- Administer 100% oxygen.
- Intubate the trachea if:

– adequate oxygenation cannot be maintained with spontaneous ventilation
– further tracheobronchial suction is required
– the patient is unable to protect their own airway.

The decision to continue with surgery depends on the severity of the aspiration and the urgency of surgery.

The management of established aspiration is largely supportive. Treatment is described in Figure 5.

Management of established aspiration

Oxygen therapy
- Guided by blood gas estimations or pulse oximetry

Ventilatory support
- Spontaneous ventilation may be adequate in mild cases
- Continuous positive airway pressure can be used for more severe cases, but requires alert, cooperative patient at no further risk of aspiration
- For severe cases, or those who cannot maintain a patent airway, mechanical ventilation via a tracheal tube is indicated
- Positive end-expiratory pressure is applied to increase functional residual capacity of the lung and minimize intrapulmonary shunting

Removal of aspirate
- Regular suctioning and physiotherapy are needed
- Bronchoscopy is required in more severe cases

Bronchodilators
- Given regularly by nebulizer

Antibiotics
- No proven benefit from prophylactic use
- Antibiotics often prescribed before identification of any pathogens

Fluid balance
- Shifts of fluid from the circulation to the lungs can result in pulmonary oedema
- Central venous pressure and urine output monitoring help guide fluid management
- A positive fluid balance worsens gas exchange and should be avoided

Corticosteroid therapy
- Routine use of corticosteroids is not indicated – no current evidence has shown benefit from their use

Surgical Diathermy: Mechanisms, Use and Abuse

Andrew D Farmery

Andrew D Farmery is Consultant Anaesthetist at the John Radcliffe Hospital, Oxford, UK. He trained in London, Cambridge and Oxford. His interests are in bio-mathematical modelling and clinical medical education.

The application of heat to wounds is evident in unearthed Neolithic skulls. Thermal cautery to ulcers and tumours of the breast was described in a papyrus from about 3000 BC, and later described by Hippocrates in 300 BC. Electrical diathermy is at least 250 years old, predating the practice of anaesthesia by a century.

Diathermy (*dia*, through; *thermy*, heat) strictly applies to the uniform heating of tissues by radiofrequency current or radiation. As a surgical tool, uniform heating is not required, but rather discrete and destructive heating in a specific area. This application is called 'electrosurgery' in the USA, and 'surgical diathermy' in the UK, but the term diathermy has remained.

Basic electrical principles

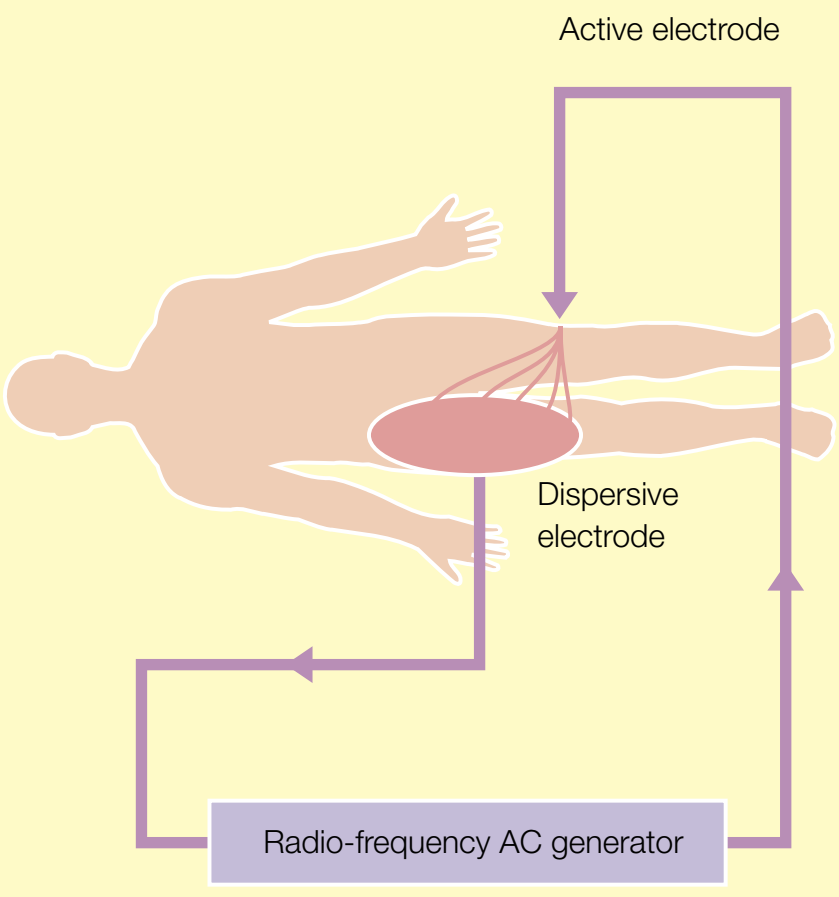
Forcing current through a resistance liberates heat

The power to heat, cut or vaporize tissues is derived from passing an electrical current through it. At any point in an electric circuit, the power dissipated is given by the formula:

$$\text{Power} = \text{Current}^2 \times \text{Resistance} \qquad (P = I^2 \times R) \quad 1$$

Current forced through regions of high resistance produces more heat than the same current passed through regions of low resistance. Figure 1 shows how the current density (and resistance) at the tip of a diathermy probe is many orders of magnitude higher than the current density elsewhere in the circuit, namely the patient's body and the large 'dispersive' electrode. This is analogous to a large crowd of people moving along a wide walkway to gain access to a football stadium. The flow is ordered and comfortable at the rear of the walkway, but when the same 'flow' is forced through a narrow turnstile, the 'power' of the crowd will be liberated (destructively) at this high resistance, high flow-density point.

Current density



The tiny active electrode/tissue contact has a high resistance, therefore a high power is liberated ($P = I^2 \times R$). Because this power is delivered to a small area, the power density, and ability to heat the tissue, is great. By contrast, the dispersive electrode, with its larger area of contact, has a low resistance and thus little power is liberated and it is distributed over a wide area, therefore the heating effect is negligible.

1

Using high-frequency alternating current prevents 'electrocution'

In Equation 1, both direct current (DC; e.g from a large battery) or alternating current (AC; e.g. from the mains supply) produce the same amount of heat for the same mean current. However, DC polarizes a tissue such that tissue connected to the anode becomes 'positive', and that connected to the cathode, 'negative'. This triggers ion channel opening and depolarizes important excitable tissues such as nerves, striated muscle and myocardium. The same is true of moderately low-frequency AC (e.g. 50 Hz), in which the tissue is alternately polarized and depolarized because the polarity of the applied voltage changes sinusoidally. This can result in convulsions, tetanic muscle twitch and ventricular fibrillation (i.e. electrocution).

High-frequency current is less prone to causing these phenomena because voltage-sensitive ion channels in excitable tissues do not respond instantly to an applied depolarizing voltage, but have a finite response time. An analogy is when the rudder of a tanker is turned suddenly, there is a delay before it slowly starts to change direction. If the rudder is turned from left to right with a low frequency, the tanker steers a course veering from left to right sinusoidally. However, if the rudder is oscillated from left to right with a high frequency, the ship steers a straight course because it does not have enough time to respond to a rudder movement in one direction before being directed to move in the opposite direction.

In the same way, a high-frequency AC voltage applied to the myocardium will neither polarize nor depolarize the membrane, because the ion channels will not have time to open or close before the polarity of the applied voltage is reversed and so the tissue will continue to function normally. Electrosurgical generators typically operate at frequencies of 0.5–4 MHz.

Surgical effects of diathermy

There are three main diathermy modes: desiccation, cutting and coagulation.

Desiccation

To cause desiccation (drying out), a low power current is passed through the tissues, as in Figure 1. The aim is to increase tissue temperature at the site of contact with the active electrode. Intracellular water is slowly driven off as steam and the tissue is dried out. This produces a blanching of tissue. Because the current is of low power, it is effective only in delicate tissues and small vessels (e.g. it is often used to blanch the fallopian tube before surgical division in laparoscopic sterilization). When tissue has been desiccated, its resistance to current flow becomes very high and current flow effectively ceases, thus terminating the heating process. It is impossible to 'cut' tissue in this mode. The current waveform is not important in this application.

Cutting

In the cutting mode, the aim is to make a discrete cut through the tissue. Initial contact with the electrode heats the tissue rapidly so that cells explode and their contents are instantly vaporized. Heat is not conducted very far from the site of contact because most of the liberated power is used to vaporize water (i.e. is consumed as latent heat of vaporization). The heating effect is therefore concentrated and neighbouring tissue is undamaged. Unlike desiccation, 'sparking' is a key feature.

The vaporized desiccated tissue is a poor electrical conductor and therefore breaks the circuit so that current flow ceases through this pathway. However, if the voltage (the driving force for current) is high enough, air around the electrode is ionized. Ionized air is a better conductor than desiccated tissue, and so current will now flow as a spark jumps to the nearest region of moist tissue. Tissue heating is produced by:

- current delivered by the spark ($I^2 \times R$)
- radiant heat from the spark
- collision of electrons bombarding the tissue.

This causes intense local heating, vaporization and thermal destruction. Cells are torn apart. The current waveform used is a continuous radiofrequency sinewave (Figure 2a).

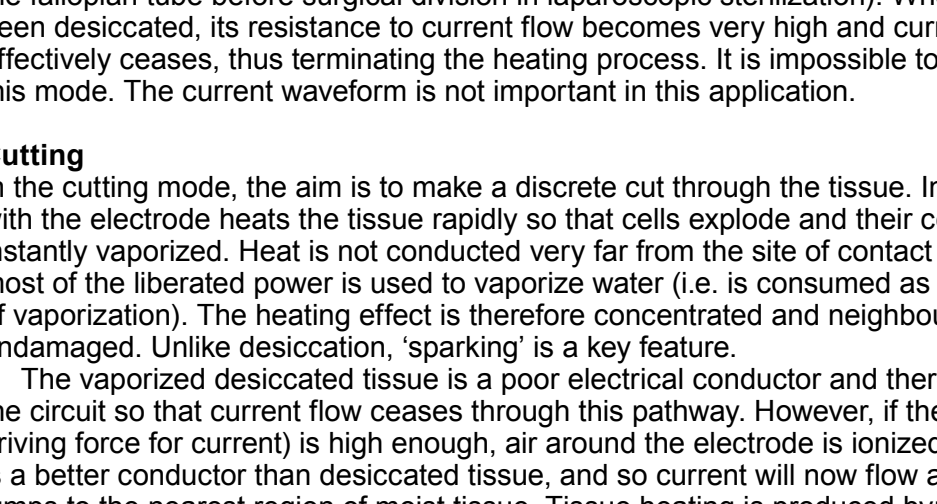
Coagulation

In coagulation mode (Figure 2b), the current waveform comprises short bursts of radiofrequency sinewaves (about 1 MHz), with bursts occurring about 20,000 times per second (burst frequency 20 kHz). The coagulation waveform can cause sparking to tissues. However, the radiofrequency current is delivered in intermittent bursts and therefore the ion cloud generated at each spark has a chance to disappear between bursts. Therefore, with each current burst, ionization occurs afresh, and because this is a random process sparking occurs more randomly and over a wider area than it does in cutting mode. This reduces the concentration of the sparking power and allows effective coagulation of vessels without tissue cutting. Peak voltages are much higher in the coagulation mode than in the cut mode because the current is zero for most of the time and so in order to deliver the same average power, the coagulation waveform generator has to deliver more power in the short periods when current is switched on.

Waveforms

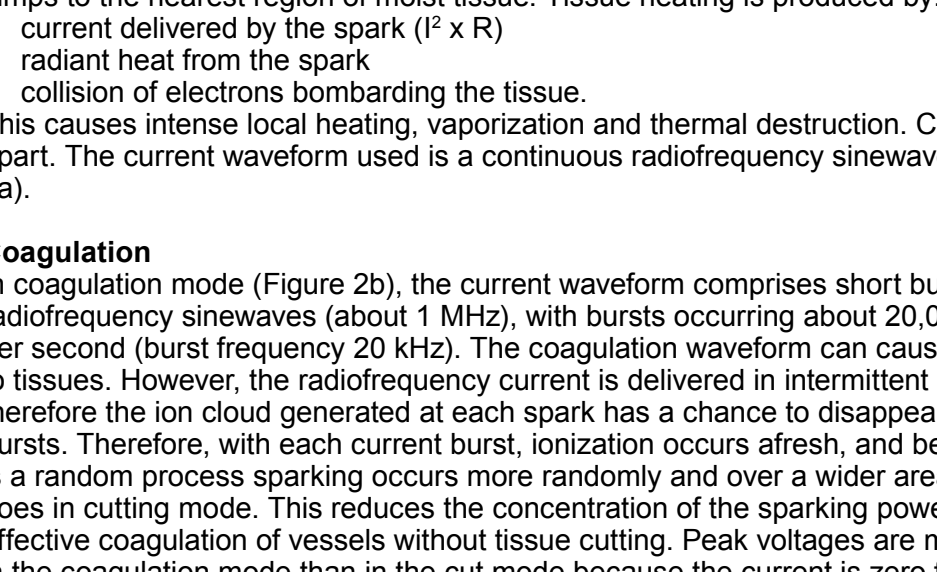
a Cutting waveform

A continuous radiofrequency sinewave of about 1 MHz



b Coagulation waveform

A 1 MHz sinewave delivered in bursts (20,000/second)



2

Monopolar and bipolar systems

Monopolar

The system described in Figure 1 is monopolar. Current is delivered via a pinpoint active electrode, which then passes through the patient (in a low-density path) to return via the dispersive electrode. This is the most widely used system because it is most effective in producing cutting as well as coagulation.

Bipolar
In a bipolar system, current is delivered via one arm of a pair of insulated forceps. It passes through any tissue grasped between the arms of the forceps and returns via the opposite arm. With a bipolar system, only desiccation can be achieved. The system is of limited power, and sparking does not occur. If the arms of the forceps are allowed to make contact with each other directly, despite there being some tissue in the path, current will be 'shorted-out', and diathermy will be less effective. Bipolar diathermy is indicated where it is undesirable to pass current through the patient's body to a distant dispersive electrode; some examples are given below.

Narrow current conduits to extremities (e.g. testicle surgery) – if a monopolar system were used, with the dispersive electrode placed on the abdominal wall, current would be forced to pass from the testicle along the vas deferens (the path of least resistance) to the trunk. Because the vas deferens is a narrow tube, current density would be high within it, and thermal injury might result.

Metal prostheses – if a metal prosthesis lies between the dispersive and active electrode, current preferentially passes through this low resistance route, producing a high current density and heating in narrow points such as a cortical screw. This may necrose bone or conduct heat to neighbouring soft tissue or vessels, sufficient to perforate an artery.

Cardiac pacemakers – the cable connecting a pacemaker generator box (implanted in the anterior chest) to the electrode in the right ventricle and/or atrium constitutes a low impedance pathway for radiofrequency current if it lies between the active and dispersive diathermy electrodes. This may result in a high current density at the point of pacemaker electrode insertion into the myocardium. Tissue desiccation may occur at this point, increasing the resistance of the contact. The 'threshold' potential may increase, such that the pacing pulse fails to trigger the heart.

More sophisticated pacemakers are capable of detecting intrinsic cardiac activity and withholding activation of the pacemaker. It is possible that stray radiofrequency current may be detected by the pacemaker, and interpreted as intrinsic cardiac activity, resulting in inappropriate inactivation of the pacemaker. For this reason, it is advisable, if possible, to have the pacemaker programmed so that this function is disabled. The safest precaution, however, is to avoid monopolar diathermy.

Patient safety

The principal issues are:
- avoidance of inadvertent thermal burns from stray diathermy current
- avoidance of inadvertent electrocution from stray 50 Hz mains current.

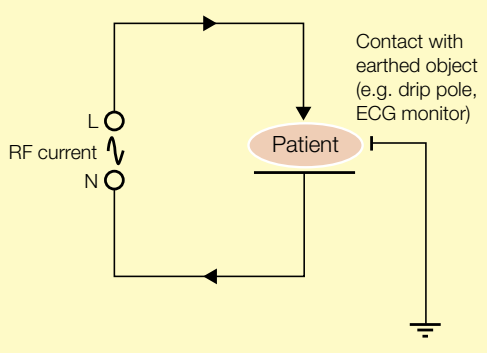
Isolated (unearthed) dispersive electrode system
Figure 3a shows a simple circuit in which neither live nor neutral terminals of the radiofrequency current generator are connected to earth.

A fundamental law of electricity is that all the current leaving the live terminal is returned to the neutral terminal. Therefore, if the patient makes contact with an earthed object (e.g. lithotomy pole, drip stand or faulty low impedance ECG electrode) none of the radiofrequency diathermy current should pass via this contact to earth because such a stray current would not be able to return to the neutral terminal. All the current should pass to the neutral terminal via the large dispersive electrode, thereby eliminating the potential for burns. This might seem a safe system but it is possible to burn patients inadvertently with isolated systems because of the phenomenon of 'capacitive coupling'. It is difficult to confine very high-frequency currents to wires, and currents tend to pass out of the cables like a radio transmitter because a wire and another conductor (e.g. earth) can behave like the two plates of a capacitor. Capacitors can conduct high-frequency current, even though insulation and a few feet of air separate the wire and earth. Radiofrequency leakage current flows only if there is a route for it to return to the neutral terminal; Figure 3b shows how this might happen. A certain amount of current from the active lead is leaked to earth via this capacitive coupling. This can return to the patient via any small, grounded contact point and potentially cause a burn at this site. From this point, the leakage current joins the main current and returns to the neutral terminal via the dispersive electrode.

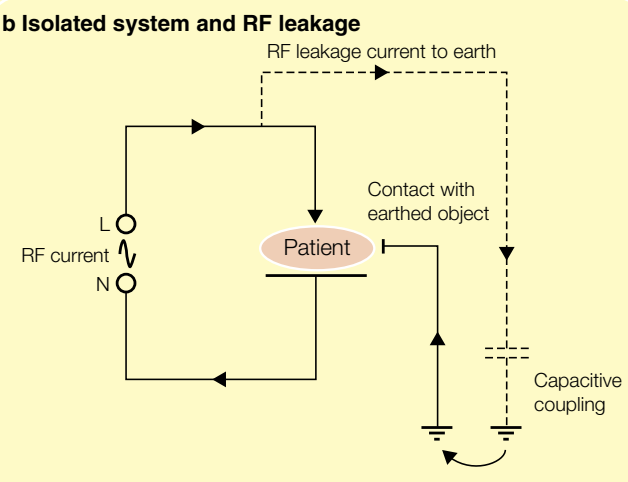
Early electrosurgical generators were not truly isolated. There was usually some connection of the neutral terminal and dispersive electrode cable to earth because of capacitive coupling between them, in a similar way to that described above. Figure 3c shows how this allows current to flow to earth through grounded contact points and complete the circuit to the neutral terminal via the 'virtual' earth connection. The amount of stray current passing through the grounded contact points depends on the relative impedance of the pathways. Given that one cannot avoid some current passing to ground, the best way to prevent this passing through unwanted pathways is to provide a route to ground via the dispersive electrode which is more 'attractive' than the alternative routes. This is done by physically earthing the dispersive plate and making the impedance of this connection as low as possible.

Isolated and earthed systems

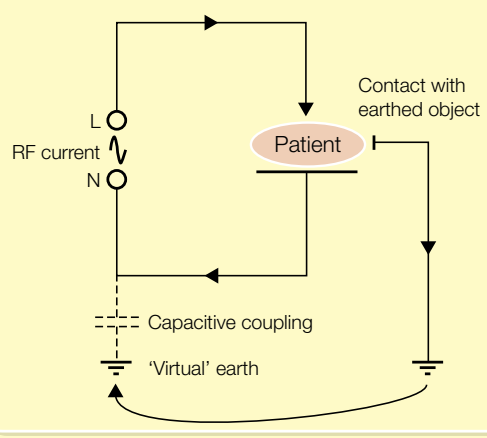
a Isolated system



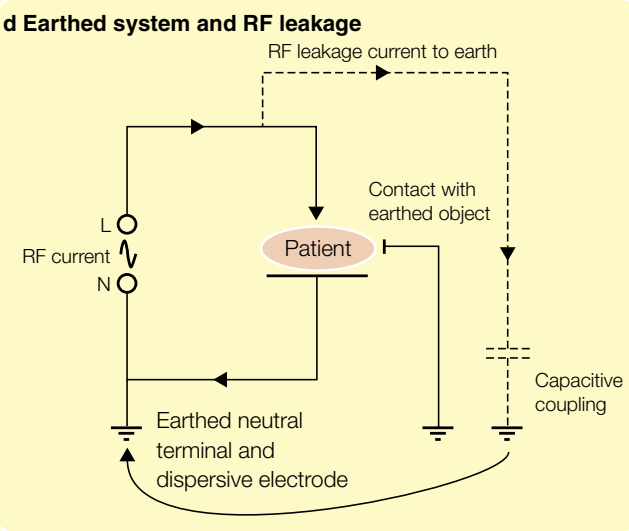
b Isolated system and RF leakage



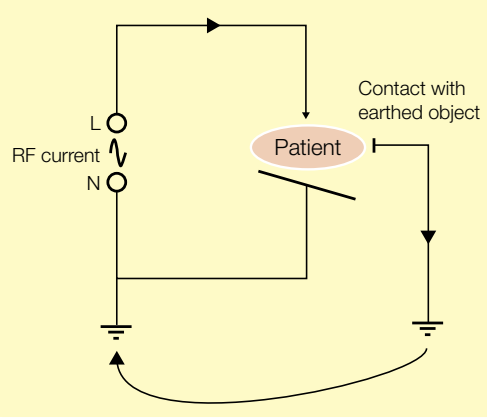
c Isolated system and 'virtual' earthing of dispersive electrode



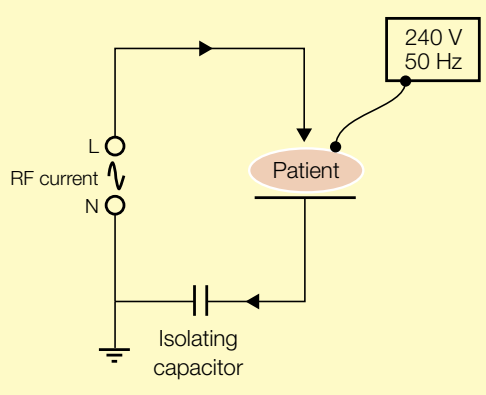
d Earthed system and RF leakage



e Earthed system and poor dispersive electrode contact



f Earthed system and isolating capacitor



L, live; N, neutral; RF, radiofrequency

Earthed dispersive electrode system
Earthing the dispersive electrode overcomes both the 'virtual' earth problem (Figure 3c) and the radiofrequency leakage problem (Figure 3b). Figure 3d shows how if the dispersive electrode and neutral terminal are earthed, any radiofrequency leakage current can return to the neutral terminal via a direct low impedance earth route that bypasses the patient. However, earthing poses other problems.

Dispersive electrode detachment: the dispersive electrode is an attractive route for ground-seeking radiofrequency current only if its impedance is many orders of magnitude lower than unwanted stray routes. If the dispersive electrode becomes detached or makes poor contact, all of the radiofrequency current can pass to earth (and hence return to the neutral terminal) via unwanted grounded contact point, as shown in Figure 3e, thus causing burns.

Mains electrocution: if the patient is exposed to a live mains voltage (e.g. via a faulty monitor lead) the earthed dispersive electrode provides a low impedance pathway for this dangerous 50 Hz current to pass through the patient to earth, thus causing electrocution. This is because mains voltage is ground seeking. This problem can be overcome by placing a capacitor in the circuit as in Figure 3f. This is capable of passing radio-frequency current, but does not conduct low frequency (50 Hz) current. Even though the patient is exposed to a live mains cable, no 50 Hz current will flow through the patient to the ground.

Techniques of Cricoid Pressure

Richard Vanner

Richard Vanner is Consultant Anaesthetist and Clinical Director in a large District General Hospital in the UK. He is a generalist with a specific interest in obstetric anaesthesia.

In 1956, the Association of Anaesthetists had collected 1000 reports of anaesthetic deaths; 110 from pulmonary aspiration of stomach contents. This often occurred during induction of general anaesthesia especially when muscle-relaxant drugs were used. Anaesthetic techniques were developed to prevent aspiration in patients at risk and included:

- emptying the stomach before induction
- intravenous induction with head-up tilt position
- inhalational induction in the lateral and head-down position.

In 1961, Sellick described cricoid pressure as a technique used to prevent regurgitation of stomach contents during the induction of general anaesthesia. It was brought into widespread practice in the UK by 1970 and largely replaced the other techniques, despite no randomized controlled trials demonstrating its benefit. It has become a routine part of anaesthetic practice for patients at risk of aspiration in combination with pre-oxygenation, an intravenous induction and tracheal intubation. All UK maternity units routinely apply cricoid pressure during induction of general anaesthesia.

Before the introduction of cricoid pressure, the incidence of aspiration pneumonitis in obstetric general anaesthetics was about 0.15%. If cricoid pressure prevents aspiration, the number needed to treat to prevent one case of aspiration would be 666. A controlled trial would be difficult because of the large numbers of patients needed and the difficulty of obtaining ethical approval.

Indications

In a patient who has been prepared for elective surgery and has not eaten for 6 hours or drunk for 2 hours, regurgitation of stomach contents during the induction of anaesthesia is unusual even when muscle-relaxant drugs are used, which relax the upper oesophageal sphincter. In these patients, cricoid pressure is unnecessary, because its benefits have to outweigh the risk of complications. However, cricoid pressure is indicated if:

- surgery is necessary before the patient is fasted
- gastric emptying is delayed
- the lower oesophageal sphincter is incompetent (e.g. in the last half of pregnancy or in reflux oesophagitis). With a full stomach from any cause, distention of the fundus causes reflex relaxation of the lower oesophageal sphincter.

Mechanism of action

Regurgitation is the flow of fluid from the oesophagus into the pharynx and is a passive process. When patients are awake the upper oesophageal sphincter prevents regurgitation. The pressure that this sphincter exerts is about 40 mm Hg and it relaxes during swallowing and during sudden distension of the oesophagus (e.g. belching, vomiting). The sphincter is mainly the cricopharyngeus muscle, a skeletal muscle, which is attached to the lateral aspects of the cricoid cartilage and is positioned behind it like a sling. The lumen of the hypopharynx within the cricopharyngeus is therefore crescent shaped. The oesophagus begins below the level of the cricoid cartilage.

The upper oesophageal sphincter relaxes during intravenous induction with thiopental (thiopentone), with heavy sedation, during deep sleep or following muscle-relaxant drugs. In all of these situations the sphincter pressure is reduced to less than 10 mm Hg, which is low enough to allow regurgitation. Following thiopental (thiopentone) the sphincter starts to relax just before loss of consciousness but is not fully relaxed until 30 seconds later. Ketamine does not relax the upper oesophageal sphincter, nor does an inhalational induction. Coughing during an inhalational induction increases upper oesophageal sphincter pressure to over 100 mm Hg.

Cricoid pressure prevents regurgitation by replacing the function of the upper oesophageal sphincter by compressing the hypopharynx against the prevertebral fascia muscles and vertebrae behind. The convex cricoid is pressed against the convex body of either the 5th or 6th cervical vertebrae. Inevitably the cricoid cartilage is deviated slightly laterally (Figures 1 and 2). Part of the crescent-shaped lumen is compressed against the vertebral body and the rest of it is less well compressed against the longus colli muscle to one side. A nasogastric tube is squeezed laterally towards the less well compressed part of the lumen and makes the occlusion of the hypopharynx more complete and therefore cricoid pressure more efficient.

A study of women undergoing emergency caesarean section under general anaesthesia with muscle relaxation showed that gastric pressure is likely to be less than 25 mm Hg in 99%. Oesophageal pressure can rise to equal gastric pressure during gastro-oesophageal reflux as the lower oesophageal sphincter relaxes to create a common cavity. A study of ten cadavers showed that 20 Newtons (N) of force applied to the cricoid cartilage prevented the regurgitation of oesophageal fluid at a pressure of 25 mm Hg in all cases and 30 N prevented regurgitation at a pressure of 40 mm Hg in all cases. Therefore, 20 N of cricoid pressure is probably sufficient and 30 N is more than enough to prevent regurgitation into the pharynx. Anaesthetic assistants can be trained to apply the correct force by practising on weighing scales and by doing this they can apply a range of forces between 5 N above or below the target force. A reasonable recommendation is to apply 30 N (3 kg).

Correct technique

Although cricoid pressure is apparently a simple technique there is growing evidence that incorrect application can cause serious problems during induction of anaesthesia. The anaesthetic assistant should practise the correct forces on weighing scales. The anaesthetist should be confident that the anaesthetic assistant knows the anatomical landmarks of the cricoid cartilage. Although Sellick suggested that the patient's head should be extended, the author recommends that it should rest on a pillow because intubation is easier and cricoid pressure is just as effective in this position. After pre-oxygenation, but before intravenous induction, lightly applied cricoid pressure should be started with a force of 10 N (1 kg), after loss of consciousness the force is increased to 30 N (3 kg). Forces of 20 N or more are not tolerated by awake patients and may cause them to retch and vomit. Normally the assistant applies cricoid pressure with their dominant hand because this can be maintained more accurately and for longer (3–5 minutes). There is no evidence that a bimanual technique, with the assistant's other hand supporting the patient's neck, improves the view at laryngoscopy when the correct forces are applied. The assistant's other hand is best kept free to assist with a difficult intubation if necessary.

Patients with small bowel obstruction should have a nasogastric tube inserted preoperatively. This should be aspirated before induction and left in place during induction. This does not make cricoid pressure less efficient and may improve it. As the tube is not compressed, it is possible, by leaving it open to atmospheric pressure, to vent liquid and gas remaining in the stomach, minimizing any increase in gastric pressure.

Sellick described the application of cricoid pressure with three fingers, thumb and middle finger on each side of the cartilage with the pressure applied with the forefinger. However, with the head on a pillow it is more comfortable to apply it with two fingers, forefinger and thumb on each side of the cartilage. This gives flexibility to apply upward and backward cricoid pressure, which improves the view at laryngoscopy if this becomes necessary. As the cricoid inevitably moves slightly laterally during cricoid pressure, it is better to ensure that it moves to the patient's right rather than to the left because this also makes intubation easier with a Macintosh laryngoscope.

Complications

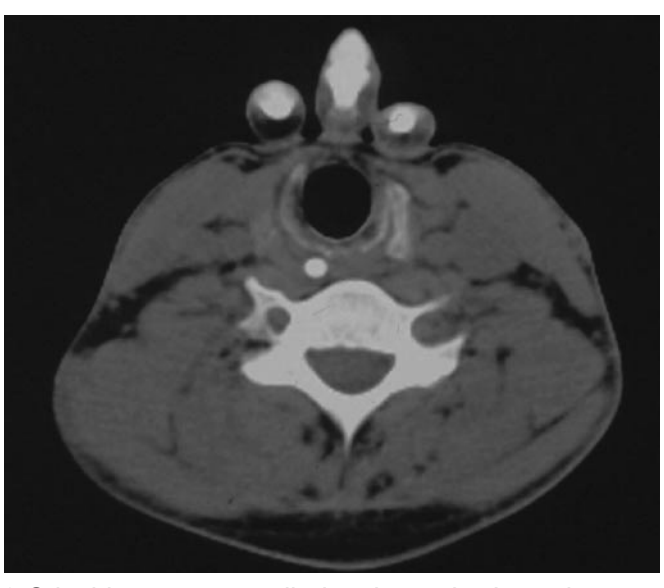
Excess force applied to the awake patient has caused retching and death from aspiration and ruptured oesophagus.

Difficult intubation can be caused by cricoid pressure if the force is applied to the thyroid cartilage or if the larynx is pushed laterally to the left or if too much force is used, which compresses the airway. When cricoid pressure is applied properly with a force of 30 N (3 kg) the view at laryngoscopy is improved compared with the situation when no cricoid pressure is used. However, if only the epiglottis can be seen, then the slight lateral displacement of the larynx, which is inevitable, will make the passage of a gum elastic bougie more difficult because this is normally passed in the midline.

The so-called 'cricoid yoke', a force transducer applied to the neck, is not ideal, because it may not be applied accurately to the cricoid cartilage and may cause tracheal compression or extreme lateral displacement of the larynx, resulting in difficulty with tracheal intubation.

Difficult ventilation – cricoid pressure can obstruct the airway and prevent ventilation of the lungs with a face mask and Guedel airway. This is proportional to the force applied; 30 N causes complete obstruction in 2% of patients and 40 N does in 35%. Upward and backward cricoid pressure at a force of 30 N causes airway obstruction in 56% possibly because it tilts the cricoid cartilage and opposes the vocal cords. Following a failed intubation in a patient with a full stomach when the lungs cannot be ventilated, the force of cricoid pressure should be reduced by half. If this does not allow ventilation, cricoid pressure should be released completely to allow ventilation, with laryngoscope and suction immediately available. Further airways that may then be necessary (e.g. laryngeal mask, *Combitube*, cricothyrotomy cannula) are all better placed without cricoid pressure applied.

1 Axial CT scan of the author's neck at the level of the cricoid cartilage showing a nasogastric tube filled with radio-opaque contrast media.



2 Cricoid pressure applied to the author's neck showing the slight lateral displacement of the cricoid and the lateral position of the nasogastric tube.

Tracheal Intubation: Management of Difficult and Failed Intubation

Stuart W Benham

Stuart W Benham is Consultant in Anaesthetics and Intensive Care Medicine at the John Radcliffe Hospital, Oxford, UK. He qualified from Glasgow University and trained in anaesthetics and general medicine in the west of Scotland before finishing his training in intensive care in Oxford. His research interests include acute renal failure on the ICU and difficult airway training and research.

Securing the airway with a tracheal tube is a core skill for anaesthetists. The technique may be required during anaesthesia, resuscitation or intensive care. The ability to manage patients when laryngoscopy is predicted to be difficult, or when intubation has previously failed, requires a methodical approach and a workable back-up plan. Indications for tracheal intubation are given in Figure 1.

Patients with depressed conscious levels (e.g. following head injury, self-poisoning, vascular accident, infections) need careful assessment. If there is any concern that airway reflexes are diminished, the airway must be secured with a tracheal tube. A low Glasgow Coma Score (e.g. GCS < 9) should not be relied on as the sole indication of airway compromise.

Intermittent positive-pressure ventilation can be achieved by non-invasive means without tracheal intubation. In the operating theatre this is often performed with the laryngeal mask airway (LMA), and in the ICU with a secure fitting face mask with head strapping.

Indications for tracheal intubation

Surgical indications
- Shared airway surgery
- Requirement for one lung ventilation
- Prone or sitting position for surgery
- Open abdominal or thoracic surgical procedures
- Major head and neck surgery
- Prolonged surgery

Emergency indications
- Prevention of aspiration in unfasted patients requiring general anaesthesia
- Impending airway obstruction (e.g. epiglottitis, airway burns)
- Maxillofacial trauma (blood in the airway)
- Depressed conscious level with poor airway reflexes

Ventilatory failure indications
- For intermittent positive-pressure ventilation
- Prevent aspiration of gastric contents
- Advanced ventilation strategies (e.g. partial liquid ventilation, high frequency jet ventilation)
- Prone ventilation strategies
- Ventilatory failure unresponsive to non-invasive positive- pressure ventilation

1

Management of difficult airway and failed intubation

The maintenance of alveolar ventilation is the most important aspect of difficult airway management. Patients in whom intubation is difficult or has failed, and in whom mask ventilation is also difficult are uncommon (about 1:10,000 routine anaesthetics). The anaesthetic plan must not render an awake patient who can maintain a patent airway into an unconscious patient with an unsafe and obstructed one. Preoperative assessment aims to identify patients in whom laryngoscopy and/or airway maintenance are likely to be difficult when consciousness is lost. Patients generally fall into one of three categories:
- anticipated difficult laryngoscopy
- elective unanticipated difficult laryngoscopy
- emergency unanticipated difficult laryngoscopy or failed intubation.

Anticipated difficult laryngoscopy
A comprehensive plan is required involving a primary plan and a secondary plan to be used if the primary plan fails. Two common pitfalls are:
- the operator is inexperienced in the technique chosen (e.g. flexible fibre-optic laryngoscopy – FFL)
- the back-up plan involves staff, skills and equipment that are not readily available at the time of induction (e.g. tracheostomy).

Anaesthetists have to develop plans with their own skill levels in mind, incorporating available equipment and supporting staff. Patient safety is of paramount importance. Generally, less invasive, atraumatic techniques should be preferred to surgical airway control, especially in elective patients. However, the emergency anticipated difficult airway (e.g. patients with severe maxillofacial trauma, or enlarging wound haematoma and stridor following head and neck surgery) may require a surgical airway as the primary plan.

Patients with bony abnormalities may have restricted mouth opening due to temporo-mandibular joint disease, or a cervical spine with limited neck flexion or extension (Figure 2). There is an expectation that the oropharynx and periglottic regions will be normal. In these patients, direct laryngoscopy may be impossible, but the normal oropharyngeal anatomy allows the passage of an FFL under general anaesthesia and assisted ventilation should be possible. If the primary plan fails during this elective surgery, the patient may be woken before implementing the secondary plan.

2 Restricted neck extension in ankylosing spondylitis.

Patients with obstruction in the supraglottic region include those with previous major oral surgery or radiotherapy. If there is evidence of stridor, the patient should be treated with extreme caution and one of the plans outlined below for periglottic or infraglottic obstruction should be considered. Stridor implies 50% airway narrowing. These patients may develop complete airway obstruction when anaesthetized and a surgical airway should be included in the management plan. Depending on the anaesthetist's skill, two options for the non-stridulous patient are:
- an awake fibre-optic endoscopy and intubation, before any relaxant or induction agent is given
- an inhalational induction and direct laryngoscopy to define the anatomical situation, and the feasibility of passing a tracheal tube.

Patients with obstruction in the periglottic region (including obstructing laryngeal tumours) require a thorough preoperative evaluation (e.g. CT, MRI) to assess the degree of obstruction and clinical assessment of the degree of stridor. Indirect laryngoscopy and flexible fibre-optic nasendoscopy are necessary to determine the extent of the obstruction and the feasibility of passing a tracheal tube, which should be performed by an experienced ENT surgeon. Non-stridulous lesions can be managed similarly to lesions causing supraglottic obstruction. Stridulous lesions are the most difficult to manage because neither awake fibre-optic endoscopy nor inhalational induction guarantees success. The choice of technique depends on the degree of stridor, the general condition of the patient and the experience of the anaesthetist. Severe cases may best be managed by awake tracheostomy under local anaesthesia. Depending on the level of the lesion, particularly with infraglottic obstruction, even emergency tracheostomy may not be realistic. For the most severe lesions it may be necessary to consider extracorporeal oxygenation as part of the secondary plan.

Elective unanticipated difficult laryngoscopy
Elective unanticipated difficult laryngoscopy is best managed using a stepwise approach.
- Reconfirm that assisted bag and mask ventilation is possible.
- Consider repositioning the head and neck and the use of a bougie.
- Avoid prolonged attempts at direct laryngoscopy. Change the length of laryngoscope blade once and the type of blade once to achieve the optimum view.
- Call for help and for the FFL if competent in its use.
- Consider the use of the LMA or the intubating LMA (ILMA) for ventilation.
- Consider using the LMA/ILMA as a conduit for intubation (see below).
- Consider abandoning anaesthesia, and performing an awake intubation.

Emergency unanticipated difficult laryngoscopy and failed intubation
This is a failure to secure the airway with a tracheal tube following a rapid sequence induction. Remember that it is failure of oxygenation, rather than a failure of intubation, that accounts for morbidity and mortality. The same stepwise approach as that for the elective unanticipated difficult laryngoscopy should be followed. All departments of anaesthesia should have a failed intubation drill for these circumstances, and clinicians should be familiar with their local protocols (see *Anaesthesia and Intensive Care Medicine* **2:6:** 221). It should be noted that in these situations the removal of cricoid pressure may help ventilation attempts, especially through the LMA. The risks of aspiration are small in comparison to the potential for morbidity and mortality caused by hypoxia from failed ventilation.

Techniques to overcome difficult intubation

Many devices have been developed to improve the chances of securing the airway with a tracheal tube. Some of those used by practising clinicians are described below.

Position and simple manoeuvres
Optimizing the patient's position (flexion of the cervical spine and head extension at the atlanto-occipital joint – the 'sniffing the morning air' position) is the first step to improve the view at direct laryngoscopy. Simple manoeuvres such as external laryngeal manipulation, especially backwards, upwards and rightwards pressure on the larynx can improve the view by more closely aligning the visual axis with the laryngeal inlet.

Laryngoscopes
There is a range of curved and straight blades, as well as blades with movable hinged tips (McCoy), that may improve the view at direct laryngoscopy (see *Anaesthesia and Intensive Care Medicine* **1:1** 34). Many experienced anaesthetists, however, tend to use the same type of laryngoscope blade for all their patients. Skills in the use of different blades are best acquired during routine intubations. The McCoy, or the angled Belscope laryngoscope, may be able to convert a Cormack/Lehane grade 3 view to a grade 2 view, though familiarization with the technique is required.

Simple props and aids
Gum elastic bougies should be used when:
- direct laryngoscopy allows visualization of the epiglottis but not the larynx (a grade 3 view)
- visualization of the larynx is possible but direct passage of the tracheal tube is prevented by awkward oral anatomy or teeth
- a reinforced or flexible tracheal tube cannot be directed into the visualized larynx.

Aintree intubation catheter (Cook©) (Figure 3) can be used like a gum elastic bougie, or in combination with other airway and intubating devices such as the LMA or FFL. It is sufficiently long and thin to allow a tracheal tube to be railroaded over it. It is hollow and has a detachable tube connector/adaptor that allows ventilation during the intubation process. An FFL can also be passed through it if required.

a Flexible fibre-optic laryngoscope and Aintree intubation catheter passed through the laryngeal mask airway (LMA).
b Fibre-optic endoscopy through the LMA with the Aintree exchange catheter.

3

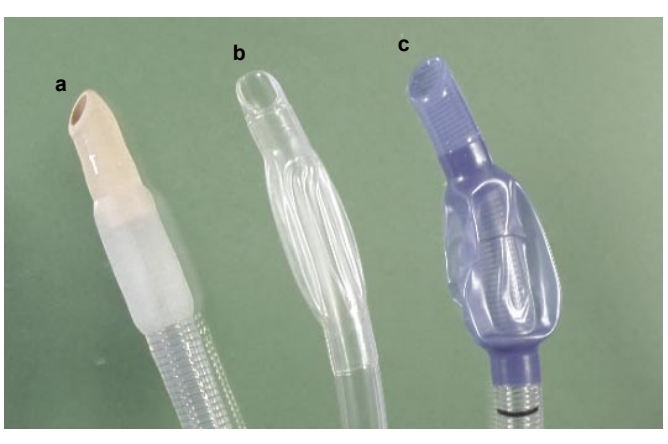
LMA and ILMA
Most anaesthetists use the LMA regularly for patients not requiring intubation. The ability to insert an LMA to allow spontaneous or assisted ventilation is a core skill for anaesthetists. It also provides a route guide for intubation, either blind or guided by an FFL. The LMA may help to achieve ventilation in patients who are otherwise difficult to intubate and ventilate.

The ILMA is modified to improve the chances of passing a tube blindly through the mask into the trachea. There is an initial short learning curve for the operator, and the clinician should practise using the ILMA in patients with normal airways before it is used in those with difficult or abnormal ones.

The main limitation on both devices is that there has to be enough mouth opening to permit inserting the device. Intubation can be blind, but both devices can be used with an FFL to visualize laryngeal anatomy and aid intubation.

Railroading the tracheal tube
The need to railroad the tracheal tube over the guide is the final step in intubation. Two manoeuvres to increase its success rate and minimize laryngeal trauma are choice of tracheal tube and bevel direction.

- The ILMA tube (softer tip) or reinforced tracheal tube (less acute bevel and softer tip) has a higher chance of passing through the vocal cords (Figure 4).
- The bevel of the standard tracheal tube is directed to lie in the right or left lateral position as it reaches the vocal cords. It is then rotated 90° as it is pushed gently through the cords. If this is unsuccessful, the tube is rotated through 360° continuously with gentle pressure to slip through the cords. If still unsuccessful, direct laryngoscopy can be performed to check the position of the route guide, and to lift the epiglottis to facilitate tube railroading.



4 Tracheal tube tips. **a** The intubating laryngeal mask airway tube, **b** standard tube, and **c** the flexometallic tube

FFL and intubation
FFL and intubation can be performed with the patient awake or anaesthetized. Awake fibre-optic intubation performed by a competent endoscopist is safe (Figure 5). The patient remains awake and self-ventilating with maintained pharyngeal muscle tone.

5 Awake fibre-optic intubation. Note the use of propofol sedation and jaw thrust.

Suggested procedure for awake fibre-optic intubation
1 Premedication of morphine, 0.1–0.15 mg/kg i.m., and hyoscine (scopolamine), 200 µg i.m., 1 hour before procedure.
2 The patient should lie semi-reclined on a trolley in the anaesthetic room, facing the anaesthetist.
3 Intravenous sedation should be administered cautiously. Target-controlled infusion with propofol (plasma concentration 0.5–1.5 µg/ml) is well tolerated.
4 Topical anaesthesia of the upper airway should be provided:

- Nasal mucosa; mixture of 5% cocaine, 2 ml, and 8.4% bicarbonate, 2 ml, as topical spray, with the patient taking deep breaths in with each spray. If the patient requires orotracheal intubation the oropharynx can be anaesthetized with lidocaine (lignocaine) spray or gel. Oropharyngeal route guides (e.g. *Ovassapian* or *Berman* airway) can be used to aid orotracheal intubation. These allow the operator to pass the FFL and tracheal tube through them. They prevent soft tissue collapse and are sized to guide the FFL through the mouth, and emerge at the epiglottis, where it can be directed into the larynx.
- Spray as you go (SAYGO) with 4% lidocaine (lignocaine) through the working channel of the FFL. Insertion of an epidural catheter through the working channel to the tip of the scope, with the catheter end trimmed to produce one end-hole, can facilitate accurate delivery of the local anaesthetic injection. Inject 1 ml solution with 4–5 ml air to help disperse the anaesthetic. Before the first attempt to pass the FFL, and before each subsequent attempt, oropharyngeal suctioning with a Yankaur sucker may be required.
- Administer supplemental oxygen. This can be delivered conveniently via a flexible suction catheter passed into the opposite nostril.

5 Allow adequate time (at least 30 seconds) after topicalization before the FFL is advanced. Avoid passing the FFL blindly. If the view ahead becomes obscured, gently withdraw the insertion cord until airway anatomy is again identified. Ask the patient to take deep breaths when advancing towards the laryngeal inlet. This opens the airway and abducts the vocal cords. If visualization of the larynx is difficult, performing a gentle jaw thrust manoeuvre on the patient can help.
6 Once the scope has been advanced through the cords it should be advanced to just proximal to the carina. A common error is to allow the FFL to withdraw, or even become displaced from the trachea while the tube is railroaded into place. This happens more often if the patient coughs at this time. The operator should attempt to keep the FFL in the centre of the airspace at all times. This minimizes trauma to the delicate tracheal mucosa and reduces the amount of blood in the airway.
7 Railroading the tracheal tube is described above. It is helpful for the assistant to hold the FFL stationary allowing the operator to railroad the tube into place using both hands.
8 A final useful check to estimate the distance from the end of the tracheal tube to carina can be performed as follows. Once intubation has been performed, the FFL is passed down just proximal to the carina. The assistant lightly pinches the FFL as it enters the proximal end of the tracheal tube. The FFL is then withdrawn slowly until the distal end of the tracheal tube comes into view. As soon as this is seen, the distance from the assistant's fingers to the tube connector of the tracheal tube is noted. This is the distance from tip of tube to carina.
9 The breathing system with capnograph is connected. The patient may then be anaesthetized and laid flat. Satisfactory ventilation is confirmed, and muscle relaxant can be given if required.

