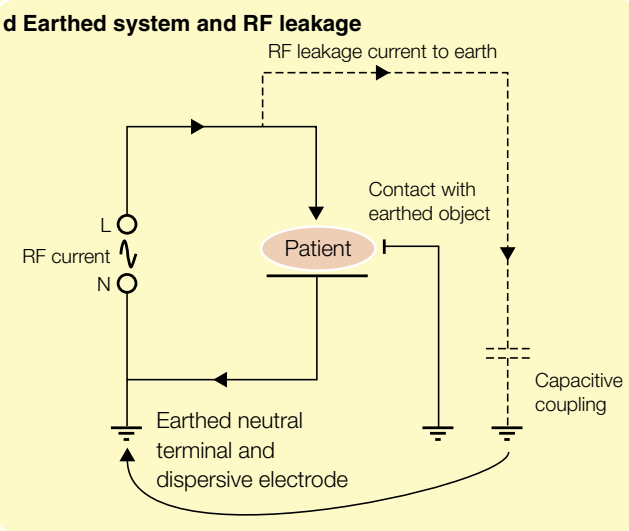
b Isolated system and RF leakage



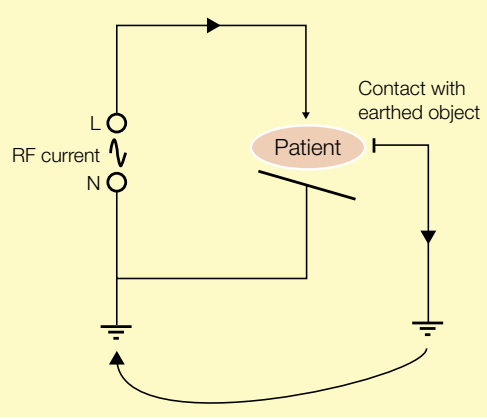
c Isolated system and 'virtual' earthing of dispersive electrode



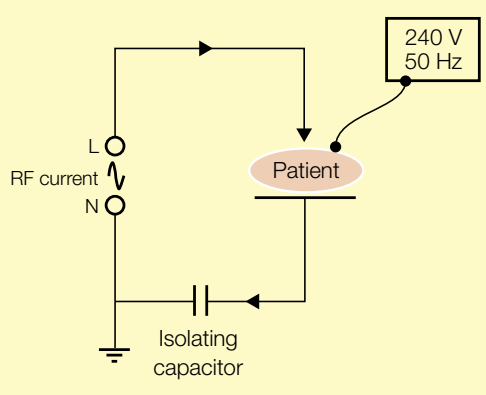
d Earthed system and RF leakage



e Earthed system and poor dispersive electrode contact



f Earthed system and isolating capacitor



L, live; N, neutral; RF, radiofrequency

Earthed dispersive electrode system
Earthing the dispersive electrode overcomes both the 'virtual' earth problem (Figure 3c) and the radiofrequency leakage problem (Figure 3b). Figure 3d shows how if the dispersive electrode and neutral terminal are earthed, any radiofrequency leakage current can return to the neutral terminal via a direct low impedance earth route that bypasses the patient. However, earthing poses other problems.

Dispersive electrode detachment: the dispersive electrode is an attractive route for ground-seeking radiofrequency current only if its impedance is many orders of magnitude lower than unwanted stray routes. If the dispersive electrode becomes detached or makes poor contact, all of the radiofrequency current can pass to earth (and hence return to the neutral terminal) via unwanted grounded contact point, as shown in Figure 3e, thus causing burns.

Mains electrocution: if the patient is exposed to a live mains voltage (e.g. via a faulty monitor lead) the earthed dispersive electrode provides a low impedance pathway for this dangerous 50 Hz current to pass through the patient to earth, thus causing electrocution. This is because mains voltage is ground seeking. This problem can be overcome by placing a capacitor in the circuit as in Figure 3f. This is capable of passing radio-frequency current, but does not conduct low frequency (50 Hz) current. Even though the patient is exposed to a live mains cable, no 50 Hz current will flow through the patient to the ground.

Techniques of Cricoid Pressure

Richard Vanner

Richard Vanner is Consultant Anaesthetist and Clinical Director in a large District General Hospital in the UK. He is a generalist with a specific interest in obstetric anaesthesia.

In 1956, the Association of Anaesthetists had collected 1000 reports of anaesthetic deaths; 110 from pulmonary aspiration of stomach contents. This often occurred during induction of general anaesthesia especially when muscle-relaxant drugs were used. Anaesthetic techniques were developed to prevent aspiration in patients at risk and included:

- emptying the stomach before induction
- intravenous induction with head-up tilt position
- inhalational induction in the lateral and head-down position.

In 1961, Sellick described cricoid pressure as a technique used to prevent regurgitation of stomach contents during the induction of general anaesthesia. It was brought into widespread practice in the UK by 1970 and largely replaced the other techniques, despite no randomized controlled trials demonstrating its benefit. It has become a routine part of anaesthetic practice for patients at risk of aspiration in combination with pre-oxygenation, an intravenous induction and tracheal intubation. All UK maternity units routinely apply cricoid pressure during induction of general anaesthesia.

Before the introduction of cricoid pressure, the incidence of aspiration pneumonitis in obstetric general anaesthetics was about 0.15%. If cricoid pressure prevents aspiration, the number needed to treat to prevent one case of aspiration would be 666. A controlled trial would be difficult because of the large numbers of patients needed and the difficulty of obtaining ethical approval.

Indications

In a patient who has been prepared for elective surgery and has not eaten for 6 hours or drunk for 2 hours, regurgitation of stomach contents during the induction of anaesthesia is unusual even when muscle-relaxant drugs are used, which relax the upper oesophageal sphincter. In these patients, cricoid pressure is unnecessary, because its benefits have to outweigh the risk of complications. However, cricoid pressure is indicated if:

- surgery is necessary before the patient is fasted
- gastric emptying is delayed
- the lower oesophageal sphincter is incompetent (e.g. in the last half of pregnancy or in reflux oesophagitis). With a full stomach from any cause, distention of the fundus causes reflex relaxation of the lower oesophageal sphincter.

Mechanism of action

Regurgitation is the flow of fluid from the oesophagus into the pharynx and is a passive process. When patients are awake the upper oesophageal sphincter prevents regurgitation. The pressure that this sphincter exerts is about 40 mm Hg and it relaxes during swallowing and during sudden distension of the oesophagus (e.g. belching, vomiting). The sphincter is mainly the cricopharyngeus muscle, a skeletal muscle, which is attached to the lateral aspects of the cricoid cartilage and is positioned behind it like a sling. The lumen of the hypopharynx within the cricopharyngeus is therefore crescent shaped. The oesophagus begins below the level of the cricoid cartilage.

The upper oesophageal sphincter relaxes during intravenous induction with thiopental (thiopentone), with heavy sedation, during deep sleep or following muscle-relaxant drugs. In all of these situations the sphincter pressure is reduced to less than 10 mm Hg, which is low enough to allow regurgitation. Following thiopental (thiopentone) the sphincter starts to relax just before loss of consciousness but is not fully relaxed until 30 seconds later. Ketamine does not relax the upper oesophageal sphincter, nor does an inhalational induction. Coughing during an inhalational induction increases upper oesophageal sphincter pressure to over 100 mm Hg.

Cricoid pressure prevents regurgitation by replacing the function of the upper oesophageal sphincter by compressing the hypopharynx against the prevertebral fascia muscles and vertebrae behind. The convex cricoid is pressed against the convex body of either the 5th or 6th cervical vertebrae. Inevitably the cricoid cartilage is deviated slightly laterally (Figures 1 and 2). Part of the crescent-shaped lumen is compressed against the vertebral body and the rest of it is less well compressed against the longus colli muscle to one side. A nasogastric tube is squeezed laterally towards the less well compressed part of the lumen and makes the occlusion of the hypopharynx more complete and therefore cricoid pressure more efficient.

A study of women undergoing emergency caesarean section under general anaesthesia with muscle relaxation showed that gastric pressure is likely to be less than 25 mm Hg in 99%. Oesophageal pressure can rise to equal gastric pressure during gastro-oesophageal reflux as the lower oesophageal sphincter relaxes to create a common cavity. A study of ten cadavers showed that 20 Newtons (N) of force applied to the cricoid cartilage prevented the regurgitation of oesophageal fluid at a pressure of 25 mm Hg in all cases and 30 N prevented regurgitation at a pressure of 40 mm Hg in all cases. Therefore, 20 N of cricoid pressure is probably sufficient and 30 N is more than enough to prevent regurgitation into the pharynx. Anaesthetic assistants can be trained to apply the correct force by practising on weighing scales and by doing this they can apply a range of forces between 5 N above or below the target force. A reasonable recommendation is to apply 30 N (3 kg).

Correct technique

Although cricoid pressure is apparently a simple technique there is growing evidence that incorrect application can cause serious problems during induction of anaesthesia. The anaesthetic assistant should practise the correct forces on weighing scales. The anaesthetist should be confident that the anaesthetic assistant knows the anatomical landmarks of the cricoid cartilage. Although Sellick suggested that the patient's head should be extended, the author recommends that it should rest on a pillow because intubation is easier and cricoid pressure is just as effective in this position. After pre-oxygenation, but before intravenous induction, lightly applied cricoid pressure should be started with a force of 10 N (1 kg), after loss of consciousness the force is increased to 30 N (3 kg). Forces of 20 N or more are not tolerated by awake patients and may cause them to retch and vomit. Normally the assistant applies cricoid pressure with their dominant hand because this can be maintained more accurately and for longer (3–5 minutes). There is no evidence that a bimanual technique, with the assistant's other hand supporting the patient's neck, improves the view at laryngoscopy when the correct forces are applied. The assistant's other hand is best kept free to assist with a difficult intubation if necessary.

Patients with small bowel obstruction should have a nasogastric tube inserted preoperatively. This should be aspirated before induction and left in place during induction. This does not make cricoid pressure less efficient and may improve it. As the tube is not compressed, it is possible, by leaving it open to atmospheric pressure, to vent liquid and gas remaining in the stomach, minimizing any increase in gastric pressure.

Sellick described the application of cricoid pressure with three fingers, thumb and middle finger on each side of the cartilage with the pressure applied with the forefinger. However, with the head on a pillow it is more comfortable to apply it with two fingers, forefinger and thumb on each side of the cartilage. This gives flexibility to apply upward and backward cricoid pressure, which improves the view at laryngoscopy if this becomes necessary. As the cricoid inevitably moves slightly laterally during cricoid pressure, it is better to ensure that it moves to the patient's right rather than to the left because this also makes intubation easier with a Macintosh laryngoscope.

Complications

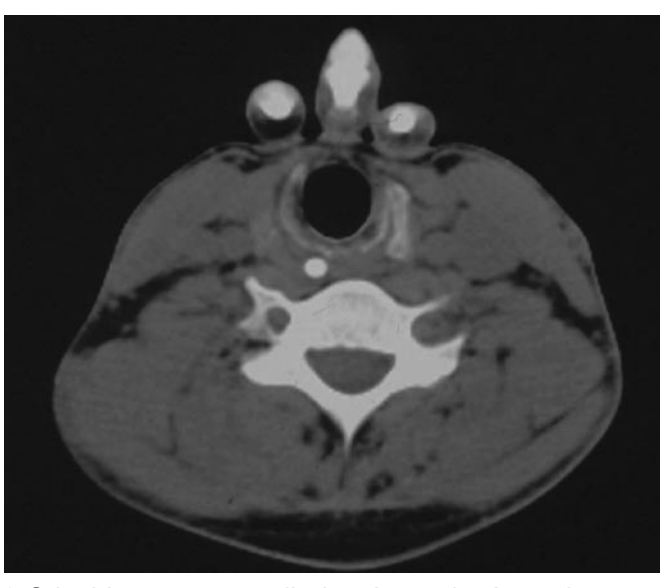
Excess force applied to the awake patient has caused retching and death from aspiration and ruptured oesophagus.

Difficult intubation can be caused by cricoid pressure if the force is applied to the thyroid cartilage or if the larynx is pushed laterally to the left or if too much force is used, which compresses the airway. When cricoid pressure is applied properly with a force of 30 N (3 kg) the view at laryngoscopy is improved compared with the situation when no cricoid pressure is used. However, if only the epiglottis can be seen, then the slight lateral displacement of the larynx, which is inevitable, will make the passage of a gum elastic bougie more difficult because this is normally passed in the midline.

The so-called 'cricoid yoke', a force transducer applied to the neck, is not ideal, because it may not be applied accurately to the cricoid cartilage and may cause tracheal compression or extreme lateral displacement of the larynx, resulting in difficulty with tracheal intubation.

Difficult ventilation – cricoid pressure can obstruct the airway and prevent ventilation of the lungs with a face mask and Guedel airway. This is proportional to the force applied; 30 N causes complete obstruction in 2% of patients and 40 N does in 35%. Upward and backward cricoid pressure at a force of 30 N causes airway obstruction in 56% possibly because it tilts the cricoid cartilage and opposes the vocal cords. Following a failed intubation in a patient with a full stomach when the lungs cannot be ventilated, the force of cricoid pressure should be reduced by half. If this does not allow ventilation, cricoid pressure should be released completely to allow ventilation, with laryngoscope and suction immediately available. Further airways that may then be necessary (e.g. laryngeal mask, *Combitube*, cricothyrotomy cannula) are all better placed without cricoid pressure applied.

1 Axial CT scan of the author's neck at the level of the cricoid cartilage showing a nasogastric tube filled with radio-opaque contrast media.



2 Cricoid pressure applied to the author's neck showing the slight lateral displacement of the cricoid and the lateral position of the nasogastric tube.

Tracheal Intubation: Management of Difficult and Failed Intubation

Stuart W Benham

Stuart W Benham is Consultant in Anaesthetics and Intensive Care Medicine at the John Radcliffe Hospital, Oxford, UK. He qualified from Glasgow University and trained in anaesthetics and general medicine in the west of Scotland before finishing his training in intensive care in Oxford. His research interests include acute renal failure on the ICU and difficult airway training and research.

Securing the airway with a tracheal tube is a core skill for anaesthetists. The technique may be required during anaesthesia, resuscitation or intensive care. The ability to manage patients when laryngoscopy is predicted to be difficult, or when intubation has previously failed, requires a methodical approach and a workable back-up plan. Indications for tracheal intubation are given in Figure 1.

Patients with depressed conscious levels (e.g. following head injury, self-poisoning, vascular accident, infections) need careful assessment. If there is any concern that airway reflexes are diminished, the airway must be secured with a tracheal tube. A low Glasgow Coma Score (e.g. GCS < 9) should not be relied on as the sole indication of airway compromise.

Intermittent positive-pressure ventilation can be achieved by non-invasive means without tracheal intubation. In the operating theatre this is often performed with the laryngeal mask airway (LMA), and in the ICU with a secure fitting face mask with head strapping.

Indications for tracheal intubation

Surgical indications
- Shared airway surgery
- Requirement for one lung ventilation
- Prone or sitting position for surgery
- Open abdominal or thoracic surgical procedures
- Major head and neck surgery
- Prolonged surgery

Emergency indications
- Prevention of aspiration in unfasted patients requiring general anaesthesia
- Impending airway obstruction (e.g. epiglottitis, airway burns)
- Maxillofacial trauma (blood in the airway)
- Depressed conscious level with poor airway reflexes

Ventilatory failure indications
- For intermittent positive-pressure ventilation
- Prevent aspiration of gastric contents
- Advanced ventilation strategies (e.g. partial liquid ventilation, high frequency jet ventilation)
- Prone ventilation strategies
- Ventilatory failure unresponsive to non-invasive positive- pressure ventilation

1

Management of difficult airway and failed intubation

The maintenance of alveolar ventilation is the most important aspect of difficult airway management. Patients in whom intubation is difficult or has failed, and in whom mask ventilation is also difficult are uncommon (about 1:10,000 routine anaesthetics). The anaesthetic plan must not render an awake patient who can maintain a patent airway into an unconscious patient with an unsafe and obstructed one. Preoperative assessment aims to identify patients in whom laryngoscopy and/or airway maintenance are likely to be difficult when consciousness is lost. Patients generally fall into one of three categories:
- anticipated difficult laryngoscopy
- elective unanticipated difficult laryngoscopy
- emergency unanticipated difficult laryngoscopy or failed intubation.

Anticipated difficult laryngoscopy
A comprehensive plan is required involving a primary plan and a secondary plan to be used if the primary plan fails. Two common pitfalls are:
- the operator is inexperienced in the technique chosen (e.g. flexible fibre-optic laryngoscopy – FFL)
- the back-up plan involves staff, skills and equipment that are not readily available at the time of induction (e.g. tracheostomy).

Anaesthetists have to develop plans with their own skill levels in mind, incorporating available equipment and supporting staff. Patient safety is of paramount importance. Generally, less invasive, atraumatic techniques should be preferred to surgical airway control, especially in elective patients. However, the emergency anticipated difficult airway (e.g. patients with severe maxillofacial trauma, or enlarging wound haematoma and stridor following head and neck surgery) may require a surgical airway as the primary plan.

Patients with bony abnormalities may have restricted mouth opening due to temporo-mandibular joint disease, or a cervical spine with limited neck flexion or extension (Figure 2). There is an expectation that the oropharynx and periglottic regions will be normal. In these patients, direct laryngoscopy may be impossible, but the normal oropharyngeal anatomy allows the passage of an FFL under general anaesthesia and assisted ventilation should be possible. If the primary plan fails during this elective surgery, the patient may be woken before implementing the secondary plan.

2 Restricted neck extension in ankylosing spondylitis.

Patients with obstruction in the supraglottic region include those with previous major oral surgery or radiotherapy. If there is evidence of stridor, the patient should be treated with extreme caution and one of the plans outlined below for periglottic or infraglottic obstruction should be considered. Stridor implies 50% airway narrowing. These patients may develop complete airway obstruction when anaesthetized and a surgical airway should be included in the management plan. Depending on the anaesthetist's skill, two options for the non-stridulous patient are:
- an awake fibre-optic endoscopy and intubation, before any relaxant or induction agent is given
- an inhalational induction and direct laryngoscopy to define the anatomical situation, and the feasibility of passing a tracheal tube.

Patients with obstruction in the periglottic region (including obstructing laryngeal tumours) require a thorough preoperative evaluation (e.g. CT, MRI) to assess the degree of obstruction and clinical assessment of the degree of stridor. Indirect laryngoscopy and flexible fibre-optic nasendoscopy are necessary to determine the extent of the obstruction and the feasibility of passing a tracheal tube, which should be performed by an experienced ENT surgeon. Non-stridulous lesions can be managed similarly to lesions causing supraglottic obstruction. Stridulous lesions are the most difficult to manage because neither awake fibre-optic endoscopy nor inhalational induction guarantees success. The choice of technique depends on the degree of stridor, the general condition of the patient and the experience of the anaesthetist. Severe cases may best be managed by awake tracheostomy under local anaesthesia. Depending on the level of the lesion, particularly with infraglottic obstruction, even emergency tracheostomy may not be realistic. For the most severe lesions it may be necessary to consider extracorporeal oxygenation as part of the secondary plan.

Elective unanticipated difficult laryngoscopy
Elective unanticipated difficult laryngoscopy is best managed using a stepwise approach.
- Reconfirm that assisted bag and mask ventilation is possible.
- Consider repositioning the head and neck and the use of a bougie.
- Avoid prolonged attempts at direct laryngoscopy. Change the length of laryngoscope blade once and the type of blade once to achieve the optimum view.
- Call for help and for the FFL if competent in its use.
- Consider the use of the LMA or the intubating LMA (ILMA) for ventilation.
- Consider using the LMA/ILMA as a conduit for intubation (see below).
- Consider abandoning anaesthesia, and performing an awake intubation.

Emergency unanticipated difficult laryngoscopy and failed intubation
This is a failure to secure the airway with a tracheal tube following a rapid sequence induction. Remember that it is failure of oxygenation, rather than a failure of intubation, that accounts for morbidity and mortality. The same stepwise approach as that for the elective unanticipated difficult laryngoscopy should be followed. All departments of anaesthesia should have a failed intubation drill for these circumstances, and clinicians should be familiar with their local protocols (see *Anaesthesia and Intensive Care Medicine* **2:6:** 221). It should be noted that in these situations the removal of cricoid pressure may help ventilation attempts, especially through the LMA. The risks of aspiration are small in comparison to the potential for morbidity and mortality caused by hypoxia from failed ventilation.

Techniques to overcome difficult intubation

Many devices have been developed to improve the chances of securing the airway with a tracheal tube. Some of those used by practising clinicians are described below.

Position and simple manoeuvres
Optimizing the patient's position (flexion of the cervical spine and head extension at the atlanto-occipital joint – the 'sniffing the morning air' position) is the first step to improve the view at direct laryngoscopy. Simple manoeuvres such as external laryngeal manipulation, especially backwards, upwards and rightwards pressure on the larynx can improve the view by more closely aligning the visual axis with the laryngeal inlet.

Laryngoscopes
There is a range of curved and straight blades, as well as blades with movable hinged tips (McCoy), that may improve the view at direct laryngoscopy (see *Anaesthesia and Intensive Care Medicine* **1:1** 34). Many experienced anaesthetists, however, tend to use the same type of laryngoscope blade for all their patients. Skills in the use of different blades are best acquired during routine intubations. The McCoy, or the angled Belscope laryngoscope, may be able to convert a Cormack/Lehane grade 3 view to a grade 2 view, though familiarization with the technique is required.

Simple props and aids
Gum elastic bougies should be used when:
- direct laryngoscopy allows visualization of the epiglottis but not the larynx (a grade 3 view)
- visualization of the larynx is possible but direct passage of the tracheal tube is prevented by awkward oral anatomy or teeth
- a reinforced or flexible tracheal tube cannot be directed into the visualized larynx.

Aintree intubation catheter (Cook©) (Figure 3) can be used like a gum elastic bougie, or in combination with other airway and intubating devices such as the LMA or FFL. It is sufficiently long and thin to allow a tracheal tube to be railroaded over it. It is hollow and has a detachable tube connector/adaptor that allows ventilation during the intubation process. An FFL can also be passed through it if required.

a Flexible fibre-optic laryngoscope and Aintree intubation catheter passed through the laryngeal mask airway (LMA).
b Fibre-optic endoscopy through the LMA with the Aintree exchange catheter.

3

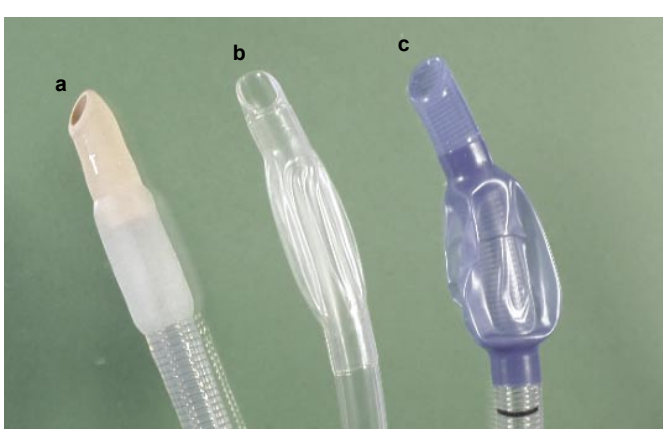
LMA and ILMA
Most anaesthetists use the LMA regularly for patients not requiring intubation. The ability to insert an LMA to allow spontaneous or assisted ventilation is a core skill for anaesthetists. It also provides a route guide for intubation, either blind or guided by an FFL. The LMA may help to achieve ventilation in patients who are otherwise difficult to intubate and ventilate.

The ILMA is modified to improve the chances of passing a tube blindly through the mask into the trachea. There is an initial short learning curve for the operator, and the clinician should practise using the ILMA in patients with normal airways before it is used in those with difficult or abnormal ones.

The main limitation on both devices is that there has to be enough mouth opening to permit inserting the device. Intubation can be blind, but both devices can be used with an FFL to visualize laryngeal anatomy and aid intubation.

Railroading the tracheal tube
The need to railroad the tracheal tube over the guide is the final step in intubation. Two manoeuvres to increase its success rate and minimize laryngeal trauma are choice of tracheal tube and bevel direction.

- The ILMA tube (softer tip) or reinforced tracheal tube (less acute bevel and softer tip) has a higher chance of passing through the vocal cords (Figure 4).
- The bevel of the standard tracheal tube is directed to lie in the right or left lateral position as it reaches the vocal cords. It is then rotated 90° as it is pushed gently through the cords. If this is unsuccessful, the tube is rotated through 360° continuously with gentle pressure to slip through the cords. If still unsuccessful, direct laryngoscopy can be performed to check the position of the route guide, and to lift the epiglottis to facilitate tube railroading.



4 Tracheal tube tips. **a** The intubating laryngeal mask airway tube, **b** standard tube, and **c** the flexometallic tube

FFL and intubation
FFL and intubation can be performed with the patient awake or anaesthetized. Awake fibre-optic intubation performed by a competent endoscopist is safe (Figure 5). The patient remains awake and self-ventilating with maintained pharyngeal muscle tone.

5 Awake fibre-optic intubation. Note the use of propofol sedation and jaw thrust.

Suggested procedure for awake fibre-optic intubation
1 Premedication of morphine, 0.1–0.15 mg/kg i.m., and hyoscine (scopolamine), 200 µg i.m., 1 hour before procedure.
2 The patient should lie semi-reclined on a trolley in the anaesthetic room, facing the anaesthetist.
3 Intravenous sedation should be administered cautiously. Target-controlled infusion with propofol (plasma concentration 0.5–1.5 µg/ml) is well tolerated.
4 Topical anaesthesia of the upper airway should be provided:

- Nasal mucosa; mixture of 5% cocaine, 2 ml, and 8.4% bicarbonate, 2 ml, as topical spray, with the patient taking deep breaths in with each spray. If the patient requires orotracheal intubation the oropharynx can be anaesthetized with lidocaine (lignocaine) spray or gel. Oropharyngeal route guides (e.g. *Ovassapian* or *Berman* airway) can be used to aid orotracheal intubation. These allow the operator to pass the FFL and tracheal tube through them. They prevent soft tissue collapse and are sized to guide the FFL through the mouth, and emerge at the epiglottis, where it can be directed into the larynx.
- Spray as you go (SAYGO) with 4% lidocaine (lignocaine) through the working channel of the FFL. Insertion of an epidural catheter through the working channel to the tip of the scope, with the catheter end trimmed to produce one end-hole, can facilitate accurate delivery of the local anaesthetic injection. Inject 1 ml solution with 4–5 ml air to help disperse the anaesthetic. Before the first attempt to pass the FFL, and before each subsequent attempt, oropharyngeal suctioning with a Yankaur sucker may be required.
- Administer supplemental oxygen. This can be delivered conveniently via a flexible suction catheter passed into the opposite nostril.

5 Allow adequate time (at least 30 seconds) after topicalization before the FFL is advanced. Avoid passing the FFL blindly. If the view ahead becomes obscured, gently withdraw the insertion cord until airway anatomy is again identified. Ask the patient to take deep breaths when advancing towards the laryngeal inlet. This opens the airway and abducts the vocal cords. If visualization of the larynx is difficult, performing a gentle jaw thrust manoeuvre on the patient can help.
6 Once the scope has been advanced through the cords it should be advanced to just proximal to the carina. A common error is to allow the FFL to withdraw, or even become displaced from the trachea while the tube is railroaded into place. This happens more often if the patient coughs at this time. The operator should attempt to keep the FFL in the centre of the airspace at all times. This minimizes trauma to the delicate tracheal mucosa and reduces the amount of blood in the airway.
7 Railroading the tracheal tube is described above. It is helpful for the assistant to hold the FFL stationary allowing the operator to railroad the tube into place using both hands.
8 A final useful check to estimate the distance from the end of the tracheal tube to carina can be performed as follows. Once intubation has been performed, the FFL is passed down just proximal to the carina. The assistant lightly pinches the FFL as it enters the proximal end of the tracheal tube. The FFL is then withdrawn slowly until the distal end of the tracheal tube comes into view. As soon as this is seen, the distance from the assistant's fingers to the tube connector of the tracheal tube is noted. This is the distance from tip of tube to carina.
9 The breathing system with capnograph is connected. The patient may then be anaesthetized and laid flat. Satisfactory ventilation is confirmed, and muscle relaxant can be given if required.

Problems with flexible fibre-optic intubation: the FFL is an intubating tool, not a ventilation device. Oxygenation and ventilation must be maintained throughout the intubation procedure.

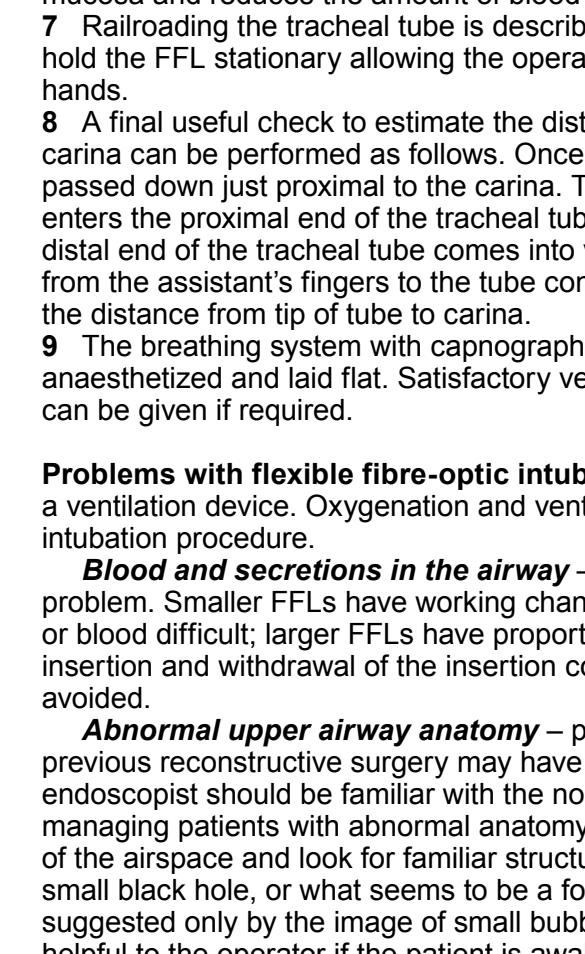
Blood and secretions in the airway – a poor view is the endoscopist's main problem. Smaller FFLs have working channels that make suctioning of sticky secretions or blood difficult; larger FFLs have proportionally larger suction channels. Repeated insertion and withdrawal of the insertion cord may precipitate bleeding and should be avoided.

Abnormal upper airway anatomy – patients with oro-pharyngeal lesions or previous reconstructive surgery may have abnormal upper airway anatomy. The endoscopist should be familiar with the normal appearances through the FFL before managing patients with abnormal anatomy. In all patients, keep the FFL in the centre of the airspace and look for familiar structures. Often the larynx is identified only as a small black hole, or what seems to be a fold in the mucosa. Identification is sometimes suggested only by the image of small bubbles appearing from a dark crevice. It is helpful to the operator if the patient is awake, semi-recumbent, and cooperating by taking deep breaths.

Equipment problems – the FFL should be checked and cleaned before use.

- The tracheal tube should be loaded on the FFL before endoscopy; forgetting to do this is a common mistake.
- Ensure that the light is on and working with white balance and focus optimal before commencing endoscopy.
- Lubricating jelly should be applied to the outside of the scope, and the tracheal tube, to facilitate easy nasal passage and tracheal intubation.
- Difficulties in railroading the tracheal tube can sometimes result from a large difference in the external diameter of the scope and internal diameter of the tracheal tube. This may be overcome by use of the Aintree intubation catheter. The intubation catheter can be railroaded over the scope, and then the tracheal tube railroaded over this.

Lack of hand–eye coordination can be remedied by practice on simulators, manikins and learning models such as an artificial bronchial tree or the Oxford 'hit-the-hole' box (Figure 6). It is indefensible to acquire these basic skills at the expense of the patient's mucosa.



6 The Oxford 'hit-the-hole' training box.

An inability to recognize anatomy is easily addressed by experience gained from instructional videos, clinical teaching and supervision. The case for using an FFL to aid routine nasal intubation is robust. In addition to the excellent learning opportunity afforded by routine use of the FFL, it assists in the selection of the best nostril and largest airspace, and identifies vulnerable nasal pathology such as polyps.

Transtracheal access

The final route for rescuing an obstructed airway is direct transtracheal access. This can be through the cricothyroid membrane, or through the upper trachea. Most anaesthetists never need to resort to this. Elective procedures, such as cricothyroid puncture used to inject local anaesthetic, or performing percutaneous tracheostomies in the ICU, provide valuable experience in tracheal access. The ability to identify the cricothyroid membrane and to insert a cricothyroid airway catheter rapidly may be a life-saving procedure. See Anaesthesia and Intensive Care Medicine issue 2:7: 268 for discussion of emergency tracheal access.

Airway Control

Oliver J Dyar

Oliver J Dyar is Consultant Anaesthetist and Intensivist at the John Radcliffe Hospital, Oxford, UK. He qualified from University College, Dublin and St Vincent's Hospital, Dublin, Ireland. He trained in anaesthetics and intensive care in the Nuffield Department of Anaesthetics, Oxford. His research interests include intravenous anaesthesia and the use of nitric oxide in the ARDS.

Securing control of the airway is one of the most important skills required of the anaesthetist. Whether for elective or emergency surgery, and whether the need for airway control has been predicted or not, the safety of the patient depends on the anaesthetist's ability to intervene to ensure adequate oxygenation and ventilation should the need arise. The anaesthetist must:

- develop the skills of airway assessment and management
- be familiar with the equipment and techniques available for control of the airway
- be able to choose the appropriate measures for the individual patient.

This contribution focuses on these basic principles.

Assessment of the airway

The anaesthetist must assess the airway before undertaking any anaesthesia. When general anaesthesia is contemplated, assessment facilitates a planned approach to anticipated difficulties with laryngoscopy and intubation. When a regional or local technique is contemplated, the need for airway intervention may also arise, for example, following respiratory embarrassment as a result of a high spinal or epidural blockade level, over-zealous sedation, or more rarely, following an allergic reaction to a drug.

The patient's previous anaesthetic notes should be consulted if available. It is important to realize, however, that the patient's circumstances may have changed, and a previously easy intubation may have become difficult (e.g. as a result of pregnancy). A number of anatomical factors are associated with difficulty in laryngoscopy and intubation:

- obesity, pregnancy
- large protruding incisor teeth
- short neck, especially in a heavy patient
- reduced mobility of the neck (e.g. rheumatoid arthritis)
- instability of the neck
- reduced mouth opening
- intraoral masses
- large goitre.

Anatomical assessment

Whether laryngoscopy and intubation would be possible with reasonable ease should be assessed using a reliable and reproducible bedside method of airway assessment that has minimal false-positive and false-negative rates. No single test provides this information, but the modified Mallampati test in conjunction with an assessment of thyromental distance combines ease with reasonable accuracy.

The modified Mallampati test assesses the size of the base of the tongue in relation to the size of the oropharynx. The patient sits upright with the head in the neutral position. The assessor sits in front of the patient at the patient's eye level. The patient opens their mouth as wide as possible. Without phonating, the tongue is protruded as far as possible. The assessor inspects the pharyngeal structures visible and a score is allocated according to which structures are visible (Figure 1).

Modified Mallampati test

Class	Pharyngeal structures visible
1	Fauces, faucial pillars (the palatoglossal and palatopharyngeal arches), uvula, soft palate
2	Faucial pillars are obscured leaving the fauces, uvula and soft palate visible (i.e. posterior pharyngeal wall visible below soft palate)
3	Only the soft palate and the base of the uvula seen (i.e posterior pharyngeal wall not visible below soft palate)
4	Even the soft palate obscured

1

The measurement of thyromental distance as recommended by Frerk is obtained by maximally extending the head on the neck and measuring from the prominence of the thyroid cartilage to the bony point of the chin.

A modified Mallampati grade of 3 or 4 combined with a thyromental distance of 7 cm or less gives a bedside assessment system with a sensitivity of 81% and a specificity of 98% for difficulty with intubation.

The view of the laryngeal structures obtained at direct laryngoscopy is often classified according to the system described by Cormack and Lehane (Figure 2). In this system, grades 3 and 4 constitute difficult laryngoscopies. Fairly severe difficulty with intubation may occur with grade 3, and the use of a bougie/introducer, posterior to, but held up against the epiglottis may permit blind intubation. With a grade 4 view, intubation by standard methods is virtually impossible despite optimal positioning.

Cormack and Lehane classification system

Grade	Laryngeal structures visible
1	Most of the glottis visible
2	Only the posterior part of the glottis (posterior commissure, arytenoid cartilages) visible

Airway patency

Partial obstruction of the airway in the awake patient may be caused by masses in the upper airway (e.g. tonsils, adenoids, tumour), foreign bodies, or epiglottitis. In the sedated or unconscious patient, laxity of the muscles that normally keep the tongue anterior to the posterior pharyngeal wall allows the tongue to fall back and obstruct the airway. Partial obstruction is recognized by noisy inspiration (stridor), tracheal tug, and dyssynchronous movements of the thorax and abdomen on inspiration.

In normal, unobstructed breathing, the abdomen expands as the diaphragm descends in inspiration and the thorax expands as indrawn gas fills the lungs. With obstruction, the abdomen still expands, but if inspired gas cannot be inhaled at a sufficiently fast rate, the sternum is drawn inwards by the increasing, unrelieved negative intrathoracic pressure. Partial obstruction and its cause (and therefore ease of reversal) must be recognized before embarking on anaesthesia. The technique of airway management is highly modified in the presence of partial obstruction.

Aspiration risk

For elective anaesthesia, the patient is fasted. Solid food, non-clear liquids (especially those containing milk) and chewing gum should not be consumed in the 6 hours before anaesthesia. Clear liquids are permissible up to 2 hours before induction.

For emergency anaesthesia, the interval between last food or drink and the injury or onset of illness is assessed. Gastrointestinal obstruction or other abnormal motility state (e.g. ileus, diabetes mellitus, renal failure, acute pain) all increase the risk of aspiration on induction of anaesthesia.

Equipment and techniques for routine airway management

Before embarking on general anaesthesia, the equipment required should be to hand and its correct function checked. A preoperative checklist such as that proposed by the Association of Anaesthetists of Great Britain and Ireland is particularly useful (see *Anaesthesia and Intensive Care Medicine* **1:2:** 65). The minimum equipment required includes:

- source of pressurized oxygen (plus bag-valve-mask or anaesthesia circuit)
- selection of face masks
- selection of oropharyngeal and nasopharyngeal airways
- high-flow suction
- Yankauer suction catheter, and selection of narrow-bore suction catheters
- two laryngoscopes
- selection of tracheal tubes
- selection of laryngeal mask airways
- Magill's forceps
- sterile lubricating gel
- ties and padding to secure tracheal tube
- gum-elastic or other suitable bougie.

For non-emergency anaesthesia, several interventions to control the airway are available. These range from oxygen administration through a face mask, delivery of inhalational anaesthesia via an anaesthetic face mask or laryngeal mask airway, through to tracheal intubation.

Non-relaxant anaesthesia

If relaxant anaesthesia is not required (e.g. for body-surface surgery in the patient not at risk for aspiration) then inhalational anaesthesia via a face mask is appropriate. In the absence of flammable anaesthetic agents, the mask is usually clear plastic with an inflatable rim that provides a good seal in contact with the face. The size of the mask is determined by the patient's size and physical features, but a range of sizes (Figure 3) should be available. For paediatric anaesthesia, the mask should have as little dead space as possible (e.g. the Rendell-Baker–Souchet mask). Nasal masks are indicated for anaesthesia in the dental chair.

Induction in the absence of airway obstruction may be inhalational or by intravenous injection of a suitable induction agent. If there is any suggestion of airway obstruction then inhalational induction or another approach (e.g. awake fibre-optic intubation) is required.

3 Selection of face masks, including Rendell-Baker–Souchet paediatric masks (lower row).

Supporting the airway

Whatever the means of induction, once the patient is unconscious it is necessary to support the airway. There is a tendency for the airway to become partially obstructed at this stage because the tongue falls back against the posterior wall of the pharynx. Induction will normally have occurred with the patient supine, head resting on a pillow. This allows the anaesthetist to extend the head on the neck at the same time as applying a jaw thrust and opening the mouth. To achieve this triple manoeuvre, the mask is secured on to the face using one or both hands, with the thumbs on the upper part of the mask, index fingers on the lower part and the rest of the fingers effectively pulling the patient's mandible forward into the mask. It is crucial that unopposed downward pressure on the mask is not used to obtain a seal between mask and face because this will close the airway. Likewise, the third, fourth and fifth fingers must stay on the mandible and must not press on the floor of the mouth, which also tends to cause obstruction. If it is impossible to open the airway using these techniques, an artificial airway is required. Two methods are available: the oropharyngeal and the nasopharyngeal airway (Figure 4).

4a Nasopharyngeal airway.
b Selection of smaller oropharyngeal airways.

The oropharyngeal (Guedel) airway is a curved tube that has a flanged and reinforced oral end. The flange enables correct positioning at the incisor teeth, and the reinforcement prevents the patient from obstructing or severing the device by biting down. This airway is available in a range of sizes (size 3–4 is usually required for an adult, Figure 4b), and it is vital that the appropriate size is used for the patient. An easy way to determine size is to choose the airway in which the length is equal to the distance between the corner of the patient's mouth and the angle of the jaw. If the airway is too short it tends to push the tongue backwards and cause increased obstruction. If too long, the device tends to stimulate the larynx, provoking spasm, and it fails to sit securely with the flange at the front incisors. The Guedel airway is usually inserted upside-down (the pharyngeal opening facing the roof of the mouth, then rotated 180° as it passes the back of the tongue). A lightly anaesthetized patient may gag or cough with this intervention. It may also provoke laryngeal spasm.

The nasopharyngeal airway is a less stimulating intervention. It is a soft curved tube with a flanged nasal end and a bevelled pharyngeal end (Figure 4a). It is also available in a range of sizes. Sizes 6–8 mm (measured as internal diameter) are suitable for adults, the usual measure is the diameter of the patient's little finger. Before inserting the airway, a safety pin is inserted eccentrically at the flanged end, to prevent inhalation of the device. The airway should be coated with lubricating gel, and inserted into either nostril. It is advanced along the floor of the nose in a posterior direction, and should come to lie with the bevelled end in the oropharynx, behind the tongue and above the glottis. The eccentric positioning of the pin permits access of a catheter for suctioning secretions from the pharynx and airway.

Face mask: for brief procedures, anaesthesia can be maintained using a face mask, with or without airway adjuncts. For longer procedures, when it is desirable for the anaesthetist to have both hands free, the standard mask can be supported by a harness. It is now more common to insert a laryngeal mask airway for such procedures. This has the advantage of maintaining the airway without additional instrumentation, in addition to providing a more secure airway and providing hands-free operation.

The laryngeal mask airway (LMA) was designed to provide a connection between the artificial and anatomical airways in a less invasive way than with a tracheal tube, and yet with greater convenience and reliability than a conventional face mask. The standard LMA is made from silicone and is designed for multiple patient (up to 40) uses. It consists of a silicone bowl surrounded by a thin-walled elliptical ring that can be deflated to form a thin wedge shape, and which when inflated in the space posterior to the pharynx creates a seal around the laryngeal aperture. This seal permits ventilation of the airway under positive pressure. It also prevents insufflation of gas into the oesophagus and stomach, unless high inflation pressures (20–30 cm H_2O) are used. The device has a central aperture, with vertical bars, designed to prevent prolapse of the epiglottis into the tube that connects the mask to the anaesthetic circuit.

The LMA is available in a variety of sizes (Figure 5).

Correct placement is important to ensure a high-performance seal without overinflation of the cuff, and the appropriate size is chosen for the size of the patient (Figure 6).

The LMA is also available with a flexible, reinforced, non-kinking tube instead of the standard tube. This type is particularly useful for situations in which the head may be moved during surgery and for oral and ENT surgery. The intubating LMA is a development of the standard airway designed to act as a conduit permitting blind intubation of the trachea using a specially designed silicone tube.

A full description of the recommended technique for inserting the LMA is beyond the scope of this contribution. Briefly, the device is completely deflated (preferably using a cuff deflation tool, which will ensure deflation to the correct shape). The patient's head is supported on a pillow, in the classic intubating position. Extension of the head and flexion of the neck on the thorax is achieved by the non-dominant hand. The posterior surface of the LMA is lubricated with water-soluble gel. The LMA is held between index finger and thumb, with the index finger of the operator's gloved dominant hand at the junction of the mask and the tube. The aperture of the device faces caudally. An assistant holds the patient's mouth open, and the device is inserted under direct vision, with its posterior, lubricated surface firmly against the hard palate. The LMA is pushed, keeping it firmly against the palate at all times following the palate posteriorly and down into the hypopharynx. Resistance to insertion is met when the tip of the device is in the hypopharynx, with the tip resting at the upper oesophageal sphincter. It may be necessary to push the device using the non-dominant hand, if the inserting finger is not long enough. The device is released. The cuff is inflated with the recommended volume of air, at which point the tube may rise from the mouth as the device seats itself around the larynx. The tube of the LMA is connected to the anaesthetic circuit, if necessary using a swivel connector.

The LMA may be used to ventilate the anaesthetized muscle-relaxed patient, provided that the inflation pressures do not exceed about 20 cm H_2O. Above this pressure, the risk of gradual insufflation of the stomach with anaesthetic gas increases. This increases the risk of regurgitation and aspiration of gastric contents.

5a Standard laryngeal mask airways, sizes 2½, 3, 4. **b** Reinforced laryngeal mask airway, size 4.

Relaxant anaesthesia

Anaesthesia requiring a muscle-relaxant technique most commonly requires tracheal intubation. Indications for relaxant techniques and/or intubation are:

- provision of clear airway
- airway protection from blood, oral or gastric secretions
- facilitation of suctioning of airway
- prone or sitting patient, airway inaccessible
- abdominal, thoracic anaesthesia
- likelihood of postoperative respiratory support
- administration of positive end-expiratory pressure.

Tracheal intubation

Equipment: in addition to the equipment for inhalational anaesthesia using a face mask, a suitable laryngoscope, with a spare available, and a range of suitable tracheal tubes are necessary.

The laryngoscope consists of a handle (which houses the batteries) and a detachable blade, which has a screw-in bulb. Alternatively, the bulb may be in the handle, and a fibre-optic bundle transmits the light to the blade. Two basic types of laryngoscope are available (Figure 7):

- curved-blade (usually Macintosh)
- straight-blade (e.g. Wisconsin, Seward, Magill).

The curved-blade instruments are most commonly used for adults and larger children: the tip is placed in the vallecula, anterior to the epiglottis. Forward traction elevates the epiglottis without touching the posterior surface of the epiglottis. By contrast, straight-blade laryngoscopes are inserted posterior to the epiglottis and lift it from behind. These instruments are most often used for smaller children, because the epiglottis is longer and more floppy in this age group. The blades are available in a number of sizes, with the Macintosh 3 being suitable for most adults.

Tracheal tubes – an extensive range of tracheal tubes is available (Figure 8). They are most commonly made from polyvinylchloride or polyurethane and are bevel-ended. They may be plain or have a high-volume low-pressure cuff, which provides a seal enabling positive-pressure ventilation and preventing aspiration of secretions into the airway. Uncuffed (plain) tubes are used in children. This avoids the potential for ischaemic damage on the tracheal lining from high cuff pressure and maximizes tube size available. The presence of an air leak around the plain tube ensures that the fit is not too tight.

Tracheal tubes are usually inserted via the mouth, or if necessary via the nose (e.g. for intraoral surgery). Tube size is measured by the internal diameter, ranging from 2.5 mm to about 10 mm in 0.5 mm increments. The tube is usually cut to the appropriate length for the patient. Adult males usually require size 8–9 mm and adult females 7–8 mm, cut to 21–23 cm for oral intubation. For children, the tube size can be estimated from the formula (age/4 + 4 mm), and length (age/2 + 12 cm), with age being in years. This is an approximate size, and tubes 0.5 mm greater than and less than the estimated size should be available.

The tube is connected to the anaesthetic circuit at the proximal end with a tapered connector of suitable size (see *Anaesthesia and Intensive Care Medicine* **1:2:** 68). The distal end may have, in addition to the end hole, a side opening (Murphy eye) to allow passage of gas should the bevelled end be occluded by abutting on the tracheal wall.

Sizes of laryngeal mask airway

Size	Patient	Cuff volume (ml)
1	Neonates up to 6.5 kg	4
2	Patients 6.5–20 kg	10
2½	Patients 20–30 kg	14
3	Children and small adults	20
4	Normal adults	30
5	Large adults	40

8 Tracheal tubes. Nasal: **a** cuffed, **b** plain. Oral: **c** North-facing plain polar. Magill pattern oral tubes: **d** plain, **e** cuffed.

Anaesthetic management

Positioning the patient correctly before intubation is crucial. Tracheal intubation requires approximate collinearity between the axes of the mouth, oropharynx and larynx. True collinearity of these structures is impossible, but appropriate positioning can make the difference between a relatively easy laryngoscopy and intubation, and failure to visualize the larynx at laryngoscopy. The classic intubating position is the sniffing position: the head is extended on the neck (atlantoaxial extension) and the neck is flexed on the thorax. For most adults this is easily achieved by having the patient lie supine on the trolley or bed and placing a pillow under the occiput. If the pillow is too caudad (elevating the shoulders) then extension of the neck on the thorax occurs. This almost always makes laryngoscopy more difficult. In small children, the relatively large head provides the correct position without the use of a pillow.

Induction – if the patient is not at risk of aspiration of gastric content, difficulty with laryngoscopy is not anticipated, and the airway is unobstructed, induction of anaesthesia is as for the mask techniques outlined above. Following induction, it is possible, providing the patient is deeply anaesthetized, to perform laryngoscopy and intubation. This practice is relatively uncommon. More usually, the anaesthetist confirms that it is possible to ventilate the patient using the mask (with an artificial airway if needed). Then an intubating dose of a muscle relaxant is given (e.g. suxamethonium, 1–1.5mg/kg). While the advantages of the speed of onset and quality of relaxation

obtained with suxamethonium are significant, its side-effects include myalgia (which can be quite severe), occasional profound bradycardia (especially in children, and particularly likely with second doses of the drug given shortly after a first dose), hyperkalaemia, and precipitation of malignant hyperthermia in susceptible individuals. To overcome these disadvantages, an intermediate-duration non-depolarizing drug such as vecuronium, 0.1 mg/kg, atracurium, 0.5 mg/kg, or rocuronium, 0.6 mg/kg, can be used. However, they commit the anaesthetist to providing ventilation by mask for a prolonged period if intubation proves more difficult than anticipated, or is impossible. With the exception of rocuronium they also take a longer time to achieve good intubating conditions, which makes them much less suitable for the patient at risk of aspiration of gastric content. The lungs are usually manually ventilated while awaiting the onset of muscle relaxation. A mixture of oxygen and the volatile agent chosen to maintain anaesthesia is used, together with nitrous oxide, if desired. The use of nitrous oxide reduces the interval allowable for laryngoscopy and intubation. The patient will become hypoxaemic more rapidly following cessation of ventilation if this gas is used, because available oxygen stores will be reduced. A peripheral nerve stimulator may be used to confirm the presence of adequate paralysis, as demonstrated by the absence of twitch response to a supramaximal stimulus.

Laryngoscopy is then performed. The right hand opens the patient's mouth and the assistant separates the patient's lips to expose the teeth. Using a curved-blade laryngoscope, held in the left hand, the blade is inserted into the right-hand side of the mouth, and advanced as far as the tonsillar bed. Sweeping the blade into the midline at this point should displace the tongue to the left, and give a view of the tip of the epiglottis. The blade is advanced, with force applied along the shaft of the laryngoscope directed upwards and outwards (at about 30–45° to the horizontal). The patient's upper incisors or gum must not be used as a fulcrum. The tip of the blade should enter the vallecula in front of the epiglottis, and the applied force elevates the epiglottis, exposing the larynx. The tracheal tube is picked up in the right hand and advanced from the right-hand side of the mouth, using the natural curvature of the tube to place the tip in the larynx under direct vision. Once the cuff of the tube is safely past the cords, the laryngoscope is carefully removed. The anaesthetic circuit is connected to the tube using a swivel connector and a catheter mount (if desired). The lungs are ventilated and the cuff of the tube inflated with just sufficient air (or gas mixture) to abolish the audible leak of gas on inflation of the lungs. Bilateral breath sounds and absence of sounds of gastric insufflation help confirm placement, however monitoring for appropriate and continuous concentration of carbon dioxide in the exhaled gas is mandatory.

Extubation – anaesthesia is maintained with inhalational agents, and the patient is ventilated using intermittent positive-pressure ventilation throughout the operation. At the end of the operation, residual neuromuscular blockade is reversed using a combination of a cholinesterase inhibitor and a muscarinic blocking drug (to prevent bradycardia). The drugs most commonly used are neostigmine, 0.05 mg/kg, with either atropine, 0.02 mg/kg, or glycopyrrolate, 0.01 mg/kg. Secretions and occasionally gastric content will have accumulated in the pharynx during the procedure. To prevent aspiration of these secretions and severe laryngeal spasm on removal of the tracheal tube, these are removed using a Yankauer sucker or equivalent, under direct vision (with a laryngoscope). The patient is ventilated with 100% oxygen. As the patient starts to breathe, the circuit is changed to permit spontaneous ventilation, with the reservoir bag providing visible confirmation of ventilatory effort and volume.

The tracheal tube is removed when the patient is breathing adequately and has regained protective airway reflexes (the patient is actively resisting the presence of the tube). The patient may be extubated in the supine position if the anaesthetist is satisfied that a clear airway can be maintained and the patient is not at risk for aspiration. If the patient is at risk, then extubation should take place in the lateral position, with the patient as fully awake as possible. Extubation should be performed during inspiration. Having deflated the cuff of the tracheal tube, the bag on the anaesthetic circuit is squeezed to expel secretions above the cuff into the oropharynx, away from the vocal cords. The tube is removed in a smooth movement, the breathing circuit rapidly reconnected to an anaesthetic mask, and the mask closely applied to the face.

Partial obstruction of the airway may occur at this stage if the tongue falls back into the pharynx, or more often because of mild laryngeal spasm. It may respond to the application of positive end-expiratory pressure. This may be achieved by partially closing the exhaust valve on the anaesthetic circuit, but the airway pressure must be monitored. If the airway is obstructed by the tongue, then an oral or nasopharyngeal airway may be required to relieve the obstruction. When the patient is breathing adequately, he is transferred to the recovery room, ensuring that he breathes supplementary oxygen during the transfer.

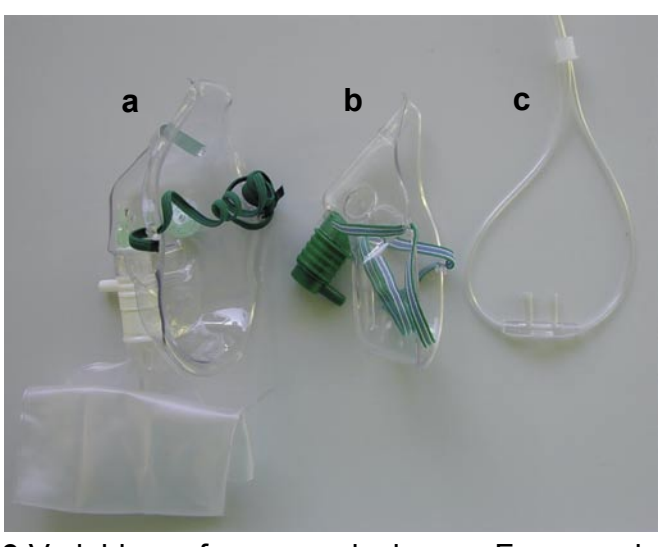
Recovery

Supplementary oxygen should be administered to all patients in the immediate recovery period. This is to prevent hypoxaemia that may otherwise occur from the ventilation–perfusion mismatch induced by surgery and anaesthesia, and the hypoventilation that may ensue from respiratory depressant drugs. Hypoxaemia may also be caused by dilutional hypoxia following cessation of nitrous oxide.

The duration of oxygen therapy may be limited to 15 minutes for young healthy patients undergoing minor day- case procedures, but extended for many hours or days for those with more serious pathology or complicated surgery. Therapy is guided by pulse oximetry or blood gas estimation, and oxygen therapy is usually titrated to achieve oxygen saturation greater than 95%.

Oxygen therapy devices may deliver either a variable or fixed concentration of supplementary oxygen to the inspired gas.

Variable performance devices include nasal prongs and simple 'Hudson'-type face masks with or without an oxygen reservoir (Figure 9). The oxygen flow delivered to the device is typically 2–4 litres/minute, which will be diluted by the air entrained during inspiration. The concentration of inspired oxygen depends on the oxygen flow rate, the patient's respiratory rate and peak inspiratory flow. Typically, 30–40% inspired oxygen is achieved when 4 litres/minute is delivered to a patient via a Hudson mask, and this concentration reduces as respiratory rate and inspiratory flows increase, due to increased air entrainment. The oxygen concentration delivered cannot be predicted accurately. This is usually of no consequence to a patient on the recovery ward, who simply needs supplemental oxygen, though the precise concentration is not critical. The inspired oxygen percentage can be increased further if an oxygen reservoir is used with the mask, and 80% inspired oxygen may then be achieved using a 12–15 litres/minute oxygen flow rate.

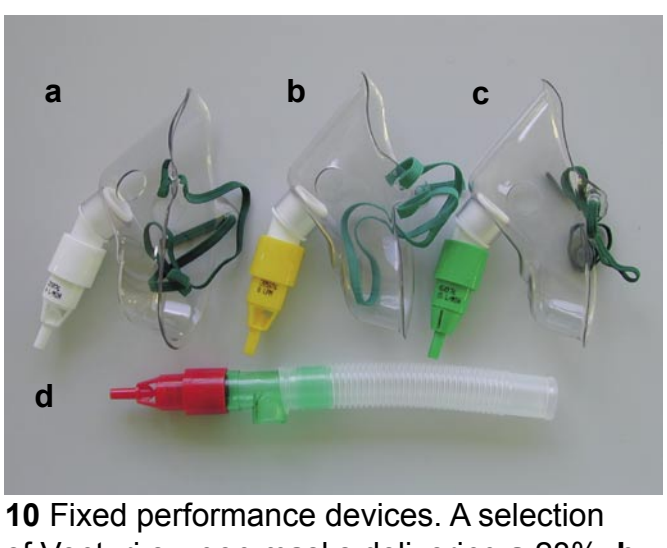


9 Variable performance devices. **a** Face mask with oxygen reservoir bag (folded); **b** simple Hudson-type oxygen face mask; **c** nasal prongs.

Fixed performance devices include face masks with Venturi-type injectors (Figure 10). They achieve a fixed inspired oxygen concentration by ensuring that a high flow rate of oxygen and entrained air is delivered, in excess of the patient's maximum peak inspiratory flow rate.

The use of a Venturi injector face mask delivers about 60 litres/minute of gas and so the inspired oxygen concentration is independent of the characteristics of inspiratory flow. Venturi devices are available to deliver fixed oxygen concentrations between 24% and 60%. The correct oxygen flow rate must be selected for the correct Venturi injector, and used with the correct mask. Details are printed on each Venturi, but typically 2 litres/minute delivers 24% oxygen, and 8 litres/minute delivers 35% oxygen. Venturi injector devices are not interchangeable with masks from different manufacturers, because the mask volume allows for adequate mixing of driving and entrained gases.