Problems with flexible fibre-optic intubation: the FFL is an intubating tool, not a ventilation device. Oxygenation and ventilation must be maintained throughout the intubation procedure.

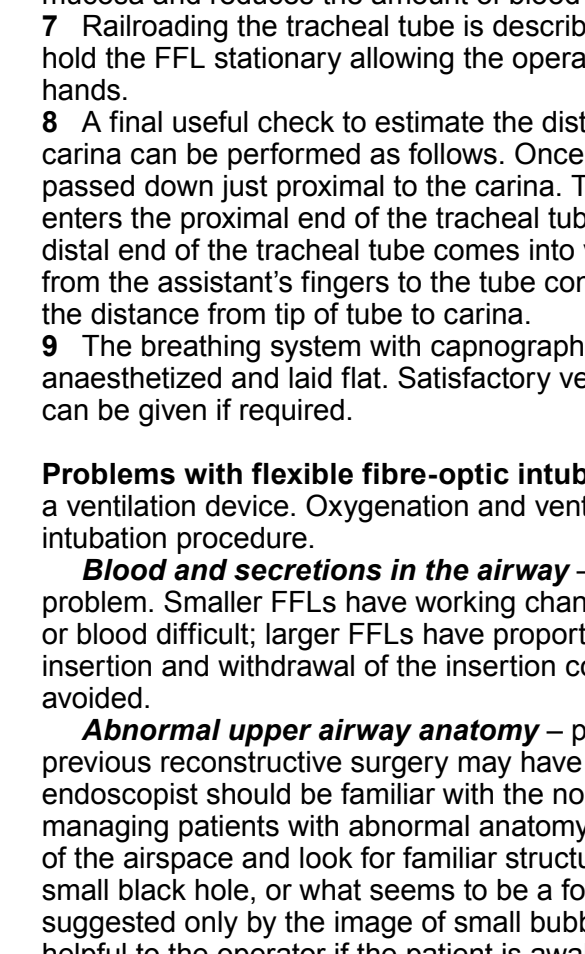
Blood and secretions in the airway – a poor view is the endoscopist's main problem. Smaller FFLs have working channels that make suctioning of sticky secretions or blood difficult; larger FFLs have proportionally larger suction channels. Repeated insertion and withdrawal of the insertion cord may precipitate bleeding and should be avoided.

Abnormal upper airway anatomy – patients with oro-pharyngeal lesions or previous reconstructive surgery may have abnormal upper airway anatomy. The endoscopist should be familiar with the normal appearances through the FFL before managing patients with abnormal anatomy. In all patients, keep the FFL in the centre of the airspace and look for familiar structures. Often the larynx is identified only as a small black hole, or what seems to be a fold in the mucosa. Identification is sometimes suggested only by the image of small bubbles appearing from a dark crevice. It is helpful to the operator if the patient is awake, semi-recumbent, and cooperating by taking deep breaths.

Equipment problems – the FFL should be checked and cleaned before use.

- The tracheal tube should be loaded on the FFL before endoscopy; forgetting to do this is a common mistake.
- Ensure that the light is on and working with white balance and focus optimal before commencing endoscopy.
- Lubricating jelly should be applied to the outside of the scope, and the tracheal tube, to facilitate easy nasal passage and tracheal intubation.
- Difficulties in railroading the tracheal tube can sometimes result from a large difference in the external diameter of the scope and internal diameter of the tracheal tube. This may be overcome by use of the Aintree intubation catheter. The intubation catheter can be railroaded over the scope, and then the tracheal tube railroaded over this.

Lack of hand–eye coordination can be remedied by practice on simulators, manikins and learning models such as an artificial bronchial tree or the Oxford 'hit-the-hole' box (Figure 6). It is indefensible to acquire these basic skills at the expense of the patient's mucosa.



6 The Oxford 'hit-the-hole' training box.

An inability to recognize anatomy is easily addressed by experience gained from instructional videos, clinical teaching and supervision. The case for using an FFL to aid routine nasal intubation is robust. In addition to the excellent learning opportunity afforded by routine use of the FFL, it assists in the selection of the best nostril and largest airspace, and identifies vulnerable nasal pathology such as polyps.

Transtracheal access

The final route for rescuing an obstructed airway is direct transtracheal access. This can be through the cricothyroid membrane, or through the upper trachea. Most anaesthetists never need to resort to this. Elective procedures, such as cricothyroid puncture used to inject local anaesthetic, or performing percutaneous tracheostomies in the ICU, provide valuable experience in tracheal access. The ability to identify the cricothyroid membrane and to insert a cricothyroid airway catheter rapidly may be a life-saving procedure. See Anaesthesia and Intensive Care Medicine issue 2:7: 268 for discussion of emergency tracheal access.

Assessment of Gastrointestinal Problems

David James

David James is Consultant Anaesthetist at Guy's and St Thomas' Hospital Trust, London. He graduated from St Bartholomew's Hospital, and trained in anaesthesia in London. His interests are perioperative medicine and training.

Anaesthetists encounter patients with gastrointestinal problems in two contexts.

- As critical care physicians caring for patients with gastro-intestinal problems that occur as a cause of and a consequence of critical illness.
- As perioperative physicians caring for patients undergoing elective and emergency gastrointestinal surgery. The importance of this role was emphasized by the CEPOD and NCEPOD reports, and is considered in this article.

Primary problems

Bleeding into a viscus may arise from the upper gastrointestinal tract. Bleeding from duodenal ulcers, gastric erosions, gastric ulcers and oesophagitis accounts for almost 75% of cases; other causes such as gastritis and oesophageal varices are less common. Patients commonly present with haematemesis, melaena, with or without pain, and varying degrees of shock. Physical examination aims to assess the degree of shock and primary cause of the bleeding, which may be elucidated only by upper gastrointestinal endoscopy or mesenteric angiography. Lower gastrointestinal haemorrhage, most commonly encountered in the elderly, is often a result of colorectal carcinoma, colonic polyps, ischaemic colitis, inflammatory bowel disease or diverticular disease. The clinical presentation varies with the cause, often with few symptoms.

Perforation of a viscus is characterized by sudden onset of acute abdominal pain and peritonitis, with the patient lying still with a rigid abdomen and absent bowel sounds. Common causes include perforations of peptic ulcer, appendix or diverticulum. Malignant and inflammatory bowel diseases may also present in this way. An erect plain chest radiograph looking for free gas under the diaphragm may confirm the diagnosis.

Obstruction of a viscus is suggested by colicky abdominal pain, vomiting, constipation and abdominal distension. Common causes include intra-abdominal adhesions, hernias, inflammatory bowel disease and malignancies. Plain and contrast-enhanced abdominal radiographs aid diagnosis.

Infarction of a viscus may be secondary to torsion or strangulation of a viscus, thromboembolic occlusion of its arterial inflow or venous outflow or vasculitis. Pain and peritonitis are common clinical features.

Inflammation of a viscus – the history, onset of pain and site of maximal tenderness help to determine the origin of the inflamed viscus. Common conditions include appendicitis and diverticulitis. Crohn's disease and Meckel's diverticulitis are less common causes. Other intra-abdominal structures can present in a similar way (e.g. salpingitis, cholecystitis, adenitis, pancreatitis, cystitis, pyelonephritis).

Gastrointestinal emergencies may be complicated by hypovolaemic shock or endotoxaemia/bacteraemia, culminating in the development of a systemic inflammatory response syndrome and multi-organ dysfunction.

The urgency of the surgery is usually defined by the degree of acute systemic disturbance. Surgery and anaesthesia for gastro-intestinal problems carry a high risk of complications, principally affecting the respiratory, cardiovascular and renal systems. The mortality rate for elective intra-abdominal procedures is up to 5%. Patients having upper abdominal procedures have a higher risk of complications and are twice as likely to die postoperatively as those having lower abdominal procedures. Factors increasing the risk of an adverse postoperative outcome include the site of surgery, its urgency and patient co-morbidities such as cardiac failure, physical status, those rated as ASA III or IV, and age over 50 years. This emphasizes the need for careful preoperative patient assessment, so that informed decisions can be made about the appropriateness of surgery and what measures can be taken to achieve the best outcome for the patient.

Secondary problems

Water and electrolyte depletion: the magnitude of any water and electrolyte deficit reflects the duration of the primary problem and the site of the fluid loss. Gastrointestinal fluid and electrolyte losses (Figure 1) may lead to severe hypovolaemia and acid–base and electrolyte imbalances. Clinical estimation of the volume of fluid lost is difficult and often underestimated.

Daily volume and electrolyte content of gastrointestinal secretions

Secretion	Volume (litres)	Na^+ (mmol/litre)	K^+ (mmol/litre)	Cl^- (mmol/litre)	HCO_3^- (mmol/litre)
Saliva	1.5	15	30	10	30
Gastric	2.0	50	15	120	0
Small bowel	3.0	140	10	100	30
Bile	0.6	140	5	100	35
Pancreatic	0.7	140	5	70	100
Total	7.8	725	112	764	226

1

Water – extracellular volume deficit is a common problem before any gastrointestinal surgery. It is caused by preoperative water deprivation, extracorporeal water losses (e.g. vomiting, diarrhoea, fistulae, nasogastric suction), sequestration of water into bowel lumen, bowel wall and peritoneum and preoperative bowel purgation. The clinical features are outlined in Figure 2 and depend on the severity of the water deficit and factors affecting cardiovascular reflexes (e.g. age).

Clinical features of water loss

Percentage body weight lost as water	Clinical signs
> 4%	• Thirst • Reduced skin turgor • Dry tongue • Reduced sweating
> 6%	• All above • Orthostatic hypotension • Reduced peripheral venous filling • Oliguria • Apathy • Low central venous pressure • Haemoconcentration • Raised serum urea out of proportion to raised serum creatinine (pre-renal pattern) • Low urinary sodium concentration (0–15 mmol/litre) • High urinary osmolality (800–1400 mosmol/kg)
> 8%	• All above • Hypotension • Thready pulse • Cool peripheries
> 10%	• Coma • Shock

2

Electrolytes and acid–base – significant loss of oral and pharyngeal secretions predominantly affects water balance, with minimal effects on serum electrolyte concentrations, whereas significant loss of gastric secretions can result in hypochloraemic alkalosis (caused by loss of hydrochloric acid) with hypovolaemia (caused by sodium and water loss) and hypokalaemia. In the early stages of this problem, the urine is alkaline in an attempt to maintain a normal pH. As the condition worsens, the kidneys attempt to preserve sodium ions, therefore hydrogen and potassium ions are preferentially excreted, producing a paradoxically acid urine, thereby exacerbating the alkalosis and the hypokalaemia. Hypocalcaemia can also occur as a consequence of calcium lost in the vomitus and a reduction of the serum concentration of ionized calcium owing to alkalosis (increased protein binding). Loss of lower gastrointestinal secretions from massive diarrhoea, duodenal, jejunal and pancreatic fistulae is more commonly associated with hypovolaemia and metabolic hyperchloraemic (normal anion gap) acidosis, due to the loss of bicarbonate. Hypomagnesaemia has been associated with loss of upper and lower gastrointestinal secretions and malnutrition.

Abnormalities of serum phosphate can also be associated with gastrointestinal disease. Hypophosphataemia may occur secondary to dietary deficiency and systemic alkalosis.

Haemorrhage: bleeding into the gastrointestinal tract sufficient to cause intravascular volume depletion is a common cause of emergency hospital admission (Figure 3). It is seldom possible to estimate the magnitude of gastrointestinal blood losses from the patient's history or by measuring overt blood losses. A better estimation is gained from clinical assessment of the patient's intravascular volume, bearing in mind that age and co-morbidities significantly affect the clinical cardiovascular signs of hypovolaemia.

Clinical signs of hypovolaemia

Grade of hypovolaemia	Clinical signs[1]
1 10% IVBV lost	• HR normal • SAP normal • Urine output normal • Peripheral circulation 1 ml/kg/hour • Normal sensorium
2 20% IVBV lost	• HR 100–120 • SAP orthostatic hypotension • Urine output < 1 ml/kg/hour • Peripheral circulation cool and pale • Normal sensorium
3 30% IVBV lost	• HR 120–140 • SAP systolic pressure < 100 • Urine output < 1 ml/kg/hour • Peripheral circulation cold, pale with slow capillary refill • Restless
4 > 40% IVBV lost	• HR > 140 • SAP systolic pressure < 80 • Urine output nil • Peripheral circulation cold and clammy with peripheral cyanosis • Impaired consciousness

[1] Typical signs in a young healthy adult with normal cardiovascular reflexes.
IVBV, intravascular blood volume; HR, heart rate (beats/minute); SAP, systemic arterial pressure (mm Hg)

3

Pulmonary problems: respiratory dysfunction commonly arises from factors such as diaphragmatic compression by an intra-abdominal process that decreases functional residual capacity (FRC) and may lead to atelectasis. Pleural effusions, mediast-inal emphysema, pneumothorax, and acute respiratory distress syndrome also occur. Loss of muscle mass and weakness from malnutrition, accumulation of thick bronchial secretions in dehydrated patients, and high metabolic demands resulting from sepsis may cause functional and mechanical respiratory dysfunction. Such patients often breathe shallowly, at higher than normal rates, and are often hypoxaemic. Chest radiographs help to exclude pneumonia in these patients.

Aspiration of gastric contents can cause pulmonary damage including fulminant aspiration pneumonitis. Fasting before anaesthesia reduces this risk (Figure 4). Some clinical situations are always associated with an increased risk of aspiration:

- reduced gastrointestinal motility secondary to metabolic causes (e.g. diabetes mellitus, renal failure), peritonitis, head injury, trauma, pain, drugs (e.g. opioids)
- gastrointestinal obstruction of pylorus or small bowel
- reduced lower oesophageal function secondary to raised intra-abdominal pressure (e.g. pregnancy, gastro-oesophageal reflux disease) and hiatus hernia.

The interval between the last oral intake and the injury is the fasting period. The American Society of Anesthesiologists (ASA) has recommended preoperative fasting times for healthy patients undergoing elective surgery (Figure 4).

Preoperative fasting times for healthy patients undergoing elective surgery

Ingested material	Minimum fast (hours)
Clear fluids	2
Breast milk	4
Formula milk	4–6
Non-human milk	6
Light meal	6

4

Sepsis is associated with the gastrointestinal tract; it divides broadly into primary and secondary types. Primary acute intestinal infections (e.g. gastroenteritis) can be confused with inflammatory bowel disease and are caused by a variety of pathogens. Secondary acute intestinal infections cause inflammation of a viscus and are usually associated with obstruction (e.g. appendicitis, diverticulitis) or another abnormality (e.g. trauma, adenitis, peritonitis). The causative bacteria are usually the commensals (e.g. *Escherichia coli*, enterococci, *Streptococcus milleri*, *Bacterioides fragilis*). Peritonitis is often secondary to another intra-abdominal process (e.g. perforation of a viscus). These infections are often polymicrobial, requiring broad-spectrum antibiotics until the causative organism is isolated.

Patients with severe sepsis secondary to an intra-abdominal cause usually present with abdominal symptoms (pain, vomiting, diarrhoea) and signs of peritonism (abdominal tenderness, rigidity, guarding) together with signs of a systemic response to the inflammatory process, the so-called ‘systemic inflammatory response syndrome’ characterized by fever, raised white cell count and insidious multiple organ dysfunction.

Nutritional deficiencies: malnutrition is commonly caused by failure to absorb multiple nutritional components (protein, fat, carbohydrate, vitamins, minerals). It often occurs in association with chronic disease states. In normal individuals, a 30–40% weight loss due to starvation may be fatal. During starvation, metabolic adaptation aims to conserve essential tissues. Once glycogen stores are exhausted as a source of glucose (in about 24 hours in normal individuals) protein and fat are broken down to provide energy. Protein is initially catabolized, with the resultant urinary loss of urea, sodium, potassium, magnesium and calcium, followed by fat as the chief source of energy once the metabolic pathways are established with reduction of protein catabolism. Once fat reserves are exhausted, protein catabolism begins. The physical result is a decrease in basal metabolic rate due to decreasing lean body mass, decreased physical activity and reduced thyroxine production. The co-existence of severe illness may compound the rate of decline and cause fatality sooner. Starvation and malnutrition are prevalent on surgical wards (notably following major abdominal surgery), in long-term hospitalized patients and cancer patients. They occur through poor appetite, impairment in digestion and absorption, and the increased metabolic demands of acute illness. Nutritional support in malnourished patients undergoing major surgery reduces their postoperative morbidity and mortality.

General assessment

Any clinician approaching a patient for the first time should rapidly assess the life-threatening conditions that, if left unrecognized and unmanaged, can be lethal. When problems associated with the airway, breathing and circulation are solved, a definitive diagnosis can be sought and a management plan instigated.

Airway problems are uncommon unless consciousness is obtunded. Immediate attempts to secure a patent, protected airway should ensue.

Breathing – if vomiting is a significant feature, the risk of pulmonary aspiration of gastric contents should be borne in mind; a nasogastric tube to drain fluid and gas from the stomach may reduce this risk. Clinical features of respiratory dysfunction (e.g. dyspnoea, tachypnoea, hypoxia) may occur for a variety of reasons, including diaphragmatic splinting secondary to pain with or without abdominal distension causing raised intra-abdominal pressure. Respiratory distress may be a sign of shock or sepsis. Kussmaul’s respiration (tachypnoea with deep inspiratory excursions) is associated with acidaemia from metabolic causes. Immediate steps should be taken to ensure adequate oxygenation and ventilation, with interventions ranging from providing supplemental oxygen to mechanical ventilation of the lungs.

Circulation – hypotension is the most common circulatory problem asssociated with gastrointestinal problems. Occult bleeding can occur in the gut lumen, peritoneal cavity or retroperitoneum. Patients with septic shock are classically vasodilated and warm, with hypotension and a fever, but many (particularly if presenting late) are peripherally vasoconstricted and have a normal or even low body temperature. Atrial fibrillation in the elderly patient with abdominal pain means that mesenteric artery embolism should be considered in the differential diagnosis. Two large-bore peripheral intravenous cannulae should be inserted and venous blood taken for a full blood count, biochemistry (including amylase) and blood cross-match, and a coagulation screen, blood cultures, pregnancy test and sickle screen if appropriate. Suspected hypovolaemia should be treated by fluid resuscitation, septic shock with fluid resuscitation and intravenous broad-spectrum antibiotics.

A portable ultrasound scan (if available) may confirm the cause of hypovolaemic shock (e.g. a leaking aortic aneurysm, free intraperitoneal fluid, an ectopic pregnancy).

Anaesthetic assessment

Items of interest in the history include the presence and nature of pain, other gastrointestinal symptoms (e.g. anorexia, dyspepsia, nausea, vomiting, haematemesis, melaena, diarrhoea, constipation), previous abdominal surgery and recent drug ingestion.

Physical examination should concentrate on the general appearance of the patient, in particular their posture, pigment-ation, pallor and pattern of respiration. The following should be specifically examined:

- cardiovascular system – particularly signs of intravascular and extracellular fluid volume deficits
- respiratory systems – particularly signs of respiratory distress or areas of lung collapse
- signs of sepsis.

This is followed by a review of all appropriate investigations to help estimate the magnitude of the secondary effects of the gastro-intestinal problem. Haematological, blood chemistry, arterial blood gases and imaging techniques should be ordered only if the result is likely to alter the management of the patient.

Preoperative management

When surgery is necessary and the secondary anaesthetic assessment is completed, preoperative management should begin.

Analgesia: early judicious analgesia is advocated for the patient with acute abdominal pain. If opioid analgesia is given as a dilute solution by slow intravenous injection, the dose can be titrated against the patient’s pain. Adequate analgesia reduces the patient’s suffering and may allow them to give a clearer history and be easier to examine.

Anti-emetic and nasogastric tube: the ASA recommend physical and pharmacological methods to reduce the risk of regurgitation and aspiration. They do not recommend routine use of these agents in healthy, elective patients. Physical methods involve nasogastric drainage of gastric contents. For most laparotomies a PVC/polyurethane 16 FG Ryles or Salem tube is adequate.

Pharmacological methods include antacids, which neutralize acid in the stomach, to reduce the risk of damage should aspiration occur. Particulate antacids are not recommended. Sodium citrate solution administered shortly before induction is the agent of choice in high-risk cases (e.g. pregnancy) but this results in an increase in gastric volume. Additionally, antihistamines (e.g. ranitidine and proton-pump inhibitors such as omeprazole) decrease acid secretion in the stomach and should be used for high-risk patients. Ideally, they should be administered on the evening before surgery (or early morning for an afternoon list) and a second dose given 2 hours preoperatively. Gastric prokinetic agents (e.g. metoclopramide) increase gastric emptying in healthy patients, but a clear benefit in trauma patients has not been demonstrated. Anticholinergic agents do not have a significant effect and are not routinely recommended.

Fluid and electrolyte replacement: signs of intravascular and extracellular volume depletion require immediate correction with intravenous fluids, and the response to fluid resuscitation should be monitored. Fluid and electrolyte deficits should be replaced with an appropriate crystalloid solution; haemorrhage with clear colloid until red cells are available for transfusion. Central venous pressure monitoring is often required to manage fluid replacement in the elderly or those with cardiac disease.

Preoperative ‘optimization’ of cardiovascular and respiratory function reduces mortality, morbidity and length of stay in the ICU and hospital. High-risk patients include those with severe cardiovascular and/or severe respiratory diseases; those having aortic surgery, major surgery for malignancy or surgery for abdominal sepsis; and those with haemodynamic instability due to an acute intra-abdominal catastrophe. It has been suggested that haemodynamic monitoring should start in the preoperative period, using a pulmonary artery catheter to assess fluid requirement and cardiac output. Patients in studies by Boyd and colleagues were given blood if anaemic and oxygen if hypoxaemic and subsequently colloid with or without an inotrope until a predetermined level of pulmonary capillary wedge pressure and oxygen delivery were achieved. Such an approach makes heavy demands on staff and resources. In emergencies, a balance has to be struck between the benefits of optimization before surgery and commencing surgery. If bleeding is the main problem, surgery may be part of the resuscitation process, and time should not be wasted preoperatively.

Antibiotics are needed for localized infection or if clinical sepsis is thought to have an intra-abdominal source (e.g. perforation of the colon in an elderly patient). Patients who are septicaemic should start treatment with a broad-spectrum intravenous antibiotic without waiting for the result of blood cultures. ◆

Clinical Aspects of Hepatic Problems

Elizabeth Sizer
Simon Cottam

Elizabeth Sizer is Specialist Registrar in Anaesthesia at King's College Hospital, London, currently working in the Liver Unit. Her interests include liver transplantation, liver intensive care and anaesthesia for hepatobiliary surgery.

Simon Cottam is Consultant Anaesthetist at King's College Hospital, London. His main interests include intensive care and hepatobiliary anaesthesia.

Advanced liver disease is a classic example of multisystem failure resulting from a single organ disease. Historically, even minor surgery on cirrhotic patients resulted in high mortality. Liver transplantation has dramatically improved the prognosis for these patients. It is important for clinicians to appreciate the multisystem sequelae of end-stage liver disease, to assess risk and manage patients appropriately. Recognition of severe disease is crucial; improved perioperative care has not significantly reduced operative mortality. These patients should be referred for transplant assessment or, if surgery for unrelated conditions is considered, should be managed in specialist centres.

Risk assessment
The Child–Pugh classification of liver disease (Figure 1) was originally described to assess operative risk in cirrhotic patients undergoing surgery for variceal bleeding. Its use has extended to predict outcome in cirrhotic patients for all types of surgery.

Pugh's modification of the Child classification of severity of liver disease

Clinical and biochemical measurements	Points scored for increasing abnormality		
	1	2	3
Encephalopathy	None	Grade 1–2	Grade 3–4
Ascites	None	Slight	Moderate
Bilirubin (μmol/litre)	< 35	35–60	> 60
Prothrombin (seconds prolonged)	1–4	4–10	> 10
Albumin (g/litre)	> 35	28–35	< 28

The points for the five variables are added to give a score ranging from 5 to 15. Patients with scores 5–6 are Grade A, 7–9 are Grade B and 10–15 are Grade C. Grade A represents 'good' risk with 5% mortality, Grade B represents 'moderate' risk with 10% mortality, Grade C represents poor risk with mortality > 50%

1

Others have studied the effects of systems failure on outcome in patients with severe liver disease (Figure 2). Optimizing treatable complications (e.g. ascites) may decrease mortality significantly. Causes of death in these patients are sepsis, renal failure, bleeding, hepatic failure and encephalopathy. Poor nutrition, portal hypertension with ascites and encephalopathy herald poor prognosis for any surgery in these patients. However, recent work suggests that cirrhotic patients with good function who are well compensated (i.e. Child–Pugh Grade A) are good candidates for certain types of surgery (e.g. liver resection for hepatocellular carcinoma or portosystemic shunt surgery).

Preoperative variable and mortality in cirrhotic patients

Variable	Mortality if present (%)
Pulmonary failure	100
Cardiac failure	92
Gastrointestinal bleeding	86
More than two antibiotics	82
Second operation required	81
Renal failure	73
More than 2 units of blood required	69
Hepatic decompensation	66
Positive blood/urine culture	61
Albumin < 30 g/litre	58
Ascites	58
Less than 2 units of blood required	22

2

Extrahepatic effects of end-stage liver disease

Cardiovascular system: in end-stage liver disease the systemic circulation is characterized by various pathological changes. Peripheral vasodilatation and shunting (cutaneous, intrapul-monary, portopulmonary and pleural) result in increased cardiac output. This can mimic the hyperdynamic picture of a septic state. Activation of the renin–aldosterone–angiotensin (RAA) system causes an increase in plasma and extracellular fluid volume, though effective circulating volume is reduced. Cirrhotic cardiomyopathy may be masked by the reduction in afterload, and is difficult to detect by non-invasive preoperative investigations. Pulmonary hypertension is also seen and is a rare cause (< 1%) of right ventricular failure. Cardiac arrhythmias also occur, associated with cardiomyopathy or electrolyte abnormalities such as hypomagnesaemia and hypokalaemia. The responsiveness to catecholamines is reduced.

Respiratory system: respiratory compromise may result from restrictive lung disease caused by ascites or pleural effusions, the hepatopulmonary syndrome, pulmonary hypertension, defects in alveolar oxygen diffusion or pulmonary manifestations of systemic disease (e.g. α_1-antitrypsin deficiency, autoimmune disease). Several factors dispose the cirrhotic patient towards hypoxaemia: a rightward shift in the oxygen-dissociation curve (due to decreased levels of 2,3-diphosphoglycerate (2,3-DPG)), intrapulmonary shunting due to capillary vasodilatation and restrictive defects due to large volume ascites and pleural effusions. These effects are compensated for by the raised mixed venous oxygen saturation consequent on poor oxygen extraction and the raised resting cardiac output. All patients with end-stage liver disease and a partial pressure of oxygen (pO_2) less than 9 kPa should be considered hypoxic. In patients with the hepato-pulmonary syndrome (chronic liver disease, increased alveolar–arterial gradient while breathing room air, and evidence of intrapulmonary vasodilatation) transplantation is associated with a good outcome and improvement of hypoxia as vascular remodelling occurs. By contrast, in patients who have porto-pulmonary hypertension and an increase in pulmonary vascular resistance, transplantation does not result in improvement. Severe pulmonary hypertension (mean pulmonary arterial pressure > 50 mm Hg) is associated with right ventricular failure and sudden cardiac death; mortality is 100% in this group. Preoperative therapy with prostacyclin and nitric oxide may improve outcome in this group though treatment needs to continue long term, suggesting that the benefit is obtained from vascular remodelling not just a decrease in pulmonary pressures. Large volume ascites also increases the risk of pulmonary aspiration.

Renal and endocrine system: some renal dysfunction is common in patients with cirrhosis, portal hypertension and ascites. Compensatory mechanisms to restore mean arterial pressure in cirrhotic patients result in activation of the RAA system with sodium and water retention and the development of ascites. Non-osmotic hypersecretion of vasopressin occurs due to the relative decrease in central blood volume due to splanchnic pooling. As the severity of the disease progresses, disproportionate water retention occurs and dilutional hyponatraemia results. At its most severe this can lead to the 'hepatorenal syndrome'. This represents severe renal vasoconstriction. Renal angiography in this setting demonstrates absent cortical blood flow. Hepatorenal syndrome is characterized by a rapid deterioration in renal function associated with low urinary sodium excretion. Strategies to improve renal function in this setting include the use of splanchnic vasopressors (e.g. terlipressin) with volume resuscitation, transjugular intrahepatic portosystemic stent (TIPSS) placement to reduce portal hypertension, and liver transplantation. Prognosis is poor for hepatorenal syndrome. Renal function is difficult to assess in end-stage liver disease because reduced muscle mass and hepatic synthesis of creatine reduce serum creatinine inappropriately. Creatinine clearance overestimates glomerular filtration rate, and inulin or ^{51}Cr EDTA clearance remain the gold standard.

Endocrine dysfunction is common in end-stage liver disease, due to inappropriate activation of some systems (RAA system, vasopressin release), abnormal responses (insulin resistance), over-secretion of growth hormone and glucagon, and abnormal metabolism (steroid hormones). This leads to clinical syndromes of insulin resistance and impaired glucose metabolism, a shift towards lipid utilization as a preferred energy substrate, and depletion of glycogen stores. Hypoglycaemia in cirrhosis is uncommon and a poor sign. The abnormal metabolism of sex hormones leads to feminization, gonadal atrophy and gynaecomastia in men, and amenorrhoea in women.

Gastrointestinal system: advanced cirrhosis is characterized by portal hypertension and portosystemic shunting, typically resulting in oesophageal varices, which can cause massive gastro-intestinal haemorrhage. Varices may also be present on the anterior abdominal wall and may cause severe blood loss during laparotomy. Ascites develops due to a combination of portal hypertension, poor synthetic function with hypoalbuminaemia and the pathophysiological activation of the RAA system. The volume of ascites may be such that intra-abdominal pressure exceeds renal perfusion pressure causing deterioration in renal function. For this reason, draining ascites (especially if intra-abdominal pressure is > 25 mm Hg) is regaining popularity, especially in those resistant to diuretic treatment. Nutritional abnormalities are common in these patients and associated with peripheral and hepatic insulin resistance and a poor outcome. Glucose utilization is impaired and lipid utilization is increased in fasting and fed conditions. Hypermetabolism seems to predate the malnutrition seen with increasing severity of cirrhosis and in contrast to earlier regimens a high-protein, high-calorie intake, taken little and often, seems to prevent the catabolic state without increasing the incidence of hepatic encephalopathy.

Haematological system: the liver has a central role in the control of coagulation. Impairment of haemostasis is common in liver disease, bleeding is a leading cause of death in cirrhotic patients. The liver is the main site of synthesis of all coagulation factors except von Willebrand's factor. It is also the key site for clearance of activated clotting factors and plasminogen activators; the coagulation state depends on the balance of hepatic synthesis of clotting factors and clearance of activated clotting factors, their inhibitors and fibrinolytic proteins. Failure of bile salt secretion results in poor absorption of vitamin K and low levels of the vitamin K-dependent clotting factors (II, VII, IX, X), but inactive prothrombin complexes are present in liver disease without vitamin K deficiency suggesting an acquired defect in activation.

Many platelet abnormalities occur in patients with liver disease.

Thrombocytopenia may result from hypersplenism secondary to portal hypertension in cirrhotic patients, bone marrow suppression, abnormalities in platelet metabolism or autoimmune causes. In alcohol-related liver disease thrombocytopenia may result from folic acid deficiency. Qualitative platelet dysfunction is also seen in liver disease, with impaired aggregation and clot retraction.

CNS: hepatic encephalopathy is the decrease in conscious level seen in association with severe liver disease. In the early stages a reversal of the sleep–wake cycle is seen with patients sleeping during the day. As encephalopathy advances, subtle changes in intellectual function occur with confusion, memory loss and irritability being common. Finally, changes in conscious level are observed. Work in liver failure shows intracranial hypertension, brain oedema and herniation with altered perfusion. Encephalopathy can be precipitated by a variety of factors including hypovolaemia, sepsis, gastrointestinal haemorrhage and hypoglycaemia. The final common pathway in the aetiology of brain oedema may be increased cerebral blood flow with consequent increased ammonia uptake across the blood–brain barrier. Hyperventilation and consequent alkalosis increase the ammonia available to cross the blood–brain barrier.

Immune system: patients with advanced cirrhosis are relatively immunocompromised. Low complement levels, loss of effective white cell opsonization and dysfunctional macrophage phagocytosis contribute to anergy, leading to high levels of bacteraemia. Spontaneous bacterial peritonitis is common in end-stage liver disease. Increasingly, Gram-positive bacteria, which may be multiresistant, are being cultured in these patients. ◆

Laboratory Tests in Hepatic and Renal Failure

Simon Cottam
Elizabeth Sizer

Simon Cottam is Consultant Anaesthetist at King's College Hospital, London. His main interests include intensive care and hepatobiliary anaesthesia.

Elizabeth Sizer is Specialist Registrar in Anaesthesia at King's College Hospital, London, currently working in the Liver Unit. Her interests include liver transplantation, liver intensive care and anaesthesia for hepatobiliary surgery.

Laboratory tests of liver function are of little use unless combined with a thorough history and examination. In this situation they may be used to pursue a diagnosis, to assess degrees of acute or chronic liver failure, or as trends to map disease progression or response to treatment. With the advent of automated serum multi-channel analysis the most common indication for 'liver function' testing is as a screening test (often mistakenly performed to exclude a problem). Normal values for tests are defined around 95% confidence intervals, therefore multiple tests commonly produce false-positive results. True abnormal results usually represent liver dysfunction. The most common profiles include bilirubin, aminotransferases, alkaline phosphatase and γ-glutamyl transpeptidase (GGT).

True liver function tests
True liver function tests include tests of synthetic function such as estimation of serum albumin, clotting factors or dynamic tests that estimate the liver's capacity to metabolize drugs or endogenous substances.

Albumin is the most abundant plasma protein and is largely synthesized by the liver. In stable chronic liver disease, monitoring serum albumin is a valuable indicator of hepatic synthetic function and as such is incorporated in many prognostic scoring systems (e.g. the Child–Pugh (see page 42) and Mayo End-stage Liver Disease (MELD) score). Albumin has a long half-life of 20 days; this, combined with the possibility of regulation of albumin synthesis in liver disease, can make interpretation of serum albumin levels difficult in an acute situation. Peri-operative albumin levels may change as a result of supplementation, changes in vascular permeability and in volume of distribution. In these situations, measurement of albumin is an unreliable measure of liver function.

Prothrombin time (PT): in the acute situation, assessment of the coagulation factors of the extrinsic cascade (with their much shorter half-lives) are a more reliable monitor of liver failure than albumin. Failure of a prolonged PT to correct with parenteral vitamin K supplementation defines hepatocellular failure, and is one of the most reliable prognostic indicators of survival in acute liver failure. Inter-laboratory variations can occur with different thromboplastin reagents. This may also occur when the PT is expressed as the international normalized ratio (INR). Therefore, trends in prothrombin time measured in a single laboratory are more useful than isolated values.

Blood lactate concentration reflects the balance between production and elimination. Under normal conditions, the liver removes 40–60% of lactate. Hypoperfusion, hypoxia and severe ischaemic damage convert the liver from a lactate-consuming to a lactate-producing system. In acute liver failure, hyperlactacidaemia may be used as a marker of hepatic injury and the accompanying multiple organ failure. Assuming adequate oxygen delivery, blood lactate levels have been shown to correlate with survival in paracetamol-induced liver failure.

'Dynamic' tests of liver function
'Dynamic' tests measure the ability of the liver to clear or metab-olize an infused substance.

Formation of monoethyleneglycine (MEGX): this lidocaine (lignocaine) metabolite can be measured 15–30 minutes after injection of lidocaine (lignocaine), 1 mg/kg. Theoretically, it can be used to quantify the hepatic cytochrome P450 family metabolism. However, lidocaine (lignocaine) is a flow-limited rather than capacity-limited drug. Although MEGX measurements have been shown to correlate with survival in chronic liver disease, they probably reveal more about liver blood flow than functional capacity. Inevitably there is a delay while assay results are obtained.

Indocyanine green (ICG) clearance: the elimination of injected ICG, 0.5 mg/kg, has been used to assess liver function. Interest in this method was fuelled by the introduction of a bedside non-invasive monitor of ICG clearance. ICG has a high hepatic extraction ratio and measurements reflect changes in liver blood flow. Reports suggest it is useful for assessing donor livers for transplantation and following liver resection.

Conventional tests of liver dysfunction
Bilirubin is the by-product of haem metabolism. Unconjugated bilirubin is water insoluble and transported bound to serum albumin. Hepatic conjugation produces a water-soluble compound, normally excreted in the bile. Total bilirubin levels therefore represent the balance between production metabolism and excretion. Excessive production may result from disease processes resulting in increased red cell turnover leading to unconjugated hyperbilirubinaemia. Conjugated hyperbilirubinaemia results from leakage of bilirubin into the blood directly from the hepatocytes or distal to the liver in the case of biliary obstruction. Conjugated bilirubin released into the blood stream tends to be excreted and can be measured in the urine, however, because some of the conjugated bilirubin can covalently bind to serum albumin, bilirubin is not always detected in the urine. The presence of bilirubin in the urine (as tested by a Diazo impregnated test strip) is sensitive and may detect liver dysfunction before overt jaundice is detected.

Aminotransferases: aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are released into the blood stream as a result of cell damage or necrosis. AST is a sensitive but nonspecific marker of hepatocellular damage. AST can be released from a number of damaged organs including liver, heart muscle, kidney, pancreas and red blood cells. ALT is slightly more specific for liver damage with less extrahepatic production, but may be elevated in conditions such as myositis. High (> 1000 IU/litre) levels of AST usually represent hepatitis of viral, drug or ischaemic origin. Intermediate levels (200–400 IU/litre) may be seen in acute alcoholic hepatitis with more severe clinical dysfunction. Absolute levels of transaminases do not correlate with outcome.

Glutathione-S-transferase (GST): one problem with AST and ALT as measures of hepatocellular damage and necrosis is that these enzymes are not uniformly distributed throughout the liver, being predominantly concentrated in periportal hepatocytes. Centrilobular hepatocytes are most prone to hypoxia and are relatively deficient in AST and ALT, this may explain some of the difficulties when correlating absolute values of transaminases with outcome. GST is more evenly distributed throughout the liver. In addition, its relatively small molecular weight encourages rapid release following hepatocellular damage. A short half-life of 90 minutes means that acute changes can be tracked rapidly but that peak effects may be missed, depending on the sampling time after injury. GST is increasingly used as a sensitive marker for changes in hepatocellular function following surgery and anaesthesia.

Alkaline phosphatase (AP): this family of enzymes is located in liver, bone, placenta and intestine. In healthy individuals, circulating AP is derived from bone or liver. In pregnancy, AP is often twice the upper range of normal. Elevations also occur in peri-pubertal children. The wide distribution of the enzyme can cause confusion in the assessment of liver function, and extrahepatic elevation may occur as a result of hyperthyroidism, cardiac failure, hypernephroma and Paget's bone disease. In the liver, AP is located in the microvilli of the biliary canaliculi and on the sinusoidal surface of the hepatocyte. Classically, AP levels in liver disease are elevated when there is intra- or extrahepatic obstruction to biliary drainage or due to space-occupying lesions such as tumours. The raised levels in the blood seem to be due to increased synthesis in the canalicular membrane rather than failure of excretion. The diversity of AP families makes isoenzyme determination desirable, but this assay is not widely available and other markers of biliary obstruction, such as GGT, are often monitored.

GGT is a membrane-bound glycoprotein found in cells with a high secretory or absorptive activity (e.g. liver, kidney, pancreas intestine, prostate). 90% of patients with hepatobiliary disease have raised GGT, but specificity is low. Its main value is in combination with AP to convey additional liver specificity. Raised levels of GGT have been associated with obesity, alcohol use and raised cholesterol levels. In non-drinking, obese individuals the most common cause of raised GGT is a fatty liver.

Tests of renal failure
In perioperative care, laboratory tests are commonly requested to aid in the diagnosis and management of acute renal failure. This brief review concentrates on tests of function rather than those requested to confirm or refute a specific diagnosis. Classically, renal impairment (Figure 1) is classified as:

- pre-renal (poor perfusion), often correctable with volume resuscitation
- renal (intrinsic renal disease)
- post-renal (obstruction).

Urinary measurements in pre-renal and renal failure

Indices	Pre-renal	Renal
Urinary sodium (mmol/litre)	< 20 (low)	> 40 (high)
Urine osmolarity (mosmol/litre)	> 500 (high serum +100)	< 350 (low)
Urine/plasma urea	> 8 (high)	< 3 (low)
Specific gravity	High 1.020	Fixed 1.010–1.020

1

Post-renal failure is common and is often excluded by ultrasound. Clinical acumen is vital for the detection of hypovolaemia and low cardiac output states. Laboratory examination of the urine can sometimes be useful in the differentiation of pre-renal and 'true' renal failure.

Measuring urinary biochemical indices has limitations because typical values are seldom present and concomitant diuretic therapy often confuses estimates of urinary sodium in pre-renal failure. Hepatorenal failure mimics pre-renal failure with extremely low urinary sodium levels, but fails to respond to volume loading.

Urine analysis is an important, but often neglected, investigation. A normal urine analysis in the presence of impending acute failure supports the presence of pre-renal or obstructive patterns. Abnormal results may help to discriminate tubular and glomerular problems. Red blood cells suggest the presence of glomerular or vascular inflammatory disease. Urine protein excretion can occur as a result of glomerular damage (increased loss) or tubular failure of absorption.

Blood urea is often measured automatically when concentrations of sodium and potassium are requested. There is a common misconception that plasma urea usefully relates to glomerular filtration rate (GFR), however it is altered by diet, fever, gastro-intestinal haemorrhage, renal blood flow, urine flow rates and in liver disease. Some laboratories no longer offer it as a routine assay. It still has a place in assessing the effect of compliance or alterations to diet in patients with stable chronic renal failure or in assessing the need for, or effects of, renal replacement therapy.

GFR, classically measured by inulin clearance, would be the ideal measurement to detect alterations in renal function, but in early renal disease, GFR is normal or increased. Inulin clearance is seldom measured in clinical practice and the serum creatinine and the creatinine clearance are used as estimates of GFR.

Serum creatinine is the most commonly used indirect estimate of GFR. The exponential rise in serum creatinine with falling GFR limits its use in assessing patients with low clearances. With low concentrations of creatinine, cross-reaction in the assay may overestimate the creatinine concentration and consequently underestimate creatinine clearance. Also, creatinine secretion by the tubules occurs and creatinine production is determined by muscle mass. Wasted patients have low levels of creatinine, which underestimate deterioration in renal function. Serum creatinine is also affected by age as muscle mass falls.

Attempts to correct for age and muscle mass have resulted in formulae that attempt to compensate for these changes.

$$\text{Creatinine clearance} = \frac{1.22 \times (140 - \text{age}) \times \text{Weight}}{\text{Serum creatinine } (\mu\text{mol/litre})}$$

Creatinine clearance can be calculated by combining a timed urine collection with estimations of plasma and urine creatinine concentration.

$$\text{Creatinine clearance} = \frac{\text{Urine concentration } (\mu\text{mol/litre}) \times \text{Urine volume (ml/minute)}}{\text{Serum concentration } (\mu\text{mol/litre})}$$

Measuring creatinine clearance removes some of the problems associated with the use of isolated creatinine values, but it necessitates a 24-hour urine collection and assumes that serum creatinine is constant over 24 hours.

Measuring GFR using radioactive indicators: labelled chromium ethylenediamine tetraacetic acid (^{51}Cr EDTA) is the most widely used indicator. Clearance of this agent is almost identical to inulin even down to a GFR of 3–15 ml/minute. Following a single injection of 2 MBq ^{51}Cr EDTA, clearance can be calculated by serial blood sampling over 5 hours. ◆

Cardiac Output Measurement

Robin Berry
Jeremy A Langton

Robin Berry is Specialist Registrar in Anaesthetics with the Royal Air Force, currently based at Derriford Hospital, Plymouth. He qualified from Nottingham University Medical School. He is interested in the transport of the critically ill as part of his military role.

Jeremy A Langton is Consultant Anaesthetist at Derriford Hospital, Plymouth. He qualified from Guy's Hospital, London and trained in anaesthesia in London and Leicester. His research interests include airway reflexes and anaesthesia.

The cardiac output is the volume of blood in litres pumped by the left ventricle per minute and is the product of heart rate and stroke volume. It changes with heart rate as well as with preload, afterload and contractility (the three determinants of stroke volume).

Cardiac output is measured primarily because it is thought to reflect the adequacy of global blood flow. However, poor tissue perfusion and cellular hypoxia can exist despite normal blood oxygen content and cardiac output. Therefore, the clinician must be wary of relying on absolute values and should concentrate on trends and their physiological effect on the patient. Numerical data should be evaluated frequently in the context of clinical and laboratory findings rather than relying on accepted normal values. The values obtained should also be considered in the context of the patient's age, sex, weight, pre-morbid condition and current disease process. Cardiac output measurements are used to determine myocardial performance, oxygen delivery, derived variables (e.g. systemic vascular resistance), to calculate shunt, and as a measure of therapeutic intervention.

In laboratory animals, cannulation of the aorta and pulmonary artery allows direct measurement of output with flowmeters, but such invasive practices are unacceptable in human medicine. The essence of clinical cardiac output measurement is to quantify end-organ perfusion and therefore clinical examination should be the cornerstone of good practice. Level of consciousness, unprovoked urine output and examination of the skin for colour, temperature and capillary refill are good indicators of circulating volume and the adequacy of cardiac output. Blood pressure measurement provides a poor guide to pump function, and may be maintained despite a failing myocardium by increased systemic vascular resistance. In critical illness or its recovery phase, simple assessment of organ function may be difficult to interpret owing to the disease process, associated medical interventions and the combined effects on normal physiology.

The ideal method of measuring cardiac output would be non-invasive, continuous, accurate over the range of cardiovascular function encountered in intensive care, operator independent and labour free. In the absence of this ideal method, the 'gold standard' for cardiac output measurement in intensive care remains the indirect thermodilution technique using the highly invasive, balloon-tipped, flow-directed, pulmonary artery catheter. Earlier methods employed the Fick principle and dye dilution, based on the theory of volume displacement.

The Fick method

The Fick principle states that the total uptake or release of a substance by an organ is the product of the blood flow through that organ and the arteriovenous concentration difference of the substance in question. Applying the Fick principle to cardiac output measurement, the pulmonary blood flow over 1 minute may be determined by measuring the arteriovenous concentration difference of oxygen across the lungs and the rate of oxygen uptake. In the absence of intracardiac or intrapulmonary shunts, the pulmonary blood flow is equal to systemic blood flow and thus cardiac output.

The Fick principle will not give a dynamic measure of output and the procedure is time-consuming, with blood sampling and the need for steady-state haemodynamic, respiratory and metabolic conditions over the period of measurement. For these reasons, and the development of the pulmonary artery catheter, the Fick method has remained largely a laboratory tool, despite its accuracy, especially in low-output states.

Indicator dilution methods

An indicator mixed into a flowing volume of blood can be used to determine the position of that volume in time and space, provided that the following conditions are met:

- the indicator remains in the system between the points of injection and measurement
- complete mixing of the indicator and the blood occurs
- blood flow is constant during the measurement phase.

Dye dilution

Classically, the non-toxic dye, indocyanine green is injected into the pulmonary artery and its transit time through the systemic circulation monitored by aspirating peripheral arterial blood through a densitometer. A washout curve is then plotted on semi-logarithmic paper to describe the changing concentration of dye from injection through to steady state. The cardiac output can be derived from this curve, by dividing the dose of dye injected by the area under the washout curve. Recirculation of the dye distorts the time–concentration curve and therefore the downslope to point zero has to be extrapolated from the primary curve and an exponential decay assumed (Figure 1). Furthermore, steady-state conditions are assumed over the 40-second measurement period. Errors may occur in the mixing and administration of the dye, which is photosensitive and unstable with time. The technique is invalidated by intracardiac shunts owing to inadequate mixing and severe valve regurgitation and shock, because the first-pass curve is so prolonged that recirculation occurs before the downstroke is fully inscribed. For these reasons, as well as the elevation of the baseline concentration with repeated injection and the need for referenced controls, this method has been superseded by thermodilution.

1

Thermodilution

Heat can also be used as a detectable indicator in the blood and has the advantage of rapid dissipation into the tissues and consequently no recirculation peak or elevation of the indicator baseline. As a result, cardiac output measurements can be repeated at frequent intervals and thermodilution is therefore the established method of measuring cardiac output.

Using a pulmonary artery catheter, a 10 ml bolus of ice-cold saline is injected into the right atrium and the ensuing temperature change recorded by a thermistor at the catheter tip located in the pulmonary artery. A plot of temperature against time gives a washout curve, from which cardiac output can be calculated using a modification of the Stewart–Hamilton conservation of heat equation:

$$Q = \frac{V \times Di \times Si[Tb - Ti] \times 60}{dT \times t \times Db \times Sb \times 1000}$$

where: V = volume of injectate; Di and Db = densities of injectate and patient's blood; Si and Sb = specific heats; Ti and Tb = temperatures; dT = mean temperature change; t = duration of temperature change in seconds. To convert cardiac output to litres/minute a scaling factor of 60/1000 is used.

In current practice, a microprocessor system measures the area under the curve and calculates cardiac output. The manufacturers of the sensors add correction factors to account for the mixture of cold indicator with warm residual fluid in the catheter injection lumen and heat transfer from the catheter walls to the cold indicator.

Sources of error include any circumstances that affect the temperature versus time graph. For example, intracardiac shunts and severe tricuspid and mitral regurgitation.

- The presence of thrombus on the thermistor can delay cooling and rewarming, and therefore overestimate the area under the curve.
- Distal migration of the catheter can lead to disproportionate blood flow with variability in the volume of cold bolus reaching the thermistor.
- The volume, temperature and rate of delivery of the injectate are important variables. For example, the cold saline bolus has been associated with bradycardias and supraventricular tachyarrhythmias.
- Alteration in ventricular performance owing to an arrhythmia also affects the thermal dilution washout curve.

It is possible to 'lose' the thermal indicator, especially in low cardiac output states if the baseline temperature is variable, for example during large-volume transfusion or rewarming following cardiopulmonary bypass. The temperature of pulmonary artery blood changes with respiration, owing to the different contributions of blood from the superior and inferior venae cavae at different stages of the respiratory cycle, which is exacerbated by mechanical ventilation.

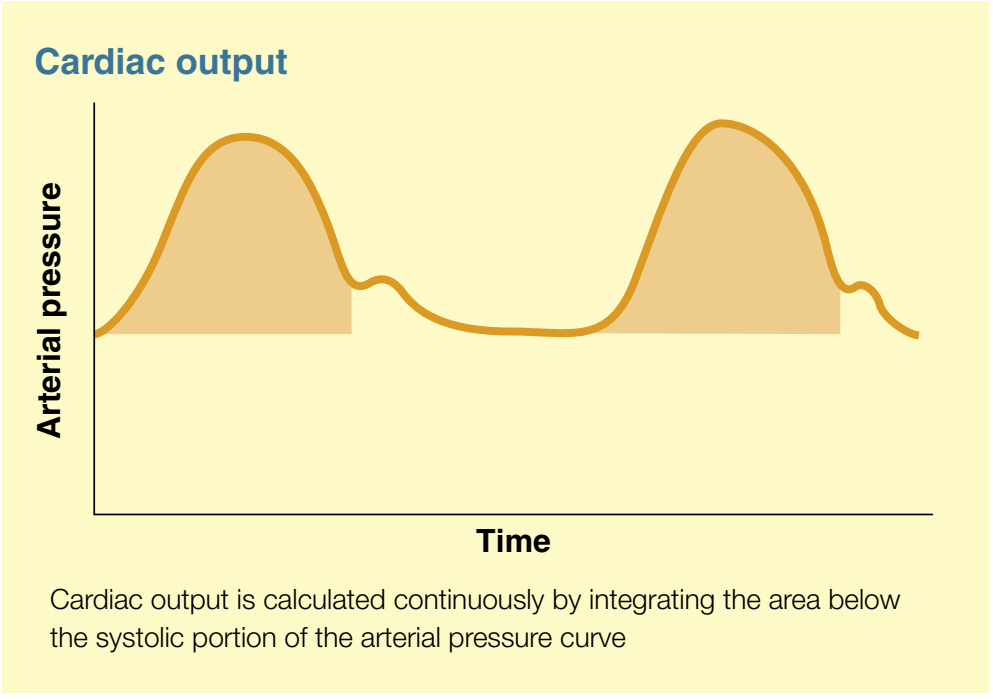
Modified pulmonary artery catheter: this apparatus was developed to address the intermittent nature of the thermodilution method. A thermal filament placed in the right atrium and ventricle gives 15 W pulses, which are recorded by a thermistor at the catheter tip to generate washout curves and 'continuous' cardiac output measurements. Since bolus injections are not required, this system avoids what can be a considerable volume load to the patient with the attendant risk of infection. Described as a continuous output monitor, this apparatus has a lag time of about 10 minutes. It has the potential to detect changes in myocardial function more rapidly than traditional thermodilution, but it does not give beat-to-beat output data. Concerns about thermal damage to the myocardium and red blood cells appear unfounded, but this technique suffers from many of the limitations of the bolus method.

Future developments: although the pulmonary artery catheter is well established, derangements in the normal physiological function of the heart and lungs make errors in interpretation likely. Furthermore, it is an invasive tool and is associated with risks regarding initial central venous access, floating the catheter and its residence in the right heart and pulmonary circulation. As a result of these problems, there is a reluctance to initiate early invasive monitoring, which may delay appropriate therapeutic intervention. For these reasons, and the desire to obtain continuous cardiac output data, a number of non-invasive or minimally invasive monitors have been developed, though they have not received universal acceptance.

Oesophageal probes have been developed to determine cardiac output from measurements of blood velocity. Doppler devices derive flow in the descending aorta from integrals of the systolic velocity versus time curve, the aortic cross-sectional area and the heart rate. Transoesophageal echocardiography generates outputs from flow through the mitral valve, multiplied by the calculated valve area, a computation constant and the heart rate. These devices have the advantage of giving anatomical information about ventricular function, but they require constant repositioning. There are also questions about their safety, related to bleeding and unrecognized oesophageal rupture. The greatest restriction to their use, however, is that the patient has to be intubated, ventilated and sedated to tolerate the probe which offsets the benefits of avoiding invasive vascular monitoring.

Recently, transpulmonary thermodilution with pulse contour analysis has been advocated as a 'minimally invasive' means of continuous (30 seconds) cardiac output measurement. Left ventricular stroke volume is computed by measuring the area under the systolic part of the arterial pressure waveform (Figure 2) and dividing by aortic impedance. When multiplied by the heart rate, this gives the cardiac output. Initial studies suggested that cannulation of a central artery was necessary for accurate measurement, however, the radial artery has been found to be satisfactory. Before using pulse contour analysis, cardiac output has to be measured by an alternative method to derive the aortic impedance used in the pulse contour equation. Traditionally, thermodilution using a pulmonary artery catheter would have been used, but now a less invasive transcardiopulmonary method is applied. A cold fluid bolus (0.2 ml/kg) is injected into the right atrium via a central venous line and a temperature washout curve recorded by a thermistor located in a peripheral artery. When the aortic impedance is known, further cardiac outputs are recorded 'continuously' by pulse contour analysis, with calibration by thermodilution as required. Under steady-state conditions, this can be as infrequent as 8 hourly, but when changes in systemic vascular resistance are anticipated, calibration should be more frequent.

The technique uses central venous and peripheral arterial lines, and its advocates suggest that it is no more invasive than standard intensive care monitoring. It is not affected by the respiratory cycle, because the washout curve is at least 20 seconds long, but it is subject to thermal baseline drifts, with inadequate volumes of injectate or too warm a solution giving inaccurate dilution curves. Errors can also be generated by air in the manometer lines, giving dampened arterial waveforms and therefore inaccurate pulse contour analysis.



Cardiac output is calculated continuously by integrating the area below the systolic portion of the arterial pressure curve

Measurement of Pressure: Direct and Indirect Methods of Measuring Blood Pressure and Pulmonary Artery Pressure

Balraj L Appadu
Mahesh Prabhu

Balraj L Appadu is Consultant Anaesthetist at the Peterborough Hospitals Trust, UK. He qualified from Saint Etienne University, France where he trained in internal medicine and haematology. He trained in anaesthetics in Ashford, London, Southend and Leicester. His research interests include basic sciences, receptor pharmacology and intensive care.

Mahesh Prabhu is Specialist Registrar at Peterborough Hospitals Trust, UK. He qualified from Bombay University, India, and trained at Bedford and Cambridge, UK. His interests include basic sciences, cardiothoracic anaesthesia and day surgery.

Pressure is defined as force per unit area. In clinical practice, the units commonly used to measure pressure are mm Hg and kPa. The SI unit of pressure is Newton per square metre (N/m^2) or Pascal (Pa).

Instruments used for measuring pressure

Liquid manometers
There are two types of liquid manometers (Figure 1).

- In the 'closed' mercury manometer (e.g. barometer) there is a virtual vacuum (Torricellian vacuum) above the mercury, such that the height of the mercury column indicates absolute pressure.
- In the 'open' mercury manometer (e.g. sphygmomanometer), the tube is opened at both ends and thus the height of the fluid column indicates the amount by which the pressure exceeds atmospheric or gauge pressure. The force exerted by a column of fluid is equal to:

height x density x acceleration due to gravity.

Thus, pressure is independent of the width of the fluid column and of the shape of the liquid column. In single tube manometers, pressure is defined by the height of the fluid column as measured from the meniscus in the reservoir. One source of error is that the level of the meniscus in the reservoir falls as fluid is forced up the tube so that a fixed graduated scale does not accurately reflect the true difference between the two menisci. This error can be minimized either by making the cross-sectional area of the reservoir large compared with the cross-sectional area of the tube or shortening the scale length to allow for the fall in reservoir level. Another potential source of error is caused by the surface tension of the liquid. Most liquids have a meniscus that is concave upwards, and surface tension causes the position of the meniscus to appear to be higher than it is. However, in mercury manometers, the meniscus is concave downwards and this causes a negative error in the reading.

Liquid manometers

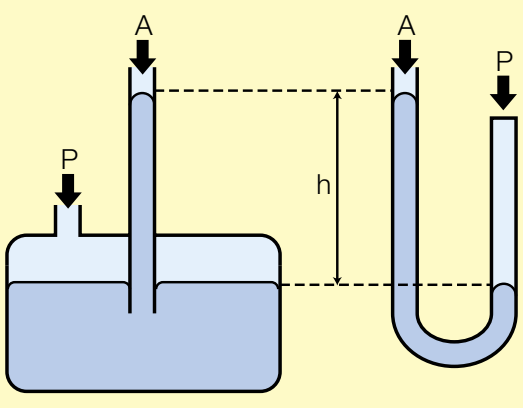
Mercury manometer giving gauge pressure



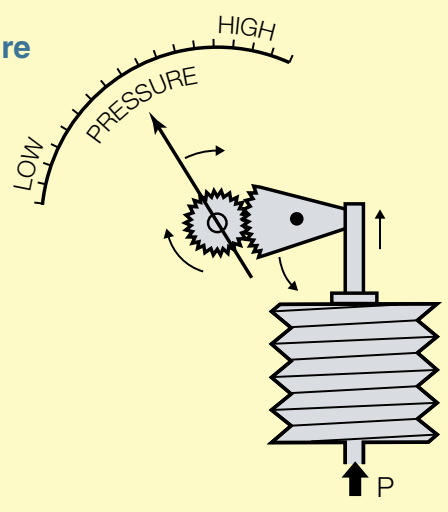
P, applied pressure; A, atmospheric pressure; h, measured pressure

1

Mechanical pressure gauges
Aneroid gauge is used to sense and measure small pressures (Figure 2). Expansion of a small metal bellows is detected by a lever mechanism, which amplifies the movement and drives a pointer on a scale.

Bourdon gauge is used for measuring high pressure. It consists of a coiled tube, flattened in cross-section. One end of the coil is anchored to the case and connected to the pressure source, while the other end is closed and attached to a mechanism that drives a pointer across a dial. Application of pressure causes the cross-section to become more circular, thus causing the coiled tube to straighten and, with one end fixed, the pointer moves across the dial.

Aneroid pressure gauge



P, pressure

2

Measuring blood pressure

Indirect measurement of arterial pressure
Most indirect methods of measuring blood pressure are based on the occlusion of a major artery by a cuff. In clinical practice, systolic and diastolic end points are detected by auscultation of the Korotkoff sounds. The systolic point is marked by the sudden appearance of tapping sounds (phase I) synchronous with the heart beat. The sounds then become quieter (phase II) and as the cuff pressure decreases further the sounds become louder with a tapping quality (phase III), then the sounds become muffled (phase IV) and disappear (phase V). Errors may occur related to the site of the measurement, because arterial blood pressure is not identical in every artery. Pulse pressure is greater in peripheral arteries because the velocity of the pulse wave increases as it travels from the heart to the artery. Blood pressure may also differ in the limbs. Indirect methods are intermittent, with systolic and diastolic readings reflecting conditions in the artery at two instants at which they are measured. The end point of diastolic blood pressure measurement is also the subject of controversy; there is a difference of 5–10 mm Hg between Korotkoff phases IV and V. This is not important in clinical practice but may affect epidemiological studies. A short or narrow cuff may cause readings to be too high, while a wide cuff gives a low reading. The cuff should cover about two-thirds of the length of the upper arm, or its width should be 20% greater than the diameter of the arm. Zero and calibration errors in aneroid manometers also occur.

Oscillometric measurement of blood pressure depends on the principle that blood pressure can be estimated by analysing the pressure oscillations in the cuff as it is slowly deflated. Most instruments use a single pressure cuff applied to the arm, which is inflated to about 30 mm Hg above systolic blood pressure. During slow deflation, each pulse wave leads to a pressure transient in the cuff, which is transmitted to the connecting tube, where a transducer detects it. Above systolic blood pressure, the transients are small and, at the systolic point, they quickly increase in magnitude. As the cuff pressure decreases, the transients reach a peak amplitude and then decrease. The mean arterial pressure is the lowest cuff pressure where the peak amplitude is maintained and at diastolic blood pressure is the point where the transients abruptly decrease in amplitude.

This oscillometric principle is used in the *Dinamap* (a non-invasive, automatic method of measuring blood pressure) where at each pressure plateau point, successive pulses are compared and accepted only if their amplitude is similar. With this device, systolic blood pressure shows good correlation with direct pressure measurement with a bias towards overestimation at low blood pressure and underestimation at high blood pressures. Newer devices operate in a similar fashion, but cuff deflation is continuous, rather than in steps, leading to shorter measurement time. However, all these devices rely heavily on a regular cardiac cycle with no great difference between successive pulses.

Continuous non-invasive blood pressure measurement is based on the Penaz technique, which makes use of the principle that the force exerted by a body may be measured by determining the counterforce needed to stop the original force from causing physical disruption. This principle works only if the counterforce can be measured accurately and the detection does not need to be linear because it should be capable of detecting the null condition only.

A small cuff is placed round a finger and can be inflated or deflated at high speed. Inside the cuff is a light-emitting diode, which transilluminates the finger, and on the other side is a photodiode that detects light intensity after it has passed through the finger (using the same principle as a pulse oximeter). The detected light intensity is a crude measure of the blood volume in the finger, but is a precise indicator of any change in volume. The system inflates the cuff rapidly to above systolic blood pressure and then deflates. As soon as the optical detector senses the pulse wave, the pressure in the cuff is increased such that flow is decreased to maintain a constant volume of blood in the finger, thus maintaining a constant signal. The pressure waveform applied to the finger by the cuff closely mirrors the pressure waveform within the arteries. This device not only measures systolic and diastolic blood pressure but also reproduces the actual arterial waveform. These devices are highly accurate in the normal or vasodilated finger but less effective in patients with poor peripheral perfusion or in hypotensive patients. They show marked variability between patients, and small differences in the positioning and tightness of the cuff produce significant differences in recorded blood pressures.

Direct methods of monitoring blood pressure
Continuous monitoring of arterial blood pressure using intra-arterial cannulation, pressure transduction and display is particularly useful during cardiovascular instability, massive fluid shifts, drug-induced manipulation of blood pressure and when non-invasive blood pressure measurement is inaccurate (e.g. with obesity, cardiopulmonary bypass, arrhythmias). Intra-arterial cannulation also allows repeated sampling of arterial blood for blood gas analysis.

The ability to provide a continuous, accurate, beat-to-beat reproduction of the arterial waveform depends on a structured pressure transducer system. The lumen of the vessel is connected to the pressure transducer by a fluid-filled catheter. The components of the system include a short, parallel-sided, *Teflon* or polyurethane cannula inserted into one of the peripheral arteries; a catheter (a short length of narrow-bore, stiff, non-compliant tubing containing saline or heparinized saline); a flush system to prevent occlusion of the cannula with clots by flushing with saline at the rate of 1–4 ml/hour; and a pressure transducer. A transducer is any device that converts energy from one form to another. Most physiological pressure measurements are made by sensing the movement of a flexible diaphragm, which can be converted into an electrical signal for processing and display. The most common method of pressure transduction uses a strain gauge (an electrically conductive elastic material that responds reversibly to deformation by a change in its electrical resistance). Silicon strain gauges are more sensitive, but they are affected by temperature and are non-linear. In a silicon strain gauge, a thin slice of silicon crystal is bonded on to the back of the diaphragm. The movement of the diaphragm causes a change in the resistance of the crystal, which can be converted into an output signal using a Wheatstone bridge circuit. The movement of the diaphragm may also be sensed optically by reflecting a beam of light off the silver back of the diaphragm on to a photoelectric cell, which measures changes in electrical output. These transducers have a high-frequency response and eliminate the risk of microshock.

The sensing element of the diaphragm may rely on capacitance. The diaphragm forms one plate of the capacitor, the second plate being fixed. The capacitor is part of a bridge circuit that is energized by an alternating current source. The impedance of the transducer changes with the displacement of the plates of the capacitor. The output is an alternating signal with an amplitude that varies with pressure. Inductance may also be used, in which case the diaphragm moves a soft iron core between the primary and secondary coils of a transformer. An alternating current energizes the primary coil. The movement of the soft iron core modulates the voltage in the secondary coil. The voltage is then rectified, filtered and amplified.

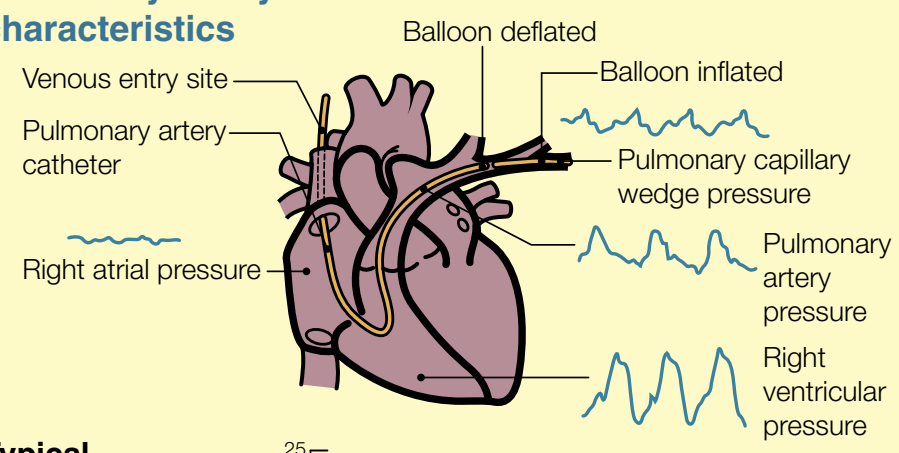
Pulmonary artery catheter pressure measurements

Pulmonary artery catheterization was introduced into clinical practice in the early 1970s for the treatment of patients with cardiac diseases. While many physicians believe that a pulmonary artery catheter is useful in guiding intravascular volume expansion and pharmacological intervention in selected critically ill patients, its use is controversial.

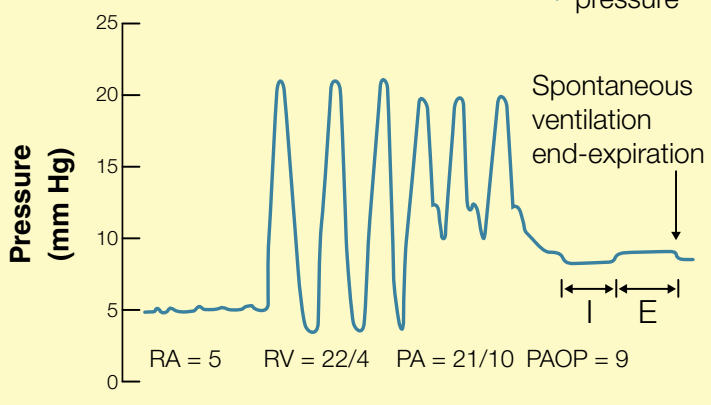
The balloon-tipped, flow-directed, pulmonary artery catheter (Swan–Ganz) is commonly used to measure pulmonary artery pressure and pulmonary capillary wedge pressure (PCWP) or pulmonary artery occlusion pressure (PAOP) as a means of assessing left ventricular filling pressures. It also allows the measurement of cardiac output by a thermodilution technique and the measurement of mixed venous oxyhaemoglobin saturation. A pulmonary artery catheter should be inserted by a physician who knows about the complications, and is capable of interpreting and using the data obtained (Figure 3). Figure 4 gives normal values for pulmonary artery measurement.

PCWP or PAOP reflect mean left atrial pressure, which reflects left ventricular end-diastolic filling, which reflects left ventricular preload. However, preload is the stretch placed on the left ventricle by the end-diastolic volume. Assuming changes in left ventricular end-diastolic pressure are predictive of changes in left ventricular end-diastolic volume implies that the compliance of the left ventricle is constant, which may not always be the case. Therefore PCWP is not a perfect reflection of left heart preload, because changes in the myocardium may alter left ventricular compliance (i.e. during myocardial ischaemia). Other factors that may adversely affect the accuracy of PCWP measurements include significant mitral valve stenosis and pulmonary venous resistance (as may be seen in patients with chronic obstructive airways disease).

The insertion path of a balloon-tipped, flow-directed, pulmonary artery catheter with its waveform characteristics



Typical pressure waveforms



Typical pressure waveforms of a pulmonary artery (PA) catheter as it travels through the right atrium (RA), right ventricle (RV), and PA where it is wedged to give the pulmonary capillary wedge pressure (PCWP) or pulmonary artery occlusion pressure (PAOP). I, inspiration; E, expiration. The diastolic PA pressure is usually significantly higher than RV diastolic pressure and the PAOP is necessarily lower than PA diastolic pressure. To record otherwise suggests that blood is flowing from the left heart to the right heart. It is essential to read the PAOP at the end-expiration

3

Normal values of physiological measurement obtained using a pulmonary artery catheter

Value	Normal range
• Right atrial pressure (RAP)	2–8 mm Hg
• Right ventricular pressure	Systolic: 20–30 mm Hg; diastolic RAP less or equal to RAP
• Pulmonary artery pressure (PAP)	Systolic: 20–30 mm Hg; diastolic: 5–15 mm Hg
• Pulmonary capillary wedge pressure (pulmonary artery occlusion pressure)	2–12 mm Hg; must be less than diastolic PAP
• Cardiac output	4–6 litres/minute (adult)
• Mixed venous oxyhaemoglobin saturation	65–75%

Principles of Cardiac Pacemakers and Defibrillators

Richard Griffiths

Richard Griffiths is Consultant Anaesthetist at Peterborough District Hospital. He qualified from St Thomas' Hospital and trained in anaesthesia in Nottingham, Leicester and San Francisco, USA. His main interests are vascular anaesthesia and medical education.

A patient presenting for surgery with a permanent cardiac pacemaker is a common occurrence. The anaesthetist must be familiar with the type of pacemaker that has been inserted and the potential malfunctions that can occur during surgery. Over 1 million pacemakers have been implanted worldwide and in 1994 the estimated new implant rate was 295/1 million population.

The pacemaker system

The system consists of a generator and one or two leads. The pulse generator has three basic components, a power source, an electrical impulse former and a timer. The early pacemakers had a fixed rate, but most new devices are demand units. The life of the battery is 8–15 years, and the units are checked regularly for battery life and performance. The circuitry and battery are contained in a titanium or stainless-steel box attached to a block that contains the electrode connections through which the pacemaker leads interface with the generator circuit.

The leads are non-thrombogenic, resistant to fracture and have to be insulated. The wire is made of metal alloy covered by an insulating layer of silicone or polyurethane. The pacing lead can be connected to the epicardial or endocardial surface of the heart. The endocardial surface is used if the unit is inserted via a subcostal approach or if inserted at the time of cardiac surgery. The epicardial surface is most commonly used and is reached transvenously either through the internal jugular or subclavian veins. The femoral and antecubital veins have also been used. Electrical impulses are formed in the pulse generator and are transmitted to the myocardium by the lead, resulting in mechanical contraction of the heart (Figure 1).

The distal end of the pacing lead is attached to the myo-cardium. The lead can be anchored by passive or active fixation. Passive fixing is achieved using a system of fins, which become entangled in the myocardium. Active fixation is used in patients with dilated right ventricles and involves insertion of the lead into the myocardium with a screw mechanism.

Cathodal stimulation is used in permanent pacing systems because the thresholds are lower and the risk of induced arrhythmias is reduced. The electrode has a small surface area to enhance current density and thus reduce the stimulation threshold. Permanent pacing systems are able to cause myocardial contraction (capture) and can sense the intrinsic electrical activity. The minimum stimulation needed to cause capture is the pacing threshold. The voltage is set at twice the threshold level to ensure reliable capture. The sensing threshold is the voltage at which the pacemaker is able to detect the intrinsic signal in the chamber being sensed. The current returning via blood to the anode completes the circuit. The anode is just proximal to the tip in a bipolar system and is part of the pacemaker unit in a unipolar system.

1 Chest radiograph showing the leads and generator unit of a dual-chamber system.

Types of pacemakers

In the 1960s, pacemakers were introduced to treat bradycardias, but now they can also be used to treat tachycardias. Pacemakers can pace both cardiac chambers to improve the physiological performance of the heart. They can also respond to the patient's activity and enable heart rate to alter with exercise. A common nomenclature has been described by the NASPE (North American Society of Pacing and Electrophysiology) and BPEG (British Pacing and Electrophysiology Group) known as the NBG pacemaker code (Figure 2).

In fixed-rate modes, the pacemaker paces but does not sense the myocardium. The NBG codes for these pacemakers are VOO, AOO or DOO. Fixed-rate pacing can interfere with the intrinsic cardiac rhythm and may lead to other arrhythmias. Owing to the risk of spontaneous cardiac activity, demand units have superseded fixed-rate pacemakers.

Demand mode pacemakers sense the electrical activity of the atria (P wave) or the ventricle (R wave). When spontaneous ventricular activity is sensed, the output of the pacemaker is suppressed (R wave inhibited) or the unit is made to discharge instantly (R wave triggered) so that the impulse will occur within the safe period of the QRS complex.

Most pacemakers are on-demand units with a single pacing lead passing to the right ventricle. In cases where there is sinus node disease and normal atrioventricular (AV) conduction, the lead may be located in the right atrium to maintain the normal sequence of atrial and ventricular depolarization.

The NASPE/BPEG Generic (NBG) Pacemaker Code

Letter position	I	II	III	IV	V
Category	Chamber paced	Chamber sensed	Response to sensing	Programmability rate modulation	Anti-tachycardia functions
	O = none A = atrium V = ventricle D = dual	O = none A = atrium V = ventricle D = dual	O = none T = triggered I = inhibited D = dual R = reverse	O = none P = simple programmable M = multiprogrammable C = communicating R = rate modulation	O = none P = pacing S = shock D = dual

The code is a five-letter system in which the first three letters describe the basic anti-bradycardia functions and the last two letters describe programmability and anti-tachycardia functions. Clinically the first three letters are often used alone if the last two letters have no function (e.g. fixed-rate modes are VOO, AOO or DOO)

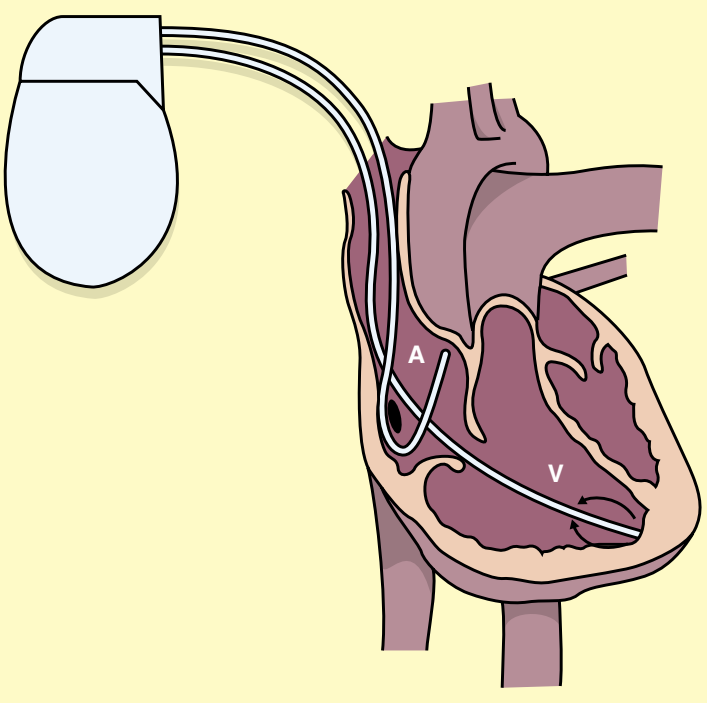
2

Atrial only: the NBG codes for these pacemakers are AAI or AAT. The atrium is paced and sensed, and is either inhibited or triggered. These modes are used for sinus node dysfunction when the AV conduction system is normal.

Ventricular only: the NBG codes for these pacemakers are VVI or VVT. The ventricle is sensed and paced, and either inhibited or triggered. However, there is no AV synchrony and these modes are not used for patients who rely on coordinated atrial contraction to improve end-diastolic filling of the left ventricle. A single ventricular lead is shown in Figure 3.

Dual chamber pacemakers have pacing electrodes in both the right atrium and ventricle (Figure 3). They are designated VAT, VDD, DVI or DDD. AV synchronous pacing is provided with VAT and VDD modes, and the ventricle is paced after sensing atrial activity. These modes are useful in patients with abnormal sinus node function who have an intact AV conduction system. Atrial synchronous pacemakers enable the heart rate to increasein response to an increase in sinus rate during exercise. These modes also maintain the physiological relationship between the atria and ventricles.

Position of leads in single and dual pacemaker systems



In the single chamber system, the lead is implanted in the ventricle only (V). In the dual system, one lead is implanted in the ventricle (V) and the other in the atrium (A)

3

Rate-responsive pacemakers can sense other stimuli as well as atrial and ventricular activity and can increase the basic pacemaker rate. Dual-chamber pacemakers are unable to increase heart rate during exercise in patients with severe sinus node disease, because the node fails to respond to stimuli. There may also be a need to increase heart rate and cardiac output during physiological stimuli other than exercise. Various sensors are used to detect muscle activity, movement and an increase in minute ventilation, temperature and mixed venous oxygen saturation. Rate-responsive modes include VVIR, DVIR and DDDR. Most modern implanted pacemakers have some programmable features.

Implantable cardioverter defibrillators are used in patients who have sustained ventricular tachycardia (VT) and syncope caused by VT. They are described according to a separate NASPE/BPEG code – the defibrillator code (Figure 4). The typical code is VVEV. Early models could deliver countershocks only, but now the pacemakers can cardiovert episodes of VT with anti-tachycardia pacing.

The NASPE/BPEG Defibrillator Code

Letter position	I	II	III	IV
Category	Shock chambe	Anti-tachycardia pacing	Tachycardia detection chamber	Anti-bradycardia pacing
	O = none A = atrium V = ventricle D = dual	O = none A = atrium V = ventricle D = dual	E = electrogram H = haemodynamic O = none	A = atrium V = ventricle D = dual

4

Surgery for patients with a pacemaker

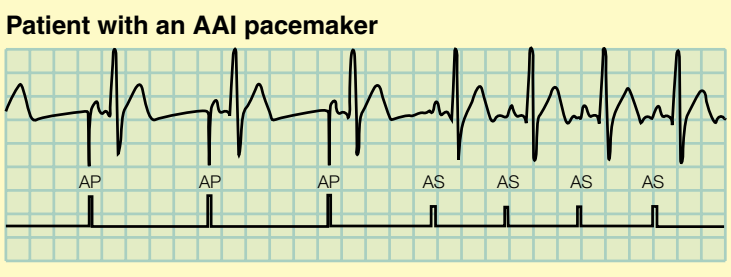
The two primary concerns during anaesthesia in patients with a pacemaker are whether the unit will continue to function and the consequences of using diathermy.

Preoperative assessment

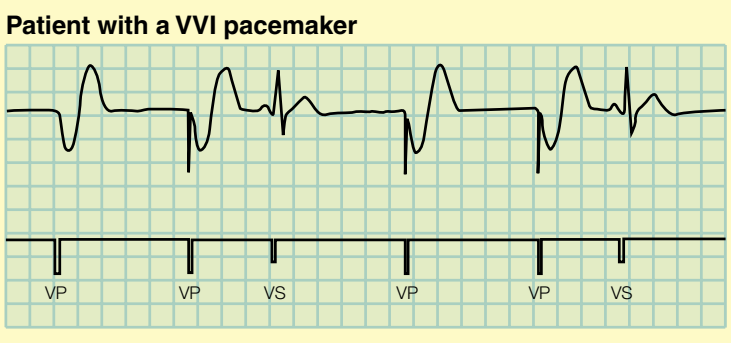
Full preoperative assessment must be undertaken. Of particular note in the history is the initial indication for pacemaker insertion and an assessment of the present function of the unit. The type and mode of pacemaker can be obtained from the patient's pacemaker identity card. The date of the most recent check should be noted with specific reference to the state of the battery. The ECG should be examined for evidence of sensing, pacing and capture (Figure 5). If the intrinsic heart rate is greater than the preset rate of the pacemaker, applying a magnet over the unit can check the correct functioning of the unit. This converts the unit to an asynchronous mode and captured beats should appear on the ECG. A chest radiograph should be taken to confirm the position of the leads. The potassium level should be determined because hypokalaemia increases the resting membrane potential and may lead to loss of capture. Acute hyperkalaemia decreases the resting membrane potential and thus increases ventricular irritability.

ECGs of patients with pacemakers

Patient with an AAI pacemaker



Patient with a VVI pacemaker



AP, atrium paced; AS atrium sensed; VP, ventricle paced; VS, ventricle sensed

Anaesthetic technique

The anaesthetic technique should avoid suxamethonium because muscle fasciculations can inhibit demand pacemakers (myopotential inhibition). The pacemaker senses skeletal muscle electrical activity, which can be caused by mechanical ventilation and myoclonic movements from induction agents (e.g. etomidate). Normothermia should be maintained because shivering can also change the performance of demand pacemakers. Evidence of mechanical, as well as electrical, heart function is provided by looking at the pulsemeter that accompanies a pulse oximeter. Mechanical and electrical function should be checked after any patient movement and also at the start of mechanical ventilation. An external converter magnet should be available in the operating room. This should not be placed over the pacemaker routinely because it may adversely affect a programmable unit; however, it may prove invaluable if the unit has to be converted to an asynchronous mode because of interference from diathermy. Atropine and isoprenaline should also be readily available in the event of pacemaker failure. Ventricular fibrillation is managed conventionally in pacemaker patients, but the paddles must not be placed directly over the pulse generator. The stimulation threshold may alter following defibrillation, therefore equipment must be available for temporary pacing or for non-invasive transcutaneous pacing.

Interference from diathermy

Current pacemakers are well shielded and are less likely to be affected by electrodiathermy than older types. Monopolar diathermy involves the passage of radio-frequency alternating current between an active electrode and a return electrode (the ground pad). The electrical artefact from the diathermy may be sensed as an intrinsic myocardial potential resulting in inhibition of the pacemaker. In some units, if the electrical interference continues, the unit can revert to a fixed rate until the interference ceases. To ensure that interference is minimized, the ground pad of the diathermy unit should be positioned close to the site of surgery and as far away as possible from the pacemaker unit and leads. Diathermy must also be used in short bursts. Current flow between the two elements of the diathermy unit should not cross the pacemaker system. Bipolar diathermy should be considered if interference continues with monopolar diathermy.

Pacemakers and unusual environments

MRI is contraindicated in pacemaker patients. If an MRI scan is absolutely necessary the pacemaker can be removed before the scan and reimplanted afterwards.

Lithotripsy is a safe procedure in patients with permanent pacemakers. The pulses from the lithotripsy should be timed with the electrical activity of the heart. Care must be taken when the pacemaker has been placed in the upper abdomen, because direct impulses should not be sent through the unit.

Other methods of cardiac pacing

Non-invasive transcutaneous pacing is useful following cardiac arrest and can buy time before a transvenous system can be inserted. Electrode patches are placed on the anterior and posterior aspects of the chest. The anterior patch should be the cathode and be placed along the left costal margin. It is important to avoid placing the electrode patches over a muscle mass, because it will be stimulated by the applied current. The anode should be placed posteriorly, inferior to the left scapula. Pacing is done with the lowest effective power output; this is usually 80 mA.

Temporary transvenous pacing: through central venous access, a temporary pacing wire can be inserted and connected to an external pulse generator. These devices can operate in either asynchronous (fixed rate) or in synchronous (demand rate) mode.

Defibrillators are used to deliver electrical energy to the myocardium, which depolarizes a critical mass of the muscle to allow a stable heart rhythm to be restored. In the defibrillator, direct current (DC) is stored and released in a controlled fashion. DC is preferred to alternating current (AC) because it is more effective and causes less damage to the myocardium. DC is also less likely than AC to cause arrhythmias. The electrical charge is stored in a capacitor. The electrical energy delivered from the defibrillator depends on the charge and the potential. When charged, the electrical energy is discharged across the patient's chest as a current pulse. The pulse is applied via two paddles, which are placed on the sternum and the left mid-axillary line at the 5th to 6th rib space. In order to ensure that most of the applied charge depolarizes the myocardium, the transthoracic impedance of the patient should be low. The impedance can be reduced by applying firm pressure and by the use of conductive gel pads.

Defibrillators can also be used to correct atrial fibrillation. Less energy is applied and the charge is synchronized so that it is delivered during the R wave of the cardiac cycle. Internal defibrillators are also used when the chest is open during cardiac surgery. The electrodes are applied directly to the heart and less energy is used.

Principles of Pressure Transducers, Resonance, Damping and Frequency Response

Mark R Stoker
Jeremy A Langton

Mark R Stoker is Specialist Registrar in Anaesthetics, Anglia Anaesthesia Training Scheme, at Norfolk and Norwich Hospital, Norwich, UK. He qualified from Oxford University and trained in anaesthetics in High Wycombe, Oxford, Cambridge and Peterborough.

Jeremy A Langton is Consultant Anaesthetist at Derriford Hospital, Plymouth. He qualified from Guy's Hospital, London, and trained in anaesthesia in London and Leicester. His research interests include airway reflexes and anaesthesia.

The types of pressure of most clinical importance to anaesthetists are those within the blood vessels, such as the central veins, systemic arteries, intracardiac chambers, pulmonary arteries and the pulmonary capillary wedge pressure. Pressures of additional clinical significance are those generated within enclosed spaces such as the skull (intracranial pressure) or limb compartments and CSF pressure.

All body pressures are composed of a static and a dynamic component.

- The static component ('hydrostatic' pressure) is related to the weight of fluid supported above the reference point and to any externally applied or internally generated pressure. Internally generated pressure within the skull or limb compartments is most commonly caused by tissue swelling within the confines of an enclosed space.
- The dynamic component of pressure is related to kinetic energy generated by the interaction of contractile cardiac activity with the blood vessel walls, to which is added changes in flow resulting from fluctuations in intrathoracic pressure with respiration. These cause blood flow and rapidly travelling pressure waves within the circulatory tree. Pressure waves within blood vessels are progressive and mechanical, in that they carry energy associated with their oscillation through the bloodstream. The dynamic component of intracranial and intracompartmental pressure waves is also associated principally with the flow of blood through vessels and is transmitted throughout the enclosed space.

Methods of direct pressure measurement

Accurate recording of '*in vivo*' pressure waveforms involves the conversion of the biological pressure wave into an electrical signal by a transducer. The resultant electrical signal can then be amplified, processed and displayed electronically. Two alternative transducer arrangements are used clinically for measuring biological pressure waveforms (Figure 1).

- A miniaturized sensor on the tip of a catheter can be placed in the patient at the point of measurement.
- A fluid-filled pathway (manometer) can be used to link a catheter or cannula to a transducer placed some distance away from the site of measurement.

Although catheter tip sensor systems are the most accurate, their disadvantages are that they are more expensive because of their greater complexity, they are prone to fibrin deposition if used within the circulation, and they cannot be recalibrated once *in situ*. Therefore, manometric transducer systems are in more widespread clinical use.

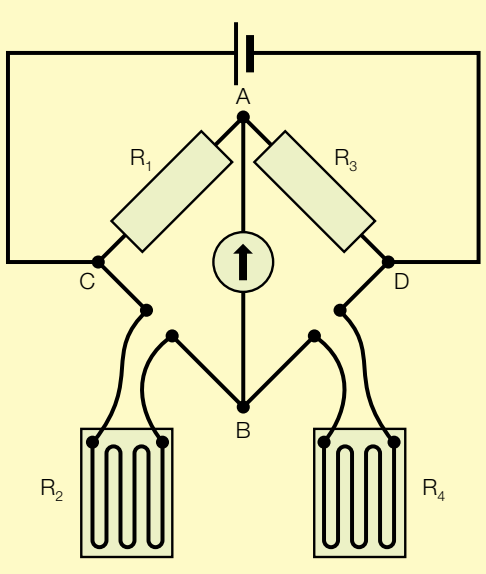
A miniaturized strain gauge is situated at the tip of the fine white catheter. The natural frequency of the transducer is over 10 kHz. *Photograph courtesy of Codman/Johnson & Johnson*.

A variety of methods is used to convert pressure changes into an electrical signal, the most common of which is the strain gauge. A strain gauge consists of a fine metal wire bonded to a diaphragm. Pressure changes distort the diaphragm and stretch the wire, thus altering its electrical resistance. Piezo-resistive strain gauges measure the change in the electrical resistance of silicon when exposed to pressure. A Wheatstone bridge is used to detect the change in electrical resistance (Figure 2). Strain gauges have been miniaturized to allow their use on the tip of catheters to measure intracranial pressure. Other catheter tip transducer systems use pressure-induced changes in the intensity of light travelling along a fibreoptic pathway to measure intracranial pressure.

Strain gauge transducer and Wheatstone bridge

Resistors R_2 and R_4 are strain gauges incorporated into a Wheatstone bridge circuit with conventional resistors R_1 and R_3. A potential difference is applied between points C and D. The bridge is adjusted so that it is balanced when no strain is applied, and no potential difference is measured between points A and B. When strain is applied to gauge R_4, the bridge becomes unbalanced, and a potential difference proportional to the strain is measured between points A and B. Gauge R_2 may be placed close to R_4 without strain being applied to compensate for changes in resistance due to temperature. Alternatively, the two gauges may be sandwiched back to back so that applied strain causes an increase in resistance within one gauge, which is matched by a fall in resistance in its partner. This amplifies the magnitude of the potential difference between points A and B, and increases the sensitivity of the transducer.



2

Setting up a pressure transducer
Setting up a transducer system correctly is crucial to its accuracy. Manometric sets must be carefully primed with sterile flush solution at room temperature without pressurization of the solution bag, to avoid micro and macro air bubble formation within the fluid pathway. A manometric transducer should be positioned at mid-heart level. Each 10 cm height difference from this point equates to a hydrostatic error of 7.4 mm Hg from the true pressure reading.

All pressure transducers require zero balancing to atmospheric pressure before use, and at regular intervals thereafter, to compensate for drift. This may be impossible for catheter tip sensors once *in situ*. The electronic monitoring equipment, to which the transducer system is connected, must also be suitably calibrated.

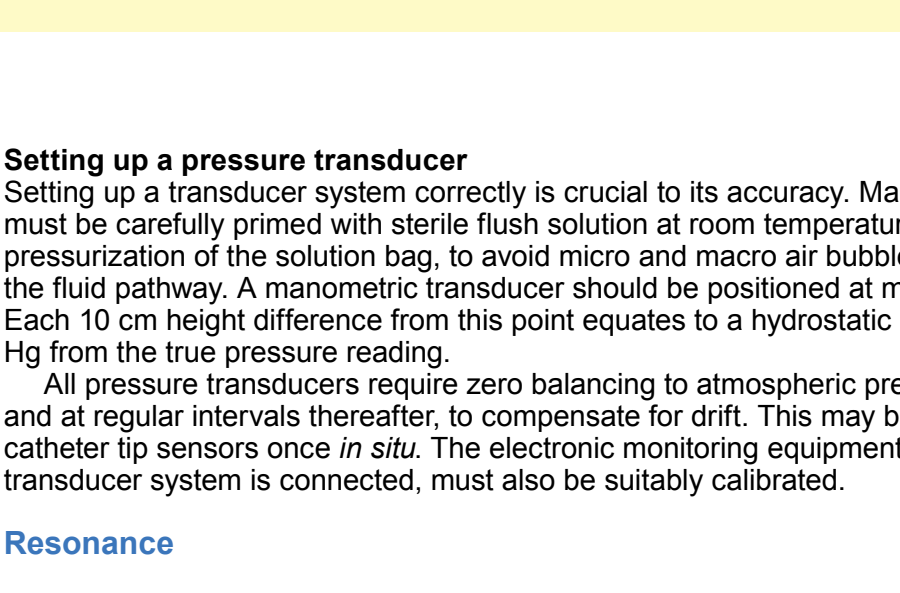
Resonance

Resonance occurs when the frequency of the *in vivo* driving oscillations matches the natural frequency of the driven transducer system, and oscillations of large amplitude are induced (Figure 3). This results in significant error by overshooting of the peaks and troughs in the actual pressure waveform, with an overestimation of the systolic pressure and underestimation of the diastolic pressure.

The natural or resonant frequency is the frequency at which the undamped transducer system oscillates freely with maximal amplitude. The natural frequency of a transducer system is proportional to the square root of the stiffness of the diaphragmand is inversely proportional to the square root of the mass of the oscillating fluid and diaphragm (Figure 3). The mass of oscillating fluid is proportional to the length and radius of the fluid pathway and density of fluid.

The resonant frequency of the system can therefore be raised by including a short, stiff, parallel-sided catheter joined to short, stiff, narrow-bore, interconnecting tubing, together with a transducer with a stiff diaphragm. Increasing tubing length from 30 to 150 cm can reduce resonant frequency by over 50% and from 15 to 150 cm may decrease resonant frequency from 30 to 7 Hz, leading to an overestimation of systolic blood pressure by up to 17%.