Fixed performance devices are often used in the high-dependency setting to enable accurate assessment of oxygenation, in patients with chronic lung disease who depend on a hypoxic respiratory drive, and on the general wards.



10 Fixed performance devices. A selection of Venturi oxygen masks delivering **a** 28%, **b** 35%, **c** 60% oxgen. **d** Venturi T-piece delivering 40% oxygen for use with laryngeal mask airway, tracheal tube or tracheostomy tube.

Anaesthesia for Laparoscopic Surgery

Michael W Platt

Michael W Platt is Consultant in the Department of Anaesthesia, St Mary's Hospital, London. He qualified in Western Australia. His research interests include anaesthesia and pain relief in the elderly, ethical issues at the end of life and aspects of neuropathic pain.

Laparoscopic surgery is a revolution in modern surgical techniques and has reduced postoperative pain, respiratory complications and hospital stay considerably. However, it produces extra stresses on the heart and lungs, therefore patients should be screened carefully and the risks explained fully as part of obtaining consent for the procedure. Anaesthetists should consult their surgical colleagues about the relative risks in those with cardiac and respiratory disease and should be prepared to cope with complications as they arise.

History

The earliest recorded references to endoscopy are from Hippocrates in Greece (460–375 BC), who made reference to a rectal speculum. It was only in the 1970s that the problems of transmitting light, insufflation technology and optical technology were surmounted sufficiently for gynaecologists to embrace laparoscopic surgery. Laparoscopic techniques were not supported whole-heartedly by general surgeons until after 1987, when Mouret performed the first laparoscopic cholecystectomy in France. Following this, the rapid development of solid state video camera technology has further broadened the field of laparoscopic surgery.

The advantages of minimally invasive surgery are less ileus, the greatly reduced stress response to surgery and trauma, reduced acute phase reaction, reduced pain, reduced post-operative pulmonary dysfunction and reduced hospital stay. These also have economic advantages.

More procedures are being developed for laparoscopic surgery, including extraperitoneal inguinal hernia repair and retro-peritoneal nephrectomy and adrenalectomy. Routine general surgical laparoscopic procedures now include: oesophagectomy, Nissen's fundoplication, gastric banding, oversewing of peptic ulcer, intestinal resections, including hemicolectomy and col-ectomy, rectopexy and hernia repair.

Pathophysiology and complications of laparoscopy

The complications of laparoscopy include: haemorrhage, hypotension, decreased cardiac output, acidosis, pneumothorax, pneumomediastinum, subcutaneous emphysema, retroperitoneal carbon dioxide (CO_2), venous stasis, bradycardia, increased vagal tone, cardiac arrest, fatal venous CO_2 embolism, regurgitation and aspiration. Many of these complications are the result of peritoneal insufflation (pneumoperitoneum).

Pneumoperitoneum, the insufflation of the peritoneal cavity, is required to enable a gas milieu for visualization through the laparoscope (the operating telescope). CO_2 is used for laparoscopy because it is highly soluble in blood. Blood can carry large quantities of CO_2 as bicarbonate, carboxyhaemoglobin, and in plasma proteins. Carbon dioxide is eliminated rapidly and the lethal dose as an embolus is five times that of air. Usually a CO_2 gas embolism resolves rapidly, but if it is large, it can be fatal.

Pneumoperitoneum is achieved by insufflating the peritoneal cavity with CO_2 to a pressure of 10–18 mm Hg. The intra-peritoneal insufflation of CO_2 to these pressures causes respir-atory and haemodynamic changes.

Respiratory changes that occur as a result of pneumoperitoneum consist of a reduction of chest compliance by 30–50%. Airway pressures to maintain tidal volume rise to counter the reduction of chest compliance and the elevation of the diaphragm. Functional residual capacity of the lungs decreases and there is an increase in physiological dead space and shunt because of basal compression by the diaphragm and increased ventilation/perfusion mis-matching, which may result in a reduced arterial partial pressure of oxygen. Basal atelectasis may persist into the postoperative period. If minute volume is kept constant, end-tidal CO_2 increases due to absorption of CO_2 from the peritoneal cavity. The latter changes are usually countered by increasing the tidal volume and applying positive end-expiratory pressure (PEEP).

Haemodynamic changes also occur as a result of the pneumo-peritoneum. Compression of the inferior vena cava leads to a reduction in venous return, potentially followed by a fall in cardiac output. However, a reflex tachycardia and a massive increase in peripheral vascular resistance tends to maintain cardiac output at near-normal levels, by pulling blood centrally from the periphery, but with a concomitant increase in mean arterial blood pressure. This increase in myocardial work can result in myocardial ischaemia in those at risk and can lead to infarction, which may not occur until the postoperative period. Active vasodilatation and β blockade are often required to counter these effects.

Compression of the inferior vena cava causes reduced venous flow from the legs, resulting in venous stasis and an increased risk of venous thrombosis. Prophylactic anticoagulation and elastic stockings or pneumatic calf compressors should be used, especially in the elderly.

Respiratory and haemodynamic changes are affected by the patient's position. For example, head-up tilt, used for upper abdominal operations (e.g. cholecystectomy, Nissen's fundoplication) further inhibits venous return. Head-down tilt, used for colonic and pelvic surgery, promotes venous return, but aggravates respiratory changes, further reducing chest compliance and functional residual capacity and increasing basal compression.

Other complications of pneumoperitoneum include surgical emphysema, which can affect most tissues, including the conjunctivae and the scrotal sack. Cardiac arrhythmias can be secondary to vagal stimulation (bradycardia) or to hypercarbia (tachyarrythmias). Pneumothorax (including tension pneumo-thorax) may occur, particularly with upper abdominal procedures such as Nissen's fundoplication. Gastric reflux can occur because of increased intraperitoneal pressure, although retained gas in the stomach may obstruct the surgeon's view for upper abdominal operations. Pressure on the renal veins and arteries may cause a temporary reduction in renal function, due to reduced renal blood flow. Major CO_2 gas embolus seldom occurs and is usually the result of accidental direct injection of gas into a major vessel (e.g. the inferior vena cava). This may cause an obstruction to cardiac output when it reaches the heart. The treatment is to turn the patient onto the right side immediately and position them head down, causing the gas embolus to occupy the apex of the right ventricle, relieving the obstruction to ventricular outflow.

Anaesthetic technique

Preoperative assessment

Patients should be assessed carefully preoperatively, focussing on their cardiac function and reserve, because of the amount of extra cardiac work required during pneumoperitoneum. Patients with significant cardiac disease and limited cardiac reserve should be assessed by a cardiologist. It may be that an open procedure or even cancelling the procedure would be best for the patient. Patients with added risks of venous thrombosis should be treated prophylactically with fractionated heparin, elastic stockings and calf compressors during surgery. Surgery for patients with previously untreated hypertension should be postponed until treatment has stabilized. Respiratory function should also be assessed. Pulmonary function tests should be performed in those with significant pulmonary disease. Liver and renal function need to be ascertained because these organs may also be affected by pneumoperitoneum. Intercurrent medications (especially antihypertensives) should be given as normal on the morning of operation. A light sedative, such as a short-acting benzodiazepine, may be given before surgery.

Perioperative management

A routine intravenous induction is appropriate. It is preferable to intubate and ventilate patients undergoing laparoscopic surgery. This ensures a secure airway while ventilating with higher airway pressures and reducing the inherently small risk of aspiration from gastric regurgitation. A large-bore intravenous cannula should be placed to allow ready access for the management of major complications. In upper abdominal procedures a 12–16 FG oro- or nasogastric tube is passed to allow egress of gas from the stomach to facilitate the surgeon's view.

Maintenance may be by total intravenous or inhalational anaesthesia. Intermittent positive-pressure ventilation is preferable, to ensure adequate ventilation in the presence of the reduced compliance and elevated diaphragm caused by the pneumo-peritoneum.

Opioid supplementation aids analgesia and improves post-operative analgesia. This may be as intermittent morphine and diamorphine or as an infusion of a short-acting agent such as alfentanil or remifentanil.

Monitoring should be the minimum standard of non-invasive blood pressure, electrocardiograph, end-tidal CO_2, anaesthetic gases and pulse oximetry. For patients who require laparoscopic surgery, but who have very borderline cardiac function, invasive blood pressure and central venous pressure may be necessary, to allow closer control of cardiac function, in particular myocardial work. A pulmonary artery flotation catheter may be considered if there is concern regarding left heart function.

When peritoneal insufflation begins, there is often a reflex tachycardia and significant increase in blood pressure, even at deep levels of anaesthesia. To avoid hypertensive crises, with diastolic blood pressures above 120 mm Hg, it is advisable to have a vasodilator and β blocker available. Carefully titrated doses of labetalol can be effective, with its combined α and β effects. Occasionally, vagally-mediated bradycardia, even to the point of sinus arrest, may be seen. In this case, insufflation should cease immediately, while an appropriate vagolytic (e.g. atropine) is given. Ventilation should be adjusted to increase tidal volume and PEEP applied to counter the reduced compliance, elevated diaphragm and increased CO_2 load.

At the end of the procedure, it is preferable for the surgeon to infiltrate the small port wounds with long-acting local anaesthetic to reduce postoperative pain. The raw areas of tissue that occur after cholecystectomy can contribute to pain, due to carbonic acid formation by CO_2. Spraying the peritoneal cavity with bupivacaine may be effective in these cases.

Recovery

Pain in the immediate postoperative period can be severe, presumably due mainly to stretching of the tissues. Shoulder-tip pain is common, secondary to diaphragmatic irritation. Sitting the patient up and giving systemic analgesia should help this to settle. Occasionally, large doses of intravenous opioid are required for adequate relief. However, once the pain is controlled, recovery is rapid and the patient usually goes home in 2–3 days.

Postoperative complications

Surgical emphysema is occasionally alarming because it involves much of the trunk. It is advisable to deflate the scrotal sack before recovery. More generalized emphysema settles rapidly with time, but a pneumothorax should be excluded. The main problem with surgical emphysema is pain, which should be controlled systemically. Basal atelectasis with secondary pulmonary infection may also occur. It is more common in those with pre-existing pulmonary disease, and should be treated with antibiotics and physiotherapy. Aspiration may manifest as pleural effusions or rarely as Mendelson's syndrome. These may require the input of a respiratory physician, but are not usually a major problem in fasted patients.

The most serious complications are usually haemodynamic. Postoperative myocardial infarction can occur as a result of the increase in myocardial work during the procedure.

Deep venous thrombosis may occur due to venous stasis in the legs during surgery. This occasionally presents postoperatively with pulmonary embolus. ◆

Anaesthesia for Reconstructive Free Flap Surgery

Jane Quinlan

Jane Quinlan is Consultant Anaesthetist at the Radcliffe Infirmary and the John Radcliffe Hospital, Oxford. She qualified from St Thomas' Hospital, London, and trained in anaesthesia in London and Oxford. Her interests include anaesthesia for plastic surgery and acute pain management.

Reconstructive free flap surgery is a complex method of wound closure for large wounds not amenable to linear (primary) closure. It involves the transfer of free tissue (skin, muscle, bone, bowel or a combination) to a site of tissue loss where its circulation is restored via microvascular anastomoses. A muscle flap produces a more even contour and better aesthetic appearance than that achieved by a simple skin graft and provides a better defence against infection. The defect may be caused by trauma, infection or extensive surgery (e.g. mastectomy, head and neck cancer). The site and size of the defect determines which flap is used. The most commonly used flaps are the gracilis muscle for lower leg trauma; latissimus dorsi and rectus abdominis for breast reconstruction; and pectoralis major and radial forearm flap for head and neck reconstruction.

In patients with lower third tibulofibular defects, free tissue transfer is typically required. The bony injury should be repaired and adequate debridement achieved before skin and muscle coverage begins. This should occur within the first 6 days after injury before colonization of the wound and the risk of complications increases. In patients with multiple trauma, any life-threatening injuries must be addressed first and the patient's haemodynamic status stabilized before reconstructive surgery is contemplated.

Flap transfer

The free flap is transferred with its accompanying artery and vein, which are then reattached to vessels at the donor site using microvascular techniques. The stages of flap transfer are:

- flap elevation and clamping of vessels
- primary ischaemia as blood flow ceases and intracellular metabolism becomes anaerobic (this is dependent on surgical time and lasts 60–90 minutes)
- reperfusion as the arterial and venous anastomoses are completed and the clamps released
- secondary ischaemia is subsequent to hypoperfusion of the flap (minimized by appropriate anaesthetic management).

Primary ischaemia

With cessation of blood flow, the flap becomes anoxic. In the presence of anaerobic metabolism, lactate accumulates, intra-cellular pH drops, ATP decreases, calcium levels rise and pro-inflammatory mediators accumulate. The severity of the damage caused by primary ischaemia is proportional to the duration of ischaemia. Tissues with a high metabolic rate are more susceptible to ischaemia, therefore skeletal muscle in a flap is more sensitive to ischaemic injury than skin. At the conclusion of primary ischaemia, the changes in the flap tissue include:

- narrowed capillaries due to endothelial swelling, vasoconstriction and oedema
- sequestration of leucocytes ready to release proteolytic enzymes and reactive oxygen intermediates
- diminished ability of endothelial cells to release vasodilators and degrade ambient vasoconstrictors
- end-organ cell membrane dysfunction and accumulation of intracellular and extracellular toxins
- up-regulation of enzyme systems to produce inflammatory mediators.

Reperfusion begins with the release of the vascular clamps. Normally, the re-establishment of blood flow reverses the transient physiological derangement produced by primary ischaemia. The flap recovers with minimal injury and normal cellular metabolism is restored. However, an ischaemia/reperfusion injury may result if factors in the flap are unfavourable. Prolonged ischaemia time or poor perfusion pressure make this more likely. Reperfusion injury occurs when the restored blood flow allows the influx of inflammatory substrates that may ultimately destroy the flap.

Secondary ischaemia occurs after a free flap has been transplanted and reperfused. This period of ischaemia is more damaging to the flap than primary ischaemia. Flaps affected by secondary ischaemia have massive intravascular thrombosis and significant interstitial oedema. Fibrinogen and platelet concentrations are increased in the venous effluent. Although skin flaps can tolerate 10–12 hours of ischaemia, irreversible histopathological changes in muscle can be seen after 4 hours.

Causes of flap failure: the general causes of poor flap perfusion may be classified as arterial, venous or resulting from oedema. The arterial anastomosis may be inadequate, in spasm or thrombosed. The venous anastomosis may similarly be defective, in spasm or compressed (e.g. by tight dressings or poor positioning). Oedema reduces flow to the flap and may be a result of excessive crystalloids, extreme haemodilution, trauma from handling or a prolonged ischaemia time. Flap tissue has no lymphatic drainage and is therefore susceptible to oedema.

Microcirculation: the blood flow through the microcirculation is crucial to the viability of a free flap. The microcirculation is a series of successive branchings of arterioles and venules from the central vessels. Regulation of blood flow and oxygen delivery is accomplished by three functionally distinct portions of the microcirculation: the resistance vessels, the exchange vessels and the capacitance vessels.

The resistance vessels are the muscular arterioles that control regional blood flow. Arterioles range in diameter from 20 μm to 50 μm and contain a relatively large amount of vascular smooth muscle in their walls. Alterations in vascular smooth muscle tone are responsible for active constriction and dilation in arterioles and thus control resistance to blood flow.

The capillaries constitute the network of vessels primarily responsible for the exchange function in the circulation. Small bands of vascular smooth muscle, the precapillary sphincters, are located at the arterial end of many capillaries and are responsible for the control of blood flow within the capillaries.

The venules act as the capacitance vessels, which collect blood from the capillary network and function as a reservoir for blood in the circulation.

The vascular bed of skeletal muscle has rich adrenergic in-nervation and therefore has a marked vasoconstrictor response to neural stimulation, primarily through the resistance vessels. Precapillary sphincters also constrict in response to sympathetic stimulation, but are sensitive to local factors such as hypoxia, hypercapnia, and increases in potassium, osmolality and mag-nesium, which may cause relaxation. Other vasoactive hormones (e.g. renin, vasopressin, prostaglandins, kinins) also have a role in microvascular control.

Transplanted vessels in a free flap have no sympathetic innervation but are still able to respond to local and humoral factors, including circulating catecholamines.

The flow behaviour (rheology) of blood in the microcirculation is determined by the red cell concentration, plasma viscosity, red cell aggregation and red cell deformability. Following all surgery under general anaesthesia, the changes in blood rheology include:

- increased platelet aggregation and adhesion
- an impairment of red cell deformability
- an increase in whole blood viscosity
- increased clotting factors
- increased plasma fibrinogen and red cell aggregation
- disturbance of fibrinolysis.

Normal levels of 2,3-diphosphoglycerate (2,3-DPG) are required for optimal red cell deformability. After blood transfusion, this deformability is impaired owing to the negligible amount of 2,3-DPG in stored blood.

Physiology

The physiological status of the patient has a major influence on the viability of the transferred tissues, so the conduct of anaesthesia and postoperative management have a direct effect on outcome. Surgery is long (often 6–8 hours) with multiple sites for tissue trauma, resulting in extensive blood and fluid losses as well as heat loss. The resulting hypovolaemic vasoconstriction and hypothermia, if not corrected, compromise blood flow to the flap and result in flap failure.

Even with good fluid management, blood flow to a flap may decrease by 50% for 6–12 hours postoperatively. The guiding principle of anaesthesia for free flap surgery is the maintenance of optimum blood flow. The determinants of flow are summarized by the Hagen–Poiseuille equation:

$$\text{Laminar flow} = \frac{\Delta P \times r^4 \times \pi}{8 \times \eta \times l}$$

where: ΔP is the pressure difference across the tube, r is the radius of the vessel, η is viscosity and l is the length of the tube.

From this we may deduce that the goals of anaesthesia for free flap surgery are vasodilatation, good perfusion pressure and low viscosity.

Vasodilatation

Vessel radius is the most important determinant of flow, for the vessels supplying the flap as well as those in the flap.

Temperature – the patient should be kept warm in theatre, the recovery room and the ward for the first 24–48 hours. This is best achieved by raising the ambient temperature in theatre and by using a warm air blanket. Active warming should begin before the start of anaesthesia because patient cooling occurs rapidly after induction of anaesthesia. In an awake patient, the central core temperature is higher than that of the peripheral tissue and skin temperature. After the induction of anaesthesia, vasodilatation modifies the thermal balance between compartments. The volume of the central compartment enlarges leading to a decrease in its mean temperature, while the temperature of the peripheral and skin compartments increases. At thermoregulation, the size of the central compartment becomes smaller owing to vasoconstriction, which leads to an increase in the mean temperature, although the peripheral and skin temperatures fall.

In addition to vasoconstriction, hypothermia also produces a rise in haematocrit and plasma viscosity, the aggregation of red blood cells into rouleaux, and platelet aggregation. These effects may reduce the microcirculatory blood flow in the flap.

Fluid – peripheral vasoconstriction due to an underestimation of fluid losses is common. There are two operating sites in free flap transfer: the donor site and the recipient site. Both have insensible fluid losses and both may have blood losses. A warm theatre environment also increases fluid loss. Modest hypervolaemia reduces sympathetic vascular tone and dilates the supply vessels to the flap. An increase in central venous pressure of 2 cm H_2O above the control measurement can double the cardiac output and produce skin and muscle vasodilatation. Figure 1 gives a guide to fluid management.

Guide to fluid management

Crystalloids
- 10–20 ml/kg to replace preoperative deficit
- 4–8 ml/kg/hour to replace insensible losses

Colloids
- 10–15 ml/kg for haemodilution
- To replace blood loss

Blood
- To maintain haematocrit at 30%

Dextran
- Often given postoperatively

1

Anaesthesia – isoflurane has the advantage over other volatile anaesthetics and propofol that it causes vasodilatation with minimal myocardial depression. Propofol inhibits platelet aggregation which could reduce the risk of thrombosis. This may be due to an effect of intralipid on the platelet–erythrocyte interaction, and by the increased synthesis of nitric oxide by leucocytes.

Vasospasm of the transplanted vessels may occur after surgical handling or after damage to the intima of the vessels, and can occur during surgery or postoperatively. The surgeons may use topical vasodilators such as papaverine, lidocaine (lignocaine) or verapamil during the operation to relieve the vasospasm.

Sympathetic blockade – epidural, brachial plexus or interpleural local anaesthetic infusions, used intraoperatively and postoperatively, provide sympathetic blockade to further dilate vessels. Concerns have been raised that the sympathetically-denervated transplanted vessels would be unable to dilate after lumbar epidural blockade, resulting in a 'steal' effect reducing flap blood flow. In fact, provided any hypotension due to the sympathetic block is treated appropriately, blood flow to the flap improves as a result of the increased flow through the feeding recipient artery. Other advantages of epidural analgesia include a reduction in intraoperative and postoperative blood loss and vessel spasm; a lower incidence of deep venous thrombosis; improved diaphragmatic function and more rapid post-operative recovery. Good analgesia reduces the level of circulating catecholamines and avoids the vasoconstrictor response to pain.

Perfusion pressure

The preservation of a good perfusion pressure with wide pulse pressure is essential to flap survival. Appropriate anaesthetic depth and aggressive fluid management are usually all that is needed. Most inotropes are contraindicated owing to their vasoconstrictive effects, but if required, dobutamine and low-dose dopamine could be used.

Viscosity

Isovolaemic haemodilution to a haematocrit of 30% improves flow by reducing viscosity, reducing reperfusion injury in muscle and increasing the number of patent capillaries, which decrease tissue necrosis. Further reductions in haematocrit do not provide much more advantage because the curve of viscosity versus haematocrit flattens off markedly (Figure 2). If the haematocrit falls further, the marginally improved flow characteristics from a lower viscosity may then be offset by a reduction in oxygen delivery:

$$DO_2 = CO \times [(Hb \times sat \times 1.34) + (PaO_2 \times 0.003)]$$

A low haematocrit also increases myocardial work, therefore care should be taken in patients with poor cardiac reserve.

Viscosity versus haematocrit

Practical conduct of anaesthesia

Monitoring

In addition to basic monitoring, these patients require invasive blood pressure monitoring to enable safe manipulation of the perfusion pressure. Direct measurement of arterial pressure gives a continuous record of the pressure and is more accurate than non-invasive indirect techniques. An arterial cannula also provides access to blood gas analysis and haematocrit estimations.

Central venous pressure reflects cardiac filling pressures and can be manipulated to increase cardiac output.

Core temperature measurement is essential when active warming is instituted. A nasopharyngeal or rectal probe is used intraoperatively for a continuous reading, while intermittent tympanic or axillary measurements are used in the recovery and ward areas.

Peripheral temperature is also measured because a fall in skin temperature can reflect hypovolaemia and vasoconstriction. A difference of less than 2°C between core and peripheral temp-eratures indicates a warm, well-filled patient. The temperature of the skin flap is sometimes monitored postoperatively because a drop in temperature may herald flap failure. However, this is not a sensitive test, because by the time the temperature has fallen the flap will have suffered sufficient vascular damage to render it virtually unsalvageable.

Urine output is another indicator of volume status. A urine output of 1–2 ml/kg/hour should be maintained intraoperatively and postoperatively with appropriate fluid management. Diuretics are contraindicated in these operations because volume depletion compromises flap survival.

Induction

Active warming starts before the patient is asleep. The ambient temperature in theatre is raised to about 22–24°C, a level high enough to reduce patient heat loss, but not too hot to be uncomfortable for the theatre staff. The patient is covered in a hot air blanket before induction of anaesthesia and this remains in place while the patient is prepared for theatre. Once in theatre, the blanket is moved to enable surgical access, but with as much surface area coverage as possible.

If appropriate, a regional block is inserted, preferably to cover the free flap recipient site (rather than the donor site) for the full benefit of the sympathetic block. The patient is intubated and ventilated; and a large gauge peripheral line, central line, arterial line, urinary catheter and core temperature and skin temperature probes are positioned.

Nitrous oxide diffusion into air in the stomach combined with gastric stasis results in gastric distension, with associated post-
operative nausea and vomiting. A nasogastric tube is therefore sited at intubation, left on free drainage, then aspirated and removed at the end of the operation.

Fluid, administered through a fluid warmer, is started in the anaesthetic room to compensate for preoperative dehydration.

Maintenance

Careful positioning of the patient is imperative for such a long operation. Limbs are positioned and supported to avoid neuro-logical damage or vascular compression. Eyes are taped and lightly padded to reduce the incidence of corneal abrasion and prevent drying of the cornea.

Prophylaxis against deep venous thrombosis is necessary for all patients. Subcutaneous heparin or low-molecular-weight heparin is given preoperatively, while anti-embolism (TED) stockings and compression boots are used intraoperatively.

The patient is ventilated to normocapnia. Hypocapnia increases peripheral vascular resistance and reduces cardiac output, while hypercapnia causes sympathetic stimulation. If the surgeon uses the microscope for vessel preparation or anastomosis on the chest or abdomen, the tidal volume is reduced to minimize movement in and out of the surgeon's field of vision. The respiratory rate is then increased to maintain minute ventilation.

Controlled hypotension is useful during the initial dissection and is most easily achieved using epidural local anaesthetic and/or isoflurane. An infusion of glyceryl trinitrate may be added if needed.

Crystalloids are used to replace the preoperative fluid deficit from starvation and to cover intraoperative insensible losses. The latter are high because the warm theatre increases evaporative losses from the two operating sites. Excessive use of crystalloid may precipitate oedema in the flap.

Hypervolaemic haemodilution is achieved using colloids.

Blood gas analysis and haematocrit measurement should be carried out at the start of the operation and repeated every 2 hours.

By the time the flap is reperfused, the patient should be warm, well-filled and sympathetically blocked with a high cardiac output.

Emergence and recovery

The patient should wake up pain-free. Analgesia is maintained postoperatively with local anaesthetic infusions for regional blocks, intravenous patient-controlled analgesia, or both. Coughing and vomiting increase venous pressure and reduce flap flow, so smooth emergence and extubation are needed. The principles of perioperative and postoperative care are listed in Figure 3. ◆

Principles of perioperative and postoperative care

- Maintain high cardiac output
- Normal arterial blood pressure (systolic >100 mm Hg)
- Low systemic vascular resistance
- Normothermia
- High urine output (> 1 ml/kg/hour)
- Effective analgesia
- Haematocrit 30–35%
- Monitoring of blood flow in flap (Doppler postoperatively)

The Anaesthetic Machine

Michael O'Connor
Ian Taylor

Duncan Parkhouse is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Ian Taylor is Specialist Registrar in Anaesthesia in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and is training at the Wessex School of Anaesthesia, based in Southampton, UK. His interests are vascular and obstetric anaesthesia.

Many anaesthetic machines incorporate patient monitoring; conventionally this is considered separately and will not be discussed here.

Types of anaesthetic machine

Demand and intermittent flow machines
The patient's inspiration controls the flow of fresh gases. Such machines have been used for dental anaesthesia (e.g. the McKesson anaesthetic machine) and for military field anaesthesia (the Triservice apparatus).

Continuous flow machines (Boyle's machine)
Continuous flow machines are encountered in day-to-day hospital practice in the UK. The driving force for gas flow is compressed gases. This contribution discusses continuous flow machines.

Pressures in the anaesthetic machine

Units of pressure
To understand the anaesthetic machine, it is important to be able to relate the various different units that are used to describe pressure; 1 atmosphere pressure is approximately:

- 101 kPa
- 760 mm Hg
- 1035 cm H_2O
- 1 bar
- 15 psi.

Absolute and gauge pressure

- Absolute pressure is pressure above that in a vacuum.
- Gauge pressure is pressure above atmospheric. Pressures in the anaesthetic machine are always quoted as gauge pressures.

All pipeline pressures are 400 kPa except for pressure in the air pipeline used to drive equipment such as orthopaedic drills, which is 700 kPa. Cylinder pressures are reduced to a machine working pressure of 400 kPa by pressure regulators (see below, page 66).

Pressure downstream of the flowmeters can range between zero (i.e. 1 atmosphere pressure), when the common gas outlet is open to the atmosphere, and about 33 kPa if the common gas outlet is completely obstructed and the safety valve in the back bar vents to the atmosphere.

Measurement of pressure
Cylinder and pipeline pressures are measured by a Bourdon pressure gauge (Figure 1). This is an aneroid (i.e. without liquid) gauge consisting of a coiled tube attached at one end to the gas supply and at the other to a pointer. The pressure of the gas causes straightening of the coil and thus movement of the pointer over the colour-coded, labelled and calibrated dial (Figure 2). The gauge is faced with heavy glass and designed such that leaks vent from the back of the valve casing and do not blow out the glass.

Bourdon pressure gauge

1

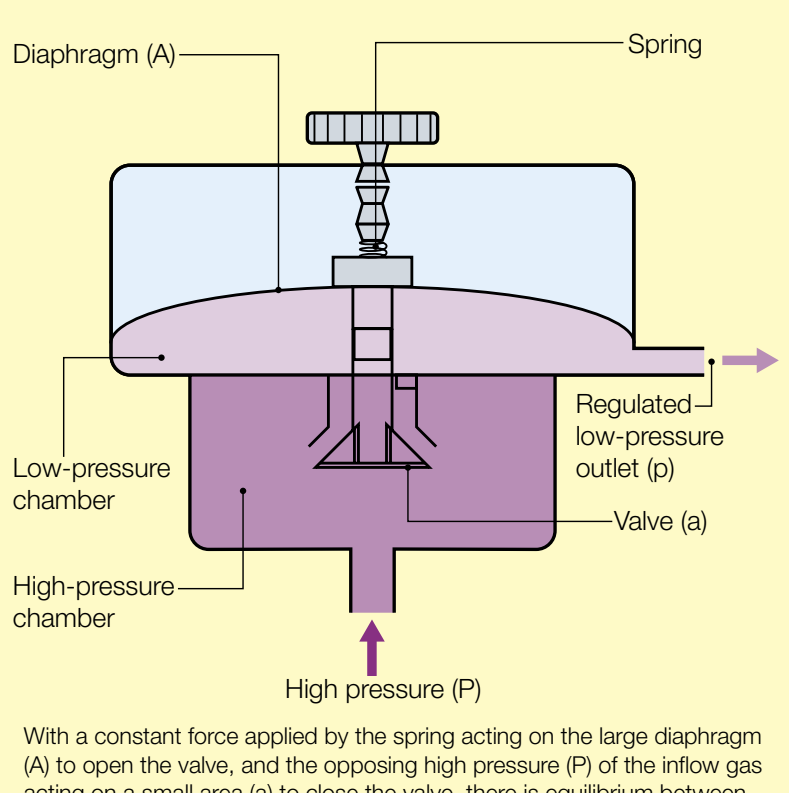
2 Bourdon pressure gauge.

Pressure regulators
Although sometimes referred to as pressure-reducing valves, the term pressure regulators is preferred because their function is not simply to reduce pressure, but in doing so to allow more accurate control of flow and to make up for the fall in cylinder pressures as they empty.

Figure 3 demonstrates the function of a pressure regulator. The principle is similar to that of the pressure-relief valve (see *Anaesthesia and Intensive Care Medicine* **1:3:** 107) except that there are two chambers, one of high pressure and the other of low, and two discs of different areas.

Pressure regulator



With a constant force applied by the spring acting on the large diaphragm (A) to open the valve, and the opposing high pressure (P) of the inflow gas acting on a small area (a) to close the valve, there is equilibrium between the high- and low-pressure chambers. To balance the equilibrium and keep the valve open, the pressure in the second chamber is thus reduced. Thus: P x a = p x A, where P = pressure in the high-pressure chamber; p = pressure in the low-pressure chamber; A = area of large diaphragm; a = area of small diaphragm.

Adjustment of the tension in the spring and thus the force it applies to the discs, regulates the pressure at the outlet to produce a constant operating pressure. As the inlet pressure falls during use of the cylinder, the force from the spring opens the valve wider, allowing more gas to flow into the second chamber and maintaining pressure at the outlet. The opposite happens if the inlet pressure rises, resulting in valve closure and thus less flow into the second chamber.

3

Flowmeters

Rotameters
Flow in most anaesthetic machines is measured by a variable orifice flowmeter known as a rotameter. A rotameter consists of a bobbin that floats in a glass tube with a diameter that increases with height up the tube. The pressure drop across the bobbin remains constant, and as flow increases it rises up the tube.

The two important properties of the gas flowing through a rotameter that influence its calibration are:

- viscosity
- density.

Gas flows in the annulus between the bobbin and the tube. At the lower end of the tube the annulus is long with respect to its cross-sectional area, and flow is laminar and dependent on the viscosity of the gas. Higher up the tube, the cross-sectional area of the annulus is greater, the gas is effectively flowing through an orifice, and flow is turbulent and dependent on the density of the gas (Figure 4).

Flowmeter

Laminar flow around the bobbin at the bottom of the tube, turbulent flow at the top. NB Pitch of the rotameter tube has been greatly exaggerated

4

Features of rotameters

- For any given gas, the flow through a rotameter depends on both its viscosity and its density. Rotameters therefore have to be calibrated individually for the gas they will be measuring.
- The bore may be varied to measure low flows accurately.
- The back plate may be luminous.
- Calibration is from the lowest accurate point, not zero.
- Accuracy is ± 2%.
- In many machines there is a constant low flow of oxygen.

Potential sources of inaccuracy in rotameters

- If the tube is not truly vertical, the annulus between the tube and the bobbin is altered.
- Static electricity can cause inaccuracies. To minimize this, glass is conductive and sprayed with antistatic material.
- Dust can collect on the bobbin or within the tube.
- Tubes may be damaged. In the UK, the oxygen rotameter tube is on the left (said to be because Boyle was left-handed). This can mean that any damage to the tubes would preferentially leak oxygen and result in the delivery of a hypoxic mixture. Many manufacturers now arrange the order in which the gases finally mix so that oxygen is the last gas added to the mixture.
- The top-sealing washer may be defective.
- The carbon dioxide bobbin may become stuck at the top of the tube.
- Back pressure from a minute volume divider such as a Manley ventilator increases the density of the gas and may cause the rotameter to under-read by about 7%.
- Atmospheric pressure affects density. Low pressure gives over-reading.
- Temperature affects density and viscosity. Increased temperature causes decreased density and increased viscosity.

Vaporizers

Vaporizers are discussed elsewhere.

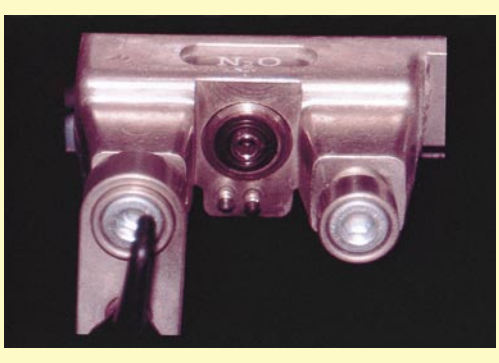
Safety

The anaesthetic machine has several in-built safety features that vary from machine to machine. The commonly found features that are of importance to anaesthetists are listed in Figure 5.

Perhaps the most important safety feature is that the machine should always be checked in a systematic fashion before use. The Association of Anaesthetists of Great Britain and Ireland has published a useful checklist, part of which is reproduced in Figure 6. These checks must be performed at the beginning of each theatre session.

Anaesthetic machine – safety features

- Non-interchangeable pipeline outlets (often referred to as Schrader connectors, though this is really a trade name)
- Pipelines are coloured and marked with the name of the gas
- Non-interchangeable screw thread connectors connect the pipeline to the anaesthetic machine
- The pin index system prevents accidental connection of the wrong cylinder to the wrong yoke
- Cylinders are coloured and marked with the name of the contents
- Grease can be flammable or explosive in contact with gases at high pressure. A Bodok seal (see below) makes a gas-tight connection between cylinder and yoke
- There are pressure gauges for pipelines and cylinders
- Rotameter knobs are identified by the oxygen knob being a distinctive colour and shape and more prominent
- The oxygen rotameter outlet may be diverted to enter the gas flow last
- Oxygen and nitrous oxide rotameters may be linked to prevent delivery of a hypoxic mixture
- The oxygen bypass can provide oxygen at high flow (> 30 litres/minute) directly to the common gas outlet
- There is an oxygen failure warning device triggered by a dropin the oxygen pressure, which also vents the flow of anaesthetic gases to the atmosphere to prevent delivery of a hypoxic mixture
- Vaporizer fillers are keyed to prevent a vaporizer being accidentally filled with the wrong agent
- Vaporizers may be arranged so that only one can be turned on at a time
- There is a machine pressure-relief valve in the back bar that prevents the pressure rising above about 33 kPa
- The machine is serviced regularly by a qualified engineer



Bodok seal.

Anaesthesic machine – safety checks

Anaesthetic machine

- Check that the anaesthetic machine and relevant ancillary equipment are connected to the mains electrical supply (where appropriate) and switched on
- Careful note should be taken of any information or labelling on the anaesthetic machine that might refer to its current status

Oxygen analyser

- The oxygen analyser should be placed where it can monitor the composition of the gases leaving the common gas outlet
- The analyser should be switched on, checked and calibrated according to the manufacturer's instructions

Medical gas supplies

- Identify and take note of the gases that are being supplied by the pipeline, confirming with a 'tug test' that each pipeline is correctly inserted into the appropriate gas supply terminal
- Check that the anaesthetic apparatus is connected to a supply of oxygen and that an adequate reserve supply of oxygen is available from a spare cylinder
- Check that adequate supplies of any other gases intended for use are available and connected as appropriate. All cylinders should be securely seated and turned ***Off*** after checking their contents. Carbon dioxide cylinders should not normally be present on the anaesthetic machine. A blanking plug should be fitted to any empty cylinder yoke
- All pressure gauges for pipelines connected to the anaesthetic machine should indicate 400 kPa
- Check the operation of flowmeters, ensuring that each control valve operates smoothly and that the bobbin moves freely through its range without sticking. With only the oxygen flow control valve open and a flow of about 5 litres/minute, check that the oxygen analyser display approaches 100%.

Turn off all flow control valves

- Operate the emergency oxygen bypass control and ensure that flow occurs without significant decrease in the pipeline supply pressure. Confirm that the oxygen analyser display approaches 100% during this test. Ensure that the emergency oxygen bypass control ceases to operate when released

Vaporizers

- Check that the vaporizer(s) for the required volatile agent(s) are fitted correctly to the anaesthetic machine, that any back bar locking mechanism is fully engaged and that the control knobs rotate fully through the full range(s). Ensure that the vaporizer is not tilted.

Turn off the vaporizers

- Check that the vaporizer(s) are adequately filled and that the filling port is tightly closed
- Set a flow of oxygen of 5 litres/minute and, with the vaporizer turned off, temporarily occlude the common gas outlet. There should be no leak from any of the vaporizer fitments and the flowmeter bobbin should dip.

Turn each vaporizer on in turn and repeat this test. There should be no leak of liquid from the filling port.

After this test, ensure that the vaporizers and flowmeters are turned off

Should it be necessary to change a vaporizer at any stage, it is essential to repeat the leak test.

Failure to do so is one of the most common causes of critical incidents

Removal of a vaporizer from a machine in order to refill it is not considered necessary

Artificial Ventilation in the Operating Theatre

Elaine M Wilson-Smith
J Duncan Young

Elaine M Wilson-Smith is Anaesthetic Specialist Registrar and Neuroanaesthesia Fellow at the Radcliffe Infirmary, Oxford, UK. She qualified from Guy's Hospital, London, and has trained in anaesthetics in Leicester, Alder Hey Hospital, Liverpool, and Oxford.

J Duncan Young is Clinical Reader in Anaesthetics at the Oxford Radcliffe Hospitals Trust. He qualified from Southampton University and trained in anaesthesia and intensive care in Southampton, Oxford and North America. His interests include artificial ventilation and techniques to improve arterial oxygenation in ICU patients.

Ventilators are used in two main settings: the operating theatre and the ICU.

- In the operating theatre, ventilators are used to maintain ventilation in anaesthetized, intubated, pharmacologically paralysed patients who have predominantly normal lungs. These ventilators are designed to interface with anaesthetic gas circuits to allow varying concentrations of oxygen, anaesthetic gases and volatile agents to be delivered to the patient. Most theatre ventilators are relatively simple, mechanical or electromechanical devices that do not have patient-sensing capabilities.
- Ventilators are often used in the ICU to ventilate patients with abnormal lungs, who require only air and oxygen as respiratory gases; these patients are seldom paralysed and often require only partial respiratory support. The ventilators used are almost all complex, computer-controlled devices with sensitive mechanisms to detect the patient's respiratory efforts.

This contribution discusses ventilators for theatre use, though many of the basic principles apply to ICU devices.

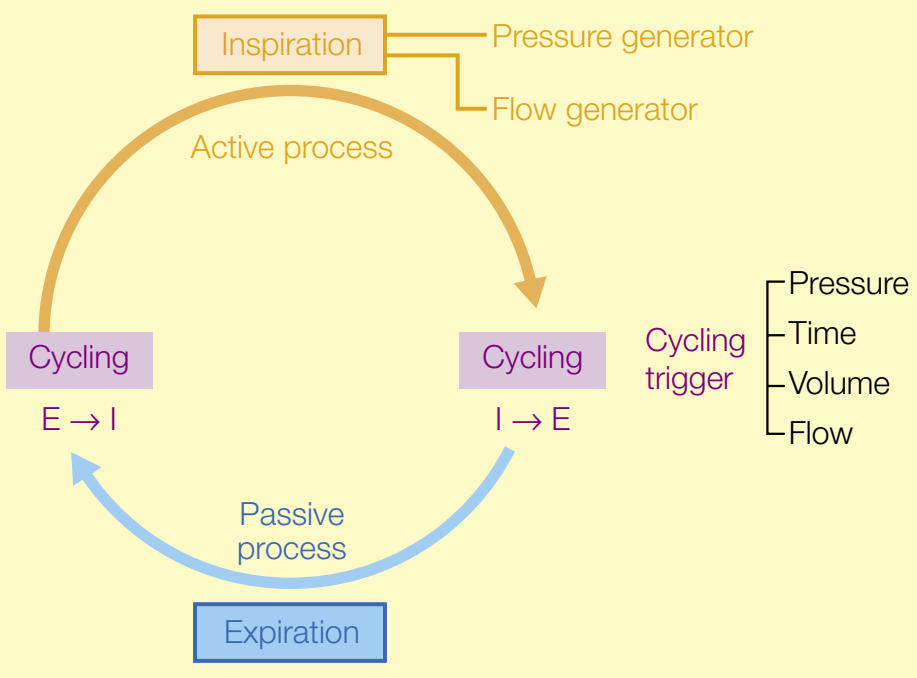
Classification of anaesthetic ventilators

Ventilators can be classified according to their function and operation.

- Functional classification is the most common and clinically useful system. It is based on the pattern of gas that the ventilator generates during inspiration, and the mechanism that cycles between inspiration and expiration (Figure 1).
- Operational classification is based on parameters such as power source or driving mechanism. Operational classification is not covered in this contribution.

Ventilator classifications were devised when most ventilators had only one mode of ventilation. Examples of such ventilators are the Manley ventilator (a time-cycled pressure generator), the Nuffield 200 ventilator (a time-cycled flow generator) and paediatric theatre ventilators (time-cycled pressure generators). Modern theatre ventilators and all ICU ventilators can operate in two or more ventilatory modes and so do not fit neatly into one single category of the traditional functional classification.

Functional classification of the respiratory cycle during intermittent positive-pressure ventilation



Based on Mapleson classification. I, inspiration; E, expiration

1

Functional classification of ventilators

The important difference between pressure and flow generators is the pattern of gas flow produced during inspiration. This influences the effects of changes in airway resistance, or lung and chest wall compliance, or if there is leak of delivered gases from the system. A summary of the important differences between pressure and flow generators is shown in Figure 2. Knowledge of the basic respiratory mechanics is vital to understanding ventilator–patient interactions.

Pressure generators and flow generators

2

Resistance, compliance and time constants: the pressure required to cause gas to flow into the lungs has two components:

- that required to maintain gas flow along the airways, overcoming airways resistance
- that required to overcome the elastic recoil of the respiratory system, determined by compliance.

The interaction of these components determines the time constant (TC).

TC defines the rate of a simple (first-order) exponential process. It is equivalent to the time taken for the exponential process to complete if it were to continue at the same rate as that at which it began. TC describes how fast the lungs fill with a constant applied airway pressure or how fast they empty during expiration. (TC = compliance x resistance.) It increases with increasing resistance (e.g. in asthmatics) and decreases with decreasing compliance (e.g. in pulmonary fibrosis).

Resistance is a measure of the resistance to gas flow. The major site of respiratory resistance is in the medium-sized bronchi, but total respiratory resistance during positive-pressure ventilation also includes the contribution of the endotracheal tube and to a lesser extent the circuit. In a patient with normal lungs, this increases the total respiratory resistance from 2 to 4–6 cm H_2O/litre/second.

Compliance describes the elasticity of the respiratory system, or the ease with which it inflates, and is measured as the volume change per unit pressure. Total respiratory compliance consists of combined lung and chest wall compliance and is normally 50–70 ml/cm H_2O.

Within the normal working range of the lung compliance is constant though it decreases at extremes of volume. The contribution to compliance from the ventilator circuit is usually small. The exception is during anaesthesia in neonates and infants when the tidal volume is small compared with the circuit volume, and compression of gas within the circuit can make it difficult to ensure that accurate and adequate tidal volumes are delivered (Figure 3).

Effect on artificial ventilation − increased airways resistance and reduced lung and chest wall compliance are the most clinically significant changes in respiratory mechanics affecting artificial ventilation. Some causes are shown in Figure 4.

Resistance, compliance and time constant

3

Causes of increased airways resistance and reduced respiratory compliance

Increased airways resistance	Reduced respiratory compliance
• Bronchospasm – asthma, chronic obstructive airway disease (COAD)	• Within lung – pulmonary oedema, adult respiratory distress syndrome, fibrosis, atelectasis
• Mucosal swelling – asthma, COAD	• Around lung – pleural effusion, upward compression from abdominal contents when supine, especially if obese
• Luminal obstruction – excessive secretions	• Chest wall – surgeon compressing chest, expiration retractors, scoliosis, contractures
• Foreign body – tumour	
• Emphysema – dynamic airway compression during	
• Low lung volume	

4

Pressure and flow generators: an understanding of the different types of ventilator and how they function helps predict the behaviour and limitations of each type of machine when resistance and compliance of the lungs change (Figure 5).

Pressure generators - a pressure generator applies a preset positive-pressure waveform to the airway for the duration of inspiration. In its simplest form this pressure is constant (Figure 6).

If the inspiratory time is sufficiently long, the respiratory compliance determines the tidal volume delivered when a given airway pressure is applied. The respiratory compliance decreases linearly with lung size, therefore a pressure generator set at 15−20 cm H_2O delivers an appropriate tidal volume to a small child or an adult with normal lungs.

Pressure generators can maintain the required airway pressure, even in the presence of a leak, within reasonable limits. As a result, the main use for pressure generators in anaesthetic practice is to ventilate children. The cricoid ring is the narrowest point of the airway in children. The insertion of endotracheal tubes can lead to compression of the tracheal mucosa against the cricoid cartilage, resulting in pressure necrosis. This can be avoided by using uncuffed endotracheal tubes; the presence of an air leak during inspiration confirms that the endotracheal tube is not lodged tightly in the cricoid ring.

The pressure generator ensures that adequate tidal volumes are delivered because a consistent pressure is maintained despite the leak. Paediatric patients, particularly neonates, are prone to ventilator-induced lung damage, and constant pressure generators ensure that even when lung dynamics change, the applied pressure remains constant.

Pressure generators are designed for use with normal lungs that remain normal during surgery (delivered tidal volume = pressure x compliance.) The main disadvantage of a pressure generator is that tidal volume is determined by compliance and reductions in compliance may cause significant reductions in delivered tidal volume and minute ventilation. Therefore, pressure generators may not be appropriate when precise control of arterial carbon dioxide tension ($PaCO_2$) is important, for example, during neurosurgery.

Flow generators (Figure 7) are devices that produce a constant gas flow independent of respiratory compliance or resistance. The volume delivered per unit time remains constant even in the presence of high airway pressures. All flow generators need a high-pressure gas source. This can be delivered by compressing bellows or by using proportional control valves, which control gas flow from the pipeline supply.

The delivered tidal volume is determined by control of the inspiratory flow rate and inspiratory time. The peak and mean airway pressure generated depends on the tidal volume, inspiratory flow rate, respiratory compliance and resistance.

The main advantage of a constant flow generator is that a constant tidal volume and minute ventilation are maintained even when the mechanics of the lung are changing. The tidal volume can be set precisely and minute ventilation is predictable and consistent, giving precise control of $PaCO_2$.

The main disadvantage is the potential for high airway pressures and barotrauma if changes in lung mechanics occur. There is also no ability to compensate for leaks. Flow generators are used mainly for adults, particularly where lung mechanics are abnormal, and when precise control of $PaCO_2$ is required.

Cycling parameters - cycling is the process of stopping one phase of ventilation and changing to the next. This occurs twice within each delivered breath. For the purposes of classification, cycling marks the end of inspiration and the beginning of expiration. Ventilators may be:

- time-cycled – cycling occurs after preset time
- volume-cycled – cycling occurs after preset volume delivered
- pressure-cycled – cycling occurs after preset pressure attained
- flow-cycled – cycling occurs when flow falls below a preset value.

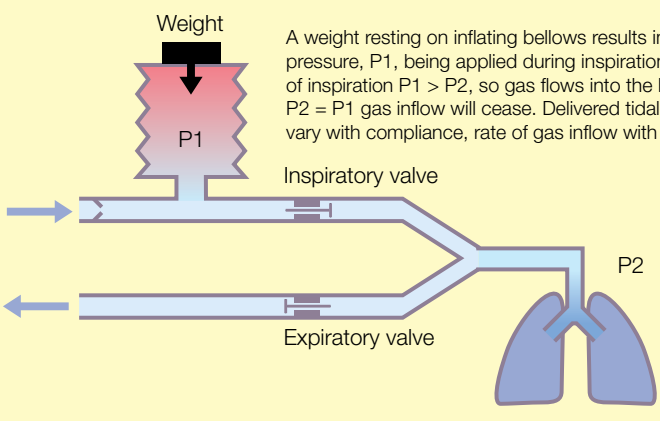
Time cycling is the most common technique. Flow cycling is used in inspiratory pressure support in the ICU but seldom in theatre. Volume and pressure cycling are used infrequently. In most ventilators, cycling from expiration to inspiration is by time.

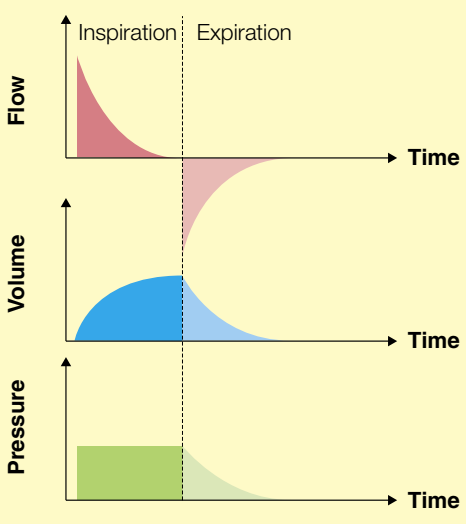
Advantages and disadvantages of pressure and flow generators

	Pressure generators	Flow generators
Advantages	• Protection from high airway pressures and barotrauma • Compensate for leaks	• Ability to maintain a constant tidal volume and minute ventilation even with significant changes in lung mechanics • Precise control of $PaCO_2$
Disadvantages	• Hypoventilation as a result of changes in lung mechanics	• Potential for high airway pressures and barotrauma • Inability to compensate for leaks

5

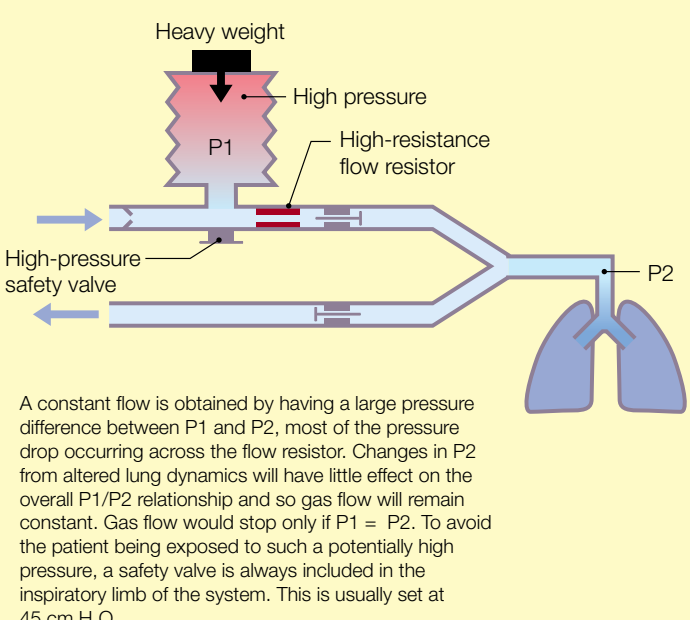
Constant pressure generator



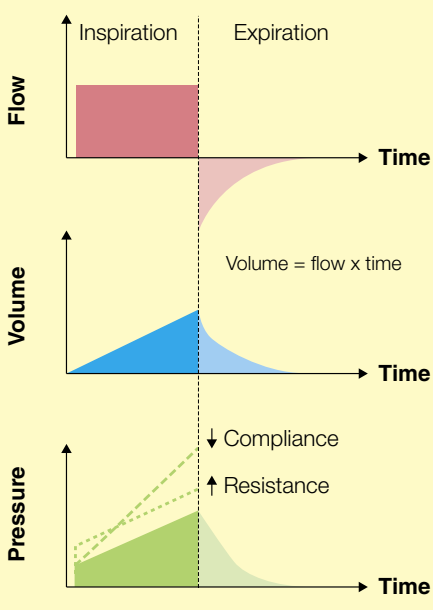


6

High-pressure, high-resistance flow generator



A constant flow is obtained by having a large pressure difference between P1 and P2, most of the pressure drop occurring across the flow resistor. Changes in P2 from altered lung dynamics will have little effect on the overall P1/P2 relationship and so gas flow will remain constant. Gas flow would stop only if P1 = P2. To avoid the patient being exposed to such a potentially high pressure, a safety valve is always included in the inspiratory limb of the system. This is usually set at 45 cm H_2O.



7

Single- and double-circuit ventilators

In a single-circuit ventilation system the anaesthetic gas is also the driving gas. A well-known example is the Manley ventilator, where the fresh gas flow set on the rotameters is divided into tidal volume (hence the term minute volume divider). The fresh gas flow powers the ventilator and is also delivered to the patient.

In a double-circuit ventilation system the anaesthetic gas and the driving gas are in separate circuits. The clearest example of this is a 'bag in bottle' or bellows ventilator. The anaesthetic gas is contained within the circuit and a set of bellows, which act as a reservoir. After delivering the tidal volume, the bellows refill during expiration. The bellows are contained within an air-tight cylinder and a separate high-pressure driving gas is used to pressurize the cylinder periodically, compressing the bellows and thereby generating inspiratory gas flow. Most modern circle/ventilator systems are double circuits.

Bellows can be of the standing or hanging variety. Standing bellows rise as they refill; hanging bellows are mounted inverted and fall as they refill. The advantage of standing bellows is that a leak of anaesthetic gases will be noticed by a failure of the bellows to rise to the full height. This is especially useful during low-flow circle anaesthesia. Hanging bellows are usually weighted at the base and entrain room air if there is a circuit leak.

The Nuffield 200 series of ventilators are functionally double circuit. Although there is no physical separation of the driving and fresh gas flow, the configuration of these ventilators ensures that fresh (anaesthetic) gases and driving gas do not mix. This is achieved by using a connector hose with an internal volume that is greater than the tidal volume.

Pulmonary physiology and the effects of intermittent positive-pressure ventilation (IPPV)

When a patient breathes spontaneously the expansion of the chest wall creates a negative pressure relative to atmospheric pressure between the visceral and parietal pleura. The transpulmonary pressure gradient created causes the lung to expand and fill. Thus, during inspiration the intrathoracic pressure is negative.

During IPPV the patient makes no respiratory effort and the transpulmonary pressure gradient required to expand the lung is generated by raising the airway pressure. With inspiration, intrathoracic pressure is positive. During artificial ventilation the mean intrathoracic pressure is increased compared with spontaneous ventilation and this has effects on the respiratory, cardiovascular, renal and endocrine systems. The effects of IPPV are wide ranging and must be viewed in the context of the position of the patient on the operating table and the effects of general anaesthesia.

Normal respiratory physiology and the effects of general anaesthesia

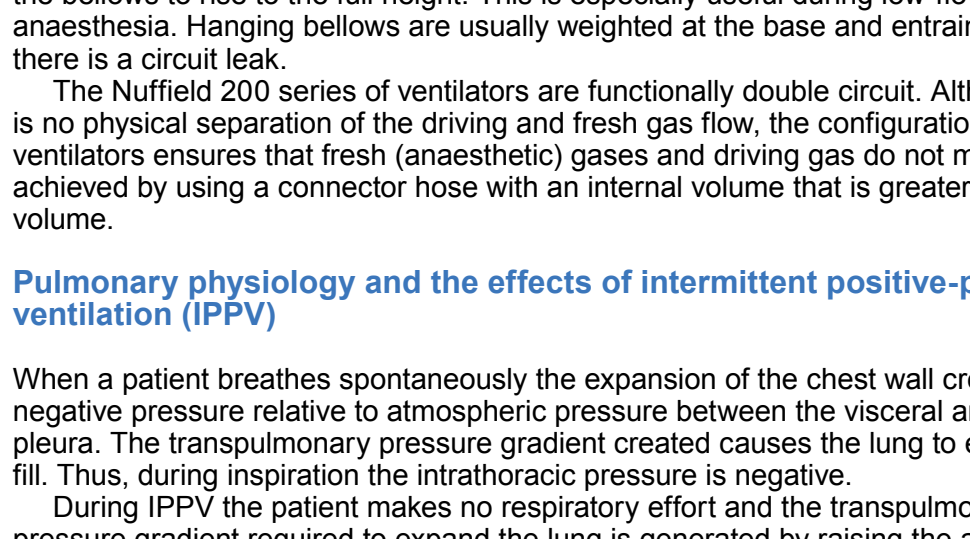
The primary function of ventilation is to move air in and out of the lungs so that carbon dioxide can be eliminated and arterial oxygenation maintained. In healthy individuals it is the requirement to eliminate carbon dioxide that is the prime determinant of minute ventilation. A normal tidal volume is about 500 ml in an adult (8 ml/kg); of this, about 150 ml (2 ml/kg) remains in the conducting airways (anatomical dead space), and the remaining 350 ml enters the alveoli and is available for gas exchange. The respiratory rate depends on the requirement for carbon dioxide elimination, but is usually 10−15 breaths per minute in adults. Effective ventilation maintains a normal arterial $PaCO_2$ of 4.5−5.5 kPa and an arterial oxygen tension (PaO_2) of 13.5 kPa in healthy young adults breathing room air.