Resonance



As the frequency of driving oscillations increases, the amplitude of induced oscillations rises to a maximum at the natural or resonant frequency of the transducer system (f_0u). If the system is damped by absorbing some of the energy of the induced oscillations, the maximal amplitude attained is reduced. Damping also reduces the resonant frequency of the transducer system (from f_0u to f_0d), and extends the flat range of the system from XY to XZ. The resonant frequency of a manometric transducer system is calculated as:

$$\text{Resonant frequency} = \frac{1}{2\pi}\sqrt{\left(\frac{\text{stiffness of diaphragm}}{\text{mass of oscillating fluid and diaphragm}}\right)}$$

3

Damping

Damping is the process whereby some of the energy of the driven oscillations within the transducer system is absorbed, thus reducing their amplitude. Damping also reduces the resonant frequency of a transducer system (Figure 3), but this relationship is complex. Damping in the correctly functioning manometric system arises mainly from viscous drag in the fluid pathway, tubing connections and stopcocks. Damping increases by the third power of any decrease in the diameter of the tubing (33% narrower tubing increases damping by 135%); a far greater change than the rise in resonant frequency. As a consequence, the diameter of interconnecting tubing has the greatest effect on system performance.

Excessive damping, sufficient to obtund the shape of the pressure waveform, commonly results from compressible large air bubbles, a blood clot, soft compliant connector tubing, numerous connections and stopcocks, and catheter kinks within the system.

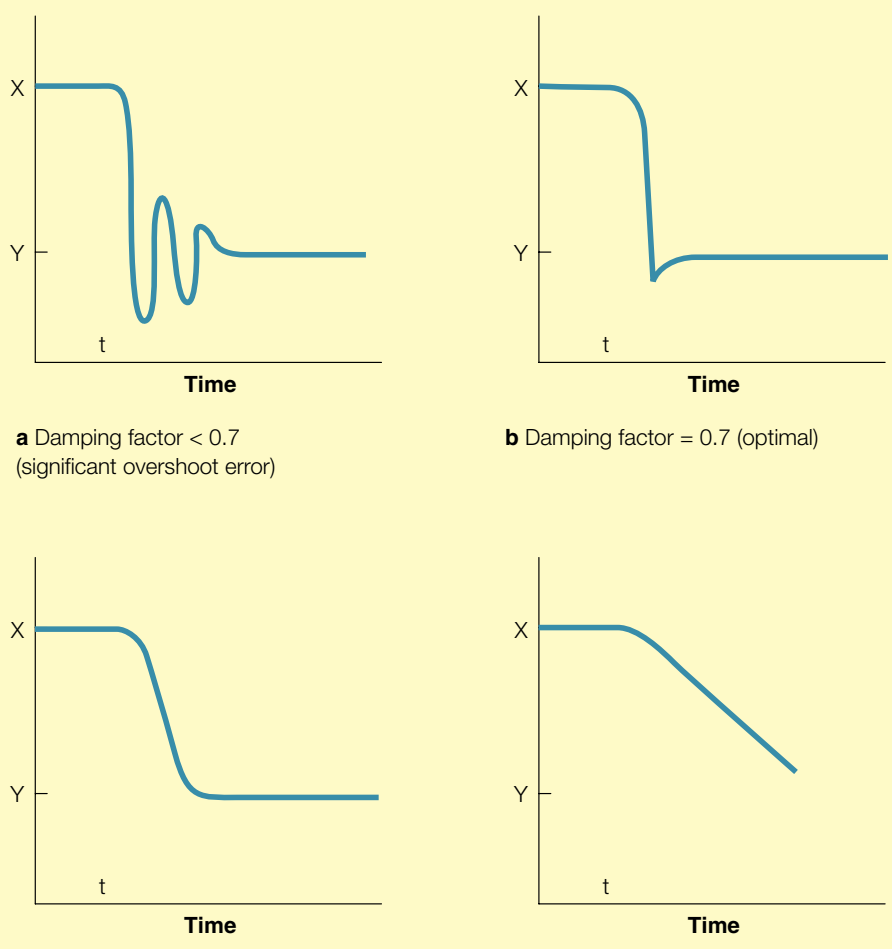
The damping factor is an index of the tendency of a transducer system to resist oscillation.

- Critical damping corresponds to a damping factor of 1, and represents the amount of damping required such that when a stepwise change in pressure is applied, the system returns to rest in the shortest possible time without overshooting the baseline (Figure 4).
- In contrast, optimal damping is the amount of damping necessary to maximize the frequency response or flat range of the system and corresponds to a damping factor of 0.7 (Figure 4). At this level, overshoot of the baseline is limited and the response of the pressure transducer accurately reflects the actual pressure change up to two-thirds of the natural frequency of the system in a close to linear fashion.
- Excessive damping with factors greater than 1 causes a significant delay between the input arriving at the transducer and an output being generated. This is called phase shift (Figure 4) and is measured in degrees. Distortion of the output by phase shift is minimal with a damping factor of 0.7.

Damping of a manometric transducer system

a In an underdamped transducer system, where the damping factor is < 0.7, significant overshoot and subsequent oscillation occurs when a stepwise pressure change from X to Y is imposed at time t. This results in a significant overestimation of the magnitude of the pressure change.
b In an optimally damped system, where the damping factor is 0.7, overshoot is limited to 6–7% of the initial pressure change and no oscillation occurs.
c In a critically damped system, where the damping factor is 1.0, the change in pressure is measured accurately with no overshoot.
d In an excessively damped system with a damping factor > 1.0, the full magnitude of the pressure change may not be registered.

With increasing degrees of damping, the system is progressively slower to respond to the applied change in pressure, and the increasing delay in the transducer output is termed phase shift

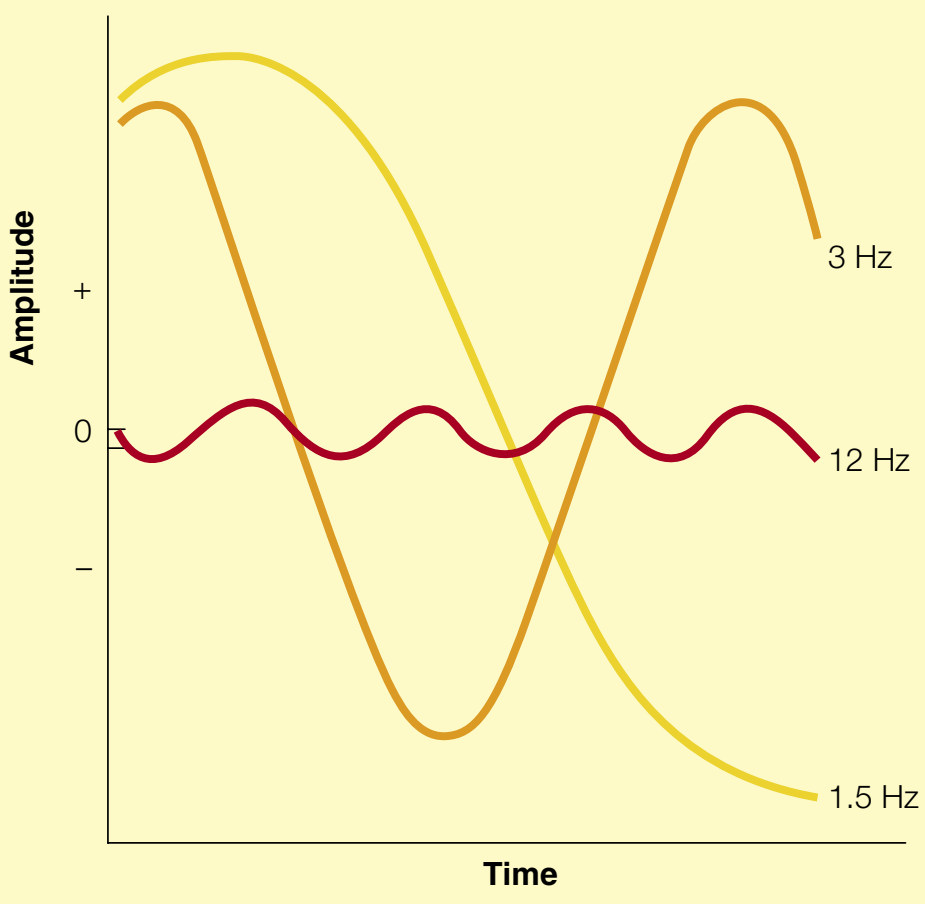


a Damping factor < 0.7 (significant overshoot error)
b Damping factor = 0.7 (optimal)
c Damping factor = 1.0 (critical)
d Damping factor > 1.0 (excessive with marked phase shift)

Waveforms

By means of Fourier analysis, it is possible to split complex waveforms mathematically into a summation of simple sine waves or ascending harmonics, each of which has an increasing frequency and decreasing amplitude (Figure 5). Summation of the first eight to ten harmonics of an arterial blood pressure waveform gives a reasonably accurate representation of its shape. This number of harmonics is required to track accurately the initial steep rate of rise in the pressure waveform corresponding to left ventricular ejection.

Fourier analysis of the arterial pressure waveform



The first or fundamental harmonic (1.5 Hz) together with the second (3 Hz) and eighth (12 Hz) harmonics of a single blood pressure beat waveform are shown, for a heart rate of 90 beats/minute. Progressively higher harmonics display decreasing amplitude. As a consequence, only the first 8–10 harmonics need to be summed to reproduce the shape of the arterial pressure waveform accurately

Minimum bandwidth
Minimum bandwidth is the minimum frequency range over which measurement by a transducer system is sufficiently accurate to reproduce the first eight harmonics of the *in vivo* pressure signal, resulting in an accurate electronic representation of the shape of the pressure waveform. For the measurement of arterial blood pressure, this is equal to eight times the fundamental frequency of the expected heart rate. At 90 beats/minute (fundamental frequency of 1.5 Hz), the minimum bandwidth would be 12 Hz, with the first eight harmonics comprising sine waves with frequencies of 1.5, 3, 4.5, 6, 7.5, 9, 10.5 and 12 Hz. At a heart rate of 120 beats/minute (2 Hz), minimum bandwidth would be 16 Hz. Progressively higher harmonics display rapidly decreasing amplitude, contribute less to the shape of the transduced waveform and are eventually lost within the 'noise' of the measuring system. Accurate reproduction of the amplitude of the pressure waveform, rather than its shape, requires accurate measurement of only the first five harmonics of the fundamental frequency.

Frequency response
The frequency response or flat range of a transducer system is the highest frequency to which the system can be exposed before it registers significant overshoot. Accurate measurement to a limit of 10% greater than the actual pressure is generally acceptable. The frequency response must be equal to, or greater than, the minimum bandwidth. The frequency response of the measuring system depends on its resonant frequency and the amount of damping.

The ideal measuring system has a resonant frequency much higher than the frequencies to be measured; frequencies up to 10–20% of the resonant frequency are accurately reproduced and no damping is required. This is because initial resonance occurs at a frequency much higher than the necessary bandwidth for accurate waveform reproduction. Catheter tip sensors are the closest available systems to this ideal. For the more commonly used manometric systems, the total measuring chain (consisting of catheter or cannula, tubing, stopcocks and transducer) has a much lower resonant frequency, and damping is therefore vital for increasing accuracy. Optimally damped systems can reproduce frequencies up to 67% of the resonant frequency accurately. Continuing the calculations introduced above, an optimally damped transducer system with a resonant frequency of 30 Hz or more will accurately reproduce the shape of the arterial pressure waveform.

Anaesthesia for the Obese Patient

David W Noble
Fiona McCallum

David W Noble is Consultant in Anaesthesia and Intensive Care at Aberdeen Royal Infirmary. He trained in Aberdeen and Edinburgh. He is interested in the pharmacological and immunological aspects of anaesthesia and intensive care.

Fiona McCallum is Specialist Registrar in Anaesthetics at Grampian University Hospitals NHS Trust. She qualified from Edinburgh University and worked in Stirling and Elgin before moving to Aberdeen. She is interested in medical education.

The incidence of obesity, with its attendant health risks, continues to rise. Consequently, increasing numbers of obese patients are presenting for surgery and their perioperative care presents a significant challenge to the anaesthetist. In 1997, in Britain, 13% of men and 16% of women were considered to be obese. Obesity is defined according to the body mass index (BMI) or with reference to the ideal body weight (IBW) (Figure 1).

- BMI = weight (kg)/[height (m)]^2
- IBW (kg) = height (cm) – 100 (men) or 105 (women).

Classification of obesity

	Body mass index	Percentage above ideal body weight
Overweight	> 26	30
Obese	> 30	40
Morbidly obese	> 40	100

1

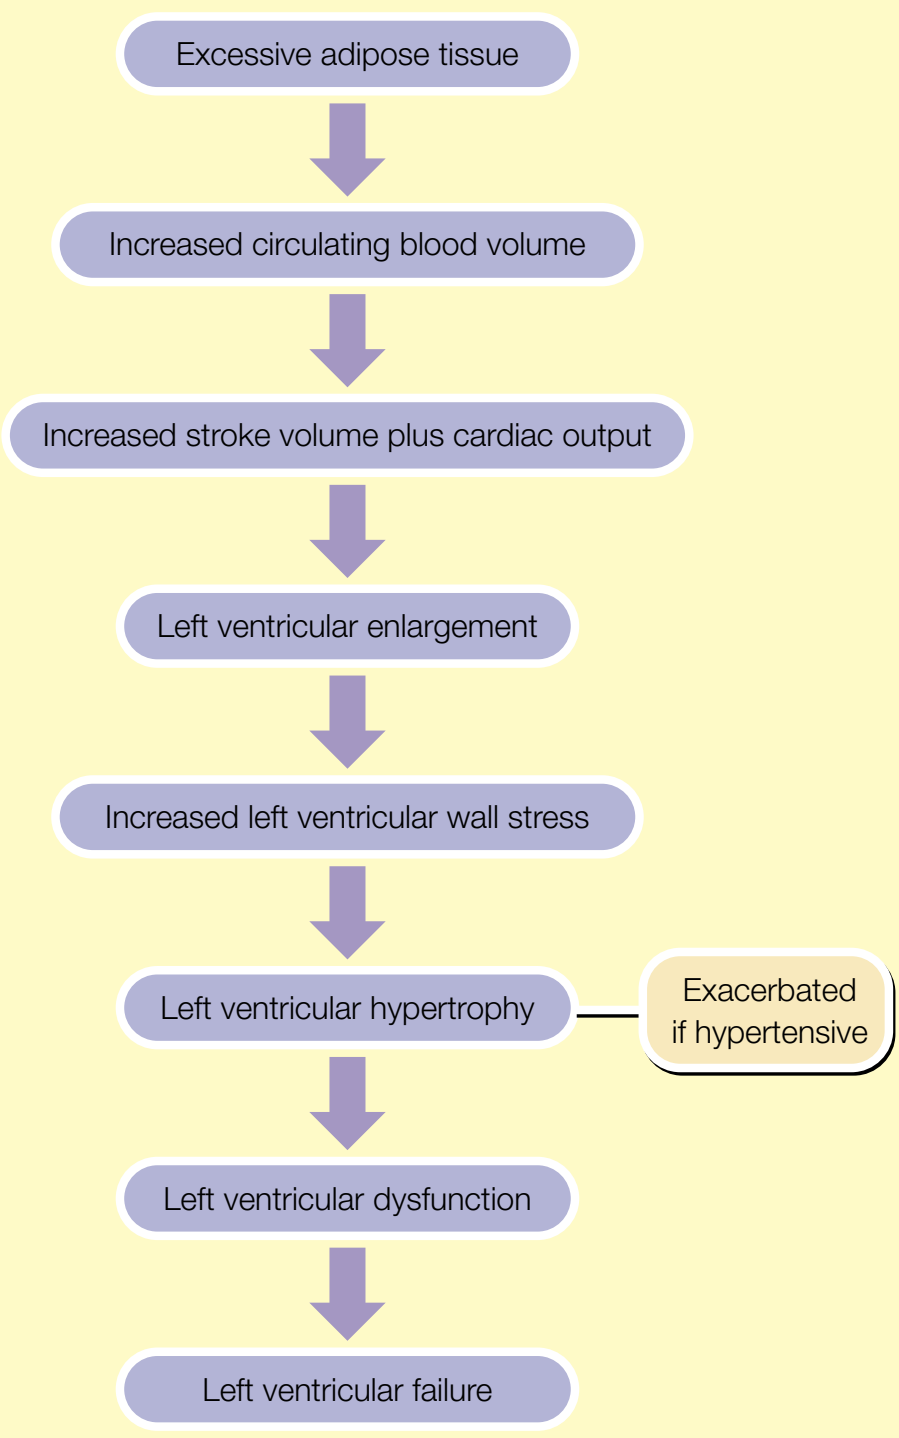
Pathophysiological effects of obesity

The pathophysiological effects of obesity are wide ranging and are greatest in the morbidly obese, though they occur in all obese individuals.

Cardiovascular system

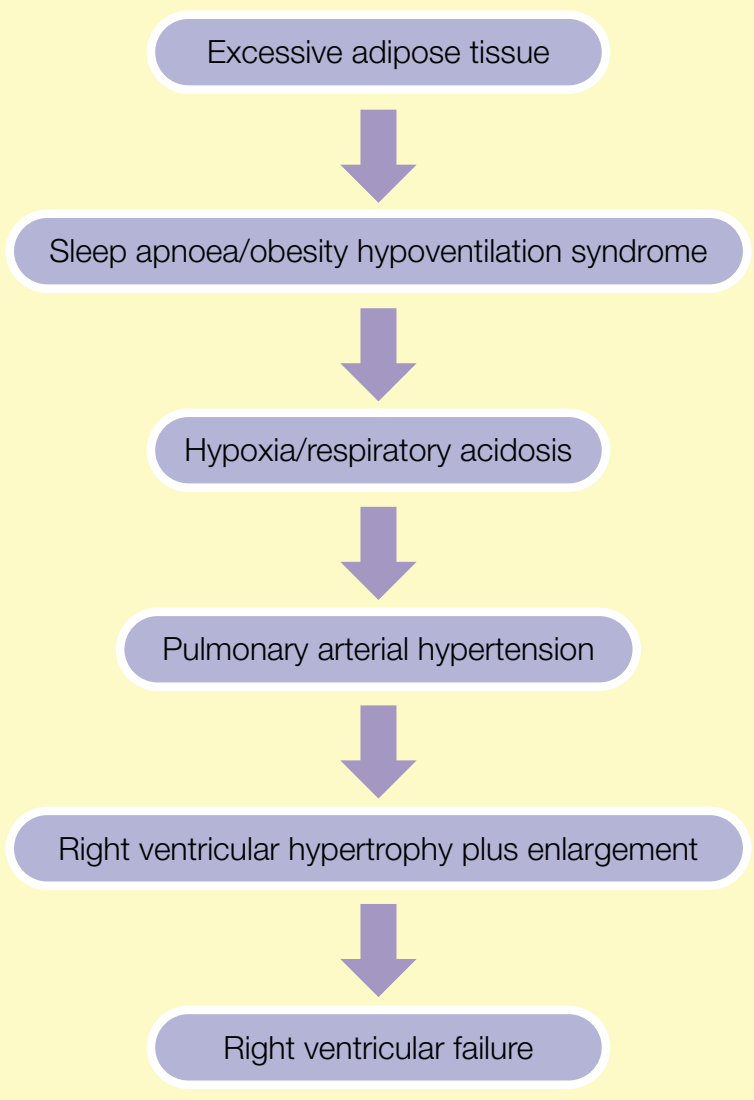
Cardiac structure and function: cardiac output and blood volume are increased in obesity to meet the increased metabolic demands of a greater body mass. Chamber dilatation and ventricular hypertrophy occur to reduce wall stress and can progress to ventricular dysfunction and cardiac failure – a condition known as obesity cardiomyopathy (Figure 2). Cor pulmonate may also develop (Figure 3). These changes are related to the severity of obesity and are improved by weight loss.

Development of cardiomyopathy in obese patients



2

Development of cor pulmonale in obese patients



3

Hypertension is present in 60% of obese individuals and is severe in 10%. The aetiology remains unclear, but weight loss reduces blood pressure.

Coronary artery disease: the role of obesity as a risk factor for coronary disease is difficult to evaluate because of the association between obesity and hypertension, diabetes mellitus and hypercholesterolaemia, which are all coronary risk factors. There is an association between central obesity and an early age of onset of obesity, and the development of coronary artery disease.

Cardiac arrhythmias may occur secondary to chamber dilatation, ischaemic heart disease or fatty infiltration of the conducting system.

Respiratory system
The increased metabolic demands of obesity also require an increased minute ventilation to meet the increase in oxygen consumption and carbon dioxide production. The work of breathing is further increased because of the reduction in chest wall and lung compliance. Obese patients tend to take rapid shallow breaths, leading to greater mismatching of ventilation and perfusion. There is a reduction in functional residual capacity (FRC) because the increased adipose tissue in the chest wall and abdomen limits diaphragmatic excursion. If the FRC falls below closing volume, small airway closure occurs resulting in intrapulmonary shunting and hypoxaemia. This situation may occur in obese individuals under normal circumstances and is exacerbated by increasing age, the supine position and general anaesthesia (Figure 4). As a result of the above mechanisms, obese patients may become chronically hypoxic and develop secondary polycythaemia, pulmonary hypertension and ultimately right ventricular failure.

Relationship between functional residual capacity and closing volume

FRC, functional residual capacity; CV, closing volume

4

Obesity hypoventilation syndrome occurs in 4–10% of morbidly obese patients. It is characterized by chronic hypoxia and its sequelae, in association with a decreased responsiveness to carbon dioxide, and results in hypoventilation and hypercapnia.

Airway problems: excess adipose tissue in the soft tissues of the head and neck makes airway problems more likely, and intubation is difficult in 13% of this pateint population. Obesity also predisposes to the development of the sleep apnoea syndrome, which is characterized by upper airway obstruction and hypoxic episodes when the conscious level is reduced (e.g. during sleep). Classically, these patients have a history of heavy snoring, periods of apnoea during sleep and daytime somnolence because of disturbed sleep at night.

Gastrointestinal system
Hiatus hernia and gastro-oesophageal reflux are more common in obese individuals. Fasting, obese patients have higher residual gastric volumes of lower pH than the non-obese. Liver disease, mainly in the form of cholelithiasis, and fatty infiltration are more common in obese individuals, but hepatitis, fibrosis and cirrhosis can also occur. Obesity is a recognized risk factor for the development of hepatitis following volatile anaesthesia.

Endocrine system
Endocrine disturbances such as hypothyroidism and Cushing's syndrome may have a causal role in obesity. The most important consequence of obesity for the endocrine system is the development of diabetes mellitus.

Anaesthetic management

Preoperative assessment
Common to all patients, preoperative assessment comprises the history, physical examination and preoperative investigations, as well as discussing with the patient the proposed anaesthetic technique and perioperative care plan. The following aspects of the history and examination are of particular importance in obese patients.

- Evaluation of the severity of any cardiorespiratory compromise.
- Careful airway assessment to decide safe airway management.
- Assessment of acid aspiration risk (this also influences airway management).
- Confirmation of the presence of conditions associated with obesity (e.g. diabetes).
- Examination of potential sites for venous access, which may be problematic.
- Examination of the spine if epidural or spinal anaesthesia is contemplated.
- Establishment of a rapport and providing relevant information to the patient.

Preoperative investigations depend on the findings of the history and examination, and the intended surgery, but the following investigations may be helpful in obese patients:

- urinalysis to screen for diabetes
- full blood count to identify polycythaemia
- urea and electrolytes, which may be altered by antihypertensive or diuretic drug therapy
- ECG which may show ventricular hypertrophy, arrhythmias or ischaemic changes
- chest radiography, which is useful for determining heart size, signs of pulmonary oedema and as preoperative baseline
- pulmonary function tests to reveal any restrictive defects; any obstructive component should prompt a trial of bronchodilator therapy
- arterial blood gases to confirm hypoxia and hypercapnia; the response to oxygen therapy should be elicited if the patient is hypoxic on air
- echocardiography and exercise testing which may help to assess the severity of cardiac compromise
- specialist opinions for optimization of medical therapy before elective surgery.

Pharmacological considerations: the changes in blood volume, cardiac output, adipose tissue and total body water content that occur in obesity can alter drug pharmacokinetics.

Intravenous agents – propofol kinetics appear unaltered though recovery from thiopental (thiopentone) and benzo-diazepines may be prolonged.

Volatile anaesthetics – there is little evidence that recovery is prolonged in obesity despite the lipophilicity of these agents. Toxicity from metabolic products may be reduced by using relatively insoluble and minimally biotransformed anaesthetics (e.g. isoflurane, desflurane).

Muscle relaxants – pseudocholinesterase activity is increased, but doses of suxamethonium, less than 1 mg/kg, have been shown to provide adequate vocal cord paralysis. The dose and duration of action of atracurium is unaltered. Vecuronium has a prolonged duration of action and the dose should be calculated according to lean body weight.

Opioids – the doses of alfentanil and remifentanil should be calculated according to lean body weight. Although this restriction does not apply to other opioids, careful dose titration of all opioids is warranted because of their respiratory depressant effect.

Regional anaesthesia avoids the problems associated with general anaesthesia in obesity but is not without problems. Landmarks may be difficult to define and long needles may be required. For spinal or epidural anaesthesia the sitting position aids location of the midline and a nerve stimulator can aid needle placement for other blocks. Smaller volumes of local anaesthetic solutions should be used for spinal and epidural blocks, because spread is greater in obese patients. A final consideration, if a regional technique alone is planned, is the ability of the patient to tolerate the position required for surgery. Some obese patients are unable to lie flat because of respiratory compromise, which may be exacerbated by a regional block affecting thoracic segments. A combination of regional and general anaesthesia may be the optimal technique.

Pre-medication: H_2-antagonists or proton pump inhibitors combined with a prokinetic agent can be prescribed because of the risk of acid aspiration. An anxiolytic can be given, but heavily sedative or opioid premedication should be used with caution and perhaps avoided in the morbidly obese. The oral route is preferable to the intramuscular or subcutaneous routes because absorption from these sites is unpredictable.

Induction and airway management
Tracheal intubation and controlled ventilation are required for all but the shortest procedures in carefully selected patients. During the preoperative assessment, a decision should be made regarding the need for an awake fibre-optic intubation, but difficult intubation equipment and a range of face masks, laryngoscope blades, bougies and other airway adjuncts must always be available immediately. For difficult cases, two anaesthetists and an experienced assistant should be present. Careful positioning of the patient's head and shoulders will make airway management and intubation easier, and a rapid-sequence induction technique should be used because of the risk of acid aspiration. Adequate pre-oxygenation is essential because the combination of increased oxygen consumption and a reduced oxygen reservoir can cause a precipitous fall in oxygen saturation once apnoea occurs. Suxamethonium remains the muscle relaxant of choice because of its rapid onset and offset of action. The choice of induction agent depends on individual circumstances (e.g. cardiorespiratory disease) and obesity *per se* does not influence drug selection. All the commonly used anaesthetic agents have been used successfully in obese patients.

Maintenance and intraoperative care
A balanced anaesthetic technique with muscle relaxation and controlled ventilation, combined with regional anaesthesia is appropriate for many patients. As with induction agents, the choice of agent used to maintain anaesthesia depends on the patient's co-morbidities, the duration of surgery and whether elective ventilation is planned postoperatively. Some important aspects of intraoperative care in obese patients are described below.

Operating table – the table must be wide enough for the safe positioning of the patient and strong enough to take the patient's weight.

Staff – adequate numbers of staff must be present for patient transfer. The patient should be anaesthetized on the operating table so that only one transfer is required with the patient anaesthetized.

Monitoring the correct size of blood pressure cuff is required for the accurate measurement of blood pressure. Arterial cannulation is often desirable for serial blood gas analysis during and after surgery as well as for arterial pressure monitoring. Capnography must be available for induction to confirm correct tracheal tube placement. Central venous monitoring may be necessary for venous access and will aid fluid management, particularly in those with cardiac compromise. The use of an ultrasound probe is recommended to aid placement. Pulse oximetry is an essential tool for rapid detection of hypoxaemia during and after surgery.

Controlled ventilation is almost always required to ensure adequate gas exchange, often with a combination of high-inspired oxygen concentration and the application of positive end expiratory pressure. High inflation pressures may be unavoidable particularly if the lithotomy or Trendelenburg positions are used.

Blood loss is likely to be greater in the obese because surgery is technically more difficult. Adequate venous access must be secured and the threshold for cross-matching of blood may need to be reduced.

End of surgery – if extubation at the end of surgery is intended, it should not be attempted until residual neuro-muscular blockade has been reversed, the patient is awake, cooperative, has a good cough, and an acceptable respiratory pattern and oxygen saturation.

Postoperative complications
Postoperative complications are more common in obese patients, therefore transfer to a high dependency unit or ICU should be considered. Some patients undergoing minor surgery may be nursed safely on the general ward.

Respiratory complications: basal lung collapse during anaesthesia and resulting hypoxia is common, and is exacerbated by
the respiratory depressant effects of residual anaesthetic agent and/or opioid therapy in the postoperative period, as well as the effects of surgery. Collapsed lung segments also act as a focus of infection.

Hypoxia can also occur as a result of airway obstruction if the conscious level is reduced (e.g. in patients with obstructive sleep apnoea receiving opioids).

Respiratory complications may be minimized by:

- humidified oxygen therapy with pulse oximetry
- adequate 'balanced' analgesia
- aggressive physiotherapy and early mobilization
- using continuous positive airway pressure in patients at risk of airway obstruction during sleep or sedation
- nursing patients upright or in the lateral decubitus position is preferable to a recumbent position.

Thromboembolic complications are more common in obese patients. Adequate prophylaxis for deep venous thrombosis is mandatory and early mobilization should be encouraged.

Wound infections: longer incisions, greater wound retraction and the poor blood supply to adipose tissue make wound infections more common in the obese.

Postoperative analgesia
Adequate analgesia allows deep breathing and coughing, facilitates chest physiotherapy and aids early mobilization, which reduces the incidence of postoperative complications. In obese patients, various options for postoperative analgesia, either alone or in combination, are available.

Parenteral opioids are administered intravenously, most commonly using a patient-controlled analgesia device. Standard dosing regimens are adequate for obese patients. Careful monitoring of respiratory parameters and conscious level is necessary in obese patients and supplemental oxygen is essential.

Epidural analgesia using low-dose local anaesthetic solutions, alone or in combination with opioids, is the best method of providing analgesia following thoraco-abdominal surgery in obese pa♦ients, provided the epidural can be sited successfully. It may also be useful following pelvic or lower limb surgery.

Local anaesthetic techniques: local anaesthetic blocks performed for surgery will last for a variable length of time into the postoperative period. By using a catheter technique, useful analgesia can be extended.

Supplementary analgesics: though seldom sufficient alone, the use of regular paracetamol and non-steroidal anti-inflammatory drugs (if not contraindicated) has an additive effect with opioid or epidural analgesia. A balanced approach to analgesia may be particularly helpful in obese patients.

Hepatitis and HIV Infections

Rick Keays
Neil Soni

Rick Keays is Consultant Intensivist at the Chelsea and Westminster Hospital, London, UK

Neil Soni is Consultant at the Chelsea and Westminster Hospital, London, UK.

Blood-borne viral infections have implications for anaesthesia and intensive care because of their potential for transmission and as disease entities.

Hepatitis

Recently, there has been an explosion in the understanding and diagnostic subcategorization of viral hepatitis. The terminology has changed from either 'serum' or 'epidemic' hepatitis to a recognition of the many causative agents of hepatitis acquired either from faecal contamination (hepatitis A and E) or parenterally via body fluids (hepatitis B, C, D and G). Many hepatologists were aware that hepatotropic agents were responsible for the hepatitis seen in patients in whom neither hepatitis A or B could be identified and an increasing alphabet is now filling the gap formerly known as non-A, non-B hepatitis.

Hepatitis A virus (HAV)
HAV is a small RNA virus that causes acute hepatitis only. It is a common cause of both sporadic and epidemic hepatitis and is spread by the faeco-oral route. Symptoms appear about 2 weeks after infection, with an associated rise in transaminase levels and excretion of viral particles in the faeces. At the same time, anti-HAV and IgM anti-HAV antibodies appear; the former persist for life and the latter disappear within 3–12 months of infection. HAV antigen is present in the stools in the late prodrome and early symptomatic phase of the infection, and its presence in serum indicates viral shedding. The features of acute hepatitis and the presence of IgM anti-HAV and HAV antigenaemia are usually diagnostic. The disease is self-limiting and seldom leads to fulminant hepatic failure. It is possible to become infected with HAV after transfusion, if the donor was in the viraemic phase of the illness. This risk is estimated to occur with 1/1 million units of blood and its rarity is explained by the absence of a chronic carrier state with HAV.

Treatment: vaccines are available, but are not wholly effective in controlling outbreaks. They are not recommended for children under 2 years of age, but can be given to pregnant women because the virus is inactivated.

Hepatitis B virus (HBV)
HBV is a DNA virus and has the smallest genome of any DNA virus infecting humans. It has four gene regions: the S or envelope region (HBsAg), the C or nucleocapsid region (HBcAg and HBeAg), the P region (DNA polymerase), and a fourth region which is a transactivator of HBV replication (HBxAg). Genotypic variants exist with a geographical distribution similar to human ethnic distribution. In the UK, the prevalence is about 0.1%. As many as 10^{13} viral particles can be found in 1 ml of infected blood; this compares with 10^{1}–10^{4} particles in HIV-infected blood. HBV can survive in dry blood for up to 1 week. Trans-fusion-transmitted HBV has, however, been dramatically reduced since the introduction of third-generation screening tests in the mid-1970s.

Symptoms usually appear about 2 months after infection, with a concomitant rise in alanine aminotransferase (ALT) in the acute phase. HBsAg, HBeAg and HBV-DNA are all detectable in the blood slightly before the appearance of jaundice and other symptoms. Also, at this time, anti-HBc and IgM-anti HBc become evident, denoting acute infection. A month later, antibodies to HBe appear, resulting in clearance of HBeAg and a gradual reduction in HBV-DNA levels. Some months after this, HBsAg clears from the blood and anti-HBsAg antibodies become detectable. In 10–25% of patients, a chronic carrier state develops and there is persistence of HBV-DNA, indicating continuing viral replication, and HBsAg and HBeAg, which if found together indicate continuing viral replication with a high level of infectivity and active liver disease. The development of anti-HBe antibodies, which can occur at any time, implies disease resolution and quiescence of liver disease. However, in the face of increasing host immune activation, the virus can mutate to different forms that replicate, though they may not produce HbeAg. These forms are infective and can cause severe liver disease.

Treatment: vaccination is effective in eradicating HBV from the population. However, there are genetic variants of the HBsAg epitope cluster, which results in poor binding of some polyclonal and monoclonal antibodies. These variants are capable of transmission and of causing liver disease, and may be best dealt with by administering polyvalent (multiple antigen) vaccines.

In patients with chronic disease, 10–15% develop cirrhosis and 10% develop hepatocellular carcinoma. Interferon-α is effective in achieving sustained response rates in 30–40% of patients with chronic hepatitis B and for those who do not respond, nucleoside analogues may be promising adjuncts. In un-immunized individuals, percutaneous exposure leads to seroconversion in 12% (if infected blood is only HBsAg positive) rising to 30% if infected blood is also HBeAg positive. In such cases, the exposed individual should be given hepatitis B immunoglobulin and the recombinant DNA vaccine as soon as possible.

Seroconversion rates are high, therefore it is extremely important that healthcare workers are properly immunized, but vaccine failure can occur in as many as 12%. Achieving a protective titre of antibody will sometimes last up to 9 years, though boosters are recommended more regularly than this.

Hepatitis delta virus (HDV)
HDV is a small defective RNA virus, which has some similarity to satellite viruses that infect higher plants. It causes liver disease only in those already infected with HBV (superinfection) or where HBV is transmitted simultaneously (co-infection). In the acute phase, the disease has a high mortality and, in the chronic phase, there is a high risk of developing cirrhosis. HBV is the helper virus and provides surface antigen for the delta particle envelope, without which it is non-infectious.

Diagnosis depends on the circumstances. In cases of co-infection, anti-HDV may never become detectable or is detectable only in the convalescent serum sample, whereas in superinfection anti-HDV may rise to high titres. The level of IgM anti-HDV is also useful for diagnosis, but it tends to be present at low levels in some patients with chronic delta hepatitis. HDV-RNA can be detected in the serum of infected patients, but its disappearance does not mean the disease has been eradicated.

Treatment: interferon therapy has transient effects. The virus replicates by RNA control without the need for protein enzymic assistance and this ribozymic activity is attracting interest as a potential target for therapy.

Hepatitis C virus (HCV)
HCV was identified a decade ago and appeared to be responsible for most non-A, non-B post-transfusion viral hepatitis. It is an RNA virus that causes both acute, though seldom fulminant, hepatitis and chronic hepatitis. There is an 85% chance of the infection becoming chronic with the attendant risks of developing cirrhosis (20%) and hepatocellular carcinoma (1–5%). In addition, there is an increased chance of developing a variety of non-hepatic autoimmune conditions. Its prevalence worldwide is about 1%, though it is less in the UK.

Exclusion of blood donors with known risk factors for HIV, or with raised transaminases or antibodies to hepatitis B core antigen has reduced the incidence of transfusion-related non-A, non-B hepatitis. However, the real breakthrough came with the introduction of a test for antibodies to HCV. It is now estimated that the risk of developing HCV is about 1/103,000 transfusions. Although transfusion is an uncommon cause of HCV infection, once a patient is infected the likelihood of complications is high. For percutaneous exposure, the seroconversion rate is as high as 6–10%, which represents a risk 10–33 times greater than for HIV, but 10–20 times less than for HBV. This correlates very closely with the average measured viral loads encountered in these three diseases.

The variants of HCV seem to be distributed on geographical grounds and depend on the type of exposure that an individual has encountered. Type 3 occurs more commonly in intravenous drug users, whereas types 4, 5 and 6 seem to have some geographical concentration. HCV-RNA can be detected in the serum about 1 month after exposure to the virus and symptoms and transaminasaemia develop 1 or 2 weeks later. Symptoms are usually mild in the acute stage and may not include jaundice. It seldom progresses to a fulminating hepatitis. Anti-HCV is detected only after symptoms have appeared, generally 4–24 weeks later, and is of little use in establishing the diagnosis of acute HCV. The clinical disease may be related to different genotypes, for example hepatocellular carcinoma may be linked with subtype 1b, which is also more resistant to interferon therapy.

Treatment: response rates for chronic HCV infection treated with interferon are low (10–25%), especially in Europe and the USA, which may be explained by a higher prevalence of HCV-1b. Post-exposure immunoglobulin is not useful and there is no available vaccine against HCV. In the USA, the Food and Drug Administration has recently approved the combination of interferon and ribavirin, which several studies have shown leads to a sustained response in 40–50% of patients.

Hepatitis E virus (HEV)
HEV is similar to HAV in that it is contracted enterally in sporadic or epidemic outbreaks. It leads to an acute illness with no chronic carrier state, but mortality is increased in pregnant women in endemic regions. Diagnosis is usually made on the clinical and laboratory features of acute hepatitis, in the absence of serological markers for other forms of viral hepatitis, and a history of recent travel to endemic areas. Viral RNA can be detected with molecular amplification techniques and assays for antibody to the virus are available.

Hepatitis G virus (HGV, GBV-C)
Even with the discovery of HCV, it was appreciated that there remained a subgroup of transfusion-related hepatitis that was non-A to non-E related. Two separate centres discovered the viral sequence; one from a surgeon (initials GB) and one from a West African individual. Three related sequences are known as GBV-A, GBV-B and GBV-C, of which the first two are thought not to be pathogenic to humans whereas the immunoassay industry is holding out hopes for the latter. This somewhat confusing nomenclature rests under the canopy of HGV. It is doubtful whether HGV is especially hepatotropic or causes any particular disease. The prevalence of HGV viraemia, at least among donors in the USA, is about 1–2%, whereas in Africa it is at least 12%. Thus, the virus can be transmitted by blood transfusion and this raises some ethical considerations because molecular techniques have demonstrated the presence of a viral sequence that can be transmitted. For example, is it right knowingly to infect others and will the repeated transmission of this virus lead to pathogenicity? In 10% of individuals, seroconversion will follow percutaneous exposure to infected blood.

Other viruses
The potential for transmitting other viruses during transfusion also exists. Those capable of manifesting hepatitic features include cytomegalovirus, Epstein–Barr virus and herpes simplex virus – usually with other accompanying systemic symptomatology.

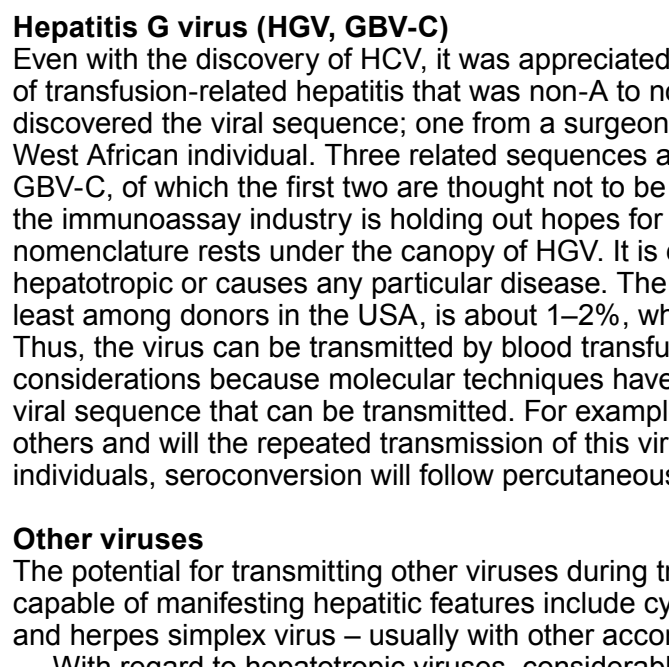
With regard to hepatotropic viruses, considerable efforts are being applied to characterize a new transfusion-transmitted virus (TTV) and time will tell whether this yields a new letter for the hepatitis alphabet.

Anaesthesia and intensive care
In the absence of chronic liver disease, with the associated alterations in drug handling, there are no extra implications for anaesthesia. Standard precautions should always be adopted. It is important to obtain evidence of the extent of hepatic synthetic dysfunction, generally by measuring the international normalized ratio. This may preclude neuraxial local anaesthetic techniques and suggest extra vulnerability to ischaemic hepatitis if the hepatic blood flow decreases. Managing acute and end-stage chronic liver failure is complex because multiple organ systems are involved and transplantation is often the only realistic option.

Human immunodeficiency virus (HIV)

HIV was first described in 1981, through the emergence of *Pneumocystis* pneumonia associated with candidiasis in otherwise healthy homosexual men. The retrovirus was identified as being a Lentiviridae. There are two main types, HIV-1 and HIV-2, but they also demonstrate significant genetic variation and there are subgroups of each virus. The viral genome has a propensity for change and evolution. As with other blood-borne viral infections, the patient develops viraemia following an initial inoculum, with a rapid increase in the viral load. The immune response then becomes established over a variable period of time and this has an impact on the viral load, which may stabilize or decrease (Figure 1).

Acute HIV infection



Transmission
It has been estimated that 56–92% of all infection is transmitted during the acute phase of infection when the viral load is high and the host is unaware of the infection. The virus is probably present in a range of body fluids, but those considered to be of high risk are blood, semen, vaginal secretions, peritoneal fluid, CSF and other cavity fluids. Less risk is associated with faeces, nasal secretions, saliva and urine, provided they are not contaminated with blood. There are several levels of screening for donated blood for transfusion, which start with donor selection. In the UK, blood is tested for HIV-1 and HIV-2 antibodies. In some countries it is also screened for HIV p24 antigen. A needlestick injury is associated with a 0.3% chance of seroconversion. Hollow needle injuries are more risky than solid needle injuries, because a larger inoculum is likely.

Presentation
Acute infection occurs after initial exposure, when there is a phase of viral replication and initiation of a host immune response. In this response phase, the patient may have a viral-type illness, which is non-specific and probably corresponds to seroconversion. This response varies between individuals but, in one study, 89% of patients experienced symptoms and signs including fever, fatigue, skin rash, myalgia, headache, pharyngitis, lymphadenopathy, arthralgia, oral ulcers, weight loss, nausea, vomiting and diarrhoea. Patients commonly present with opportunistic infections. These may be typical of an immunocompromised patient (e.g. *Pneumocystis* pneumonia, disseminated *Cryptococcus*, toxoplasmosis, widespread candidiasis) or may be more general (e.g. tuberculosis, pneumococcal pneumonia). Multi-resistant tuberculosis is a transmissible problem and precautions should be taken to minimize the risk of spread if the diagnosis is considered. Gastrointestinal disturbance is extremely common and may be infective, though a non-specific enteropathy is also seen (Figure 2). Neurological complications, often infective, are common. Non-infective presentation includes Kaposi's sarcoma.

Clinical syndromes associated with HIV[1]

Gastrointestinal
- Weight loss and malnutrition
- Diarrhoea – bacterial, viral, fungal
- Parasitic *(Cryptosporidium, Giardia, Entamoeba histolytica)*
- HIV enteropathy
- Hepatic – viral hepatitis B, C or D, tuberculosis, fungal *Cryptococcus, Candida*, histoplasmosis)
- Kaposi's sarcoma, lymphoma

Ocular
- Non-infective – conjunctivitis, keratitis, haemorrhage, cotton wool spots
- Infective – conjunctivitis, keratitis, retinitis, uveitis

Respiratory
- Any bacterial infection, *Pneumocystis carinii,* cytomegalovirus, cryptococcosis, coccidiomycosis, histoplasmosis
- Tuberculosis including *Mycoplasma avium type*
- Kaposi's sarcoma, non-Hodgkin's lymphoma

Bone marrow
- Peripheral blood cytopenias, anaemia, thrombocytopenia, granulocytopenia

Rheumatological
- Arthralgia, Reiter's syndrome, psoriatic arthritis, vasculitis

Cardiac
- Pericardial effusions, non-specific impairment of left ventricular function, myocarditis

Neurological
- Brain – HIV-related meningo-encephalitides, infections including herpes, varicella, cytomegalovirus
- Toxoplasmosis, *Cryptococcus, Nocardia*, tuberculosis, syphilis, Kaposi's sarcoma, lymphoma
- Spinal cord – vacuolar myelopathy, infection
- Peripheral neurology, polyneuropathy, demyelination, neuralgic amyotrophy

Psychological
- Any of the neurological causes above
- HIV encephalopathy

Renal
- HIV nephropathy (glomerular disease)

Oral problems
- Candidiasis, herpes simplex, varicella zoster
- Gingivitis, periodontitis
- Kaposi's sarcoma

[1] The list is not comprehensive, but indicates the range of problems.

Laboratory testing
Antibodies to HIV-1 can be demonstrated using enzyme-linked immunosorbent assay or Western blot techniques. In the acute phase, HIV-1 and HIV-2 antibodies are at best weakly positive or non-reactive and this will be misinterpreted as a negative result. HIV-1 RNA or viral p24 antigen should be tested; levels of 13 x 10^6 RNA particles/ml may be seen. A false-positive rate of 2–5% has been reported, therefore all tests should be repeated. This should be confirmed when seroconversion occurs later. During the acute phase, the CD4 count often falls and is followed by an expansion of the CD8 population, thereby altering the CD4:CD8 ratio at about day 16 of the acute illness. The expansion of the CD8 cytotoxic T cell subgroup is probably associated with antiviral activity.

Treatment
After the initial infection, the viraemia and the immune response 'equilibrate' at a 'set-point'. At this stage, there is a relationship between the viral load and prognosis. Those with a high persistent load do less well than those with a low load. Early aggressive treatment to reduce the load may lead to a better prognosis. It is hypothesized that, in the acute phase, when there is rapid proliferation of the virus, highly active antiretroviral therapy (HAART) may reduce the viral load and minimize damage to the CD4 T-helper lymphocytes. It may also reduce the emergence of resistance.

Nucleoside reverse transcriptase inhibitors (NRTI) (e.g. zidovudine, lamivudine) were used as monotherapy, with limited effect in suppressing HIV except materno-fetal transmission, but some patients have become resistant to them. Side-effects include gastrointestinal problems (e.g. diarrhoea, vomiting), pancreatitis and peripheral neuropathy.

Non-nucleoside reverse transcriptase inhibitors (NNRTI) (e.g. nevirapine, efavirenz) bind only to HIV-1 reverse transcriptase.

Protease inhibitors (e.g. saquinavir, ritonavir, indinavir, nelfinavir) are particularly effective when used in conjunction with NRTI. HIV-1 protease is an essential enzyme for viral replication and acts at the point at which virions become mature. Treatment results in the release of immature non-infectious viruses, which can be eliminated. Viral load is reduced, often to levels that are undetectable. It acts on maturing virus particles, therefore it does not have any impact on cells. CD4 that are already infected will be destroyed, but it does prevent spread of infection. The use of dual therapy seems to improve CD4 counts and to reduce viral load. Protease inhibitors have led to a dramatic alteration in the pattern and natural history of HIV, with decreased hospital admissions and fewer opportunistic infections. However, even with imperceptible viral load, an infective risk still exists. Protease inhibitors are metabolized by the P450 system and tend to either inhibit or induce cytochrome P450 isoenzymes. They therefore have the potential for drug interaction. They have a range of side-effects (Figure 3).

Side-effects of protease inhibitors

- Onset of diabetes mellitus and insulin resistance, type II diabetes
- Fatty deposition in neck – buffalo hump
- Peripheral lipodystrophy, hyperlipidaemia
- Gastrointestinal problems (nausea, vomiting, diarrhoea)
- Elevations of creatine phosphokinase, hepatic transaminases (occurs with saquinavir)
- Circumoral and peripheral paraesthesia (occurs with ritonavir)
- Hepatitis with elevations of transaminases and bilirubin (occurs with indinavir)
- 'Mitochondrial' toxicities (non-specific)

Anaesthesia
The problems that HIV poses for anaesthesia relate to the general problems of the disease and drug therapy. There are also non-specific considerations relating to dealing with a potentially infective condition. General problems include the chronic health status of the patient, who may be malnourished and wasted, and may have haematological, hepatic or renal problems. Local manifestations of the disease can cause technical difficulties. Chronic respiratory problems may alter oxygenation, in particular those who have had *Pneumocystis* pneumonia and are taking prophylaxis. Airway problems are common, from infection or from Kaposi's sarcoma. The implications of using an epidural should be discussed because of possible neurological involvement and the increasing number of HIV-positive women of child-bearing age. There is no evidence to suggest that complications following epidural are any higher in this population. This is important because caesarean section may reduce vertical transmission of HIV. There are inadequate data to make any statement about using blood patches if dural puncture occurs.

The side-effects of the drugs used to treat HIV may add to anaesthetic considerations.

Pain control in HIV patients is also a problem. This may be associated with the disease or the opportunistic infections, or be drug related.

Contaminating equipment is another problem when dealing with potentially infective patients. A sensible and hygienic approach to cleaning and sterilizing devices such as filters on anaesthetic circuits all help to reduce the risk of transmission; these measures should be universal.

Intensive care
The management of patients with HIV in the ICU should be the same as for other patients. Difficulties encountered include trying to maintain HAART, particularly if the gut is non-functional.

Presentation with HIV-related disease is also common. Primary presentation with *Pneumocystis carinii* is less common than it used to be. When it does present, it may be in undiagnosed patients. Neurological and gastroenterological presentation is also common. Rapid diagnosis is important. Prognosis is determined by the condition, the chronic health status of the patient and their immune system, and appropriate treatment. Prognosis appears to be worse in patients who fail to respond to appropriate treatment in the first few days. For example, *Pneumocystis carinii* pneumonia that is unresponsive after 4–5 days of aggressive treatment has a poor prognosis. The pattern of presentation is undoubtedly changing with the advent of HAART, but it is too early to anticipate the long-term effects on ICU admission.

Healthcare workers and HIV
The risk of contracting HIV infection at work is perceived to be low. Sensible precautions, such as wearing gloves, attention to hygiene and avoidance of 'sharps' injuries by careful practice are all advocated. Exposure to fluids or blood that might be infected constitute an exposure. Specialist advice should be sought immediately after exposure and it is likely that post-exposure prophylaxis would be implemented, within 1–2 hours. This should always be done with guidance from an HIV specialist. Currently it consists of a combination of two NRTI drugs (zidovudine and lamivudine) added to a protease inhibitor (e.g. indinavir). The side-effects of indinavir can be daunting and include gastrointestinal upset, headache, fatigue, paraesthesia or hypaesthesia, myalgia, nephrolithiasis, hyperbilirubinaemia and change in liver function (Figure 3).

The risk of an HIV-infected healthcare worker transmitting the disease to a patient is considered to be very low, provided the healthcare worker does not carry out 'exposure prone procedures'. These are procedures where the healthcare worker is at risk of injury with sharp instruments within an open body cavity and where the operator's hands may not be visible. If injured, the patient will be exposed to blood. A health worker infected with HIV should seek appropriate medical and occupational health advice.

Pacemakers and Anaesthesia

Caroline Bateman
Brian Keogh

Caroline Bateman is Senior Clinical Fellow in Cardiothoracic Anaesthesia at the Royal Brompton Hospital, London UK. Her interests include cardiothoracic anaesthesia and intensive care.

Brian Keogh is Consultant Anaesthetist at the Royal Brompton Hospital, London, UK. His interests include cardiothoracic anaesthesia and severe acute pulmonary failure.

The first permanent transvenous pacemaker was implanted in 1962. It weighed about 250 g and was expected to last for less than 2 years. Since then, advances in microprocessor technology and the introduction of lithium power sources have resulted in the development of more complex and reliable pacing systems. As a result, the number of patients with pacemakers inserted to treat bradycardia and tachyarrhythmias has increased. Implantable cardioverter defibrillators (ICD) were first used in 1980; they provide a method of treatment for patients with ventricular arrhythmias that are not managed or amenable to anti-arrhythmic agents, ablative techniques or surgery.

Many patients present for surgery with a pacemaker or ICD implanted and anaesthetists need to understand the problems that can be encountered with all types of pacing device.

Pacemaker insertion

Indications: guidelines specifying the indications for insertion of a permanent pacemaker have been published but are likely to expand with increasing sophistication of the devices. Current indications for permanent pacing include symptomatic complete heart block, prolonged sinus arrest associated syncope, carotid sinus syndrome and malignant vasovagal syncope. Asymptomatic second degree and complete heart block remain controversial indications, as does pacing for cardiomyopathy and congestive cardiac failure.

In general, the pacemaker should aim to mimic normal physiological conditions. The ventricle should be paced if there is actual or potential atrioventricular (AV) block. The atrium should be sensed and paced unless there are contraindications such as chronic or repetitive atrial flutter or fibrillation. Rate-responsive pacemakers respond to the increased physiological demands of exercise in active patients, but may be unnecessary in inactive patients or in those with a normal chronotropic response.

Anaesthesia: pacemakers are often inserted under local anaesthesia but if general anaesthesia is required the technique and monitoring should be tailored to the individual. A temporary wire may be inserted and external defibrillator pads used.

Insertion of ICD: patients requiring insertion of an ICD are likely to have severe underlying cardiac dysfunction. Cardiac function should be optimized preoperatively. Invasive monitoring, external defibrillator pads and an emergency method of pacing are required.

Management of a patient with a pacemaker

Preoperative management

The general condition of the patient has the most important influence on the anaesthetic management. Co-morbid conditions should be addressed with further investigation and treatment as necessary. The original indication for pacemaker insertion should be sought and any recurrence or development of new cardiac symptoms noted and investigated.

Information about the type of pacemaker, its mode and rate of pacing, and the cardiologist and centre responsible for insertion are included on the pacemaker registration card, carried by the patient, and on the notes in the cardiology unit. A code on the card indicates the symptoms, ECG abnormalities and aetiology of the condition that precipitated pacemaker insertion. If the card is unavailable, the information can be obtained from the British Pacing and Electrophysiology Group National Database (website http://ccad3.biomed.gla.ac.uk/bpeg).

Pacemakers should be checked annually (including a battery check) or every 6 months for devices implanted more than 6 years previously. An up-to-date pacing check in a patient without new cardiological symptoms should ensure effective pacemaker function and an additional preoperative pacemaker check is not required.

A thorough examination of the cardiovascular system is required and the position of the pacing box must be confirmed. Usually, the box is in the pectoral region, though abdominal sites are used. Investigations should be performed as indicated by the patient's condition and the type of surgery. Electrolyte abnormalities, particularly of potassium, should be corrected. ECG can help determine the type of pacing by the position of the pacing spike. All patients should have a chest radiograph so that the position, number and integrity of the leads may be determined.

Intraoperative management

The patient should be monitored in a manner appropriate to the underlying condition and the type of surgery being performed. ECG monitoring is essential and mechanical methods of verifying pacing capture include pulse palpation, pulse oximetry and direct arterial pressure monitoring (if this is indicated by the patient's condition). Central venous cannulation may be appropriate, but should be performed with caution if the leads have been placed within the past month because they may be dislodged.

The presence of a pacemaker has little influence on the choice of anaesthetic drugs. However, there are reports of demand pacemakers being inhibited as a result of suxamethonium-induced fasciculations being interpreted as myocardial activity. Conditions likely to precipitate arrhythmias (e.g. hypercarbia, electrolyte disturbances) must be avoided.

The risk of developing bacterial endocarditis as a result of the implanted lead is small and prophylactic antibiotics are not recommended unless there is some other indication for their use.

Emergency drugs (e.g. atropine, isoprenaline) and alternative methods of pacing must be available in case of pacemaker failure. Transvenous wires with an external pulse generator or transcutaneous pacing, which uses electrodes attached to the skin, may be useful. Transoesophageal atrial pacing is also an effective and simple pacing method that can be used in anaesthetized patients, but requires an intact AV pathway; the system consists of a pacing oesophageal stethoscope, which paces the left atrium, the structure closest to the oesophagus.

Postoperative management

Reprogramming, particularly an increase in heart rate, should always be considered in patients with haemodynamic compromise or critical illness. Following exposure of the pacemaker to possible interference or damage, it is necessary to perform a pacing check.

Specific problems

Electromagnetic interference – advances in the design of protective circuits in the pacemakers have reduced, but not eliminated, the risk of damage from external electrical sources. The most common source of electromagnetic interference is surgical diathermy. Risks are reduced by the use of bipolar diathermy, application of diathermy in short bursts and, in monopolar systems, positioning of the ground plate as far away as possible from the pulse generator and leads. If difficulties are anticipated, it may prove necessary to reprogramme the pacemaker to a fixed rate mode preoperatively. Diathermy also interferes with ECG monitoring and alternative methods of monitoring the pulse should be used (e.g. direct palpation, pulse oximetry). At one time, magnets were used to convert the pacemaker to a fixed rate mode intra-operatively, but this is no longer recommended because the combination of diathermy and the magnet may induce a programme change (so called phantom reprogramming). The use of magnetic instrument pads during surgery can also cause phantom reprogramming.

Cardioversion or defibrillation may damage the circuitry inside the pulse generator. If the lead is damaged, the current can pass down the lead and may burn the myocardium, causing a threshold increase and loss of capture. If defibrillation is necessary, the current path should be perpendicular to the lead and as far away from the pulse generator as possible.

Mobile telephones – there have been reports of interference with certain types of mobile telephones. The ringing phase is the most vulnerable time especially if the phone is in a pocket near the pulse generator.

Transcutaneous electrical nerve stimulators (TENS) and peripheral nerve stimulators can cause a tachycardia or inhibit a DDD or rate-responsive pacemaker and it is recommended that these are reprogrammed to simpler modes.

MRI – a pacemaker is a relative contraindication to MRI. If MRI is essential, the pacemaker must be turned off or explanted before the examination (provided that the patient is not pacemaker-dependent). Scans can be performed with a pacemaker *in situ* but require multidisciplinary support and specialist expertise.

Ionizing radiation can damage the internal circuits in the pulse generator. Therefore a paced patient undergoing radiotherapy treatment should have the function of the pacemaker checked following treatment.

Lithotripsy treatment of renal calculi uses high-energy shock waves. In a patient with a pacemaker the shock wave must be carefully timed with the ECG and the focal point of the delivery probe must be kept at least 15 cm away from the pulse generator. If the pulse generator is positioned in the abdomen it is important to avoid passing a direct impulse through it. Rate-responsive and DDD pacemakers should be programmed to a simpler mode for the treatment and the function checked following treatment.

Management of a patient with an ICD

Patients presenting for surgery who have an ICD must have the anti-tachycardia and other functions disabled before surgery. Diathermy must not be used in the presence of an active ICD unit because of the risk of damage. External defibrillation facilities must be available and if defibrillation is required then the paddles or pads should be placed at a right angle to the plane of the defibrillating/pacing lead.

Passing the defibrillator current through the pulse generator will damage it permanently. The ground plate for the diathermy unit must be placed as far away from the surgical site and the ICD as possible, and this distance should be at least 15 cm. Central venous cannulation using the Seldinger technique can be arrhythmogenic and back-up defibrillation facilities must be available. Care must be taken with recently placed leads because of the risk of dislodgment. Following surgery, the device can be reactivated and the function checked.

Repeat Anaesthesia: Hepatic Injury

Olga Siemaszko
Hamish A McLure

Olga Siemaszko is Specialist Registrar in Anaesthesia working on the North West Thames Rotation. She qualified from St Bartholomew's Hospital, London. Her interest is chronic pain management.

Hamish A McLure is Consultant at the Royal Marsden Hospital. He qualified from the University of Manchester. His interests are intensive care and regional anaesthesia.

Hepatic injury following repeat anaesthesia is a rare complication that may be precipitated by many of the commonly used volatile anaesthetic agents. Halothane is the most common culprit, causing either a mild dysfunction or a more severe fulminant liver injury. Similar immune-mediated reactions may occur with enflurane, isoflurane and desflurane. There are no investigations that can accurately predict who will be affected, therefore those with a history of recent halothane anaesthesia or unexplained fever or jaundice after a previous anaesthetic should avoid repeat volatile anaesthesia. No cases of propofol-induced liver failure in adults have been published, therefore total intravenous anaesthesia may be suitable for these patients.

Postoperative hepatic injury has profound effects on the future conduct of anaesthesia. The injury ranges from asymptomatic derangement of liver enzymes to fatal liver failure. The major precipitants are non-anaesthetic such as sepsis, hypotension, hypoxaemia, transfusion-related viral infection (hepatitis B, hepatitis C, cytomegalovirus, herpes virus), transfusion reaction, surgical trauma to the liver or biliary tract, prolonged nutritional deficiency, or a combination of factors in patients with pre-existing liver dysfunction.

Aside from the usual measures to minimize physiological stress by careful attention to oxygenation, blood pressure and fluid status, there is little the anaesthetist can do to prevent recurrent hepatic injury during repeat anaesthesia.

Pre-operative assessment: comfort may be gained from the knowledge that a patient has survived a previous anaesthetic. If the patient's previous anaesthetic charts are available, valuable information may be gathered regarding difficulties with the airway or drug reactions. Vigilance must be maintained, even if the patient's last anaesthetic was uneventful, because new and significant pathology may have emerged since then. Also, postoperative complications may not have been recorded in the anaesthetic chart or in the medical case notes.

Halothane hepatitis

Halothane was introduced into clinical practice in 1956. Compared with other inhalational agents of the time, it was potent, non-irritant and non-flammable with minimal toxicity, and it rapidly gained widespread popularity. However, within2 years, reports describing cases of massive hepatic necrosis after halothane anaesthesia were published.

Incidence

In 1969, the National Halothane Study was published in the USA. In this retrospective study, the incidence of fatal hepatic necrosis was investigated in 856,000 patients undergoing general anaesthesia. Fatal hepatic necrosis occurred in 7/255,000 of the patients who received halothane. The study could not show a definite link between halothane and hepatic injury, but confirmed that fatal liver disease following halothane anaesthesia was uncommon. Subsequent studies have demonstrated an increased incidence of hepatitis of about 1/6000 halothane anaesthetics, and there is now a wealth of data describing the patterns of hepatic damage after halothane.

Characteristically, but not exclusively, halothane hepatitis develops in patients who have had repeat halothane anaesthesia over a short period of time. It may have been required for dressing changes, diagnostic radiology, or as part of multi-stage procedures for the treatment of trauma, burns or complications of previous surgery. The peak incidence occurs in those aged 50–60 years, and 70% of affected patients are over the age of 40 years. Children seldom develop halothane hepatitis (1/82,000). Obese patients appear more at risk, possibly because of increased halothane metabolism, or prolonged duration of exposure as halothane that has accumulated in adipose tissue is metabolized and excreted. Despite equal exposure to halothane, women are at greater risk than men (about 2:1). Drugs that induce cytochrome P450 (e.g. isoniazid, dexamethasone, phenobarbital (phenobarbitone)) increase the degree of hepatic injury.

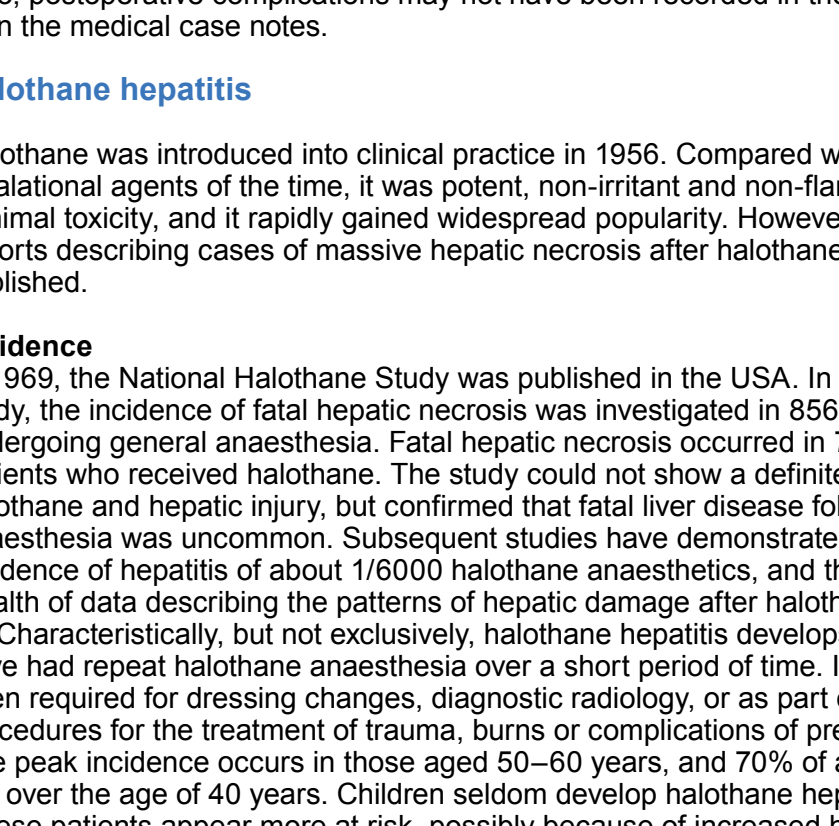
Pathology

Two forms of hepatic injury after halothane anaesthesia have been described:

- a common (20–30%), but mild, form in which there is a transient rise in liver enzymes
- a rare fulminant form with massive hepatic necrosis.

These are thought to be separate processes initiated by different metabolic pathways, and not varying severities of the same pathological mechanism. Halothane is metabolized in the liver by an oxidative pathway when the oxygen tension is high and by a reductive pathway when the oxygen tension is low (Figure 1); both may occur during uneventful anaesthesia.

Oxidative and reductive pathways of halothane metabolism



The main products of oxidative metabolism are HBr and trifluoroacetic acid (TFAA). The main products of reductive metabolism are bromine, fluorine, 2-chloro-1,1,1-trifluoroethane (CTF), 2-chloro-1,1-difluoroethylene (CDF).

Source: *Br J Anaesth* 1991; **67:** 88

1

Reductive halothane metabolism occurs when there is an imbalance between liver perfusion and oxygen demand, resulting in relative hepatocyte hypoxia. Under these conditions, the mixed function oxidase, P450, favours a reductive metabolic pathway with the formation of 2-chloro-1,1,1-trifluoroethane or 2-chloro-1,1-difluoroethylene. These byproducts have not been shown to be directly hepatotoxic. However, liver damage by free radical intermediates has been proposed. This type of hepatic injury is more common if halothane anaesthesia is associated with hypotension and hypoxia. The clinical features of this short, self-limiting illness are non-specific and include lethargy, fever, nausea and jaundice. Biochemical tests show an elevation of alanine and aspartate aminotransferase.

Oxidative halothane metabolism is more common than reduction metabolism and proceeds via a trifluoroacetyl (TFA) halide, which is not thought to be hepatotoxic. However, TFA halide may bind covalently to liver microsomal proteins. In susceptible patients, this TFA–protein complex acts as a hapten against which anti-TFA antibodies are formed.

On repeated exposure to halothane, a hypersensitivity response mediated by anti-TFA antibodies occurs and liver damage ensues. Typically, liver failure develops within 15 days of the last exposure to halothane. The clinical picture is similar to viral hepatitis or drug-induced hepatic damage, but as there are no pathognomonic features the diagnosis is often made by exclusion. Histologically, the pattern is predominantly centrilobular necrosis, but may range from multifocal necrosis to panlobular massive necrosis.

Treatment is essentially supportive, with transfer to a specialist unit when severe. Fulminant disease has a mortality of up to 50%.

Immunological effects: features supporting an immunological basis for the hepatic injury include the clinical picture of hepatitis with fever, rash, arthralgia and eosinophilia in pat*i*ents with a history of atopy, drug allergy or adverse reactions to halothane. In addition, there is a clear association with prior exposure to halothane and worsening response with subsequent halothane anaesthetics. In up to 70% of patients with halothane hepatitis, an enzyme-linked immunosorbent assay may be used to detect antibodies to TFA proteins. Proponents have suggested that free radicals from the reductive pathway may initiate the hepatic damage, which is then exacerbated by an immunological response.

Prevention

Halothane should be avoided in patients who have been exposed to halothane recently, or who have a history of halothane hepatitis. The Committee on Safety of Medicines (CSM) advises that halothane should be avoided if a patient has had an adverse reaction following a halothane anaesthetic, previous exposure within 3 months or a history of unexplained jaundice or pyrexia after exposure to halothane.
Hepatitis associated with other volatile agents

The use of halothane has declined with the introduction of newer volatile agents (enflurane, isoflurane, desflurane, sevoflurane). Isoflurane and desflurane are oxidatively metabolized producing an identical TFA hapten to that seen with halothane. The metabolite of enflurane is immunologically similar though not structurally identical. Consequently, enflurane, isoflurane and desflurane have the potential to produce hepatic injury by an immune response directed at TFA haptens or similar structures. The incidence of hepatotoxicity correlates with the degree of cytochrome P450-mediated metabolism, which is 20% for halothane, compared with 2%, 0.2% and 0.02% for enflurane, isoflurane and desflurane, respectively.

Enflurane hepatitis is uncommon with an incidence of 1/800,000. Isoflurane hepatitis is less common and a literature review revealed only one case report of desflurane-associated hepatitis. Isoflurane does not undergo reductive metabolism (nor does enflurane), free radicals are not produced and hepatic perfusion is maintained to a greater degree than with halothane, contributing to the low incidence of isoflurane-induced hepatotoxicty. With both enflurane and isoflurane hepatitis, the initial exposure has been reported to be to a different ♋gent than that believed to be precipitating the hepatic damage, indicating possible cross-reactivity. Consequently, the CSM guidelines regarding patients who sustain a hepatic injury after one halogenated agent indicate that it is probably best to avoid all others.

Sevoflurane is metabolized to a similar degree to enflurane but does not form trifluoroacetic acid. A mild elevation of liver enzymes after repeat sevoflurane anaesthesia has been shown, but there have been no cases of fulminant hepatic necrosis.

Day case

Anaesthesia
and intensive care medicine
on CD-ROM

Assessment of Recovery in Day Surgery

Alexander P L Goodwin

Alexander P L Goodwin is Consultant in Anaesthesia and Intensive Care at the Royal United Hospital, Bath, UK. He qualified from St Thomas's Hospital Medical School, London, and, after serving in the Royal Navy for 7 years, completed his anaesthetic training in Cambridge and Oxford. His research interests include morbidity in day surgery and analgesic pharmacology.

Surgical procedures of increasing complexity and duration can now be undertaken in day surgery units. For example, cholecystectomy and prostatectomy are now acceptable day case procedures. These procedures are appropriate for day surgery only if the clinician can ensure that the patient will return home safely, having recovered from the effects of anaesthesia and surgery. The assessment of recovery is therefore an important part of the patient's hospital stay. Recovery includes return of normal physiological and psychomotor function together with a minimal level of morbidity associated with anaesthesia and surgery.

Phases of patient recovery

Recovery is a continuous process, the beginning of which overlaps with the end of the surgical procedure. Patients are not fully recovered until they have returned to their preoperative physiological and psychomotor state. The process may last for days, but it can be divided into distinct phases.

Early recovery (first-stage recovery) – end of anaesthesia until the patient has recovered protective reflexes and motor function. This occurs in the recovery unit or post-anaesthesia care unit.

Intermediate recovery (second-stage recovery) – patients are fit enough to be transferred to the day surgery ward and then home. Patients are considered to have achieved 'street fitness'.

Late recovery (third-stage recovery) – full recovery and physiological recovery. The patient can return to work. Late recovery occurs in the patient's home.

Tests of recovery

Clinical

Day case anaesthetists may use their experience and knowledge to decide when a patient is fit for discharge. However, if clinicians are to delegate this decision, a well-designed scoring system is a useful tool for those assuming this responsibility. In some countries, time dictates how long patients remain in recovery areas. However, time-based recovery is inappropriate because of inter-patient variation and advances in surgery and anaesthesia that allow patients to move from one recovery phase to another more quickly than previously laid down or expected. Thus, criteria-based recovery has been introduced. In this system, the patient dictates the speed at which he or she progresses from one recovery stage to another.

Tests of early recovery involve recording the time at which specific events occur:

- eyes open
- date of birth recalled
- orientation
- able to obey commands
- stable vital signs
- recovered protective reflexes.

Scoring systems involve the evaluation of a number of patient factors. For first-stage recovery the Steward Score (Figure 1) and Modified Aldrete Scoring System (Figure 2) are used to determine when patients are ready for discharge from the recovery room; for second-stage recovery the Excitement Score or the Post-anaesthesia Discharge Scoring System (PADS; Figure 3) is used.

Scoring systems cannot be used to determine the patient's suitability for discharge home because they fail adequately to address pain, nausea, vomiting, surgical complications and patient ambulation. Discharge criteria have therefore been laid down to assist in the evaluation of a patient's street fitness following day surgery. Street fitness is an ill-defined term, which implies that the patient has recovered the ability to make everyday decisions under everyday circumstances. However, decision-making is not amenable to objective testing. Each day surgery unit has discharge criteria tailored to the population served by the hospital (Figure 4). One criterion that is often devalued is that the patient should feel confident about leaving hospital. In the author's hospital, this criterion is considered most important.

The patient must be discharged by the person who administered anaesthesia and the person who performed surgery, or by their designates. Written instructions for the postoperative period at home should be provided, including a contact telephone number. Owing to anxiety, extraneous noise and the amnesic effects of some drugs, patients may not assimilate verbal information, therefore written instructions are necessary. The patient must be accompanied by a responsible adult who will escort them home and ensure that they are not alone for at least the first 24 postoperative hours. Patients should avoid alcohol and refrain from driving for at least 48 hours.

Recently, the need to void urine and tolerate oral fluids before discharge has been questioned. In one study, the mandatory drinkers had a higher incidence of nausea and a longer discharge time. No patient in either group required admission. Eliminating the requirement to tolerate oral fluids may shorten the stay in the day surgery unit. Waiting for the patient to pass urine may also delay discharge. There is some evidence that patients who are not considered to be at high risk of developing urinary retention can be discharged safely without developing urinary problems at home. Risk factors for postoperative urinary retention are:

- history of postoperative urinary retention
- spinal/epidural anaesthesia
- pelvic surgery
- urological surgery
- perioperative catheterization.

Removing the requirement to tolerate oral fluids and void urine and separating the pain and nausea/vomiting scores has led to a modified version of PADS (Figure 3).

The use of guidelines together with common sense should prevent the premature discharge of patients who later experience postoperative complications requiring their readmission to hospital.

Steward Score[1]

Consciousness

• Awake	2
• Responding to stimuli	1
• Not responding	0

Airway

• Coughing on command or crying	2
• Maintaining a good airway	1
• Airway needs maintenance	0

Movement

• Moving limbs purposefully	2
• Non-purposeful movement	1
• Not moving	0

[1] Six points are required for discharge.

Modified Aldrete Scoring System[1]

Activity: able to move, voluntarily or on command

• Four extremities	2
• Two extremities	1
• No extremities	0

Respiration

• Able to breathe deeply and cough freely	2
• Dyspnoea, shallow or limited breathing	1
• Apnoea	0

Circulation

• Blood pressure within 20 mm Hg of preoperative level	2
• Blood pressure within 20–50 mm Hg of preoperative level	1
• Blood pressure ± 50 mm Hg of preoperative level	0

Consciousness

• Fully awake	2
• Arousable on calling	1
• Unresponsive	0

Oxygen saturation

• Saturation > 92%	2
• Needs oxygen to maintain saturation > 90%	1
• Saturation < 90% with oxygen	0

[1] Nine or more points are required for recovery to be confirmed.

Post-anaesthesia Discharge Scoring System for assessing home readiness[1]

Vital signs

Vital signs must be stable and consistent with age and preoperative baseline

• Blood pressure and pulse within 20% of baseline	2
• Blood pressure and pulse within 20–40% of baseline	1
• Blood pressure and pulse within 40% of baseline	0

Activity level

Patient must be able to ambulate at preoperative level

• Steady gait, no dizziness, or meets preoperative level	2
• Requires assistance	1
• Unable to ambulate	0

Nausea and vomiting

• Minimal: successfully treated with oral medication	2
• Moderate: successfully treated with intramuscular medication	1
• Severe: continues after repeated treatment	0

Pain

The patient should have minimal or no pain before discharge
The level of pain that the patient has should be acceptable to the patient
Pain should be controlled by oral analgesia
The location, type and intensity of pain should be consistent with the anticipated postoperative discomfort

Acceptable	2
Unacceptable	1

Surgical bleeding

Postoperative bleeding should be consistent with the expected blood loss for the procedure

• Minimal: does not require dressing change	2
• Moderate: up to two dressing changes required	1
• Severe: more than three dressing changes required	0

[1]Nine points are required for discharge.

Guidelines for safe discharge after day surgery

Vital signs must have been stable for at least 1 hour

The patient must be able to:
- orientate themselves in person, place and time
- keep oral fluids down
- void urine
- dress
- walk without assistance

The patient must not have
- more than minimal nausea and vomiting
- excessive pain
- bleeding

4

Psychomotor tests
Most psychomotor tests are complex and difficult to use routinely (Figure 5). To assess psychomotor function accurately requires tests to measure sensory, motor, physiological and central processing. This is difficult in the conventional setting. When testing any individual's psychomotor function the following precautions must be taken.
- Each individual acts as his/her own control.
- Time of day may affect performance.
- The hormonal effects of the menstrual cycle must be taken into account.
- Practice or learning effects must be reduced, either by allowing sufficient learning time before collecting results, or by having a control group not undergoing anaesthesia.

The ideal psychomotor test has the following qualities:
- quick and simple to perform
- no learning effect
- uses inexpensive equipment
- needs an unskilled operator
- is sensitive to the residual effects of all drugs used in anaesthesia
- has sufficiently reproducible results that firm conclusions may be drawn from individual measurements.

Despite the number of available tests, none has been validated by follow-up studies to provide adequate criteria to guide discharge in the day surgery environment. Lockwood has suggested that a psychomotor test suite comprising body sway, inspection time, critical flicker fusion, digital symbol substitution and a picture recall test should be used to study recovery from anaesthesia. It is unlikely that additional tests would reveal an effect not shown by this suite of tests.

Psychomotor testing therefore allows comparison between anaesthetic regimens. If one anaesthetic regimen leads to a swifter return to baseline psychomotor function then it would be valid to assume that the higher intellectual functions also return more quickly. At present, there is no place for these psychomotor tests in routine clinical practice.

Examples of psychomotor tests

Paper and pencil tests (measure the number of correct entries in a specific time)
- Trieger dot test
- Perceptual speed tests
- P deletion tests
- Digit symbol substitution test (most sensitive paper and pencil test)

Other tests
- Maddox wing test (measures imbalance of extraocular muscles)
- Reaction time tests
- Peg board tests
- Flicker fusion tests (tests central integrity)
- Tapping board tests
- Driving simulators
- Balance tests (measure postural sway)

5

Following regional anaesthesia
In the UK, the use of regional anaesthesia (spinal and epidural blocks) is uncommon. The perceived problems are concerns over post-dural puncture headache, urinary retention and the local anaesthetic agents available. However, if regional anaesthesia is used, it is important to ensure that the motor, sensory and autonomic blocks have receded before allowing patients to ambulate. Suitable criteria to judge if this has occurred are:
- normal perianal sensation
- plantar flexion of foot
- proprioception in big toe
- normal blood pressure on standing and sitting.

Ability to walk to the lavatory to pass water may be a suitable test of recovery from regional anaesthesia.

Patients, who have had a more peripheral nerve block (e.g. brachial plexus block) do not need to wait for the return of full sensation before discharge. They may be sent home with the anaesthetized area protected, with precise written and verbal instructions, and a 24-hour contact number.

Causes of prolonged recovery following regional and general anaesthesia are given in Figure 6.

Causes of prolonged recovery following regional and general anaesthesia

- Pain
- Nausea and vomiting
- Haemorrhage
- Cardiovascular or pulmonary dysfunction
- Wound drains
- Needing observation
- Lack of escort or inadequate home conditions

6

Safety and legal considerations

Following day case surgery, a patient may leave the clinician's care under the residual effects of anaesthetic drugs. It is an offence for a person to drive while under the influence of drugs. Operating machinery under the influence of these drugs may lead to an accident causing injury and/or damage to property. The effects of alcohol may be potentiated.

If not warned about these potential problems, the patient and anybody injured as a result of the patient's actions may hold the anaesthetist responsible. Patients must be warned of the danger and the fact documented.

Driving after anaesthesia
In 1972, Ogg found that 73% of car owners drove within 24 hours of outpatient anaesthesia. In 1996, the author found that no patients drove within 12 hours of surgery, but that 3.5% drove within 24 hours of general anaesthesia. The patients who drove within 24 hours had all been warned not to drive for at least 24 hours but were convinced that they were safe to drive. Safe driving requires an effective response to multiple secondary tasks. The primary task of control can be undertaken with impaired cerebral functioning, but the ability to react to the unexpected is crucial. A higher level of coordination is required to control a motorcycle or bicycle because the rider also has to balance. Previous research into the effects of anaesthesia on the ability to drive has involved single anaesthetic agents in volunteers not undergoing surgery.

A survey of motor insurers found that generally they would accept the medical advice given to the patient. However, one company commented that in the event of a claim, if the advice given was shown to be wrong, they might seek reparation from the hospital or individual concerned.

In the UK, 24 hours is the most common period of abstinence advised and is the time considered appropriate by the Medical Advisor to the Driver and Vehicle Licensing Agency. Recently, it has been suggested that the residual effects of anaesthesia and surgery extend into the second and third postoperative days. This may be a result of the residual effects of anaesthetic agents on higher cerebral centres or caused by the increased metabolic demands induced by the endocrine response to surgery. It is the author's practice to advise patients not to drive for 48 hours following general anaesthesia.

Clinical Service and Audit: Working Clinical Systems

Kerri Houghton

Kerri Houghton is Consultant Anaesthetist and Director of Day Surgery in the Department of Anaesthesia, Torbay Hospital, Torquay, Devon, UK.

Day surgery environment

In response to the Royal College of Surgeons' Working Party Report (1992) and the Audit Commission (1992) advice on day surgery, day surgery rates have increased and new facilities have been developed. Different day surgery services have evolved with different styles of management: premises vary from modifications of existing facilities, to free-standing units; operational policies vary from the proactive to the non-existent; and case mix is variable and not always 'true' day case. Where day surgery is not actively and continuously monitored and audited, good facilities can remain under-utilized or unpopular, or become inappropriately used. Some purpose-designed facilities still treat in-patients, thereby defeating much of the purpose of the original development and making audit more difficult. Many units still lack good information systems and have difficulty defining, auditing and controlling their activity, yet the success of their parent hospital in managing surgical beds is largely dependent on the good use of their day surgery facilities.

Information to enable audit to track the success of a day surgery clinical service closely parallels that required for management in this setting, and systems should be contemporaneous and accessible to busy clinicians, though they seldom are. The information generated should enable analysis of:

- the success and viability of the day surgery facility as a whole
- the quality of the day surgery practice within the facility.

If the clinical process fails and the patient is admitted, then not only has the patient's experience fallen short of what he/she and the clinicians expected, but also the savings have not been made. If operating lists are under-used, fewer patients are treated. If patients fare badly at home, clinicians are discouraged from undertaking day surgery or at least extending their practice. Information should be available to enable rapid identification of activity, and recognition and anticipation of both clinical and managerial problems on a daily basis. Such information can be used to drive true audit and continuous quality improvement.

Use of clinical systems

The need for clinical information systems that help patients and provide sound data to support clinical and managerial decisions is well recognized. The Audit Commission has stated that 'information is one of the most important resources that a hospital holds'. In order for a clinical service to evolve, data about individual patients must be grouped and abstracted, and then related to data about staffing facilities and other resources. It has been shown that clinical practice is seldom altered by evidence-based medicine. This must be due, at least in part, to the difficulties in obtaining relevant information.

Clinicians require different types of information, which is gained from diverse sources. In the context of daily practice, a high-quality clinical database can be used to provide accurate information for clinical practice, audit and administration. Clinicians perceive most health service information systems as offering no obvious benefits for patient care or themselves.

Service, audit and systems

Essential features of a computerized day surgery system

Patient information should be available for every stage of the process from pre-assessment and booking, through anaesthesia and surgery, to recovery, discharge and follow-up. Ideally, the patient record should be held on an on-line computerized management information and audit system, and should be instantly retrievable. It should be perceived as being easy to use and helpful by all staff, and be capable of being integrated with other systems to provide the comprehensive Electronic Patient Record (EPR) of the future. Alternatively, the ideal features of a day unit system should be embedded in a total EPR solution. The ability to cross-reference data easily, from a user-friendly and virtually instantaneous database, without the need to use complicated report packages, is particularly helpful in this environment. It should also be possible to identify omissions and inconsistencies in data entry readily. Clinical coding in hospitals is known to be fraught with difficulties. If surgical teams enter the diagnosis and procedures performed directly on to a system that already holds the relevant clinical codes, the coding can be automated. Sample parallel manual and automatic coding checks should be undertaken intermittently to validate coding and should demonstrate a high level of accuracy and completeness.

Any computerized system should also facilitate management processes in a fast throughput environment, and provide features such as:

- individualized surgical diaries
- direct booking on to operating lists in a manner that complies with the National Booked Admissions Project objectives
- a pre-assessment module to record clinical and booking details, decisions and alerts
- automatic generation of reminders for patients who have not confirmed their attendance
- automated communications with primary care workers
- automated generation of operating lists and, subsequently, the individual operating record
- automated coding
- extensive and flexible reporting.

As large numbers of patients pass through day surgery units, there is a potential wealth of clinical information waiting to be gathered; information relating to the unit as a whole, and to individual patients and clinicians.

The day surgery process – the need for information

The essential criteria for successful day surgery are well understood.

- Operations should be appropriate.
- Suitable patients should be identified.
- The work should be undertaken by experienced surgeons and anaesthetists.

Additional criteria for success include:

- well-informed patients
- good dedicated facilities
- first-rate organization
- good liaison with primary care workers
- follow-up and audit.

As more patients and procedures are perceived as treatable on a day-stay basis, successful application of these criteria becomes increasingly important. The ideal 'process' through which patients pass for their treatment should therefore incorporate:

- good identification of appropriate procedures by the referring surgeon (i.e. those without the expectation of excessive postoperative pain, bleeding or other complications)
- elimination of patients identified as unsuitable on medical or social grounds through a comprehensive pre-assessment process, now normally nurse-based and supported by anaesthetists
- efficient (and ideally integrated) booking and pre-assessment to minimize steps in the process, align urgency with the date of surgery and maximize use of operating time
- information for patients and carers about pre- and post-operative expectations.

Measures of all of these 'process functions' can be developed and easily audited. For example, numbers of patients who 'do not attend' on the expected day of surgery are likely to be higher when negotiated booking and pre-assessment are not performed. Poor pre-assessment, or none at all, results in a higher rate of cancellation on the day of surgery. Poor selection of either surgical procedure or inadequate pre-assessment results in higher unplanned admission rates. Poor discharge processes are likely to produce higher re-admission rates, callout of primary care services or difficulties at home. Poor booking processes can result in under-utilized operating time and wasted resources.

Standard management reports

Any day surgery facility should be capable of producing standard reports easily.

Simple, automated, daily reports showing cases performed, those who do not attend, cancellations and unplanned admissions can point to specific difficulties.

At a minimum, monthly reports should be generated (Figure 1). This data can be used to shape the service by determining:

- the correct number of lists for each specialty or surgeon
- the impact of pre-assessment
- the need for in-patient beds
- clinical complications.

Only when data of this quality are widely available will it be possible to compare general and specific practice in different units.

Suggested items for standard monthly reports

- Total activity of the unit
- Number of cases per specialty
- Pre-assessments performed and numbers accepted/rejected
- Numbers and procedures for each referring consultant
- Numbers and procedures for each operating surgeon
- Numbers, procedures and codes by specialty
- Cancellations on the day of surgery and reasons
- Non-attendance rates
- Unplanned admissions with reasons
- Sessions/lists used and utilization per session

1

Qualitative data

Information should not only ensure a successful, viable unit, but also help to promote safe clinical practice and a good experience for the patient. Data to promote safe clinical practice should be available through monthly reports as described above. Clinical complications and other important aspects of patient feedback require some direct information gathering. Clinical outcome measures and patient feedback are both desirable and increasingly sought by purchasers, and should include patient satisfaction as well as clinical outcome and complications. The increase in day surgery has been a cause of concern for all clinicians, including GPs, who are anxious about quality of care for their patients and a possible rise in night calls at a time when the availability of district nursing services is decreasing.

One system allowing access to qualitative data, which was first designed for use in the pioneering Norfolk and Norwich Day Surgery Unit (Daynamics® Calcius Systems Ltd), incorporates all the functions described above. The system is also used in the author's unit, in which an additional module was developed for audit. The responses to our structured postoperative telephone questionnaire, which patients receive the day after surgery, are entered directly on to the system, thereby linking the follow-up with the entire patient episode. This addition represents a significant advance in clinical audit by allowing rapid identification of clinical problems, and their relationship to procedures within the unit, answering many questions on a daily basis. Reasons for analysing patient responses through a postoperative telephone call are summarized in Figure 2. The format of the questionnaire is simple and contained on one screen. The enquiry is kept simple because telephone calls are time-consuming and complexity can impede decision making. The questions chosen (Figure 3) are directed at identifying;

- postoperative symptomatology
- recourse to primary care services
- patient expectation
- patient satisfaction
- readmission rates (i.e. readmitted after discharge).

Analyses of responses from telephone questionnaires carried out by other units have been published but, inevitably, if a manual collection process is used, a research worker is required to gather the data over a long period. It is preferable to be able to look at large numbers of variables in a short time, in order to 'trawl' for problem (or successful) areas of practice without having to set up complex reports each time (Figure 4). It should be possible for a clinician with minimal computer expertise to run reports such as these virtually instantaneously and the data should be easily importable into a standard data-handling package for further analysis if required (Figure 5).

Despite the efficiency of entering patient responses directly, the generation of hard copies of the patient feedback telephone calls makes daily review by a doctor or senior nurse easier. Patients' concerns can then be responded to, compliments passed on to the individual staff concerned (which appears to have a positive impact on staff attitudes and practice) and complications immediately identified.

Specific clinical issues that have been identified and followed up in the author's unit through this process include patients readmitted with retention or bleeding postoperatively, a low-risk patient suffering a pulmonary embolus the day after arthroscopic knee surgery (subsequently confirmed), and a non-epileptic child who had two possible convulsive episodes the day after surgery; the child was referred for further investigation and possible drug causes were investigated and reported. Patient complaints about waiting times have persuaded some surgeons to pilot an appointment system for operating lists. It is highly unlikely that these incidents would have been picked up without the follow-up.

Improvements in clinical practice have been made through education of clinicians, particularly in relation to performance of local anaesthetic techniques and postoperative analgesia. Clearly, a further, later follow-up for all patients would be desirable.

Rationale for the postoperative telephone call

- To provide a clinical service to patients
- To detect and remedy areas of practice that are unsuccessful
- To obtain patient 'feedback' for audit purposes
- To reassure hospital clinicians that their practice is safe and encourage more referrals
- To provide some outcome measures for clinicians, managers and purchasers
- To promote a good image for the day surgery facility

2

Example of a telephone follow-up questionnaire[1]

- In general, how did you feel?
  - very good
  - good
  - reasonable
  - not so good
  - bad

- Was this
  - better than expected
  - much as expected
  - worse than expected?

- Did you experience any
  - dizziness
  - drowsiness
  - feverishness
  - pain[2]
  - nausea[2]
  - vomiting[2]
  - bleeding?

- Have you had to contact anyone since discharge (unplanned)? Was it GP/ District Nurse/Practice Nurse/A & E Dept/Day Unit/SHO on-call?

- Is further help required?
- From whom?

- Overall were you
  - very satisfied
  - satisfied
  - dissatisfied?

- Did you like the unit?
- Did you like being a day case?
- Did you have trouble parking?
- General comments (entered free hand)

[1]Failure to contact the patient is also recorded.
[2]Quantified if present.

3

Examples of useful practical monitoring

- Complete breakdown of workload by specialty, surgeon, and age/sex of patient over any chosen period
- Individual clinician's personal records including their own patients' feedback
- Seniority of surgeons and anaesthetists working in the unit
- Procedures producing most postoperative difficulties
- Patients' experience of individual postoperative symptoms, by severity (graded), specialty, procedure, surgeon, anaesthetist, time of day, ASA grade and anaesthetic type
- Unplanned admissions by reason, surgeon, anaesthetist, and procedure
- Factors contributing to unplanned admissions, such as patient selection, pre-assessment, experience of surgeon, surgical technique, experience of anaesthetist, anaesthetic technique, timing of session (a.m./p.m.), and nursing factors
- Success rates in contacting patients postoperatively
- Patient satisfaction across all specialties, adults and children
- Primary care callouts
- Readmissions from home overnight
- Analysis of cancellations and rebooking workload for clerical staff

4

Examples of specific reports or audits

- Nausea and vomiting rates in children under 14 years undergoing squint surgery
- Patient satisfaction and unplanned admissions following the introduction of new lists or procedures to the unit
- Unplanned admission rates and reasons in gynaecological laparoscopy and inguinal hernia repair
- Comparison of individual anaesthetists' techniques in laparoscopic surgery
- Procedures producing 'severe' pain identified at patient feedback
- Success in contacting patients after discharge
- Satisfaction of carers with transfer of the service for special needs patients undergoing dental treatment in the new day surgery unit
- Use of laryngeal mask airways and endotracheal tubes
- Profile of unit work for identification of specialist registrar training requirements
- Analysis of patient comments/complaints
- Review of workload on some operating lists (leading to an increase in cases booked)
- Compliance with unit policy for senior operators and anaesthetists
- Identification of numbers of intraocular lenses following both extracapsular extraction and phaco-emulsification to obtain accurate costings for the lists
- Review of paediatric activity

5

Potential for future anaesthetic and surgical practice

Ideally, any patient's electronic record should include an anaesthetic record-keeping system to allow specific techniques, perioperative events, and drugs and their doses to be linked to postoperative follow-up.