Functional residual capacity (FRC): the various subdivisions of lung volume that can be determined by spirometry, whole-body plethysmography or helium dilution are shown in Figure 8. Of these, the most important for anaesthesia and the care of patients in the ICU is FRC. FRC is the end-expiratory volume of the lungs and is determined by the balance between:

- the elastic recoil of the lungs
- the outward recoil of the chest wall
- the respiratory muscle tone
- the position of the diaphragm.

FRC gradually reduces with age and is reduced on lying supine (by 500−800 ml) as a result of upward displacement of the diaphragm by the abdominal contents. This effect is enhanced in patients with abdominal distension or obesity. During general anaesthesia, reduction in diaphragmatic and chest wall tone and function lead to a reduction in FRC of about 20%. The effects of general anaesthesia and the supine position are additive, and can cause a significant reduction in FRC.

Lung volumes (70 kg adult)



Normal values

- Functional residual capacity 2.5 litres
- Inspiratory reserve volume 2.5–3.0 litres
- Tidal volume 0.5–0.6 litres
- Expiratory reserve volume 1.5 litres
- Residual volume 1.5–2 litres
- Vital capacity 3.5–5.5 litres
- Total lung capacity 6 litres

Minute ventilation 7.5 litres/minute
Alveolar ventilation 5 litres/minute
Vd/Vt 0.3

8

Closing capacity (CC) is the lung volume at which small airway closure begins. Closing volume is an alternative term that is equivalent to CC minus residual volume (RV). Normally CC is less than FRC, but they converge with increasing age. When FRC decreases to below CC, airway closure occurs during normal expiration and the resulting decrease in ventilation to areas of the lung distal to the closure worsens the ventilation-perfusion (V/Q) relationship. FRC usually remains greater than CC when supine until about 45 years of age but the additional reduction in FRC that occurs during general anaesthesia makes it more likely that FRC will fall below CC during anaesthesia. The resulting increase in V/Q mismatch leads to a decrease in arterial oxygenation, which is normally countered by increasing the inspired oxygen fraction.

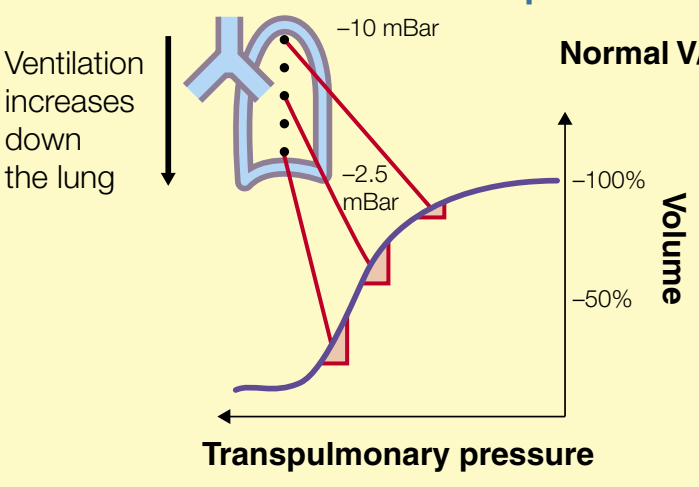
Distribution of ventilation and perfusion: during spontaneous ventilation in an upright position, distribution of ventilation and perfusion are not uniform throughout the lungs. Blood flow increases linearly from the top to the bottom of the lungs as a result of the effects of gravity on the low-pressure pulmonary circulation. The lower zones ventilate better than the upper zones because the dependent parts are on a more compliant (i.e. steeper) part of the pressure-volume curve. During normal inspiration, diaphragmatic contraction is enhanced in the parts of the diaphragm most displaced, aiding increased ventilation of the dependent parts of the lung (Figure 9).

Ideally, ventilation and perfusion at the alveolar level should be matched. Alveolar ventilation should equal perfusion and the V/Q ratio equal 1. In this situation no ventilation or perfusion is 'wasted'. However, the normal V/Q ratio is 0.8. The further the V/Q ratio deviates from 1, the more inefficient the ventilatory process becomes (Figure 10).

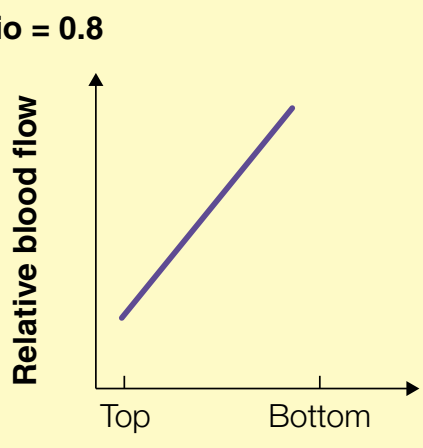
In the supine position, the gravitational effects on the lung are more limited, and perfusion is more homogeneous. However, the reduction of FRC, which is compounded by anaesthesia and the patient's position, leads to uneven ventilation because of airway closure and the tendency of the dependent portions of the lung to reduce in volume more than the superior parts (compression atelectasis).

Therefore, in the supine position (especially under anaesthesia) V/Q relationships worsen. This tends to cause hypoxaemia, which, because it is caused by a V/Q mismatch rather than a true shunt, can be reversed with added inspired oxygen.

Distribution of ventilation and perfusion in the lungs



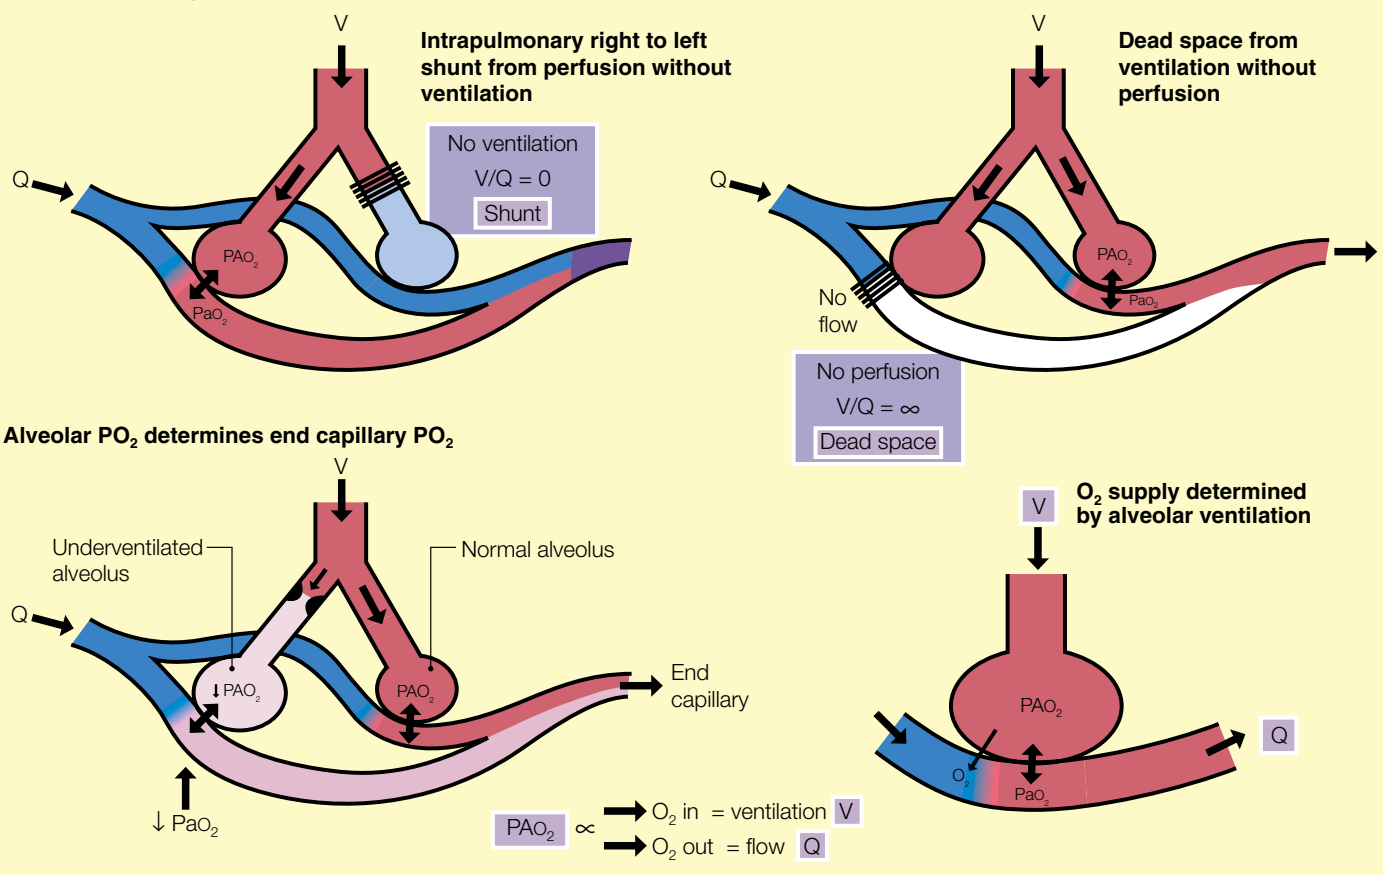
Ventilation increases from the apex to the base. Dependent parts of the lung are on a more compliant part of the pressure–volume curve



Perfusion increases on moving down the lung. The low-pressure pulmonary circulation is affected by gravity

9

Ventilation and perfusion



In an ideal alveolus capillary P_{O_2} (Pa_{O_2}) comes close to alveolar P_{O_2} (PA_{O_2}). PA_{O_2} is determined by the balance between the rate of O_2 uptake by the pulmonary capillaries (Q) and continued supply of O_2 by alveolar ventilation (V). The rate of O_2 removal is determined by the rate of O_2 consumption (metabolic rate). In an under-ventilated alveolus, the supply of O_2 is reduced. If O_2 uptake continues, the result is for PA_{O_2} to fall and so Pa_{O_2} will fall

10

Hypoxic pulmonary vasoconstriction (HPV): when the alveolar PO_2 or, to a lesser extent, the mixed venous PO_2 decreases, smooth muscle contraction occurs in small pulmonary arterioles. This diverts blood from unventilated areas to better-ventilated areas and helps minimize the effects of V/Q imbalance. Volatile anaesthetic agents as well as many vasodilators (e.g. sodium nitroprusside) inhibit HPV, worsening the effects of V/Q mismatching.

Respiratory effects of IPPV

Changes in distribution of ventilation: the preferential ventilation of the non-dependent parts of the lung in the anaesthetized, supine position is increased by IPPV. The non-dependent areas are more compliant than the dependent zones after induction of anaesthesia and muscle relaxation, and so preferentially expand in response to positive pressure. This effect is further exaggerated if the lungs have an increased density, as in the adult respiratory distress syndrome or in patients with cardiogenic pulmonary oedema. It is also compounded by compression of basal areas of the lung as a result of the upward displacement of the paralysed diaphragm.

Changes in distribution of perfusion: normal distribution of perfusion is usually maintained during IPPV. However, in the presence of high intra-alveolar pressures, compression of the alveolar capillaries occurs and flow stops. Capillary pressures are lower in the upper zones because of the effect of gravity on the low-pressure pulmonary circulation, and these zones are particularly vulnerable to increases in airway pressure. These preferentially ventilated upper zones now have much reduced flow and V/Q mismatch is further increased. This is more likely to occur when mean airway pressures are high and with the use of positive end-expiratory pressure (PEEP).

PEEP is the application of a residual positive pressure to the airway at the end of expiration instead of atmospheric pressure. This improves oxygenation by increasing FRC and thus reduces the effects of airway closure and lung volume reduction on V/Q relationships. PEEP may also reopen previously collapsed lung units and maintain their patency (alveolar recruitment).

Barotrauma is the result of excessive pressure gradients between alveoli and the interstitium, with rupture occurring. Air can spread along perivascular spaces into the mediastinum, pericardium, up into the neck, down into the abdomen or into the pleural cavity (pneumothorax). Risk factors include:

- large tidal volumes
- excessive inflation pressures, especially > 40 cm H_2O
- use of PEEP
- non-uniform lung disease
- increased airway resistance.

Recently, the term ‘volutrauma’ has been used in the ICU setting. This refers to overdistension of ‘normal’ areas of the lung by the high pressures required to inflate the diseased areas.

Other respiratory effects of IPPV: during general anaesthesia with intubation and ventilation, there is loss of the ability to cough and so secretions are retained. Inhaled anaesthetics and cold, dry gases inhibit ciliary activity in the bronchial tree, again leading to a tendency to retain secretions. In addition, if the anaesthetic gases are not warmed and humidified, the respiratory tract can be a major source of heat loss.

Cardiovascular effects of IPPV

The major effect of IPPV is to reduce cardiac output via a reduction in venous return. In most patients, this can be counteracted by fluid loading (e.g. 500−1000 ml crystalloid). There are additive effects on the pulmonary circulation and heart, but their relative contribution is thought to be minor, and significant changes occur only with high mean airway pressures.

Cardiac output: a decrease in cardiac output occurs when beginning IPPV, which can cause significant hypotension. The increase in mean intrathoracic pressure during inspiration with positive-pressure ventilation causes the low-pressure veins in the chest to be compressed. Cardiac output falls because of the reduction in venous return to the heart. The decrease in cardiac output and mean arterial blood pressure can be particularly marked in patients who are hypovolaemic or have limited cardiovascular reserve and is further worsened by PEEP. The expected fall in cardiac output can be reduced by prompt infusion of fluids to increase central venous pressure and maintain venous return.

Effects of IPPV on pulmonary vascular resistance and the heart: increased pulmonary vascular resistance occurs when airway pressures are high, from direct compression of alveolar capillaries. As pulmonary vascular resistance increases, there is an increase in right ventricular afterload and right ventricular end-diastolic volume. If end-diastolic volume becomes significantly raised, bulging of the intraventricular septum into the left ventricular cavity can occur, reducing left ventricular compliance and reducing left ventricular stroke volume. In addition, the increased wall tension in the right ventricle, coupled with a reduced arterial pressure, can compromise right ventricular perfusion in compromised patients. The final effect is right heart strain further augmenting a reduction in cardiac output. Paradoxically, in patients with existing heart failure, the increase in transpulmonary pressure transmitted to the thorax can occasionally help to off-load the left heart by reducing venous return from the pulmonary veins, thus reducing left atrial pressures. Left ventricular performance may then improve.

Other effects of IPPV

Renal: mechanical ventilation causes a reduction in urine volume, and thus sodium and water retention. A fall in renal perfusion pressure associated with the reduced cardiac output and a rise in renal venous pressure as a result of impedance of venous return, along with increased levels of antidiuretic hormone associated with IPPV, are thought to be important. An increase in sympathetic stimulation triggered by baroreceptors sensing the changes in pressure and flow may also contribute. The renal effects are persistent and are not fully reversed with fluid infusion or improvement in cardiac output.

Liver: the reduction in cardiac output and increased venous pressure leads to a fall in hepatic blood flow proportional to the drop in cardiac output. Hepatic blood flow may be reduced by up to 50% and hepatic metabolism is reduced. This can be reversed by infusion of fluid. The increased venous pressure caused by the positive intrathoracic pressure can cause hepatic venous congestion, and hypocapnia will lead to vasoconstriction.

Endocrine: antidiuretic hormone levels are increased during IPPV, with corresponding increases in renin and angiotensin levels. This contributes to salt and water retention.

Practical aspects of positive pressure ventilation

Adequate ventilation requires an adequate tidal volume and minute ventilation to be delivered, time for gas distribution and gas exchange to occur, and sufficient time for expiration to be completed. Adequate ventilation results in a normal $PaCO_2$ tension (4.5−5.0 kPa), and in anaesthetic practice this is usually estimated by the end-tidal carbon dioxide tension ($P_{E'}CO_2$). In patients with normal lungs the arterial $PaCO_2$ is about 0.5 kPa greater than the $P_{E'}CO_2$. $P_{E'}CO_2$ is measured from alveolar gases from all ventilating lung units with a spread of V/Q ratios. Units with high V/Q ratios have a reduced alveolar PCO_2 and so ‘dilute’ the gas from units with a V/Q ratio close to unity. This relationship is lost in patients with lung disease; arterial blood gas monitoring may be required in these patients. The minute volume and tidal volumes used should aim for peak airway pressures of 15−20 cm H_2O in most patients.

Arterial oxygenation is determined primarily by the inspired oxygen, which should never be below 30% (FiO_2 0.3) initially. The required inspired oxygen is determined by the saturation recorded by the pulse oximeter; 95% or greater is appropriate. After monitoring the effect of the initial settings in each patient, appropriate alterations can be made to suit the individual.

Initial IPPV settings for routine general surgical cases

Adults:

- flow generator mode of ventilation
- tidal volume 8−10 ml/kg
- respiratory rate 10−12 breaths/minute
- inspiratory/expiratory (I:E) ratio 1:2
- Fi_{O_2} 0.4 (40% oxygen)
- maximum airway pressure 30 cm H_2O.

If a circle absorber system is in use, an initial fresh gas flow of 6 litres/minute should be used.

A tidal volume of 8−10 ml/kg is appropriate for adults. An I:E ratio of 1:2 allows sufficient time for equilibration in inspiration and time for full expiration, in relation to the TC of normal lung. A starting inspired oxygen concentration of 40% helps to prevent a fall in PaO_2 and overcomes the expected increase in V/Q mismatch that occurs during IPPV. Barotrauma is avoided if peak pressures are kept below 30 cm H_2O.

Flow generators are the preferred method of ventilation in adults. A reliable and predictable tidal volume and minute ventilation can be achieved even when there are alterations in lung mechanics from pre-existing lung disease or when temporary peroperative changes occur related to the effects of patient positioning and surgery.

Children:
- pressure generator mode of ventilation
- inspiratory pressure 20 cm H_2O irrespective of weight
- respiratory rate 30−40 breaths/minute for neonates; 20−25 breaths/minute for infants; 15−20 breaths/minute for older children
- I:E ratio 1:2
- Fi_{O_2} 0.5 (50% oxygen).

Owing to their increased basal metabolic rate relative to their weight, neonates and infants have an oxygen requirement (6 ml/kg/minute) twice that of adults. As a result, they have a high carbon dioxide production, hence the need for a high respiratory rate. Young children also have a reduced FRC, high CC and relatively high airways resistance with low respiratory compliance. Their increased metabolic rate and relatively low FRC means they have limited oxygen stores and so their arterial oxygen saturation falls rapidly if ventilation is inadequate. Loss of respiratory gases as an air leak from around their uncuffed endotracheal tube is expected and indeed desirable. It provides evidence that the endotracheal tube is not so tightly fitting as to cause tracheal mucosal compression at the level of the cricoid ring. Pressure generators, which compensate for gas losses and limit peak pressures, are commonly used in paediatric anaesthesia. At puberty, differential growth of the cricoid ring and laryngeal aperture means that the larynx becomes the narrowest part of the airway as in adults, so cuffed tubes may then be used.

Safety issues

Detection of ventilator disconnection

Anaesthetized, paralysed patients are wholly dependent on the ventilator and the anaesthetist to keep them alive. In this respect, a paralysed patient is much more vulnerable than one who is breathing spontaneously. The anaesthetist should be alerted to a disconnection promptly by a disconnect alarm, which may also indicate when inadequate ventilation is occurring.

Disconnections can be sensed by:
- loss of the rhythmic increase in airway pressure
- reduction in expired gas volume
- loss of expired carbon dioxide.

Monitoring of airway pressures and exhaled CO_2 are part of minimum monitoring requirements during mechanical ventilation.

Airway pressure sensors are either aneroid gauges or, more commonly, electronic pressure transducers. The gauge the anaesthetist uses for monitoring and the alarm system are often separate devices. Airway pressure alarms detect an increase above a threshold pressure. If an increasing pressure that exceeds the threshold is not detected in the preset time, an alarm is sounded. This system does not normally detect a blocked endotracheal tube, but an alarm for the excessive inspiratory pressures generated in this scenario is usually incorporated in the same system.

Expired tidal volume or expiratory flow over time can also be measured. A minimum preset volume must be exhaled at a frequency above the preset minimum rate or the alarm will be triggered. Expired tidal volume is usually measured by integrating the expired flow signal.

Capnographs are fitted with limit alarms and often with apnoea detectors, which detect apnoea from the carbon dioxide waveform. In addition, respiratory movements are sometimes sensed via ECG leads and as a very late indicator, pulse oximeters will alarm if significant arterial desaturation occurs.

Ventilator checks

The anaesthetist is responsible for the state of the equipment he or she uses. It is expected that equipment is systematically checked before use. Although on occasion this may be delegated to trained assistants, the final responsibility lies with the anaesthetist. To this end, guidelines for machine checks have been issued by the Associaton of Anaesthetists of Great Britain and Ireland (Figure 11). With the increasing use of sophisticated, electronically controlled anaesthesic machines and ventilators, a ‘generic’ checklist must be used only with reference to the manufacturer’s suggested protocol for each machine.

Ventilator checks

- Ensure that ventilator tubing is correctly configured and securely attached
- Set the controls for use and ensure that an adequate pressure is generated during the inspiratory phase
- Check that the pressure relief valve functions
- Check that the disconnect alarm functions correctly
- Ensure that an alternative means to ventilate the patient’s lungs is available

Breathing Systems

Gordon W G French

Gordon W G French is Consultant Anaesthetist at Northampton General Hospital, UK. He qualified from Glasgow University and trained in Nottingham and Oxford. His research interests include the detection of silent myocardial ischaemia perioperatively, the use of starches for volume preloading in obstetric anaesthesia and modes of paediatric resuscitation teaching.

A 'breathing system' is the name given to apparatus that delivers and removes gas and vapour to or from a patient. The three main functions of the breathing system are:

- to supply adequate oxygen
- to remove carbon dioxide
- to supply adequate inhalational anaesthetic agent.

The perfect system has yet to be developed but the ideal breathing system should:

- be simple and safe
- deliver the intended mixture
- allow manual and intermittent positive-pressure ventilation (IPPV) in all age groups
- be efficient (able to use low gas flows)
- protect the patient from barotrauma
- be sturdy, lightweight yet compact
- be easy to scavenge
- be cheap.

Essential components of a breathing system

Tubing (hose): originally this was carbon-impregnated rubber (an antistatic design), corrugated to prevent kinking, but it was heavy and prone to perishing. Modern tubing is usually plastic, disposable or designed for single use, and often has a smooth inner bore that reduces resistance to airflow. Early systems had various means of inter-linking tubes, including tapered metal connectors that pushed into each other and screw mountings. These were manufactured in various sizes, with many systems being non-interchangeable, clearly a dangerous situation. The International Standards Organization (ISO.5356, 1987) and British Standard (BS 3849) recommend the following sizes for all breathing systems:

- 30 mm tapered connections for scavenging hose to breathing systems
- 22 mm taper for connections within breathing systems
- 15 mm connections between the breathing system and the endotracheal tube.

An upstream 'male' connector traditionally fits into a downstream 'female' part. The ISO 15 mm standard connector is cumbersome for small paediatric endotracheal tubes (2–6 mm internal diameter). Smaller, lighter 8.5 mm connectors may be used, which have adapters to connect to the 15 mm standard system. Tapered connections between plastic, metal and rubber can be 'locked' by giving them a slight twist after connecting. Systems designed for repeated use can usually be autoclaved, which does not affect their connectors. Single-use systems often distort if heated, making the connectors unsafe.

There is controversy among practising anaesthetists as to exactly what 'for single use only' means. Clearly it would be expensive to use a new breathing system for each patient, and almost certainly unnecessary. Many departments employ a cost-effective compromise by using a new disposable antibacterial filter for each patient, but only changing the actual breathing system weekly. It may be changed more often depending on clinical need (e.g. after use in a patient with known lung infection such as tuberculosis).

Reservoir bag: this stores fresh gas when the patient is exhaling and accommodates the high peak inspiratory flow rates during inspiration. Made of rubber or plastic, the common adult size is 2 litres and 0.5 litres for children, but some ventilators use other sizes up to 6 litres. The bag's motion allows observation of ventilatory patterns but does not reflect the tidal volume accurately. As the bag stretches, the pressure in its walls reaches a limit of about 40 cm H_2O (Laplace's law); further distension does not result in greatly increasing pressures. This partly protects the lungs from barotrauma should the breathing system outlet become obstructed, such as when the adjustable pressure-limiting (APL) valve is left fully screwed down. An open-ended reservoir bag is commonly used in paediatric circuits, allowing manual ventilation and assessment of the compliance of a child's lungs (e.g. Mapleson type F).

APL valve: this is a one-way, spring-loaded valve consisting of a thin, lightweight disc (made of hydrophobic material) held by an adjustable spring against knife-edged seating. This arrangement (Figure 1) reduces the area of contact between the disc and the seating, lessening any surface tension that condensed water vapour might create, causing the disc to stick. The disc prevents movement of air into the system when the patient inhales, but opens at low pressure (about 1 cm H_2O) to allow exhaled and surplus gas to be vented during expiration. When fully screwed down, modern valves open at about 60 cm H_2O positive pressure, acting as a safety feature.

Expired gases can be conveniently scavenged by surrounding the valve with a hood. If the valve is sucked open continuously by a faulty scavenging system, a huge increase in the dead space of the apparatus will result. The APL valve should be fully open during spontaneous respiration, partially closed during manual IPPV and fully closed during ventilator IPPV.

Cross-section of an adjustable pressure-limiting valve

1

Classification of breathing systems

The historical development of breathing systems was largely based on the intuition and practical experience of individual anaesthetists. As a result, there are many different systems. One classification based on function is described below.

Non-rebreathing systems

Non-rebreathing systems use one-way valves to separate inspired and expired gases. When the patient inspires, the expiratory valve closes and the inspiratory valve opens, allowing inhalation of fresh gas. There is usually a reservoir bag on the inspiratory limb, which provides enough gas for the maximum peak inspiratory flow rate (often > 30 litres/minute), and collects fresh gas when the inspiratory valve is closed in expiration. It may also allow for manual-assisted ventilation. Resuscitation devices commonly include a bag constructed of foam-lined rubber or silicone, which remains inflated in the resting state, in addition to a thin-walled reservoir bag. Manual ventilation is provided by squeezing this bag, which automatically refills from the oxygen inlet and reservoir bag when hand pressure is released. The fresh gas flow (FGF) should at least equal the patient's required minute volume. Examples are resuscitation devices such as the Ambu bag, Laerdal silicone resuscitator, drawover units and the 'Triservice' apparatus.

Rebreathing systems

In rebreathing systems, the inspiratory and expiratory gases can mix in the tubing and re-inhalation of expired gas can occur. Rebreathing refers to inhaling part or all of the previously exhaled tidal volume. In particular, it is the inhaling of previously exhaled carbon dioxide (i.e. alveolar gas) which is of most concern to the anaesthetist. A system is efficient if it can preferentially vent alveolar gas, retaining dead space (non-carbon-dioxide-containing) gas and thus use an FGF that approximates to the patient's alveolar minute ventilation. The extent of carbon dioxide rebreathing thus depends on the FGF flushing the expired gas away before the next inspiration. The normal respiratory cycle consists of an inspiration followed immediately by expiration, but there is then an expiratory pause. It is during this period that the FGF flushes the system. In 1954, Mapleson classified five commonly used systems according to their efficiency at eliminating expired carbon dioxide in spontaneously breathing patients (Mapleson systems A–E). An F system was added in 1975 (Figure 2).

The Mapleson classification of anaesthetic breathing systems and adaptations

Mapleson type		Recommended fresh gas flow	General points
System A **a** Magill **b** Lack **c** Parallel Lack		**Spontaneous** AMV (70 ml/kg/minute) **IPPV** 2–3 x AMV	**a, b, c** Efficient for spontaneous, not for IPPV Heavy, especially at patient end Unsuitable for children < 25 kg because large dead space **b** Lack: coaxial, APL and reservoir bag at machine end Inspiratory gases through outer (30 mm) tube Expiratory via inner (14 mm) **c** Parallel Lack: separate inspiratory and expiratory tubes
System B		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	FGF near patient end. Performs similarly in both modes. Seldom used
System C		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Similar arrangement to system B. The large-bore tubing to bag is shorter **a** Waters' 'to and fro' circuit: inefficient but small size and simplicity means useful for resuscitation and patient transfers **b** Waters' canister: heavy because incorporates a 1 lb soda lime container between bag and mask or ET tube Channelling occurs if incompletely packed. Nylon pot scourer compresses at bag end. Filter at patient end prevents soda lime dust movement. NB Filter to patient = dead space. Easily sterilized. Now little used. Superseded by circle absorber systems
System D **a** Bain		**Spontaneous** 2–3 x AMV **IPPV** AMV (70 ml/kg/minute)	Inefficient for spontaneous but good for IPPV Manley ventilator on spontaneous ventilation mode is a Mapleson D Safety problems include kinking of inner tube Disconnection of inner tube increases dead space. Both lead to hypoxia and hypercarbia **a** Bain: coaxial D. Length of tube does not affect properties (180–540 cm). FGF through inner tube (opposite to Lack) Ventilate with Penlon 200 replacing bag. Connecting tube long > 500 ml (usually 1 m) to prevent driving gas entering circuit. Lightweight, easy to scavenge. Ga in expiratory limb warm inspiratory gases
System E		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Used for children up to 30 kg. Low resistance, small dead space, lightweight, no valves. Inefficient but used for spontaneous and IPPV. Expiratory limb is reservoir and should be > V_T to prevent air entraining Ayre's T-piece: developed for neuro/cleft palate surgery
System F		**Spontaneous** 2–3 x AMV **IPPV** 2–3 x AMV	Jackson Rees modification. Reservoir bag allows rate and chest compliance to be monitored, ventilation by hand and continuous positive airway pressure application. Barotrauma and humidification a problem

AMV, alveolar minute volume; FGF, fresh gas flow; IPPV, intermittent positive-pressure ventilation; V_T, tidal volume

2

Mapleson A: classically describes the Magill system. The APL valve and any scavenging device make this system cumbersome at the patient's end. Lack solved this problem by creating a co-axial arrangement where the expiratory gases were carried up an inner hose to the APL and scavenging system, both of which were thus distant to the patient. However, this system is bulky, even though it is less weighty at the patient's end. In addition, if the inner tube breaks and this goes unrecognized, the system may become dangerous because carbon dioxide elimination is drastically reduced. It is also difficult to use with a ventilator. A parallel hose breathing arrangement (parallel Lack) eliminates this problem.

The Mapleson A system is an efficient system for spontaneous ventilation because it selectively vents alveolar gas through the APL valve. The first part of the exhaled tidal volume (non-carbon-dioxide-containing dead space gas) is retained in the system and is available for inhalation during the next breath. This efficiency is lost when the system is used for IPPV.

Mapleson B and C: in both systems the FGF, reservoir bag and APL are near the patient, creating a compact and portable system. However, they are both inefficient and only the Waters' 'to and fro' system is commonly used, mainly for patient transport and in postoperative recovery units.

Mapleson D: exhaled gas passes into a reservoir bag along with the fresh gas, so rebreathing occurs unless the FGF is high. The system is efficient for IPPV.

The Bain system is a coaxial version, which is particularly useful for limited-access surgery because of its light weight and the fact that the tubing can be lengthened without affecting the flow characteristics. The system can be connected to a ventilator by replacing the reservoir bag with tubing connected to a ventilator such as the Penlon Nuffield 200. The tubing should be of sufficient length to prevent the ventilator driving gas entering the breathing system (in practice > 500 ml or 1 metre of standard hose). In this system, the FGF is along a narrow internal tube (the opposite of the Lack system), and the expired gas moves along the outer tube, usefully heating up the dry FGF. It is vital that the inner tube is intact because disconnection leads to a huge increase in dead space and possible hypercarbia or hypoxia.

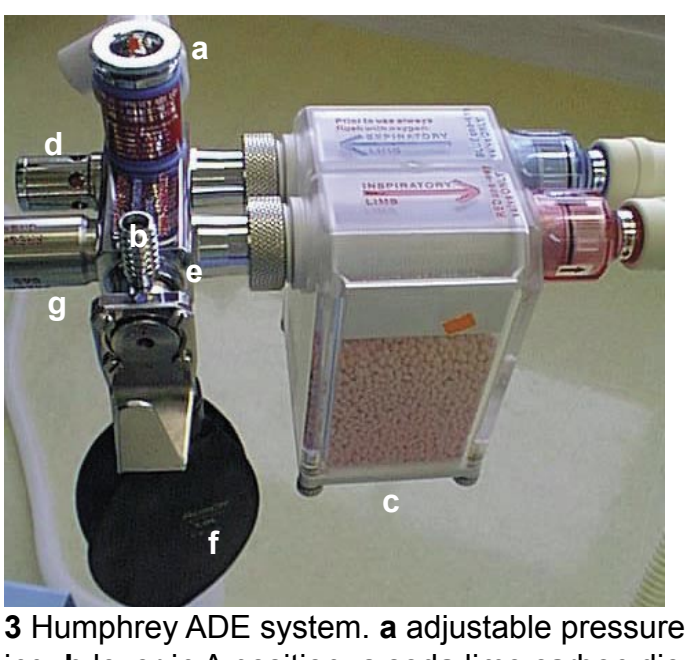
Mapleson E: the Ayre's T-piece is a valveless, lightweight system, with low internal resistance and dead space. In inspiration, gas is inhaled from both the inspiratory and expiratory limb. The volume of the expiratory limb needs to be at least equal to the tidal volume or air may be entrained. If it is too large, then rebreathing can occur because expired gas may not have vented to air before the next inhalation. Occluding the outlet intermittently allows IPPV.

Mapleson F: adding an open-ended reservoir bag to the expiratory limb of the Ayre's T-piece allows manual control of ventilation, observation of breathing and assessment of lung compliance. Some continuous positive airway pressure (CPAP) is also achieved with the system during spontaneous respiration, which, in an infant, may help to increase the functional residual capacity. Scavenging is a problem for both the Mapleson E and F systems. The routine use of capnography allows the FGF to be tailored precisely to achieve normocapnia in individual patients for all these systems.

Humphrey ADE system (Figure 3) is one of a number of hybrid systems that has become popular. It is a low-flow multipurpose system that appears to combine the best of the Magill, Lack and T-piece systems but not their disadvantages. It is cost effective in all modes, being more efficient than the Magill for spontaneous ventilation. The 15 mm, smooth-bore tubing has one-quarter of the resistance to flow of 15 mm corrugated tubing, which allows use in adults and children; 8.5 mm tubing is available for neonates. The reservoir bag, APL, scavenging shroud and a pressure-limiting valve are all located on the 'Humphrey block'. The system tubing connects to the patient via a symmetrical Y-piece, which probably accounts for much of its efficiency as it produces less turbulence than the conventional Magill–patient interface. One lever allows conversion from A mode to E mode, with only a slight increase in FGF being required to eliminate rebreathing. In E mode, the reservoir bag and APL are isolated from the system, and the expiratory tubing acts as the reservoir limb of a T-piece. This is open to the atmosphere via a port on the block to which a bag squeezer ventilator such as the Manley Servovent or Penlon Nuffield 200 or 400 can be attached. The D mode could be engaged by simply attaching a reservoir bag and APL to this port for spontaneous ventilation, but this is much less efficient than the A mode.

The APL valve provides positive end-expiratory pressure of 1 cm H_2O without increasing the airway resistance of the apparatus. The APL valve does not have to be screwed down for IPPV, except if used in the A mode. However, there is a long orange valve seat stem that can be temporarily held down instead. This also moves slightly during spontaneous respiration and gives a visual indication of respiratory movement. A separate 60 cm H_2O pressure-limiting valve lies behind the APL valve on the block. This is always in-line, whatever mode is being used. The system can be fixed on to the anaesthetic machine via a locking nut. A 500 g soda lime canister (lifespan 12 hours), which has a low resistance to flow and is autoclavable, can be fitted in front of the block. This circle system arrangement requires no other alterations in FGF for adults or children.

The entire system is MRI compatible, being made of plastic and brass. In addition, tubing lengths of over 3 m can be used without compromising its function. The main disadvantages are that it protrudes out of the anaesthetic machine, is heavy and can be knocked, which theoretically could fracture old anaesthetic machine outflow pipes.



3 Humphrey ADE system. **a** adjustable pressure limiting valve with scavenging; **b** lever in A position; **c** soda lime carbon dioxide absorber; **d** pressure relief (60 cm H_2O) valve; **e** port for ventilator; **f** reservoir bag; **g** fresh gas flow. Fresh gas flow: A mode (lever up) = 50 ml/kg/minute; E mode (lever down) = 70 ml/kg/minute. Children start at 3 litres/minute.

Systems using carbon dioxide absorbers

The circle system (Figure 4) was first described in the 1920s. It uses soda lime to absorb exhaled carbon dioxide. Partial rebreathing of other exhaled gases can thus be undertaken, depending on the arrangement of the components and the FGF.

Circle systems can be classified as follows:

- semi-open – no rebreathing, very high FGF, APL valve wide open
- semi-closed – rebreathing occurs, low flow, APL valve partly closed
- closed – FGF inflow exactly matches uptake by patient; complete rebreathing of exhaled gases after carbon dioxide uptake and APL valve fully closed.

A circle system consists of:

- FGF source
- inspiratory and expiratory unidirectional valves
- inspiratory and expiratory corrugated tubes
- a Y-piece connector
- an APL valve or pop-off valve
- a reservoir bag
- a canister containing a carbon dioxide absorbent.

Fresh gas enters the circle by a connection from the common gas outlet of the anaesthetic machine. Various arrangements of components are possible, but there are three golden rules to prevent carbon dioxide rebreathing.

- A unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs of the circuit. These valves commonly have a clear plastic cover so that their correct movement can be observed during use.
- The FGF cannot enter the circuit between the patient and the expiratory valve.
- The APL valve cannot be located between the patient and the inspiratory valve.

The most efficient circle system has the unidirectional valves near the patient and the APL valve just downstream from the expiratory valve. This arrangement conserves dead space gas and preferentially eliminates alveolar gas. The advantages and disadvantages of a circle system are listed in Figure 5.

Nitrogen washout – at the start of anaesthesia, non-nitrogen-containing gas (unless medical air is being used) is inspired and body nitrogen passes into the lungs. This effectively reduces the oxygen concentration in the alveoli and circle system, producing a potentially hypoxic mixture. The use of high flows of gas at the start of anaesthesia can 'washout' this nitrogen. Pre-oxygenation with 100% oxygen for 7–10 minutes is also effective and can theoretically then allow low circle FGF to be used from the start. Basal metabolic oxygen requirements are about 250 ml/minute, but to allow for leaks in the circle and patient variability, 500 ml/minute oxygen is the minimum recommended flow rate. 'Low flow' anaesthesia is usually regarded as less than 1 litre/minute FGF.

The uptake of volatile agents is highest initially. Fast FGF inflows and large minute volumes produce fast induction of anaesthesia as well as facilitating denitrogenation. As equilibrium is reached, the expired concentration of volatile agent begins to reflect the inspired value, and flows can be reduced. The exhaled gases are added to the fresh gas and have a dilutional effect on the concentration of oxygen and vapour, which will be proportionally greater at low flows. A potentially hypoxic alveolar concentration of oxygen can develop as the FGF reduces. Using an inspired oxygen concentration of 50% to prevent these low oxygen levels in the circle was customary before the advent of in-line gas/vapour analysers. However, this was associated with an increased chance of awareness if the inspired volatile concentration was not increased to compensate for the lower inspired nitrous oxide and volatile concentrations.

Vaporizers can be placed outside (VOC) or inside (VIC) the circle (Figure 6). Most modern vaporizers tend to be outside the circle (e.g. Back bar units such as a TEC vaporizer) and are accurate at low flows. With this set-up, the concentration of volatile gas in the circle is reduced with increased patient uptake and low FGF (due to the dilutional effect of exhaled gas), until uptake reduces and equilibration begins to occur. With a vaporizer in the circle (e.g. Goldman vaporizer), both the fresh and exhaled gas (which already contains vapour) pass through the vaporizer. When the FGF is low and alveolar ventilation high, the concentration of volatile will rise. Thus the concentration of the alveolar and circle vapour is a function of ventilation. In spontaneous ventilation, with deepening anaesthesia and depression of ventilation, the concentration of volatile gas will fall and result in the patient becoming lighter, a useful safety feature. However, low flow controlled ventilation may result in high levels of volatile gas.

Future developments in circle technology may incorporate the VIC arrangement but use a system of vapour injectors instead of the vaporizer. This would be linked to a feedback mechanism incorporating circuit vapour analysis.

Carbon dioxide absorption – closed or semi-closed circle systems require carbon dioxide absorption to make rebreathing possible. Desirable features of a carbon dioxide absorption mechanism are lack of toxicity (intrinsic or with common anaesthetics), low resistance to air flow, low cost, ease of handling and efficiency. Soda lime and baralyme are the two formulations commonly used for carbon dioxide absorption (Figure 7). Both need water but because baralyme contains water as a barium hydroxide octohydrate salt it performs better in dry climates. Soda lime (but not baralyme) is capable of some regeneration after exhaustion. Maximum absorbency of both systems is 26 litres of carbon dioxide per 100 g absorbent.

Dyes (acids or bases) are also added, which change colour as the hydrogen ion concentration changes:

- ethyl violet (colourless to violet; fluorescent light deactivates it)
- phenolphthalein (white to pink)
- Clayton yellow (red to yellow)
- ethyl orange (orange to yellow)
- mimosa z (red to white).

The chemical reaction in soda lime is:

$CO_2 + H_2O \rightleftarrows H_2CO_3$

$H_2CO_3 + 2NaOH\ [KOH] \rightleftarrows Na_2CO_3\ [K_2CO_3] + 2H_2O + heat$

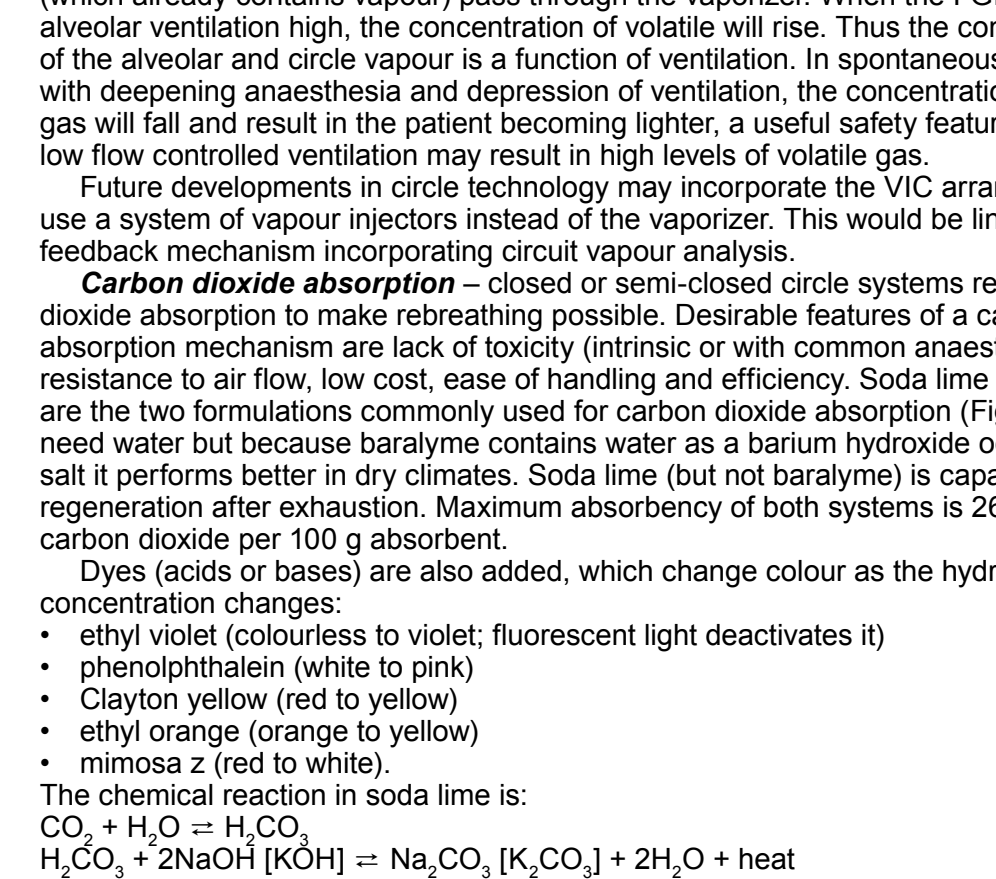
$Na_2CO_3\ [K_2CO_3] + Ca(OH)_2 \rightleftarrows CaCO_3 + 2NaOH\ [KOH]$

Some carbon dioxide reacts directly with calcium hydroxide but this is much slower. In baralyme the carbon dioxide acts directly with barium hydroxide and much more water is released. In the UK, the size of granules is 4–8 mesh (a compromise between surface area for absorption and air flow resistance). Mesh refers to the number of openings per linear inch in a sieve through which the granules pass. A 4-mesh screen indicates four quarter-inch openings per linear inch.

Soda lime and baralyme are not inherently toxic, but at low flows intrinsically produced acetone can accumulate and has been linked to nausea and vomiting. Carbon monoxide can also accumulate at low flows of dry gas (e.g. oxygen running overnight) leading to the formation of carboxyhaemoglobin.

The volatile agent trilene degrades into dichloroacetylene (a neurotoxin causing cranial nerve damage and encephalitis) and phosgene (a potent pulmonary irritant causing adult respiratory distress syndrome).

Sevoflurane and halothane are slightly unstable in soda lime, the rate of degradation increasing with temperature. Sevoflurane degrades into several compounds. Compound A (a vinylether) has been associated with lung haemorrhage and renal tubular necrosis in rats, but neither compound has been shown to cause problems in humans. Many of these problems are resolved by flushing the system regularly.



Properties of a circle system

Advantages	Disadvantages
• Heat/moisture conservation • Easy scavenging • Reduced cost • Small dead space • Good for long cases	• Multiple connections • Valves can stick • Open – leads to rebreathing • Closed – leads to asphyxia • Bulky • Inefficient for short cases • Soda lime changeover a hazard • Gas analyser necessary for accuracy • Potential for infection

5

Properties of vaporizers

Inside the circle	Outside the circle
• Low internal resistance • Low efficiency desirable • Higher concentrations at low fresh gas flow	• High internal resistance (plenum) • High efficiency desirable • Lower concentrations at low fresh gas flow (diluted)

6

Properties of soda lime and baralyme

Soda lime	Baralyme
• Calcium hydroxide (94%) • Sodium hydroxide (the catalyst) (5%) • Potassium hydroxide (1%) • Silica (calcium and sodium silicate harden it and reduce dust formation)	• Calcium hydroxide (80%) • Barium hydroxide (the catalyst) (20%) • More stable so does not contain silica • Denser and 15% less efficient than soda lime

7

System checks

All systems should be checked visually for broken parts and disconnections and a push-and-twist connector test performed. In addition, there are checks specific to individual systems.

- Occluding Mapleson types B and C causes their reservoir bags to fill, testing the air-tightness of the system. Releasing the valve causes the bag to deflate if the valve is functioning normally.
- The Bain system inner tube can be tested in two ways. Occluding the end of the inner tube causes the rotameter bobbin to dip and the pressure alarm/valve to blow if there are no leaks/disconnections up to that point. Occluding the patient end of the system will fill the reservoir bag, testing overall air- tightness. Releasing the occlusion causes the bag to deflate, then continue to empty as a result of the negative pressure caused by the Venturi-effect of the fast FGF leaving the inner tube. The connection of the inner tube can also be visually inspected because the outer corrugated tubing is often made from transparent plastic. This outer tubing may also be temporarily disconnected and a secure inner tube connection confirmed.
- To carry out the low-pressure circle leak test, the end of the system should be occluded and the APL valve closed off. The system is filled using the oxygen flush until the airway pressure gauge registers 30 cm H_2O. The pressure should remain at 30 cm H_2O if no leaks are present.

Cleaning, Disinfection and Sterilization of Equipment

Duncan Parkhouse
Jonathan Warwick

Duncan Parkhouse is a Military Anaesthetic Trainee. He joined the Royal Army Medical Corps as a medical cadet while a medical student at University College Hospital, London. During his anaesthetic training he has spent time at both military and NHS Hospitals including St Mary's Hospital, the Brompton Hospital and the National Hospital for Neurology and Neurosurgery, London.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

Hospital-acquired infections have significant implications for the morbidity and mortality of patients as well as for the economics of health care. The protection of patients and medical staff from medical equipment that has come into contact with patients or their body fluids, requires the adoption of various processes enforceable by law. Changes in these laws and guidelines, published by the Department of Health and the Medical Devices Agency, are expected in the near future. One of the reasons for the introduction of new guidelines is the development of new variant Creutzfeldt–Jakob disease, which is resistant to the standard methods of decontamination used in hospital sterile services departments.

Contamination is the soiling or pollution of an inanimate object with harmful, potentially infectious, material. In the clinical setting, this is most likely to be organic material or microorganisms. Contamination may place the patient at risk and may adversely affect equipment.

Decontamination is a method used to remove contamination and prevent microorganisms reaching a susceptible site in large enough numbers to initiate infection or other adverse effects. The three methods of decontamination routinely used are cleaning, disinfection and sterilization. The method of decontamination chosen takes into account the infection risk from the reprocessed piece of equipment. The risk is dependent on:

- the amount of contact the patient has with the piece of equipment (i.e. how invasive)
- the susceptibility of the patient (i.e. immunocompromised, potential hypersensitivity)
- the nature, extent and amount of microbial contamination on the piece of equipment (the bio burden).

The type of equipment and its intended use determine the method of decontamination used (Figure 1). The manufacturer should provide instructions for cleaning, disinfection and sterilization techniques that are effective without affecting the performance of the equipment.

It is essential that records are kept to demonstrate the number of times an item has been decontaminated and the effectiveness of each process. The documentation should allow patients to be traced in the event of any malfunction in the decontamination process.

Risk of contamination for equipment and suggested decontamination process

Risk	Application of equipment	Recommendation
High	• In close contact with a break in the skin or mucous membrane • For introduction into sterile body areas	Sterilization
Intermediate	• In contact with mucous membranes • Contaminated with particularly virulent or easily transmissible organisms • Before use on immunocompromised patients	Sterilization or disinfection (Cleaning may be acceptable in some agreed situations)
Low	• In contact with healthy skin • Not in contact with patient	Cleaning

1

'Single use' equipment

Manufacturers should state in the product literature any restrictions on the number of re-uses. Any device deemed by the manufacturer as unsuitable for reprocessing is labelled 'single use'. Devices labelled 'single patient use' may be used for an extended period of time or intermittently on the same patient. Users who disregard the manufacturer's guidelines, for example by reprocessing single use items or reprocessing more than the recommended number of times may be transferring legal liability for the safe performance of that product from the manufacturer to themselves or the organization for which they work.

Many anaesthetic departments routinely use disposable anaesthetic breathing systems marked as single use for extended periods with multiple patients. The wisdom of this practice is the subject of much controversy. The advantages of these breathing systems include safety (often pre-assembled with fewer opportunities for connection errors by the user), lightweight and low cost if used on several patients. The disadvantage is that this practice may contravene the manufacturer's recommendation for single use only and risk transmission of infection. The responsibility for use of equipment marked single use then lies with the hospital. Departments of anaesthesia should have an operational policy on the management of breathing systems marked for single use. This may include:

- the use of a new bacterial (heat and moisture exchanger type) filter for each patient
- change of all breathing systems weekly
- change of breathing system following use on a patient with known or suspected lung infection
- change of breathing system whenever there is visible contamination from blood or body fluids.

Cleaning

Cleaning physically removes contaminants without necessarily destroying microorganisms. It removes organic material and is required before disinfection or sterilization.

Manual cleaning

Manual cleaning does not disinfect. It should be used only when other mechanical methods are inappropriate or unavailable.

Immersion – wearing appropriate protective clothing, the cleaner should submerge the device in compatible water/detergent solution at the correct dilution and not exceeding 35°C. It is important to ensure that the cleaning solution reaches all surfaces of the device, including lumen surfaces. Endoscopic equipment that may be totally immersed for cleaning is marked with a blue line, usually around the eyepiece adjacent to the focussing ring. The device should be brushed or agitated to remove any visible contaminants. The device should be thoroughly drained and rinsed in clean water. This method is generally satisfactory for the routine cleaning of laryngoscopes between patients. Disinfection with an alcohol spray is then commonly used.

Non-immersion – wearing appropriate protective clothing, the cleaner should immerse a cleaning cloth into the detergent solution and wring it out. The equipment should be cleansed by wiping its surfaces. The surfaces should be hand dried using a cloth, hot air dryer or drying cabinet. This method of cleaning is often used for electrical or electronic equipment which cannot be immersed in water.

Mechanical cleaning

Mechanical cleaning uses automated washers to clean equipment and often combines cleaning with disinfection.

Thermal washer – cleaning occurs by continually spraying the equipment with water and detergent during a timed cycle. During the first process, cleaning occurs at 35°C. The second wash heats the surface of the equipment to a minimum temperature of 71°C for a minimum of 3 minutes, 80°C for 1 minute, or 90°C for 1 second to disinfect it.

Chemical washer – the first part of the cleaning process is the same as the thermal washer. Disinfection occurs by exposing the equipment to an approved disinfectant for a particular period of time at less than 60°C. The residue disinfectant is then removed by a rinse cycle.

Ultrasonic cleaners are often incorporated into washer disinfectors. These work by rapidly forming bubbles in the liquid, which immediately collapse (cavitation). This cavitation agitates the liquid, producing a highly effective cleaning system. The process does not disinfect.

Disinfection

Disinfection is used to reduce the number of viable micro-organisms, but it may not kill all microbial agents such as some viruses and bacterial spores.

Low temperature steam disinfection

Low temperature steam disinfection is also known as pasteur-ization. It kills most vegetative microorganisms and viruses by exposure to moist heat. The equipment is exposed to dry saturated steam at a temperature of 73°C for at least 10 minutes at below atmospheric pressure. The low temperature steam kills vegetative microorganisms and some heat-sensitive viruses. It cannot be used for sealed, oily or greasy pieces of equipment or those with sealed cavities due to the variation in pressure.

The advantages of this system are its broad spectrum of disinfection, it is non-toxic, non-corrosive and the equipment is relatively safe and simple to use. The disadvantages are that it requires a trained operator and that much equipment is unsuitable for disinfection in this way. The capital cost of the disinfector is high and the equipment is fixed and not portable.

Boiling water disinfection

Boiling water is an effective disinfectant against many microorganisms. Immersing a piece of equipment in soft water and boiling at 100°C for at least 5 minutes produces disinfection. Boiling inactivates most non-sporing microorganisms, fungi, viruses and some heat-sensitive spores. This method is not used if a better method is available. It is unsuitable for heat-labile pieces of equipment, hollow or porous items into which the water will not penetrate, or tubing over 1 metre in length.

The advantages are that boiling water has a broad disinfecting effect. The process is non-toxic and inexpensive. The disadvantages are that boiling water is a potential cause of injury. Following disinfection, items are wet and unfit for immediate use and must be allowed to dry and cool, which may allow recontamination. There is also no method of checking the efficacy of the process.

Washer disinfectors

Washer disinfectors are described above. They inactivate all microorganisms except bacterial spores and some heat-resistant viruses. They are unsuitable for equipment that may be heat labile or corroded by chemical disinfectant, and for hollow or porous equipment that does not allow all surfaces to come into contact with the chemical disinfectant or heat.

These methods are safe for the operator. There is minimal handling of the equipment by staff and therefore a low risk of recontamination. Another advantage is that they combine cleaning and disinfection. The disadvantages are the high cost of the equipment and the requirement for trained staff.

Liquid chemical immersion

Liquid chemical immersion relies on good contact between the chemical disinfectant and the equipment. The equipment therefore requires thorough cleaning beforehand. It is then immersed in the chemical disinfectant, ensuring that the disinfectant reaches all surfaces. The equipment is immersed for a predetermined time depending on the chemical disinfectant used. The spectrum of activity also depends on the type of chemical disinfectant used (Figure 2).

The method is unsuitable if the corrosive nature of the chemical disinfection may damage the equipment or if the equipment has areas inaccessible to liquid. It requires trained staff wearing protective clothing. It is potentially toxic, corrosive or volatile. Also, the equipment may have to be hand dried after disinfection allowing possible recontamination.

Equipment disinfectants commonly used and their spectrum of activity and physical properties

Disinfectant	Microbiological activity					Stability	Inactivation by organic matter	Corrosive/ damaging matter	Irritant
	Spores	Mycobacteria	Bacteria	Viruses[1] Enveloped	Viruses[1] Non-enveloped				
• Glutaraldehyde 2%	+++ (slow)	+++	+++	+++	+++	Moderate (fixative)	No	No	Yes
• Peracetic acid 0.2–0.35%	+++	+++	+++	+++	++	Poor (< 1 day)	No	Slight	Slight
• Alcohol (ethyl alcohol) 60–80%	None	++	+++	+++	++	High	Yes (fixative)	Slight	No Flammable
• Peroxygen compounds	None	+	+++	+++	++	Moderate (7 days)	Yes	Slight	No
• Chlorine-releasing agents >1000 ppm average Cl_2	+++	+++	+++	+++	++	Poor (< 1 day)	Yes	Yes	Yes
• Clear soluble phenolics 0.6–2%	None	+++	+++	+	None	Good	No	Slight	Yes
• Quarternary ammonium compounds	None	Variable	Moderate	+	+++	Good	Yes	No	No

[1] Activity varies with concentration of product.

Sterilization

Sterilization is used to produce an object free from viable microbial organisms including viruses and bacterial spores. There are several types of sterilizer (Figure 3).

Steam

When steam is pressurized it reaches a temperature greater than that of boiling water at atmospheric pressure and destroys or renders non-viable, bacteria, viruses and their spores. For this process to be effective, direct contact between the pure dry saturated steam and the object being sterilized is required at the specific temperature and in the absence of air. The temperature reached by the object determines the time required for sterilization. The lowest temperature recommended is 121°C for 15 minutes; the highest temperature of 134°C requires only 3 minutes.

This process is effective against all microorganisms with a significant safety factor. Problems occur with wrapped items because all air must be removed. To overcome this, porous load sterilizers are used, which incorporate a vacuum pump. Air is removed before steam is added. This is the most commonly used method for sterilization in hospitals today (Figure 4). However, it cannot be used for any material that cannot withstand the temperatures or pressures required for sterilization (e.g. thermo-labile plastics, fibre-optic endoscopes).

The advantages of this process are that steam is non-toxic, non-corrosive and a highly effective sterilizing agent. This system can be incorporated into a fully automated process on a large scale, coping with a high turnover of equipment. Disadvantages are that the operator must wear protective clothing to avoid direct contact with the steam.

Different types of hospital sterilizers

Types of sterilizer	Use	Minimum time / temperature
• Steam sterilizer		
Porous load	Wrapped instruments, dressings, utensils	134–138ºC for 3 minutes
Fluid cycle	Fluids in sealed containers	121–124ºC for 15 minutes,
	or 115ºC for 30 minutes	
Unwrapped instruments	Unwrapped instruments and utensils	134–138ºC for 3 minutes
• Hot air sterilizer	Oils, powders, heat-resistant instruments that must be kept dry	160ºC for 2 hours
• Low temperature steam formaldehyde sterilizer	Heat-sensitive equipment	73ºC for 3 hours
• Ethylene oxide	Heat-sensitive equipment	Various temperatures and times

Dry hot air

In this process, sterilization takes place by raising the ambient temperature. Typical processes consist of 160°C for 2 hours, 170°C for 1 hour, 180°C for 30 minutes. If all the items are completely clean and dry before this sterilization process starts, then all microorganisms will be killed. However, it cannot be used for materials that would be damaged by these temperatures (e.g. rubber, plastic).