Computer-aided drawing tools for surgical operating records could, potentially, allow data collection of the site and frequency of pathological lesions and their treatment.

The concept of being able to set up automatic reports to allow re-runs of previous audits is attractive and should be striven for.

Using the data to inform clinical practice

Clearly, the data collection described is not clinical research and, if these data are to become true audit information, audit criteria must be defined and performance measured against them. Nevertheless, important information can be gained and may provide pointers for more structured research projects. It becomes possible to gain a picture of what is really happening to patients. The patients have not been subject to double-blind, controlled trials; they have been treated in a real hospital by identifiable clinicians under real conditions. Such information is now essential to produce a realistic clinical governance agenda for day surgery.

Presenting results of surveys and audits at local surgical and anaesthetic audit meetings, to individuals and other groups (e.g. GPs) informs local practice. The information can be sensitive and requires diplomatic handling. It is wise to insist that clinicians who request data for audits gain prior permission from all colleagues whose work is involved, and that no clinical data are presented in identifiable form without the permission of the individual. Information should be provided to managers only with the permission of the clinician, though anonymized monthly activity reports are generally less contentious. Increasingly, however, clinicians will have to be accountable for their own information on outcomes and wide variations in practice will have to be justified.

Design Requirements of Day Care Units

Mark Hitchcock
Inge Falk van Rooyen

Mark Hitchcock is Consultant Anaesthetist and Director of Day Surgery at Addenbrooke's NHS Trust, Cambridge, UK. He qualified from St Bartholomew's Hospital, London, and trained in anaesthetics in Cambridge and Bristol, UK.

Inge Falk van Rooyen is Specialist Registrar in Anaesthesia at the Norfolk and Norwich Hospital, East Anglia, UK. After qualifying from Stellenbosch University, South Africa, she specialized in anaesthesia. Her main interests are day stay anaesthesia and teaching.

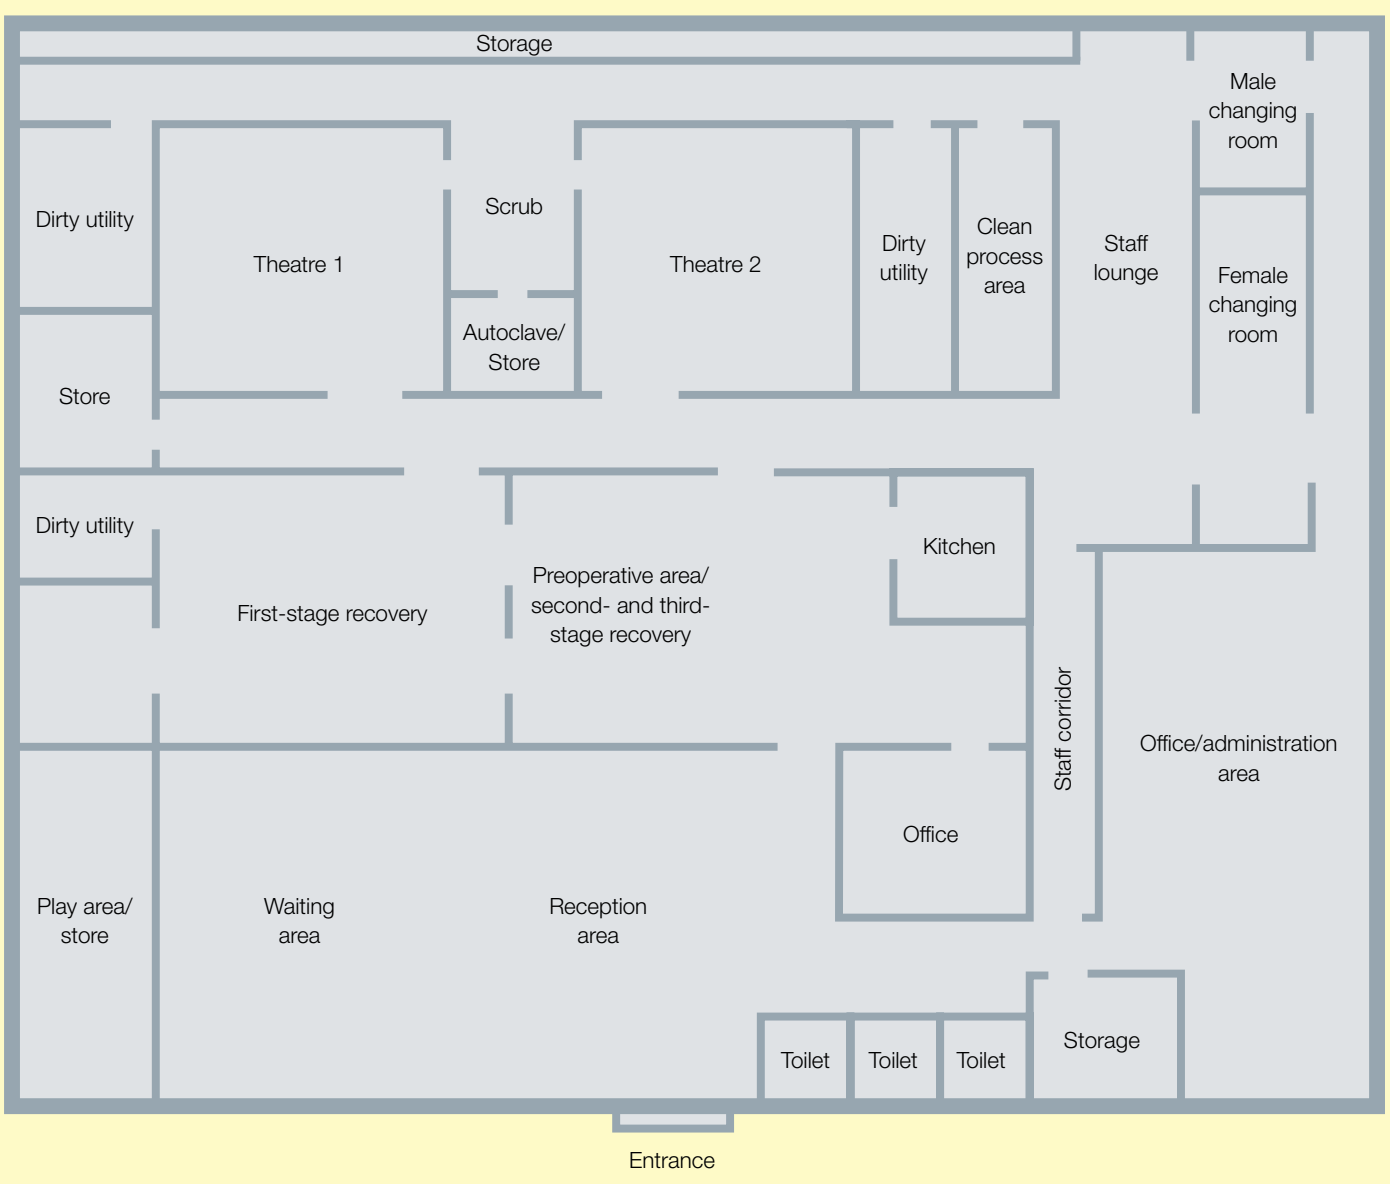
The efficient design of day care units is important to optimize costs and maintain quality of care and patient safety while processing large numbers of patients.

The rules that preclude the treatment of adults and children alongside each other significantly influence the provision of day surgery services for children. The design of the day care unit will reflect the level of need for paediatric care in the community by providing a dedicated children's unit, dedicated children's sessions within the adult unit, or accepting the fact that the use of the unit by children will be limited.

Basic design considerations

The day care unit must allow direct flow lines for patients and supplies, in order to avoid cross-infection and to maintain sterility. The layout must ensure that preoperative and postoperative patients do not meet. To maximize the efficient use of resources, the level of double handling of patients and supplies must be minimized, and careful consideration must be given to staff traffic patterns. The plan of a typical day care unit is shown in Figure 1.

Basic day unit design



1

Traffic patterns

In the USA, which has led the field in day surgery, there is a fixed prototype design for day care units. Each unit is divided into three zones. The front third is a non-sterile reception area for the public and houses the administration centre. The sterile area, containing the operating theatres, is situated in the back third of the building, and the middle section comprises patient preparation and recovery areas, storage facilities and staff lounges. The central section is accessible from both the sterile and non-sterile sides of the building along one or two corridors, one of which may be sterile.

Within the unit, the traffic pattern flows from front to back. Patients and staff enter through reception, staff move to the facilities in the central section, while patients complete the administrative procedures, and can remain with their escorts before moving into the central section for preoperative preparation. After surgery, patients are taken to the recovery area and monitored until they are safe to be discharged. They pass back through reception, where they can be collected by their escort.

Technology

An integrated management system, networked to the main hospital, provides an efficient method of processing patients on a daily basis, and produces statistical information, which can be used as an audit tool to ascertain patterns, manage productivity and resources. Such a system should improve legibility and accuracy of information and allow efficient management of supplies and a reduction in storage requirements in the unit.

General requirements

The decor should create a sense of relaxation and use finishes that are easy to clean and maintain. Floors should be on a single level, and should be non-slippery and hardwearing. Wherever possible, natural daylight should be used. Fire precautions should ensure that the building can be evacuated quickly and easily.

Specific requirements

Location/site selection and entrance

The main requirement is the need for easy access for patients, staff and services. Ideally, the unit should be freestanding, and of single-storey construction with dedicated car parking. Siting the unit on in-patient hospital sites allows direct access to support services without compromising independence. An easily identifiable main entrance is essential. There should be entrances for secondary supplies off the street. It should be possible for patients to be dropped off and collected by their escort at the entrance, which may be covered by a canopy to offer weather protection.

Reception area

The reception area is the non-sterile area of the unit where the administrative centre is located. It should contain a reception desk with information technology facilities and allow good visibility over the waiting area and any play facilities for children. The design of the desk should accommodate disabled patients.

The main waiting area should be informal, perhaps containing a fish tank and reading material, and should provide space for people using walking aids or wheelchairs. Sufficient lavatories should be provided including some with disabled access; one per ten users is recommended.

Patient preparation, second- and third-stage recovery area

The design of the patient preparation area and the second- and third-stage recovery area should incorporate administrative facilities.

Patients' trolleys may be separated by curtains hung from suspended tracks, and should allow adequate space for changing. A bedside cabinet should be provided for storage of valuables and a chair provided for the escort.

Male and female patients can be separated most easily by grouping those of the same gender together, according to the numbers of each on the operating list. This obviates the need to duplicate the facilities, and allows most efficient use of the ward area.

Trolleys are preferred to beds because they are more economical, occupy less space and avoid the need to transfer immobile patients from one platform to another. The use of thick mattresses makes them comfortable, while a 90° adjustable backrest promotes their use for first- and second-stage recovery. A mobile resuscitation trolley is needed.

The provision of hand basins (two per ten trolleys) and face mirrors allows patients to check their appearance before discharge. There should be a separate consulting/ examination room to provide privacy if required. This can also be used for pre-assessment or teaching.

Anaesthetic room and operating theatre(s)

Ideally, there should be a separate anaesthetic room that is large enough to allow free access around the patient's trolley to permit the use of local or general anaesthesia.

The room should contain a full suite of equipment to the level provided in a standard theatre suite. The alternative of anaesthetizing patients in theatre is less efficient because it requires the anaesthetist's time to prepare the patient, and causes delay while the theatre is cleaned. However, the cost involved in providing and equipping this second room may be prohibitive. Alternatively, a single anaesthetic room may serve two theatres, depending on list allocation.

The operating theatre should be large enough to accommodate the usual surgical equipment. It should also provide a good operating light, air-conditioning, piped services and scavenging facilities as well as scrub-up and lay-up facilities of a comparable standard to in-hospital theatres. Scrub facilities and sterile services may be designed to serve two theatres if interposed between them.

First-stage recovery area

The first-stage recovery area should have direct access to the theatres to allow access in the case of emergencies and to shorten transfer times. Piped services and the full range of monitoring and resuscitation equipment are mandatory. A minimum of two bed spaces per theatre should be accommodated to ensure rapid turnover times.

Ancillary services

Ancillary services must be provided in the most efficient manner.

- The delivery of sterile supplies and the removal of dirty utility needs to be effected directly through secondary entrances to prevent disruption to the flow of patients within the unit.
- It is important to situate the kitchen in the second-stage recovery area, where it can serve the needs of postoperative patients and offer their escorts light refreshments and beverages. Ideally, a well-stocked vending machine should be available within the waiting area.
- Sufficient accessible storage facilities must be incorporated in the design of the unit; the need for them is often under-estimated.
- The staff of the unit should have a private rest area incorporating kitchen facilities and pleasant changing rooms with personal lockers. Consideration has to be given to the ratio of female to male staff and this should be reflected in the area assigned to each changing room.

General and Regional Anaesthesia for Day Case Surgery

Peter Davies

Peter Davies is Consultant Anaesthetist and Lead Clinician in Day Surgery at Derriford Hospital, Plymouth, UK.

Day case patients are discharged soon after surgery and thus need complication-free anaesthesia and surgery provided by senior staff. Although unexpected overnight admission (Figure 1) following day care surgery is often required for surgical reasons, it may also result from anaesthetic causes such as pain, postoperative nausea and vomiting (PONV) and delayed recovery. Attention to detail is therefore vital when selecting an appropriate anaesthetic technique for each patient.

Much day case surgery and anaesthesia is viewed as routine or simple, but it has to be performed to a high standard, therefore senior staff should perform day case anaesthesia. If complications arise when the patient has been discharged, they have to contact their GP or return to hospital. Following day surgery, 5–40% of patients contact their GP, usually for wound problems, but sometimes because of pain or PONV. With the increase in pressure on in-patient beds, many operations are now performed almost exclusively as day case procedures, therefore trainees in anaesthesia will have to gain supervised experience in the day surgery unit.

Reasons for unexpected overnight admission

Surgical reasons
- Longer operation than planned
- Bleeding
- Urinary retention
- Surgical complications

Social reasons
- Failure of escort
- Changed social circumstances

Anaesthetic reasons
- Pain
- Nausea and vomiting
- Drowsiness
- Anaesthetic complications

1

Premedication

Anxiolytic premedication
Anxiolytic premedication is seldom prescribed in day case patients because it is thought to delay discharge, though the few studies investigating it have demonstrated no increase in overnight admission or delayed discharge.

A patient who has had adequate preoperative counselling and preparation is less likely to be anxious. The simplest treatments for anxiety include reducing the waiting time for that particular patient by reorganizing the list and providing a relaxing environment with entertainment such as magazines or television.

If this is inadequate, temazepam, 20 mg p.o., is a suitable regimen. In children, midazolam, 0.5 mg/kg p.o., is an effective anxiolytic, if required. Most children also have local anaesthetic cream applied to prospective cannulation sites if intravenous induction is to be used.

Antacid therapy
There is an increase in volume and acidity of gastric contents in day case patients, and many advocate the routine use of an H_2-receptor blocker and metoclopramide. However, there is no evidence of an increased incidence of regurgitation and aspiration, therefore their routine use is unnecessary. For full effect, they must be taken the night before, and on the morning of, surgery.

In patients with a high risk of aspiration (e.g. those with gastro-oesophageal reflux or obesity), it may be necessary to prescribe the drugs and give detailed instruction at the pre-assessment clinic for them to be taken at home the night before surgery.

Perioperative analgesic drugs
Perioperative analgesic drugs can be given orally, rectally or intravenously. Oral absorption may be affected by anxiety and the rectal route may not be popular with the patient. It is important to obtain specific oral consent for rectal medications given under general anaesthesia or sedation.

- The mean time to peak plasma levels of diclofenac is 120 minutes orally (enteric-coated oral form) and 60 minutes rectally. Slow-release oral preparations are available, but they do not reach a steady state until several doses have been given. Intravenous drugs can be given but have their own problems. Diclofenac must be given by infusion over 20 minutes to avoid venous sequelae. The quickest-acting drug with the least complications is probably diclofenac, 1 mg/kg p.r. This can be self-administered by the patient preoperatively or given just after induction of anaesthesia.
- Parenteral ketorolac has few local effects, but its data sheet in the UK limits the initial dose to 10 mg. Most of the studies into the effect of this drug used doses of 30–90 mg.
- Tramadol is an opioid drug that is meant to be devoid of central side-effects, but it increases the incidence of PONV.

General anaesthesia

There has been an increase in the availability of short-acting agents for induction and maintenance of anaesthesia and although all of these drugs appear more expensive initially, there is increasing evidence of a reduced overall cost to health services and society. Few studies have examined the overall implications of different anaesthetic regimens, or surgical treatments, on total costs to the hospital, the patient or society. Early return to work, less use of expensive primary care resources, reduced overnight admission and less PONV could provide cogent arguments for the use of total intravenous anaesthesia with propofol, for all day case patients, despite the increase in total propofol costs to the hospital. This would help patients who are more worried about PONV than postoperative pain, as well as managers of day case units who are concerned about increased overnight admissions and surgeons who do not want in-patient beds filled with day case patients. Anaesthetists should provide high-quality symptom-free anaesthesia using multimodal postoperative analgesia.

Day case anaesthetic agents
Until recently, induction and maintenance of anaesthesia would have been discussed separately, but with the advent of total intravenous anaesthesia (TIVA), and volatile induction and maintenance anaesthesia (VIMA), the distinctions are blurred. Face masks and needles are still used with VIMA because it is safer to induce with a cannula *in situ*. Coughing and breathholding occur in 5–15% of inductions, though less often in more experienced hands.

The qualities of an ideal day case anaesthetic agent are listed in Figure 2.

Qualities of an ideal anaesthetic agent

- Fast predictable onset
- Fast predictable elimination
- Easily titratable depth of anaesthesia
- No active metabolites
- No accumulation
- Stable in solution in water/volatile liquid at room temperature
- No pain on injection/non-irritant on inhalation
- Good side-effect profile
- No PONV

2

Propofol is the most widely used induction agent in ambulatory surgery and, when used as part of TIVA, produces smooth induction with a rapid return to 'clear-headedness'. Propofol induction and maintenance anaesthesia, without nitrous oxide, using combination analgesic therapy is the treatment of choice for most patients undergoing day case anaesthesia. It has a low incidence of PONV. Its side-effect of pain on injection can be ameliorated by injection into larger forearm veins and the addition of 1% lidocaine (lignocaine), 2 ml.

The advent of target-controlled infusions (TCI) of propofol has made training in TIVA easier. Studies have shown TIVA- naïve anaesthetists find it easier to learn TCI compared with manually controlled infusions, but in experienced hands, the outcome of the two methods is similar. Figure 3 gives typical dose requirements for TCI and manually controlled propofol. The rate of infusion of propofol affects the speed of induction and the total dose required. With a rate of 600 ml/hour,induction takes up to 90 seconds requiring 1.96 mg/kg, whereas 1200 ml/hour takes about 60 seconds requiring 2.6 mg/kg, an increase of about 40 mg for a 70 kg patient.

Typical doses of propofol for manually controlled infusion and target-controlled infusion

	Manually controlled	Target controlled
Induction	1.5–2.5 mg/kg	4–8 μg/ml
Maintenance	12,10, 8 mg/kg/hour[1]	3–5 μg/ml

[1]The maintenance dose manually without nitrous oxide is 12 mg/kg/hour for 10 minutes, followed by 10 mg/kg/hour for 10 minutes with a maintenance thereafter of 8 mg/kg/hour.

3

Sevoflurane and desflurane have blood gas partition coefficients of 0.67 and 0.42, respectively, and are thus rapid acting with a short duration of action. Both drugs have demonstrated faster early recovery than older agents (e.g. isoflurane, propofol), but time to discharge is not reduced. The higher incidence of PONV with these volatile agents may account for this. Desflurane alone has demonstrated time to home readiness more than three times longer than propofol and, even when combined with ondansetron, desflurane does not lead to earlier discharge. Desflurane is unsuitable for gaseous induction of anaesthesia owing to its pungent odour and irritant airway effects. Sevoflurane produces rapid smooth induction of anaesthesia, and rapid offset with few side-effects except for PONV.

Isoflurane is widely used for maintenance of anaesthesia, despite higher incidences of PONV compared with propofol. Like desflurane, it is unsuitable for gaseous induction. The main reasons for continuing with isoflurane in the ambulatory setting are cost, familiarity with volatile anaesthesia and lack of equipment.

Opiates: despite the increased risk of PONV associated with the use of opiate drugs, they are used in most general anaesthetics as part of a balanced anaesthetic technique. The shorter-acting drugs (fentanyl, alfentanil, remifentanil) are in widespread use because they are cardiostable, non-allergenic and have a short duration of action. The older opiates (morphine, pethidine) provide good longer-lasting analgesia, but are associated with an increased incidence of PONV. These drugs are useful for treating severe postoperative pain when shorter-acting agents and other analgesic modalities have been tried.

Remifentanil is a relatively new esterase metabolized opiate, which has many of the requirements of the ideal ambulatory surgery anaesthetic agent. As more complex procedures are being performed in the ambulatory setting, the availability of a drug that can produce deep anaesthesia for a short period of time combined with haemodynamic stability and rapid recovery is of great benefit (e.g. for wisdom teeth extraction or anal surgery). In ventilated patients, it is given in doses of 1 μg/kg followed by infusion ranging from 0.1–0.75 μg/kg/minute (usually 0.25–0.5) when combined with expired isoflurane 0.8%, or propofol, 100 μg/kg/minute. A reduced induction dose of propofol, 1–1.5 mg/kg, is generally required. The time to wake-up is short owing to the context sensitive half-time of 3 minutes, but it is the quality of wakening which is impressive, with reduced coughing and breathholding. Fast recovery has been shown in studies demonstrating better psychomotor tests at 30, 60 and 90 minutes compared with alfentanil use.

In spontaneously breathing patients, it has been difficult to find a dose of remifentanil that produces anaesthesia but allows adequate respiration. Doses of remifentanil, 0.025–0.05 µg/kg/minute, with expired isoflurane 0.8–1.3% or propofol, 120–140 µg/kg/minute, provided maintenance of anaesthesia. In studies, the induction boluses of drugs have produced periods of apnoea, which makes dose selection difficult.

In some studies, remifentanil has been shown to produce a significant incidence of PONV but, owing to its rapid elimination, this effect is short lived. The short action of remifentanil means that any analgesic opiate effect wears off rapidly after termination of the drug, which may limit its usefulness in operations with significant postoperative pain

PONV

PONV is one of the main symptoms causing distress to day case patients and unexpected admission. The risk factors for PONV are listed in Figure 4.

Every day unit should have an action plan for patients at risk of PONV (Figure 5).

Airway maintenance

Risk factors for postoperative nausea and vomiting (PONV)

- Female gender
- Ambulatory surgery
- Opiates
- Starvation
- Gynaecological, ENT or ophthalmic surgery
- Early in menstrual cycle
- Previous PONV
- Motion sickness
- Nitrous oxide
- Non-smoker

4

Action plan for postoperative nausea and vomiting (PONV)

- All patients or high-risk patients
- Total intravenous anaesthesia, no nitrous oxide
- Triple analgesic therapy (non-steroidal anti-inflammatory drugs, opiates, local anaesthetics)
- Hydration
- Early treatment of postoperative pain
- Early treatment of PONV with 5-HT_3 antagonist

5

The advent of the laryngeal mask in 1988 revolutionized anaesthetic practice (Figure 6), particularly in ambulatory surgery. The laryngeal mask is less likely to cause sore throat compared with a tracheal tube and, in gynaecological laparoscopy, it decreases total operation time, which may allow more patients to be treated on an operating list, thus reducing overall costs.

In paediatric tonsillectomy, airway contamination is reduced when an armoured laryngeal mask airway is used compared with an uncuffed tracheal tube. Desaturations and surgical time are reduced in grommet insertion when compared with a face mask, and coughing and breathholding are reduced in cataract patients when compared with intubation. In short procedures, the laryngeal mask and spontaneous respiration avoid some of the problems of muscle relaxants. Though it has a short duration of action, suxamethonium causes muscle pains. None of the currently available non-depolarizing muscle relaxants can be given with certainty of easy intubation at 2 minutes and easy reversal after 10 minutes.

Much has been made of the dangers of unintubated spontan-eously breathing laparoscopy. With careful selection of patients, modern drugs and monitoring, this is a safe procedure. Complications arose in the past because of inadequate airways, unmonitored end tidal carbon dioxide concentrations and halothane anaesthesia, which all increase the likelihood of cardiac arrhythmias. Although in current use for ventilated gynaecological laparoscopy, ventilation through the laryngeal mask airway will occur against the increased intra-abdominal pressure which may overcome the laryngeal mask leak pressure of about 20 cm H_2O and cause increased intragastric air insufflation, perhaps resulting in an increased risk of regurgitation. Guidelines for laryngeal mask airway laparoscopy are given in Figure 7.

Uses of the laryngeal mask airway

- Gynaecological laparoscopy
- Tonsillectomy (adults and children)
- Dental extractions
- Intranasal surgery
- Head and neck procedures
- Shoulder operations
- Ocular surgery

6

Guidelines for laryngeal mask airway laparoscopy

- Elective gynaecological surgery only
- Body mass index < 31
- No symptoms of reflux
- Short procedures (< 30 minutes)
- Full monitoring
- Spontaneous breathing
- 2 litres of gas
- Trendelenburg tilt as needed
- Propofol infusion

7

Regional anaesthesia

Regional anaesthesia alone or combined with general anaesthesia or sedation should be standard practice for many ambulatory patients because it provides optimum operating conditions for the patient and the surgeon, with minimal side-effects. Regional anaesthesia alone is particularly suitable for less fit patients who would otherwise need overnight admission for general anaesthesia. Regional techniques provide good postoperative pain relief for patients and may allow the addition of more complex procedures to the routine mix of day case operations.

Regional anaesthesia for day case surgery has not been undertaken with great enthusiasm in the UK for various reasons, including the incidence of post-dural puncture headache in young people following early ambulation. Also nerve and plexus blocks take time and skill to set up and have a high failure rate. The advantages and disadvantages of regional anaesthesia compared with general anaesthesia are listed in Figure 8.

In the UK, much health authority funding has been used to increase the range and complexity of day case surgery, which requires long-lasting postoperative pain relief. The addition of drugs to local anaesthetics, and the manipulation of local anaesthetic drug concentrations and baricity have allowed a more predictable onset and offset of motor block, often providing prolonged analgesia, without delayed discharge. Many operations can be performed under local or regional anaesthesia. Plexus blocks and other regional techniques can also be performed with sedation or general anaesthesia to provide good postoperative analgesia. This reduces the benefit of avoiding sedative drugs in terms of PONV and recovery, but allows patients who would not otherwise tolerate regional anaesthesia the best of both worlds. Some advantages and disadvantages of local anaesthetic techniques in common day case surgical operations are given in Figure 9.

Comparison of regional and general anaesthesia

Advantages

Regional anaesthesia

- Prolonged analgesia
- Reduced postoperative nausea and vomiting
- Reduced confusion

General anaesthesia

- Fast
- No failures

Disadvantages

- Prolonged motor block
- Post-dural puncture headache
- Slow onset
- High failure rate
- Postoperative nausea and vomiting
- Confusion

8

Regional techniques for some common day case procedures

Surgical procedure	Regional technique	Advantages	Disadvantages
• Hernia repair	Field block	Good postoperative pain relief Speed Low failure rate	Needs supplementation
	Spinal	Speed Llittle supplementation	Post-dural puncture headache Urinary retention Delayed mobilization
• Cataract extraction	Peribulbar block	Reduces confusion and	Ocular complications discharge time
• Knee surgery	3-in-1 block	Good analgesia	Failed blocks
	Spinal	Speed Little supplementation	Post-dural puncture headache Urinary retention Delayed mobilization
• Foot surgery	Popliteal block, ankle blocks	Good analgesia	Failed blocks
• Hand surgery	Bier's block, brachial	Analgesia plexus blocks	Failed plexus blocks Minimal systemic disturbance

9

Spinal anaesthesia

The advent of 26–27 G pencil-point spinal needles has reduced the incidence of post-dural puncture headache from over 10% to about 1.5% for ambulatory patients. Few direct comparisons between spinal and general anaesthetic techniques have been conducted in the ambulatory setting, but time to fitness for discharge is longer after spinal anaesthesia compared with general anaesthesia, and is related to time to return of motor and bladder function.

Concerns regarding the neurotoxicity of high concentrations of lidocaine (lignocaine) have led to questions about its use in spinal anaesthesia. It has been widely used because of its fast onset and short duration of action, but it has been suggested that spinal bupivacaine should be used instead. Much research has been directed towards elucidating the optimum dose, concentration and baricity of bupivacaine to provide an adequate spinal block for surgery to proceed, but a short enough duration of action to allow timely discharge home. The optimum drug for knee arthroscopy is bupivacaine, 7.5 mg, which provides 100% success and street fitness after only about 3 hours (Figure 10). Clonidine, adrenaline (epinephrine) and fentanyl have been studied as additives to spinal local anaesthetics; the addition of fentanyl, 20 µg, can increase the length of postoperative analgesia, but not delay discharge.

Choice of spinal anaesthesia for knee arthroscopy

Drug	Dose (mg)	Time to discharge (minutes)	Successful block (%)
• 2% lidocaine (lignocaine)[1]	40	178	91
	60	216	91
	80	214	97
• Hyperbaric 0.5% bupivacaine diluted to 3 ml[2]	5	181	73
	7.5	202	100
	10	260	100

[1]Urmey *et al Anesthesiology* 1995; **83:** 528–34
[2]Ben David *et al Anesth Analg* 1996; **83:** 716–20

10

Major orthopaedic surgical techniques are being performed regularly as day case procedures. Arthroscopic shoulder surgery, and ligament reconstruction in the knee are operations with a high incidence of postoperative pain unless regional anaesthesia is used as part of the perioperative technique. Interscalene or suprascapular nerve block in the upper limb and 3-in-1 femoral block in lower limb procedures can produce long-lasting pain relief. Prolonged motor block is seen after these procedures and, in many UK orthopaedic centres, the discharge criteria after knee surgery include production of an adequate quadriceps contraction. Adequate physiotherapist-led instruction for the patient is needed regarding ambulation and protection of the blocked limb (Figure 11).

Postoperative instructions following local anaesthetic block

Local anaesthetic block	Postoperative instructions
• Spinal	Needs full ambulation and ability to pass urine
• Bier's block	No discharge for 30 minutes after release of tourniquet
• Brachial plexus block	Sling for limb, protection of numb, weak limb Return if no full return of power and sensation in 18 hours Take analgesics as soon as the first pain is felt
• Lower limb nerve block	Teach ambulation with crutches, protection of numb, weak limb Return if no full return of power and sensation in 18 hours Take analgesics as soon as the first pain is felt
• Inguinal field block	Discharge early so patient reaches home before block wears off Take analgesics as soon as the first pain is felt

Postoperative Analgesia for Day Case Surgery

Anna Johnson

Anna Johnson is Consultant Paediatric Anaesthetist at Derriford Hospital, Plymouth, UK. She qualified from St Andrews University and Manchester Medical School and trained in anaesthesia at University College, the Hammersmith Hospital and Great Ormond Street Hospital, London. She is dedicated to raising the standards and quality of paediatric anaesthesia in the district general hospital and is especially interested in providing good paediatric pain control.

A significant proportion of surgical procedures are performed as day cases and, owing to economic pressures, this is continuing to increase. However, inadequate postoperative analgesia is a major problem resulting in patient dissatisfaction, delays in discharge and in the resumption of normal activities.

Analgesia needs to be maintained throughout the recovery period and to allow comfortable mobilization. Many studies suggest that, despite good analgesia at discharge, patients suffer pain once they are home; this has recently been highlighted as a major problem in children. The provision of good postoperative analgesia needs careful planning, which should begin in the preoperative period.

Preoperative management

Explanation is of paramount importance, because allaying anxieties can decrease the severity of postoperative pain. A verbal description of the analgesia to be provided should be reinforced with concise written information. If local anaesthesia is planned, it is necessary to explain how this will feel on wakening, the duration of its action and any side-effects. Consent for suppository administration and neural blockade should be obtained.

Patients need to be educated about how to express any postoperative pain they may feel and how it may be treated. Regular, pre-emptive analgesia is a particularly important concept, which must be explained to the patient. In paediatric day case surgery, it is important to communicate appropriately with both the parent and child.

Preoperative analgesics, usually oral or rectal non-steroidal anti-inflammatory drugs (NSAIDs), may be given though the usefulness of preoperative pre-emptive analgesia is debatable.

Peroperative management

Analgesic strategies should be aimed at enabling the patient to be pain free on regaining consciousness. This can be achieved using a balanced approach with a combination of NSAIDs, local anaesthesia and, if necessary, small amounts of short-acting opiates.

NSAIDs (Figure 1): paracetamol acts synergistically with other NSAIDs, so both should be given. In children, paracetamol, 30–40 mg/kg p.r. or 20 mg/kg p.o., is the accepted loading dose, followed by regular dosing of up to 90 mg/kg/day. Diclofenac is also available as topical eye drops, which are effective as analgesia following strabismus surgery.

Side-effects – concerns have been raised over the side-effects of NSAIDs. They inhibit platelet function and should not be used in patients with pre-existing coagulation defects or those undergoing extensive tissue dissection. NSAIDs are commonly given for adenotonsillectomy, but should be withheld if there is excess blood loss or if there is any evidence of a coagulopathy.

No increase in gastrointestinal side-effects is seen with short-term use (up to 3 days) of NSAIDs, provided that the patient has no history of gastrointestinal irritation.

NSAIDs should be avoided if there are any signs of renal impairment or if other nephrotoxic drugs are being administered. The renal tubules are protected from the effects of dehydration by mechanisms utilizing prostaglandins, so it is important to keep patients well hydrated.

Of adults with asthma, 5–10% are sensitive to NSAIDs, therefore it is worth checking specifically if such individuals have taken NSAIDs previously without problems; if in doubt, NSAIDs should not be given. In children with asthma, NSAIDs seldom cause respiratory complications, but they should be avoided if nasal polyps are present or if the child has had recent repeated hospital admissions, especially if they have required intensive care.

NSAIDs commonly administered peroperatively

Drug	Route of administration	Dose (mg/kg)
Diclofenac	Oral or rectal	1
Ibuprofen	Oral	5
Ketorolac	Intravenous	0.5

1

Local anaesthesia can be used in a number of ways to provide excellent analgesia with few side-effects and often obviates the need for opiates (Figure 2). However, care must be taken not to delay early ambulation and patients must be advised about any possible interference with motor function. If sensation is impaired at discharge, warnings should be given especially about touching or drinking hot liquids, which may cause inadvertent scalds.

In laparoscopic cholecystectomy, 20 ml of 0.5% bupivacaine may be administered into the hepatodiaphragmatic space. Bupivacaine is generally preferred to lidocaine (lignocaine), because of its longer duration of action, which can be prolonged by the addition of 1:200,000 adrenaline (epinephrine). Ropivacaine has recently been introduced and has a similar duration of action, but causes less motor blockade.

Spinal and epidural anaesthesia are seldom used in the UK, but are commonly used in day case procedures in other countries.

Opioids: if possible, opioids should be avoided because of the increased incidence of nausea and vomiting but, if their use is necessary, the shorter-acting opioids are preferred.

- Remifentanil and alfentanil are so short-acting that they provide little postoperative analgesia.
- Fentanyl, 1–2 μg/kg provides 30–60 minutes of analgesia allowing time for NSAIDs to become effective. Fentanyl is the drug of choice in treating significant postoperative pain in the early stages of recovery and should be given in small boluses of 0.2–0.4 μg/kg.
- Morphine causes increased nausea and vomiting especially if administered intravenously. However, doses of 0.1 mg/kg are used intramuscularly, for example, in day case adenotonsillectomy.
- Codeine phosphate may be given by the intramuscular, rectal or oral routes, and it may be useful for more painful procedures.
- Tramadol combines an opioid action with a central adrenergic effect, but has a significant incidence of postoperative nausea and vomiting.

Examples of the use of local anaesthesia

Technique	Type of local anaesthetic	Surgical procedures	Comments
Topical	*Emla* 4% lidocaine (lignocaine) gel	Myringotomy Circumcision	Emla for myringotomies 4% lidocaine (lignocaine) gel for circumcision which can be continued on discharge
		Laparoscopic sterilization	4% lidocaine (lignocaine) gel can be applied to clips
Infiltration	0.25% bupivacaine 1–2% lidocaine (lignocaine)	All surface wounds	Pre-incisional wound infiltration probably offers no benefit
		Laparoscopic sterilization	Mesosalpingeal infiltration
Intra-articular	0.5% bupivacaine	Arthroscopy and arthroscopic surgery	Usually 25–30 ml are used for knee arthroscopy
Nerve blocks	0.25–0.5% bupivacaine 1–2% lidocaine (lignocaine)	Upper limb surgery	No adrenaline (epinephrine) for digital nerve blocks
		Lower limb surgery Hernia repair Orchidopexy	Inadvertent femoral nerve block may result in leg weakness
		Circumcision	No adrenaline (epinephrine) for dorsal nerve blocks
		Otoplasty	Great auricular nerve block decreases vomiting
		Eye surgery	
Plexus blocks	0.25–0.5% bupivacaine 1–2% lidocaine (lignocaine)	Upper limb surgery Lower limb surgery	
Caudal epidural block	0.125% bupivacaine 0.75% ropivacaine	Surgery below the umbilicus	Ketamine (preservative-free), 0.5 mg/kg, or clonidine,1–2 μg/kg, prolongs the block
Intravenous regional	0.5% prilocaine	Upper limb surgery	Limited postoperative analgesia

2

Postoperative management

In the immediate postoperative period, it is important to establish good analgesia before discharge. Small amounts of intravenous fentanyl may be given until analgesia is achieved. Most patients can tolerate oral medication shortly after surgery. A large variety of soluble oral analgesics are available, enabling rapid absorption and action.

Most day case units have a drug discharge policy with combinations of paracetamol, NSAIDs and codeine preparations as regular oral analgesics continued for at least 3 days postoperatively (Figure 3). If paracetamol and codeine (or its derivatives) are used as a combined preparation, the patient should be warned not to take other medications containing paracetamol. Also, higher doses of codeine may cause constipation. The discharge drugs should be given to the patient with both verbal and written instructions emphasizing the importance of regular pre-emptive analgesia. Controlled or slow-release preparations may be beneficial, especially at maintaining analgesia overnight.

Patients need to know who to contact in the event of any problems. Postoperative follow-up, either by a community nurse or by telephone, increases patient satisfaction and can help improve postoperative analgesia. The adequacy of the analgesia provided should be regularly assessed and audited.

Non-pharmacological techniques of improving patient comfort may help. Psychological strategies such as relaxation and distraction therapy and physical strategies such as the application of heat or cold, massage, exercise or rest have been used in combination with pharmacological methods. Acupuncture and transcutaneous electric nerve stimulation and other similar techniques have also been studied but their clinical efficacy is yet to be proven.

Postoperative oral analgesia

Expected severity of pain	Analgesic regimen
Mild	Paracetamol, 15 mg/kg (up to a maximum of 1 g) 6 hourly
Moderate	Paracetamol, 15 mg/kg (up to a maximum of 1 g) 6 hourly plus NSAID (e.g. ibuprofen, 5–10 mg/kg 8 hourly, or diclofenac, 1 mg/kg 8 hourly)
More severe	Paracetamol and codeine combination (e.g. Co-codamol, 2 tablets 6 hourly[1], Co-dydramol, 2 tablets 6 hourly[2], Co-proxamol, 2 tablets 6 hourly[3] plus NSAID (e.g. ibuprofen, 5–10 mg/kg 8 hourly, or diclofenac, 1 mg/kg 8 hourly)

[1]Co-codamol tablet is paracetamol, 500 mg, with codeine, 8 or 30 mg.
[2]Co-dydramol tablet is paracetamol, 500 mg, with dihydrocodeine, 10 mg.
[3]Co-proxamol tablet is paracetamol, 500 mg, with dextropropoxaphene, 32.5 mg.

Selection Criteria and Preoperative Evaluation for Day Surgery

Stuart Collins

Stuart Collins is Consultant Anaesthetist and Lead Clinician of the Day Surgery Unit at Musgrove Park Hospital, Taunton, UK. He qualified in Nottingham and trained in anaesthesia in Bristol and Oxford. His main interests include total intravenous anaesthesia for day surgery and quality assurance.

Day surgery has expanded rapidly in recent years and it is estimated that soon 60–70% of all elective surgery will be performed as day cases. Correct patient selection and preoperative evaluation are important to minimize morbidity and unplanned overnight stays, and to maintain patient satisfaction.

Preoperative assessment

Assessment should identify patients who are suitable for day surgery, prepare them for their operation and enable any preoperative testing to be performed. Questionnaires or structured telephone calls can be used, but many units now use a nurse-led clinic under clinical guidance with a standardized questionnaire and predetermined selection criteria (Figure 1). It is important to establish that the patient is in the optimum condition for the planned procedure.

Pre-assessment questionnaire

Suitable for day surgery? Yes No If no inform: GP Consultant Patient

Name: Date of assessment: Proposed date of operation:
Consultant: Proposed operation:
Unit no.: Patient Tel. no. Home: Work:
Date of birth:
Next of kin: Telephone no.: Relationship:

Have you had any serious illness in the past?

Previous admissions to hospital (date, problem, type of operation, type of anaesthetic)

Have you or any of your relatives ever had a problem with a general anaesthetic?
Yes / No Action taken

Medications currently being taken. include all prescriptions, aspirin and 'the pill'

BMI Blood pressure Weight Height Pulse

Investigations ordered

- Do you have haemophilia, anaemia or another blood disorder? Yes / No
- Do you have diabetes? Yes / No
- Do you have kidney disease or kidney failure? Yes / No
- Have you ever had liver disease, hepatitis or been jaundiced? Yes / No
- Have you had a heart attack? Yes / No
- Do you get angina or chest pain at rest or with minimal exercise? Yes / No
- Do you have a pacemaker? Yes / No
- Have you had heart disease, rheumatic fever or high blood pressure? Yes / No
- Do you get breathless walking, climbing one flight of stairs or lying flat? Yes / No
- Do you have asthma, bronchitis, or chest disease? Yes / No
- Have you ever had a convulsion, fit, blackout, or do you have epilepsy? Yes / No
- Do you get swollen ankles? Yes / No
- Do you have a hiatus hernia? Yes / No
- Do you get indigestion or heartburn? Yes / No
- Have you ever had a stroke? Yes / No
- Do you have arthritis or muscle disease? Yes / No
- Have you had any corticosteroid drugs in the past? If so when? Yes / No
- If female, are you or could you be pregnant? Yes / No
- Do you smoke or have you smoked in the last 6 months? Yes / No
  If you smoke, how many a day? Yes / No
- Do you drink alcohol? If yes, how many units per week? Yes / No
- Urinalysis Yes / No

Anaesthetist's comments:

1

Selection criteria

The boundaries in day surgery are continually being pushed back and recent studies suggest that significant associated morbidity is low, even in patients with controlled systemic disease. Selection criteria help to establish consistency and agreement among medical staff. The appropriateness of the selection criteria should be reviewed regularly by auditing cancellation rates, patient morbidity and patient satisfaction. Determining suitability solely on the American Society of Anesthesiologists (ASA) classification is unhelpful.

Social factors – the patient must be prepared to have the procedure performed as a day case, live close to the hospital, and have a responsible, able, adult carer at home with them for 24 hours postoperatively.

Surgical factors – the proposed surgery must have a low incidence of postoperative complications and any pain should be controllable by local anaesthetic techniques and analgesics administered orally or rectally. The duration of surgery does not affect the likelihood of same-day discharge, provided longer cases are listed early in the day. A stand-alone unit is different from an integrated unit with facilities for overnight stay, and the patients and surgical procedures should be selected accordingly.

Medical factors – it is difficult to agree on absolute medical contraindications to day surgery because significant postoperative morbidity is uncommon. However, certain medical conditions are associated with an increased risk and render the patient unsuitable for general anaesthesia (Figure 2). With invasive procedures, it is essential that the patient's physical condition is matched to the planned procedure. It is important to consider whether treating the patient as an in-patient would lessen the risks or change the anaesthetic approach.

Medical contraindications for day case anaesthesia

Morbid obesity
- Body mass index > 35 kg/m^2 or weight > 125 kg

Cardiovascular disease
- Poorly controlled angina, arrhythmia or cardiac failure
- Hypertension > 180/100 mm Hg
- Significant valvular or congenital heart disease
- Myocardial infarction or stroke within 6 months

Respiratory disease/airway
- Poorly controlled asthma or chronic obstructive pulmonary disease (patients taking oral corticosteroids, with poor exercise tolerance or with a peak expiratory flow rate < 200 litres/minute are unlikely to be suitable)[1]
- Severe restrictive lung disease (e.g. kyphoscoliosis)
- Previous failed intubation
- Significant obstructive sleep apnoea

Metabolic/endocrine/haematological
- Poorly controlled diabetes or insulin dependent[1]
- Active liver disease
- Anaemia (haemoglobin < 10 g/dl)[1]
- Haemophilia/anticoagulation[1]
- Cholinesterase deficiency[1]
- Hypo- or hyperkalaemia (acceptable range 3–6 mmol/litre)

Renal disease
- Patients requiring renal support[1]

Neuromuscular disease
- Myasthenia gravis
- Significant multiple sclerosis
- Malignant hyperpyrexia susceptibility
- Poorly controlled epilepsy
- Parkinson's disease interfering with daily activity
- Significant motor neuron disease

Acute substance abuse

[1] Patients might be suitable – discuss with lead clinician.

2

Cardiovascular disease
Patients with well-controlled cardiovascular disease should not be denied the opportunity to have their surgery in the ambulatory setting. However, patients with poorly controlled angina, congestive cardiac failure, symptomatic valvular disease, uncontrolled arrhythmias or recent myocardial infarction or stroke (within 6 months) are unsuitable for elective surgery. Minor surgical procedures are categorized as being of low risk for significant cardiac events. Hypertension is associated with an increased risk of developing perioperative cardiac events and should be treated before surgery. A reasonable upper limit for blood pressure is 180/100 mm Hg. It is important to explain to the patient, and their GP, the reasons for controlling hypertension perioperatively so that treatment is initiated. In general, cardiac medication should be taken as usual on the day of surgery.

Respiratory disease
Asthma, chronic obstructive pulmonary disease and smoking all predict adverse perioperative events, but patients with well-controlled disease are likely to be suitable for day surgery. A regional anaesthetic technique can be considered for the more seriously affected. Patients with poorly controlled disease, marked exercise limitation or a recent exacerbation of their condition should have their surgery postponed. Smokers should be encouraged to stop smoking.

Diabetes
Diabetes may be associated with cardiovascular and renal disease or autonomic dysfunction. Diabetes is a predictor of adverse intraoperative and postoperative events, but patients with good diabetic control and a good understanding of their disease should be allowed day surgery. Patients with Type 2 diabetes are, in general, more suitable for day surgery than those with Type 1 diabetes; however, well-motivated patients taking insulin can be considered if their procedure is of short duration and carried out early in the morning. Many Type 1 diabetics understand their insulin requirements better than their anaesthetist does. Hypoglycaemic agents are best avoided until the procedure is completed and the patient has resumed eating and drinking.

Obesity
Obesity is often associated with cardiac disease, diminished respiratory reserve and gastro-oesophageal reflux. A body mass index greater than 35 kg/m^2 is associated with perioperative anaesthetic and surgical problems, and is often used as a cut-off point for patient suitability. Obese patients can be anaesthetized in a day case setting, but they should be encouraged to lose weight before agreeing to any elective procedure in any setting. The patient trolleys and operating tables in the day unit have a maximum safe weight limit. Antacid prophylaxis can be prescribed for symptomatic reflux.

Renal and hepatic disease
Patients on renal support or those with active liver disease are usually unsuitable for day surgery.

Neuromuscular disease
Patients with myasthenia gravis, motor neuron disease, hereditary dystrophies or a susceptibility to malignant hyperpyrexia are generally unsuitable for general anaesthesia in the day unit. Patients with poorly controlled epilepsy are unsuitable, but well-controlled epileptics can have day surgery, provided appropriate drugs are chosen. Although not strictly a neuromuscular disease, pseudocholinesterase deficiency is a relative contraindication to day surgery.

Musculoskeletal disease
Patients with severe degenerative neck disease, predicted difficult airway, or previous failed intubation are probably best anaesthetized in the main hospital, depending on the facilities of the day unit. Patients with significant obstructive sleep apnoea should be observed overnight in hospital.

Haematological disease
Patients with bleeding diatheses may be suitable for day surgery if the deficient factors are corrected preoperatively and the surgery is not too invasive. The opinion of a haematologist should be sought.

Medication
Corticosteroids: patients taking corticosteroid supplements are usually able to undergo day surgery because the stress response to minor surgery has not been found to cause problems. Oral supplementation can also be prescribed. However, patients taking higher doses of corticosteroids require individual medical review.

Oral contraception and hormone replacement therapy are associated with a slightly increased risk of thromboembolic events, but patients are not advised to stop their medication before surgery because the risk of unwanted pregnancy is felt to be greater. Their continued use in patients undergoing lower limb surgery or requiring tourniquet use is more contentious and, if they are continued, the use of subcutaneous heparin would seem prudent.

Warfarin: if the patient needs to stop taking warfarin before surgery, but has a significant risk of thromboembolic events, admission and anticoagulation therapy with heparin are required.

Monoamine oxidase inhibitor use does not preclude day surgery, but suitable anaesthetic drugs should be selected carefully.

Age
Old age should not be a barrier to day surgery. The patient's physiological age is more important than their chronological age; however, they must be assessed carefully for social and physiological factors. The lower age limit for day surgery depends on many factors and should be set locally.

Investigations

In general, patients are over-investigated for day surgery, and the cost:benefit ratio is not always apparent. Preoperative testing should be performed only if indicated by the medical history or by physical examination and if an abnormal test would affect patient management.
Blood tests: full blood counts are usually performed to detect anaemia and therefore should be reserved for patients with a history of heavy bleeding, dyspnoea, renal disease or if they appear unduly pale. Urea and electrolyte assays are usually performed to detect abnormalities in potassium or to detect abnormalities in renal function, and should be reserved for hypertensive and diabetic patients, patients taking diuretics and those with a history of renal disease. A blood sugar level should be performed if indicated by urinalysis. Clotting studies may be indicated if there is a history of excessive bleeding or hepatic disease.

Radiographs: chest radiographs are seldom required. A radiograph of the cervical spine may be indicated in patients with rheumatoid disease or Down's syndrome.

ECG: the usefulness of a preoperative ECG in day surgery is controversial. Up to 30% of ECGs are abnormal in patients over 60 years old, but in only 20% of patients does this lead to a change in management. Patients over the age of 60 or with a history of chest pain, dyspnoea, diabetes or hypertension, should be considered for an ECG. A preoperative ECG can provide a useful baseline.

Anaesthesia and Dental Trauma

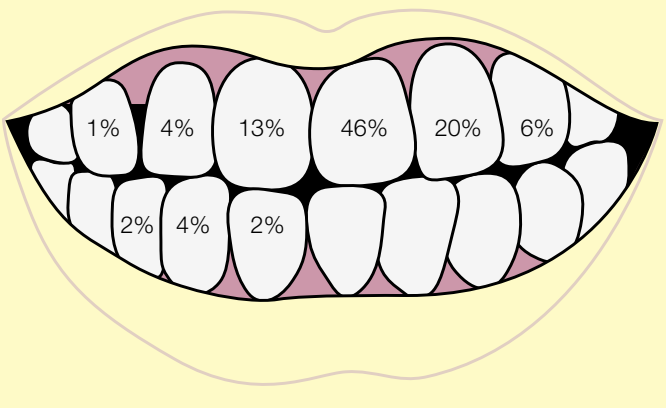
Harry Owen

Harry Owen is Associate Professor in Anaesthesia and Intensive Care at Flinders University of South Australia and Honorary Consultant at Flinders Medical Centre. He graduated from Bristol University and trained in anaesthesia in Bristol, Melbourne and Glasgow. His research focuses on use of new technologies, including simulation, to improve undergraduate education and postgraduate training.

Dental trauma is unpleasant for the patient and the anaesthetist. Dental trauma caused by the straight Magill blade was well known and Macintosh claimed an advantage of his curved blade was a reduced risk of trauma to teeth. The incidence of dental trauma in anaesthesia is 0.01–0.7%. In malpractice claims, anaesthetic-related dental trauma is the most common injury accounting for up to 33% of claims filed in the UK, the USA and Australia. In Australia, the average cost of settling a claim for dental damage is A$2,400 (range A$100–12,800) but the total costs incurred in managing these claims are far higher.

The most common technique of tracheal intubation involves using a laryngoscope to lift the base of the tongue and epiglottis. The pattern of dental trauma, shown in Figure 1, confirms reports that a common mistake is to use the laryngoscope blade as a lever with the upper teeth as the fulcrum. The left upper central incisor is the tooth most at risk.

Pattern of dental trauma in patients examined by a dentist after anaesthesia



1

In the early 1960s, Dr William Haddon launched a movement to base injury-prevention programmes on sounder scientific concepts. Haddon developed a generic approach to the analysis, control and management of injury, which can be applied to all types of hazards associated with energy transfer. Haddon divided accidents into three phases, pre-event (factors that determine whether an accident occurs), the event itself and post-event (everything that determines the consequences of the injuries received). Combining the phases and factors (humans involved, equipment and environment) yields a matrix, that can be used to determine where best to apply strategies to prevent or control injury (see Figure 2). Applying this to the problem of dental trauma in anaesthesia reveals three broad strategies:

- risk avoidance – don't let the event happen
- damage control – if damage occurs, minimize its consequences
- insurance – have someone else pay for the damage.

Haddon's Matrix applied to dental trauma during anaesthesia

Phases	Factors		
	Human	**Equipment**	**Patient factors**
Pre-event	• Good intubation technique • Aware of risk factors for dental damage • Dental history and examination undertaken and understood • Know when and how to use different intubation techniques	• Appropriate range of intubation equipment readily available in hospital • Dental protection devices readily available	• Good dental hygiene • Normal oral anatomy • No drug therapy or diseases contributing to dental problems • Knows what dental treatment has been undertaken • Elective procedure
Event	• Careful and appropriate use of equipment • Good assistance	• Use devices to protect teeth • Use laryngoscope blades designed to reduce contact with teeth • Use warning devices on laryngoscope blades • Intubating without a laryngoscope	• No loose teeth • No malaligned or prominent teeth • No isolated teeth • No heavily restored teeth • No dental prostheses • Normal airway anatomy and no risk factors for difficult intubation • No urgency
Post-event	• Know how to manage situation • Dental help readily available	• Materials to splint teeth safely readily available	• Able and willing to cooperate with treatment

2

Preventing dental trauma is the ideal approach, but the perceived costs of managing occasional dental trauma have to be balanced by the inevitable increased costs to reduce the incidence of dental trauma. A logical approach to reduce dental trauma is to consider intubation strategies for each patient, based on the history, examination and planned procedure.

The primary objective of intubation is patient safety and oxygenation must always be prioritized above dental protection. However, if two alternatives are equally suitable, the most 'tooth-friendly' technique should be preferred. It is important to warn patients of the risk of dental damage associated with intubation. If risk factors for dental damage are present an alternative to direct laryngoscopy should be considered.

Patient factors

The preoperative assessment must include a dental history and an oral examination and the findings should be noted.

Condition of teeth

Major restorations and caries reduce the strength of teeth and make them more likely to break even when small forces are applied to them. Periodontal disease affects the supporting structures of the tooth and increases the risk of dislodgement. Malaligned teeth are more likely to be exposed to unusual forces. An isolated tooth does not have the support of its neighbours and may also have the same condition that led them to be lost so is more likely to be dislodged.

Patient's age

The neonate may not have teeth on view, but delicate tooth structures are just under the gum and can easily be damaged. Infants and young children may have loose deciduous teeth that are easily dislodged. Force applied to a deciduous tooth can also damage the underlying developing permanent tooth. Occasionally, severe caries is seen in adolescents and young adults though this age group generally has healthy teeth. In older patients, dental prostheses are more common.

Dental prostheses

Bridges, particularly to replace upper incisors, are most at risk of damage. They are designed to sustain the forces associated with mastication and do not tolerate forces applied in other directions. Crowns can be weaker than normal teeth. While the porcelain 'jacket' is strong, the supporting post may give way under pressure. Veneers may sheer off if lateral forces are applied. Composite resins are being used increasingly to restore teeth and may be used to repair chipped teeth or as a veneer. Resin restorations can be difficult to detect but forces applied through the laryngoscope can fracture this material. Devitalized teeth as a result of trauma or root canal treatment become more brittle than healthy teeth and are more likely to break when loaded.

Difficulty with intubation

Difficulty with intubation is an important risk factor because it may lead to additional or unusual forces being applied to oral structures including teeth. Earlier use of a bougie or flexible-tip laryngoscope or an alternative method of intubation should always be considered when risk factors for difficult intubation are observed.

Emergency surgery

Urgent cases have an increased risk of dental damage possibly because of the necessary haste and because a laryngoscope is usually used. It is probably prudent to explain this to the patient.

Drug therapy and co-morbidities

Many conditions and drug treatments have dental implications, which is why taking an accurate history is important. Any drug or disease that results in a dry mouth (xerostomia) increases the risk of dental pathology. For example a patient taking methadone as part of a drug rehabilitation programme has an increased risk of dental disease. All opioids reduce salivary flow and promote dental disease. While a patient is abusing narcotic drugs it is likely that dental hygiene is not attended to, making dental pathology even more likely. Methadone is presented in a sugary syrup and this also promotes caries. Also, if the patient has acquired HIV or AIDS, problems may arise from HIV periodontitis and xerostomia from the disease and/or drug treatment.
Intubation alternatives

There are several alternative intubation techniques that may reduce the risk of dental trauma.

Flangeless or reduced-flange laryngoscope blades: the most extreme example of this is the Bizzarri-Guiffrida blade which has no flange at all, but this makes it more difficult to use. The Bellscope blade is shaped to reduce the risk of contact between teeth and flange.

Warning devices: a number of prototype systems that warn when pressure is being applied to teeth have been described.

Lightwand intubation: the malleable wand of the *Trachlight*® and the need for very little mouth opening should reduce the incidence of dental trauma from intubation.

The intubating laryngeal mask airway (LMA): the *Fastrach*® could reduce the risk of teeth being broken, but loose teeth could still be subluxed during insertion and manipulation of the LMA.

Fibre-optic intubation is used routinely in some centres but the cost limits its routine use in most hospitals.

Don't intubate: the growing range of airway management systems (e.g. the LMA Proseal®) may provide an acceptable alternative to intubation in some patients. However, objects put in the mouth to protect the device (e.g. a Guedel airway) may increase the risk of dental damage. A real 'bite block' sits between the molars which are designed to tolerate high forces. Anything put between the incisors increases the risk of subluxation of the upper incisors.

Mouthguards: there is no good evidence that using a generic mouthguard protects teeth from damage during laryngoscopy. In one study, when the mouthguards were removed they sometimes had teeth embedded in them. Custom mouthguards may be useful, especially if there are anterior bridges, but they need to be fabricated in advance of the procedure and may make intubation more difficult. ◆

Anaesthesia for Facial Trauma

Joy E Curran

Joy E Curran is Consultant Anaesthetist at the Queen Victoria Hospital, East Grinstead, West Sussex, UK. She is currently College Tutor and is the South East Thames Lead Consultant for flexible training. She qualified from St Thomas' Hospital, London, and trained as an anaesthetist at St Bartholomew's, St George's and King's College Hospitals, London. Her main interests are in anaesthesia for head and neck

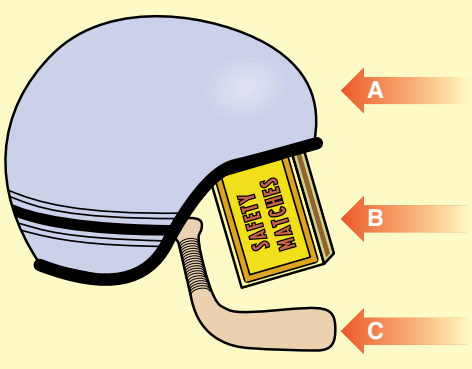
Facial trauma has particular importance for anaesthetists because it directly involves the upper airway. Trauma to the face can also affect the vital structures involved in four of the five senses, the underlying brain, the soft tissues (with implications for the cosmetic result) and the bony skeleton.

The main cause of facial injury in developed countries was road traffic accidents (RTAs) until the later half of the 20th century when assault became the most common cause. Sports injuries and falls (especially in those under 5 years of age) are the second most common cause. Industrial accidents have decreased as safety regulations have become more stringent, but like gunshot and missile injuries they can cause complex fractures with gross comminution and soft tissue loss.

Many patients with facial trauma following RTAs and assaults have ingested alcohol and/or social drugs. Young men account for 75% of facial trauma patients.

Types of injury
Figure 1 shows the relative strength of the bones of the skull and face. Facial fractures follow the lines of weakness of the facial bones. Guerin in 1866 and Le Fort in 1901 described these in their classic papers. Facial fractures are still known by the Le Fort classification (Figure 2). A patient may have multiple levels of fracture.

Strength of the skull and face bones



The 'matchbox' structure of the mid-facial skeleton provides a 'crumple zone' which cushions the effect of impact force B on the brain. Impact force A is transmitted directly to the brain producing the most severe injury. Impact force C is transmitted indirectly to the cranial base via the rigid structure of the mandible (represented here as a bent baseball bat)

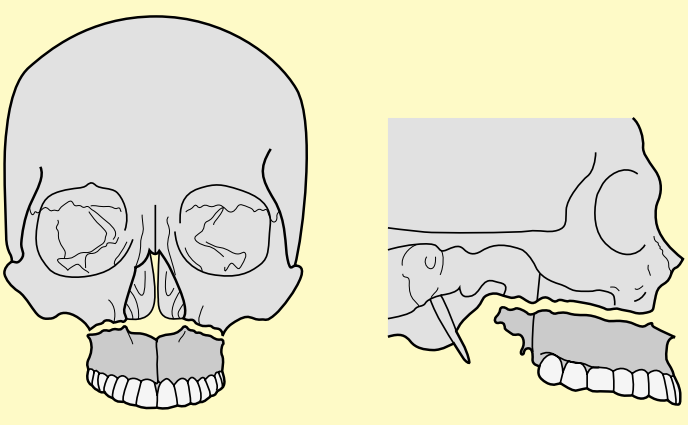
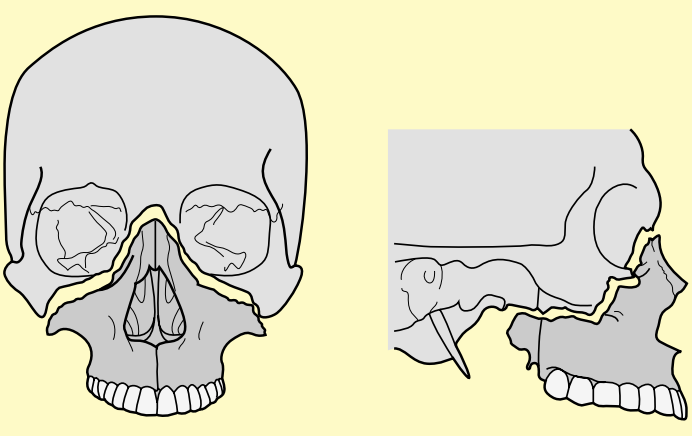
1

Le Fort fracture lines

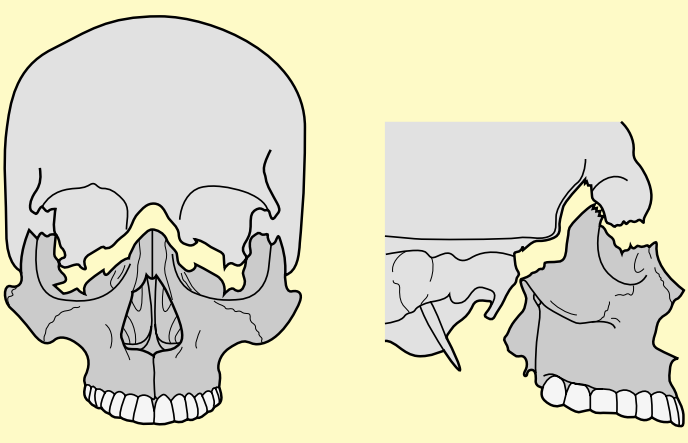
a Le Fort I fracture



b Le Fort II fracture



c Le Fort III fracture



a The Le Fort I fracture line passes through the inferior wall of the antrum and allows the tooth-bearing segments of the upper jaw to move in relation to the nose. **b** In a Le Fort II fracture the maxilla and nose can move as a block in relation to the frontal bone and zygoma. **c** In a Le Fort III fracture the facial bones are able to move separately from the base of the skull. Le Fort II and III fractures may be associated with a dural tear resulting from fracture of the cribriform plate of the ethmoid bones

2

Initial management

Other injuries
About 15% of severely traumatized patients also have maxillofacial injuries. 5–10% of patients with blunt trauma to the head and face have an associated cervical spine injury; cervical spine immobilization is essential until this is excluded. A survey of patients with Le Fort fractures in the late 1980s found that 26.5% presented with either airway obstruction or decreased respiration requiring immediate airway and ventilatory control. The head injury that often accompanies facial injury affects the need for airway control.

Early management
The immediate and early management of all trauma patients must follow the ABC of resuscitation. Of the facial injuries, the eye should be treated first, then the soft tissues (within the first 12 hours) and finally reconstruction of the facial skeleton (this can wait for a semi-elective theatre slot).

Airway problems
Minor airway problems become major ones in the presence of decreased consciousness, examples are:
- blood, which can be considerable
- vomit, teeth, dentures, bony fragments
- the anterior insertion of the tongue can be disrupted in bilateral mandibular fractures allowing the tongue to fall back.

All of these can be compensated for in the awake patient but can cause rapid loss of the airway once consciousness is lost or diminished. Conscious patients tend to place themselves in the best position for their airway.

Problems with the airway that need immediate control occur with extensive disruption as a result of missile or industrial injuries; they are uncommon following RTAs or assaults. Infrequently, a bleed from a mandibular fracture into the floor of the mouth and base of the tongue can obstruct the oropharynx. Haemorrhage may be closed within the maxilla causing significant swelling over a few hours (resulting in typically tense shiny cheeks; Figure 3), or open, in which case there can be a large blood loss from the pterygonal venous plexus or maxillary artery.

3 The classic 'moon-face' appearance of a patient with multiple fractures of the mid-facial skeleton. 'Tramlines' can be seen caused by CSF leak (arrows).

Airway control
In the emergency situation, a straightforward route to securing the airway is required. This should be via an oral tracheal tube or a surgical airway (tracheostomy or cricothyroidotomy under local anaesthesia). Retrograde passage of a guide (e.g. an epidural catheter) via the cricothyroid membrane in severe disruption is potentially useful. The main problems are:
- blood and debris preventing a good view (ensure effective suctioning with a wide bore, blunt ended sucker; induction in the lateral or prone position will allow blood to drain)
- distorted anatomy
- cervical spine immobilization (removing the hard collar and using manual in-line stabilization allows better oral access; a gum-elastic bougie is useful and must be to hand)
- full stomach needing cricoid pressure (if this makes the view impossible, release it)
- associated head injury may make the patient uncooperative (protect the brain from further damage by avoiding hypoxia, hypotension and hypercapnia).

Good assistance is crucial and fibre-optics not very useful. The classic rapid sequence induction is the best choice, but if lying on their back being pre-oxygenated for 3 minutes will cause the patient to drown in their own blood then think again (Figure 4). Local anaesthesia works poorly on surfaces covered with blood or clot therefore awake intubation is difficult. A surgical airway under local anaesthesia might be possible, if the patient is cooperative and able to lie on his back. Cricothyroidotomy is quicker and requires less expertise than a formal tracheostomy. Each case should be considered on its merits, bearing in mind one's own expertise. Always have a backup plan should the first plan fail.

Haemorrhage control
Bleeding from the soft tissues of the face can be packed and explored later. A maxillofacial surgeon is the best person to carry this out and to suture facial lacerations under local anaesthesia. A steady flow of blood from the nose and mouth with profound cheek swelling is probably the result of a closed injury to the middle third. Bleeding from a base of skull fracture should be excluded by palpating the pharyngeal wall for tears and fractures. The anterior and posterior nasal spaces can then be packed (Figure 5).

Occasionally a tear of the terminal branches of the maxillary artery can result in life-threatening haemorrhage. This requires a good nasal pack. Careful application is essential because this is not well tolerated by an awake patient and when incorrectly placed can cause partial obstruction of the airway.

4 Intubation with a bougie.

Method of inserting a postnasal pack

5

A fracture of the body of the mandible occasionally causes complete rupture of the inferior alveolar artery. Normally, the artery goes into spasm, but if it fails to do so, copious haemorrhage can occur. This is an emergency, which requires immediate reduction of the fracture followed by the bone segments being held in rough alignment by wires around the adjacent teeth. A laceration to the tongue can cause profuse haemorrhage that is hard to control. Bleeding from the ear can be caused by a fracture of the base of the skull or a fracture of the condylar head, which has been forced backwards and torn the external auditory meatus.

After securing the airway, follow the BCDE priorities of basic life support (Figure 6). Ensure good ventilation, check the chest and obtain a radiograph of the chest and the cervical spine and pelvis if appropriate. It is rare to get circulatory shock from maxillofacial injuries, therefore if it is present look elsewhere for the loss. Monitor the neurological deficit, initially by using the AVPU scale (Figure 7) together with pupillary reactions. Then the Glasgow Coma Score (see *Anaesthesia and Intensive Care Medicine* **3:4:** 132) should be measured at frequent intervals.

Priorities for basic life support

- A Airway with spine control
- B Breathing and ventilation
- C Circulation and control of haemorrhage
- D Assessment of disability and neurological deficit
- E Exposure and environmental control

6

Monitoring neurological deficit using AVPU scale

- A responds appropriately and is aware
- V responds to verbal stimuli
- P responds to painful stimuli
- U does not respond – unconscious

7

Soft tissue injuries
Soft tissue swelling can occur rapidly or insidiously. It is at its maximum 10–12 hours after injury. Therefore, patients who have suffered more than a single isolated fracture should be kept under close observation for this time.

Lacerations to the soft tissue should be thoroughly cleaned and sutured under local anaesthesia within 24 hours. Fractures to the facial skeleton can be treated later if the patient's underlying condition is poor or an experienced surgeon is unavailable. This may involve reopening wounds, but most facial fractures are reduced and plated via the oral mucosa; only upper facial injuries require skin incisions.

Pain control
In general, even extensive trauma to the face does not cause a large amount of pain. One exception is a mobile fracture of the body of the mandible, which can give a lot of discomfort and be a cause of restlessness. Minor analgesics such as paracetamol and a non-steroidal anti-inflammatory drug (NSAID) usually suffice. In general, avoid excessive sedation in case there is occult head injury.

Preventing infection
There is widespread use of prophylactic broad-spectrum antibiotics; usually amoxicillin (amoxycillin) with metronidazole or augmentin. Although they do not penetrate the CSF well, neurosurgical opinion is that if there is a breach in the CSF then antibiotics that are in the oral and pharyngeal tissues will penetrate sufficiently. However, retrospective studies indicate that prophylactic antibiotics do not significantly affect the incidence of meningitis in patients with a CSF leak.

Dural tears
A dural tear is possible with all Le Fort II and III mid-face fractures. Normally the CSF leak stops after a few days. Its detection is possible clinically from the observation of tramlines on the face or the halo effect on bedding; this can be seen in the patient in Figure 3. These are caused by CSF not coagulating and blood that does. Testing glucose and protein levels is of little clinical help. Definitive diagnosis is by high resolution CT or MRI.

There is a small risk (about 1%) of meningitis, at the time of injury and also years later, if the cribriform plate is involved. If the posterior wall of the frontal sinus has been fractured, a late presentation of a mucocele may occur, which requires neurosurgical input. Most cases of CSF rhinorrhoea stop spontaneously and virtually all stop after the fractures have been reduced.

Late management
Delaying definitive treatment for facial fractures allows resolution of head injury, treatment of other more life-threatening conditions, soft tissue swelling to diminish and an experienced surgeon to be present.

Preoperative assessment
Particular areas for preoperative anaesthetic assessment are the mechanism of trauma; any possibility of head, cervical spine or other injury, and any history of drug or alcohol abuse.

Airway assessment
In mandibular fractures, trismus caused by pain is likely to limit mouth opening. This usually disappears on induction. Fragments of bone in the temporomandibular joint can prevent mouth opening even after induction. The mobility of early fractures tends to make laryngoscopy easier than normal. Check for teeth that have been loosened or broken in the impact of the trauma and be aware that missing teeth could have been inhaled.

Intubation
Before commencing induction it is essential to discuss the operative plan with the surgeon. In most patients with mid-facial fractures intraoperative dental occlusion is required and an oral tracheal tube prevents this. For surgery to the zygoma and orbital floor an oral south-facing tracheal tube is probably best. Panfacial fractures involve the structural bones and the smaller bones of the nasal complex, which means that access to the nose as well as occlusion is required.

There is debate regarding the nasal route of tracheal intubation in the presence of a base of skull fracture or the Le Fort II and III fractures. Two cases of intracranial placement of a nasal tracheal tube have been reported in the literature. Only two, retrospective, studies have looked at outcome for this group of patients, but they did not show any increase in the incidence of meningitis when the nasal route was used for intubation.

If surgery cannot be carried out with an oral tube, the three main options are: formal tracheostomy; nasal intubation (using fibre-optic guidance); and submental intubation. Submental intubation involves passing the tracheal tube through the floor of the mouth. Figure 8 lists the advantages and disadvantages of each approach. Unless postoperative ventilation for more than 24–48 hours is likely to be required the author favours using the nasal route.

In complex cases the position of the tracheal tube may need to be changed intraoperatively. The author usually starts with an oral tube and then the surgeon places a nasal tube through to the pharynx after fixation of the small bones in the mid-zone, the author then re-intubates with the nasal tube.

Maintenance
For maintenance of anaesthesia, a total intravenous technique using propofol and a short-acting opiate (alfentanil or remifentanil) has a number of advantages. It allows rapid awakening, with early return of glottic reflexes, immediate assessment of conscious level in the patient with head injuries, and cooperation with eye testing after zygomatic and orbital floor work. It is also less emetogenic than the volatile agents. Deliberate hypotension is of limited benefit in most cases and may harm the patient with a head injury.

The general principles of a head-up tilt, carbon dioxide control and rehydration should be borne in mind. Most of these injuries cause little pain and so large doses of opiates are unnecessary. The surgeon will often use local anaesthetic with adrenaline (epinephrine), which is helpful. A rectal or intravenous NSAID is useful and intravenous or intramuscular tramadol is a good analgesic because it causes less respiratory depression and sedation.

Comparison of tracheostomy, nasal intubation and submental intubation

Advantages	Disadvantages
Tracheostomy	
• Avoids controversial nasal route • Allows dental occlusion intra- and postoperatively • Better for long-term ventilation	• Most invasive of the techniques • Extra procedure • Risks of haemorrhage, tracheal damage – stenosis, tracheomalacia and infection
Nasal intubation	
• Allows dental occlusion intraoperatively • Avoids an extra surgical procedure • Avoids a surgical scar •	• A fibre-optic scope is preferable • Poor for prolonged postoperative ventilation and weaning • The nose must be patent Risks of nasal haemorrhage, sinusitis and unproven possibility of an increase in the infective complication of meningitis
Submental intubation	
• Technically easy • Allows dental occlusion intra- and postoperatively • Low complication rate • Cosmetically acceptable scar	• Many surgeons are unfamiliar with the technique • Not good in prolonged ventilation and weaning • If an armoured tube is used re-intubation may be necessary, because the connector does not detach from the tube

Most patients can be extubated at the end of surgery. This should be awake if the stomach is full or if re-intubation would be difficult. A deep extubation is less likely to lead to laryngospasm and coughing. Airway problems at extubation are as common as at intubation. If a nasal tube has been used, it can be left in the nose and pharynx until the patient is fully awake to maintain a clear airway and splint any nasal haemorrhage until the airway is safe.

Postoperative care

Good recovery facilities are important. Patients must be observed for further soft tissue swelling, eye signs may need checking and the Glasgow Coma Score should be monitored if there was any suggestion of head injury. For moderate and severe facial injuries, high dependency facilities are required for 10–12 hours postoperatively. ◆

Anaesthesia for Maxillofacial Surgery

S Fadheel
H Drewery

S Fadheel is Specialist Registrar in anaesthetics at the North Thames School of Anaesthesia – East. He qualified from the University of Baghdad, Iraq, and trained in anaesthesia in Iraq and the UK. His interests include management of the difficult airway and day stay anaesthesia.

H Drewery is Consultant Anaesthetist at The Royal London Hospital.

Maxillofacial surgery encompasses a range of hospital-based procedures of the head, neck and mouth that overlap with ENT, plastic, general surgical and neurosurgical operations. In the UK, most maxillofacial surgeons are qualified as dental and medical practitioners. Because of the wide range of maxillofacial procedures, the patients encountered range from the very young to the elderly.

Dental procedures include exodontia and removal or biopsy of orocutaneous lesions. The most common maxillofacial surgical operation is dental extraction. In the UK, most dental extractions are carried out under local anaesthesia in 'high street' dental clinics, only the more complicated cases are referred for hospital care.

Facial injuries or trauma involve skin, soft tissues and/or bony fractures. Most trauma patients can be operated on in a planned manner though some require urgent intervention, for example if the airway is compromised or if scalp lacerations threaten to cause large blood losses.

Corrective (orthognathic) procedures for facial bone deformities are sometimes carried out for aesthetic reasons but more commonly for orthodontic ones. Most patients are young children and adults.

Excision of benign or malignant tumours necessitates long, extensive operations, sometimes involving pedicle or free-flap techniques.

Tracheostomies are often carried out by maxillofacial surgeons.

General procedures such as thyroidectomy, parathyroidectomy and excision of parotid glands occasionally come under the maxillofacial remit.

General considerations

The presence of an experienced anaesthetist is essential because the incidence of a difficult airway and/or intubation is high.

Routine monitoring for general anaesthesia should include inspired oxygen concentration, oxygen saturation, ECG, capnography, agent monitoring, non-invasive blood pressure and temperature. For extensive procedures, invasive monitoring should be considered, such as invasive blood pressure, central venous pressure and urinary catheterization.

Intravenous access is mandatory, even for minor non-invasive procedures.

Generally, nasal intubation is preferred for intra-oral procedures. However, simple extractions can be carried out safely with an orotracheal tube or a laryngeal mask airway (LMA).

The surgical field interferes with the airway therefore LMAs, tracheal tubes and tracheostomy tubes should be well secured and observed for position and patency.

A mouth or throat pack is often placed to prevent blood and debris falling down the trachea and oesophagus; however, great care must be taken to document this and fail-safe mechanisms should be developed to ensure their removal before extubation. Orogastric or nasogastric tubes are required for extensive operations.

Head and neck operations often require a head-up tilt position and normotension; occasionally, the surgeon requires controlled induced hypotension. Discussion with the surgeon regarding the extent of the procedure and airway maintenance is necessary before starting any anaesthetic.

Postoperative admission to a high dependency unit or ICU should be considered for patients undergoing extensive prolonged operations.

Concomitant head injury, cervical spine instability and a full stomach should be considered to be present in trauma patients until proved otherwise.

Inhalational or intravenous induction of anaesthesia is suitable for most patients. Inhalational induction is preferred for children and also whenever a difficult airway and/or intubation are anticipated. Some patients require awake fibre-optic intubation. Inhalational agents or intravenous propofol are suitable for maintenance of anaesthesia. Remifentanil, either with propofol or with an inhalational agent, is sometimes an extremely favourable option. Spontaneous ventilation may be a suitable technique, but controlled ventilation with or without muscle relaxation is preferred for longer procedures. Dexamethasone is commonly administered to reduce surgical oedema. Paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs; e.g. diclofenac, ibuprofen) and opioids (e.g. fentanyl, alfentanil, remifentanil, morphine, codeine) may be used for intraoperative analgesia. Local anaesthetic infiltration may also be used for procedures carried out under general anaesthesia as an adjunct to other analgesics.

Extubation may be carried out in the lateral position under deep anaesthesia, or when the patient is awake (especially after difficult intubation). Consideration should be given to extubating 'difficult' airways over a tube exchange catheter with the facility to insufflate oxygen if necessary. Recovery in the post-tonsillectomy position is preferred.

Postoperatively, patients are generally nursed with some head-up tilt once they have regained consciousness, which helps to control bleeding, reduce swelling and minimize venous engorgement in free flaps.

Postoperative analgesia is best provided as a combination of residual local anaesthesia, together with simple analgesics and the addition of opioids when necessary, either by patient-controlled or nurse-controlled analgesia. Care should be given to patients who have had a free-flap procedure to treat opioid-induced constipation, which can lead to venous engorgement and possible flap failure.

Anaesthesia for dental procedures

In the UK, general dental practitioners working in dental clinics are not permitted to perform dental procedures under general anaesthesia or sedation in children. Therefore, all children requiring such treatment must be treated in hospital. Since 1 January 2002, general anaesthesia for adults requiring dental extraction can be performed only in hospital. Before a patient is offered a general anaesthetic for dental extraction a thorough and clear explanation of the risks involved and the alternative methods of pain control available must be given to them (see page 239). However, certain groups of patient require general anaesthesia:

- children, commonly those less than 10 years of age, who will not tolerate the dental chair and local injections
- patients with special needs
- adults who cannot tolerate local anaesthesia (e.g. needle-phobia, multiple impacted wisdom teeth, failed local anaesthesia, previous allergy to local anaesthesia).

Dental extraction in children

Extraction of decidual teeth is usually easy and quick and can be performed as an outpatient procedure. The child should be prepared and fasted as for any general anaesthetic. The anaesthetic technique should allow rapid recovery and discharge from hospital. Premedicant analgesia (e.g. oral paracetamol) before induction is helpful. Local anaesthetic cream (*Emla* or *Ametop*) can be applied for older children who may agree to intravenous cannulation and induction. Occasionally, sedation with oral midazolam may be used as premedication. However, most children choose inhalational induction. Each child needs to be assessed as to which monitors will be tolerated before induction; most will accept a pulse oximeter. Sevoflurane is particularly suitable for both induction and maintenance of anaesthesia. Once anaesthesia is deep enough, intravenous access is secured and the remaining monitors attached. For intravenous induction, propofol is useful for its rapid recovery and anti-emetic properties, though pain associated with the injection is possibly more evident with children.

Airway management depends on the extent of the procedure. A nasal mask for extraction of incisor teeth alone or easily accessible molars, can be used with or without a nasal airway. Usually the surgeon uses a mouth pack, and a mouth 'prop' on the opposite side of the mouth to the proposed extractions. Jaw thrust may be needed to maintain airway patency but a fastidious surgeon ensures that the lower jaw is always supported. The reinforced LMA (RLMA) is preferred for multiple extractions or if surgical difficulty is anticipated. The RLMA can easily be moved from one side of the mouth to the other as the operator moves and usually provides an unobstructed airway. Additionally, the inflated cuff probably prevents airway and stomach soiling by blood better than a tracheal tube (Figure 1). Some anaesthetists prefer tracheal intubation.

1 This child is having multiple extractions under general anaesthesia.
Note the reinforced laryngeal mask airway (RLMA) and gauze pack. The anaesthetist's hand can steady the head and the surgeon holds up the lower jaw. The LMA is removed while inflated and the child still deeply anaesthetized.

Intraoperatively, NSAIDs or paracetamol administered as a suppository provide some postoperative analgesia. Additionally, local anaesthetics can be infiltrated, especially if large back molars are being extracted. It is rare to require opioids, but rectal codeine phosphate may be the most suitable.

When the procedure is finished, the child is placed on his side. The LMA is removed with the cuff inflated, or extubation is performed, preferably under deep anaesthesia. Recovery is initially best in the post-tonsillectomy position, but once the child is awake he or she should be sat up. Further postoperative analgesia (e.g. paracetamol and/or ibuprofen) may be prescribed to take home.

Children who are unsuitable to be treated as outpatients for medical reasons, should be assessed for treatment as a day case or in-patient.

Dental extraction in adults

Dental extraction in adults is usually performed as a day case procedure either under general anaesthesia or sedation. Patient preparation and monitoring for sedation, is the same as for general anaesthesia. Midazolam in small incremental doses is most commonly used together with local anaesthetic infiltration, though propofol in subanaesthetic doses is an alternative in experienced hands. Supplemental oxygen via nasal cannulas is given, and jaw support may be needed to maintain the airway. An alternative is inhalational sedation using up to 70% nitrous oxide in oxygen or sevoflurane in oxygen followed by local anaesthetic infiltration. Many patients are willing to try sedation rather than general anaesthesia once the technique has been explained carefully.

Some adults may request or require general anaesthesia. Intra-venous induction is most commonly performed although many of these patients are needle phobic. The airway can be maintained on LMA or by tracheal intubation, the choice depends on the anticipated ease of extraction and whether or not the surgeon is familiar with working around an LMA. If nasal intubation is to be performed, nasal bleeding can be reduced by using a nasal vasoconstrictor preparation (*Otrivine*) or by warming the tracheal tube. Local anaesthetic infiltration intraoperatively by the dentist is recommended. Intravenous NSAIDs (e.g. diclofenac) with suitable opioids are also used for analgesia. Dexamethasone is optional, but may have an anti-emetic effect. The LMA or tracheal tube is removed with the patient in the lateral position under deep anaesthesia or awake if preferred, bearing in mind that blood pressure surges associated with awake extubation with a nasal tracheal tube in place can lead to bleeding. NSAIDs, paracetamol or occasionally opioids are given for postoperative analgesia. Tramadol may be useful if the extractions are difficult and painful and the patient wishes to go home.

Anaesthesia for orthognathic surgery

Patients requiring orthognathic surgery are either children with congenital or familial facial bone and soft tissue deformities, or adults who have sustained previous facial trauma or infection, or have unresolved childhood deformities.

Cleft lip and palate
Cleft lip and palate are the most common congenital maxillo-facial deformities. They can occur in isolation or as part of a syndrome (e.g. Pierre Robin syndrome, Treacher Collins syndrome, Stickler syndrome). Other bony deformities such as maxillary dysostosis can also be isolated, or part of a syndrome (e.g. Goldenhar's syndrome). Cleft lip is usually corrected in infancy. A specialized paediatric anaesthetist should be involved and difficult intubation should be anticipated. Inhalational induction, oral tracheal intubation with spontaneous or controlled ventilation, is a standard technique. Paracetamol, NSAIDs and local anaesthesia are used intraoperatively for analgesia. Opioids may be added if required. Extubation is best achieved after full awakening and paracetamol supplied for postoperative analgesia, with codeine if necessary.

In adults, bone deformities are usually corrected in specialized centres with surgery often involving osteotomies based on the Le Fort classification. Invasive monitoring and intravenous fluid and blood transfusion may be required. Inhalational or intravenous induction, followed by nasal tracheal intubation and inhalational maintenance is common practice. Fibre-optic intubation may be needed, particularly if fixed trismus follows disturbance of the mandibular condyles after childhood infection or trauma. Analgesia is achieved intraoperatively with opioids, local anaesthesia and NSAIDs. A nasogastric tube is useful to empty the stomach of blood, and can be removed at the end of the case. Bi-maxillary osteotomies may be extensive and lead to considerable blood loss. Extubation can be awake or ‘deep’ depending on the surgical procedure and the pre-existing deformity. Postoperatively, patient- controlled analgesia may be needed in conjunction with simple analgesics.

Anaesthesia for maxillofacial tumours

Benign or malignant tumours, cysts and abscesses can develop in most oral and facial zones. Tumours and cysts are usually scheduled for elective operations, but abscesses and biopsies may require more urgent intervention. Patients requiring biopsies can usually be fasted adequately before induction of anaesthesia. A difficult airway should be anticipated and a plan for intubation prepared.

Patients with oral cancers can be elderly, with a high incidence of excessive alcohol or cigarette consumption. Operations for such malignant tumours may be extensive, requiring prosthetic implants, bone grafts (from the iliac crest, ribs, radius or scapula) or flaps (local or free transfer) and can be prolonged (some procedures last more than 12 hours; Figure 2). Before induction of anaesthesia, the airway should be assessed to plan for possible intubation difficulties, paying particular attention to the position of the tumour in relation to the airway. Other investigation results such as nasendoscopy (performed by the surgeons) or CT scans should be sought if appropriate.

2 This patient has had several intra-oral tumour resections and a scapular flap forms the base of the mouth. A pedicle flap is also present. Intubation was achieved on three separate occasions using an awake fibre-optic technique.

The mode of induction of anaesthesia depends on the degree of anticipated difficulty. Intravenous or inhalational induction, asleep or awake fibre-optic intubation are all suitable. Usually a nasal tracheal tube is required. If tracheal intubation is deemed impossible, then tracheostomy should be performed in the awake patient with local anaesthetic infiltration, or in the asleep patient by inhalational anaesthesia with a facemask or LMA. A nasogastric tube is required for postoperative feeding following extensive resections. Ventilation for long operations has to be controlled and muscle relaxants may be used as needed unless contraindicated (e.g. dissection for motor nerves with the use of nerve stimulator). For maintenance of anaesthesia, inhalational or intravenous agents are suitable. Opioid analgesia is required in most patients.
A tracheostomy may be performed at the beginning or at the end of the operation particularly if resections have been extensive and swallowing dysfunction is anticipated postoperatively. Invasive monitoring is required. The surgeon may request controlled hypotension, dexamethasone, antibiotics and anticoagulation. Postoperative sedation and possibly ventilation in the ICU should be planned for extensive long procedures or if free-flap vasculature is dependent on patient position, when a ‘still’ head is advantageous. In cases where a tracheostomy is not performed and the patient is not going to ICU postoperatively, extubation should be performed as appropriate with provision for dealing with any subsequent difficulties should they arise. Postoperative analgesia is usually achieved with NSAIDs and opioids.

Patients with oral tumours may require repeated anaesthetics, testing the anaesthetist’s skill with airway management. Even the technique of awake fibre-optic intubation may progressively prove to be difficult in these patients. ◆

Blind Nasal Intubation

Adrian J England

Adrian J England is Consultant Anaesthetist and Honorary Senior Lecturer at the Royal Free NHS Trust, London, UK.

Magill and Rowbotham pioneered blind nasal intubation in the 1920s as an alternative to oral intubation at the Queen's Hospital, Sidcup, to facilitate surgical access for head and neck surgery performed by Gilles. With practice many anaesthetists became proficient at the technique, which involved careful positioning of the head to facilitate the passage of a tube through the nose and into the trachea without the need for laryngoscopy, forceps to guide the tip of the tracheal tube, or deep anaesthesia. The introduction of muscle relaxants in the 1940s, allowing oral intubation without deep planes of anaesthesia, led to the blind nasal approach to intubation waning in popularity. Recently, agents such as sevoflurane and propofol that allow laryngeal depression and intubation with rapid recovery and equipment such as the intubating fibre-optic laryngoscope, have resulted in the blind nasal intubation technique becoming rarely used in current practice.

However, with concerns about prion transfer from lymphoid tissue leading to the introduction of disposable equipment for tonsillectomy, there may now be a case for re-evaluating blind nasal intubation. It is an easily learnt and safe technique, which provides a secure airway using disposable equipment and without the need for inserting a re-usable laryngoscope blade or forceps next to the tonsillar lymphoid tissue in the oropharynx. Indications and complications of the technique are given in Figure 1.

Blind nasal intubation

Indications when its use can be considered
- Poor mouth opening (e.g. trismus)
- Surgery on the jaw, teeth or maxilla
- Trauma to the jaw, teeth or maxilla
- Swelling of the tongue, or soft tissues of the oral cavity
- Lack of equipment (e.g. laryngoscope, in an emergency)

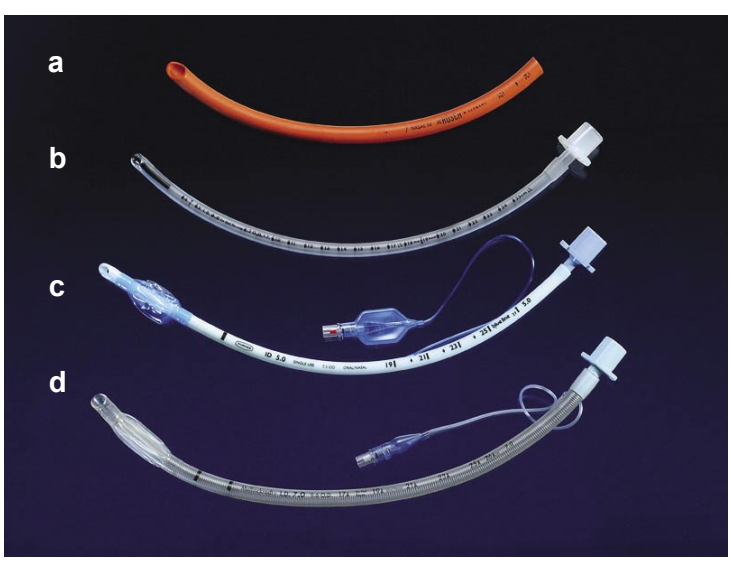
Complications
- Trauma to the structures in the nasopharynx
- Trauma to the larynx and vocal cords
- Perforation of the pharynx or trachea
- Misplacement of the tracheal tube
- Oesophageal ventilation causing air to fill the stomach
- Anaesthesia (local or general) may obstruct an already compromised airway
- Haemorrhage, causing airway obstruction
- Coughing

Contraindications
- Inadequate depth of anaesthesia
- Bilateral blocked nostrils
- Partial airway obstruction from tumour, abscess or trauma
- Recent surgery to the airway
- Coagulopathy
- Fractured base of skull
- Unprepared patient (e.g. full stomach)

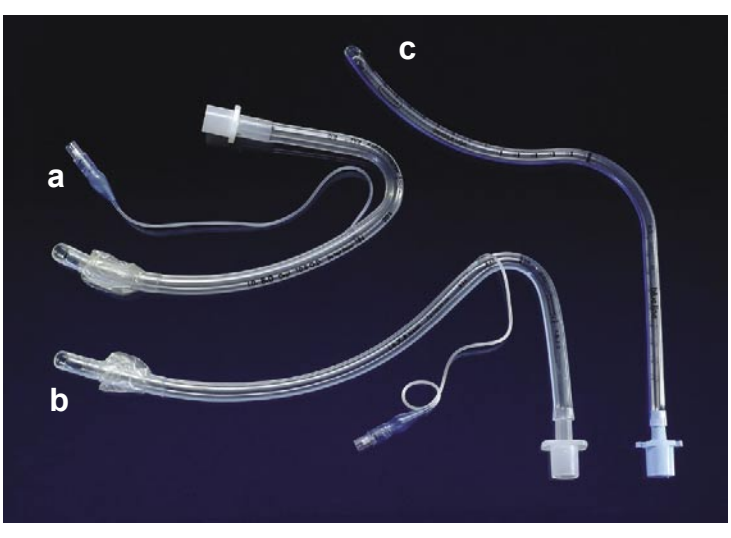
1

Equipment
The first nasotracheal tubes used by Magill were cut from red rubber hose purchased from a hardware store, trimmed to size and smoothed with emery paper. Advances in plastic and latex technology now allow the manufacture of preformed, soft, shaped tubes with cuffs to ensure an airtight seal (Figure 2). Universal connectors allow attachment to standard anaesthetic circuits.