Dry heat can be used to sterilize stable powders, waxes and non-aqueous liquids. It is also effective for non-stainless metals, hollow needles and glass syringes. However, the sterilization time is long compared with other methods, and items have to cool slowly afterwards. Many pieces of equipment cannot withstand these high temperatures for the allocated time.

Ethylene oxide

Ethylene oxide at ambient pressure and temperature vaporizes easily and thus has good penetrative properties. It is also non-corrosive and has a wide spectrum of activity against bacteria, spores, fungi, viruses and other living cells. Sterilization is usually carried out at 20–60°C for 2–24 hours.

Ethylene oxide is most often used under three different conditions:

- normal atmospheric pressure using undiluted ethylene oxide – the gas is very flammable, and so is often diluted to reduce explosion risk
- ethylene oxide with a diluent gas such as nitrogen at a pressure of 2 bar
- ethylene oxide diluted with carbon dioxide at a pressure of 6 bar.

This process should not be used if heat sterilization is possible. Organic material has a marked protective effect and therefore prior cleaning is essential. Ventilatory or respiratory equipment is contraindicated. Ethylene oxide does not penetrate plastic; therefore items must be wrapped in sterilization paper.

Ethylene oxide is a highly effective sterilizing agent. In particular it is used to sterilize single use medical items that would be damaged by the excessive heat used in other sterilization methods. Disadvantages of ethylene oxide are that it is toxic and long periods of aeration are required after sterilization therefore turn-around time is long. The process is expensive and there are significant health and safety issues concerning ethylene oxide and the equipment required to use it. Because of this, ethylene oxide is not often used in hospitals but is commonly used by industry.

Low temperature steam and formaldehyde

This process uses a combination of dry saturated steam and formaldehyde, which together kill vegetative bacteria, spores, fungi and most viruses. Objects are placed in the sterilizer to allow maximum contact with the steam. Air is actively removed from the container and replaced by dry saturated steam at 73°C at subatmospheric pressure. Formaldehyde is entrained as the steam enters the sterilizer.

The subatmospheric pressure may damage hollow objects. Formaldehyde may be corrosive with certain materials and some fabrics may absorb formaldehyde. This method cannot be used for items contaminated with body fluids, because the proteins in the fluids congeal and produce hard fixed deposits.

Advantages of the process are that it can provide dry, packaged items in a sterile form and the process is fully automated. Disadvantages are that the process is complex and formaldehyde is toxic, irritant and possibly mutagenic. The equipment required is also expensive, with the added problem of toxic waste products.

Irradiation

Irradiation uses γ rays or accelerated electrons. A dose greater than 25,000 Gray produces sterility. Irradiation is often used to sterilize single use items on an industrial scale. It has a broad spectrum of activity. Irradiation can cause significant degradation of materials and is unsuitable for the resterilization of hospital equipment.

The advantages are that it is reliable on an industrial scale for heat-labile pieces of equipment. However, irradiation can damage equipment particularly on re-exposure. Monitoring the process and the required safety equipment is expensive.

Special circumstances

Recent work has identified that the prion strain causing bovine spongiform encephalopathy (BSE) in cattle has infected humans, manifesting itself as a novel human prion disease, new variant Creutzfeldt–Jakob disease (vCJD). The abnormal prion protein is a new class of transmissible agent that demonstrates resistance to the standard methods of sterilization used in hospital sterile services departments.

Affected individuals accumulate prion protein in lympho-reticular tissues (e.g. appendix, tonsils), as well as in the CNS. The number of people incubating the disease is unknown, and there are concerns that prions might be transmitted iatrogenically via contamination of surgical instruments. Such risks remain unquantified, and there have been no identified cases involving vCJD transmission via surgical instruments. All neurosurgical instruments used on patients suspected of carrying vCJD are destroyed. However, there are significant implications for the safety of surgical instruments in ENT and other surgical practice.

The Spongiform Encephalopathy Advisory Committee (SEAC) has recommended that, where feasible, the move to single use instruments is appropriate. From January 2001, the Department of Health requires tonsillectomy and adenoidectomy to be performed using single use instruments in England and Wales. The recommendations are that instruments used to dissect or cut lymphoid tissue are to be disposed of. Anaesthetic equipment may also provide theoretical risk for prion disease transfer. This risk is as yet unquantified and accepted practice is continuing to evolve. It is likely that, in the near future, anaesthetic practice will change to incorporate disposable, single patient use equipment wherever possible (e.g. disposable laryngoscope blades and laryngeal mask airways).

Critical Incidents: The Cardiovascular System

Joy E R Beamer
Jonathan Warwick

Joy E R Beamer is a locum Consultant Anaesthetist at the Horton Hospital, Banbury, UK. She was recently awarded a CCST in Anaesthetics. She qualified from St George's Hospital Medical School, London, and undertook a specialist registrar training programme in the Oxford Region.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. He qualified from Birmingham University Medical School and trained in anaesthesia in the Royal Air Force. Further training as a Senior Registrar in the NHS was spent in Oxford. He now specializes in anaesthesia for plastic surgery and head and neck surgery.

Hypertension

Hypertension is a common critical incident during anaesthesia. Whether it is harmful depends on its severity, cause and duration, and on the condition of the patient. These factors also determine how actively it needs to be treated. Hypertension is difficult to define because of observer and subject variation, and the arbitrary nature of cut-off values, but definitions include:

- elevation of blood pressure at least 15% above patient's baseline
- systolic blood pressure greater than 160 mm Hg and/or a diastolic blood pressure greater than 95 mm Hg. Figure 1 lists the causes of hypertension during or persisting after anaesthesia.

Causes of hypertension during or persisting after anaesthesia

- Inadequate anaesthesia/analgesia
- Tracheal intubation/extubation
- Inadequate muscle relaxation
- Pre-existing hypertensive disease
- Hypoxaemia
- Hypercapnia
- Aortic clamping
- Raised intracranial pressure, cerebral ischaemia or cerebrovascular accident
- Drugs (e.g. ketamine, adrenaline (epinephrine))
- Metabolic disorders (e.g. malignant hyperpyrexia, thyroid crisis, phaeochromocytoma, carcinoid syndrome)
- Postoperative urinary retention, pain, anxiety

1

Complications

Cardiovascular – hypertension may precipitate myocardial ischaemia (especially subendocardial), infarction or failure.

Neurological – cerebral haemorrhage may result, especially in patients with vascular malformations. Cerebral oedema or encephalopathy are less common complications of uncontrolled hypertension.

Haemorrhage at the operation site or from pre-existing vascular malformations.

Renal – severe hypertension may precipitate acute renal failure.

Management

Management of hypertension should be directed towards the underlying cause. The usual cause is inadequate anaesthesia for the level of surgical stimulation being employed and treatment requires an increase in the inhalational or intravenous anaesthetic drug, or an increase in analgesia. Confirmation of the diagnosis may require a trial of therapy. If the cause of the hypertension cannot be diagnosed or removed, an appropriate antihypertensive drug may be used. The following are examples of drugs commonly used.

- Labetalol – combined α- and β-blockade; dose 5–20 mg i.v. over 2 minutes with increments up to 200 mg. Onset 5–30 minutes, duration 50 minutes.
- Metoprolol –β_1 (cardioselective) blockade; 2 mg increments slow i.v., maximum dose 15 mg.
- Esmolol – rapid onset; short half-life of 9 minutes; 500 µg/kg loading dose; 50–200 µg/kg/minute infusion.
- Nifedipine – calcium-channel blocker, sublingual or intranasal; onset 1–5 minutes following a 10 mg dose.
- Phentolamine – α-blockade; 0.5–2 mg i.v., repeated as necessary, rapid onset, short half-life 10–15 minutes.
- Hydralazine – direct-acting arteriolar dilator, peak action after about 20 minutes following 10–20 mg slow i.v. injection over 20 minutes. Onset occurs after 15–20 minutes; duration is 2–6 hours.
- Glyceryl trinitrate – arterial and venous dilator; use 1 mg/ml solution i.v. (preferably a central vein) via syringe driver, dose 10–200 µg/minute, maximum effect after 1–2 minutes.
- Sodium nitroprusside – arteriolar dilator; very rapid response, administered by continuous intravenous infusion via a dedicated vein, 0.5–1.5 µg/kg/minute. Direct arterial blood pressure recording is mandatory. Doses greater than 4 µg/kg/minute may cause cyanide poisoning.

Hypotension

Mild-to-moderate falls in blood pressure are common during anaesthesia, but seldom result in any harm to the patient. It is difficult to determine what is a dangerous level of hypotension; it depends on the duration of hypotension and the patient's preoperative medical condition. Two signs of inadequate myocardial perfusion are the development of ST segment depression and ectopic beats. Increased ventilation–perfusion mismatch secondary to pulmonary hypotension causes a fall in oxygen saturation (SpO_2). In awake patients receiving regional anaesthesia, nausea and dizziness are common symptoms of excessive hypotension. The lower limit of cerebral, renal and hepatic autoregulation occurs at a mean arterial pressure of about 60 mm Hg in otherwise healthy individuals.

Causes

Anaesthesia

- Volatile agents produce a dose-related fall in blood pressure (vasodilatation, myocardial depression, impaired baroreceptor response).
- Induction agents cause a dose-related fall in blood pressure owing to a complex combination of effects involving myocardial depression, vasodilatation, altered baroreceptor reflex and bradycardia (especially propofol).
- Opioids may precipitate histamine release and vasodilatation. Larger doses are associated with bradycardia.
- Non-depolarizing muscle relaxants may produce hypotension secondary to histamine release.
- Positive-pressure ventilation increases intrathoracic pressure and produces a decrease in venous return and cardiac output.
- Spinal and epidural anaesthesia produce sympathetic blockade. This results in vasodilatation, reducing venous return, cardiac output and systemic vascular resistance. Although reflex vasoconstriction occurs above the level of the block, blood pressure usually falls. Higher blocks (T4 or above) obtund the cardiac sympathetics, preventing a compensatory tachycardia.
- In obstetrics, aortocaval compression impairs venous return and in combination with spinal and epidural anaesthesia may produce profound hypotension.

Hypovolaemia, regardless of aetiology, becomes less concealed following induction of anaesthesia owing to impairment of compensatory mechanisms. Hypotension then ensues. Hypovolaemia may occur in patients with:

- trauma or burns
- gastrointestinal disease (e.g. haematemesis, melaena, small bowel obstruction, acute inflammatory bowel disease)
- dehydration from poor fluid intake, vomiting or diarrhoea
- metabolic disorders (e.g. diabetic ketoacidosis, diabetes insipidus, hypercalcaemia).

Surgical causes of hypotension include:

- haemorrhage
- head-up position
- excessive intra-abdominal pressure during laparoscopic surgery may impair venous return causing hypotension
- release of aortic cross-clamping or lower limb tourniquets causes an acute fall in systemic vascular resistance and blood pressure secondary to vasodilatation in the ischaemic tissues.

Cardiovascular disease may lead to hypotension:

- ischaemic heart disease with impaired cardiac contractility (including unstable angina and recent myocardial infarction)
- heart failure
- valvular heart disease (mitral or aortic stenosis and regurg-itation)
- dysrhythmias (fast atrial fibrillation, complete heart block)
- hypertension, especially if poorly controlled
- others (e.g. myocarditis, cardiomyopathy, constrictive pericarditis, myocardial contusion, tamponade, aortic coarctation, congenital cardiac anomalies).

Cardiovascular medication such as β-blockers, angiotensin-converting enzyme (ACE) inhibitors, calcium antagonists, nitrates, α_1-antagonists (prazosin) and centrally acting α_2-agonists (e.g. clonidine, methyldopa) may cause hypotension.

Autonomic neuropathy produces impaired baroreceptor response and may be present in a variety of disease states:

- diabetes mellitus (incidence and severity increase with the duration of the disease)
- Guillain–Barré syndrome
- spinal cord injury and following cerebrovascular accident
- Parkinson's disease
- AIDS.

Other causes

- Anaphylaxis may result in massive histamine-mediated vasodilatation, producing cardiovascular collapse.
- Pulmonary embolus from deep vein thrombosis, or emboli from air, carbon dioxide or fat may reduce cardiac output. Hypotension is accompanied by desaturation and a fall in end-tidal carbon dioxide.

Management

- Identify and remove the precipitating cause.
- Increase fraction of oxygen in inspired air (F_iO_2) to maintain SpO_2.
- Position patient supine, possibly with the legs raised to improve venous return. The head-down position is no longer recommended because it also raises cerebral venous pressure and therefore cerebral perfusion pressure may not be improved.
- Give a rapid intravenous infusion. The type and amount of fluid depends on aetiology and patient factors. A useful guide is to infuse 10 ml/kg of colloid or 20 ml/kg crystalloid initially and assess the response.
- Vasopressors may be considered, particularly if the cause of hypovolaemia is non-haemorrhagic (e.g. ephedrine, 3–6 mg i.v., metaraminol, 0.5–1.0 mg i.v., or phenylephrine, 0.5–1.0 mg i.v.).
- Consider an infusion of a positive inotrope (e.g. adrenaline (epinephrine), dobutamine) or vasoconstrictor (e.g. noradrenaline (norepinephrine)).

Massive haemorrhage

Bleeding is a significant cause of mortality and morbidity because of the loss of blood volume and its constituents and also the effects of infusions of products aimed at compensating for the loss. Massive blood transfusion can be defined as the transfusion of blood, blood products and fluids equivalent to the circulating blood volume in any 24-hour period. The most profound physiological, haematological and biochemical effects occur in those who have the most rapid loss and replacement therapy.

Causes of massive haemorrhage include:

- trauma
- major elective surgery such as orthopaedic or vascular surgery, especially rupture or dissection of the aorta
- during pregnancy and the puerperium (e.g. massive antepartum or post-partum haemorrhage)
- urgent operations and/or procedures in patients with abnormalities of haemostasis or coagulation.

Management

Measuring blood loss: the quantity of blood lost can be estimated by a number of methods.

- Weighing swabs and measurement of blood aspirated into suction apparatus. With major haemorrhage, these methods become less useful because a considerable amount of blood is spilled on to the drapes and floor. In traumatized patients, major blood loss may have occurred before arrival in hospital or may be concealed in the chest or abdomen, or in the limbs and pelvis at the site of fractures.
- Measuring packed cell volume. Blood lactate concentration gives an indication of the adequacy of organ perfusion.
- Clinical observation. The monitoring of cardiovascular variables such as heart rate, arterial pressure, capillary return, central venous pressure, and in some cases pulmonary capillary wedge pressure and cardiac output, allows a clinical impression of the adequacy of volume resuscitation to be made.

Compensatory mechanisms initially maintain the blood supply to vital organs. Unless adequate and appropriate corrective measures are taken, these mechanisms will decompensate. With increasing volumes of blood loss, there is an increase in heart rate, decrease in stroke volume, reduced pulse pressure, increased respiratory rate and a reduction in cerebral blood flow leading to a reduction in conscious level. These compensatory mechanisms are less efficacious in the elderly and very young and may be impaired by disease or medication. Figure 2 shows the relationship between the changes in vital signs and the volume loss from the circulation.

Relationship between the changes in vital signs and the volume loss from the circulation

	Blood loss (ml)			
	≤ 750	**750–1500**	**1500–2000**	**≥ 2000**
Loss as % of blood volume	≤ 15	15–30	30–40	≥ 40
Heart rate	< 100	> 100	> 120	≥ 140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Capillary return	Normal	Slowed	Slowed	Slowed
Respiratory rate (breaths/minute)	14–20	20–30	> 30	≥ 35
Urine output (ml/hour)	> 30	20–30	5–15	Negligible
Mental status	Normal	Anxious	Confused	Drowsy
Suggested volume replacement	Crystalloid	Crystalloid/colloid	Blood	Blood

Active management: the rapid and effective restoration of an adequate circulating blood volume is the primary responsibility of the anaesthetist during periods of heavy blood loss.

Establish adequate venous access by siting at least two large-bore cannulae to allow rapid fluid infusion. The most important pre-determinants of the flow rate of fluid are the diameter of the cannula and the ability to apply a continuous pressure of 2–300 mm Hg via a pressurized infusion system. Crystalloids and synthetic colloids may be used initially and should be followed by the administration of blood if bleeding continues.

Commence intravenous fluids – internationally accepted practice is to use Hartmann's solution as the initial resuscitation fluid for trauma and burns. The success of initial resuscitation in an acutely hypovolaemic patient probably depends more on adequacy of repletion than on which fluids are used. For a given blood volume expansion about twice the volume of crystalloid compared with colloid is required. In practice, combined therapy using both crystalloids and colloids is often used.

Fluids should be warmed – a transfusion system should have the ability to transfuse blood at fast flow rates (up to 500 ml/minute) and at temperatures greater than 35°C. Some systems use a constant-pressure infusion device combined with an efficient blood warmer and a purpose-designed blood-warming coil (e.g. *Level One*™). Priming or flushing blood through the system after fluid containing calcium has been used (such as *Haemaccel*) should be avoided, because this may cause blood clot formation in the tubing by reversal of the anticoagulant effect of citrate.

Blood should be taken for grouping and cross-matching, for coagulation studies and for biochemical analysis. Accurate identification of transfusion specimens and of designated units of blood, platelets and fresh frozen plasma (FFP) is particularly important in patients undergoing massive transfusion. It should be noted that most incompatible blood transfusions occur in emergency situations. For operations where significant blood loss is anticipated, replacement therapy should be available in advance of surgery.

Red cell transfusions are given to increase the haemoglobin concentration and thus improve or normalize the delivery of oxygen to the tissues. The haemoglobin concentration at which blood transfusion is commenced depends to a certain extent on the individual patient (e.g. elderly patients are at greater risk of complications from anaemia). A haemoglobin value below 8.5 g/dl would be an indication to transfuse in all apart from the younger fitter patient. A postoperative haemoglobin level of about 10 g/dl is widely accepted as a general guideline in adult surgical patients. However, it is more appropriate to base transfusion decision on a clinical assessment of the patient. If a major surgical procedure is planned, it may be possible to decrease the amount of donor blood transfusions by using an automated cell saver system.

About 80% of patients who have massive haemorrhage develop diffuse ooze from raw or cut surfaces. The causes are multifactorial but include relative hypothermia, abnormal platelet function, dilution of clotting factors, consumption of factors and enhanced fibrinolysis. It is critically important to monitor platelet numbers and the coagulation process during major bleeding and its resuscitation. The platelet count falls steadily with the transfusion of each successive unit of blood. Platelet infusion is indicated if there is:

- a platelet count less than 50 x 10^9/litre and there is impending surgery or an invasive procedure
- diffuse microvascular bleeding and transfusion greater than one blood volume and a platelet count of 50 x 10^9/litre or less, or the result is unavailable
- diffuse microvascular bleeding following cardiopulmonary bypass and the platelet count is 100 x 10^9/litre or less, or the result is unavailable
- bleeding in a patient with a qualitative platelet defect, regardless of platelet count.

Moderate deficiency of coagulation factors is common in massively transfused patients, but does not contribute to microvascular haemorrhage until levels fall below 20% of normal. These levels are reliably reflected by prolongation of the prothrombin (PT) and activated partial thromboplastin times (aPTT) to values of more than 1.5 times the control value. If the PT and aPTT are more than 1.5 times normal, 4 units of FFP should be given. If PT and aPTT are prolonged and fibrinogen is less than 0.8 g/litre, cryoprecipitate is indicated.

Arterial and central venous lines may be sited to allow rapid blood sampling, for acid–base and potassium status, and the direct measurement of arterial and central venous pressures. The central venous catheter also provides access for intermittent bolus administration of drugs or drug infusions.

A urethral catheter should be passed unless contraindicated by pelvic or urethral injury, and urine output monitored.

Core temperature should be measured continuously and every effort made to prevent heat loss. Hypothermia causes platelet dysfunction, reduced metabolism of citrate and lactate and an increased tendency to cardiac arrhythmias. This may result in bleeding diathesis, hypocalcaemia, metabolic acidosis and cardiac arrest.

Arrhythmias

Arrhythmias are one of the most commonly reported critical incidents. About 12% of patients undergoing anaesthesia develop arrhythmias; this increases to 30% in patients with cardiovascular disease. Treatment may not be required; this depends on the nature of the arrhythmia and its effect on cardiac output. Single supraventricular or ventricular ectopic beats, and slow supraventricular rhythms, do not require treatment unless cardiac output is compromised.

Management

Fluid, electrolyte and acid–base disturbances should be corrected preoperatively. Particular attention should be paid to the level of potassium ions in the plasma because they have a vital role in the generation of the resting membrane potential and thus muscle and nerve function. Patients with hypokalaemia may be prone to the development of supraventricular or ventricular extrasystoles and tachycardias. ECG changes of hypokalaemia include a long PR interval, ST depression, T wave flattening and a prominent U wave. Rapid treatment is indicated if arrhythmias are present. Intravenous administration of potassium supplements should not exceed 0.5 mmol/kg/hour.

Continuous intraoperative ECG monitoring is essential. The ECG gives no indication of cardiac output or tissue perfusion, therefore the detection of an abnormal cardiac rhythm should be followed by clinical assessment of the circulation. An absent pulse, severe hypotension or ventricular tachycardia or fibrillation should be treated as a cardiac arrest.

Correcting the precipitating factor is often the only treatment required. Hypoxaemia and inadequate anaesthesia or analgesia must be excluded. Factors associated with the development of arrhythmias are listed in Figure 3.

Intervention with a specific antiarrhythmic agent or cardioversion is indicated if there is:

- a risk of developing ventricular tachycardia or fibrillation (e.g. frequent, multifocal ectopic beats, or 'R on T' complexes)
- a significant decrease in cardiac output (causing dizziness or hypotension)
- evidence of myocardial ischaemia (causing chest pain or ST segment changes).

Factors associated with the development of arrhythmias

Preoperative conditions

- Ischaemic heart disease
- Pre-existing arrhythmias
- Congestive heart failure
- Hypertension
- Valvular heart disease
- Electrolyte disorders
- Medications (theophylline, β_2-agonists, tricyclic antidepressants)
- Others (thyrotoxicosis, myocarditis, cardiomyopathies, trauma, drug and solvent abuse)

Anaesthetic factors

- Hypoxaemia
- Hypo/hypercapnia
- Hypo/hypertension
- Laryngoscopy
- Drugs (e.g. volatile anaesthetic agents, suxamethonium, central venous pressure lines)

Surgical factors

Catecholamines

- Exogenous (e.g. infiltrated adrenaline (epinephrine))
- Endogenous (inadequate analgesia, inadequate anaesthesia)

Autonomic stimulation

- Oculocardiac reflex
- Laryngoscopy, bronchoscopy, oesophagoscopy
- Carotid artery and thyroid surgery
- Peritoneal and visceral traction
- Peritoneal insufflation

Direct stimulation of the heart

- Cardiac and thoracic surgery

Embolism

- Thrombus, fat, air, carbon dioxide, amniotic fluid

Others

- Limb reperfusion
- Aortic cross-clamping

Bradycardia can be treated with an anticholinergic agent such as atropine, 0.6 mg i.v., or glycopyrrolate, 0.2–0.4 mg i.v. If the bradycardia is refractory to treatment, cardiac pacing or an intravenous infusion of isoprenaline, 0.5–10 µg/minute, may be indicated. An anticholinergic drug may be given prophylactically if there is risk of bradycardia (e.g. strabismus surgery or following a second dose of suxamethonium).

Sinus tachycardia associated with myocardial ischaemia may be controlled by administration of a β-blocker such as metoprolol, 2 mg increments slow i.v., maximum dose 15 mg, or esmolol, 500 µg/kg, loading dose followed by 50–200 µg/kg/minute infusion.

Junctional rhythms are usually associated with the use of halothane. A reduction in concentration and/or changing the volatile agent is indicated. An anticholinergic drug may restore sinus rhythm.

Accelerated nodal rhythms may be precipitated by an increase in sympathetic tone in the presence of sensitizing volatile agents. Treatment includes adjusting the depth of anaesthesia and/or changing the anaesthetic agent.

Supraventricular tachycardia (SVT) can occur in susceptible patients, such as Wolff–Parkinson–White or other 'pre-excitation syndromes'. Treatment of SVT consists of:

- carotid sinus massage
- adenosine, 3–12 µg i.v.
- DC cardioversion if haemodynamic decompensation is present
- if there is no decompensation give verapamil, 5–10 mg slow i.v. over 30 seconds; the injection should stop when the SVT is controlled
- in sepsis-related or refractory SVT, volume loading plus amiodarone, 300 mg i.v. by infusion over 20 minutes, then 900 mg over 24 hours
- if the patient is thyrotoxic a β-blocker is useful.

Atrial fibrillation or flutter is often seen as a paroxysmal increase in the ventricular rate in patients with pre-existing atrial fibrillation or flutter. Having corrected any precipitating factors, the therapeutic options include:

- digoxin, 10 µg/kg by slow i.v. injection over 20 minutes, repeat after 4 hours according to response, maintenance dose 125–500 µg/day. Peak effect after 2 hours. Slows the ventricular rate and is a positive inotrope
- amiodarone produces a more rapid ventricular response and may re-establish sinus rhythm, give 300 mg i.v. by infusion over 20 minutes, then 900 mg over 24 hours
- β-blockers, especially in thyrotoxicosis, in combination with digoxin (e.g. propranolol 1 mg slow i.v. repeated every 2 minutes, maximum 5 mg)
- cardioversion is an option if the ventricular rate is fast with a clinically reduced cardiac output.

Premature ventricular contractions are common in healthy patients. Perioperatively they seldom progress to more serious arrhythmias unless there is underlying hypoxaemia or myocardial ischaemia. An underlying cause should be sought before antiarrhythmic agents are considered. If associated with a slow atrial rate, increasing the sinus rate with an anticholinergic drug will abolish them. Halothane lowers the threshold for catecholamine-induced ventricular arrhythmias; this is exacerbated by hypercapnia. Halothane should be used with care in patients receiving sympathomimetic drugs (including local anaesthetics containing adrenaline), and in patients taking tricyclic antidepressants and aminophylline.

Ventricular tachycardia and fibrillation should be treated as a cardiac arrest.

Malignant hyperthermia

Malignant hyperthermia is a rare inherited complication of general anaesthesia triggered by inhalational agents or suxamethonium in susceptible patients. The inheritance is complex and it is a genetically heterogeneous condition. These patients have a defect in intracellular calcium binding within the sarcoplasmic reticulum of skeletal muscle cells. Calcium ions are released on exposure to trigger agents, which initiates widespread skeletal muscle contraction and generalized membrane permeability. There is severe metabolic disturbance and catabolism runs unchecked, because raised levels of myoplasmic calcium ions result in increased production of pyruvate and heat. A successful outcome relies on making an early diagnosis, discontinuation of trigger agents, prompt treatment with intravenous dantrolene and supportive care. The mortality today has decreased to about 25% owing to increased awareness, monitoring and prompt treatment. The mode of presentation is variable and a high index of suspicion is required for early diagnosis.

Signs of malignant hyperthermia include:
- unusual muscle rigidity following suxamethonium (especially masseter spasm)
- unexplained tachycardia and arrhythmias
- rise in end-tidal carbon dioxide
- metabolic acidosis
- fall in oxygen saturation
- hyperkalaemia
- rise in core temperature (about 1–2°C/hour)
- evidence of a coagulation disorder, oozing from wound sites.

Management

Immediate actions
- Discontinue inhalational agents and inform the surgeons. Stop surgery if feasible, make the operating site safe and close wounds.
- Continue sedation or anaesthesia with a total intravenous technique. Hyperventilate with 100% oxygen using a clean breathing system. Change the circle system using fresh soda-lime, or use a non-rebreathing system.
- Immediately instruct staff to prepare dantrolene and commence as soon as available in an intravenous infusion of 1 mg/kg repeated at 10 minute intervals up to 10 mg/kg.
- Remove drapes, fully expose the patient and promote surface cooling with avoidance of vasoconstriction.
- Insert an arterial line to aid monitoring, and allow regular estimation of arterial blood gases, potassium and creatine kinase.
- Monitor the patient's core temperature.

Intermediate actions
- Control life-threatening dysrhythmias (e.g. β-blockers).
- Control hyperkalaemia with intravenous glucose or insulin.
- Control metabolic acidosis by hyperventilation, consider sodium bicarbonate (2–4 mmol/kg) if acidosis is severe (e.g. pH < 7.0).

Later actions
- Send blood for clotting screen (PT, aPTT, fibrinogen).
- Catheterize the patient. Test their urine for myoglobin. Collect samples for vanillylmandelic acid estimation to exclude phaeochromocytoma. Promote diuresis with intravenous fluids and mannitol, 0.5 g/kg over 20 minutes.
- Request a chest radiograph. Send blood for full blood count, biochemistry and thyroid function tests.
- Notify the intensive care unit.
- Repeat the creatine kinase estimation in 24 hours.
- Consider other diagnoses such as recreational drug ingestion (e.g. Ecstasy), neuroleptic malignant syndrome or myopathy.

Future care

The patient and their family should be counselled as to the likely diagnosis and the implications for future anaesthetics. Wearing a Medic-Alert bracelet should be encouraged. The patient and immediate family should be referred for further investigation and muscle biopsy to:

UK MH Investigation Unit, Academic Unit of Anaesthesia
Clinical Sciences Building
St James's University Hospital Trust
Leeds LS9 7TS
Tel: 0113 206 5274
Emergency hotline: 07947 609601

Future anaesthetic care can be provided safely with the avoidance of trigger agents – the volatile anaesthetics and depolarizing muscle relaxants. Prophylactic dantrolene is not recommended. Phenothiazines, antidepressants and haloperidol have been suggested as possible trigger agents, because of the similarity between malignant hyperthermia and the neuroleptic malignant syndrome, but this is unlikely. All other anaesthetic drugs appear to be safe.

Critical Incidents: The Respiratory System

Orlando J Warner
Jonathan Warwick

Orlando J Warner is Specialist Registrar in Anaesthetics at the Oxford Radcliffe NHS Trust Hospital, Oxford, UK. He qualified from the Royal London Hospital Medical School. For the past 2 years he has been the Advanced Trainee in Neuroanaesthesia at the Department of Neuro-surgical Critical Care and Anaesthetics, Radcliffe Infirmary, Oxford.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. He qualified from Birmingham University Medical School and trained in anaesthesia in the Royal Air Force. Further training as a Senior Registrar in the NHS was spent in Oxford. He now specializes in anaesthesia for plastic surgery and head and neck surgery.

A critical incident during anaesthesia is any event that may result in actual or potential harm to the patient if uncorrected. It may cause severe morbidity or even mortality. It is often preventable by a change in practice. Incident reporting is the key to preventing future disaster. There is observer bias concerning which incidents are recorded, and the problem for anaesthetists is to distinguish between a critical incident and the normal course of clinical practice.

This contribution deals with life-threatening problems in the management of the respiratory system including the clinical and physiological presentation of some commonly encountered critical incidents and their treatment. All may be a cause of alarming cyanosis under anaesthesia. Not all the problems discussed can be prevented and so some may not meet the precise definition of critical incidents. The recommendations aim to provide the anaesthetist with fast and effective solutions that may be used in clinical, examination or simulation situations. In all cases, the trainee anaesthetist must request senior help at the earliest opportunity.

Aetiology

The 2000 report of the National Confidential Enquiry into Perioperative Deaths (NCEPOD) cites hypotension, hypoxaemia, arrhythmia and cardiac arrest as the most common critical events that occur during or immediately following surgery. It also concludes that modern anaesthetic equipment, when properly checked, is very reliable. Human factors often play a major role in the aetiology of adverse events (Figure 1).

Factors involved in avoidable deaths

- Error of judgement
- Error of clinical expertise
- Lack of experience
- Lack of assistance
- Lack of equipment
- Equipment failure

1

Preparation is an important factor in predicting and treating these events and should involve:

- thorough preoperative patient assessment
- check of all anaesthetic equipment
- appropriate selection of drugs
- appropriate level of clinical expertise.

The Association of Anaesthetists of Great Britain and Ireland (AAGBI) has recently published new recommendations for standards of monitoring during anaesthesia and recovery. The Royal College of Anaesthetists (RCA) has a web page (http://www.rcoa.ac.uk/critincident/ciweb.html) that deals with the processing of critical incidents. The RCA is committed to setting up a national database so that even rare incidents can be reported and acted on. Critical incidents should be discussed locally at regular departmental audit meetings to complement the process of clinical governance.

Respiratory obstruction and increased peak airway pressure

Obstruction to the airway is an immediate threat to life and is the most common critical incident registered. The 'airway' can be considered as the conducting pathway responsible for the delivery of oxygen from anaesthetic machine to the alveolar/blood interface. Thus, obstruction may occur from outside or within the patient. The anaesthetic machine, breathing system and connections must be checked to ensure their patency and correct function before anaesthesia.

Obstruction of the airway within the patient may arise from the upper, supraglottic region, to the lower bronchiolar region. It may be caused by the devices used during anaesthesia or result from airway anatomy, pathology or trauma. Figure 2 shows some of the likely causes of airway obstruction in the perioperative period.

Possible causes of airway obstruction

Supraglottic

- Tongue
- Periglottic abscess, tumour, haematoma
- Regurgitation of solid material
- Blood or secretions
- Laryngeal mask airway (LMA) or tracheal tube luminal occlusion or misplacement

Laryngeal

- Laryngospasm
- Tumour or oedema
- Post-thyroidectomy (laryngeal nerve injury)
- LMA or tracheal tube luminal occlusion or misplacement

Tracheal or bronchial

- Aspiration
- Asthma
- Anaphylaxis
- Pneumothorax
- Pulmonary oedema
- Tracheal obstruction by retrosternal goitre
- LMA or tracheal tube luminal occlusion or misplacement

2

Respiratory obstruction during induction of anaesthesia

Preoperative evaluation of the airway is vital and should include mouth opening, dentition, Mallampati score, jaw movement, thyromental distance and neck movement. The aim is to predict which patients may present difficulty with direct laryngoscopy and intubation and those in whom difficulty may arise with airway maintenance following loss of consciousness, such as those with:

- obesity or a 'bull neck'
- limited mouth opening (e.g. trismus, following infection, trauma)
- restricted head and neck movement (e.g. severe ankylosing spondylitis, rheumatoid arthritis)
- stridor resulting from tumour, trauma, infection or haem-atoma
- upper airway soft tissue swelling (e.g. burns, pre-eclampsia). About 10% of reported critical incidents occur in the anaesthetic room. Patient monitoring during induction of anaesthesia should follow the guidelines established by the AAGBI. The patient must be monitored adequately during this stage of anaesthesia. If the required equipment is unavailable, induction should take place in the operating theatre.

Induction of anaesthesia in patients with upper airway obstruction requires specialized expertise. Management must involve a clear plan of how to proceed in the event of total airway obstruction during induction. These patients are best managed in the operating theatre with surgeons gowned and ready to perform immediate tracheostomy under local anaesthesia if necessary.

In routine practice, airway obstruction that occurs following induction is apparent from:

- paradoxical (see-saw) chest movement (when breathing spontaneously)
- noisy airway
- absent or diminished movement of the reservoir bag
- absent or diminished capnograph trace
- increased airway pressure (when mechanically ventilated)
- progressive oxygen desaturation.

Simple airway manoeuvres such as chin lift and jaw thrust, often combined with the insertion of a correctly sized oropharyngeal or nasal airway are necessary to maintain airway patency following induction. In apnoeic patients or those requiring assisted ventilation, bag and mask ventilation by two operators is more effective than that provided by one operator (Figure 3), allowing more effective face mask application and upper airway management. Manual ventilation with bag and mask is then easier to perform. If management is difficult, it is important to switch to 100% oxygen and call for senior help early on.

Two operators providing bag and mask ventilation

3

If airway obstruction persists, a laryngeal mask airway (LMA) often corrects the situation. While tracheal intubation provides a definitive airway, it may be difficult to insert in a patient who has not received muscle relaxants. Neuromuscular blockade should never be administered unless airway patency can be assured. However, if airway maintenance is lost following the administration of muscle relaxants then swift direct laryngoscopy and tracheal intubation should be attempted. Some patients (e.g. those with adenotonsillar hypertrophy, the obese or heavy snorers) are often easy to intubate despite having a difficult airway to maintain with bag and mask. The LMA is also the technique of choice following a failed intubation if subsequent airway management is difficult. Numerous reports testify to the ability of the LMA to provide a clear airway following a failed intubation. The *Combitube* may also be useful, though it is less commonly used in the UK. Both are 'supraglottic' airway devices, therefore it is unlikely that the *Combitube* will provide a clear airway if the LMA does not.

Can't intubate, can't ventilate (CICV)

The inability to intubate or ventilate a patient is rare, with an estimated incidence of 1/10,000 anaesthetics. It occurs when alveolar ventilation cannot be maintained despite best attempts at intubation and bag-mask ventilation (Figure 4).

Analysis of closed-claims in the USA revealed that the most common predisposing factor in the development of CICV was repeated and continued attempts at intubation. With each successive period of re-oxygenation between intubation attempts, bag-mask ventilation became increasingly difficult as laryngeal oedema evolved. The anaesthetist should limit intubation attempts to a maximum of three. The decision must be made early to abandon further attempts at intubation and the anaesthetist must use an alternative airway device, or wake the patient. The main causes of CICV are:

- repeated failed attempts at intubation
- airway or neck trauma
- burns to the head and neck
- pregnancy (especially pre-eclampsia)
- tumour (e.g. larynx)
- infection.

Requirements for optimum best attempts

Optimum best bag-mask ventilation

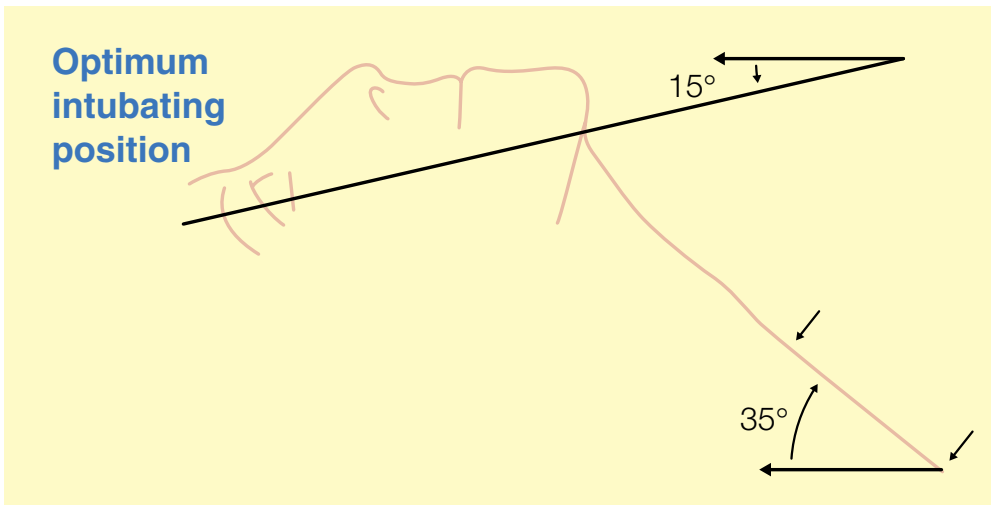
- Correctly sized oral or nasal airway
- Two-operator technique

Optimum best laryngoscopy

- Trained anaesthetist (3 years' training)
- Optimal intubating position
- Optimal external laryngeal manipulation
- Optimal laryngoscope

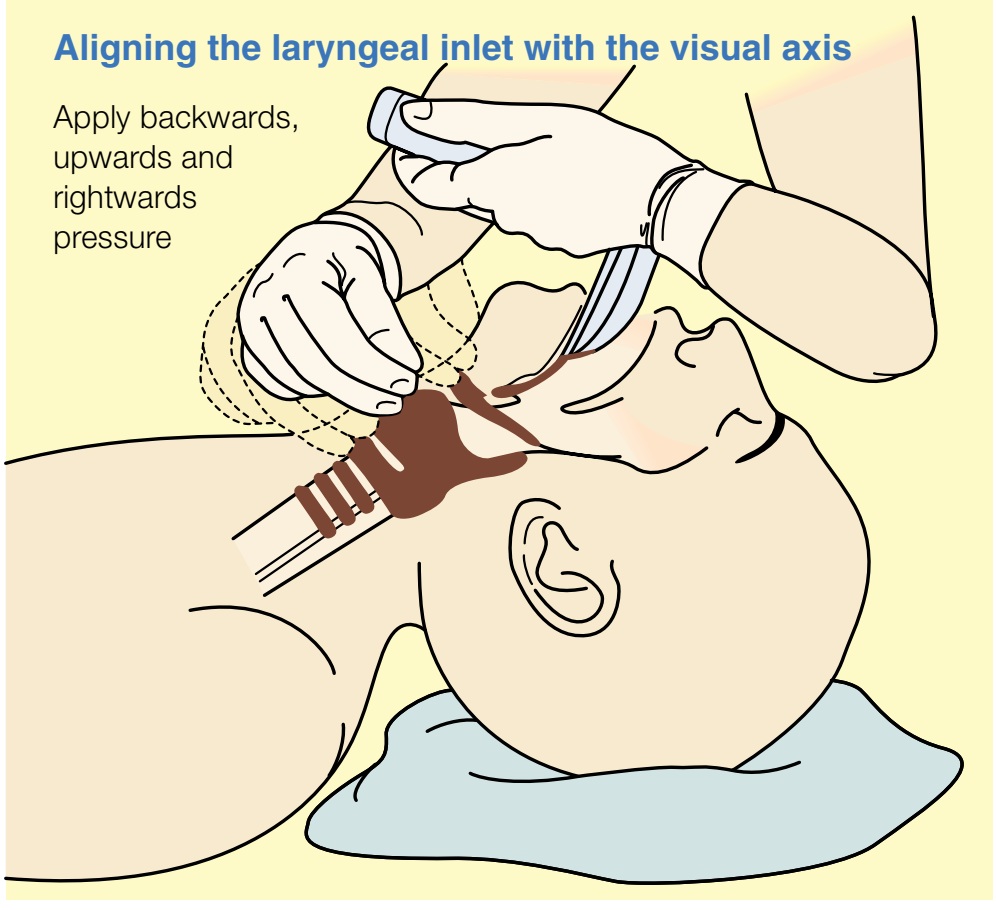
4

The optimal intubating position is shown in Figure 5. Flexion of the cervical spine, and extension of the head at the atlanto-occipital joint, aligns the glottis with the visual axis. In the obese or pregnant woman at term, this may require at least one pillow under the shoulders and two pillows beneath the head and neck. Anaesthetic induction and tracheal intubation should be avoided when patient positioning is not ideal.



5

The larynx should be manipulated from the front of the neck by the operator's free hand to help provide the best view. This position is maintained by the anaesthetic assistant while intubation is performed. Optimum external laryngeal manipulation does not mean 'cricoid pressure', which may further distort the view and make direct laryngoscopy more difficult. Optimum manipulation involves direct manipulation of the thyroid cartilage of the larynx. The application of backwards, upwards and rightwards pressure aligns the laryngeal inlet more closely with the visual axis. Correct optimum external laryngeal manipulation is shown in Figure 6.



6

The choice of laryngoscope blade is important. A useful guideline is to change the length of blade once, and the type of blade once, to achieve the best view. A variety of blades is available in clinical practice. The standard Macintosh blade (size 3) may need to be changed to a longer blade (size 4) or to a levering blade such as the McCoy. The McCoy blade can be successful in improving the laryngoscopic view by one grade (Cormack and Lehane grade 3 to 2). The Belscope blade has a 45° angle and a detachable prism, and may similarly improve a grade 3 view. The Polio blade is inclined at an angle greater than 90° to the handle, which may aid insertion into the mouth (Figure 7).

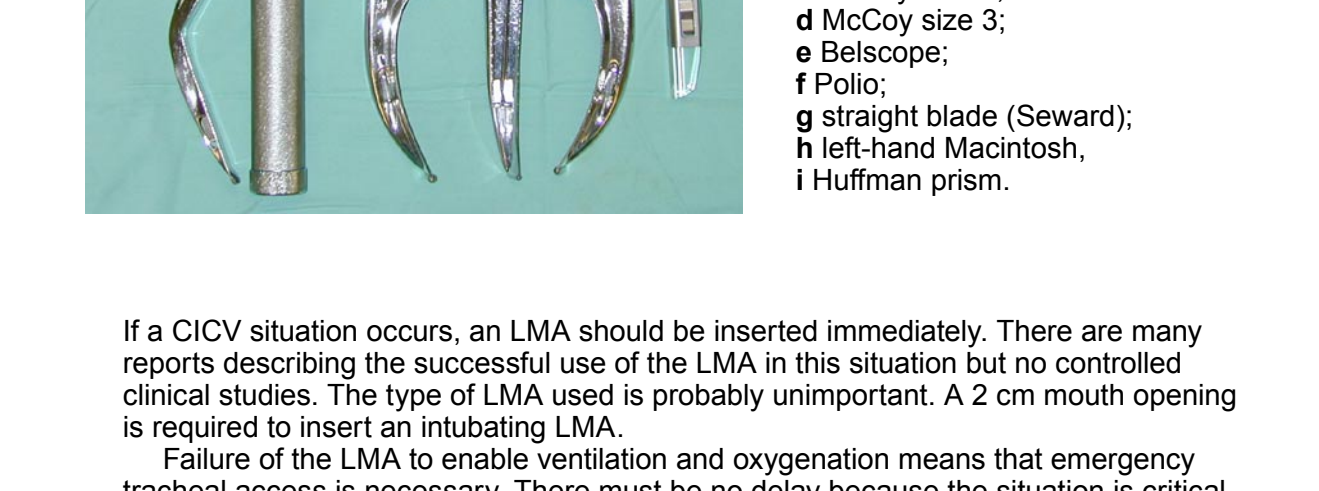
7 Laryngoscope blades:
a Macintosh size 4;
b Macintosh size 3;
c McCoy size 4;
d McCoy size 3;
e Belscope;
f Polio;
g straight blade (Seward);
h left-hand Macintosh,
i Huffman prism.

If a CICV situation occurs, an LMA should be inserted immediately. There are many reports describing the successful use of the LMA in this situation but no controlled clinical studies. The type of LMA used is probably unimportant. A 2 cm mouth opening is required to insert an intubating LMA.

Failure of the LMA to enable ventilation and oxygenation means that emergency tracheal access is necessary. There must be no delay because the situation is critical in a patient with marked hypoxia. Tracheal access is best achieved via the cricothyroid membrane by needle puncture, percutaneous cricothyrotomy or surgical cricothyrotomy. The precise technique depends on: the equipment available; the experience of the anaesthetist; and the nature of the emergency.

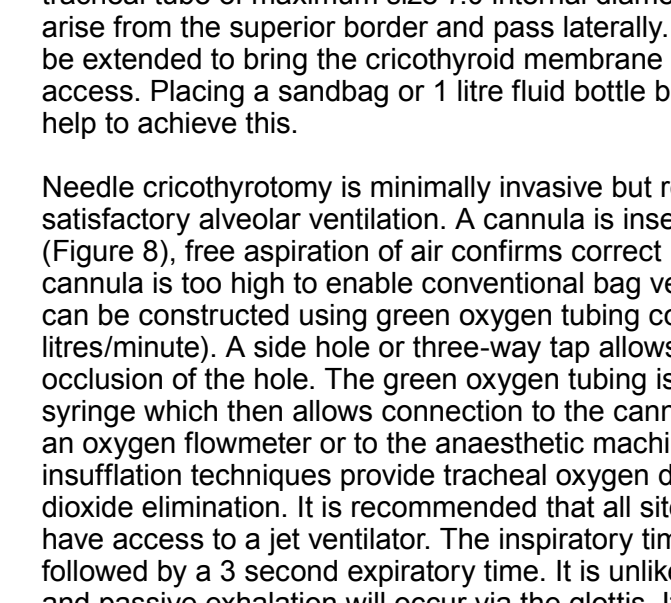
It is impossible to give firm recommendations but whatever the means used, the immediate aim is to achieve oxygen delivery to the trachea (and alveoli) via the cricothyroid membrane. This membrane lies subcutaneously between the cricoid and thyroid cartilages of the larynx and in the adult measures 1 x 3 cm. It will accept a tracheal tube of maximum size 7.0 internal diameter (ID). Paired cricothyroid arteries arise from the superior border and pass laterally. The patient's head and neck should be extended to bring the cricothyroid membrane closer to the skin surface to facilitate access. Placing a sandbag or 1 litre fluid bottle between the patient's scapulae may help to achieve this.

Needle cricothyrotomy is minimally invasive but requires a jet ventilator to achieve satisfactory alveolar ventilation. A cannula is inserted via the cricothyroid membrane (Figure 8), free aspiration of air confirms correct placement. Resistance through the cannula is too high to enable conventional bag ventilation. Simple emergency systems can be constructed using green oxygen tubing connected to a flowmeter (e.g. 10-15 litres/minute). A side hole or three-way tap allows for intermittent insufflation by finger occlusion of the hole. The green oxygen tubing is inserted into the barrel of a 2 ml syringe which then allows connection to the cannula. The free end is connected to an oxygen flowmeter or to the anaesthetic machine via a 15 mm connector. Oxygen insufflation techniques provide tracheal oxygen delivery but not satisfactory carbon dioxide elimination. It is recommended that all sites where anaesthesia is administered have access to a jet ventilator. The inspiratory time of about 1 second should be followed by a 3 second expiratory time. It is unlikely that airway obstruction is absolute and passive exhalation will occur via the glottis. If this is deemed inadequate a second cannula should be placed to allow exhalation and prevent overinflation and barotrauma. A needle cricothyrotomy is a temporary measure and preparations should be made for a formal tracheostomy.



8

Specific cricothyroid cannulae are available for emergency tracheal access (Figure 9). The Ravussin 13 G jet ventilation catheter (VBM Medical) is flanged to simplify fixation, and has both Luer-lock and 15 mm connections. The Cook 6 F emergency transtracheal catheter is spiral reinforced and kink-resistant; a standard 14 G intravenous catheter is easily kinked and difficult to fix. The main complication of the technique is incorrect needle position and subcutaneous/mediastinal emphysema.



9 Cricothyrotomy needles.
a 13 G Ravussin jet ventilation catheter (VBM Medical);
b 6 F Cook emergency transtracheal catheter;
c 14 G Venflon cannula.

Percutaneous cricothyrotomy allows emergency placement of a tracheal tube to allow more conventional ventilation via bag and mask. Several commercial kits are available, which differ in insertion technique (Seldinger or non-Seldinger), size of tube (3.5-6.0 ID), and time taken for tube placement. There are insufficient data to make recommendations concerning the optimum technique and the anaesthetist should be familiar with the equipment available in their hospital. A non-Seldinger kit (e.g. VBM Quicktrack, 4.0 mm ID) generally allows the most rapid access by direct cricothyroid puncture using a large diameter sharpened stylet. A Seldinger technique (e.g. Cook Melker kit 3.5-6.0 mm ID) may be safer to perform but requires several stages including the use of a dilator. All techniques require familiarization. Complications include bleeding, malposition and subcutaneous emphysema.

Surgical cricothyrotomy rapidly provides a definitive airway, though it requires more surgical experience and bleeding is likely to be considerable. It is ideally suited to the emergency trauma setting in the presence of severe maxillofacial, neck or laryngeal injury. Thorough training is necessary for this seldom performed but life-saving procedure. Practising on the sheep's larynx provides a realistic training model.

With finger and thumb either side, the cricothyroid membrane should be stabilized. A 22 scalpel blade is used to make a 2 cm vertical skin incision to part the skin. The scalpel should then be horizontally inserted into the cricothyroid membrane, perpendicular to the skin. This incision should be enlarged laterally. The scalpel handle should be inserted through the cricothyroid incision and rotated through 90°, then removed. A well-lubricated size 7.0 ID cuffed tracheostomy tube should be inserted. The main complications are bleeding and malposition.

Respiratory obstruction during the intraoperative period

If respiratory obstruction occurs during surgery, the following procedure will help to diagnose the cause of obstruction (Figure 2) and guide appropriate action to correct the situation. Surgery can then recommence.

- 100% oxygen should be commenced.
- The surgeons should be alerted to the problem and advised to stop surgery. The surgical stimulation may have caused the obstruction. Procedures such as dilation of the cervix or anus may precipitate severe stridor especially if anaesthesia is 'light'.
- The anaesthetic delivery circuit should be checked rapidly.

If it is patent, the obstruction must be within the patient.

- Access to the airway may be difficult, especially in head and neck surgery. Extreme circumstances of continued patient deterioration require the complete uncovering of surgical drapes and exposure of the airway.
- The upper airway should be checked for secretions, signs of regurgitation or obvious tube or LMA obstruction. The mouth and trachea should be suctioned if indicated.
- The capnograph confirms alveolar ventilation by displaying a carbon dioxide trace. Absence of a trace is a sign of complete airways obstruction. The normal capnograph trace may change in airways obstruction with a characteristic marked upslope to the alveolar plateau.
- The urgency of the situation is indicated by the oxygen saturation. If there is any doubt about the tracheal tube position, immediate replacement is needed. An LMA will need repositioning or changing to a tracheal tube. Careful observation of the chest wall during manual ventilation may show unilateral or little chest movement. Auscultation of the chest may detect unilateral air entry, wheeze or absent breath sounds. Withdrawing the tracheal tube slightly may alleviate this if the distal end has migrated to the endobronchial position, or is in contact with the carina.
- Fibre-optic bronchoscopy will confirm the position of the tracheal tube and that there is no intraluminal obstruction such as a sputum plug, blood clot or in rare circumstances, an endoluminal tumour.

Bronchospasm during anaesthesia

Bronchospasm is reversible airways obstruction most commonly associated with patients who have asthma or chronic chest disease. The incidence of asthma is 5-10% with a higher prevalence in children. Smokers and patients with upper respiratory tract infection are also at increased risk of bronchospasm. Bronchospasm occurs as a result of smooth muscle constriction within the respiratory subepithelial layers in the bronchioles. It may be accompanied by other pathological effects (e.g. mucosal oedema, cellular infiltrates, mucus secretion, desquamation of surface epithelial cells, goblet cell hyperplasia) which exacerbate smooth muscle contraction. Contraction is stimulated by neural or paracrine effects. Chemical mediators such as histamine and products of arachidonic acid, the leukotrienes, may act locally to initiate bronchoconstriction.

Bronchospasm is not the only cause of intraoperative wheeze (Figure 10). Luminal occlusion from eccentrically inflated tube cuffs (cuff herniation) used to occur with red rubber tracheal tubes, but modern disposable materials have made this complication less common, however the tracheal tube cuff should not be over-distended. The old adage 'if in doubt – take it out' remains true. A monophonic wheeze developing immediately after intubation may indicate tube occlusion, or a distal position next to the carina or within a bronchus.

Bronchospasm is suggested by:

- increased respiratory effort, tachypnoea and intercostal recession (if spontaneously breathing)
- expiratory wheeze (wheeze throughout the respiratory cycle may indicate obstruction within the breathing equipment)
- rise in inspiratory airway pressure (if mechanically ventilated). Management of wheeze while under anaesthesia is as follows.
- The surgeons should be alerted and asked to stop surgery.
- 100% oxygen should be delivered and anaesthesia deepened. Bronchospasm may result from a depth of anaesthesia that is too light for the degree of surgical stimulation. This includes stimulation of the airway by the anaesthetist. All modern inhalational agents are bronchodilators.
- The breath sounds over both lung fields and over the stomach should be listened to. Capnography confirms tracheal intubation. Tracheal tube position should be adjusted if necessary. Signs of pulmonary oedema or tension pneumothorax should be sought.• The position of the tracheal tube should be adjusted if necessary.
- The airway should be checked and the trachea should be suctioned looking for signs of aspiration.
- Full monitoring should be in place. Extreme tachycardia and cardiovascular collapse suggest anaphylaxis.

The treatment of bronchospasm includes the following.

- The inspired concentration of volatile anaesthetic agent should be increased.
- The patient should be treated with continuous inhaled salbutamol nebulizers, 5 mg, and ipratropium, 500 µg, until the wheeze settles. This is best delivered using a separate oxygen cylinder with nebulizer attachment, connected to the tracheal tube on the patient side of any heat/moisture exchange filter.
- If wheeze persists, aminophylline, 250−500 mg (5 mg/kg) i.v.in 500 ml normal saline over 20 minutes can be given (if notalready treated with theophylline or aminophylline preparations); continue with an infusion of 0.5 mg/kg/hour if needed.
- If bronchospasm is severe, salbutamol, 250 µg bolus i.v. over 5−10 minutes may be given, and continued as an infusion of 5 µg/minute, adjusted according to the heart rate and bronchospasm response.
- It may be necessary to adjust ventilator settings. A longer expiratory time may be needed to allow more complete exhalation, though a short inspiratory time will produce higher peak inspiratory pressures. An I:E ratio of 1:2 or 1:1.5 is usual.
- Hydrocortisone, 200 mg i.v., is not immediately effective but provides bronchospasm relief within 6–12 hours.
- Management of anaphylaxis will be covered in **CLINICAL ANAESTHESIA.**

Causes of intraoperative wheeze

- Endobronchial intubation
- Mechanical obstruction of the tracheal tube
- Bronchospasm
- Anaphylaxis
- Pulmonary oedema
- Tension pneumothorax
- Aspiration of gastric contents

Failure to breathe

A delay in the return of spontaneous respiration following anaesthesia is most commonly the result of an imbalance between the:

- patient requirements of anaesthesia and analgesia (differences caused by normal variation and the effects of coadministered drugs or disease)
- doses of drugs used
- timing of their administration.

In all patients, maintain ventilation to ensure satisfactory oxygenation and carbon dioxide removal. The patient is likely to be unconscious and usually all that is required is more time. If there is continued apnoea, inconsistent with the clinical picture, then a careful evaluation of the cause is needed. The patient should be reassured if they are conscious.

Assess neuromuscular block − a train-of-four ratio of 75% is usually adequate for satisfactory ventilation following anaesthesia. The presence of four good twitches with absent fade implies adequate reversal. Modern nerve stimulators (e.g. the train-of-four watch) can provide more accurate assessment of neuromuscular function by measurement of thumb acceleration (and thus force, because the mass of the thumb is constant). The standard 1 ml ampoule of glycopyrrolate, 0.5 mg/neostigmine 2.5 mg, is the correct reversal dose for a 50 kg patient. The ability to sustain a 5-second head lift from the pillow is a useful clinical indicator of neuromuscular recovery. Figure 11 shows factors that prolong the action of a non-depolarizing neuromuscular block.

Factors that may increase duration of non-depolarizing neuromuscular block

- Hypokalaemia
- Hypothermia
- Hypocarbia
- Neuromuscular disease (e.g. myasthenia gravis, Eaton-Lambert syndrome)
- Inhalational anaesthetic agents
- Aminoglycosides
- Calcium antagonists
- Magnesium
- Local anaesthetics
- Lithium
- Frusemide

Partial reversal of neuromuscular block presents as respiratory inadequacy together with jerky, uncoordinated gross muscular movement. Laryngeal muscle weakness can produce airway obstruction and stridor. The best treatment is to:

- reassure the patient (they may be distressed and feel unable to breathe, with tachycardia and hypertension) and administer 100% oxygen
- help allay anxiety by giving midazolam, 2 mg i.v. or reintroduce general anaesthesia for a short period of time
- correct any underlying cause
- administer further neostigmine (with glycopyrrolate) to a total of 70 µg/kg i.v. (maximum dose 5 mg) if necessary.

Plasma cholinesterase activity − if suxamethonium (or mivacurium) has been used and return of adequate neuro-muscular function is delayed, it is likely that plasma cholin-esterase activity is decreased. This may be an inherited abnormality of cholinesterase activity or an acquired reduction in enzyme activity (Figure 12). The genetic variants have autosomal dominant inheritance, and the prevalence of homozygotes for the atypical gene is 1:2500 of the Caucasian population. Only homozygotes display significantly prolonged apnoea. This may produce many hours of continued paralysis. The patient will come to no harm providing ventilation is supported and adequate sedation is continued (e.g. propofol, 4−6 mg/kg/hour). Neuromuscular block should be monitored with a nerve stimulator and eventually wears off. Infusion of fresh frozen plasma containing cholinesterase enzyme speeds recovery of neuro-muscular function. The benefits must be balanced against the cost and infection risk. Acquired conditions (Figure 12) that reduce plasma cholinesterase activity may slightly increase suxamethonium duration.

Factors that may cause decreased plasma cholinesterase activity

Congenital

- Autosomal dominant inheritance of abnormal enzyme Four alleles have been identified: $E1^n$ normal, $E1^a$ atypical, $E1^f$ fluoride-resistant, $E1^s$ silent

Acquired

- Infections
- Malignancy
- Chronic disease
- Liver disease
- Renal failure
- Pregnancy, oral contraceptives
- Hypothyroidism
- Drugs (monoamine oxidase inhibitors, ecothiopate eye drops, organophosphorus compounds, chemotherapy)

Doxapram is a central respiratory stimulant that may reverse the respiratory depression caused by general anaesthetic agents and potent analgesics. It does not reverse the other effects of opioids. It acts by direct stimulation on the carotid body chemoreceptors. A maximum dose of 1.5 mg/kg slow i.v. can be given.

Benzodiazepines − flumazenil can be used to reverse the central sedative effects of benzodiazepines. It has a shorter half-life than midazolam and diazepam, and therefore re-sedation is possible. Flumazenil, 200 µg i.v., should be given followed by 100 µg i.v. every minute as necessary. The maximum total dose is 1 mg. While benzodiazepines may contribute to postoperative sedation, they seldom cause apnoea unless large doses are used or the patient is elderly and frail.

Opioid drugs − if excessive narcotic is suspected, then give naloxone by titrating dose to effect. Dilute 400 µg in 10 ml normal saline and give 1−2 ml every few minutes to achieve the desired effect. It is important not to use excessive naloxone to prevent reversal of the analgesic effect. Pain, hypertension and tachycardia may result. The patient must be observed closely for the next 4−6 hours because the duration of the naloxone effect may be shorter than that of the opioid.

Check end tidal carbon dioxide tension ($P_{E'}CO_2$) – hyperventilation during anaesthesia results in reduced respiratory drive. Spontaneous ventilation is unlikely to occur until the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) and $P_{E'}CO_2$ have normalized. The addition of 5% carbon dioxide to the inspiratory gas mixture was common in older anaesthetic practice to stimulate respiratory drive. Hazards associated with carbon dioxide use, in particular the inadvertent use of carbon dioxide from incorrect flowmeter settings, have removed the use of this gas from modern practice.

The $P_{E'}CO_2$ should be allowed to rise by itself by either reducing minute volume, or adding dead space into the breathing system (e.g. disconnection of the absorber from a circle system).

Body temperature – hypothermia delays recovery from anaesthesia, prolongs the duration of neuromuscular blockade and is an important cause of postoperative hypoventilation. The fall in core temperature that occurs with anaesthesia should be anticipated and minimized using passive or active rewarming (see *Anaesthesia and Intensive Care Medicine* **1:3:** 122). Continued ventilation in the recovery area or ICU may be required until rewarming is completed and spontaneous ventilation is satisfactory.

Neurological vital signs − an intracranial bleed during surgery is a rare cause of continued unconsciousness and apnoea. It may occur as a result of an undetected head injury in patients undergoing surgery for trauma, or coincidentally in patients with cerebrovascular disease. A CT scan is required for diagnosis.

Investigations in the patient who fails to breathe following anaesthesia should include:

- blood gases, electrolytes and glucose
- body temperature
- neuromuscular function (nerve stimulator)
- ECG and chest radiograph
- CT head scan
- blood for serum cholinesterase activity if indicated.

Air embolism

If bubbles of gas enter the circulation, they may accumulate in the right ventricle. Unlike liquid, gases are compressible, and therefore adequate ejection of blood is not achieved, reducing stroke volume and cardiac output. This can present clinically as a minor fall in blood pressure, hypoxaemia or complete cardiovascular collapse with electromechanical dissociation. If a patent foramen ovale is present, or any other shunt-causing communication between the right and left sides of the heart, the air could enter the systemic circulation and cause neurological injury or coronary artery embolism and infarction (paradoxical air embolism). The effects of air embolism depend on the:

- volume of air entrained
- rate at which it enters the circulation
- general condition of the patient.

Experiments in dogs suggest that volumes greater than 20 mlare potentially fatal.

Some operations carry an increased risk of air embolus (Figure 13). Air may be entrained into an open vein when the venous pressure is subatmospheric. Air embolism occurs in 25−50% of all craniotomy operations in the sitting position and the incidence has reduced now this position is seldom used. The prone position with head tongs appears to be safer for posterior fossa surgery.

Procedures with increased risk of air embolus

- Posterior cranial fossa neurosurgery (especially in the sitting position)
- Lumbar laminectomy and head and neck surgery when the vertebral column is positioned above the level of the heart
- Hepatic surgery that carries a risk of opening the inferior vena cava
- Any patient with a central venous pressure catheter in situ that may result in accidental entrainment of air
- Varicose vein ligation
- Surgery combined with low venous pressures (e.g. in children)

13

Signs that alert the anaesthetist to the development of air embolism are usually detected by monitoring. Early diagnosis allows prompt institution of preventive measures before the situation becomes critical. The signs of air embolus include:

- sudden fall in $P_{E'}CO_2$ despite unchanged ventilatory settings (if breathing spontaneously the patient may develop respiratory distress)
- turbulent blood flow (monitored by precordial Doppler probe; conventional auscultation may reveal continuous ‘millwheel’ murmur as a late sign)
- fall in oxygen saturation
- pulmonary artery pressure increases during air embolism (it is not often monitored)
- arterial hypotension
- tachycardia, dysrhythmias or cardiac arrest.

Management (Figure 14) comprises prevention of further air entrainment, attempts to remove the air and supportive measures.

Management of air embolus

- Ventilate the patient with 100% oxygen. Stop nitrous oxide administration
- Flood the surgical site with normal saline, wet packs, and apply bone wax to any area of exposed bone cortex. Manually compress the proximal veins to stop further air entrainment
- Attempt to increase venous pressure
  - Position patient head down (or surgical site down)
  - Give rapid fluid bolus (250−500 ml) and observe effects
  - Use vasopressors if the arterial blood pressure is severely affected
  - Compression of the abdomen
  - Activation of antigravity venous compression device (G suit) if fitted
- If a central venous catheter (CVC) is in situ, try to aspirate air from all lumens. Insert a CVC (right internal jugular or subclavian) if one is not present
- The left lateral position may transfer air from the pulmonary artery to the right ventricle, thereby improving pulmonary flow (there is little evidence that this is of benefit)
- Give cardiopulmonary resuscitation if required

14

Pneumothorax

The pleural cavity usually exists only as a potential space between the parietal pleura (attached to the innermost intercostal muscle, the transversus thoracus), and the visceral pleura (continuous with the lung parenchyma). A pneumothorax occurs when this potential cavity is opened, either by breaching the chest wall structures (an open pneumothorax), or by injury to the lung parenchyma (a closed pneumothorax).

- The clinical management is concerned with releasing the accumulation of air from the cavity and correcting the chest wall injury. Understanding the anatomy of the chest cavity allows cause and effect to be identified rapidly.
- The dome of the lung protrudes superiorly above the thoracic inlet to the level of the 6th cervical vertebra. The tip of a needle inserted towards the internal jugular vein could pass more posteriorly where it may cross the pleural space and enter the apices of the lung parenchyma. This is possible even with a relatively high approach.
- The inferior part of the chest cavity extends to the costo-diaphragmatic recess. This reaches to the crura of the diaphragm at the level of the 12th thoracic vertebrae. The cavity can be entered inadvertently in this low position by surgery to the renal bed or lower thoracic and upper lumbar vertebrae.
- The mediastinal pleura lies against the vertebral bodies, oesophagus, aorta, large veins, heart and trachea. Damage to many of these mid-chest structures could allow air or blood to enter the pleural cavity. Trauma from accidents or surgical instrumentation of the oesophagus or trachea may cause this.

The signs and causes of a developing pneumothorax while under general anaesthesia are shown in Figure 15; some or all may be present depending on the nature of the pneumothorax (simple or under tension), its speed of onset, the general health of the patient and whether they are breathing spontaneously or are mechanically ventilated.

Signs and causes of pneumothorax

Signs

- Hypoxaemia
- Wheeze
- Increasing airway pressure
- Unilateral chest wall motion
- Reduced air entry
- Hyperresonance
- Distended neck veins
- Shock
- Shifted trachea away from affected side

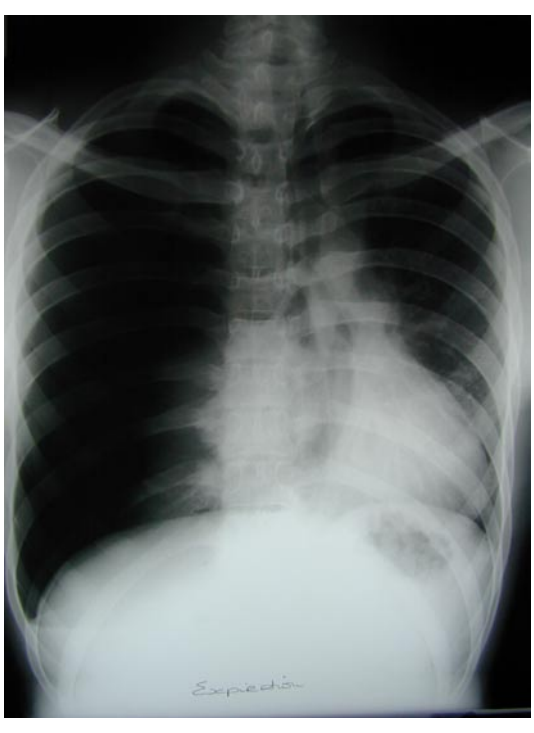
Causes

- Central venous catheter insertion
- Penetrating or blunt chest trauma
- Diaphragmatic, tracheal, oesophageal or cardiac surgery
- Chest drain clamping
- Spontaneous bullae rupture

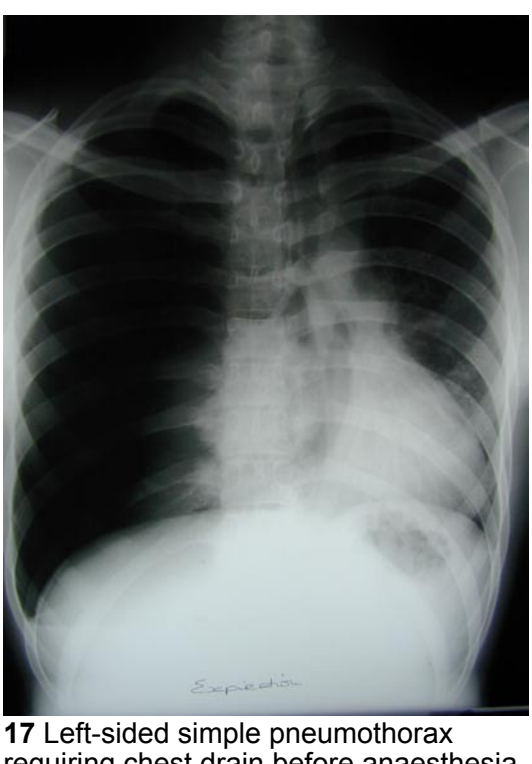
15

In trauma patients, pneumothorax should be identified and treated by chest drain insertion before anaesthesia to avoid the dangers of tension pneumothorax following the start of positive pressure ventilation (Figures 16 and 17). If there is obvious chest injury, but no clinical sign or chest radiograph appearance of pneumothorax, ‘prophylactic’ bilateral chest drains may be indicated. The risks of chest drain insertion must be balanced against the consequences of a tension pneumothorax developing during interhospital or intrahospital transfer or during the perioperative period.

Immediate management of a tension pneumothorax is chest decompression using a 14 G cannula inserted in the midclavicular line and second intercostal space. This should be followed immediately by formal chest drain insertion.



16 Right-sided tension pneumothorax requiring immediate needle decompresion followed by chest drainage. Gross mediastinal deviation is shown to the left.



17 Left-sided simple pneumothorax requiring chest drain before anaesthesia.

Electrical Hazards: Their Causes and Prevention

John Moyle

John Moyle is Consultant in Palliative Medicine in Milton Keynes and a Chartered Engineer. He trained with Philips Electrical Industries. He read medicine at St Bartholomew's Hospital, London and trained in anaesthesia and intensive care at King's College Hospital, London.

Before 1940 there was little electrical equipment in the operating theatre apart from crude radiofrequency diathermy. Since then there has been an invasion of electronic monitoring equipment and many surgical tools are electrically powered. The operating theatre and ICU are unique in electronic engineering because deliberate electrical contact is made with the human body.

The body should be protected from electric current. The body may be considered as an electrolyte solution, which is a good conductor of electricity, contained in a leather bag. Dry leather is a good electrical insulator but conducts electricity easily when damp especially with electrolyte-containing liquids such as sweat.

Electrical injury is caused primarily by the intensity of the current passing through. Current is dependent on the potential difference or 'voltage' across the body and the resistance of the tissues through which it passes (Ohm's law).

$$I = \frac{E}{R}$$

where: E, potential difference (volts); R, resistance (ohms); I, current (amperes)

Severity of injury also depends on the current pathway through the body, environmental factors and the pre-existing health of the patient.

Pathophysiological effects

The pathophysiological effects of electricity range from a mild 'tingling' feeling to ignition in extreme cases. Any electrical current passing through a resistance loses some energy by conversion to heat. The amount of heat generated depends on the current and the value of the resistance; this may be beneficial and forms the basis of coagulation by radiofrequency diathermy. Electricity may stimulate excitable tissues, both nerves and muscles. In a controlled way, this effect may be used medically (e.g. peripheral nerve stimulator, defibrillation). Direct currents, even of low intensity, may cause electrochemical effects. Very high currents, generated by high voltages, cause arcing or sparking and char the tissues. This effect may be harnessed when radiofrequency diathermy is used to cut tissues.

Complications of the inadvertent application of electric currents to the body are:

- cardiopulmonary arrest
- cardiac arrhythmia
- skin and tissue damage
- associated injuries caused by gross muscle contraction.

In the hours after an electric shock there may be further heart rhythm disturbances, hypoxia and electrolyte disturbances, and acute renal failure due to myoglobinuria. It is difficult to predict the effect of electricity on the body because of variables such as body size, proportion and general health. Pre-existing heart problems make the heart more susceptible to arrhythmias.

The current pathway through the body dictates the type of injury. Current passing through the head or across the thorax may cause loss of consciousness and respiratory arrest with or without ventricular fibrillation. Current passing from hand to hand (Figure 1) may cause ventricular fibrillation. Current passing vertically through the body is more likely to cause cardiac muscle damage and injury to other vital organs especially the spinal cord. These injuries depend on the intensity and duration of the current.

The resistance of the human body is not uniform, therefore electricity does not pass evenly through it. Skin resistance is low and allows electricity to pass easily, especially when wet with sweat. Blood has a relatively low resistance, therefore highly vascular areas or inflamed areas of skin have lower resistance. The highest skin resistance is found over heavily calloused areas such as the palm or sole.

The pathway of the current inside the body depends on the resistance of each tissue type. Tissues with the lowest resistance (the best conductance) are nervous tissue, blood, mucous membranes and muscle; the poorest conductors are tendon, bone and fat.

Direct and alternating currents have different effects on the body. Direct current of sufficient intensity causes short duration muscle spasm which may throw the victim from the source. There may be a disturbance of heart rhythm and blunt mechanical trauma. Alternating current, especially at 50 Hz (60 Hz in North America) is approximately three times more dangerous than direct current. Alternating current (40–110 Hz) causes continuous muscle spasm or tetany. As the flexor muscles are more powerful than the extensors, tetany may cause the victim to grip the offending conductor more tightly, thus prolonging the duration of current. Local diaphoresis also reduces skin resistance at the point of contact thus increasing the current.

50 Hz (or 60 Hz) is a bad choice of frequency for the public utility electricity supply because it is the frequency to which the body is most sensitive. At higher frequency the body is progressively less sensitive to the excitable effects of electricity. Radiofrequency surgical diathermy uses frequencies greater than 100 kHz at which comparatively large current may be passed, taking advantage of the heating effects of electricity without affecting excitable tissues.

Effects of hand-to-hand 50 Hz alternating current

1 mA	Tingling sensation
5 mA	Pain
15 mA	Severe pain with local muscle spasm
50 mA	Respiratory muscle spasm
80–100 mA	Dysrhythmias, pump failure, ventricular fibrillation

1

Electrical safety

The basic principle of electrical safety is to prevent the body becoming part of an electrical circuit. This requires good design of equipment, cables and connectors. Even with the highest quality of design, the user has the responsibility of using and handling equipment sensibly.

The conventional single-phase mains supply has two conductors: live and neutral. The live conductor is at a voltage dependent on the supply, normally 220–240 volts (110 volts in the USA) with respect to the neutral conductor which is 'tied' to earth at the substation. A safety or earth conductor may also be present which is connected to earth locally and therefore may be at a slightly different potential from the neutral conductor. It is unusual to get an electric shock from the neutral conductor alone but a circuit may be completed between a live conductor or component and either the neutral conductor or, more commonly, an earth pathway (Figure 2). This condition may be eased by the use of an isolation transformer (Figure 3) which will protect against electrocution via earth but not between earth and neutral. Isolation transformers are the most common form of basic protection with medical equipment and are often contained inside the equipment. (Further isolation is required when connection is made directly to the patient, this is described below.)

Conductor with earth pathway

2

Conductor with isolation transformer

3

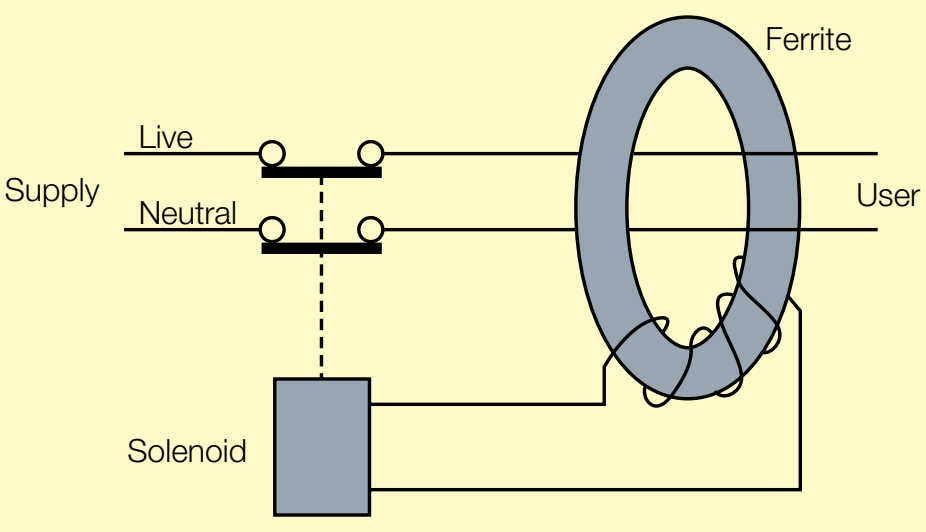
Electrocution depends on the duration of exposure and current. The shorter the duration, the higher the current required before damage is done. The earth leakage or residual circuit breaker stops the current passing through the body before any serious damage occurs. This phenomenon is used as the final level of protection from electrocution in the domestic situation and is commonly used commercially for power tools. The principle of the earth leakage circuit breaker (ELCB) is shown in Figure 4. The ferrite ring forms the core of an electrical transformer. The live and neutral conductors pass together through the ring, forming a single-turn primary of the transformer. The secondary of the transformer consists of many turns of much finer wire and is connected to a solenoid. When the solenoid is energized it breaks the supply. In the normal state, current passes down the live conductor, through the appliance and back through the neutral conductor. The current in the neutral is equal and opposite to that in the live and so their magnetic fields are cancelled out and no current is generated in the secondary winding. If some current leaks out of the appliance due to a fault or someone touching a live part, there is an imbalance between the live and neutral and a much amplified current is generated in the secondary, energizing the solenoid and disconnecting the supply.

Earth leakage circuit breaker



4

Microshock: electrocution of the intact human body is commonly referred to as macroshock to distinguish it from microshock in which smaller currents can lead to cardiac dysrhythmia or arrest because one of the points of contact is on or in the heart. 50 Hz mains electricity at a current as low as 50 μA by this route may have serious consequences. Contact may be made with the heart during thoracotomy but a more common and less obvious route is via electrolyte solutions in catheters in or near the heart. Therefore, any equipment that might make connection with the heart must be specially designed to protect against the unintentional passage of these very small currents. Such equipment includes ECG recorders, intravascular pressure monitoring systems, pacemakers and defibrillators.

Leakage current may be defined as electric current that has passed through insulators. It is difficult to design equipment with perfect insulation. The reduction of leakage in medical equipment requires special design features. The designer has to ensure that no electrically live parts are accessible. Any outer metal casing has to be connected to earth; an extra layer of insulation may also be used – the 'double insulation' often used on power tools. These techniques may make a piece of medical equipment safe to be in the patient environment. However, if there is any possibility of connection with the heart, special isolation techniques have to be employed by the equipment designer to ensure that any leakage current is less than 10 μA. This is a stringent limit to achieve.

Safety standards

All medical equipment manufacturers have to comply with published international standards. Each nation also has its own standards organization; in the UK it is the British Standards Institute (BSI). To make standards applicable on a worldwide basis, all national organizations cooperate to write international standards. The International Standards Organization (ISO) deals with everything excluding electricity; the International Electrotechnical Committee (IEC) deals with the standards of anything electrical. Both the ISO and the IEC are based in Geneva.

IEC-60601 is the basic standard for medical equipment. It classifies equipment in two ways; the method of electrical protection and the degree of protection.

- Class I equipment uses a 'protective' earth connection to the outer conductive casing.
- Class II protection is by double insulation. The degree of protection required is classified as B, BF or CF (C, intra cardiac or near cardiac; F, floating) as shown in Figure 5. Figure 6 shows the same symbols, with the indication that the equipment may withstand a defibrillator pulse without damage.

Three types of protection required

Type B applied part

- Maximum leakage current 0.1 mA
- Single fault condition 0.5 mA
- Allowed in patient care area but not in direct contact with patient
- Can be used in X-ray and suction equipment and operating theatre lights

Type BF applied part

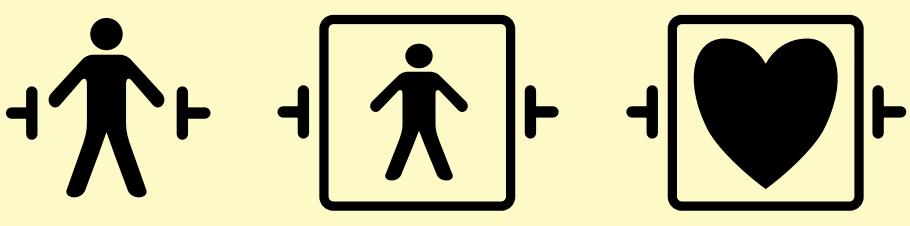
- Maximum leakage current 0.1 mA
- Single fault condition 0.5 mA
- Floating/Isolated
- May be deliberately in contact with patient but not in direct contact with heart
- Can be used in temperature measurement, non-invasive blood pressure measurement, ultrasonography, pulse oximetry, capnography

Type CF applied part

- Maximum leakage current 0.01 mA
- Single fault condition 0.05 mA
- Floating/Isolated
- Suitable for direct cardiac application
- Can be used in ECG, EEG, direct blood pressure measurement, electromagnetic blood flow

5

Symbols indicating equipment is able to withstand a defibrillator pulse



B BF CF

6

Two values of leakage current are given for each category; the lower refers to the equipment in its normal state; the higher value is the maximum allowable leakage current with a single fault condition (SFC). The Standard lists the allowable SFCs for each type of equipment. All medical equipment has to be marked with symbols to show the degree of protection. Figure 7 includes other relevant safety markings that are published in IEC 60601.

Electrical symbols

~	Alternating current
3~	3 Phase alternating current
3N~	3 Phase alternating current with neutral
⎓	Direct current
⏚	Protective earth (ground)
⏚	Earth (ground)
N	Neutral conductor (only on permanently installed equipment)
⏚	Equipotentiality

Fires and Explosions

John Moyle

John Moyle is Consultant in Palliative Medicine in Milton Keynes and a Chartered Engineer. He trained with Philips Electrical Industries. He read medicine at St Bartholomew's Hospital, London and trained in anaesthesia and intensive care at King's College Hospital, London. He teaches physics and clinical measurement to trainee anaesthetists.

Less emphasis is placed on the risk of fire and explosion in the operating theatre today than previously mainly because the use of flammable agents has decreased; for example, ether and cyclopropane are no longer used in anaesthesia. This has lead to a false sense of security and little attention to fire safety. It must not be forgotten that alcohol as an antiseptic and dry drapes are flammable and that the microenvironment around a patient may have an increased concentration of oxygen. Nitrous oxide supports combustion better than oxygen. There are also new sources of ignition, such as the intense energy at the end of fibre-optic 'light pipes' and surgical lasers as well as the dangers associated with the use of surgical diathermy.

Fire and explosion

Fire or explosion occurs when a substance combines with an oxidizing agent with the release of energy. The reaction requires activation energy to trigger it (Figure 1). If the reaction occurs slowly, heat may be the only obvious evidence, though it usually leads to fire. If the reaction proceeds rapidly, large amounts of heat, light and a rapid increase in pressure occur, making sound; this is an explosion. Fire burns slowly at atmospheric pressure at a temperature of 200–500°C. An explosion is a fast, sudden increase in pressure to a high level at a much higher temperature than fire.

If the rate of liberation of heat is equal to the amount of heat required to maintain the process, the flame will stay still as long as the reactants are made available by convection. If the rate of generation of heat is larger than that required to continue activation, the flame will travel through the mixture. The greater the difference, the greater the likelihood of the reaction travelling so fast that a shock wave occurs; this is an explosion.

On a molecular basis, combustion is a chemical process. In oxidation, the intermolecular bond energy of the end products is less than the bond energy of the reactants and the excess energy is dissipated as heat. To induce the initial deformation of the molecules which allows the rearrangement of these bonds, activation energy has to be added to the system; in the case of fires and explosions this is usually in the form of heat. When the oxidation process begins, positive feedback has to occur to maintain the reaction; if not, the process would cease immediately, before the reaction was complete.

The speed of reaction is greatest for a stochiometric mixture: defined as a mixture in such proportions that none of the reactants is left at the end of the reaction.

1

Fuel

A gas or vapour may be flammable over a range of concentrations with lower and upper limits of flammability. The stochiometric concentration occurs between these limits. Limits of flammability vary depending on the atmosphere in which the flammable gas or vapour is found (Figure 2).

Anaesthetic gases and vapours are not the only flammable substance that may put the patient at risk.

- Methane and hydrogen are found in bowel gas.
- Alcohol forms the basis of many skin preparation solutions and is in the exhaled gases of the inebriated. Isopropyl alcohol is commonly used to clean the skin before cannulation. Methyl alcohol is used in spirit burners and by down-and-out alcoholics.
- Drapes are often applied to the patient before the alcohol in skin preparation solution has evaporated completely. There may be a high concentration of the vapour, and even some of the liquid alcohol, beneath the drapes.
- Some surgeons use hydrogen peroxide to clean wounds. It rapidly decomposes by enzyme catalysis when poured on to open wounds, producing a froth of hydrogen and oxygen; the gas given off is highly flammable.
- Dry cotton or paper drapes are flammable.
- The plastic compounds used in the manufacture of conventional tracheal tubes may become flammable in high concen-tration of oxygen and high ignition energy levels.

2

Oxygen

Oxygen in the air is the usual source of oxygen involved in a fire. Figure 3 shows that the risk of ignition of any flammable gas or vapour is increased with increased concentration of oxygen above ambient level. Any fire burns more vigorously if the concentration of oxygen is increased.

Nitrous oxide is not combustible but it vigorously supports combustion.

Risks of fire and explosion arise from the strong oxidizing action of nitrous oxide and from its thermodynamic instability. At about 400°C, nitrous oxide breaks down to oxygen and nitrogen and if this comes into contact with combustible material, fire or explosion may result. The concentration of oxygen and nitrous oxide is increased around the mouth and upper airways if a tracheal tube or laryngeal mask does not seal perfectly. There is often an increased concentration of oxygen and nitrous oxide trapped between the patient and the surgical drapes.

Limits of flammability of gases and vapours encountered in the operating theatre[1]

Gas or vapour	Air		Oxygen		Nitrous oxide		30% oxygen 70% nitrous oxide		20% oxygen 80% nitrous oxide	
	L[2]	U	L	U	L	U	L	U	L	U
Diethyl ether	1.9	48	2.0	82	1.5	24				
Cyclopropane	2.4	10	2.5	60	1.6	30

All values are percentages.

3

Ignition source

Sources of ignition may be sparks generated by static electricity, flames or hot surfaces. Even shaking a bottle containing an organic compound in combination with a peroxide, may cause ignition.

The flash point of a liquid is the lowest temperature at which it gives off enough vapour to form an ignitable mixture with air. At flash point, the vapour will burn, but only briefly because inadequate vapour is produced to maintain combustion. The flash point of a liquid is always quoted but is of less significance to theatre staff than the autoignition temperature.

The autoignition temperature is the minimum temperature above which a flammable mixture is capable of extracting enough energy from the environment to self-ignite. Figure 4 shows the flash points and autoignition temperatures of some compounds in the operating theatre.

If anaesthetic agents that are flammable at clinical concen-trations are used, care must be taken to keep any possible source of ignition outside the zone of risk. There are two zones of risk around the anaesthetic machine, breathing circuit and head and neck of the patient:

- 5 cm if only air is used as the source of oxygen
- 25 cm if nitrous oxide and/or oxygen are used.

Equipment must be marked as AP where air is the only source of oxygen and APG when nitrous oxide or high oxygen concentrations are used.

Possible sources of ignition

Open flames are an obvious source of ignition; they comprise spirit and gas burners, matches and cigarette lighters.

Hot surfaces may cause ignition if the temperature is above the autoignition temperature of the liquid, vapour or solid. In some cases the high temperature of a surface is obvious because it glows or is incandescent.

Hot wire filaments used for cautery may be of high enough temperature to cause ignition. Miniature filament bulbs used in old-fashioned endoscopes may have a surface temperature of 250°C; sufficient to ignite diethyl ether in air.

Light sources – powerful light sources and fibre-optic light-guides have replaced miniature light bulbs but they should always be extinguished when not in use because the energy emitted from the light-guide when not connected to an instrument is intense enough to cause a burn on a surgical drape or the skin. The likelihood of igniting a drape is higher if the concentration of oxygen or nitrous oxide is high in the atmosphere trapped beneath it.

Surgical lasers – see below.

Sparks due to current electricity, as in radiofrequency surgical diathermy and static electricity, are the most obvious sources of ignition in surgical practice. Even sparks that are so small as to be almost invisible may be of sufficient energy to cause ignition.

Sudden increase in gas pressure causes gases to heat. Therefore it is important that no oil, grease or other flammable substance comes into contact with oxygen or nitrous oxide under high pressure.

Lasers

The energy emitted from the tip of a laser applicator is extremely high. The risk of causing ignition is higher than with any other source of emission. Extreme care must be taken to ensure that a laser beam does not come into contact with anything flammable. Any drapes or swabs in the vicinity must be kept wet with water. Care must also be taken to ensure that the beam is not inadvertently reflected on to a flammable surface. If the laser is being used in the mouth, the trachael tube should be of a non-flammable type or be suitably protected. In the case of laser in the bronchi or trachea the oxygen concentration should be 21% or only slightly higher.

Precautions

- Avoid the use of flammable liquids, gases and vapours.
- Keep unsuitable equipment out of zones of risk when flammable anaesthetic agents are in use.
- Observe antistatic precautions.
- Remember bowel gases are flammable.
- Relative humidity should not be less than 50% (a dry atmosphere promotes the generation of static electrical charge).
- At least 15–20 changes of air per hour in the operating theatre will reduce the risk of build-up of flammable vapours.
- High energy light sources must not remain on dry drapes (these sources are of high enough energy to damage tissues).
- Radiofrequency surgical diathermy is a potent source of ignition energy; evaporation of flammable skin preparation solutions must be complete and the atmosphere cleared of the vapour before diathermy is used.

Flash points and autoignition temperatures of flammable liquids encountered in the operating theatre

Compound	Flash point (°C)	Autoignition temperature (°C)
Methyl alcohol	–16	385
Ethyl alcohol	12	363
Diethyl ether	–45	160
Isopropyl alcohol	11.7	455.6

Induction of Anaesthesia

James Austin

James Austin is Specialist Registrar in Anaesthesia in Oxford, UK. He qualified in Cape Town, South Africa and trained in Anaesthesia in Reading, UK.

Induction is the process that produces a state of surgical anaesthesia in a patient. The term is used only in the context of general anaesthesia and not with local anaesthesia. It is the first step in the process of anaesthesia whereby the patient is rendered unconscious, preventing both awareness of, and response to, surgical stimuli. Anaesthesia and physiological sleep are different because sleep has structured, specific EEG patterns and endocrine changes, whereas anaesthesia is associated with a diffuse damping-down of EEG function and a stress-type endocrine response.

The process of induction should ensure patient safety, produce a state of unconsciousness, ensure optimal conditions for the surgeon and prepare the patient for waking and recovery.

Before anaesthesia is induced, the anaesthetist must:

- assess the patient as completely as circumstances allow, and institute preoperative preparations (e.g. intravenous fluids, sedative drugs, analgesics)
- discuss the surgery with the surgeon, particularly in complex or unusual cases
- plan the anaesthetic technique
- ensure all necessary equipment and drugs are available, and that the equipment is working.

On arrival in the anaesthetic suite, the anaesthetist must ensure:

- the correct patient has arrived
- the correct operation is planned on the correct side
- consent has been given
- jewellery or prostheses have been removed or declared
- blood for transfusion is available if required.

Anaesthetic room

In the UK, most inductions take place in a dedicated anaesthetic room; however, in many other countries induction takes place on the operating table in theatre. The main advantage of using a dedicated induction room is the quicker change-around as the theatre is cleaned and prepared between patients. If staffing permits, induction may take place while the previous case is being completed. A separate induction room also avoids the psychological stress (for some patients) of seeing the operating theatre. The anaesthetic room must be equipped with the necessary anaesthetic and monitoring equipment for the induction to be completed safely. The duplication of equipment between anaesthetic room and operating theatre may be a financial constraint in some locations. In urgent cases, with potentially unstable patients or with the morbidly obese, theatre is the best place for induction, because it saves the time, physical hazards and period of reduced or absent monitoring associated with transfer.

Equipment checks: successful induction requires planning and attention to detail. Before the procedure begins, checks of the anaesthetic machine must have been completed and the following must be available:

- the patient must be on a tilting bed or trolley
- two working laryngoscopes (in case of bulb failure), including standard and long blades (sizes 3 and 4)
- a selection of laryngoscope blade types (e.g. the Macintosh and the McCoy levering blade)
- a selection of tracheal tube sizes, with their cuffs checked
- suction equipment
- equipment to deal with difficult or failed intubation, including oral and nasal airways, gum-elastic bougie, laryngeal mask
- standard monitoring equipment (e.g. pulse oximeter, ECG, capnometer, blood pressure monitor).

Monitoring

In addition to the clinical observations made by the anaesthetist, the Association of Anaesthetists of Great Britain and Ireland has published recommendation for standards of monitoring equipment during anaesthesia and recovery. Monitoring should be instituted before induction whenever possible and should consist of a pulse oximeter (ideally with continuous display of pulse rate and plethysmography), an ECG and non-invasive arterial blood pressure monitoring. Following unconsciousness, other variables should also be monitored, including:

- carbon dioxide (using a capnometer)
- the anaesthetic vapour concentration
- body temperature
- neuromuscular function if muscle relaxants are used (assessed using a nerve stimulator)
- invasive arterial or central venous pressures and urine output monitoring may be required.

Induction methods

Most anaesthetic inductions are performed using intravenous or inhalational (‘gas’) induction; each has advantages and disadvantages (Figure 1). Less commonly, induction may be carried out by the intramuscular route in uncooperative patients, children or those with difficult venous access. Ketamine,10 mg/kg, provides up to 30 minutes of surgical anaesthesia, but induction times are unpredictable (15–45 minutes) and recovery is slow. Rectal induction with thiopentone, methohexitone, chloral hydrate or benzodiazepines was popular for children at one time, but is seldom used now. Oral induction is effectively a heavy sedative or ‘premedicant’, rather than induction, and recovery time is prolonged.

There are several tasks to be accomplished with any form of induction:

- last-minute preliminary checks (as specified above)
- establish monitoring
- establish intravenous access
- produce unconsciousness
- secure the airway
- establish ventilation
- commence analgesia (systemic or local)
- position the patient
- establish maintenance of anaesthesia.

Intravenous and inhalational induction

Intravenous	Inhalation
Advantages	*Advantages*
• Rapid onset • Patient comfort • Airway protection in rapid-sequence induction	• Does not require IV access • Useful for children • Useful for adults with needle-phobia
Disadvantages	*Disadvantages*
• Contraindicated in patients with a ‘difficult airway’	• Slow induction • ‘Excitement’ phase • Risk of vomiting • Risk of arrhythmias • Volatile agents contraindicated in patients susceptible to malignant hyperpyrexia

1

Intravenous induction

Pulse oximetry and ECG monitoring should be established before intravenous access because occasionally a cardiovascular event (e.g. vasovagal syncope) occurs during cannulation. Intravascular access commonly consists of a simple venous cannula; however, complex cases may require an arterial line, a central venous line and/or a pulmonary artery catheter. These may be sited with local anaesthesia before induction, to provide additional monitoring if haemodynamic instability is expected.

Following intravenous access, preliminary drugs (e.g. analgesics, antibiotics, anti-emetics) may be given. These vary according to the clinical circumstances and a detailed discussion is beyond the scope of this article. A regional analgesic block, if required, may also be given at this stage. Whether to insert the block before or after the patient is anaesthetized is the subject of some controversy (Figure 2).

Advantages of regional nerve blockade performed either before or after induction

Before induction	After induction
• Patient cooperation with correct positioning • Patient may provide feedback to minimize neural damage by needle or injection • Less requirement for anaesthetic monitoring	• Patient preference • Correct positioning may be easier (e.g. patients with painful fractures or skeletal deformity)

2

Pre-oxygenation: some anaesthetists routinely pre-oxygenate their patients before induction. The correct technique is for the patient to breathe 100% oxygen via an anaesthetic circuit and close-fitting mask for about 3 minutes of tidal volume breathing. Alternatively, pre-oxygenation by three vital capacity breaths has been demonstrated to be effective. The aim is to replace nitrogen-containing air in the resting volume of the lungs (the functional residual capacity, FRC) with a high oxygen concentration. The gas within the FRC acts as an important oxygen store, and therefore pre-oxygenation lengthens the time before hypoxaemia occurs following the onset of apnoea. This may provide valuable time in which the airway can be secured if an unexpectedly difficult airway is encountered. Mask phobia and the difficulties in achieving a mask seal in non-compliant patients and children are the only significant contraindications to pre-oxygenation. Pre-oxygenation is mandatory in rapid-sequence induction.

Intravenous drugs: slow, smooth injection of an intravenous anaesthetic agent usually results in loss of consciousness in less than 1 minute. Thiopentone, for example, starts to work in a period of one ‘arm–brain circulation time’. This is the period of time taken for the drug to travel from the site of injection (the arm) to the site of action (the brain) and is about 15 seconds in a healthy patient. The dose is carefully titrated according to patient response. Typical induction doses for healthy individuals are shown in Figure 3, but dose reduction may be required in:

- patients who are less fit
- the elderly or frail
- neonates
- patients with hypotension or poor cardiac reserve
- patients with chronic renal or liver disease
- patients with raised intracranial pressure
- patients who have been premedicated.

It can be difficult to judge when enough induction agent has been given. Care and experience are needed to titrate dose to effect but some indicators include:

- loss of response to verbal command
- loss of eyelash reflex (in which brushing the eyelash produces a blink response)
- relaxation of a motor posture (e.g. a raised arm or a grip on an object)
- cooperation with bag/mask ventilation.

The eyelash reflex has conventionally been regarded as a good end-point for thiopentone induction, but it is less reliable in propofol induction, for which loss of verbal response or motor relaxation is a more useful end-point.

Induction doses of intravenous drugs

Drug	Typical adult induction dose (mg/kg)	Notes
• Propofol	1.5–2.5	Popular and widely used drug associated with rapid and ‘clear-headed' recovery. Rapid metabolism and lack of cumulative effects has made it popular for total intravenous anaesthesia
• Thiopentone	3–5 (2.5% solution)	The ‘gold-standard’ against which all other drugs are judged. Smooth induction in one arm–brain circulation time
• Methohexitone	1–1.5 (1% solution)	Lowers the convulsive threshold, mainly used in anaesthesia for electroconvulsive therapy
• Etomidate	0.2–0.3	Marked cardiovascular stability makes this drug popular for use in unstable patients
• Ketamine	0.5–2	Useful for sedation with profound analgesia. Increases pulse rate and blood pressure and useful for the induction of patients suffering from acute trauma
• Midazolam	0.15–0.5	A benzodiazepine that may provide stable induction for the elderly and frail, in combination with an opioid

3

Further procedures: the induction agent may be followed by a muscle relaxant, particularly if tracheal intubation is planned. It is important to confirm that the patient's lungs can be ventilated via a bag and mask before paralysing. A muscle relaxant should not be given until it has been confirmed that ventilation is possible. Once anaesthesia is adequate, a clear airway is established using a simple face mask (with or without an oral or nasal airway), laryngeal mask airway or tracheal intubation. If the level of anaesthesia proves to be inadequate to allow an airway or tracheal tube to be tolerated, it may be deepened either with supplementary doses of intravenous agent, or by ventilating with volatile anaesthetic. With the airway secure, ventilation can continue by the patient's own effort, by manual 'hand' ventilation, or by mechanical ventilator.

At this stage, further invasive procedures may take place, such as additional vascular access, regional blocks, bladder catheterization, passing of a nasogastric tube or insertion of a temperature probe.

Transfer to theatre: if anaesthesia has been induced in the anaesthetic room, the patient is now transferred to theatre. This is potentially hazardous because for a short time the patient is separated from monitoring equipment and the mechanical ventilator. The patient is also potentially unstable because of the effects of induction drugs and is at risk of injury during the physical transfer. It is the anaesthetist's responsibility to guarantee the patient's safety. It should be ensured that ventilation and anaesthetic maintenance are re-established in good time, that tubes and lines are not dislodged, and that changes in clinical condition are detected promptly, in particular, cardiovascular instability, desaturation or signs of waking from anaesthesia.

Once in theatre, the priorities are:

- prompt transfer on to the operating table
- prompt re-establishment of ventilation
- prompt re-establishment of anaesthetic maintenance if using volatile anaesthetic drugs
- check correct drug delivery if using intravenous maintenance technique
- prompt re-establishment of monitoring equipment
- safe positioning of the patient
- commencement of maintenance fluids and temperature control.

Rapid-sequence induction

Rapid-sequence induction is used to decrease the risk of aspiration if the patient may have a full stomach, for example in an emergency. In patients presenting for elective surgery, a period of starvation of 2 hours for clear fluids, or 6 hours for food, is considered appropriate. Bowel obstruction, incompetent lower oesophageal sphincter, pregnancy and gastroparesis caused by disease, pain or drugs such as opiate analgesics are also causes of a potentially 'full stomach'.

The incidence and severity of aspiration of gastric contents are made worse by the nature, volume and pH of the gastric solution. Mendelson's studies on aspiration pneumonitis showed that aspiration of solid particles produced more damage than purely fluid aspirates. A potential gastric aspirate greater than 25 ml in volume and/or with a pH less than 2.5 is considered dangerous, though there is little direct clinical evidence for this. In these 'at-risk' patients it is sensible to attempt to raise gastric pH, and to try to promote gastric emptying. Pre-medication with ranitidine, 50 mg i.v., to decrease gastric acidity, and metoclopramide, 10 mg i.v., to enhance gastric emptying and increase the tone of the lower oesophageal sphincter is popular with some anaesthetists; both take at least 1 hour to take effect. A non-particulate antacid, such as sodium citrate, 30 ml of 0.3 M solution orally, given on leaving the ward or arriving in the anaesthetic room, further neutralizes residual stomach acid, but at the expense of raising gastric volume further.

Some anaesthetists advise that a nasogastric tube should be passed to drain the stomach, but it is uncomfortable and may induce vomiting. The counter argument is that any vomiting is better done while the patient is fully awake with protective airway reflexes. If a nasogastric tube is already in place it should be aspirated. If the gastric contents are still acidic on litmus test, consideration should be given to instilling sodium citrate. The old practice of inducing vomiting with ipecac or apomorphine is no longer advised.

The 'rapid sequence' of drug administration aims to produce unconsciousness and intubation conditions as rapidly as possible. The airway is swiftly protected by a cuffed tracheal tube without prior inflation of the lungs via bag and mask. This is to prevent possible gastric distension with an increased risk of gastric reflux. It is performed with the help of a trained assistant, competent in the technique of cricoid pressure.

Muscle relaxants are administered before the airway is controlled, and in this way rapid-sequence induction breaks an important rule of anaesthesia. Careful preoperative assessment of potential airway difficulty is therefore vital, and rapid-sequence induction must not be performed if this assessment predicts difficulty with intubation. The trainee anaesthetist must seek further advice, because an awake intubation technique may then be indicated.

Pre-oxygenation is mandatory, though it may be difficult to achieve in children. Pre-oxygenation reduces the need to ventilate the lungs before intubation. The correct technique is described above. Oxygen must be delivered via an anaesthetic breathing system capable of delivering 100% oxygen; standard 'Hudson' type face masks are inadequate.

Drug injection: the chosen drug is rapidly adminstered (Figure 3). Thiopentone is the drug of choice because of its rapid onset of action in one arm–brain circulation time, but propofol or etomidate are alternatives, albeit slightly slower-acting. The use of rapid-acting opioids such as alfentanil, 10 μg/kg, or fentanyl, 1 μg/kg, helps to reduce the pressor response to laryngoscopy.

Cricoid pressure: or Sellick's manoeuvre, is traditionally practised in rapid-sequence induction and is applied by the anaesthetic assistant as the patient starts to lose consciousness. Pressure is applied to the cricoid cartilage to compress it against the oesophagus, preventing passive regurgitation of stomach contents.

If active vomiting occurs, it is recommended that cricoid pressure be removed to prevent oesophageal rupture – suction, head-down tilt and turning the patient's head to one side is then used instead. Otherwise, cricoid pressure is removed only on the instruction of the anaesthetist, once the airway has been secured with a cuffed tube. Occasionally, it may be removed to facilitate an intubation that is being made more difficult by its continued application.

Muscle relaxation: suxamethonium, 1.5 mg/kg, is the drug of choice. Its rapid onset produces ideal intubating conditions, with a peak effect of muscle relaxation within 50 seconds of injection. It is important to allow the drug time to work, and not to begin the intubation sequence before muscle fasciculations have subsided.

The duration of apnoea is usually about 5 minutes in healthy individuals, and thus spontaneous respiration may be re-established early in the event of a failed intubation. Suxamethonium is contraindicated in patients with:

- previous allergy
- susceptibility to malignant hyperpyrexia
- myotonia
- severe burns, muscle damage or paraplegia (of over 1 week's duration)
- known raised serum potassium.

In these patients, rocuronium, 0.6–0.9 mg/kg, may provide relaxation as rapidly as suxamethonium, but with longer duration. Rocuronium is also the drug of choice in patients with reduced or absent plasma cholinesterase activity, in whom suxamethonium has a long and unpredictable duration of action.

Intubation: the trachea is intubated with a cuffed tube following unconsciousness and muscle relaxation. Uncuffed tubes are used in children to avoid local pressure on the tracheal wall and to maximize the internal diameter of tube available. If difficulty is encountered with direct laryngoscopy, then simple steps may be taken to facilitate intubation:

- manipulate the larynx (the assistant providing the cricoid pressure may be distorting the view of the larynx)
- change to a larger blade laryngoscope
- change to a different type of blade (e.g. a McCoy levering blade)
- use the gum-elastic bougie (this thin, flexible stylet may be used to pass through the cords providing a 'track' over which the tracheal tube can be railroaded).

Before the cricoid pressure is released, the correct position of the tube must be checked carefully by auscultation and capnometry. Once the cuff has been inflated and the airway has been secured, a nasogastric tube should be passed and aspirated, if not done previously. The rest of the anaesthetic proceeds as usual; but at the end of the procedure extubation should take place with the patient awake, with their protective airway reflexes re-established, positioned on their side in a head-down tilt, and with suction available.

Failed intubation drill – if the trachea is not successfully intubated, a failed intubation drill must be followed:

- cease further attempts at intubation
- call for help
- maintain cricoid pressure
- insert an oral airway
- hand-ventilate via bag and mask using 100% oxygen
- await return of spontaneous respiration
- once spontaneous ventilation has returned, turn the patient into the lateral position with head tilted down and await return of consciousness.

A decision to abandon further attempts at intubation must be made early and certainly before arterial desaturation supervenes. The prime concern of the anaesthetist is patient safety. The safest option following failed intubation is to wake the patient. Once the effects of the intravenous induction agent and muscle relaxant have worn off, consideration must be given to how to proceed. This requires consultation with a senior anaesthetist and may involve an awake intubation technique.

Inhalational induction

Gas induction, controversially, is often used as a means of inducing anaesthesia (particularly in a child) without having to site an intravenous cannula first. However, in the event of difficulties (e.g. laryngospasm, arrhythmias) instant intravenous access should be available, because otherwise the anaesthetist controlling the airway will be unable to attempt rapid cannulation. For this reason, some anaesthetists seldom perform gas induction; others permit gas induction if a second anaesthetist is present to assist with intravenous cannulation. Gas induction of children and adults has taken place without intravenous access for over 150 years, in most cases safely and without incident.

Indications: gas induction (with intravenous access) is indicated for patients in whom airway difficulties are expected. In these cases, the patient continues to breathe spontaneously throughout and apnoea is avoided, since it may then be impossible to manually ventilate the lungs with bag and mask.

Upper airway obstruction is an important indication for inhalation induction, and in these circumstances fibre-optic techniques for intubating the trachea are contraindicated for fear of producing complete airway obstruction. However, in patients with an unobstructed 'difficult' airway, the increasing availability of fibre-optic intubation equipment and the growing skill of anaesthetists in awake intubation techniques may reduce the need for gas induction. The difficult airway may best be secured even before anaesthesia is induced.

Technique: there is controversy over whether to induce in 100% oxygen or to use nitrous oxide as well.

- Concurrent use of volatile and nitrous oxide exploits the second-gas effect for a cumulatively more rapid induction. The rapid absorption of the second gas (nitrous oxide) has the effect of increasing the alveolar concentration of the first agent. The partial pressure of anaesthetic gas in the alveolus reflects the partial pressure of anaesthetic in the brain and hence the anaesthetic effect.
- 'Pre-induction', with 33% oxygen and 66% nitrous oxide only, may render a child sleepy enough not to resist when the odour of the volatile agent is added. Clearly the more nitrous oxide is used the more anaesthetic effect is achieved; but likewise the less reserve there is against desaturation. A minimum of 30% oxygen should be given.
- Induction in 100% oxygen is least smooth, but should laryngospasm occur, it is an advantage to have as much of the lung FRC filled with oxygen as possible. This maximizes oxygen stores and thus delays the onset of hypoxaemia.

Conventional practice for inhalational induction with halothane is to start with a low inspired concentration of 0.5%, and to increase it by 0.5% every four breaths up to 4%.

Sevoflurane has greatly enhanced gas induction, because it is faster, better tolerated by patients, and is less arrhythmogenic than halothane. It has been suggested that the lower incidence of arrhythmias has contributed to a decrease in dental anaesthetic deaths in recent years. The high blood-gas solubility of sevoflurane accounts for its rapid onset and offset. Because sevoflurane is less pungent it is often used in high concentrations (maximum 8% on most vaporizers) for faster induction.

Enflurane is seldom used for gas inductions because it is slow; isoflurane and desflurane are almost never used because they are pungent and irritating to the airway.

The last-minute checks before inhalational induction are the same as those for the intravenous route. Monitoring should be established; some children make this difficult, but ECG should be the minimum monitoring instituted. Induction should ideally take place via a tight-fitting face mask (even small leaks may significantly delay induction). However, the use of a cupped hand may be less threatening to a small child in the first instance.

'Single-breath induction' has been described with halothane and sevoflurane. A Mapleson A breathing system containing a 4-litre reservoir bag is filled with a maximum concentration of volatile anaesthetic (4% halothane or 8% sevoflurane) in 66% nitrous oxide and 33% oxygen. The patient is asked to exhale to residual volume, then, via a tight-fitting mask, to inhale a full vital-capacity breath of gas, and then to hold their breath for as long as possible. This technique produces a faster induction than conventional tidal volume inhalational induction in cooperative adults. In the case of single-breath 8% sevoflurane, the speed of induction is comparable with induction with intravenous propofol. It may be a useful technique to use in cooperative needle-phobic adults, but it offers few other advantages.

Four main variables determine the speed of inhalational anaesthetic induction.

- The inspired partial pressure of the anaesthetic agent relative to its minimum alveolar concentration (MAC) alters the speed of induction. MAC is the partial pressure of the agent, expressed in volumes %, which at equilibrium prevents gross muscle movement in response to a skin incision in 50% of patients. It is thus the effective dose in 50% of patients and is a measure of anaesthetic potency.
- The faster the patient breathes, or the greater the alveolar ventilation, the faster the alveolar partial pressure of the agent approaches the inspired partial pressure. In a child, crying speeds up gas induction by increasing minute ventilation.
- The higher the cardiac output the more anaesthetic agent is removed from the alveoli and hence the slower the partial pressure rises in the alveoli. Thus, an anxious, hyperdynamic patient is slow to induce, whereas a shocked patient with a low cardiac output is quicker.
- The higher the solubility of an agent (i.e. a high blood-gas solubility coefficient), the more the agent will dissolve in blood and thus a lower partial pressure will be generated. Agents with a low solubility (e.g. sevoflurane) result in more rapid induction.

During a gas induction, most patients pass briefly through a phase of excitability during which they may be agitated and at increased risk of laryngospasm or, more rarely, arrhythmias. If a child is being induced, it is useful to warn the parents of this disinhibition in advance. The disinhibition is not remembered by the patient.

Once the patient is unconscious, anaesthesia should be deepened, assisting the ventilation by hand, using bag and mask if necessary. If not already obtained, intravenous access should be secured, which requires the help of an assistant. Muscle relaxants may then be given intravenously to assist in securing the airway. If the patient is sufficiently deeply anaesthetized, as evidenced by a regular respiratory pattern and a forward gaze in eyes with small pupils, the airway may be secured (even by intubation) purely under inhalational anaesthesia. Nevertheless, it is valuable to have intravenous access before attempting to manipulate the airway, in case any untoward airway reflexes are produced (e.g. arrhythmias, laryngospasm). With the airway secured, the remainder of the induction sequence proceeds as above.

Historical note

In 1937, Arthur Guedel published *'Inhalational Anaesthesia – a Fundamental Guide',* three chapters of which were devoted to his observations of premedicated patients' responses to gas inductions with nitrous oxide, the ethers, chloroform and cyclopropane

Guedel's stages of anaesthesia

Stage	Definition	Features
1 Analgesia	From beginning to loss of consciousness	Sedation Loss of eyelash reflex[1]
2 Delirium	Loss of consciousness to onset of rhythmic breathing	Agitation, vomiting, arrhythmias Eyes deviated
3 Surgical		
• 1st plane	Onset of rhythmic breathing to loss of eyeball movement	Loss of eyelid reflex Loss of conjunctival reflex[1]
• 2nd plane	Loss of eyeball movement to onset of intercostal paralysis	Loss of laryngeal and gag reflexes Loss of corneal reflex[1]
• 3rd plane	Onset to completion of intercostal paralysis	
• 4th plane	Complete intercostal paralysis to respiratory arrest	Dilated pupils Loss of carinal reflex[1]
4 Respiratory paralysis	Respiratory arrest to death	Loss of anal reflex

[1] Not described in Guedel's original monograph

Induction in children

Children from about 3 months of age until the teenage years are generally more anxious, or less able to control their anxiety, than adults. The preoperative visit is important in children because meeting the anaesthetist and having the procedure explained calms the fears of children and parents. If the child is old enough, address your conversation to him or her. Explain in detail what will happen, and invite the parents and child to ask questions. Where possible, bring relevant equipment, particularly a face mask for gas induction, for the child to become familiar with.

Topical local anaesthetic cream such as EMLA (a eutectic mixture of lignocaine and prilocaine) or amethocaine gel is desirable if awake intravenous access is planned. Marking visible veins in advance helps the nurse to cover the right spots. Both preparations are similarly effective in clinical practice though onset and duration of action differ (Figure 4).

It has become common for parents to accompany children to the anaesthetic room, and this is generally helpful. Smaller children may best be anaesthetized on a parent's lap – a well-positioned hug serves to comfort the child and to restrain them during intravenous cannulation or gas induction. Strapping for the cannula, and the induction drugs, should be on hand for swift application once access has been obtained.

- For gas induction, a sideways hug helps to immobilize all the limbs, while the anaesthetist's hands control the head.
- For intravenous cannulation, a 'face-to-face' hug (Figure 5), with the child's arm under the parent's arm, helps to immobilize the arm and restrict the child's view of cannulation.
- The older child may prefer or need to be anaesthetized on the trolley. If the trolley permits, it is useful to raise the back until just before (or even during) induction itself. This more upright position allows the child a better view of their surroundings, and hence a feeling of more control and less anxiety.

Children should be treated with respect at all times. They should be spoken to in non-condescending language they can understand – if something is going to be unpleasant, it should be acknowledged. The alternative is for the child to become suspicious and uncooperative for even the most innocuous procedure. There is no formula that will ensure every paediatric induction is smooth and trouble-free; some children will be understandably fractious despite all efforts to calm them.

Comparison of EMLA cream and amethocaine gel

	EMLA cream	Amethocaine gel
Constituents	Lignocaine 2.5%, prilocaine 2.5% as an oil/water emulsion	Amethocaine 4%
Presentation	White cream, 5 g per tube	Clear gel, 1.5 g per tube
Application	2 g minimum 1 hour before venepuncture, maximum 5 hours	1 g 30–45 minutes before venepuncture. Remove after 45 minutes
Duration	Efficacy declines soon after cream is removed	Efficacy remains 4–6 hours after application
Skin effects	Usually transient paleness May produce redness and oedema	Usually transient redness May produce itching and oedema
Contra-indications	Not for children < 1 year	Not for children < 1 month

4

5 Hugging the child face to face helps to immobilize the arms.

Induction of Anaesthesia in Special Circumstances

Christopher F Kearns

Christopher F Kearns is Consultant Anaesthetist in the Nuffield Department of Anaesthetics, The Radcliffe Infirmary, Oxford, UK. He qualified from Charing Cross Hospital and trained in anaesthesia and intensive care at St Bartholomew's Hospital, London, in Toronto, Canada, and at Oxford. His clinical interest is neuroanaesthesia. He organizes the Oxford Primary FRCA courses.

A full stomach

The pulmonary aspiration of acid gastric contents has long been recognized as a major risk of anaesthesia. Patients are normally asked to fast preoperatively to allow sufficient time for gastric emptying. However, induction of anaesthesia in the presence of a full stomach may be unavoidable when normal gastric emptying is impaired, or when the urgency of surgical intervention overrides the requirement for a patient to have fasted adequately. Gastric stasis, ileus and reverse peristalsis may accompany obstruction or perforation of the gastrointestinal tract. Trauma, pain and its treatment with opioids delays gastric emptying. Gastric motility may also be abnormal in the presence of diabetes mellitus or obesity and in these circumstances no period of fasting may be considered to be safe. The hazards of induction of anaesthesia in these circumstances are listed in Figure 1.

If the patient has a full stomach an attempt to reduce intragastric volume and acidity before anaesthetic induction is desirable. Gastric fluid may be removed through a gastric tube, or if there is time and no contraindications by giving a prokinetic agent (e.g. metoclopramide, 10 mg i.v.). The pH of the gastric contents may be increased by the ingestion before induction of a non-particulate alkali, usually 30 ml of a 0.3 molar solution of sodium bicarbonate.

Induction of anaesthesia in the presence of a full stomach

Hazards	Management
Pulmonary aspiration of gastric contents	Reduce gastric volume Raise intragastric pH with alkali Use of cricoid pressure Rapid sequence induction
Unanticipated failure to intubate	Preoxygenation Rapid sequence induction Failed intubation drill

1

Rapid sequence induction

Rapid sequence induction is the anaesthetic technique indicated in the presence of a full stomach (Figure 2). It aims to reduce to a minimum the period during which the airway is unprotected after induction of anaesthesia and before inflation of the cuff of a correctly placed tracheal tube.

During preparation for rapid sequence induction, a skilled assistant should carefully identify and hold the cricoid cartilage between the thumb and forefinger, ready to apply cricoid pressure as anaesthesia is induced. Cricoid pressure (Sellick's manoeuvre) correctly applied with adequate, but not excessive, force compresses and occludes the upper oesophagus between the flat posterior surface of the cricoid cartilage and the body of the sixth cervical vertebra, preventing reflux of gastric contents without distorting the view at laryngoscopy. If a gastric tube is already in place, it should not be removed but should be allowed to act as a gastric vent.

The main risk of rapid sequence induction is that there is no prior opportunity to ensure that intubation or mask ventilation will be possible after induction. Good preparation for intubation is vital and it is essential that all equipment is checked, suction equipment and aids to oxygenation are ready and the patient is in an optimum intubating position.

The patient's lungs should be preoxygenated. This is achieved by allowing the patient to breathe 100% oxygen through a tightly fitting mask and anaesthetic circuit for about 3 minutes. When apnoea occurs at induction, the lung rests at end tidal volume where there is equilibrium between the elastic recoil of the lungs and the chest wall. Arterial oxygen desaturation follows when the oxygen content within the functional residual capacity (FRC) of the lungs is exhausted. During preoxygenation, the nitrogen in the FRC will be displaced, increasing the oxygen content of this reservoir substantially and delaying the onset of cyanosis after induction of apnoea. Despite these measures, arterial oxygen desaturation is accelerated by the presence of a reduced FRC (e.g. obesity), a raised metabolic oxygen demand (e.g. sepsis) or a combination of the two (e.g. late pregnancy).

Rapid sequence induction requires the use of rapidly acting induction and paralysing agents injected intravenously in quick succession. Most intravenous induction agents cause loss of consciousness within one arm–brain circulation time in the following doses: thiopental (thiopentone), 2–4 mg/kg, etomidate 0.2–0.3 mg/kg, propofol 2–3 mg/kg. In UK practice, suxamethonium, 1.5 mg/kg, remains the neuromuscular blocking agent of choice because it provides optimum intubation conditions in the shortest time.

Once the correct position of the tracheal tube is verified clinically and by capnography and after the cuff has been inflated, cricoid pressure can be released.

In case of failure to intubate, the duration of action of the induction and paralysing agents is critical. Despite the additional time made available by preoxygenation, it may be impossible to see the larynx or intubate the patient. It is then essential to revert to a well-rehearsed failed intubation drill. The effects of the common induction agents wear off in a few minutes and the choice of suxamethonium is reinforced by its short duration of action. The temptation to give a second dose of the drugs and prolong attempts at intubation should be resisted. At this point, resumption of patient oxygenation is the priority.

Rapid sequence induction

- Selection of intubation aids and equipment for cricothyroid puncture
- Skilled assistant applying cricoid pressure
- Patient on surface that can be tipped head down
- Suction switched on with catheter under pillow
- Optimal patient intubating position
- Good quality venous access with running intravenous infusion
- Preoxygenation with 100% oxygen through close fitting face mask
- Single sleep dose of intravenous induction agent
- Single adequate intravenous dose of suxamethonium (e.g. 1.5 mg/kg)
- Failed intubation drill

2

After head injury

Induction of anaesthesia and tracheal intubation after head injury (Figure 3) is indicated when:

- the patient's airway or oxygenation is compromised
- the patient has a depressed level of consciousness (Glasgow Coma Score of 8 or less)
- in the presence of agitation
- before emergency surgery
- in preparation for safe transfer to either CT scanner or to a neurosurgical centre.

It is vital to prevent secondary brain injury due to hypoxia, hypotension, hypercapnia or uncontrolled rises in intracranial pressure. The patient is assumed to have a full stomach so a rapid sequence induction with preoxygenation and cricoid pressure is indicated. In addition, patients presenting with a severe head injury must be assumed to have suffered a cervical spine injury. Cricoid pressure is applied using a two-handed technique, the second hand supporting the back of the cervical spine. Another assistant is required to provide manual in line stabilization of the spine during induction because any cervical collar has to be temporarily removed to facilitate intubation. Coexisting facial injuries need to be assessed carefully because they may affect intubation by displacing, distorting or obstructing the airway.

Careful monitoring of cardiovascular status is required. It may not be practical to monitor blood pressure invasively before induction, but non-invasive measurements should be made frequently. Suppression of the hypertensive response to intubation requires an intravenous induction agent, though the dose may have to be reduced in the presence of depressed consciousness. Lidocaine (lignocaine), 1 mg/kg, may also be given for this purpose. After induction there should be a smooth transition to maintenance sedation, which may include opiates, to avoid fluctuations in blood pressure.

Suxamethonium is associated with a transient rise in intracranial pressure, but this potential for harm is outweighed by its advantage of rapidly producing optimal intubating con-ditions and thereby reducing the risk of hypoxia. A peripheral nerve stimulator will help to ensure adequate neuromuscular blockade before intubation, and that a non-depolarizing agent is given in time to prevent coughing and facilitate controlled ventilation as the effect of suxamethonium wears off.

Tracheal and gastric tubes should not be placed nasally, for fear of breaching a skull base fracture. Constriction or distortion of neck veins that could result in cerebral venous hypertension should be avoided when securing the tracheal tube and applying a cervical collar. Arterial hypotension must be actively investigated and treated, while moderate hypertension should be tolerated because this may be a normal response to intracranial hypertension, preserving cerebral perfusion pressure.

Induction in head injury

Hazards	Management
Full stomach	See Figure 1
Cervical spine injury assumed	In line stabilization of neck Two-handed Sellick manoeuvre
Rising intracranial pressure	Adequate dose of induction agent Adequate neuromuscular blockade Smooth transition to maintenance sedation and paralysis
Reduced cerebral perfusion pressure	Avoid hypotension
Facial injuries	Intubation facilitated or made more difficult
Skull base fracture	Avoid nasal intubation

3

Upper airway obstruction

The management of the patient with obstruction of the upper airway, including the larynx, is a vital skill for anaesthetists (Figure 4). Adequate diagnosis of the airway pathology and the derangement of normal anatomy should precede discussion of the management plan between senior anaesthetic and ENT staff. An alternative strategy must also be agreed so that there is a back-up plan before proceeding. The management plan should be explained clearly to the patient, whose cooperation will be required.

Induction in airway obstruction

Hazards	Management
Potential for airway obstruction in expert hands	Senior help present
Abnormal anatomy	Information from imaging or endoscopy
Loss of muscle tone in upper air-way at induction may precipitate complete obstruction	Inhalation induction or awake tracheostomy
Obstruction during inhalation induction	Back-up plan in place with scrubbed ENT surgeon for surgical airway

4

Assessment of the patient may elicit stridor (inspiratory noise) at rest, which suggests that the airway is more than 50% narrowed. Results of radiographs, CT or MRI scans or nasendoscopy should be available. In their absence it may be appropriate to perform endoscopic examination by fibrescope via a topicalized and vasoconstricted nasal passage. The site of obstruction must not be approached with the fibrescope because attempted fibre-optic intubation may be impossible and may be hazardous, but endoscopy may provide important reconnaissance information. If there is doubt about the feasibility of intubation, then an awake surgical tracheostomy under local anaesthesia should be considered.

If intubation is likely to be possible, an alternative strategy must be in place before embarking on induction of anaesthesia. A scrubbed ENT surgeon must be present ready for immediate intervention and opening of a surgical airway.

The usual technique for induction of anaesthesia in the presence of upper airway obstruction is an inhalation induction. Most experience has been obtained with halothane although use of sevoflurane is growing. Gradual induction of anaesthesia while maintaining spontaneous ventilation and airway muscle tone may allow adequate depth of anaesthesia for intubation without airway closure. Should there be no obstruction, no manipulation of the airway or laryngoscopy is allowed before adequate depth of anaesthesia is achieved as judged by the pupils coming to lie centrally. It is vital that no neuromuscular blockade or intravenous sedation is used before the airway is safely secured.

Obstruction of the airway during inhalation induction prevents further uptake of anaesthetic agent, therefore allowing anaesthetic depth to lighten and the patency of the upper airway to be restored. An awake surgical tracheostomy should then be performed under local anaesthesia.

Maintenance of Anaesthesia

James Austin

James Austin is Specialist Registrar in Anaesthesia in Oxford, UK. He qualified in Cape Town, and trained in Anaesthesia in Reading, UK.

This contribution is an overview of what is meant, and required, by maintenance of anaesthesia. Many of the topics are covered in greater detail in separate contributions; the aim here is to put these topics in context.

Maintenance of general anaesthesia involves four priorities:

- keeping the patient safe
- keeping the patient comfortable
- presenting the best possible operating conditions for the surgeon
- preparing the patient for the postoperative period.

Keeping the patient safe

There are several aspects involved in keeping the patient safe:

- airway, breathing and circulation
- temperature control
- monitoring
- positioning.

Airway: this will usually have been established at the time of induction. However, it should not be assumed that this remains secure. Airway disconnection or obstruction may occur and the anaesthetist must be able to detect and correct these incidents promptly, assisted by monitors such as the capnograph, pulse oximeter, disconnect alarm and airway pressure monitor. Movement of the tracheal tube (either towards the right main bronchus or withdrawal from the trachea) or dislodgement of the laryngeal mask airway (LMA) are particularly likely to occur when patients are transferred to the operating table or when changes are made to patient position. These periods require increased vigilance by the anaesthetist. The integrity of the airway should be rechecked both clinically and by monitoring after each patient movement.

Tracheostomy, rigid bronchoscopy or 'one-lung' thoracic surgery may require intraoperative changes to the airway. The anaesthetist must be prepared for such changes and, if necessary, should formulate a plan with the surgeon in advance as to how the airway will be managed.

Breathing will often depend on whether muscle relaxants are being employed as part of the anaesthetic technique. Although the use of muscle relaxants is not essential for controlled ventilation, they are usually employed for ventilated patients. Surgical factors often influence the decision to use muscle relaxants. For example, abdominal surgery is greatly facilitated by muscle relaxation. In specialized surgery, such as ophthalmic surgery or neurosurgery, where the slightest move or cough may have disastrous consequences and carbon dioxide must be controlled, paralysis is ideal. Otherwise, anaesthetists have widely differing views as to whether breathing should be controlled. Some anaesthetists use muscle relaxants almost routinely for any operation lasting longer than about 30 minutes, on the basis that carbon dioxide retention is avoided, potent short-acting opioids can be used without fear of respiratory depression, and good lung aeration with avoidance of atelectasis may be easier to achieve. Others control ventilation less often unless indicated for reasons of airway management or the requirements of surgery. Some advantages and disadvantages of paralysis and ventilation are listed in Figure 1.

The technique of 'paralysing and ventilating' may be preferred when a tracheal tube is present. It is likely that a relaxant will already have been given to enable intubation. Also, the presence of a tube within the trachea is a potent stimulus, and unless local anaesthesia has been applied to the respiratory tract, a deeper level of anaesthesia may otherwise be needed for the patient to breathe spontaneously without coughing. Lighter planes can be tolerated when a laryngeal mask or oropharyngeal airway are employed, because these devices are less stimulating to the patient. Paralysing and ventilating may also be used for longer operations, where carbon dioxide control and prevention of atelectasis is important.

However, avoiding relaxants wherever possible can reduce two important complications of general anaesthesia:

- unrecognized awareness – patient movement usually warns of light anaesthesia before the patient becomes aware
- accidental hypoxia – the spontaneously breathing patient may maintain oxygenation even in the event of circuit disconnection.

Use of muscle relaxants and controlled ventilation

Advantages	Disadvantages
• May allow 'lighter' anaesthesia because reflex activity is abolished by neuromuscular blockade	• May allow unrecognized awareness as a result of inadequate anaesthesia
• Facilitates abdominal surgery by relaxation of abdominal muscles	• Reliance on ventilation equipment and circuit integrity to maintain alveolar ventilation
• Intracranial and intraocular pressure control by regulation of $PaCO_2$	• Possible side-effects of muscle relaxant drugs (e.g. histamine release, vagal blockade, malignant hyperpyrexia)
• Allows effective ventilation during, for example, thoracic surgery, prone positioning or long procedures	• Need for reversal of neuromuscular blockade
• Allows use of potent opioids to reduce the surgical stress response in major surgery	• Possible contraindication in patients with a difficult airway. Absence of spontaneous respiration may render ventilation impossible
• May improve surgical conditions by facilitating a hypotensive technique and lowered $PaCO_2$	• When there is requirement to monitor neuromuscular function (e.g. facial nerve during surgery on the parotid gland or acoustic neuroma)
• Decreases intraoperative atelectasis	
• Decreases energy requirements and tissue carbon dioxide production	• Contraindicated in some myopathies

1

Ventilator settings – most anaesthesia ventilators are time-cycled and volume- or flow-driven. A rate, usually with a ratio of inspiratory time to expiratory time (I:E), and a tidal volume or flow need to be set. Most adults have a minute volume of 80–100 ml/kg, therefore a tidal volume of 8 ml/kg (e.g. 500–600 ml) and a rate of 10 breaths/minute is a good starting point; this can be adjusted according to the observed end-tidal partial pressure of carbon dioxide ($P_{E'CO_2}$). For routine surgery, a $P_{E'CO_2}$ of about 4.5 kPa should be aimed for. If metabolic rate and cardiac output (and hence pulmonary perfusion) are assumed to be constant, then $P_{E'CO_2}$ varies inversely with the alveolar ventilation.

In general, an I:E ratio of 1:2 is often the best compromise between maintaining low inflation pressures (e.g. 15–20 cm H_2O), satisfactory oxygenation (Sp_{O_2} > 95%) and adequate carbon dioxide removal ($P_{E'CO_2}$ 4.5 kPa). However, this can be decreased to 1:1.5 or even 1:1 to prolong inspiratory time. This may be useful in some patients to help decrease high airway pressures (e.g. > 25–30 cm H_2O) or improve oxygenation (e.g. in the obese). Some patients with asthma or chronic airway disease may benefit from a longer expiratory time to allow the lungs to empty, and an I:E ratio of 1:3 or 1:4 may be preferable.

Children have a proportionately higher minute ventilation than adults – up to 200 ml/kg in infancy, approaching adult values weight-for-weight by about age 10 years. Given that their tidal volume is slightly less weight-for-weight than adults (7 ml/kg), this increased minute volume must be provided for by an increase in rate. For example, in a 5 kg infant, a minute volume of 1000 ml might be provided by 30 breaths each of about 33 ml/minute.

However, paediatric ventilation is complicated by the obligatory leak around the uncuffed tube. Volume control is unlikely to inflate the lungs to the set volume (especially if a Newton valve is used with T-piece ventilation). This is usually overcome by increasing the tidal volume by titrating against inflation pressure and/or $P_{E'CO_2}$. Some modern anaesthesia ventilators have pressure control capabilities (e.g. the *Draeger Julian*). Specific compliance varies little with age, therefore pressure control mode can be used to deliver an inflation pressure of 15–20 cm H_2O. This provides an adequate tidal volume for any age, despite small to moderate leaks, as long as lung compliance is normal.

Regardless of the mode of ventilation, a fresh gas flow must be selected. This depends on the breathing system in use as well as the size of the patient. A high flow should be used initially (e.g. 6 litres/minute), regardless of the circuit being used. This allows time for denitrogenation and equilibration of inhaled anaesthetic agent during this early period of rapid anaesthetic uptake. After about 10 minutes, flows can be reduced considerably if the system permits. The circle system with carbon dioxide absorber is widely used, and modern lightweight valves and low-resistance tubing make it suitable for paediatric use well below the traditional lower patient weight limit of 20 kg. With appropriate monitoring of gas concentrations within the circle, this permits total fresh gas flows of 1 litre/minute or less. Higher flows are required for T-pieces such as the Bain and Jackson Rees systems. Formulae exist for each of these circuits to predict the flow of fresh gas required per kilogram patient weight to eliminate rebreathing for controlled and spontaneous respiration. However, a more practical approach is to reduce the fresh gas flow gradually, stopping when rebreathing of carbon dioxide begins to appear on the capnograph.

General anaesthesia, particularly when using volatile anaesthetic agents, causes the development of atelectasis in the dependent parts of the lung and impairs the pulmonary vascular response to hypoxia (hypoxic pulmonary vasoconstriction). These two factors produce a small but noticeable degree of shunt, usually about 10%. This can be corrected by giving anaesthetized patients higher inspired oxygen than the 21% present in air; 30% is usually given, though this can be titrated against observed oxygen saturation.

Circulation: appropriate fluid management is an important component of anaesthetic maintenance. Intravenous fluid requirements may range from none in short and relatively non-invasive procedures, to many times the circulating volume in long and traumatic procedures. Fluid requirement consists of:

- replacement of existing deficit – crystalloid or blood
- metabolic maintenance requirements – crystalloid
- replacing additional ongoing losses – crystalloid, colloid or blood.

Existing deficit – in the adult elective surgical patient, who has been starved for at least 4 hours preoperatively (and sometimes much longer), a deficit of 500 ml of crystalloid can be assumed. This deficit is generally well tolerated and does not necessarily need replacing, but it decreases the patient's margin of reserve against any further losses, or against ongoing postoperative dehydration as a result of nausea or vomiting. Many anaesthetists routinely administer 500–1000 ml of crystalloid in all patients except those at risk from fluid overload (e.g. those with renal or cardiac failure). There is evidence to suggest that this may improve the quality of early recovery and help to decrease postoperative nausea.

In the emergency patient, fluid deficit may be considerable, as a result of either trauma-related blood loss, or anorexia, vomiting and/or interstitial (third-space) fluid loss from surgical pathology. In either case, the deficit should be assessed and replaced with the appropriate fluid. The larger the deficit, the more important that it be replaced before induction, whenever circumstances permit. The exception to this rule is during major ongoing blood loss, such as a ruptured aortic aneurysm or major trauma, where the priority is stopping the bleeding rather than prolonging attempts to normalize the circulation preoperatively.

Maintenance – for many patients this is the least important component of intraoperative fluid management – the average adult requirement of about 100 ml/hour is negligible in the context of a short procedure and other fluid losses. However, in small children, maintenance requirements are proportionately larger and more significant. Paediatric maintenance fluid is usually calculated according to: 4 ml/kg/hour for the first 10 kg, plus 2 ml/kg/hour for the next 10 kg, plus 1 ml/kg/hour for the remainder. Thus, a 25 kg child would have a maintenance requirement of 40 + 20 + 5 = 65 ml/hour. The smaller the child, the less reserve there is for managing without ongoing maintenance fluids, and the greater the impact of preoperative starvation.

Infants have small glycogen reserves, and therefore need intravenous dextrose (e.g. as 5% dextrose in 0.18% saline) as maintenance to sustain their blood sugar levels. For longer procedures, careful attention must be paid to electrolyte balance, because infants have less ability to correct excessive salt loads or water loads.

Ongoing losses – the most significant aspect of intraoperative fluid management can be the most difficult to estimate.

Losses from extravascular spaces (e.g. gastrointestinal, evaporative, third-space fluid losses) are usually crystalloid losses. Evaporative losses can be large – an adult may lose in excess of 1 litre/hour from a laparotomy or thoracotomy wound, and even larger amounts from extensive open skin wounds such as burns or large graft sites. There is no way of measuring these losses directly, and measures such as blood pressure, pulse rate or central venous pressure (CVP) provide only an indirect measure of total body water. Urine output may be the most useful clinical measure. Blood tests such as plasma urea, sodium and haematocrit may provide information regarding the hydration state, and plasma electrolytes and haematocrit are now commonly available from blood gas machines.

Losses also occur from the intravascular space (i.e. blood). Losses in suction bottles may be complicated by wash, faeces, urine or amniotic fluid. Visual estimates of blood loss on swabs are often inaccurate – weighing of swabs is more precise, but still neglects losses on drapes, gloves and instruments. A dilutional technique relies on washing all swabs, instruments and gloves in a fixed volume of water, which can then be measured colorimetrically to give an accurate measure of blood loss. Such instruments are not widely available. Intravascular loss may be estimated indirectly from clinical measures such as blood pressure, pulse rate or CVP, though other anaesthetic factors such as the balance between surgical stimulation and depth of anaesthesia complicate these measures. Estimation of haemoglobin is useful only when adequate intravascular volume has been replaced. Blood losses may initially be replaced by colloid solution (e.g. a gelatin solution or hydroxyethyl starch), but larger losses (> 20% blood volume) may require replacement by packed-cell blood. Very large losses (> 1 blood volume) may require supplementation with fresh frozen plasma and/or platelets to maintain clotting function.

In practice, it is likely that fluid losses are under-replaced in many patients. This is offset by the hormonal 'stress response' to surgery: aldosterone, cortisol and antidiuretic hormone levels rise and atrial natriuretic peptide falls; all contribute to postoperative water retention.

Temperature control: there is now good evidence that the maintenance of a physiological body temperature reduces postoperative morbidity. Patients suffering from head injury or undergoing certain neurosurgical procedures are possible exceptions. Shivering increases oxygen consumption, and predisposes to myocardial ischaemia, dysrhythmias, hypotension and acidosis. Hypothermia also increases susceptibility to infection and tends to lengthen hospital stay.

Temperature control is of particular importance in patients at the extremes of age (who have less intrinsic control over body temperature and a larger surface area-to-volume ratio through which to lose heat), in operations involving open body cavities, and in all patients undergoing lengthy procedures. About 20% of trauma patients who arrive at hospital are hypothermic (core temperature < 35°C).

A change in core temperature as a result of general anaesthesia is a three-phase response.

- The first phase is a brisk fall in core temperature as a result of vasodilatation, caused by redistribution of heat to the peripheries. Core temperature may be as low as 35.5°C in some patients after transfer to the operating theatre from the anaesthetic room.
- The second phase is a slower but more sustained fall as a result of accelerated loss of heat to the environment from the warmer peripheries.
- The third phase is a stable equilibrium at a lower core temperature.

It is important to note that the anaesthetic itself brings about these changes, which are independent of the nature of the surgery, though surgery may modify the pattern. The use of spinal or epidural anaesthesia instead of general anaesthesia reduces, but does not abolish, the three-phase response described above.

Passive rewarming is the prevention of heat loss, typically by raising the temperature of the environment. Passive rewarming can serve to modify only the second phase of the heat loss response. Covering with blankets or the use of foil 'space' blankets decreases heat loss by reduced transfer of heat by convection, conduction, evaporation and radiation.

Dry inspired anaesthetic gases need to be humidified, and a heat and moisture exchange filter in the breathing system reduces heat loss by evaporation from the respiratory tract (latent heat). Low flows in a circle system (e.g. 1 litre/minute) further reduce the quantity of dry gas needing to be humidified and help retain heat and moisture within the breathing system.

A 'normal' operating room temperature of 21°C is a compromise between that which is warm enough for the patient, but cool enough for the comfort of theatre personnel. An increase in theatre temperature (e.g. to 25°C) helps to reduce the gradient for heat loss in patients at high risk (e.g. young children, patients with extensive burns).

Active rewarming is the addition of heat into the patient. It may be used to prevent or reverse the first phase of the temperature drop. The local environmental temperature can be raised so much that the transfer of heat is reversed. Warm air convection blankets (e.g. the *Bair Hugger*) are considered as active rewarming.

Intravenous fluid warmers play an increasingly important role the greater the volume of intravenous fluid given. A fluid-warming device should be used in all at-risk patients and especially when stored blood is administered. Ventilatory gases may be warmed using a heated humidifier. Overhead radiant heaters may be used when a large area of the body needs to be exposed, and neonates may undergo surgery on an open incubator such as the *Resuscitaire*.

Cardiopulmonary bypass represents the ultimate in active rewarming, but is practical only in cardiothoracic surgery or in uncommon resuscitation situations.

Care is needed not to overheat the patient and temperature monitoring is necessary when active rewarming methods are used. Monitoring probes are available for a variety of body cavities, including nasopharynx, oesophagus, rectum, bladder and tympanic membrane. In routine clinical practice, core temperature is usually measured by nasopharyngeal or rectal temperature probes. Surface temperature monitors do not reflect core temperature, but the core–peripheral gradient may provide a useful measure of peripheral vasodilatation. A gradient of less than 2°C implies good peripheral perfusion.

Monitoring: the Association of Anaesthetists has published recommendations on standards of monitoring. A summary is given in Figure 2.

Blood sugar should be monitored in infants and diabetic patients. The blood sugar of diabetic patients should be known before anaesthesia is given, and should be estimated every 1–2 hours during routine surgery.

The Association of Anaesthetists summary of standards of monitoring

- The Association of Anaesthetists of Great Britain and Ireland strongly recommends that the standard of monitoring used during general anaesthesia should be uniform in all circumstances irrespective of the duration of anaesthesia or the location of administration
- An anaesthetist must be present throughout the conduct of general anaesthesia
- Monitoring should be commenced before induction and continued until the patient has recovered from the effects of anaesthesia
- These recommendations also apply to the administration of local anaesthesia, regional analgesia or sedation where there is a risk of unconsciousness or cardiovascular or respiratory complications
- The anaesthetist should check all equipment before use. Monitoring of anaesthetic machine function during the administration of anaesthesia should include an oxygen analyser with alarms. During spontaneous ventilation, clinical observation and a capnometer should be used to detect leaks, disconnection, and rebreathing and high pressure in the breathing system. Measurement of airway pressure, expired volume and carbon dioxide concentration is strongly recommended when mechanical ventilation is employed
- A pulse oximeter and capnometer must be available for every patient
- It is strongly recommended that clinical observation of the patient should be supplemented by continuous monitoring devices displaying heart rate, pulse volume or arterial pressure, oxygen saturation, the electrocardiogram and expired carbon dioxide concentration. Devices for measuring intravascular pressures, body temperature and other parameters should be used when appropriate. It is useful to have both waveform and numerical displays
- Intermittent non-invasive arterial pressure measurement must be recorded regularly if invasive monitoring is not indicated. If neuromuscular blocking drugs are used, a means of assessing neuromuscular function should be available
- Additional monitoring may be required in certain situations. These recommendations may be extended at any time on the judgement of the anaesthetist

2

Positioning: an unconscious patient cannot move to relieve an uncomfortable position, and it is the anaesthetist's responsibility to prevent discomfort from becoming damage. The anaesthetist is also responsible for protecting the patient during movement on and off the operating table, and during changes of position. Traditionally, the anaesthetist has particular responsibility for the head and airway. It must be ensured that all members of the team are working to a common agenda and with coordinated timing. It is usually easiest and safest to disconnect as much equipment as possible before moving the patient.

Prophylaxis against venous thromboembolism – the thrombotic process often starts intraoperatively. It is difficult to identify patients at high risk, though coexisting medical illness, major surgery, malignancy, trauma (especially hip and pelvis), obesity, high-dose oestrogen therapy and age greater than 40 years are well-known risk factors. Thromboprophylaxis should commence before anaesthesia; gradated compression stockings and low-dose unfractionated heparin, 5000 IU s.c. twice daily, continued until full mobilization, is popular and effective. When positioning for surgery, raising the heels on foam pads prevents venous stasis in the calves. Intermittent pneumatic compression pumps assist venous return, but it is not known whether this reduces the incidence of postoperative pulmonary embolism.

Keeping the patient comfortable

Traditionally, the main components of anaesthetic maintenance are unconsciousness (hypnosis), analgesia and absence of movement. Some advantages and disadvantages of using muscle relaxants have been discussed. Keeping the patient unconscious and relieving the pain of surgery are now considered.

Maintenance of unconsciousness is usually achieved by anaesthetic drug delivery via the inhalational or intravenous route, or both. The intramuscular route is seldom used in hospital practice owing to the relatively slow onset of drug action, unpredictable duration and delayed recovery. Ketamine, 10 mg/kg, is the only useful intramuscular agent, with an onset of 5–10 minutes producing up to 30 minutes of anaesthesia. It has a role in the provision of emergency anaesthesia in difficult locations.

Inhalational route – this is the most widely used technique, using a volatile anaesthetic agent with or without nitrous oxide. It therefore requires a supply of compressed gas, a vaporizer and a breathing system for drug delivery. Compressed gas may not be required if a 'drawover' type vaporizer is used.

The potency of an inhaled anaesthetic agent may be described in terms of its minimum alveolar concentration (MAC). MAC is defined as the alveolar concentration of the anaesthetic agent which at equilibrium is required to prevent gross reflex muscular movement in response to a standardized skin incision in 50% of healthy, unpremedicated patients. It is therefore a measure of anaesthetic potency, and is the effective dose in 50% of the population (ED_{50}). It should be borne in mind that not all operations are 'a standardized skin incision'. The amount of anaesthetic needed to remove a foreign body from the nose is very different from that needed for an anal stretch. It is important to know the MAC of individual inhalational agents and the factors on which they depend (Figures 3 and 4).

Of any given inhalational anaesthetic, 0.7–1.3 MAC will anaesthetize 95% of the population. MACs are also additive: 0.5 MAC of nitrous oxide (52%) plus 0.5 MAC of isoflurane (0.6%) is equivalent to 1 MAC of any other inhalational agent given alone.

The principle of MAC acts as a useful guide. It allows the anaesthetist to select a vapour concentration that is likely to maintain unconsciousness. The state of anaesthesia is related to the partial pressure of anaesthetic within the brain, which is taken to be equivalent to the alveolar partial pressure. This can be measured by analysis of the end-tidal partial pressure of the anaesthetic agent. What is dialled on the vaporizer or the nitrous flowmeter is not necessarily what is in the patient's alveoli – the fresh gas flow takes time to equilibrate both with the dead space of the circuit and with the uptake by the patient. Observing how the ratio of end-tidal to inspired partial pressure varies with time can assess this rate of uptake (or 'wash-in').

MAC is useful to estimate the amount of anaesthetic required. In clinical practice this must be adjusted against indicators such as pulse rate, blood pressure, respiratory rate, patient movement, pupillary size, lacrimation and sweating. Many of these variables may be abolished by factors other than anaesthetic depth. Tachycardia may be prevented by co-administered β-blockers, hypertension masked by hypovolaemia, respiratory rate and patient movement abolished by paralysing drugs, and pupillary size altered by use of opioids or anti-muscarinic drugs. Thus, lacrimation and sweating, though crude indicators of inadequate anaesthesia, reflect the need for clinical observation in addition to monitoring.

Minimum alveolar concentration (MAC) of inhalational anaesthetic agents

Anaesthetic agent	MAC in oxygen (%)	MAC in 70% nitrous oxide
• Halothane	0.75	0.29
• Enflurane	1.68	0.57
• Isoflurane	1.15	0.50
• Sevoflurane	2.0	0.8
• Desflurane	6–9	2.5–3.5

3

Factors affecting minimum alveolar concentration

Decrease	Increase	No change
• Increasing age	• Decreasing age	• Gender
• Alcohol (acute ingestion)	• Alcohol	• Duration of anaesthesia (chronic ingestion)
• Nitrous oxide	• Hyperthermia	• Time of day
• Analgesics	• Hyperthyroidism	• Hypercarbia
• Sedatives and hypnotics	• Hypocarbia	
• Hypotension		
• Hypothermia		
• Hypothyroidism		
• Hypoxia		

4

Intravenous route – a popular alternative to inhalational anaesthesia is total intravenous anaesthesia (TIVA). Many intravenous anaesthetics have been used for TIVA, including barbiturates, ketamine, etomidate and propofol. The pharmaco-kinetic profile of propofol makes this drug the most commonly used for TIVA. It has a high clearance (1300–1900 ml/minute), short metabolic half-life (60–100 minutes) and inactive metabolites. For short procedures, propofol may be administered following initial intravenous induction by intermittent bolus with no special infusion equipment (e.g. 50 mg as required every 3–5 minutes).

For longer procedures, the advent of reliable electronic syringe pumps, and in particular the development of target-controlled infusion (TCI) software, have contributed to the widespread use of TIVA techniques. Some advantages and disadvantages of inhalational or TIVA maintenance are shown in Figure 5.

Consider a three-compartment model: vascular space, richly perfused organs, and poorly perfused organs plus clearance. A large initial bolus of propofol is needed to fill the vascular compartment, namely the induction dose. Thereafter an initially high rate of infusion is needed to keep up with losses to the richly perfused compartment until it approaches saturation. Then a slower rate is required to keep up with losses to the poorly perfused but difficult to saturate compartment, and with metabolic clearance.

The 'Bristol regimen' reflects these kinetics. This regimen aims to maintain a plasma propofol concentration of about 3 μg/ml by giving patients receiving 67% nitrous oxide an initial bolus of 1 mg/kg, followed immediately by infusion at 10 mg/kg/hour for 10 minutes, then 8 mg/kg/hour for 10 minutes, then 6 mg/kg/hour thereafter. A dose of 10 mg/kg/hour is equal to the patient's weight (in kg) as ml/ hour of 1% propofol – hence a 60 kg patient will initially receive 60 ml/hour of 1% propofol. At the end of the operation, switching off the propofol allows rapid redistribution from the vascular compartment (and therefore from the richly perfused compartment also) to the still unsaturated third compartment. It is this rapid redistribution that allows a prompt wake-up even after a long period of TIVA.

TCI microprocessor-controlled technology (e.g. as incorporated in the Graseby 3500 'Diprifusor' syringe pump) requires manual input of patient age, weight and desired plasma concentration. The pump then administers propofol according to the three-compartment pharmacokinetic model incorporated into its software. Change to a higher propofol concentration is achieved by a rapid zero-order infusion, and the plasma concentration is calculated until the new predicted value is reached. Change to a lower concentration is achieved by temporary cessation of drug infusion until the predicted plasma level falls to the required level, followed by continuation of infusion at a lower rate. The system is used in a similar fashion to adjusting the vaporizer setting during inhalational anaesthesia; the predicted plasma concentration of drug is analogous to the end-tidal concentration of the inhalational agent. Maintenance of satisfactory anaesthesia requires a plasma concentration of propofol of 2–6 mg/ml, depending on patient fitness, coexisting drug therapy and degree of surgical stimulation.

Comparison of inhalational anaesthesia and total intravenous anaesthesia (TIVA) maintenance techniques

Inhalational maintenance

Advantages
- Cost-effective (especially when used with low-flow circle systems)
- Predictable population pharmacokinetics and confidence in anaesthetic depth achieved
- Ease of measurement of end-tidal partial pressure
- Minimal metabolism of modern agents, no accumulation and clearance independent of patient hepatic and renal function

Disadvantages
- Requires conventional tidal ventilation for drug delivery
- Requires specialized equipment (e.g. vaporizer, anaesthetic machine, agent analyser)
- Concern regarding tissue and organ toxicity (especially hepatotoxicity following repeat halothane exposure)
- All volatile anaesthetics are known triggers for malignant hyperpyrexia
- Environmental pollution

TIVA

Advantages
- Independent of airway for drug delivery. May be advantage in, for example, jet ventilation techniques
- No specialized equipment is essential. More suitable technique for patient transport and difficult locations
- Rapid increase in anaesthetic depth possible by administration of intravenous bolus
- Low incidence of postoperative nausea and vomiting and better quality of early recovery (especially for propofol)
- No contraindication in malignant hyperpyrexia

Disadvantages
- Requires patent and dependable intravenous access. Undetected failure may result in awareness
- Drug accumulation with prolonged infusion
- Inability to measure plasma concentration directly has led to concerns about possibility of awareness

5

Analgesia: modern inhalational or intravenous anaesthetic drugs possess little analgesic activity, with the exception of ketamine. For all but the simplest procedures, analgesia must be provided by systemic analgesics (usually opioids) or by local anaesthetics. Analgesia has several effects.

- It reduces the required MAC (or plasma concentration) of co-administered anaesthetic drugs. Analgesia is an important component of the balanced anaesthetic technique.
- It reduces the immediate autonomic activity in response to pain. Sympathetic stimulation otherwise results in cardiovascular and respiratory responses that may lead to myocardial ischaemia and dysrhythmias.
- It reduces the neuroendocrine 'stress response' caused by surgery.

Opioid analgesics such as fentanyl, 15 μg/kg, reduce circulating concentrations of the stress hormones that increase after moderate and major surgery (e.g. noradrenaline, adrenaline, cortisol, growth hormone, glucagon, antidiuretic hormone). The stress response is largely detrimental and leads to increased catabolism, metabolic rate and oxygen consumption. This response is not significant in minor surgery.

The short-acting synthetic opioid drugs such as fentanyl and alfentanil are widely used to provide intraoperative analgesia. Fentanyl, a synthetic opioid structurally related to pethidine, is the most popular (1–2 μg/kg for minor procedures, onset 1–2 minutes, duration 30 minutes). Its potency and minimal effect on pulse and blood pressure make it commonly used for the provision of intense analgesia during surgery. These drugs are unsuitable for routine use in postoperative analgesia because of their short duration of action and their tendency to produce marked respiratory depression. They are commonly substituted by longer-acting analgesics (e.g. morphine 0.1–0.2 mg/kg i.v.) towards the end of the procedure to provide pain relief following surgery.

Pre-emptive analgesia – laboratory work suggests that noxious stimuli produce hypersensitivity in the pain pathways both centrally and peripherally. Larger doses of analgesics are then required to have an effect. If systemic analgesia or local anaesthetics are used to prevent the initial pain, this hypersensitivity is reduced. This is the basis of pre-emptive analgesia, but its clinical significance is disappointing.

Providing the best possible operating conditions

The surgeon hopes for two things from his patient during the operation: not to move, and not to bleed. If the anaesthetist has succeeded in keeping the patient safe and comfortable as described, then the patient is unlikely to move. The anaesthetist can also help to minimize bleeding.

Tourniquets are ideal for extremity surgery. Traditionally, a 90-minute time limit is imposed on upper limb tourniquets (usually at 250 mm Hg), and a 120-minute limit on lower limb tourniquets (usually at 300 mm Hg). This is arbitrary; the longer the tourniquet is on, the greater the potential for damage. The main risk is ischaemic damage to nerves directly under the tourniquet; distal ischaemia is likely to take 4–6 hours to become significant. If antibiotics are necessary, they should be given at least a few minutes before exsanguination.

Sickle-cell disease is an absolute contraindication to tourniquet use, because sickling of haemoglobin S may be induced by the local hypoxia and acidosis.

Positioning – adequate venous drainage from the operative site is ensured by careful attention to patient positioning. Raising the operative site above heart level decreases arterial and venous pressures. Arterial pressure falls by 2 mm Hg for each 2.5 cm vertical height. Head-up tilt is commonly used in head and neck surgery to decrease bleeding, but there is a risk of venous air embolism.

Hypotensive anaesthesia – moderate reduction of systolic blood pressure (e.g. to 70–80 mm Hg) in otherwise fit patients may greatly improve the operative field. It must be used with caution in patients with coronary, cerebral, renal or peripheral vascular diseases who are at risk from ischaemic events. Techniques for deliberate hypotension are outside the scope of this contribution.

Non-steroidal anti-inflammatory drugs used intraoperatively may increase blood loss during surgery.

Blood gases – carbon dioxide is a local vasodilator, and moderate hypocapnia (e.g. P_{CO_2} 4.0–4.5 kPa) contributes to a dry surgical field.

Preparing the patient for the postoperative perio

The maintenance period is often a convenient time to complete the necessary anaesthetic record and drug prescription charts. During anaesthesia, it should be considered what else may be done while the patient is unconscious to enhance his or her postoperative course. This includes the following.

Venous access must be sufficient for postoperative requirements. A central venous line should be sited if access is likely to be difficult or prolonged, or to enable central venous monitoring. A subcutaneous cannula for analgesic administration may avoid the need for injections, especially in children.

A nasogastric tube is more comfortably inserted while the patient is asleep, and its position can be checked during laparotomy.

Analgesia – ideally, the plan for postoperative pain control should be formulated before anaesthesia, and discussed with the patient. 'Balanced analgesia' is the concept of using several analgesics with differing modes of action, thus reducing dose-related side-effects and enhancing overall analgesic effect. Typically this may involve local or regional analgesia in combination with opioids, non-steroidal anti-inflammatory drugs and simple analgesics (e.g. paracetamol).

Antiemetics should be given in particular to patients receiving opioids, and those at high risk of postoperative nausea and vomiting (PONV). High risk includes patients with a history of previous PONV or motion sickness, certain operations (e.g. gynaecological, middle ear or strabismus surgery) and female gender.

Oxygen – all anaesthetics (with the exception of ketamine) induce about 10% shunt. Atelectasis, impaired hypoxic pulmonary vasoconstriction, diffusion hypoxia from nitrous oxide use, opioid-mediated hypoventilation and other factors contribute to making the postoperative patient prone to hypoxia. Added oxygen (e.g. 30–40% via a simple face mask) should be administered in the immediate recovery period to all patients for about 15 minutes, guided by pulse oximetry. Subsequently, the need for added oxygen must be determined for each patient depending on factors such as age, pre-existing disease and the nature of anaesthesia and surgery.

Fluids – there must be clear instructions for postoperative fluid intake. Elective day-surgery patients will drink when ready, but in-patients and those undergoing major procedures require intravenous fluids to replace continuing fluid losses and provide maintenance. How far in advance fluids can be prescribed depends on the accuracy of prediction of future needs.

Thromboprophylaxis – stockings for prevention of thrombo-embolic disease and/or regular heparin should be prescribed where indicated by local policy.

Antibiotics – should be prescribed at the surgeon's discretion.

Monitoring – the anaesthetist should understand the routine standard of monitoring on the postoperative ward and ensure that it meets the needs of the patient. Specific requirements must be clearly communicated, such as hourly urine output, hourly blood pressure, overnight Sp_{O_2} or any other observ-ations in an at-risk patient. Action that should be taken if the observation deviates from the desired targets should be documented.

Medical Gas Storage, Suction Devices and Humidifiers

Ian R Taylor
Michael O'Connor

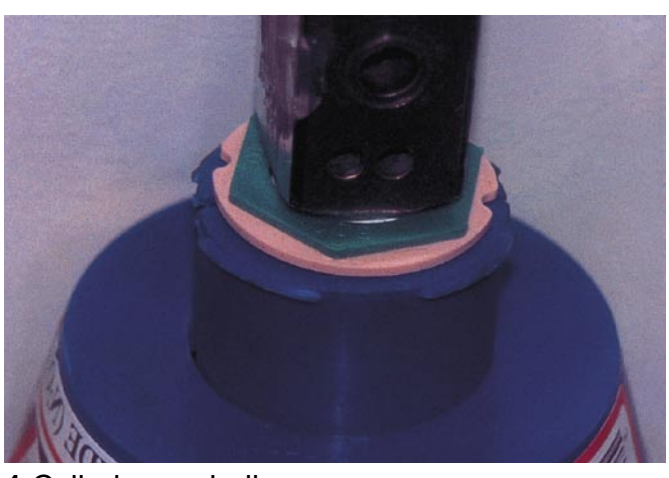
Ian R Taylor is Specialist Registrar in Anaesthesia at the Princess Margaret Hospital, Swindon, UK. He qualified from Bristol University and is training in Anaesthesia at the Wessex School of Anaesthesia, Southampton, UK. His interests are vascular and obstetric anaesthesia.

Michael O'Connor is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Cylinders

Medical gas cylinders are made of molybdenum steel to ensure they are strong and able to withstand high pressures, but are also relatively light in weight. They are constructed as a seamless tube and consist of a body, shoulder and neck. They are colour coded according to British and International Standards (BS1319C and ISO32) to identify their gas contents (see Figure 7, page 109). Cylinders are manufactured in different sizes from A, the smallest, to J, the largest. Size E cylinders are usually attached to the anaesthetic machine and size J cylinders make up manifolds.

The cylinder valve fits into the cylinder neck by a screw thread mechanism, to permit safe, controlled use of its contents. The junction between the cylinder and valve melts in the presence of intense heat, thus allowing escape of gas and minimizing the risk of explosions. Between the neck and cylinder valve is a plastic disc, the colour and shape of which denotes the year in which the cylinder was last examined (Figure 1).



1 Cylinder neck disc.

Cylinder body
The cylinder body is colour coded and engraved with:
- test pressure
- date of last test performed
- chemical symbol of contents
- tare weight (i.e. weight of empty cylinder).

It is also labelled (Figure 2) with the name and symbol of the gas it contains, its volume, pressure and minimum purity (Figure 3). The label gives additional information relating to storage, use (in conjunction with the Medical Gases Data Sheet) and safety matters. The safety points highlighted are:
- compressed gas
- flammability status
- avoidance of oil or grease because spontaneous combustion can occur with high-pressure gases.

2 Cylinder label.

Cylinder size, volume, pressure and purity of contents

Gas	Cylinder size (litres)	Volume of gas at 15°C	Pressure (kPa)	Purity (%)
Oxygen	E	680	13700	99.5
Nitrous oxide	E	1800	4400	98.0
Air	E	640	13700	21.0 (oxygen)
Carbon dioxide	C	450	5000	99.0

3

Storage
- Cylinders must be stored under cover, in a dry, clean and well-ventilated area, away from extremes of temperature.
- Smoking or the use of a naked flame in the storage area is prohibited.
- Moisture or exposure to chemicals can lead to the corrosion of the cylinder or its valve.
- Cylinders should be kept in the upright position or horizontal on shelves to avoid direct damage to the valves.
- Cylinders should be used in a sequential manner to ensure that no cylinder remains in storage for too long.
- Full and empty cylinders should be kept apart.

Testing
During manufacture, one in every 100 cylinders is cut into strips and tested for tensile strength. Cylinders in circulation are tested on a 5-yearly basis by:
- exposure to hydraulic pressure of about 22,000 kPa (far in excess of the pressures encountered in daily use)
- filling with water under pressure to assess expansion and elastic recoil
- internal endoscopic inspection.

Test date details are recorded on the plastic disc between the cylinder valve and the neck and engraved on to the cylinder body.

Filling
Medical gases are stored either in the gaseous state (oxygen and air) or as a mixture of the liquid and vapour (nitrous oxide and carbon dioxide). Cylinders that contain liquid should be used only in the upright position. Gases and vapours stored in cylinders must be free of water vapour to avoid the formation of ice (secondary to a fall in temperature on cylinder opening), which may block the exit valve. For cylinders containing gas alone, the contents can be assessed directly by measuring the pressure using a Bourdon gauge (see *Anaesthesia and Intensive Care Medicine* **1:2:** 65). In the case of cylinders containing both the liquid and vapour phases the situation is more complex. The contents of these can be determined only by subtraction of the tare weight from the cylinder weight because the pressure within will not fall until the liquid has completely vaporized, assuming the temperature stays constant.

During nitrous oxide use, the liquid within the cylinders cools owing to the uptake of latent heat of vaporization. Condensation or ice may form on the outside of the cylinder. In such circumstances, the cylinder gauge pressure may fall despite there being liquid nitrous oxide in the cylinder owing to the fall in saturated vapour pressure of nitrous oxide following the drop in temperature of the liquid. However, once the gas flow is turned off the temperature returns to that of the atmosphere and the gauge pressure returns to that at the beginning of use. Carbon dioxide is used at low flows so the chances of ice forming are low. Liquid is less compressible than gas, therefore cylinders containing nitrous oxide or carbon dioxide are only partially filled with liquid. Any change in pressure within the cylinder is minimized, thus reducing the chance of cylinder rupture should the temperature rise.

The filling ratio is that between the mass of liquid contained in the cylinder and the mass of water that it could contain if filled to the top. The filling ratios for nitrous oxide and carbon dioxide are both 0.75 in temperate climates and 0.67 in the tropics.

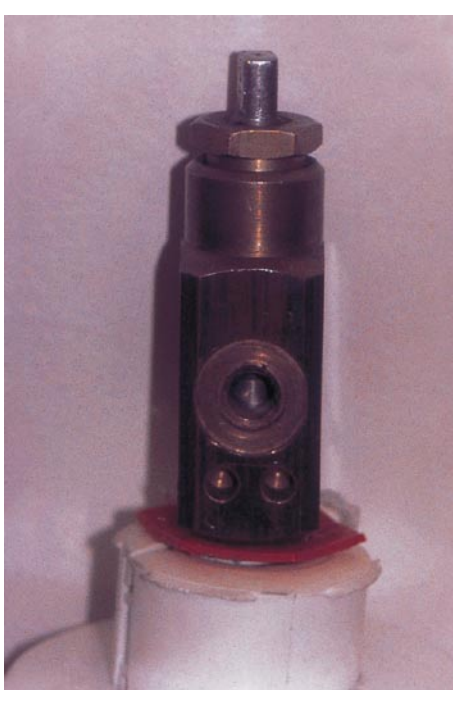
$$\text{Filling ratio} = \frac{\text{Mass of liquid}}{\text{Mass of water}}$$

Cylinder valve
Cylinder valves are made of brass and screw into the cylinder neck. There are four types of valve:
- pin-index valve block
- bull-nose valve
- hand-wheel valve
- star valve.

A pin-index valve is used on all cylinders that are to be attached to an anaesthetic machine. It is an international system (ISO2407) designed to prevent the fitting of the incorrect gas to the yoke and is fully detailed in the British Standard BS1319.

The system is made up of two components.
- Two pins projecting from the yoke, which are arranged in a gas-specific configuration in relation to the valve outlet
- Two holes within the valve block on the cylinder with a corresponding pattern for the designated gas (Figure 4).

This arrangement ensures that it is impossible to fit the incorrect cylinder to the yoke. The pin-index valve block on the cylinder is engraved with:
- tare weight
- chemical symbol for contents
- cylinder owner
- pressure of hydraulic test.



4 Pin-index valve holes on the cylinder.

Cylinder use
New or refilled cylinders are supplied from the manufacturer with a plastic dust cover over the valve to avoid dirt contamination. Before use, this cover should be removed and the valve transiently opened to expel any dirt or grease from the outlet. This reduces the chance of debris entering the anaesthetic machine and is known as 'cracking' the cylinder.

The cylinder is mounted on to the anaesthetic machine by engaging the pins on the yoke with the holes in the valve block. It is secured by tightening the wing nut.

Before use, the cylinder should be opened gently to ensure that there are no leaks, either from the cylinder valve itself or at the point of attachment to the yoke on the anaesthetic machine. A possible reason for gas leakage at the pin-index junction is the absence of the Bodok seal. This is an aluminium-rimmed neoprene washer that sits between the outlet on the valve block and the yoke on the anaesthetic machine. Gentle opening of cylinders minimizes sudden surges of high-pressure gas that may damage the pressure gauge or regulator.

Suction systems

Suction systems form part of the piped medical gases and vacuum systems (see page 107) and must comply with specifications detailed in BS4957. Portable and fixed suction systems are available to accommodate the differing circumstances of use. General operating principles are the same for both systems. Outlets from the central piped vacuum system must have the capability of maintaining a vacuum of at least 53 kPa below atmospheric pressure (101.3 kPa) and supporting a flow of 40 litres/minute.

Suction apparatus and nozzle: suction nozzles are made of either firm plastic (e.g. Yankauer) or metal. They should have a smooth tip to prevent damage to the soft tissues of the oropharynx. The tip often has more than one hole to allow continuation of suction should one hole become blocked. Suction tubing is constructed of semi-rigid plastic to minimize kinking, with a smooth internal surface to limit resistance to flow. The tubing must be of sufficient length to be practical to use, but it should be remembered that the length and width of a tube influences the laminar flow within it, according to the Hagen–Poiseuille equation:

$$\text{laminar flow} = \frac{\Delta P \pi r^4}{8 \eta L}$$

where: ΔP = pressure gradient along tube, r = tube radius, L = tube length, η = viscosity of liquid.

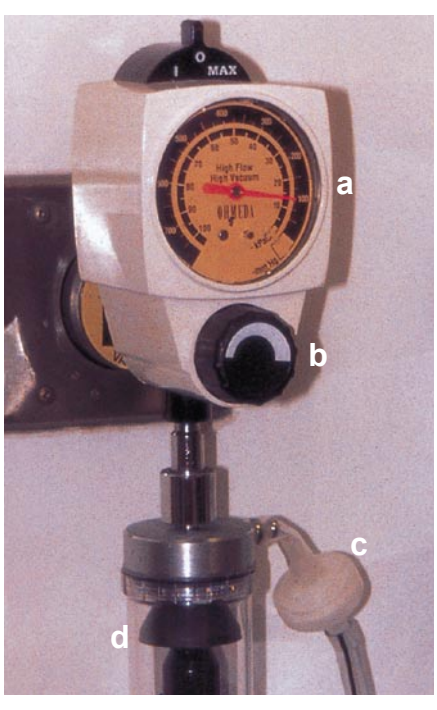
Thus, short, wide tubing maximizes laminar flow.

Reservoir: the reservoir must be of sufficient size to contain the estimated volume of suctioned material, but not so large that it increases the time taken for the vacuum to build up. Most reservoir vessels are constructed of clear material to allow the contents to be visualized and are graduated to permit accurate assessment of aspirate volume. Disposable liners are commonly used to reduce staff exposure to potentially infective material. A floating ball valve within the collection vessel prevents material from entering the control unit and the vacuum source if the container overfills.

Vacuum control regulator unit: this unit is usually situated between the reservoir and the vacuum source (Figure 5). Its function is to allow adjustment of the degree of vacuum applied to the distal suction tubing. The vacuum control adjuster acts as a variable orifice (either directly or by way of a spring acting on a diaphragm) to adjust the force of vacuum, which is indicated on a gauge. Within the unit is a filter and some form of float valve to provide protection from particulate matter.

Distribution pipeline network: between the terminal outlet and the control unit there is a colour-coded (yellow) flexible hose with a specific Schrader probe connection, as for piped medical gases.

Terminal outlet: the terminal outlet of the vacuum pipeline consists of a labelled, self-sealing valve, fronted in yellow, that accepts a probe with indexing collar to prevent misconnection.



5 Vacuum control regulation unit.
a vacuum gauge, **b** vacuum control, **c** filter, **d** float valve.

Filter unit: filters are sited within the control unit, but also in the case of piped medical gases and vacuum systems between the terminal outlet and the central vacuum source. They remove particulate matter and bacteria from the system to prevent blockage and contamination.

Central pump: the role of the pump is to generate subatmospheric pressure within the system. Pumps are commonly driven by electrical, pneumatic or manual means (Figure 6). The piston, diaphragm and rotary devices shown in Figure 6 all require some form of energy source (usually electricity) to drive mechanical pumps. In contrast to these, the gas-powered pump works on the Venturi principle and the bellows require manual input to generate subatmospheric pressure.

The type of pump is determined by the specific requirements of the suction unit. For example, most portable units use a manual pump, whereas a rotary-driven pump may be used when a large volume of aspirate is anticipated. The pump expels its exhaust gases, via a silencer, to the atmosphere at a suitable site, such that staff and patients are not exposed to the pollution.

Vacuum pumps

6

Humidification devices

Humidification strictly refers to the addition of water vapour to air. Humidification of dry, cold anaesthetic gases as they enter the patient's airway is important because dry gases result in drying of the mucosal surfaces, abnormal ciliary function and increase in the viscosity of respiratory tract secretions. Loss of these protective mechanisms can cause mucus plugging, atelectasis, reduction in gas exchange and an increased susceptibility to infection. Also, heat energy due to latent heat of vaporization is lost by the patient in warming and humidifying dry, cold anaesthetic gases.

Aims: under normal circumstances, the upper respiratory tract warms and humidifies the air to an absolute humidity (i.e. mass of water vapour in a given volume of air at specified temperature and pressure) of 34 g/m^3 at 34°C in the trachea and 44 g/m^3 at 37°C in the alveoli. These values equate to fully saturated air whereby the air contains the maximum possible water vapour at specified temperature and pressure. Achievement of these values is the 'gold standard' for humidification. The different efficiencies of various humidifiers are shown in Figure 7.

Approximate efficiency of humidifiers

The exact values depend on the model of humidifier used.

7

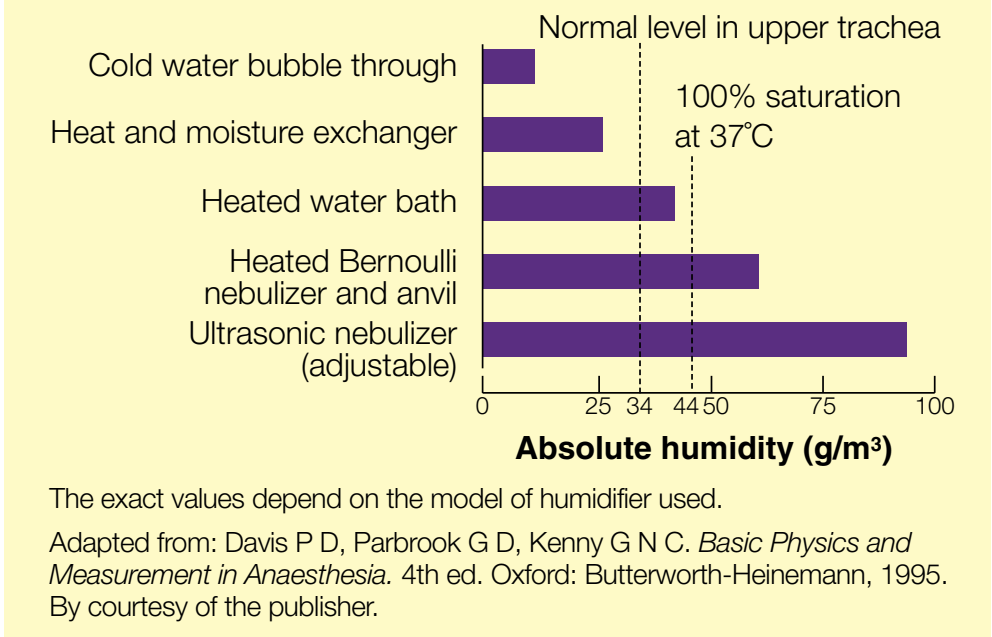
Types of humidifiers

Heat and moisture exchanger (HME) is the most commonly employed humidifier in day-to-day anaesthetic practice (Figure 8). It consists of a sealed unit that is placed within the breathing circuit. The exchanger contains a structure usually of either sponge or mesh, of large surface area, on to which water is absorbed. Absorption is maximized if the mesh is made of a hygroscopic material such as paper coated with calcium chloride or glass fibre. An additional role of some devices is to act as bacterial filters because over 99.99% of bacteria will not pass through pores of less than 0.2 microns. HMEs work on the principle that the moisture from expired gas condenses on to the mesh material within the device as it cools. The mesh is also warmed as the cooling moisture emits latent heat. As gas is inhaled it is warmed and humidified, thus exchanging heat and moisture. The advantages of the system are that it is:

- lightweight
- compact
- disposable
- efficient (60–70% relative humidity at 30–34°C, equating to absolute humidity of about 25–35 g/m^3)
- passive (requires no external power source)
- inexpensive.

The disadvantages are:

- increased dead space
- increased resistance to breathing
- single-patient use.



8 Heat and moisture exchanger.

Cold water bath humidifier (Figure 9): this operates by bubbling inspiratory gas through or over a cold water bath. The advantages are it is simple and safe. The disadvantage is that it is inefficient.

Hot water bath humidifier (Figure 10): inspiratory gases are bubbled through, or pass over, a warm water reservoir. The contact surface area is increased in some devices by the use of wicks or multiple bubble holes. The water temperature must be rigidly regulated to attain a balance between maximum humidification, bactericidal activity and heating, with the risk of thermal injury to the patient. This is achieved by the use of a thermostatic control and temperature monitoring within the circuit close to the patient. A water trap must be included on the patient side of the system and the whole apparatus must be below patient level to limit the risk of condensed water in the tubing entering the breathing circuit directly. The system is efficient but the disadvantages are:

- risk of scalding
- bacterial growth if temperature falls below 60°C
- condensation of water within tubing.

9 Cold water bath humidifier.

10 Hot water bath humidifier.

Nebulizers: the principle of nebulizers is to add tiny droplets of water to the inspired gas. Strictly speaking nebulizers are not humidifiers because they add water droplets not vapour to the gas. Nebulizers have the potential to produce water droplets of varying sizes. The result of this is that very small droplets pass into the alveoli and thus risk fluid overload, whereas large droplets risk being deposited in the breathing circuit or upper airway. Ideal droplet size is 1–5 microns. Nebulizers are highly efficient but they can be expensive and water overload may occur, especially in ultrasonic devices. There are three commonly encountered methods by which nebulizers produce water droplets.

Venturi principle – water is entrained into a jet of gas that breaks it into droplets (Figure 11). Some systems also contain a solid object (anvil) into which the droplets are propelled, thus further reducing their size. Droplet size averages 2–4 microns. Back pressure from a breathing system can affect the efficiency of the device by reducing water entrainment. Some nebulizers incorporate a heater to increase their efficiency.

Spinning disc – a rapidly rotating disc that throws off tiny water droplets.

Ultrasonic – high-frequency ultrasound waves fragment water into tiny droplets. The water may be dropped on to a vibrating surface or the device may be immersed in a water bath. Droplets 1–2 microns in size are produced.

Medical Gases and their Delivery

Ian R Taylor
Michael O'Connor

Ian R Taylor is Specialist Registrar in Anaesthesia at the Princess Margaret Hospital, Swindon, UK. He qualified from Bristol University and is training in Anaesthesia at the Wessex School of Anaesthesia, Southampton, UK. His interests are vascular and obstetric anaesthesia.

Michael O'Connor is Consultant Anaesthetist in the Swindon and Marlborough NHS Trust, UK. He qualified from Bristol University and trained in Bristol, Swindon, Adelaide, Australia, and Oxford. He is an examiner in the Primary FRCA and is involved in education as a Postgraduate Clinical Tutor.

Medical gas

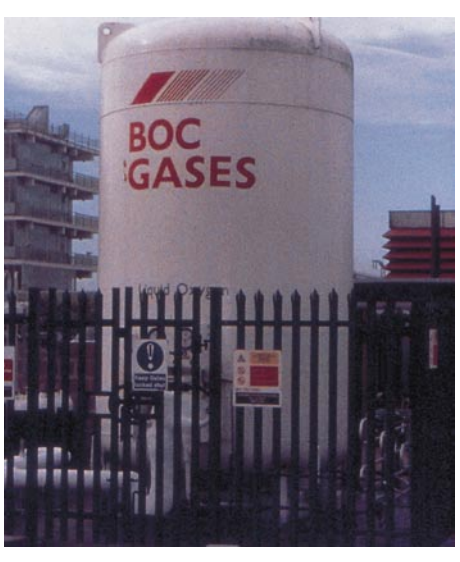
In the UK, most hospitals have piped medical gases and vacuum systems (PMGV) for convenience and economic reasons. The vacuum component of this system is discussed on page 114.

The pipeline network carries medical gases from central bulk storage sites to hose outlets in the walls of anaesthetic rooms, theatres and wards. The responsibility for this section of the PMGV is principally that of the hospital pharmacy, supplies and engineering departments. Anaesthetists have responsibility for the section of pipeline between the terminal outlet and the anaesthetic machine. The bulk store for medical gases is usually a series of cylinder manifolds (Figure 1). In the case of oxygen, the cylinder manifold is often used as a reserve because most hospitals store oxygen in a vacuum-insulated evaporator (VIE) (Figure 2). The cylinder manifold is divided into a primary unit, which is in use, and a secondary unit in reserve. As the pressure in the primary unit falls, the supply is automatically switched to the secondary unit and an alarm sounds to alert the staff to replace the empty cylinders. When there is actual or impending supply failure the alarm usually sounds in the switchboard area of the hospital.

The pipes are constructed of high-grade copper alloy to prevent degradation of gases and are de-greased to reduce the risk of combustion or explosion. They are labelled at regular intervals along their length and are separated from other pipelines within the hospital to avoid confusion. Within the network of pipes there are valves to control the supply to individual theatres or a complete department, in the event of fire or pipeline damage. These are lever-operated, non-lubricated valves housed in clearly accessible units usually behind a breakable glass cover (Figure 3).

The pressure within the pipelines is regulated at about 400 kPa.

1 Cylinder manifolds.



2 Vacuum-insulated evaporator.

3 Pipeline lever safety valve.

Terminal outlet connection

Outlet points (Figure 4) for each of the piped medical gases have specifically labelled, shaped, colour-coded and non-interchangeable Schrader sockets to prevent connection of the incorrect gas supply to the flexible hoses supplying the anaesthetic machine. These must comply with the British Standard codes (BS5682) and be labelled as such. Each terminal outlet is a self-sealing valve unit of specific size to receive the corresponding collar-indexed probe of the flexible hose.

To ensure correct connection and function of the outlet valve, the probe is firmly inserted and a sharp tug applied to ensure full engagement and opening of the valve. This simple procedure is known as the 'tug test'.

4 Terminal gas outlets.

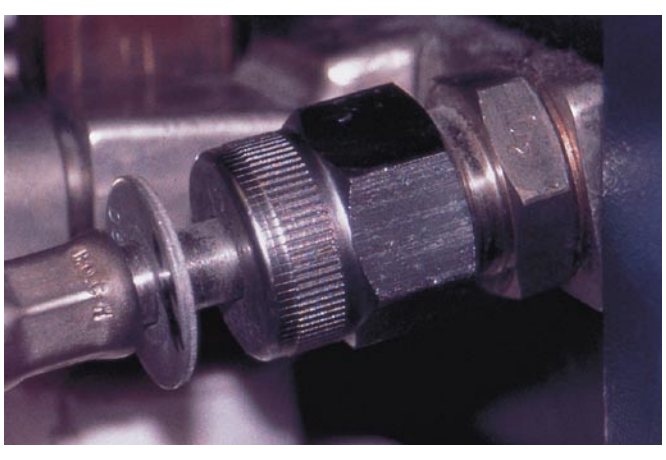
Flexible pipeline

A flexible pipeline carries medical gases from the terminal outlet to the anaesthetic machine. The terminal outlet probe (Schrader probe; Figure 5) is fitted with an indexing collar of a specific diameter for each gas, which will fit only the corresponding gas socket on the terminal outlet valve. In addition, each collar has a notch that fits over a pin within the socket to prevent rotation of the hose once installed. The entire assembly is constructed so that rapid probe insertion or withdrawal can be performed single-handedly and that once withdrawn the terminal outlet unit is self-sealing.

The flexible hose is made of a high-quality copper alloy with antistatic and bacteriostatic properties. It is colour coded and labelled in accordance with the gas it carries.

The hoses are connected to the anaesthetic machine by a non-interchangeable screw thread unit. This unit consists of a probe unique to each gas and a nut to screw the assembly on to the machine. A stainless-steel ferrule is crimped over the whole unit to seal the connection and prevent its removal (Figure 6).

5 Schrader probe.



6 Non-interchangeable screw thread.

Safety

Pipelines and flexible hoses: guidance for manufacturers, installers and maintenance engineers is in accordance with BS5682 (1987) and Health Technical Memorandum 2022 (1994). Pipelines for each of the medical gases are manufactured in different locations within the factory to prevent accidentally mixing up their unique features, for example, connection of the wrong terminal probe, non-interchangeable screw thread fitting or incorrect colour coding.

Pipelines and flexible hoses are steam cleaned, dried and sealed at both ends after internal inspection before being transported to their installation site. This is to prevent contamination and particulate matter from entering the gas supply. In the event of damage to, or technical failure of any part of the pipeline, it must be returned directly to the manufacturer for repair or replacement.

The pharmacy, supplies and engineering departments within each hospital are responsible for the pipeline supply. This includes testing of gases for purity and identity after installation of new pipelines.

The anaesthetist is responsible for ensuring that the flexible hoses are correctly engaged and that the corresponding gas passes into the anaesthetic machine. Correct engagement is checked by using the 'tug test' and the identity of the gas by using the 'single-hose test'. This is done by attaching the oxygen pipeline to the anaesthetic machine, turning on all the flowmeters and ensuring that gas flows only through the oxygen flowmeter and that it is detected by an oxygen analyser fitted at the common gas outlet.

Cylinder gas supply: cylinders and their use in conjunction with the anaesthetic machine are covered elsewhere in *Anaesthesia and intensive care medicine*.

Medical gas pressure

Working pressures within cylinder and piped medical gas supplies are outlined in Figure 7.

Pressure monitoring and display of both pipeline and cylinder gases is performed by Bourdon gauges. The Bourdon gauge is an aneroid (i.e. without liquid) gauge consisting of a coiled tube, attached at one end to the gas supply and at the other end to a pointer. The pressure of the gas causes straightening of the coil and thus causes movement of the pointer over the colour-coded, labelled and calibrated dial. The gauge is faced with heavy glass and designed such that leaks vent from the back of the valve casing and do not blow out the glass.

Cylinder and pipeline colour coding and pressures

	Body colour	Shoulder colour	Pressure (kPa) at 15°C
Cylinder			
• Oxygen	Black	White	13700
• Nitrous oxide	Blue	Blue	4400
• Carbon dioxide	Grey	Grey	5000
• Air	Grey	White/black	13700
Pipeline			
• Oxygen	White		400
• Nitrous oxide	Blue		400
• Air (clinical use)	Black		400
• Air (power tool use)	Black		700

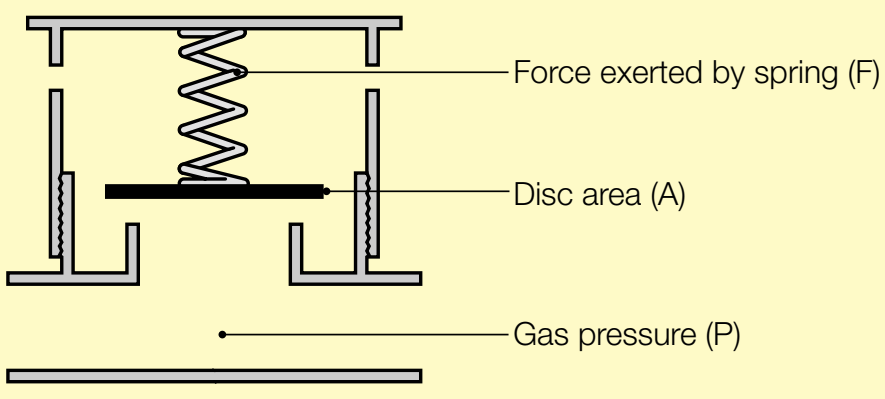
7

Pressure regulators: throughout the medical gas supply network the pressure within the system is closely regulated. This is vital for the protection of both equipment and patient. Measures to maintain a near-constant pressure are found in many sites and usually take the form of a pressure relief valve or a pressure regulator (see *Anaesthesia and Intensive Care Medicine* **1:2:** 66). Both devices are also present within the anaesthetic machine.

Pressure relief valves are designed to allow escape of gas above a certain set pressure. In the case of the VIE this protects the oxygen storage equipment from damage from pressure above 1690 kPa. Similar valves are positioned downstream of pressure regulators within the pipeline supply in case of regulator failure. These are set slightly above 400 kPa.

The principle on which the valve works relates to an equilibrium between two opposing forces: that exerted by the spring and that generated by the gas itself (Figure 8).

Pressure relief valve



$F = P \times A$

As the disc area is constant, and the force exerted by the spring to close the valve is pre-set, once the gas pressure within the system exceeds this closing force, the valve opens and gas escapes

8

Medical gases

Oxygen

Manufacture: industrial manufacture is by the fractional distillation of liquid air. This involves the removal of carbon dioxide and then the separation of oxygen and nitrogen by means of their different boiling points.

Oxygen may also be produced by oxygen concentrators, which extract oxygen from air. This process involves the passing of air through a sieve of zeolite (aluminium silicate), which absorbs the nitrogen, leaving oxygen and a trace of argon. The equipment for this process used to be bulky, but recently smaller units suitable for home use have been developed. A maximum concentration of 95% pure oxygen can be produced using these devices.

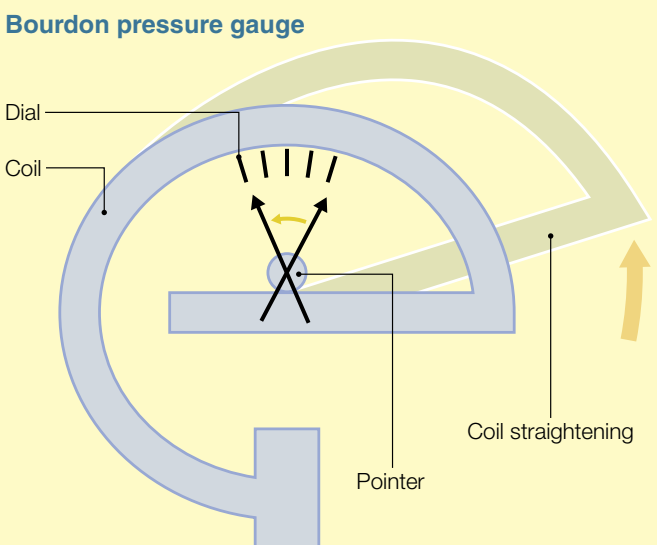
Storage: oxygen is stored either as a gas in cylinders or as a liquid in a VIE. In the UK, cylinders used for oxygen storage are black with a white shoulder (Figure 9); in the USA they are green. The oxygen is stored at a pressure of 13700 kPa at 15°C. Where piped medical gases are used, oxygen is also stored in cylinder manifolds. In cylinders, oxygen is a gas and the volume of oxygen remaining in the cylinder is directly related to the measured pressure, according to Boyle's law.

9 Cylinders. From left: oxygen, nitrous oxide, air, carbon dioxide.

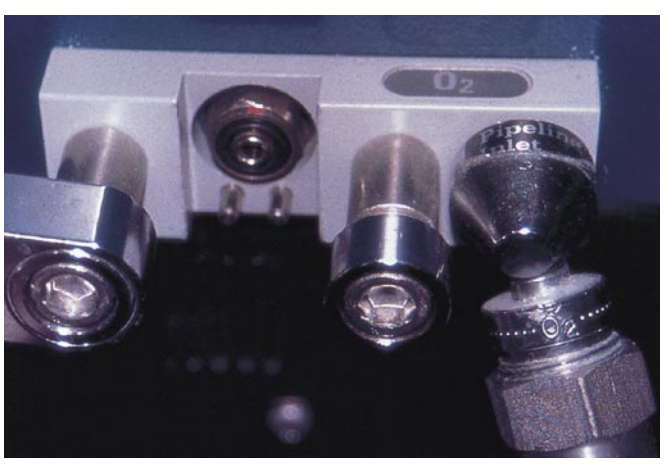
The VIE (Figure 10) is a thermally insulated device similar to a large vacuum flask. Oxygen is stored within this vessel at about –160°C and at a pressure of 5–10 atmospheres (500–1000 kPa). The low temperature is maintained by the vacuum surrounding the main chamber and by heat energy being lost from the liquid oxygen as it evaporates (latent heat of vaporization). Under normal working conditions, oxygen evaporates and passes through the pressure regulator to reduce its pressure to 400 kPa, and then enters the pipeline supply. If demand for oxygen is low, the internal pressure gradually rises until a safety valve opens at 1690 kPa to release gas to the atmosphere. When demand for oxygen is great, the control valve opens allowing liquid oxygen to pass through the pressure-raising superheater and vaporizer, evaporate and enter the pipeline supply. The superheater is a coil of uninsulated copper pipe.

The VIE (Figure 2) can be found outside all hospitals that use piped gases and may be supported by a tripod structure. Two of these legs support the weight of the evaporator, while the third is a weighing device to allow the mass of liquid contained to be measured. Modern designs stand on four legs and the contents are calculated by measuring the pressure difference between the top and bottom of the vessel.

Bourdon pressure gauge



10



11 Cylinder yoke.

Delivery: oxygen is delivered from a central supply (i.e. a manifold or VIE) or directly from cylinders. Central oxygen supply is via the pipeline system described above. Direct cylinder supply of oxygen to the anaesthetic machine involves the connection of the cylinder valve to the cylinder yoke (Figure 11) on the back of the machine.

Carbon dioxide

Manufacture: carbon dioxide is manufactured by heating calcium or magnesium carbonate in the presence of their oxides. Other sources are as a by-product of the manufacture of hydrogen, fermentation of beer or the combustion of fuel.

Storage: in the UK, carbon dioxide is stored in grey cylinders (Figure 9) at a pressure of 5000 kPa at 15°C, as a liquid in equilibrium with its vapour.

Distribution: unlike the other medical gases, carbon dioxide is not distributed via a central pipeline. The attachment of carbon dioxide cylinders to anaesthetic machines has declined in recent years to minimize the risk of accidental administration during anaesthesia. The present guidelines issued by the Association of Anaesthetists of Great Britain and Ireland state that carbon dioxide cylinders should not be routinely fitted to the anaesthetic machine.

Air

Manufacture: air for medical use is compressed, cleaned and filtered before use.

Storage: compressed air for anaesthetic use is stored in grey cylinders with black and white shoulders (Figure 9) at a pressure of 13,700 kPa at 15°C. In the USA, the cylinders are yellow.

Distribution: pipeline air is sourced from either a manifold (Figure 1) or, more economically, from an air compressor. It is important to know that air for clinical use is regulated to a pressure of 400 kPa, whereas that for the use of surgical power tools is supplied at 700 kPa. The terminal outlet for compressed air is colour coded black and white, labelled and has a non-interchangeable connection (Figure 4).

Cylinders are attached directly to the anaesthetic machine by connection of the cylinder valves to the cylinder yoke. A larger portable cylinder may be attached via a flexible hose.

Perioperative Fluids

E Anne Thornberry

E Anne Thornberry is Consultant Anaesthetist at the Gloucestershire Royal Hospital, Gloucester, UK. She qualified from King's College, London, and trained in anaesthesia in Chester, Bristol and Southampton. She has a special interest in obstetric anaesthesia.

Any surgery under anaesthesia can upset the patient's normal fluid status through preoperative restriction of oral intake of fluids. The degree of disruption depends on the patient's medical condition, the nature of the surgery and the choice of anaesthetic. Factors to consider when planning perioperative fluid management are listed in Figure 1.

Maintenance requirements: normal values for daily fluid and electrolyte requirements are shown in Figure 2. Dextrose 4% with saline 0.18% contains 30 mmol/litre of sodium and is often used for basal fluid therapy.

Determinants of perioperative fluid requirements

- Maintenance requirements
- Preoperative deficits
- Blood loss
- Third-space losses
- Transcellular fluid losses
- Effects of anaesthetic agents and technique

1

Maintenance fluid and electrolytes

Adults
- 40 ml/kg/day

Children
- 100 ml/kg/day for first 10 kg
- 50 ml/kg/day for second 10 kg
- 25 ml/kg/day for each subsequent kg

Na^+ = 1–1.5 mmol/kg/day
K^+ = 1 mmol/kg/day

2

Preoperative deficits

Preoperative assessment of the fluid status of the patient requires an appropriate history, examination and investigations.

History and examination

The following questions should be asked.
- How long has the patient been starved?
- Do they have an intravenous infusion in progress?
- Have they any reason to expect excessive losses?
- Are they taking diuretics?
- Are they pyrexic?
- Have they been vomiting or do they have a nasogastric tube *in situ*?
- Have they got diarrhoea or had a bowel preparation?
- Could they have third-space losses or occult bleeding?
- Have they any symptoms of fluid overload?

The physical examination includes evaluation of the mucous membranes and skin turgor, and measurement of the vital signs, including orthostatic changes. Ascites, pulmonary oedema and pleural effusions should be sought. Measurement of urine output may be useful.

Investigations

A normal haematocrit value may indicate that the patient has a normal fluid status or it may reflect someone with anaemia who is also dehydrated. A raised serum urea with a normal creatinine level may indicate dehydration. Raised urinary sodium levels, specific gravity and osmolality all reflect the normal homeostatic response to water depletion and can be used to monitor progress with resuscitation. The signs and symptoms of water depletion are described in Figure 3.

Estimation of total body water deficit

Deficit of body weight	For example in a 70 kg man	Signs and symptoms
Up to 5%	3.5 litres	Thirst Dry mouth
5–10%	3.5–7 litres	Decreased skin turgor Decreased intraocular pressure Tachycardia Orthostatic hypotension Tachypnoea Oliguria Skeletal muscle weakness Drowsiness
10–15%	7–10.5 litres	Severe hypotension Tachycardia Anuria Confusion/coma

3

Signs and symptoms of uncorrected acute blood loss

Volume lost	For example in a 70 kg male	Signs and symptoms
10%	490 ml	Thirst Venoconstriction
20%	980 ml	Mild increase in heart rate Systolic blood pressure normal Slight rise in diastolic pressure Decreased urine output
30%	1470 ml	Tachycardia > 120/minute Moderate hypotension Tachypnoea Cool, clammy, pale Anxious/aggressive Oliguria
40%	1960 ml	Severe hypotension and tachycardia Tachypnoea Anuria Mental confusion
50%	2450 ml	Coma

4

Fluid losses

Blood loss: the signs and symptoms of unreplaced blood loss (Figure 4) can help to estimate acute losses if accurate measurements cannot be made. Estimates of intraoperative blood losses are derived from measuring or estimating observed losses. Prediction of postoperative losses requires knowledge of the type of surgery and expected postoperative bleeding, combined with measurement of losses in the drains, vital signs, and haemoglobin and haematocrit levels.

Third-space losses are caused by sequestration of extracellular fluid into the tissues. The composition of this fluid is the same as that of interstitial fluid and losses after major bowel resection may be as great as 8 ml/kg/hour. The extent of third-space losses depends on the severity of injury to the tissues.

Transcellular fluid losses: nasogastric aspirate can be measured but pleural effusions and ascites must be estimated. Losses from evaporation occur from the surgical site and during a laparotomy these can be as much as 10 ml/kg/hour.

Effects of anaesthetic agents and techniques

Ventilation with dry anaesthetic gases increases the pulmonary losses from evaporation. General and regional anaesthesia tend to decrease the patient's blood pressure by a reduction in sympathetic tone, vasodilatation or myocardial depression. Vasopressors and intravenous fluids are used to minimize these effects, complicating the assessment of perioperative fluid status. Central venous pressure monitoring can be invaluable in helping to manage more complex cases.

Choosing perioperative fluids

Crystalloids

Dextrose solutions disperse through all the body fluid com-partments and are required to replace combined intracellular plus extracellular water depletion. Once any deficit has been replaced, dextrose is used only perioperatively as part of the basal water requirements or in a diabetic regimen.

Physiological saline disperses throughout the extracellular fluid compartments and is commonly used perioperatively to replace blood loss, transcellular losses, evaporation and third-space losses. Only one-third remains in the intravascular compartment and therefore three times the volume of the blood loss must be given if saline is used as a replacement. When large volumes of saline are administered there is a risk of developing hyperchloraemic acidosis.

Ringer's lactate (Hartmann's solution) behaves as normal saline in distribution. It is often used as the first-choice replacement fluid because the electrolyte content more accurately mimics the extracellular fluid. Its constitution varies between laboratories but in general it contains 137 mmol/litre sodium, 4 mmol/litre potassium, 3 mmol/litre calcium and 142 mmol/litre chloride. There are fewer risks of electrolyte disturbances if large volumes are administered but it is hypotonic and large volumes reduce plasma osmolality.

Colloids

The contents of the commonly used colloids are listed in Figure 5.

Properties of commonly used colloids

	Average molecular weight	Sodium (mmol/litre)	Potassium (mmol/litre)	Chloride (mmol/litre)	Calcium (mmol/litre)
Haemaccel	35,000	145	5.1	145	6.2
Gelofusine	35,000	154	0.4	154	0.4
Hetastarch	450,000	154	0	154	0
Dextran 70 in saline	70,000	150	0	150	0
Albumin 4.5%	70,000	150	2	120	0

5

Colloids used for intravenous therapy have an increased osmolality with respect to plasma and can increase plasma volume by more than the volume infused by attracting water from the interstitial fluid compartment. Consequently they are used predominantly to replace intravascular losses and are unsuitable for the treatment of dehydration. The length of time a colloid stays in the intravascular compartment depends on the shape, size and charge of the molecules suspended and the porosity of the capillary endothelium.

Gelatins are colloid solutions derived from animal gelatin. They have an average molecular weight of 35,000 but there is a wide variation in molecule size. The two commonly used gelatins are *Haemaccel*, which is urea linked, and *Gelofusine*, which is a succinylated gelatin. Their intravascular persistence is low, about 2–3 hours with *Gelofusine* and less for *Haemaccel*. Gelatins are the colloids most likely to induce an anaphylactoid reaction. Cross-matching is unaffected by the use of gelatins. *In vitro* studies suggest they interfere with clotting and platelet aggregation but in clinical practice little effect is seen.

Hydroxyethyl starches (HES) are modified natural polymers of amylopectin, which are metabolized by amylase. They are divided into high, medium and low molecular weight starches according to the range of molecular weights in the solution. *Hetastarch* is a 6% solution with an average molecular weight of 450,000 and a mean molecular weight of 70,000. The intravascular persistence of *Hetastarch* is over 24 hours. Some enters the interstitial space and is taken up by the reticulo-endothelial system where it can persist for years. Hexastarch and pentastarch are lower metabolic weight starch solutions. High molecular weight HES solutions can cause a coagulopathy by reducing factor VIII and von Willibrand factor. The lower the average molecular weight of the solution the less effect it has on coagulation. The maximum recommended dose is 33 ml/kg/day, though this has often been exceeded without any adverse effects. Anaphylactic reactions have been reported, but the incidence is low.

Dextrans are branched polysaccharides produced by the action of bacteria on a sucrose medium. Dextran solutions are divided by their average molecular weight into 10% Dextran 40 (molecular weight 40,000) and 6% Dextran 70 (molecular weight 70,000). Dextran reduces blood viscosity, reduces platelet adhesiveness and increases fibrinolysis. Doses higher than 1.5 g/kg can increase bleeding. Only Dextran 70 is used for short-term plasma expansion. Severe anaphylaxis is uncommon but has been reported.

Albumin has a molecular weight of 69,000 and is a naturally occurring plasma protein that contributes significantly to the maintenance of plasma oncotic pressure. It has been used as a colloid to treat critically ill patients with hypoalbuminaemia but there is no evidence that this improves outcome. Recent research has suggested it may worsen outcome but this is not proven. The increasing cost of production of albumin has significantly reduced its use in clinical practice.

Crystalloid–colloid controversy
It has been argued that colloids are more appropriate than crystalloids for the replacement of intravascular losses because they stay in the intravascular compartment longer, necessitating a smaller volume of replacement and a more rapid result. As stated above, the intravascular persistence varies significantly between the different colloids, while this argument holds for hydroxyethyl starches it is not so strong for the gelatins.

Opponents of colloids emphasize the incidence of ana-phylaxis with colloids, which does not exist with crystalloids. The pragmatists suggest that the normal physiological response to an acute intravascular deficit is to draw water in from the interstitial fluid compartment and therefore it makes sense to initiate resuscitation with a crystalloid and then to continue with a colloid if the loss becomes significant.

Blood and blood products
Red cell transfusions: the indication for a red cell transfusion is to increase the oxygen-carrying capacity of the blood by raising the haemoglobin concentration of patients with acute or chronic anaemia. The extent to which it should be raised depends on the balance between oxygen consumption and supply, with the aim of avoiding tissue hypoxia. Factors that affect perioperative oxygen consumption are body temperature, sympathetic activity, metabolic activity, heart rate and drug therapy.

New safety requirements are making blood products more complex and expensive to produce. Recent research suggests the traditional trigger of a haemoglobin concentration of 10 g/dl for perioperative transfusion is too high. The rate of blood loss also needs to be taken into consideration when deciding to transfuse. Suggested British Society for Haematology guidelines are summarized in Figures 6 and 7.

Need to transfuse based on an estimate of lost circulating volume

Volume lost	Indication for transfusion
15%	Only if superimposed on existing anaemia or Patient unable to compensate because of severe cardiac or respiratory disease
15–30%	As above or In the presence of continuing blood loss
30–40%	Transfusion should be considered
> 40%	Transfuse

6

Need to transfuse based on consideration of haemoglobin concentration

Haemoglobin concentration	Indication for transfusion
< 7 g/dl	Transfuse
7–10 g/dl	Transfuse patients who would tolerate anaemia poorly (e.g. those with cardiac or respiratory disease, those over 65 years of age)
> 10 g/dl	No indication

7

Concerns about the safety of transfusion have encouraged the development of alternative strategies to minimize the need for homologous transfusions. These include the use of autologous pre-donation of blood, acute normovolaemic haemodilution, intraoperative cell salvage, preoperative administration of erythropoietin and the development of blood substitutes.

Fresh frozen plasma is valuable because it contains all the clotting factors. It is used to correct a coagulopathy due to a concurrent illness, the use of anticoagulants or a dilutional coagulopathy. A coagulation screen should be requested to establish the need for fresh frozen plasma, although in the presence of a massive haemorrhage, fresh frozen plasma may be given before laboratory results are available if there are clinical signs of impaired coagulation.

Platelets should be given only if there is clinical and laboratory evidence of abnormal coagulation.

Blood substitutes
There are three different areas of research in progress: free haemoglobin solutions, encapsulated haemoglobin cells, and perfluorocarbon emulsions.

Haemoglobin-based oxygen carriers: free haemoglobin has been used as a red blood cell substitute for decades but initially there were many adverse effects including hypertension, bradycardia, renal dysfunction and a short intravascular retention time. A problem was the lack of 2,3-diphosphoglycerate (2,3-DPG) and the higher pH of plasma compared with that inside the red blood cell. There is also an increase in oncotic activity which limits the concentration of free haemoglobin that can be used to about 5–7 g/dl.

Some of the adverse effects of free haemoglobin have been reduced by a variety of modifications including polymerization and conjugation to increase the intravascular retention time and the introduction of haemoglobin into cell-like structures, using stable, porous membranes that allow molecules such as glucose to enter. Some products have reached the stage of clinical trials.

Perfluorocarbon emulsions: perfluorocarbons are synthetic carbon–fluorine compounds. They dissolve gases including oxygen and carbon dioxide. They are not metabolized *in vivo* and most are excreted unchanged via the lungs. A small amount is taken up by the reticulo-endothelial system and excreted later. They are immiscible in water and have to be emulsified. Initial emulsifiers caused numerous adverse effects. Second-generation perfluorocarbons have reduced the complications, but high doses can still interfere with coagulation, elevate liver enzymes and produce a febrile response. They are in phase III trials as a blood substitute. ◆

Positioning the Surgical Patient

Jonathan Warwick

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

The correct positioning of a patient for surgery is a balance between optimizing surgical exposure and minimizing complications for the patient. The surgeon may request a particular position and it is often the role of the anaesthetist to ensure that this is accomplished safely. The anaesthetist must consider the limits of position that may be tolerated and ensure access to the airway, monitoring and vascular devices as far as possible. In general, complications may arise from physiological consequences of the position and the effects of direct pressure on soft tissue structures.

Supine position

Indications: the supine position is the standard for most surgical procedures. The orthopaedic fracture table is a modification that enables traction to be maintained on a lower limb and provides access for an image intensifier.

Physiological consequences: when an individual is upright, ventilation per unit lung volume is greater in the lower part of the lung, because here the weight of the lung makes the intrapleural pressure–volume curve steeper (see Figure 2). The apex of the lung is on a flatter part of this curve, representing a relatively larger change in pressure for a given change in lung volume, and hence a lower compliance. The lower part of the lung is better perfused as a result of gravity.

When an individual is supine, ventilation and perfusion become more uniform and the effects of gravity less marked. The differences between base and apex are then replaced by differences between dependent and non-dependent parts of the lung. Stroke volume and cardiac output may increase as a result of the increase in central venous pressure. Baroreceptors sense an increase in arterial pressure, leading to a fall in heart rate and systemic vascular resistance.

The physiological effects of a change of posture when anaesthetized depend on additional factors:

- pharmacological effects
- circulating blood volume
- method of ventilation.

The functional residual capacity (FRC) decreases by about 20% following induction, though closing capacity remains unchanged. Anaesthetized patients are vasodilated and have diminished compensatory cardiovascular reflexes. Therefore, all positioning movements must be made slowly. The basic supine position is generally well tolerated and has no additional physiological effects in healthy patients.

Pregnant patients may suffer from the supine hypotensive syndrome, where the weight of the gravid uterus reduces venous return by compression of the inferior vena cava (IVC). This can be avoided by a lateral tilt of the operating table, usually to the left side.

Direct pressure complications: the eyes should be taped closed to prevent corneal drying or injury from scratching. Limbs must be fully supported and moved with care to prevent joint dislocation or even fracture. The arms can be secured in the drawsheet, or by the use of padded arm supports.

Skin overlying all bony points is prone to pressure damage, especially the occiput, elbows, knees, greater trochanter of the femur and sacrum. As little as 2 hours of unrelieved pressure may result in a pressure sore; the duration of pressure is considered to be more important than its intensity. The ankles should be placed in soft foam-rubber boots to avoid pressure necrosis of the heel skin.

Injury to peripheral nerves (Figure 1) is often a consequence of the way in which the patient is positioned during surgery. Nerve injury is most likely to occur with the combination of muscle relaxation, an extreme position and prolonged surgery. Peripheral nerves are damaged by local ischaemia caused by compression or stretching. This produces segmental demyelination. Complete clinical recovery usually occurs within 6–8 weeks, but may take several months. Severe damage may be associated with permanent injury. Electromyography studies may aid the prognosis.

Supine position – nerve injuries

Nerve injury	Comments
• Supraorbital	Compression by catheter mount, trachael tube connectors
• Nerves to the eye	Compression from face mask
• Facial (VIIth)	Compression by anaesthetist's fingers against ramus of mandible, face mask harness
• Brachial plexus	Stretching injury, especially when arm is abducted > 90°, externally rotated, elbow extended and forearm supinated
• Ulnar	Most common nerve injury occurring during anaesthesia. Compression between the medial epicondyle of the humerus and the edge of the operating table. Pronation of the forearm may place the nerve more at risk than supination
• Radial	Compression between the edge of the operating table or armboard and the shaft of the humerus, compression from a head-screen support
• Pudendal	Compression from the post of an orthopaedic fracture table may cause pudendal nerve injury or genital trauma
• Sciatic	Direct compression in thin patients undergoing prolonged surgery on a hard table

1

Lateral ('lateral decubitus') position

Indications:

- thoracic surgery
- lateral approach to the kidney
- surgery to the hip.

Reference to the right or left lateral position indicates the side on which the patient is lying.

Physiological consequences: when lying awake in the lateral position, ventilation to the upper and lower lungs behaves in a similar fashion to the ventilation of lung apex and base when upright. The lower lung lies on the steeper, more compliant part of the intrapleural pressure–volume curve (see Figure 2, page 12). The weight of the abdominal contents pushes the lower lung diaphragm higher than the diaphragm of the upper lung, so that it is also able to generate a higher force of contraction. The lower lung is therefore better ventilated than the upper lung. Perfusion of the lower lung is also greater as a result of gravity.

Following anaesthesia, the distribution of blood flow remains unchanged but there are significant changes to the distribution of ventilation. Muscle tone is greatly reduced or absent and the FRC of each lung falls, especially in the lower lung as a result of the weight of the mediastinum pushing down from above and the weight of the abdominal contents below. This has the effect of moving the upper lung down to a more favourable (i.e. steeper and more compliant) part of the intrapleural pressure–volume curve. The lower lung moves down to a flatter, less compliant part of the curve. Therefore the upper lung becomes the better ventilated, but because it receives less of the pulmonary blood flow, ventilation–perfusion mismatch increases.

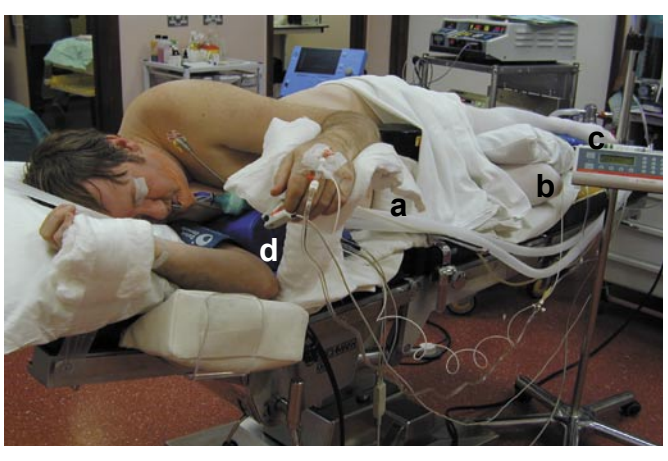
To expose the flank during the lateral approach to the kidney, the lateral flexed position over a support ('kidney position') may be necessary. Significant hypotension may result when the patient is positioned on the right side for a left kidney operation. Reduced venous return occurs as a result of partial obstruction of the IVC from the support. Hepatic encroachment on the IVC may also contribute. This problem is less common when the patient is in the left lateral position.

Direct pressure complications: the pelvis and shoulders must be well supported to prevent the patient from rolling backwards off the table, or forwards into the recovery position. The lower leg should be flexed and the upper leg extended, with a pillow between the two (Figure 2).

An axillary roll places the weight of the chest on to the ribcage and prevents direct compression injury to the shoulder and axilla, thus avoiding deltoid muscle ischaemia or neurovascular damage to the lower arm.

The lower leg is at risk from pressure damage, especially in obese patients. Compartment syndrome, myoglobinuria and acute renal failure have been reported.

Nerve injuries that may result from the lateral position are listed in Figure 3.



2 The lateral position.
a Padded supports to prevent patient rolling over – anteriorly next to iliac crests; posteriorly next to lumbar spine.
b Lower leg flexed and pillow between knees.
c Heel supported.
d An axillary roll places the weight of the chest on to the ribcage.

Lateral position – nerve injuries

Nerve injury	Comments
• Cervical spine	Lateral flexion may stretch cervical spinal nerves and make arthritic joint pain worse. May cause Horner's syndrome
• Brachial plexus	Stretching injury when the neck is extended and in lateral flexion. May occur when the arm is suspended from a bar or gutter and is inadequately supported
• Common peroneal	Compression between the operating table and the head of the fibula

3

Trendelenburg ('head-down') position

Indications:

- pelvic surgery
- insertion of central venous lines.

Friedrich Trendelenburg first described the 45° supine head-down position in 1890. This position facilitates access to the pelvis. Most head-down positions are now about 20° or less with acceptable results. The steep head-down position is now avoided because it is unnecessary and has too many disadvantages. A corrugated or non-slip mattress helps prevent patient movement.

Physiological consequences: there is a greater reduction in FRC than in the basic supine position as a result of pressure of the abdominal contents on the diaphragm. Usually ventilation is little impaired, especially in fit patients and for short periods. For longer operations and in obese patients, there is increased work of breathing against the weight of the abdominal contents, therefore controlled ventilation is preferable.

Central venous pressure rises, and cardiac output may increase. This may precipitate acute heart failure in patients with poor cardiac reserve. The position is not generally effective in improving the circulation during shock and can increase venous pooling in the upper half of the body. A prolonged head-down position will cause venous congestion and oedema in the head and neck.

Barrier pressure is the difference in intraluminal pressures either side of the gastro-oesophageal junction. The pressure within the oesophagus is normally 15–25 mm Hg higher than gastric pressure and gastro-oesophageal reflux is prevented. Barrier pressure is maintained by the action of the smooth muscle cells of the lower oesophageal sphincter and the skeletal muscle of the surrounding crural diaphragm. The head-down position may raise intragastric pressure, reduce barrier pressure and encourage reflux to occur.

There is an increase in intracranial and intraocular pressure. While inserting central venous lines in patients with head injury, care should be taken to limit the head-down tilt to the minimum necessary so as not to worsen cerebral perfusion pressure.

Direct pressure complications: injury to the brachial plexus was common when the steep 45° head-down position was used and patient movement was prevented by shoulder supports or wrist straps. Patient movement is prevented by the non-slip mattress when lesser degrees of head-down tilt are used (e.g. 20°). Brachial plexus injury is now uncommon.

Reverse Trendelenburg ('head-up') position

Indications:
- operations on the head and neck; this position reduces venous pressure and helps reduce bleeding
- surgical access to the gall bladder and proximal gastrointestinal tract, especially during laparoscopic surgery
- operations on the shoulder joint.

Usually, 15–20° head-up tilt is sufficient.

Physiological consequences: there is a small decrease in arterial pressure; but less of a decrease in FRC than in the basic supine position because less pressure is exerted on the diaphragm by the abdominal contents. There is a reduction in intraocular and intracranial pressure, mainly as a result of improved venous drainage.

Any open vein or sinus above the level of the right atrium can cause venous air embolism.

Direct pressure complications: injury to the brachial plexus may be caused by excessive rotation and lateral flexion of the neck away from the operative site.

Lithotomy position

Indications:
- urological procedures
- operations on the perineum, anus and rectum.

The patient is positioned in the supine position, with both hips and knees flexed and the thighs abducted. The ankles and feet may be supported by lithotomy poles using stirrups or calf supports, or by strapping into padded boots. The position is usually combined with some head-down tilt to aid surgical access.

Physiological consequences: the lithotomy position is generally well tolerated. There is a reduction in vital capacity and FRC as a result of diaphragmatic splinting from upward displacement of abdominal contents. This may cause difficulty with spontaneous ventilation in obese patients and controlled ventilation may be preferable. Care should be taken when the legs are lowered because this may reveal previously unrecognized hypovolaemia and cause sudden hypotension.

Direct pressure complications: backache is common and may be reduced by providing a support to maintain the normal lumbar lordosis. The sacrum must be supported and should not hang free over the end of the table. Marked flexion of the hips and knees may cause sacroiliac strain, and the legs must be moved together to avoid pelvic asymmetry. Slippage of the lithotomy poles once the legs are positioned can cause hip dislocation. Moving the thighs too far apart may strain the adductor muscles.

Compartment syndrome in the lower leg may be initiated by pressure of the calf muscles on the stirrup pole. 'Breaking' or raising the lower end of the table when the fingers have been inadvertently trapped in the gap has caused crush injury.

Anaesthesia should not be induced with the legs elevated because raised intra-abdominal pressure may predispose to regurgitation, and turning the patient will be difficult.

Nerve injuries that may occur with the lithotomy position are shown in Figure 4.

Lithotomy position – nerve injuries

Nerve injury	Comments
• Sciatic	Stretching as a result of maximum external rotation of the flexed thigh
• Common peroneal	Compression between lithotomy pole and the head of the fibula
• Tibial	Compression if the legs are supported by stirrups behind the knees
• Femoral	Compression beneath the inguinal ligament when the thighs are fully flexed on the abdomen
• Obturator	Compression at the obturator foramen when the thighs are fully flexed on the abdomen
• Saphenous	Compression between the medial condyle of the tibia and lithotomy post or stirrup

Prone position

Indications:
- operations on the spine and posterior cranial fossa
- operations on the buttocks and natal cleft
- percutaneous extraction of renal calculi.

Physiological consequences: there is often an improvement in gas exchange in the prone position. This may be as a result of the greater inspiratory pressures required to maintain the tidal volume, which decreases atelectasis, increases FRC and improves oxygenation. Pulmonary barotrauma caused by excessive inspiratory pressures should be avoided by correct positioning of the pelvis and upper chest.

The pelvis and the upper chest must be supported so that the abdomen is not compressed and the diaphragm can descend freely during respiration. This may be particularly difficult to achieve in obese patients. Patients may be positioned by using pillows, supporting the iliac crests with cushioned props, or by the use of a specialized hollowed mattress. Controlled ventilation is preferable in most patients.

There are no significant cardiovascular changes. Pulmonary blood flow is essentially unchanged from the supine position. Poor positioning and high inspiratory pressures may decrease venous return. Patients with previous coronary artery bypass grafting may be at risk from graft occlusion.

Direct pressure complications: turning the supine patient prone requires a team of four people. Great care must be taken with the head and neck to avoid twisting or hyperextension injury to the cervical spine. The face should rest on a cushioned horseshoe with the weight of the head evenly distributed. The eyes are naturally protected within their bony sockets, but exophthalmos or a flattened nasal bridge may allow transmission of pressure to the globe. Prolonged compression may result in central retinal vein thrombosis and blindness.

The tracheal tube must be securely fixed and its position checked after the turn. Some experienced anaesthetists may use the laryngeal mask for airway maintenance in prone patients, though the use of a reinforced tracheal tube is likely to be safer for the trainee. Excessive pressure on the breasts may cause ischaemic damage to the nipples, interstitial bleeding or rupture of breast implants. In men, the penis or scrotum may become trapped and compressed.

Possible nerve injuries are shown in Figure 5.

Prone position – nerve injuries

Nerve injury	Comments
• Cervical spinal cord	Stretching injury caused by overextensio plane
• Nerves to the eye	Compression from face support
• Facial (VIIth)	Compression from face support
• Brachial plexus	Stretching injury caused by extreme abduction of the arms. Limit abduction to 90°
• Ulnar	Compression between the medial epicondyle of the humerus and the mattress
• Lateral cutaneous nerve	Compression between iliac crest of the thigh and the positioning prop. If used, props should be angulated and positioned so that the patient is unable to slip sideways
• Anterior tibial	Stretching injury caused by forced plantar flexion of the foot

The sitting position

Indications:
- operations on the posterior cranial fossa and cervical spine
- dental chair anaesthesia.

The sitting position enables the surgeon to gain clear access, with optimal venous drainage, low arterial pressure and reduced bleeding. CSF drainage is good and brain swelling is minimized.

Dental chair anaesthesia in the sitting position is now uncommon.

Physiological consequences: the patient is anaesthetized in the standard supine position and the neurosurgical pins and head frame are applied. On the operating table, the patient is progressively sat upright with the neck flexed; the knees are slightly flexed and the legs are lowered. The arms rest in the lap on a pillow, with the elbows flexed.

A small fall in systolic blood pressure of 20 mm Hg usually occurs; this can be offset by prior volume loading with 500 ml of colloid solution. Occasionally, persistent instability of blood pressure can occur that may cause the position to be abandoned despite the use of vasopressors. Controlled ventilation is the method of choice, to enable control of Pa_{CO_2} and intracranial pressure. It maintains a higher mean intrathoracic pressure and reduces the likelihood of air embolus.

Air embolus is the major complication. All patients must be considered to be at risk throughout the procedure. For this reason, many neurosurgeons seldom use this position. It is still used when insufficient access is provided by the alternative prone or semi-prone positions.

Dysrhythmias, especially bradycardia, and blood pressure instability may occur following surgical manipulation in the region of the brain stem. This is a result of direct pressure effects on the autonomic control centres of the medulla.

Direct pressure complications: nerve injuries that may result from the sitting position are shown in Figure 6.

The sitting position – nerve injuries

Nerve injury	Comments
• Cervical spinal cord	Stretching injury and spinal cord ischaemia following excessive neck flexion. A two-finger breadth gap between chin and chest is recommended
• Brachial plexus	Stretching injury if the arms are unsupported
• Ulnar	Compression between the medial epicondyle of the humerus and the arm supports
• Sciatic	Stretching injury if thighs are flexed and knees extended. Maintain adequate knee flexion

Premedication

Neal Evans
Christopher F Kearns

Neal Evans is Specialist Registrar in the Oxford School of Anaesthesia. He qualified from the Royal London Hospital, and was previously a Research Fellow in ITU in Cambridge, UK.

Christopher F Kearns is Consultant Anaesthetist in the Nuffield Department of Anaesthesia at the Radcliffe Infirmary, Oxford, UK. He qualified from Charing Cross Hospital, London, and trained in anaesthesia in London, UK, Toronto, Canada, and Oxford, UK. His interests include neuroanaesthesia and medical education. He organizes the Oxford Primary FRCA courses.

Premedication involves the prescription of drugs before the induction of anaesthesia in order to alleviate the apprehension associated with surgery, to counteract the side-effects of anaesthetic agents or to reduce the risks of pre-existing pathology (Figure 1). When choosing a premedicant drug the anaesthetist must consider which of its properties are appropriate for the individual patient, the possible side-effects and its potential effect on the proposed anaesthetic technique. The ideal premedicant is:

- painless to administer
- highly reliable and specific
- of rapid onset and rapidly cleared
- free of side-effects and interactions with other drugs.

Premedicant drugs entered anaesthetic practice in the late 19th century. Early anaesthetic agents were delivered by open systems and induced unconsciousness slowly. Ether caused an increase in pharyngeal and bronchial secretions, which interfered with smooth gaseous induction. Chloroform caused marked vagal stimulation of the heart leading to bradycardia. Atropine was first used in premedication in 1890. Hyoscine, which combined anticholinergic effects with antiemesis and sedation, was often combined with an opioid (e.g. papaveretum) to produce ‘twilight sleep’. Opioids were prescribed to aid the induction of anaesthesia before the development of more potent anaesthetic induction agents.

The routine use of drugs for premedication is now in decline. There are several reasons for this.

- Modern anaesthetic agents are potent and have a rapid, smooth onset.
- The increased use of day-care surgery requires rapid patient recovery.
- In-patients are often admitted on the day of surgery and the time available between preoperative assessment and induction of anaesthesia is short.
- Pressures of high patient turnover and staffing constraints can make premedication difficult to deliver in practice.

Rationale of premedication

- Reduction of anxiety and fear
- Sedation
- Amnesia
- Antiemesis
- Reduction in volume and acidity of gastric secretions
- Attenuation of autonomic reflexes
- Maintenance of cardiovascular stability
- Reduction of airway secretions
- Provision of analgesia

1

Anxiolysis, sedation and amnesia

The preoperative visit: anxiety is common in preoperative patients. As well as being unpleasant, this anxiety is part of a stress response that may worsen coexisting pathology such as hypertension or angina. A preoperative visit by the anaesthetist is the most effective way to allay the fears and anxieties of forthcoming surgery. This visit can be used to establish rapport with the patient, to discuss the proposed anaesthetic technique in terms that they can understand and to address their worries in a sympathetic manner. Older children will benefit from inclusion in preoperative discussions and it is becoming usual for parents to stay with children during induction of anaesthesia.

For some patients, the preoperative visit alone is insufficient to allay anxiety and pharmacological methods are required. The nature of the surgical procedure, coexisting pathology or the need for a rapid recovery from anaesthesia may dictate extreme caution before the prescription of sedating premedication (Figure 2). Co-administration of an opioid and a benzodiazepine has a potent respiratory depressant effect.

Relative contraindications to sedative premedication

- Airway obstruction or airway surgery
- Poor ventilatory reserve
- Sleep apnoea
- Intracranial pathology
- Severe hepatic or renal disease
- Rapid-sequence induction
- Obstetric anaesthesia
- Day-case anaesthesia (delayed discharge)
- Extremes of age

2

Benzodiazepines
Benzodiazepines are the most commonly used premedication. They are safe and have a broad therapeutic index though they can cause unpredictable psychological effects at the extremes of age. Those that are suitable premedicants can usually be given by mouth about 1 hour before induction, have a short duration of action and produce inactive metabolites (Figure 3).

Benzodiazepines are agonists of γ-aminobutyric acid (GABA) receptors within the CNS. GABA is an important inhibitory neurotransmitter, which hyperpolarizes the neuron by causing an influx of chloride ion. Benzodiazepines also produce sedation and amnesia by their action on the limbic system. Both these effects are variable and depend on the drug used and the dose given.

Temazepam is an effective anxiolytic and is available in elixir or tablet form. It has a sufficiently short duration of action to allow its use in day-case surgery. Midazolam is presented in 2 mg/ml or 5 mg/ml glass vials. Unlike the other benzodiazepines it is water soluble at acid pH but becomes highly lipophilic at physiological pH. It can be given orally or nasally, which makes it an attractive premedicant for children in doses of 0.2–0.5 mg/kg. Lorazepam, 0.05 mg/kg (max. 4 mg), produces intense anterograde amnesia within 30 minutes, often lasting over 3 hours. Amnesia may be viewed as an advantageous property of a premedicant but some patients find the sensation unpleasant.

Benzodiazepines commonly used as premedication

Drug	Usual adult dose	Half-life of parent drug (hours)	Half-life of active metabolites (hours)
• Diazepam	5–10 mg p.o.	24–48	4–10
• Temazepam	10–30 mg p.o.	4–10	None
• Lorazepam	2–4 mg p.o.	10–20	None
• Midazolam	5–10 mg i.m. 0.5 mg/kg (maximum 20 mg) p.o. in children	1–3	None

3

Other anxiolytics and sedatives
Phenothiazines are major tranquillizers that have sedative and anticholinergic actions. They are histamine antagonists (via H_1-receptors) and have antidopaminergic and α-adrenoceptor blocking properties. They may cause pallor and restlessness in the presence of pain and hypotension. Trimeprazine elixir is sedating and is used for children in doses of 1.5–2 mg/kg, up to 2 hours before surgery. It is not licensed for use in children less than 2 years of age.

Droperidol is the only commonly used butyrophenone in current anaesthetic practice. It has antiemetic and sedating properties. Antidopaminergic side-effects such as dystonic reactions and agitation limit its routine use at sedating doses (e.g. 10 mg orally for adults).

Antiemesis

Postoperative nausea and vomiting (PONV) is a common problem, which is distressing for the patient. There are several risk factors:

- gender (incidence is three times higher in women than in men)
- patients undergoing operations on the ear, squint surgery, gynaecological procedures and laparoscopy
- previous history of PONV or motion sickness
- use of morphine
- anaesthetic technique (volatile anaesthetic maintenance is more emetic than intravenous propofol maintenance).

The vomiting reflex is coordinated by the vomiting centre within the dorsolateral reticular formation of the medulla. It receives multiple afferent pathways from peripheral and central chemoreceptors, nociceptors, the vestibular system and the cerebral cortex. The synapses in these pathways are predominantly muscarinic. The vomiting centre also receives stimuli from the chemoreceptor trigger zone in the area postrema on the floor of the fourth ventricle, but outside the blood–brain barrier. This structure is rich in dopamine (D_2) and serotonin (5-HT_3) receptors. The antiemetics commonly used in anaesthetic practice involve inhibition at one or more of these receptor sites.

Muscarinic antagonists: hyoscine (adults, 300 μg; children 4–10 years, 75–150 μg orally) is a more effective antiemetic and is more sedating than atropine. Antihistamines, including cyclizine, 50 mg orally, i.v. or i.m., and promethazine, children 2–5 years, 5–15 mg, 5–10 years, 10–25 mg orally; adults, 25–50 mg orally or intramuscularly, also have antiemetic properties, largely as a result of their antimuscarinic activity. Antimuscarinics cause dry mouth, blurred vision, and bowel and bladder dysfunction.

Dopamine antagonists are powerful antiemetics but extra-pyramidal side-effects, such as dystonia, dyskinesia, tremor and oculogyric crisis are not uncommon.

Prochlorperazine, 12.5 mg i.m., is the most widely used phenothiazine because it is less sedating and has fewer antidopaminergic and α-blockade side-effects than others of the same group.

Droperidol is an effective antiemetic at low dose, 0.625–1.25 mg, reducing the risk of unpleasant dopaminergic or psychological effects. It is usually given intravenously at induction.

Metoclopramide, 0.1 mg/kg i.v., i.m. or orally, is a dopamine antagonist with peripheral as well as central effects. Its prokinetic effects are more marked than its antiemetic properties and comparative studies have raised doubt about its effectiveness as a prophylactic antiemetic.

5-HT antagonists are powerful new antiemetics that are relatively free of side-effects. The most widely used agent is ondansetron, 4 mg i.v., given immediately before or at the end of surgery. Their relative expense has resulted in the cost-effectiveness of their prophylactic use being questioned.

Non-pharmacological measures including acupunture and acupressure have been explored. There is some evidence that these techniques are weakly effective.

Reduction in volume and acidity of gastric secretions

The potential for lung damage from the aspiration of gastric contents increases with the volume and the acidity of the aspirate. Risk of aspiration accompanies late pregnancy, emergency or trauma surgery, symptomatic oesophageal reflux, and obesity.

Acid secretion by gastric parietal cells can be reduced by the use of H_2-histamine antagonists such as ranitidine, 150 mg p.o. Proton pump inhibitors such as omeprazole, 20 mg p.o., are more powerful in reducing acid secretion but inhibit the metabolism of other drugs such as warfarin, phenytoin and diazepam.

A 0.3 molar solution of sodium citrate, 30 ml, will raise gastric pH and is less irritant to the airway should aspiration occur. The routine use of the prokinetic agent metoclopramide, 10 mg, is common practice but of no proven value in the prevention of gastric aspiration.

Attenuation of autonomic reflexes

Parasympathetic stimulation can lead to hypotension, bradycardia or even asystole mediated via the vagus nerve. Triggers include:

- traction on the extraocular muscles during squint surgery
- surgical dilatation of the cervix or of the anal sphincter
- repeated doses of suxamethonium
- laryngoscopy in children (especially on lifting the epiglottis with a straight-bladed laryngoscope)
- opioid analgesics, propofol and halothane.

Glycopyrronium, 0.2 mg i.v. at induction, provides prophylaxis without the discomfort of a dry mouth before surgery. It does not penetrate the blood–brain barrier and lacks the central side-effects of atropine.

An increase in circulating catecholamines may be caused by several factors:

- laryngoscopy and tracheal intubation
- surgical stimulation and pain
- drugs such as ketamine, cocaine and adrenaline (epinephrine) in local anaesthetics.

This increase may cause hypertension and increased myocardial oxygen demand. It may result in myocardial ischaemia in susceptible patients. A balanced anaesthetic technique reduces these risks, and β-blocker premedication (atenolol, 50 mg p.o.) may be of benefit.

There has been recent interest in the use of α_2-adrenoceptor agonists such as clonidine, 3 µg/kg p.o., as premedicants. They reduce sympathetic activity, cause sedation, a reduction in anaesthetic requirement (decreased minimum alveolar concentration) and reduce pressor responses including that of laryngoscopy. However, there appears to be a narrow therapeutic window with the potential for development of hypotension and bradycardia.

Reduction in airway secretions

Antisialogogues are occasionally prescribed as premedicants though their use in modern-day practice is uncommon. Glycopyrronium, 0.2 mg i.v. or i.m., may be used to improve conditions before fibre-optic intubation.

Analgesia

Opioids (e.g. morphine, 0.1–0.2 mg/kg i.v. or i.m.) should be used to relieve acute preoperative pain. However, in the absence of any preoperative distress and with the development of new potent opioid analgesics with a rapid onset given at induction, such as fentanyl, alfentanil and remifentanil, an opioid premedicant is seldom indicated.

Non-steroidal anti-inflammatory drugs decrease the requirement for opioid analgesia during and after a surgical procedure. Typically, ibuprofen, 400 mg p.o., or diclofenac, 50–100 mg p.o., p.r. or i.v., may be given. They should be avoided in patients with a history of peptic ulceration or renal impairment and used with caution in asthmatic patients. Other simple analgesics such as paracetamol, 1 g, can also be given p.o. or p.r.

The concept of pre-emptive analgesia is that nociception can be modulated at the level of the spinal cord by analgesia given before surgery, thereby reducing total postoperative analgesic requirements. While this concept is attractive and has been demonstrated in animal models, clinical studies have yet to prove its value.

Topical anaesthetics such as eutectic mixture of local anaesthetic (*Emla* cream) or amethocaine gel applied to the site of venepuncture, reduce the fear of intravenous anaesthetic induction in children and many adults.

Principles of Anaesthetic Vaporizers

Eileen Palayiwa

Eileen Palayiwa is a Clinical Scientist in the Clinical Measurement Department at the Oxford Radcliffe Hospital. She graduated in physics from Oxford University and obtained her PhD from Oxford Polytechnic. Her interests include evoked potential monitoring and gas analysis.

Gases, liquids and vapours

Substances can exist in the solid, liquid or gaseous state. Below a certain temperature, known as the critical temperature, it is possible to liquefy gases by compressing them. When a gas is below this critical temperature it is referred to as a vapour.

Vapours consist of molecules that have left the surface of a liquid below the critical temperature. Vapour molecules have had sufficient energy to break away from the attraction of the molecules left behind in the liquid and are therefore the more energetic molecules. Molecules leave the surface of the liquid and return to it randomly. When the vapour is in equilibrium with the liquid, the number of molecules leaving the liquid is equal to the number returning to it, and the vapour is said to be saturated. If there is insufficient liquid for there to be a reservoir from which molecules can evaporate and to which they can return, then the vapour is unsaturated and behaves as a gas.

The pressure of a vapour in equilibrium with a liquid is known as the saturated vapour pressure (SVP).

Variation of SVP with temperature

As the temperature of the liquid increases, more molecules have sufficient energy to escape from the surface and therefore the SVP rises. When the boiling point is reached, all the molecules evaporate and the SVP is equal to atmospheric pressure. Figure 1 shows the variation of SVP with temperature for halothane, enflurane and isoflurane. Unsaturated vapours behave as gases so that the pressure is inversely proportional to the volume (Boyle's law).

Cooling due to vaporization

If molecules that have left the surface of a liquid are not allowed to return to it (e.g. if they are swept away by a stream of fresh gas) then the liquid cools. This is because the evaporating molecules are more energetic than those left behind, therefore there is a net loss of energy from the liquid, which causes a drop in temperature. The latent heat of vaporization is the heat required to convert a unit mass of liquid into its vapour phase at a constant temperature. Cooling may be prevented or reduced if the liquid is in contact with a surface that can supply heat by conduction. The amount of heat that a body can supply at a given temperature depends on its specific heat and its mass, or, in other words, on its thermal capacity. Heat is also supplied by conduction from the surroundings and the rate at which this occurs is determined by the thermal conductivity of the body.

The specific heat of a substance is defined as the amount of heat (or energy) required to raise the temperature of a unit mass of the substance through 1 deg C. The units of specific heat are joules per kilogram per Kelvin change in temperature (J/(kg.K)).

The thermal capacity of a body is the heat required to raise its temperature through 1 deg C (this is also equivalent to the amount of energy the body loses when cooled by 1 deg C). The units of thermal capacity are joules per kilogram (J/kg). The thermal capacity of a body is equal to the product of its mass and specific heat.

The thermal conductivity of a material is the rate of heat transfer per unit area when a temperature difference of 1 deg C is maintained across an insulated block of the material 1 m thick. The units of thermal conductivity are Watts per metre per Kelvin (W/(m.K)).

Values of specific heat, density and thermal conductivity for copper, aluminium, glass and stainless steel are shown in Figure 2. It can be seen from this table that copper has the highest thermal conductivity of these materials so that vaporizers made of copper are the most efficient at conducting heat from the atmosphere to replace the energy that the liquid agent loses due to evaporation. Copper has the lowest specific heat of these substances; however, since it is much denser than aluminium or glass, the thermal capacity of a given volume of copper is higher than that of either of these materials. A given volume of stainless steel has the highest heat capacity of these materials. In practice, most vaporizers are made of stainless steel because it is readily available. However, copper is thermally more suitable because its much higher thermal conductivity more than compensates for the lower heat capacity.

Anaesthetic vaporizers

The SVP of most anaesthetic agents at room temperature is too high for them to be delivered to a patient without dilution (Figure 1). For example, the SVP of isoflurane at 20°C is 236.5 mm Hg (i.e. 31% v/v if atmospheric pressure is 760 mm Hg). In general, concentrations below 2% v/v are required for maintenance of anaesthesia. An anaesthetic vaporizer is a device that dilutes the vapour to give a known concentration of the agent.

Fresh gas enters the vaporizer and is split into two portions (Figure 3). One portion flows through an area known as the vaporizing chamber, where it comes into contact with the anaesthetic vapour; the remainder of the gas bypasses this chamber. The two flows then recombine and the vapour is diluted. By varying the flow rate in the two paths the resultant vapour concentration can be varied. The concentration of agent depends on the flow through the vaporizing chamber, the total fresh gas flow and the saturated vapour pressure of the anaesthetic agent. The way in which the gas flow is split between the bypass and vaporizing chamber depends on the relative resistance of each pathway. If the total fresh gas flow (F) is split into a bypass flow (F_b) and a vaporizing chamber flow (F_v) then:

$F_v + F_b = F$

The flow rate emerging from the vaporizing chamber (F_e) will be greater than that entering it, due to the volume of vapour added:

$F_e = F_v + F_e \times SVP/100$

where SVP is expressed as a percentage.

Therefore $F_e = F_v/[1-(SVP/100)]$

The concentration (C) of the vapour in the gas emerging from the vaporizer will be given by:

$C = F_e \times SVP/(F_b + F_e)$

This calculation assumes that the gas emerging from the vaporizing chamber is fully saturated with vapour. To ensure that this is the case, manufacturers increase the surface area of liquid that the gas passes over by introducing wicks made of cloth or metal into the vaporizing chamber. In many cases the gas is forced to take a long pathway through the chamber, which also helps to ensure saturation.

Variation of saturated vapour pressure with temperature

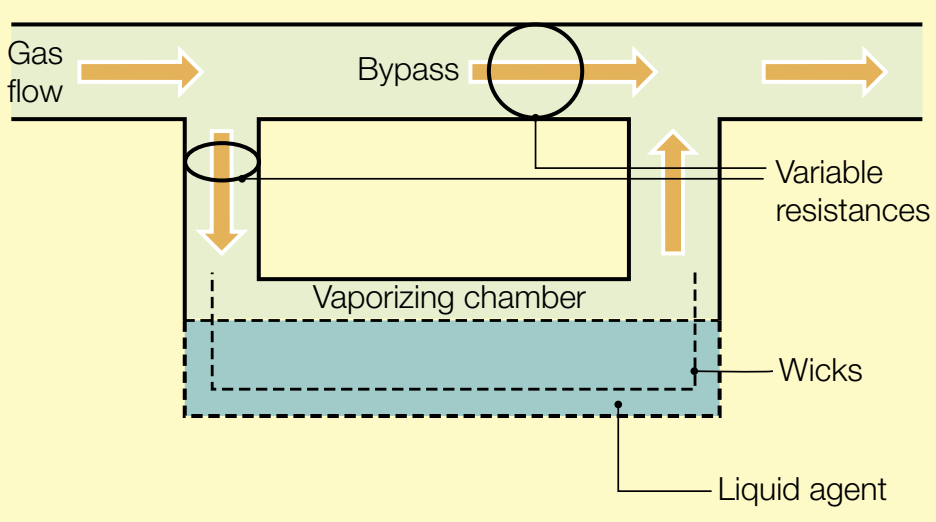
An anaesthetic vaporizer



3

Temperature compensation

As liquid evaporates from the vaporizing chamber the temperature drops, and unless there is some means of compensating for this, the output of the vaporizer also drops. The temperature drop, and hence the fall in output, is lower if the vaporizer has a large heat capacity and can therefore supply energy to the liquid to compensate for that which it has lost. For this reason most vaporizers contain a large mass of metal that can also conduct heat from the surroundings into the liquid. In addition, most vaporizers incorporate some kind of temperature compensation, which reduces the resistance of the vaporizing chamber relative to that of the bypass as the temperature drops. As a result, more gas flows through the vaporizing chamber so that the vapour concentration is maintained.

Effect of intermittent positive-pressure ventilation (IPPV)

During IPPV, the pressure at the outlet of a vaporizer is not constant. When the pressure is high, flow emerging from the vaporizer reduces and the pressure in the vaporizing chamber builds up. As the pressure drops, the excess of vapour, which has accumulated in the vaporizing chamber at this time, emerges not only from the normal outlet of the vaporizing chamber but also from the inlet. This means that the bypass gas contains vapour and therefore the concentration rises. Manufacturers have compensated for this by introducing a long inlet tube into the vaporizing chamber. When the pressure inside the vaporizing chamber drops, the vapour enters this tube, but its volume is not enough to emerge into the bypass.

Effect of flow rate on vaporizer output

The vaporizer output is dependent on the resistance of the vaporizing chamber relative to that of the bypass. With varying flows the vaporizer output remains constant only if this does not change. In practice, this is difficult to achieve over the wide range of flows used in anaesthetic practice. Only if laminar flow is maintained in each pathway throughout the flow range will this be the case. Another factor influencing the output at high flows is the increased cooling, which occurs as a result of the large amount of evaporation taking place.

Figure 4 shows the variation of output with flow for a Penlon plenum enflurane vaporizer. It can be seen that the output of this vaporizer at high settings drops as the flow rate increases. However, at the lower settings more commonly in use, the output remains reasonably constant. This indicates that the temperature compensator in the Penlon plenum vaporizer (PPV) can adjust adequately for cooling due to evaporation except at the highest dial settings and flow rates.

Effect of gas composition

The relative flow rates through the bypass and vaporizing chamber at a given dial setting remain constant only if laminar flow is maintained in both pathways. As soon as the flow in one pathway becomes turbulent, its resistance rises causing less gas to flow through it, unless it is matched by a proportional rise in the resistance of the other pathway.

Nitrous oxide has different physical characteristics from oxygen (Figure 5); in particular, the ratio of viscosity to density, which determines the flow rate at which turbulence sets in, is much lower. The effect that this has on the output of the vaporizer depends on its design. In some vaporizers, output drops when the carrier gas contains nitrous oxide whereas in others it increases.

Variation of output with flow for the Penlon plenum vaporizer

Physical properties of oxygen and nitrous oxide

Gas	Density (kg/m^3)	Viscosity ($\mu N.second/m^2$)	Kinematic viscosity ($m^2/second$)
Oxygen	1.43	18.9	10.3×10^{-5}
Nitrous oxide	1.96	13.5	6.9×10^{-5}

5

Types of vaporizer

Vaporizers fall into two broad categories.

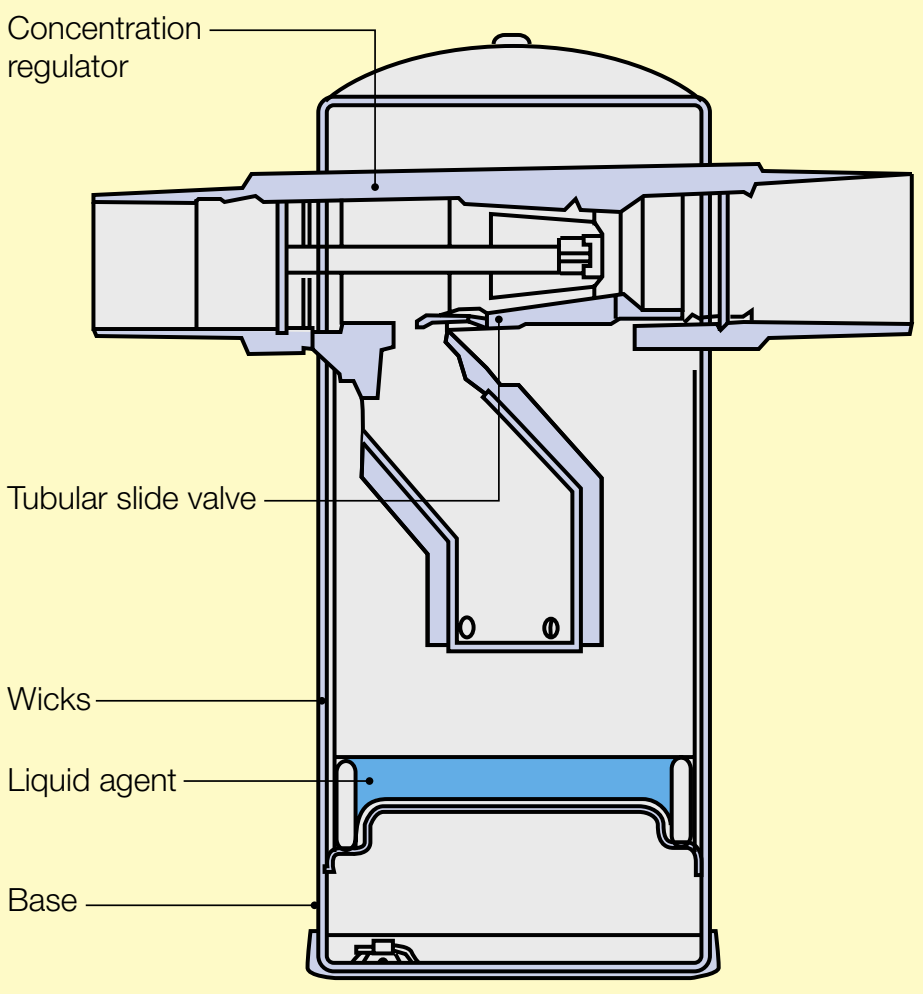
Drawover vaporizers – in a drawover vaporizer, gas is pulled through as the patient inspires (expiration is to atmosphere via a non-rebreathing valve). The flow rate of gas through the vaporizer is therefore not constant and it is necessary for the vaporizer to have a low resistance.

Plenum vaporizers – in a plenum vaporizer, gas is driven through under positive pressure. The term plenum is derived from the plenum system of ventilation where gas is forced into the system. Plenum vaporizers may have a higher resistance than drawover vaporizers though some vaporizers are designed to be used in either mode (e.g. the Oxford miniature vaporizer).

Oxford miniature vaporizer

The Oxford miniature vaporizer (Figure 6) is designed as a low resistance drawover vaporizer. It does not have any temperature compensation, but it has a water-filled jacket to increase its heat capacity.

Oxford miniature vaporizer

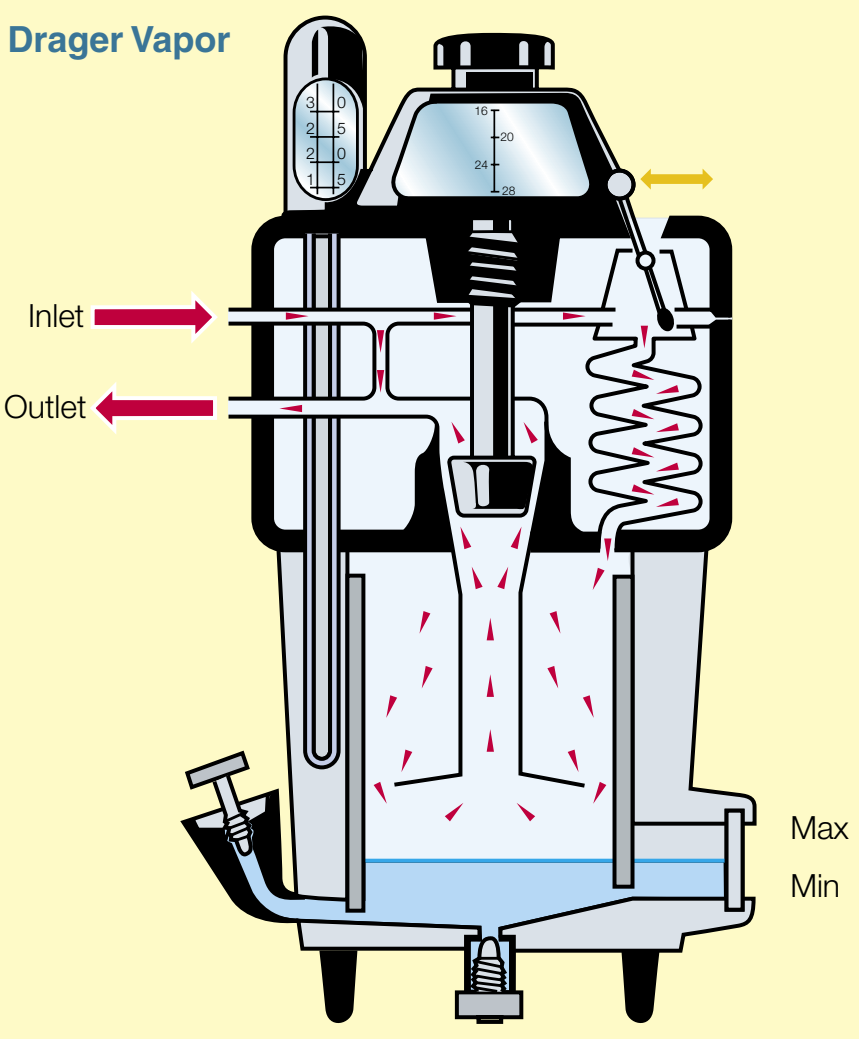


6

Drager Vapor

The Drager Vapor (Figure 7) is constructed from a large block of copper and is therefore thermally stable. It has a built-in thermometer so that the temperature of the liquid agent may be read and the position of the concentration dial is adjusted according to this temperature. In this vaporizer, the gas flow through the bypass and the vaporizing chamber is controlled by a pair of needle valves, which are carefully manufactured to ensure that gas flow is laminar in both pathways over a large range of flow rates. There is therefore little variation of output with flow rate for this vaporizer.

Drager Vapor



7

PPV

In the PPV (Figure 8), when the control dial is in the zero position the vaporizing chamber is isolated by means of a spring-loaded valve attached to the push rod, which is aligned with the control knob. When the control knob zero lock button is pressed the push rod opens the valve and as the control knob is rotated the vapour control orifice opens to allow more gas to flow through the vaporizing chamber.

Temperature compensation is achieved by a moving needle valve within the bypass orifice, which increases the bypass resistance as the temperature drops, thus forcing more gas to flow through the vaporizing chamber. The movement of the valve is controlled by a push rod attached to an ether-filled metal bellows unit. As the liquid agent changes temperature, the ether in the bellows expands or contracts causing the bellows to expand or contract linearly. Compensation for fluctuating back pressure is achieved by the inclusion of a long narrow tube in the vaporizing chamber.

Penlon plenum vaporizer

8

Tec 6 vaporizer

The Tec 6 vaporizer (Figure 9) varies from most other conventional vaporizers because it incorporates a heater element. This is necessary because desflurane concentrations up to 18% v/v may be required. The concentration knob has an interlock system, which means that it cannot be turned until the liquid agent has been heated to the correct temperature. When the control dial is turned, an electronic signal opens the shut-off valve. The pressure transducer measures the difference between the gas inlet pressure and the regulated agent pressure. The agent pressure is controlled electronically by opening or closing the pressure-regulating valve to balance the pressures. When the pressures are correctly balanced the vaporizer functions correctly.

Calibration of vaporizers

Anaesthetic vaporizers are calibrated in the factory using a refractometer (an accurate optical device) in a temperature-controlled room. In general, either oxygen or air at a medium flow rate is used for the carrier gas. The output of a vaporizer may vary under different conditions of temperature, flow or carrier gas – this is not surprising, considering the wide range of flow rates and concentrations over which a vaporizer is used. It has been said that one should expect vaporizers to produce concentrations only within 20% of their dial settings. While this is a wide margin, it is not at all unusual for concentrations to differ by 10% of the dial setting and as conditions become more extreme this difference may approach 20%. It is important that anaesthetists recognize the problems faced by manufacturers when designing vaporizers and that they do not always expect vapour concentration and dial setting to coincide.

Recognition and Management of Anaphylactic and Anaphylactoid Reactions

Andrew McIndoe

Andrew McIndoe is Consultant Anaesthetist and Senior Clinical Lecturer in the Sir Humphry Davy Department of Anaesthesia, Bristol Royal Infirmary. He is also the Director of Research and Education at the Bristol Medical Simulation Centre where he has developed a specific interest in human factors and crisis management.

The term anaphylaxis was coined by Charles Richet in 1902 to describe the reaction of dogs to a second, and often fatal, injection of foreign protein (sea anemone toxin). The term was introduced to distinguish this later injection from the first 'prophylactic' injection that induced sensitization.

Anaphylaxis is now recognized to be an immediate hypersensitivity or type I immune reaction mediated by immunoglobulin E (IgE) and resulting in mast cell degranulation and basophil activation. It is not dose related and can occur in response to minute exposure to an allergen. Typically, the severity of the response worsens on re-exposure owing to progressive sensitization of the subject. The true incidence of anaphylaxis is unknown but is estimated to be 1/6000–20,000 anaesthetics or 1/10,000 of the general population/year. Women are more likely to suffer an anaphylactic reaction than men, with a quoted increase in risk of 3–10:1. Intravenous administration of the antigen is more likely to precipitate a severe generalized reaction. Cross-sensitivities with non-steroidal anti-inflammatory drugs (NSAIDs) and muscle relaxants makes previous exposure unnecessary. Up to 80% of neuromuscular blocking agent reactions are not associated with known prior exposure.

Anaphylactoid reactions may present with a similar clinical picture, but do not result from hypersensitivity and are not mediated by IgE. Drugs such as opioids can directly stimulate mast cell degranulation with histamine release causing pruritus, rash and hypotension. They should be managed as potential anaphylactic reactions because confusion over the diagnosis merely delays effective treatment.

Pathophysiology

Primary exposure to an antigen results in the synthesis of specific IgE antibodies by lymphocytes and plasma cells. The Fc portions of these antibodies are able to fix themselves to the surface of tissue mast cells and circulating basophils. The antigen binding sites are thus presented externally. Subsequent contact with antigen causes IgE antibody:antigen cross-binding and triggers immediate degranulation of the host mast cell or basophil. Release of histamine and serotonin results in an acute inflammatory reaction, smooth muscle constriction, vasodilatation and increased capillary permeability. The clinical picture depends on the mode of exposure.

- Skin – urticaria, flare and weal reaction (hence the use of skin prick testing).
- Eyes – conjunctivitis.
- Mouth/airway – perioral and laryngeal oedema, broncho-spasm.
- Parenteral – generalized cardiovascular collapse.
- Eosinophils are mobilized by chemotaxis, attracted by histamine and other substances, they produce histaminase, helping to terminate the reaction.

History and examination

Anaphylaxis may present with a spectrum of clinical signs including hypotension, tachycardia, dysrhythmias, dyspnoea, laryngeal oedema, bronchospasm, angio-oedema, flushing, urticaria, conjunctivitis, rhinitis, abdominal pain and diarrhoea. It can therefore mimic a variety of other conditions. Diagnosis is further complicated by a variable time for exposure until symptoms develop, varying from a few seconds to several hours. 5% of patients show a biphasic response with symptoms recurring from 1–72 hours after the initial attack. Many patients do not develop all the classic signs (Figure 1).

Differential diagnoses are vasovagal faint with hypotension, bradycardia and pale, sweaty skin and panic attack with hyperventilation, tachycardia and an erythematous rash.

Percentage of patients presenting with classic signs of anaphylaxis

Signs	Patients (%)
• Cardiovascular collapse	88
• Erythema	45
• Bronchospasm	36
• Angio-oedema	24
• Rash	13
• Urticaria	8.5

1

Management

The management of anaphylaxis is summarized in Figure 2.

Management of anaphylaxis

Condition
IgE mediated immediate hypersensitivity reaction to an antigen resulting in histamine and serotonin release from mast cells and basophils

Presentation
- Cardiovascular collapse
- Erythema
- Bronchospasm
- Oedema
- Rash

Immediate action
- Remove trigger
- 100% oxygen
- Elevate legs
- Adrenaline (epinephrine) 500 μg i.m. or 50 μg increments i.v. titrated to effect
- 20 ml/kg i.v. fluid challenge

Follow-up action
- Chlorphenamine (chlorpheniramine), 10–20 mg i.v.
- Hydrocortisone, 100–300 mg i.v.
- Arterial blood gases

Investigations
- Plasma tryptase
- Urinary methylhistamine

Also consider
- Primary myocardial/cardiovascular problem
- Latex sensitivity
- Airway obstruction
- Asthma
- Tension pneumothorax
- Panic attack

2

Immediate management
- Check the airway, breathing and circulation. Stop the administration of or exposure to any potential triggers, particularly intravenous agents. Muscle relaxants, antibiotics and NSAIDs (and increasingly latex) are the most common triggers in an anaesthetic environment. Outside the operating theatre, foods (especially nuts, fish, shellfish, eggs and milk), insect venom, drugs (antibiotics, NSAIDs, contrast media, opioids) and latex are the most common precipitants.
- Call for help.
- Maintain the airway and give 100% oxygen. Reassess airway patency frequently and regularly, especially in known asthmatics and in those exposed to the allergen via the airway or mouth. If in doubt and the reaction is severe, intubate early because it may be impossible to do so later in the presence of increased oedema.
- Cardiovascular collapse is most likely following parenteral exposure to the allergen. Lay the patient flat with the legs elevated to increase central venous return.
- If the patient has a continuous ECG monitor attached, give adrenaline (epinephrine) in 50 μg i.v. increments (0.5 ml of a 1:10,000 solution) at a rate of 100 μg/minute until the blood pressure or bronchospasm improves. Alternatively, give adrenaline (epinephrine) 0.5–1 mg i.m. as 0.5–1.0 ml of a 1:1000 solution (repeated after 10 minutes if necessary). Adrenaline (epinephrine) stabilizes mast cell membranes, increases myocardial contractility, causes bronchodilatation and reverses vasodilatation; it therefore treats both cause and effect.
- Give intravenous fluid (colloid or suitable crystalloid), 20 ml/kg.
- Latex allergy may take up to 30 minutes to manifest itself. Removal of all latex triggers can then be a complex process. Allergen is more readily absorbed across mucous membranes (e.g. from surgical gloves or a urinary catheter, which should be removed immediately and hands should be re-washed to remove latex-impregnated starch granules). Inhalation of aerosolized particles within the breathing circuit is minimized by the use of an airway filter. Ensure that rubber 'corings' are not introduced intravenously (e.g. ampoule bungs and injection sets). Laryngeal mask airways are made of silicone and do not contain latex. *Diprivan* syringe bungs are also latex free.

Subsequent management
- Give an antihistamine (H_1-blocker) such as chlorphenamine (chlorpheniramine, *Piriton*), 10–20 mg by slow i.v. or i.m. injection. Consider H_2-antagonists, such as ranitidine, 50 mg slow i.v. injection.
- Give corticosteroids such as hydrocortisone, 100–300 mg by slow i.v. or i.m. injection, to inhibit later relapses.
- Give a catecholamine infusion because cardiovascular instability may last for several hours. Consider adrenaline (epinephrine) 0.05–0.1 μg/kg/minute (e.g. 4 ml/hour of 1:10,000 for a 70 kg adult) or noradrenaline (norepinephrine) 0.05–0.1 μg/kg/minute (e.g. 4 ml/hour of a solution of 4 mg made up to 40 ml in 5% dextrose for a 70 kg adult).
- Check arterial blood gases for acidosis and consider giving bicarbonate, 0.5–1.0 mmol/kg (8.4% solution = 1 mmol/ml).
- Check for the presence of airway oedema by letting down the tracheal cuff and confirming a leak before extubation.
- Consider bronchodilators for persistent bronchospasm (e.g. salbutamol, 5 mg by nebulizer or 250 μg slow i.v. injection, aminophylline 250–500 mg slow i.v. injection).

Complications

Hospital mortality to anaesthetic drug-induced anaphylaxis is 4%, despite the presence of good resuscitation facilities. Over half of those who die of anaphylaxis do so within the first hour. The deaths are related to asphyxia, from severe bronchospasm or upper airway obstruction, and from refractory hypotension.

The early use of adrenaline (epinephrine) is advisable but advice differs over the safest and most appropriate mode of administration. Adrenaline (epinephrine) is best administered by intramuscular injection (0.5 mg – usually 0.5 ml of 1:1000 solution) by first responders because it is a reliable means of achieving therapeutic plasma concentrations quickly and safely. The subcutaneous route is slow and unpredictable and is inappropriate during an acute life-threatening reaction. Anaesthetists often opt for intravenous administration of a 1:10,000 solution in incremental doses (of 50–100 μg). The intravenous route, while rapidly effective, can result in tachydysrhythmias. Cardiac complications are more common in the presence of hypoxia, hypercapnoea, and in patients taking tricyclic antidepressants or cocaine.

Patients taking β-blockers are likely to suffer more severe reactions and may be resistant to treatment with adrenaline (epinephrine). However, β-blockers are competitive antagonists and careful but continued titration of adrenaline (by sequential doubling of the initial dose in severe cases) should achieve a clinical effect.

Late diagnosis may be complicated by severe compromise of the airway and difficulty intubating the trachea.

Investigations

Investigations should be carried out when the patient has been stabilized.

Plasma tryptase: at least one 10 ml clotted blood sample should be taken 1–6 hours after the start of the reaction to perform a tryptase assay. The specimen must be spun down as soon as possible and the serum stored at –20°C, to stabilize the protein for later analysis. Tryptase is the main protein released during mast cell degranulation and is a specific marker of histamine release due to anaphylaxis or anaphylactoid reaction. Normal basal levels of serum tryptase are less than 1 ng/ml. However, unlike histamine, which is rapidly eliminated, tryptase levels remain elevated for up to 6 hours after an anaphylactic reaction. It is not a protein that is produced by RBCs or WBCs and is therefore not raised by haemolysis. Levels over 20 ng/ml may accompany an anaphylactic reaction.

Elevated metabolites in the form of urinary methylhistamine may also be measured. The value measured has to be corrected for urinary creatinine but levels in excess of 15–20 ng/ml/mmol creatinine/litre are considered higher than normal, and may indicate anaphylaxis.

Radio allergosorbent testing (RAST) is a means of searching for antigen-specific IgE in the serum. Tests are limited to specific allergens. At present only a few anaesthetic RASTs are available (e.g. suxamethonium). Fluoroimmunoassay is an alternative (*CAP System*, Pharmacia).

Follow-up and prognosis

The anaesthetist should follow up the investigation, report reactions to the Committee on Safety of Medicines via the 'yellow card' reporting scheme, and arrange skin prick testing in consultation with an immunologist. Having identified allergens, the patient should be advised to wear an alert bracelet at all times. Those who have suffered a severe reaction, especially anaphylaxis to allergens that are commonly encountered in everyday life, may be advised on how to carry and when to administer their own adrenaline (epinephrine). The *Epipen* syringe is preloaded with adrenaline (epinephrine) and will deliver a fixed intramuscular injection of 300 µg (0.3 ml of 1:1000) for adults or 150 µg for children.

Desensitization is a process that attempts to stimulate the production of IgG or IgA antibodies that competitively bind to the antigen and help block the IgE antibody–antigen hypersensitivity reaction that precipitates anaphylaxis. It is not without risk because it involves repeated inoculation with small doses of antigen.

Recognition of Correct Placement of Tracheal Tubes

Simon Berg

Simon Berg s Consultant Paediatric Anaesthetist at the Oxford Radcliffe Hospitals NHS Trust, Oxford, UK. His special interests are anaesthesia for neonatal surgery and paediatric strabismus surgery.

The technique of tracheal intubation is fundamental to anaesthetic practice. Critical incident reporting indicates that oesophageal intubation is a relatively common problem. Misplacement of a tracheal tube is not in itself harmful if the diagnosis is made promptly and corrective action taken. However, tracheal tube misplacement still accounts for a large proportion of anaesthetic deaths. It should be considered in any hypoxic intubated patient. Failure to detect incorrect tube placement is equally common for trainees and consultants. It is as likely with routine as with difficult intubation.

Methods of confirming correct tube placement

Clinical signs are often unhelpful in detecting tube misplacement and intubation should be confirmed by:

- direct visualization of the tube passing through the vocal cords
- auscultation over both axillae, lung bases and the epi-gastrium
- capnography
- oesophageal detector device or colorimetric detector if capnography is not readily available.

Visualization of larynx

The larynx is usually visualized and the tracheal tube is observed passing between the vocal cords into the trachea. However, a view of the larynx is not always possible. In routine laryngoscopy, an anaesthetist may become distracted at the moment of intubation, allowing the tube to slide past into the oesophagus. Occasionally the oesophagus may be mistakenly identified as the trachea or the tube may become displaced during fixation. Direct visualization is thus not totally reliable and may even delay a diagnosis of tube misplacement by promoting a false sense of security.

Repeat laryngoscopy is essential if a tube problem is suspected; oesophageal intubation, extubation or a kinked tube can all be identified and remedial action taken.

Chest movement

Bilateral symmetrical chest wall expansion should occur coincident with inspiration. It may be difficult to discern in the obese patient, in those with a rigid chest wall, or in chronic lung disease (e.g. emphysema). Oesophageal ventilation may imitate chest movement by expansion of the mediastinum, while gastric distension can simulate diaphragmatic and lower chest wall ventilation, especially in infants.

Auscultation

The combination of auscultation over each axilla, lung base and epigastrium achieves the most reliable results. Direct auscultation over the trachea may be of additional benefit; more obvious breath sounds can be heard, which are less likely to be confused with oesophageal ventilation.

Breath sounds over the chest wall do not always exclude oesophageal intubation. Air ventilating the oesophagus can be transmitted through the lungs to resemble convincing breath sounds. Conversely, breath sounds may be inaudible in the obese patient.

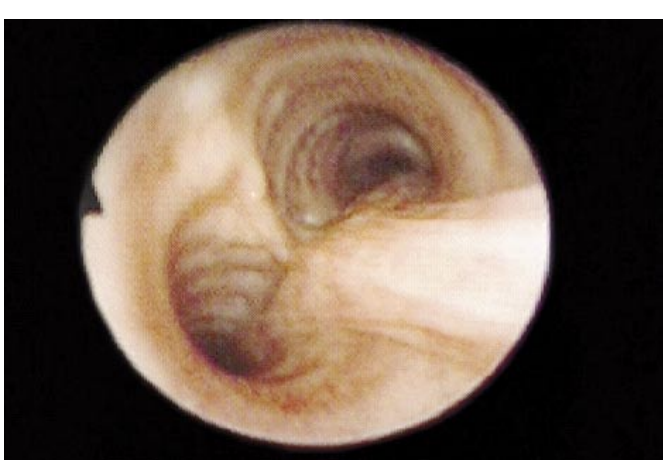
Breathing circuit

The ability to ventilate the lungs via the reservoir bag together with its typical compliance characteristics is a useful sign for the anaesthetist. In a spontaneously breathing patient the bag should empty and refill synchronously with the patient's breathing pattern. However, small movements (cardiac oscillations) can be demonstrated with oesophageal tube placement.

In contrast, it may be difficult to ventilate a morbidly obese patient via the reservoir bag or to differentiate between oesophageal intubation and partial or complete bronchospasm.

Fibre-optic laryngoscopy

The fibre-optic bronchoscope or laryngoscope can reliably confirm tracheal tube placement by identification of the tracheal rings and carina under direct vision (Figure 1). The technique requires operator experience and the equipment must be readily available.



1 View of the carina via a fibrescope, confirming the correct placement of the tracheal tube.

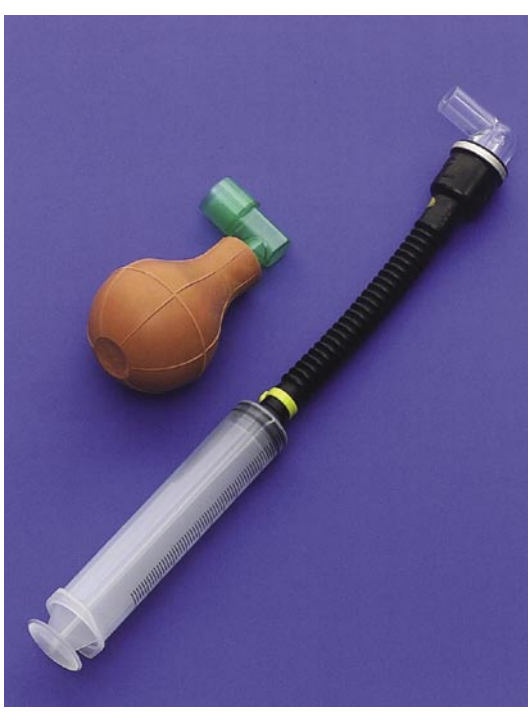
Oesophageal detector device

The Wee oesophageal detector device (ODD) consists of a 60 ml bladder syringe connected to a catheter mount. This is attached to the tracheal tube following intubation. The syringe freely aspirates gas from the patient's lungs if the tube is in the trachea (negative result). However, if this negative pressure is applied to a tube within the oesophagus, the oesophageal wall collapses and no air can be aspirated (positive result).

As a modification, the syringe has been replaced by a large rubber bulb (Ellick's evacuator) to enable the device to be used one-handed (Figure 2). In this case the bulb is first emptied and then failure to refill indicates oesophageal intubation.

The ODD is cheap, simple to construct, easy to use and reliable. It has been validated in several studies with only a small incidence of false-positive results, possibly related to endobronchial intubation or secretions blocking the lumen of the tracheal tube; there are no reported false-negative results.

It has been used successfully with uncuffed tubes in older children but is unreliable in those under 2 years of age.



2 Oesophageal detector device with Ellick's evacuator modification.

Capnography

Capnography is the real-time detection of carbon dioxide in the breathing gases and its display as a waveform that plots concentration versus time. Carbon dioxide is detected by infrared spectroscopy. It is the gold standard for verifying tracheal intubation. The guidelines of the Association of Anaesthetists state that during induction of anaesthesia, capnography is 'essential to the safe conduct of anaesthesia'.

For carbon dioxide to be detected, it must be produced in the tissues, then transported to the lungs, and finally exhaled in the expiratory gas. The capnograph is therefore an important monitor that gives information about:

- metabolic rate
- pulmonary perfusion
- alveolar ventilation.

If metabolic rate and pulmonary perfusion (or cardiac output) are constant, then changes in the capnograph trace reflect the adequacy of alveolar ventilation.

Deceptively low values may result from a large leak around the tube. Gas arising from the stomach and oesophagus usually contains only a trace of carbon dioxide, but false-positive results occur if expired alveolar gas is introduced into the stomach from mask ventilation. Significant concentrations of carbon dioxide have been reported following ingestion of carbonated drinks ('cola complication'). In these circumstances, capnography following oesophageal intubation initially resembles the normal waveform for end-tidal carbon dioxide. This initial value rapidly diminishes towards zero as the carbon dioxide is washed out. It has been suggested that the waveform should be observed for a minimum of six breaths.

Colorimetric carbon dioxide detector

This small disposable device contains a pH-sensitive indicator that displays a colour change (e.g. from purple to yellow) when exposed to carbon dioxide (Figure 3). The colour change is rapid and the detector can be left in the breathing circuit for several hours allowing continuous ventilatory monitoring. The device is about the same size and weight as a heat/moisture exchange filter and requires no power source for operation. This portability makes it useful during cardiopulmonary resuscitation or in emergency situations when capnography may not be available. Reduced carbon dioxide concentrations often present in these clinical situations, which may reduce its sensitivity.

3 Colorimetric carbon dioxide detector.

Complications of oesophageal and endobronchial tube placement

Oesophageal intubation

Undetected oesophageal intubation is a major anaesthetic cause of permanent neurological damage and death. There should be a high index of suspicion in any situation in which hypoxia develops following intubation; the onset may be delayed if preoxygenation has occurred. Difficulty in ventilation, poor or absent chest movement, inaudible breath sounds and increasing abdominal distension should all alert the anaesthetist to the possibility of tube misplacement. In practice, clinical signs are not always obvious.

Progressive gastric distension may cause regurgitation and subsequent aspiration. Splinting of the diaphragm impairs ventilation even after the patient has been correctly intubated unless the stomach is actively decompressed using a nasogastric or orogastric tube.

If there is any doubt as to correct tube placement, it is essential to remove the tube and recommence mask ventilation.

Endobronchial intubation

Endobronchial intubation is more common in children owing to the smaller length of the trachea. Flexion or extension of the neck can move the tube a significant amount within the trachea (up to 5 cm in adults), leading to endobronchial intubation or inadvertent extubation. The right main bronchus is more commonly intubated than the left side because it arises at a straighter angle from the trachea.

One-lung ventilation causes hypoxaemia due to the shunt effect that failure to ventilate the opposite lung produces. Progressive lung collapse of this unventilated side occurs. There is a reduced uptake of volatile anaesthetic agent and bronchospasm is a common occurrence, probably as a result of vagal stimulation from irritation of the carina.

The diagnosis may be obvious with asymmetric chest movement and absent breath sounds on one side of the chest, but clinical signs are often unreliable. With an uncuffed tube, breath sounds can easily be transmitted to the non-ventilated lung. A chest radiograph confirms the diagnosis and provides an estimate of the distance that the tube needs to be withdrawn. Fibre-optic bronchoscopy can also be useful.

The chances of endobronchial intubation can be lessened by cutting tracheal tubes to an appropriate size (e.g. 22–24 cm in the adult) preceding intubation. The black marker line present at the distal end of some tracheal tubes can also serve as a guide to the length of the tube to be passed through the vocal cords.

Regurgitation, Vomiting and Aspiration

Polly Davies
Jonathan Warwick

Polly Davies is Specialist Registrar in Anaesthesia rotating within the Oxford Region. She graduated from Bristol University and is currently based at Northampton General Hospital, UK.

Jonathan Warwick is Consultant Anaesthetist at the Radcliffe Infirmary, Oxford, UK. His special interests are anaesthesia for plastic surgery and head and neck surgery.

Regurgitation is the passive movement of gastric contents into the pharynx. The lower oesophageal sphincter normally prevents regurgitation. The sphincter is a physiological, rather than a distinct anatomical structure. Reflux is prevented because the lower oesophageal pressure is greater than the gastric pressure. This is referred to as the barrier pressure.

Vomiting is an active reflex usually occurring in the lighter planes of anaesthesia (i.e. induction and emergence). It is the forceful ejection of the contents of the upper gastrointestinal tract through the mouth. It is often secondary to stimulation from inappropriate airway manipulation.

The afferent limb of the reflex arc is composed of fibres from the gastrointestinal tract, the vestibular system, or from the chemoreceptor trigger zone in the brain stem. The vomiting centre' in the brain stem coordinates the reflex. The efferent limb involves autonomic outflow to the gastro-intestinal tract and also produces widespread effects such as pupillary dilation, sweating, salivation, vasoconstriction and tachycardia.

Pulmonary aspiration of gastric contents into the lungs is a serious, though infrequent, complication of modern anaesthesia. Mendleson first described it in detail in 1946 in 66 obstetric patients. Aspiration occurs following gastro-oesophageal regurgitation or vomiting when protective laryngeal reflexes are depressed or absent. Prevention of pulmonary aspiration is by measures aimed at reducing the incidence of regurgitation and vomiting.

Although silent regurgitation is thought to occur in up to 25% of patients under anaesthesia, the incidence of significant pulmonary aspiration in the general surgical population is much less at 1–6/10,000. For obstetric general anaesthesia the incidence is doubled. The mortality following aspiration is about 5%.

Pathophysiology

The adverse effects of pulmonary aspiration occur by three mechanisms.

Particle related – this could result in acute airway obstruction.

Acid related – the traditional view is that patients are 'at risk' if the gastric contents consist of a critical volume of more than 25 ml and have a pH of less than 2.5; there is little clinical evidence to support this. pH is the more critical factor for lung injury sustained following aspiration though there may not be an exact cut-off value. Significant morbidity can occur following inhalation of material with a very low pH even in small volumes due to chemical pneumonitis, and following large volumes of neutral fluid due to a 'near drowning' effect.

Bacterial related – aspirated fluid is not sterile and lung infection may result. Damaged lung is also more prone to secondary infection.

Risk factors

Predisposing factors for pulmonary aspiration are shown in Figure 1. Vomiting and regurgitation during induction of anaesthesia occur most often in emergency cases with acute abdominal pathology or following trauma. Pain, fear, anxiety and opioid administration all delay gastric emptying. These patients should be regarded as at high risk and appropriate precautions taken. The interval between last oral intake and time of injury in trauma patients is said to give a better guide to gastric emptying than the duration of fasting. In practice this is unreliable and it is often best to assume patients have a full stomach.

Risk factors for aspiration

Condition	Examples
Full stomach	Inadequate preoperative fasting Gastrointestinal obstruction, bleeding or ileus Trauma, burns, pain, anxiety Pregnancy Drugs (e.g. opioids)
Reduced lower oesophageal sphincter function	Hiatus hernia Drugs (e.g. opioids, atropine) Pregnancy Raised intra-abdominal pressure Obesity Lithotomy position
Material in oesophagus/ pharynx	Achalasia, scleroderma Strictures, carcinoma Pharyngeal pouch
Depressed laryngeal reflexes	Reduced consciousness (e.g. general anaesthesia, drug or alcohol intoxication, cerebrovascular accident, head injury, seizures or postictal state) Topical anaesthesia Neurological disease (e.g. myasthenia, multiple sclerosis, Parkinson's disease, Guillain–Barré syndrome) Muscular dystrophies
Others	Inexperienced anaesthetist Night-time surgery Emergency surgery Extremes of age

Obstetrics
In the third trimester, the enlarged uterus increases intra-abdominal pressure and therefore intra-gastric pressure. Before this, there is an increased risk of aspiration due to the production of:

- gastrin from the placenta, which increases gastric acid secretion
- progesterone, which relaxes smooth muscle and reduces gastrointestinal motility.

Anatomical changes in late pregnancy may increase the incidence of airway difficulties and thus of aspiration (e.g. increased body weight, large breasts, upper airway oedema). Surgery often occurs 'out of hours' as an emergency. Risks may be increased further during labour from the effects of pain, anxiety and opioid administration. Pregnant patients should be assumed to have a full stomach from the end of the first trimester until at least 18 hours post-partum. Regional anaesthesia should be used whenever possible to reduce the aspiration risks.

Prevention

Methods to prevent pulmonary aspiration are directed towards reducing the volume and increasing the pH of the stomach contents. The technique of cricoid pressure and induction of anaesthesia in the patient with a full stomach is elsewhere.

Fasting requirements
Traditionally, patients were fasted overnight before elective surgery. More recently it has been shown that the administration of clear fluids (e.g. water, non-particulate juice) up to 2–3 hours preoperatively does not increase residual gastric volume or alter pH. This increases patient comfort and reduces dehydration and hypoglycaemia in infants. An example of current fasting guidelines for elective, nonobstetric patients is shown in Figure 2.

Fasting requirements are less straightforward for emergency surgery. It is often necessary to provide anaesthesia to patients suspected of having a full stomach. Delaying urgent surgery to reduce the possibility of aspiration is usually of no benefit and may be detrimental. Patients requiring emergency surgery should be assumed to have a full stomach, irrespective of the duration of fasting, because gastric emptying is likely to be delayed. Following painful trauma, a significant gastric residue can be present after 24 hours. It is not currently recommended that emergency patients be allowed to drink clear fluids before surgery. Intravenous therapy should be used to prevent dehydration. At present there is no consensus regarding fasting during labour.

Preoperative fasting guidelines for patients undergoing elective surgery

	Length of fast (hours)
Adults	
• Solid food	6
• Clear fluid	2–3
Children	
• Solid food	6
• Formula milk	4
• Breast milk	3
• Clear fluid	2

Regional anaesthesia
Avoiding general anaesthesia reduces the risk of pulmonary aspiration. Both the proposed surgery and the patient must be amenable to the technique. The patient should be fasted because an inadequate or failed regional block, or adverse reaction, may make general anaesthesia necessary.

Gastric decompression
The insertion of a nasogastric tube to decompress the stomach may be useful. Liquid, but not solid, gastric contents can be aspirated via the tube. It is not usually possible to empty the stomach completely by this means, so the possibility of aspiration remains. If a nasogastric tube has been passed before surgery, it should be aspirated before induction. Effective cricoid pressure can be performed with the tube *in situ*.

Pharmacotherapy
Antacids: prophylactic administration of antacids to high-risk patients is recommended. These drugs neutralize gastric acid and raise gastric luminal pH. Neutral pH aspirate causes less lung damage than fluid of acidic pH. Antacids should be non-particulate to reduce the potential for lung damage if inhaled. 0.3 M sodium citrate, 30 ml, is effective in elevating the pH of gastric contents if given 15–20 minutes preoperatively; it remains effective for 1–3 hours. Antacids are used routinely in elective and emergency obstetric anaesthesia, but less often in the general surgical population.

H_2-receptor antagonists reduce the volume and acidity of gastric contents by the inhibition of hydrochloric acid secretion from gastric parietal cells. Cimetidine, 400 mg orally 90–120 minutes before induction, and ranitidine, 150 mg orally 120 minutes before induction, 50 mg intramuscularly or slow intravenous administration 45 minutes before induction, are commonly used H_2-antagonists. Ranitidine has a duration of action of at least 8 hours; about twice as long as cimetidine. It is also associated with fewer side-effects. Side-effects with cimetidine, though infrequent, include sedation and confusion, and the potentiation of other drugs through inhibition of hepatic enzymes. Hypotension, bradycardia and even cardiac arrest can follow rapid intravenous injection of cimetidine, and also of ranitidine, though ranitidine has a much lower incidence.

Prokinetics: metoclopramide, 10 mg orally 1–4 hours before surgery or intravenously shortly before induction, acts centrally and peripherally to stimulate gastric emptying, increases lower oesophageal sphincter pressure and is anti-emetic. Its central action is due to its antidopaminergic properties whereas peripherally it stimulates acetylcholine release, resulting in increased gastrointestinal motility.

Proton pump inhibitors: omeprazole, 40 mg orally at night and on the morning of surgery, inhibits the proton pump in the parietal cells of the gastric mucosa, resulting in prolonged suppression of acid secretion. It elevates gastric pH. Combining omeprazole with metoclopramide reduces gastric volume. It is seldom used in the UK despite proven effectiveness.

Anticholinergics (e.g. atropine, glycopyrollate) can decrease gastric acid secretion, but have an adverse effect on barrier pressure by decreasing lower oesophageal pressure. They are not used for aspiration prophylaxis.

Induction of anaesthesia
If general anaesthesia is chosen, a cuffed tube in the trachea should secure the patient's airway. The airway should be assessed to predict whether this is likely to be difficult. The laryngeal mask airway has become popular in modern anaesthetic practice, however, it does not protect the airway from aspiration of gastric contents as efficiently as a cuffed tube and should not be used routinely in patients at high risk.

Uncuffed tubes are used in children because the paediatric airway narrows at the cricoid ring. Uncuffed tubes prevent tracheal mucosal damage by excessive cuff pressure, and may allow passage of a slightly larger tube size permitting improved gas flow. There is no precise age or size at which cuffed tubes are chosen, but use of uncuffed tubes in children below 8–10 years is usual. The absence of a cuff may imply the theoretical risk that aspiration can still occur, although satisfactory airway protection still occurs in clinical practice.

Position:there is controversy regarding the optimum position for induction of anaesthesia in the patient at risk of pulmonary aspiration. Some anaesthetists argue in favour of a head-up (reverse Trendelenburg) or semi-sitting position, because this may reduce the incidence of reflux in patients prone to passive regurgitation. Others favour a head-down (Trendelenburg) position with the patient on their side, because this may decrease the likelihood of aspiration should regurgitation occur.

Patient safety is paramount and therefore clinicians should induce anaesthesia in the position in which they have the most experience and confidence. This will usually be a rapid sequence induction in the supine position.

Rapid sequence induction: if the anaesthetist is confident that tracheal intubation will be straightforward then an intravenous rapid sequence induction performed with cricoid pressure is indicated. Aspiration is most likely to occur in the time from loss of consciousness to intubation with a cuffed tracheal tube. Rapid sequence induction reduces this time to a minimum.

Awake intubation: if a difficult intubation is anticipated consideration should be given to securing the airway before induction. In modern practice this involves topical local anaesthesia to the airway, and intubation via a flexible fibre-optic laryngoscope. A 'blind nasal' technique used to be popular, but the arrival of modern fibre-optic instruments has allowed awake intubation to be performed under direct vision.

Inhalational (gaseous) induction may be indicated in a patient considered at risk from aspiration, in whom conventional laryngoscopy and intubation is predicted to be difficult and where awake intubation attempts may be hazardous (e.g. acute stridor, maxillofacial trauma). There is a trade-off between taking steps to prevent aspiration during induction, and maintaining and securing the airway. A senior anaesthetist should manage these cases and patient safety is paramount.

Extubation should be performed with the patient awake and following the return of upper airway protective reflexes. It is often safest to position the patient on their side with head-down tilt to facilitate clearance of the upper airway using suction, should regurgitation occur.

Diagnosis

Clinical signs and symptoms of aspiration are variable (Figure 3) and it is sometimes difficult to make a definitive diagnosis. 'Silent' aspiration may occur, and may not be diagnosed until after surgery when the patient has returned to the ward. The initial and most reliable sign of aspiration is hypoxia, which occurs following even mild cases. Wheezing is also common. In severe cases an acute respiratory distress syndrome can result. In such patients there is increased intrapulmonary shunting, ventilation–perfusion (V/Q) mismatch, increased lung water, increased airway resistance and reduced lung compliance. Although aspiration classically affects the posterior aspect of the right lower lobe, radiographic changes are variable, nonspecific and may be absent, particularly in the first few hours. The most usual findings are irregular fluffy den-sities, frequently bilaterally, collapse or pulmonary oedema (Figure 4).

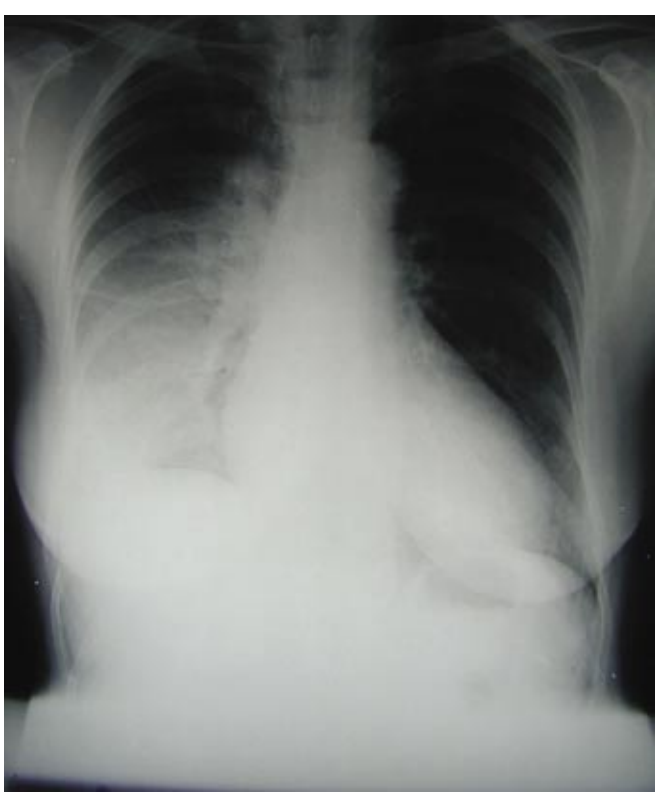
Differential diagnoses include anaphylaxis, cardiac failure, pulmonary embolism, fat embolism, sepsis and, in obstetric patients, amniotic fluid embolism.

Signs and symptoms of pulmonary aspiration

Symptoms
- Cough
- Breathlessness

Signs
- Stomach contents in oropharynx
- Tachypnoea
- Wheeze, crackles (mainly coarse)
- Cyanosis
- Tachycardia
- Pulmonary oedema
- Increased airway pressure
- Radiographic changes

3



4 Typical radiographic appearance of the chest in a patient with aspiration.

Management

If acute aspiration occurs the following procedure should be carried out.
- Place the patient in a head-down position, with head turned to one side.
- Suction material from the oropharynx.