To be suitable for blind nasal intubation, the nasotracheal tube must be soft enough not to cause trauma to the nasopharynx, but stiff enough to be pushed past the turbinates and through the vocal cords without becoming deformed. It requires a curve to allow it to sit directed dorsally as it passes through the nostril, but caudally as it enters the trachea through the larynx and this can be achieved with both preformed (Figure 3) and flexible tracheal tubes (Figure 2). Attachment to a standard anaesthetic circuit can be achieved at the nostril, but this may lead to local pressure damage because of the weight of the connectors or kinking of the tracheal tube. An alternative method is to use a preformed 'north-facing' tracheal tube of suitable length with the connector situated over the forehead (Figure 3). The connector can then be padded to prevent pressure damage to the underlying tissue.



2 Four nasotracheal tubes: **a** uncuffed red rubber tube; **b** uncuffed plastic tube; **c** blue line (Portex, Hythe, UK) ivory tube; **d** Mallinckrodt (St Louis, Missouri) flexo-metallic tube.



3 Three RAE® Mallinckrodt (St Louis, Missouri) preformed plastic tracheal tubes. **a** south-facing cuffed oral; **b** north-facing cuffed nasal; **c** north-facing uncuffed oral. Note the different angles of the north-facing oral and nasal tubes.

The diameter of the tracheal tube is important. A balance has to be achieved between a tracheal tube that is large enough to allow air to enter and leave the lungs and one that is small enough not to damage the tissues of the nasopharynx and larynx. A suitable compromise is to use one with a diameter of 6.0–7.5 mm.

Anaesthesia
Blind nasal intubation can be performed under general or local anaesthesia and in a patient who is either breathing spontaneously or who has received a muscle relaxant.

The use of antisialogogue premedication and topical vasoconstrictor nasal drops may enhance the conditions for intubation.

Local anaesthesia can be achieved using nebulized lidocaine (lignocaine), but much of the drug may be lost. Alternatively the airway can be anaesthetized using topical applications of local anaesthetic in the nose (cocaine or lidocaine (lignocaine) applied with pledgets, sprays or gels); the oropharynx and glottis (lidocaine (lignocaine) spray, gargle or through bilateral superior laryngeal nerve blocks); and the trachea (lidocaine (lignocaine) sprayed through a needle following cricothyroid puncture).

Spontaneous ventilation techniques allow breath sounds to be heard through the tracheal tube as it is guided through the airway. They also confer the advantages of a widely opened larynx during inhalation, increasing the aperture through which the tracheal tube needs to pass to enter the trachea, and allowing confirmation of correct placement of the tracheal tube in the trachea.

Position
Magill described the following position for blind nasal intubation; 'the optimum position of the patient's head for blind nasal intubation is simply that of a man sniffing the morning air. The head is in normal relation to the cervical vertebrae except for slight extension at the occiput-atlas junction. In this position the course of the airway from nose to glottis is maximally open and a catheter mounted on a stylet or a suitably curved rubber tube will follow that course naturally and enter the glottis in many cases. Of course, in the recumbent position a pillow under the occiput is usually necessary for this purpose.'

Individual anaesthetists may develop their own variations on this position through trial and error, but the 'sniffing the morning air' description remains firmly entrenched in anaesthetic teaching.

Technique
The patient is prepared for theatre, monitoring is attached and a suitable anaesthetic technique performed. The patient is then positioned, either supine or sitting, in the 'sniffing the morning air' position with the anaesthetist either above the patient's head or to the side. A suitable, lubricated tracheal tube is advanced through a nostril initially in a dorsal direction and advanced gently past the turbinates. The tracheal tube is then rotated so its curve lies in the sagittal plane with the distal end directed caudally before being advanced with gentle pressure through the pharynx. From here it will often pass into the trachea, but the tip of the tracheal tube may also advance into the oesophagus, or press against tissues anterior to the larynx, in the valecula or in the pyriform fossa. These can often be seen as bulges in the soft tissue of the neck. If the trachea is not entered, then the tracheal tube should be withdrawn into the pharynx, the patient's head repositioned appropriately and the tube re-advanced. Various modifications of the technique have been described, which may increase the chances of success, including inflation of the tracheal tube cuff when it is in the pharynx to position the tip of the tube in the midline, and palpation of the larynx while lifting the chin during tracheal tube advancement.

A disadvantage of the blind nasal technique is that direct visualization of the tube passing through the vocal cords is not performed. Confirmation of tracheal tube position is required using other methods, such as auscultation of the chest and abdomen, capnography and the oesophageal detector device, before surgery continues. ◆

Difficult Airways

Ian Calder

Ian Calder is Consultant Anaesthetist at the National Hospital for Neurology and Neurosurgery, Queen Square, London, and the Royal Free Hospital, London.

Classification of difficult airways can be based on technique (Figure 1) or aetiology, though neither is entirely satisfactory. The aetiological approach (Figure 2) is helpful for the examination candidate trying to remember the causes of airway difficulty.

Technical classification and prevalence of difficulty

Face mask	1:500
Laryngeal mask	Rare
Direct laryngoscopy	1:100
Fibre-optic laryngoscopy	Operator dependent
Intubation	1:2000 (failure, general surgery), 1:300 (failure, obstetrics)
Tracheostomy	?

1

Aetiological classification

Reflexes
Includes coughing, breath holding, laryngospasm, salivation and regurgitation

Stiffness
Includes the arthritides affecting neck, jaws and glottis, fixation devices, scleroderma

Deformity
Often allied with stiffness. Includes cervical deformities (Klippel-Feil), radiotherapy and burn contractures, dwarfism, Pierre Robin, Treacher Collins, and major facial deformity caused by trauma or chronic infections

Swelling
Includes infections, tumours, trauma, acute burns, anaphylaxis, haematoma and acromegaly

'High tariff' patients
Patients in whom additional problems may contribute to a decline in the operator's performance because of constraints in technique (e.g. patient with full stomach) or added stress (VIPs, obstetric patients, children, uncooperative patients)

2

Attempts at standardization have been made, such as that of direct laryngoscopy by Cormack and Lehane (Grades 1–4: all glottis; only arytenoids; only epiglottis; no glottic structure). Mask ventilation and intubation are more difficult to grade. Benumof has suggested that the term 'difficult mask ventilation' should apply when two operators are needed (one holding the mask, the other squeezing the bag) and oral or nasal airways are required. The American Society of Anesthesiologists (ASA) defines difficult intubation as one taking more than three attempts or longer than 10 minutes. However, Benumof notes that this misses cases in which difficulty is immediately obvious and suggests that difficulty be recorded after failure of 'an optimal best attempt'

Prediction
Difficult airways are generally symptomless and routine airway examination does not identify them. A logical approach is to try to identify patients unable to extend at the cranio-cervical junction and/or with diminished jaw protrusion, which are the main factors involved in both standard airway control and direct laryngoscopy.

Failure to predict airway difficulty seldom causes an airway disaster. The ASA's analysis of closed legal claims (Figure 3) shows that disasters usually follow repeated attempts to intubate, which result in loss of the airway due to glottic swelling, laryngospasm, or both, or perforation leading to mediastinitis or cervical abscess. These complications should be avoidable, whether difficulty has been predicted or not.

Main causes of anaesthetic airway mortality

- Oesophageal intubation
- Repeated attempts at intubation – loss of airway
- Perforation of pharynx or trachea – infection

3

Expression of risk
Various methods of predicting airway difficulty have been studied. The results express the performance of the tests in terms of sensitivity, specificity and positive predictive value. These concepts are easily misunderstood and confused (Figure 4). The likelihood ratio makes it easier to understand the significance of the sensitivity and specificity data as applied to an individual patient. The likelihood ratio is calculated by dividing the sensitivity by 1 – specificity. The result is the number of times more likely it is that a patient with a positive test result will be in the difficult group. The likelihood ratio is interpreted against the prevalence of the problem.

Terms used in prediction

Sensitivity
Positivity in disease. Makes no comment on positivity in health. High sensitivity tends to be associated with low likelihood of true result (e.g. Is the patient human? – supremely sensitive – and useless)

Specificity
Negativity in health. High specificity means few false-positive results but tends to lead to true-positive results being missed (e.g. Are the teeth wired together? – many other causes of difficulty)

Positive predictive value
The proportion of times a positive test is right; often confused with sensitivity

Likelihood ratio
Sensitivity/1 – specificity
The number of times more likely a positive test result makes a diagnosis

4

The best-known, and most studied test, the three grades (not four) of pharyngeal visibility described by Mallampati (see *Anaesthesia and Intensive Care Medicine* **1:1:** 31) has a sensitivity of about 50% and a positive predictive value of about 10% when applied to standard surgical populations. In other words, the test misses half the true positives and the prediction is wrong nine times in ten. This is not to belittle the test, which remains a logical approach to the problem, but demonstrates the difficulty of accurately diagnosing a relatively rare condition, with many causes. Other tests such as the sternomental or sternothyroid distance are even worse, and have been memorably described by Farmery as having 'an accuracy approaching worthlessness'. The positive predictive value is increased if two or more tests are positive, but it should be kept in mind that a few more true positives will be missed (decreased sensitivity) if the threshold for a positive prediction is raised.

Available tests
Most tests have been studied in relation to difficult laryngoscopy (Figure 5). A recent study of difficult mask ventilation identified five independent risk factors: age over 55 years; no teeth; beard; BMI over 26; history of snoring. Unfortunately, the likelihood ratio of difficult mask ventilation if two factors are present is only 2.6.

Airway difficulty prediction tests

Interdental distance
Lower limit of normal said to be 3.6 cm

Mallampati
Three grades, worst for observer error, probably measures mouth opening and cranio-cervical extension. No evidence that large base of tongue is a factor, though often quoted. In a general surgical population the likelihood ratio of the Mallampati is about 2, which for difficult laryngoscopy with a prevalence of about 1%, means that a positive result does not increase the risk of difficulty much

Thyromental, thyrosternal distance
Said to have 'accuracy approaching worthlessness'. Likelihood ratio about 1.8

Jaw protrusion – A, B, C
B has poor positive predictive value, while C is a reliable but rare predictor

Wilson risk sum
Scoring system based on multiple tests. No real improvement on Mallampati alone

5

Effect of increased prevalence of difficulty: the accuracy of the tests has been shown to increase when they are applied to a population with an increased prevalence. For instance, when applied to patients with cervical spine disease where the prevalence of Grade 3 laryngoscopy was 20%, the Mallampati achieved a positive predictive value of 78% and a likelihood ratio of 14. The tests are fairly reliable predictors of easiness, because the prevalence is very high.

When to attempt prediction of difficulty: in the event of a disaster, there may be criticism of aspects of the case that have little relevance to the outcome. Although the available tests are inaccurate in predicting difficulty in a general surgical population it is prudent to make the attempt. In populations with higher prevalence of difficulty, such as cervical disease, temporomandibular joint disease or acromegaly, where a positive prediction is more likely to be accurate, it is foolish not to record an attempt.

Communication
Patients found to have a difficult airway, should be told. Medic-Alert registration should be considered. Failure to communicate might be regarded later as legally actionable.

Airway plans
It is sensible to consider the consequences of failure to secure an airway. The causes of airway-related mortality mentioned above should be kept in mind. General Von Moltke's dictum 'Few plans withstand contact with the enemy' emphasizes the need for forethought and flexibility. ◆

General Anaesthesia for Dentistry

Patricia J Flynn
Leo Strunin

Patricia J Flynn is Senior Lecturer in Anaesthesia at Queen Mary's School of Medicine and Dentistry, University of London, and an Honorary Consultant Anaesthetist at St Bartholomew's Hospital and The London NHS Trust. Her research interests include the investigation of drugs and techniques for anaesthesia and sedation for dental treatment.

Leo Strunin is BOC Professor of Anaesthesia at Queen Mary's School of Medicine and Dentistry, University of London, and an Honorary Consultant Anaesthetist at St Bartholomew's Hospital and The London NHS Trust. He is a Past President of the Royal College of Anaesthetists and is currently President of the Association of Anaesthetists of Great Britain and Ireland. The research interests of the Anaesthetics Unit include neuroprotection, intensive care medicine and dental anaesthesia.

Although general anaesthesia is used to reduce the pain and anxiety associated with dental treatment, most dental procedures can be managed with good local anaesthesia, with or without conscious sedation. Since the 1960s, there has been a fall in the use of general anaesthesia for dentistry and in the mortality associated with it. However, eight people died as a result of dental anaesthesia between 1996 and 1999; five of these were children. Investigations and inquiries into these deaths were critical of the standard of care provided in areas such as preoperative assessment, peroperative monitoring, resuscitation and transfer to a critical care facility. In response to these concerns the General Dental Council (GDC), the Royal College of Anaesthetists (RCA) and the Department of Health (DOH) have issued closely linked guidelines for standards of care in dental general anaesthesia.

Who may administer general anaesthesia for dentistry?

Dental anaesthesia developed in free-standing dental surgeries and the administration of a dental anaesthetic was considered a traditional right of a medical or dental practitioner. Since 1998, the administration of dental general anaesthesia has been restricted to the following categories of staff.

- An individual on the Specialist Register of the General Medical Council as an anaesthetist, who should meet the RCA's continuing education and professional development requirements (CEPD).
- A trainee working under supervision as part of an RCA- approved training programme.
- A non-consultant career grade anaesthetist (NCCG) with a National Health Service (NHS) appointment, working under the responsibility of a named consultant anaesthetist who must be a member of the NHS department where the NCCG is employed. The NCCG should also meet the RCA's CEPD requirements.

Each anaesthetist must have had appropriate experience of, and training in, dental anaesthesia.

The RCA recommends that all children should be anaesthetized by a consultant or NCCG who has regular relevant paediatric experience, or a trainee supervised by someone in the preceding categories.

Who should receive general anaesthesia for dentistry?

There is wide variation in the use of general anaesthesia for dental treatment. In 1995, a DOH report concluded that a significant number of general anaesthetics were being given on demand, rather than to meet a defined clinical need. It was also noted that some practitioners failed to recognize that general anaesthesia is always accompanied by some risk. Most dental procedures can be performed under local anaesthesia and it is recommended that general anaesthesia is limited to the following groups.

- Patients who are unable to cooperate because of immaturity or physical or mental disability.
- Patients in whom local anaesthesia has repeatedly proved unsuccessful or is unlikely to be completely effective because of the extent of surgery or the presence of infection.
- Patients with a history suggestive of hypersensitivity or allergy to the contents of the local anaesthetic ampoule.
- Patients who suffer from extreme nervousness and who refuse to undergo any form of dental treatment while conscious. However, many nervous adults and children can undergo treatment successfully under local anaesthesia and conscious sedation and facilities for conscious sedation of a high standard should be more widely available.

Assessment of the patient

The GDC expects a dentist who refers a patient for general anaesthesia to discuss the risks involved and alternative methods of pain and anxiety control with the patient. Clear justification for the use of general anaesthesia should be contained in the referral letter together with details of the patient's relevant medical and dental history. Referral letters are inadequate in up to 50% of cases. Members of the paediatric, oral surgery and other dental departments who refer patients for general anaesthesia must also comply with the GDC guidance.

Dental, medical or nursing staff may be responsible for patient assessment and most staff are capable of selecting patients with the aid of written guidelines specifying medical, surgical and social criteria for ambulatory or in-patient general anaesthesia. Ambulatory dental anaesthesia is usually limited to patients assessed as American Society of Anesthesiologists (ASA) physical status class I and II unless the service is located within the main hospital block.

For those with health issues, an appointment should be made for assessment by an anaesthetist. In some centres the first opportunity to meet the anaesthetist occurs on the day of surgery. However, a separate preoperative assessment allows more time for the patient (or parent/legal guardian) and anaesthetist to decide together whether general anaesthesia has an acceptable risk/benefit ratio and decreases the likelihood of the treatment being cancelled on the day of surgery.

The anaesthetist and operating dentist should explain all the procedures that will be performed including the method of pain relief. Treatment should be specifically aimed at avoiding the need for repeated general anaesthesia. The current guidelines of the regulatory bodies regarding informed consent should be followed.

Where should general anaesthesia for dentistry take place?

The traditional sites for dental anaesthesia have included dental surgeries, community dental practices, dental hospitals, day care units, specialized outpatient clinics and the main in-patient operating theatre of a general hospital. However, since 1 January 2002, general anaesthesia for dentistry has been confined to a hospital setting with critical care facilities.

The DOH has defined a hospital setting as an NHS hospital and its associated clinics or day care facilities: 'where trained personnel are immediately available to assist the anaesthetist with the resuscitation of a collapsed patient so that the patient's airway, breathing and circulation are supported fully without delay and where facilities and staff are able to support and maintain a collapsed patient pending recovery or supervised transfer to a high dependency unit (HDU) or an intensive care unit (ICU) which may be on a separate hospital site'.

In the context of dental anaesthesia a critical care facility refers to: 'an area or room which has the space, equipment and appropriately trained personnel to enable critical care and resuscitation to be efficiently and effectively undertaken … and … should there be a sudden or serious collapse of the patient … to provide expert medical care and treatment with appropriate drugs and equipment immediately and to have additional skilled support from personnel trained specifically as a team which can manage life-threatening situations.

All personnel involved in the administration of general anaesthesia must have up to date advanced life support skills'.

Paediatric anaesthesia

Children requiring general anaesthesia should be treated within a hospital setting which has a 'child-friendly environment'. As far as possible, children should be treated separately from adults, with provision for parents to accompany children during anaesthetic induction and recovery. 'Teams providing dental general anaesthesia for children must be able to provide appropriate emergency care, including being fully conversant with suitable equipment and drug dose regimens and have additional skilled resuscitation support available'.

Giving a general anaesthetic for dental treatment

The same standards must apply to dental anaesthesia in terms of personnel, equipment and drugs as for other forms of general anaesthesia.

Personnel

The status of the dental anaesthetist has been specified above. The operating dentist must be appropriately trained and sufficiently experienced to undertake the planned surgery. The anaesthetist and dentist must each have appropriately trained and competent dedicated assistants (i.e. the presence of four people is required in the room wherever a general anaesthetic is administered). Patients recovering from anaesthesia must be continuously monitored and cared for by the anaesthetist or an individual who is directly responsible to the anaesthetist and is appropriately trained in adequate recovery facilities. Staffing levels should allow at least one recovery nurse for each unconscious patient. Staff must be appropriately trained where dental anaesthetic services are provided for both adults and children.

Equipment

Equipment must be suitable for the age of the patient being treated. The dental chair, trolley or operating table must be able to tilt head down and suction must be available with a selection of pharyngeal and endobronchial catheters. A continuous flow anaesthetic machine must be used. The machine must have an oxygen/nitrous oxide interlinkage to prevent delivery of a hypoxic mixture, an oxygen failure alarm, an emergency nitrous oxide shut-off system and an in-line oxygen concentration monitor.

Maintenance should be in accordance with the manufacturer's guidelines and the documentation of each service episode should be retained. Facilities for the supply, storage and scavenging of medical gases must meet relevant regulations.

The anaesthetist must check all equipment before use including the patient breathing systems. Local guidelines must be followed with regard to all equipment designed for single use only. A full selection of oral and nasopharyngeal airways, laryngeal masks, laryngoscopes, nasal and oral tracheal tubes and breathing circuits should be available in addition to appropriate dental equipment.

In the operating theatre, the Association of Anaesthetists of Great Britain and Ireland (AAGBI) considers the use of a pulse oximeter, non-invasive blood pressure monitor, electrocardiograph and a capnograph to be the minimum monitoring devices that should be available. Paediatric pulse oximeter finger probes should be used in children because adult probes may give misleading values.

The technique of anaesthesia may require vapour analysis and measurement of expired volumes and airway pressure. In addition a nerve stimulator and a means to measure the patient's temperature should be available. In recovery, pulse oximetry and non-invasive blood pressure monitoring is recommended. There should be immediate access to spare anaesthetic and monitoring apparatus in the event of failure.

Drugs

A full range of local and general anaesthetic, neuromuscular blocking, analgesic, sedative and anti-emetic drugs must be available in addition to the drugs likely to be needed in anaesthetic and medical emergencies.

Anaesthetic technique

Most patients undergoing dental anaesthesia are treated on an ambulatory basis and appropriate drugs and techniques should be used. The duration of surgery may be minutes or may extend to 1 hour or more.

In general, the age of the patient and the extent of surgery determine the choice of induction and maintenance of anaesthesia, control of the airway and management of pain relief. However brief the procedure, non-invasive monitoring should be used though it may not be practicable to apply the sensors before induction in a small child. Inhalational induction with sevoflurane is widely used in young children and it is difficult to justify the use of halothane in view of its high arrhythmogenic potential in this area of practice. An argument can be made that intravenous access for administration of anaesthetic or emergency drugs is essential in all patients regardless of the length of the procedure. It is helpful if other members of the team as well as the anaesthetist are trained to insert intravenous cannulas.

Pre-emptive analgesia with paracetamol or non-steroidal anti-inflammatory drugs by oral or other routes is effective and should be considered for every patient. The administration of a local anaesthetic by infiltration or nerve block provides analgesia and prevents surgically induced cardiac arrhythmias. For third molar extraction the addition of dexamethasone has been shown significantly to diminish postoperative swelling and decrease demand for analgesia.

Control of the airway may be by nasal mask, laryngeal mask or tracheal tube. The nasal mask, always accompanied by a mouth pack, is suitable for brief dental extractions. For more extensive surgery or in the presence of nasal obstruction a reinforced laryngeal mask (RLM) should be used. The RLM decreases the incidence of hypoxaemia when compared with the nasal mask. An RLM does not give the degree of airway protection provided by a tracheal tube, but the RLM has proved to be satisfactory in third molar extraction lasting up to 20 minutes. A mouth pack should always be used.

For more prolonged surgery a preformed nasal tracheal tube is generally used, though an oral tube is satisfactory for unilateral extractions in adults and preferable in small children in view of the risk of haemorrhage from adenoidal tissue. A throat pack is required and care must be taken to remove it at the end of the procedure.

A high incidence of hypoxaemia has been found in patients recovering from dental anaesthesia. Pulse oximetry should always be applied and supplemental oxygen given until the return of consciousness.

Management of the emergency

In addition to the risks associated with general anaesthesia, dental anaesthesia is always accompanied by the potential for obstruction and contamination of the airway, and the induction of cardiac arrhythmias associated with dental surgery.

The DOH requires that all personnel involved with the administration of general anaesthesia must have up-to-date advanced life support skills. All staff involved in the provision of dental anaesthesia or the supervision of patients during recovery should practise simulated emergency scenarios as a team. It is unacceptable for reliance to be placed on the general 'crash call' team for the immediate provision of advanced life support.

A range of appropriately sized equipment for tracheal intubation and administration of positive pressure ventilation with 100% oxygen concentrations must be available, in addition to equipment for administration of parenteral fluids and drugs. In addition, a defibrillator that is suitable for all age ranges treated must be available. Most automated external defibrillators are unsuitable for children below the age of 8 years (25 kg). Emergency drugs should include pre-loaded syringes of agents specified in current Resuscitation Council (UK) algorithms and other drugs necessary to deal with anaesthetic and medical emergencies. Up-to-date adult and child advanced life support protocols should be clearly displayed in addition to written guidelines on the management of anaphylaxis and malignant hyperthermia. ◆

Ludwig’s Angina

Hamish Gray
Mike Pead

Hamish Gray is Specialist Registrar at St Bartholomew's and the London School of Anaesthesia. He qualified from Otago University, New Zealand, and trained in anaesthesia and intensive care medicine at Christchurch Hospital, New Zealand, and the Royal London Hospital. His interests include anaesthesia for maxillofacial and dental surgery.

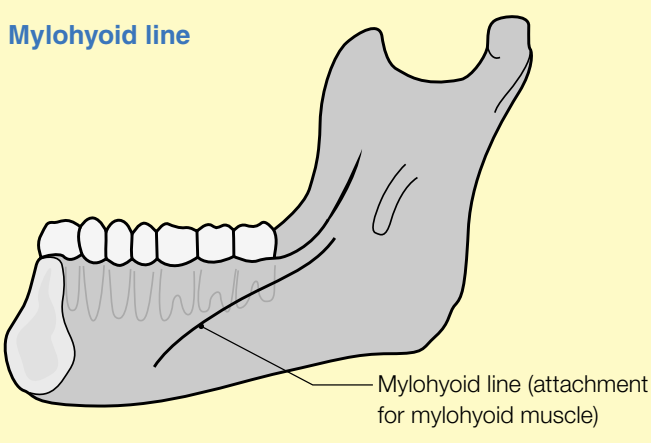
Mike Pead is Consultant Anaesthetist at St Bartholomew's Hospital and the London NHS Trust. He qualified from St Bartholomew's Hospital, London, and was a general practitioner before training in anaesthesia in the North Thames Region and in immediate medical care with the Helicopter Emergency Medical Service. His interests include management of the difficult airway and trauma care.

Ludwig’s angina is a rapidly spreading bilateral submandibular cellulitis, usually, though not always, from infection arising from the lower second or third molar teeth, and often without abscess formation. It was first described in 1836 by Wilhelm von Ludwig who noted that the tongue was pressed upwards and backwards with pressure on the larynx causing difficulty in swallowing and breathing (angina means a suffocating sensation) leading to death from respiratory arrest.

The submandibular space is a potential space lying above the hyoid bone and is made up of the sublingual space above the mylohyoid muscle and the submaxillary (or submylohyoid) space below. The sublingual space communicates anteriorly with the submental space and posteriorly with the lateral pharyngeal spaces. The submaxillary space is divided into central submental and lateral submaxillary spaces by the anterior belly of the digastric muscle. However, because of free communication around the posterior border of the mylohyoid, the sublingual and submaxillary spaces can be considered as a single unit: the submandibular space. Also, loose connective tissue, rather than true fascia, separates the two sides of the mouth allowing infection to spread bilaterally.

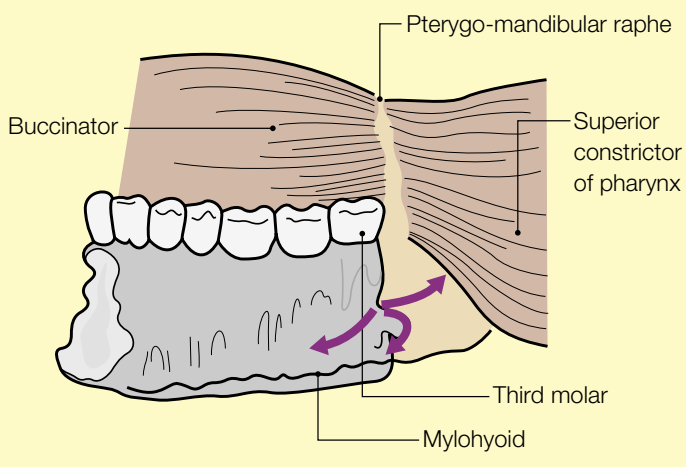
The mylohyoid forms the floor of the mouth and attaches to the lingual surface of the mandible in an obliquely downward line from posterior to anterior (Figure 1 and 2). The root apices of the bicuspid and first molar teeth are usually superior to the line of this muscle and therefore infections from these teeth tend primarily to affect the sublingual space.

Mylohyoid line



1

Paths of infection from the third molar causing Ludwig’s angina



2

Root apices of the second and particularly the third molar teeth lie inferior to the mylohyoid line of muscle attachment. Infections from these teeth primarily affect the submaxillary space producing a large indurated swelling at the angle of the mandible as well as swelling towards the hyoid bone. The mandible, hyoid and superficial layer of the deep cervical fascia limit tissue expansion anteriorly and therefore impaction and swelling spread through the whole submandibular unit producing brawny oedema with posterior and superior displacement of the tongue and airway compromise (Figure 3).

a and b Ludwig's angina. There is cellulitis and gross oedema of the left submandibular space extending to the right side and into the neck.

The authors thank Dr Mahesh Kumar for permission to use these photographs.

Clinical course

Ludwig’s angina is primarily a disease of dental origin with over 90% of cases related to dental infection (usually of third molars). Other causes include gland sialadenitis, compound mandibular fractures, lacerations and wounds of the floor of the mouth, and secondary infection of oral malignancies. The disease has also been reported in a neonate.

Improved dental hygiene and antibiotic therapy have reduced the incidence of Ludwig’s angina and most physicians and dentists seldom see the disease. Streptococci or mixed oral flora are the most commonly reported pathogens but staphylococci, *Escherichia coli, Pseudomonas* and anaerobes such as *Bacteroides* and *Peptostreptococcus* have also been isolated. There is likely to be synergism in mixed infections because the production of metabolic products by anaerobes enhances the virulence of the aerobes, which in turn provides a favourable environment for anaerobes through oxygen removal.

If antibiotic treatment is not instituted early, or is unsuccessful, the disease progresses rapidly leading to elevation and displacement of the tongue. There is firm, hard induration of the floor of the mouth with perioral oedema. The patient presents with pain, fever, trismus and dysphagia. The patient may experience anxiety about their inability to swallow or maintain an airway. Unchecked, the disease may spread posteriorly to involve secondary fascial spaces known collectively as the masticator space causing severe trismus. Occasionally there may be spread to deep cervical spaces and even to the mediastinum with serious life-threatening sequelae.

Ludwig’s angina can produce systemic sepsis with fever (or hypothermia), tachycardia, respiratory distress and leucocytosis.

Management

Patients who present to hospital with Ludwig’s angina are seriously unwell with an infection that may produce upper airway obstruction with alarming speed. Successful management involves the cooperation of the medical staff including the dentist, maxillofacial surgeon, anaesthetist, intensivist and microbiologist. Airway control is the priority.

Airway control

Asphyxia is the most common cause of death and control of the airway is essential. The swollen, elevated tongue pushed up against the palate with associated glottic oedema in an already anxious and septic patient ensures that any technique is extremely challenging. There are three options for managing the airway.

Observation may be appropriate in a high dependency environment allowing early aggressive medical therapy an opportunity to work. However, signs of impending respiratory obstruction (dyspnoea, stridor and cyanosis) may appear rapidly and late, heralding a medical emergency. Because medical staff now have little exposure to this disease a judgement to manage the patient conservatively with observation must be considered carefully by senior staff. Generally, observation is appropriate for patients who present in the early stages and who have no signs of airway obstruction.

Surgical airway – a tracheostomy performed under local anaesthesia is associated with immediate and long-term morbidity. Surgery also risks spreading the infection to deep cervical or mediastinal structures.

An anaesthetic airway can be established by a gaseous induction and direct placement of a tracheal tube or use of the fibre-optic intubating laryngoscope. The technique chosen depends on the skills of the staff involved. Although many authorities recommend the fibre-optic endoscope as the ‘gold standard’ the literature contains many case reports and series where gas induction has been used successfully to secure the airway in these patients. With either technique an armoured tracheal tube should be used as the submandibular swelling has been reported to compress an ordinary PVC tube, rendering ventilation impossible.

Choice of airway: a review of the literature found that only 35% of patients required oral or nasal tracheal intubation or tracheostomy for airway control. Since the 1980s, the use of tracheostomy under local anaesthesia has become less common. All patients with Ludwig’s angina have submandibular oedema with an elevated tongue and trismus, therefore these signs are poor differentiators of the need for definitive airway control versus observation. Radiological investigations, particularly CT scan and ultrasound, may help define the extent of tissue oedema or presence of loculated infection and therefore help in any decision about airway control.

Antibiotics

The advent of surgical decompression of the submandibular space reduced mortality from 100% in 1850 to 40–60%. The introduction of antibiotics reduced that figure to under 5%. Traditionally, high-dose penicillin was used. A broader spectrum of therapy is now recommended to cover penicillin-resistant Gram-positive cocci and anaerobes. A combination of clindamycin, penicillin (or ciprofloxacin) and metronidazole is usually recommended before definitive microbiological results are received.

Surgery

Surgical drainage was once universally required but some authorities now recommend reserving it for cases in which antibiotic therapy fails. Isolated removal of the infected tooth and limited intra-oral drainage is unsuccessful. CT-guided needle aspiration of the submandibular space has also been tried but as the disease is essentially a fascial cellulitis often without localization of pus this technique is unhelpful.

Surgery usually involves bilateral incisions parallel and inferior to the mandible with deep dissection into the submandibular triangle, through the mylohyoid muscle and into the sublingual region. The primary goal is decompression of all fascial spaces and the secondary goal evacuation of pus and obtaining tissue for microbiology. Any infected teeth are also removed. The classical ‘cut throat’ incision between the chin and the hyoid bone is no longer deemed necessary. Clinical experience has demonstrated that even if there is no pus, serious cellulitis resolves more rapidly if incised. Submandibular incisions also allow the swelling to extend inferiorly releasing the pressure that forces the tongue onto the palate and posterior pharynx.

Corticosteroids

The use of glucocorticoids in septic patients is controversial, but some authorities recommend their use to reduce the submandibular swelling. One regimen includes an initial dose of dexamethasone, 10–20 mg followed by 4–6 mg every 6 hours for 48 hours. The role of corticosteroids in outcome has not been evaluated.

Medical support of the patient
The patient must be nursed in a high dependency environment with maintenance of fluid balance/hydration and regular cardiovascular and respiratory monitoring.

Dental care
Continuing primary oral health care following the acute infection is important. ◆

Sedation for Dental Procedures

Meg Skelly
David Craig

Meg Skelly is Head of the Department of Sedation and Special Care Dentistry at the Guy's, King's and St Thomas' Dental Institute, London, UK. She qualified from Guy's Hospital Dental School, London. Her interests include pain and anxiety control in dentistry and education in this field.

David Craig is Associate Specialist in Dental Sedation at Guy's Hospital, London. He qualified from Manchester University and has held appointments in oral surgery, anaesthetics and general dental practice.

Most patients regard dental treatment as uncomfortable and potentially painful: their reactions range from normal apprehension, through various degrees of anxiety to irrational fear or even phobia. The adverse physiological effects of these psychological responses can increase the risks of treatment and should be controlled. This may be of even greater importance in patients with medical conditions (Figure 1).

Medical conditions and sedation

Conditions for which sedation is beneficial
- Angina
- Controlled hypertension
- Asthma
- Epilepsy
- Movement disorders

Conditions that may require modification of techniques
- Controlled heart failure
- Chronic anaemia (diagnosed and managed)
- Chronic airways disease
- Well-controlled diabetes

Conditions in which caution is required
- Severe cardiorespiratory disease
- Hepatic disease
- Severe psychological illness
- Drug abuse
- Alcohol abuse

1

The General Dental Council (GDC) defines conscious sedation as: 'A technique in which the use of a drug or drugs produces a state of depression of the central nervous system enabling treatment to be carried out, but during which verbal contact is maintained throughout the period of sedation. The drugs and techniques used to provide conscious sedation should carry a margin of safety wide enough to render loss of consciousness unlikely. The level of consciousness must be such that the patient remains conscious, retains protective reflexes and is able to understand and respond to verbal commands.'

The GDC also requires that all clinicians using dental sedation have clinical experience of the technique and that they are assisted by a second person who is able to monitor the patient and assist in the event of an emergency.

The purpose of sedation is to:
- enable treatment to be provided and/or accepted
- reduce stress associated with traumatic or prolonged procedures
- control gagging
- stabilize blood pressure in patients with cardiovascular or cerebrovascular disease.

Patient assessment
A satisfactory first visit is crucial to the success of subsequent treatment under sedation. Ideally, this meeting should take place away from the surgery environment. Patients should be given instructions for sedation at this visit (Figure 2). Dental treatment must be appropriate and realistic. The management options are listed in Figure 3. The simplest technique is generally considered to be best.

Instructions for patients receiving dental sedation

For your safety, please read and follow these instructions carefully

Before sedation: on the day of treatment
- Take your routine medicines at the usual times
- Have only light meals and non-alcoholic drinks on the day of your appointment
- Bring a responsible adult with you who is able to escort you home and then care for you for the rest of the day

After sedation: until the following day
- Do not travel alone – travel home with your escort, by car if possible
- Do not drive or ride a bicycle
- Do not operate machinery
- Do not drink alcohol
- Do not return to work or sign legal documents

2

Management options for dental treatment

Local anaesthesia
- Alone
- With nitrous oxide/oxygen mix
- With intravenous sedation (e.g. midazolam)
- With oral sedation

General anaesthesia

3

Inhalational sedation

The use of nitrous oxide and oxygen in subanaesthetic concentrations as a method of sedation became popular in the late 1940s. Nitrous oxide has excellent anxiolytic, sedative and analgesic properties, with little depression of myocardial function or ventilation (Figure 4). Induction and recovery are rapid. Administration by titration reduces the risk of over-sedation.

Inhalational sedation

Advantages
- No needles
- Level of sedation easily altered
- Minimal impairment of reflexes
- Rapid induction and recovery
- Some analgesia

Disadvantages
- Sedation depends on good psychological support
- Mask may limit access
- Postoperative amnesia variable
- Nitrous oxide pollution

Contraindications
- Nasal obstruction
- Poor cooperation
- First trimester of pregnancy
- Fear of masks

4

Equipment
Inhalational sedation (Relative Analgesia) machines are similar to traditional Boyle's anaesthetic machines, but modified to make them safe for use by an operator-sedationist. Typical Relative Analgesia machines have independent controls for regulating total gas flow and the mixture of oxygen and nitrous oxide. Modern machines are incapable of delivering a gas mixture containing less than 30% oxygen and have breathing systems with scavenging for the removal of waste gases.

Clinical procedure
The nasal mask is attached and the machine adjusted to administer 100% oxygen at an appropriate flow rate. Verbal encouragement is important at this stage. 10% nitrous oxide is introduced and the patient informed that they may feel light-headed, have changes in visual or auditory sensations or tingling of hands and feet and a feeling of suffusing warmth. This concentration is maintained for 1 minute, during which verbal reassurance continues. The concentration of nitrous oxide is then increased by 10% for a further 1 minute and then in increments of 5% until the patient appears and feels sufficiently relaxed. Local analgesia is then administered. When correctly titrated, patients are aware of operative procedures and are cooperative without being fearful. Restlessness is often an indication that the concentration of nitrous oxide is too high. At the end of treatment, 100% oxygen is administered.

Monitoring
The sedationist and the dental nurse must observe the patient's respiration, the level of sedation and skin colour. Electromechanical devices (e.g. pulse oximeter, ECG) are not routinely used unless the patient has serious medical problems.

Nitrous pollution and scavenging
Long-term exposure to nitrous oxide is potentially harmful. The Health and Safety Executive specifies a time-weighted maximum level of 100 ppm of nitrous oxide in the working environment. This is normally achievable only using active scavenging.

Intravenous sedation

Midazolam is well suited to sedation for dentistry (Figure 5). It is impossible to determine the correct dose of midazolam on the basis of the patient's body weight or age therefore a titration technique is essential.

Sedation with midazolam

Advantages
- Rapid onset (5 minutes or less)
- Good patient cooperation
- Good amnesia

Disadvantages
- No clinically useful analgesia
- Respiratory depression
- Occasional disinhibition effects
- Occurrence of sexual fantasies (rare)
- Postoperative supervision for a minimum of 8 hours is required
- Not reliable for sedating children
- Elderly patients are easily over-sedated

Absolute contraindication
- Allergy to any benzodiazepine

Caution required
- Pregnancy and breastfeeding
- Severe psychiatric disease
- Alcohol or drug abuse
- Impairment of hepatic function
- Needle phobia
- Doubts about the ability to provide a suitable escort

5

Intravenous midazolam produces a period of acute detachment for 20–30 minutes followed by a state of relaxation for a further 1 hour or so. Most patients have little or no recollection of the operative procedure. Some respiratory depression occurs in patients undergoing midazolam sedation. Overdosage and/or excessively rapid 'bolus' injections may cause profound respiratory depression. This is unpredictable, and so pulse oximetry must always be used.

Clinical procedure
It is important to ensure that the patient is prepared for the procedure and that the dental team is prepared for the patient. Written consent is required for both the dental procedure and sedation. Induction should be carried out with the patient lying supine. Pulse oximetry is mandatory for all patients and must be in place before induction. Continuous blood pressure and/or ECG monitoring may be advisable for unfit patients. Supplementary oxygen must be available.

The following regimen is appropriate for most fit patients aged 16–65 years, though variation in the response to sedation is common. Midazolam, 2 mg, is administered slowly, followed by a pause of 90 seconds. Additional 1 mg increments are given every 30 seconds until a satisfactory level of sedation is achieved. Slurring of speech and/or a slowed response to commands and a relaxed demeanour confirm that the sedation end-point has been reached. Ptosis is an unreliable sign. Local analgesia is then administered.

Elderly patients often require small doses of midazolam. A suggested administration regimen for these patients is 1 mg injected slowly followed by a wait of at least 4 minutes, then additional 0.5 mg increments given every 2 minutes until sedation is adequate. At the end of the procedure, the patient must remain under the supervision of the sedationist or a suitably trained nurse. Patients must be discharged into the care of an escort, who must be given written and verbal care instructions.

Reversal of midazolam sedation
Flumazenil reverses the sedative, cardiovascular and respiratory depressant effects but not intraoperative amnesia. Elective reversal with flumazenil may occasionally be indicated. Flumazenil has a shorter half-life than midazolam. However, clinically significant re-sedation does not occur when midazolam is used for short clinical procedures.

Oral and intranasal sedation

Oral sedation is useful for patients who are unable to accept venepuncture. The sedation produced may be adequate for the dental procedure to be carried out or it may then be possible to administer intravenous sedation. The most commonly used drugs are temazepam and midazolam. Midazolam may also be administered intranasally. Oral and transmucosal techniques are less predictable and should be used by experienced sedationists only. ◆

Special Needs Patients and Dental Procedures

Lisa Kritzinger
Jane M Silk

Lisa Kritzinger is Paediatric Anaesthesia Research Fellow at St Bartholomew's Hospital and the London NHS Trust. She qualified from St Bartholomew's Hospital, London, and trained in anaesthesia in Northampton and London.

Jane M Silk is Consultant Paediatric Anaesthetist at St Bartholomew's Hospital and the London NHS Trust. She qualified from St Bartholomew's Hospital, London, and completed her paediatric anaesthesia training at Great Ormond Street Hospital, London.

Terms such as special needs, disability and handicap have different interpretations. Definitions have been proposed by the World Health Organization in the International Classification of Impairment, Disabilities and Handicap, and special educational needs are defined in the 1993 Education Act. In practical terms, the special needs patient is one who has learning and/or physical disabilities. Down's syndrome, cerebral palsy and autism account for most cases, but rare syndromes are also encountered. Some rare diseases have profound anaesthetic implications, such as airway and cardiac problems in patients with Goldenhar's syndrome. An anaesthetist was recently convicted of manslaughter after a child with Goldenhar's syndrome died during dental treatment.

Special needs patients often allow only limited dental examination and treatment, so that dental care may have to be carried out under general anaesthesia. The use of local anaesthetic alone, or with sedation, has a limited place in moderately or severely affected patients.

The clinical setting: in contrast to efforts aimed at supporting special needs patients in their community, general anaesthesia is being increasingly confined to the hospital environment. Day surgery units allow patients to be treated and discharged home within 6 hours, minimizing the disruption to their lives. It is ideal to have a regular team of staff and considerate scheduling of lists within the day surgery unit.

Preoperative assessment: the patient's cooperation may be limited, making examination difficult. The patient's medical history should be sought from other sources (e.g. hospital or GP records). The anaesthetic value of any investigations should be determined. Preoperative assessment is best carried out by the same senior clinicians carrying out the procedure. Good communication between members of the dental, anaesthetic and theatre teams is important. The decision to ask patients to attend hospital for a separate pre-anaesthetic assessment must be balanced against the inconvenience caused to the patient and the risk of unexpected admissions to hospital if they do not attend. Prolonged preoperative starvation should be avoided.

Consent: in England, Wales and Northern Ireland, no one can give consent to treatment on behalf of another adult. However, doctors can treat incompetent adult patients without consent if they need treatment, and if it is in the patient's best interest. This decision is made after consulting the patient's carer, but they have no legal status in the decision-making process.

Premedication: special needs patients often require repeated general anaesthetics and any measure that improves the experience for them should be embraced. Many patients do not need sedative premedication if parents or carers are involved and simple distraction techniques are used. However, premedication is necessary for some. The choice of drug is best tailored to the individual patient, bearing in mind that some will not swallow pills or tolerate the use of topical anaesthetic cream. Intramuscular ketamine, 4 mg/kg, given 10 minutes before induction is used. However, ketamine is now a controlled drug. Therefore, injectable midazolam, 0.5 mg/kg up to a maximum of 15 mg, added to paracetamol elixir, 20 mg/kg, to mask its bitter taste and given orally 30–40 minutes before its desired effect, is a useful alternative.

Peroperative anaesthetic technique: the choice is influenced by:
- the difficulties of communicating with patients, their limited cooperation and the presence of a carer
- an understanding of the dental treatment plan, which may involve all four quadrants of the mouth and last over 1 hour.

Induction of anaesthesia can be challenging and carers often express the patient's anxiety. Practices used in paediatric anaesthesia are useful for children and adults. These include involving the carer to reassure and distract the patient, omitting formal monitoring before induction if it increases distress and a flexible approach to the choice of intravenous or inhalation induction (with sevoflurane followed by intravenous cannulation when the patient is asleep).

A nasotracheal tube is the airway of choice (unless contra-indicated) together with a throat pack, allowing good access for the dentist. Neuromuscular paralysis with a nondepolarizing neuromuscular blocker and mechanical ventilation are often used, given the high incidence of co-existing medical disease and the duration of treatment.

Simple analgesics combined with local anaesthesia are usually satisfactory. Diclofenac, 1 mg/kg, given as a suppository in children or in an infusion in adolescents and adults is helpful unless contraindicated. Opioids are seldom used.

Recovery: patients generally make a good recovery to their pre-operative status, but conventional discharge criteria must be modified for each patient, and are usually best agreed with the patient's carer. The carer will also know whether tablets or elixirs are preferred when prescribing medicines to take home. ◆

Anaesthetic Management of the Diabetic Patient

Amanda L Porter
Alastair McCrirrick

Amanda L Porter is Specialist Registrar in Anaesthesia at Gloucestershire Royal Hospital, Gloucester, UK. She qualified from St Mary's Hospital, London, and after starting anaesthesia in London, moved to the South West Deanery to complete her specialist registrar training.

Alastair McCrirrick is Consultant in Anaesthesia and Intensive Care at Gloucestershire Royal Hospital, Gloucester, UK. He qualified from Southampton University Medical School and joined the Royal Air Force. He completed his anaesthetic training in Bristol and the South West Region. He now specializes in intensive care and anaesthesia for major bowel and vascular surgery. His particular interests include anaesthesia for carotid endarterectomy.

Diabetes mellitus is the most common endocrine condition encountered in surgical patients. 50% of diabetic patients require surgical intervention, usually for ophthalmic, vascular or infective complications. They have increased perioperative mortality and morbidity compared with the general population. The main aims in the anaesthetic management of these patients are:

- to reduce the period of starvation with early recourse to oral intake and a normal glycaemic regimen
- to optimize blood glucose levels throughout the perioperative period in order to minimize metabolic disturbance and end-organ damage.

Diagnosis

Diabetes mellitus includes a number of disorders in which the universal finding is hyperglycaemia. Recently, the World Health Organization (WHO) and the American Diabetes Association (ADA) have jointly published new diagnostic criteria. This has led to an increase in the number of people recognized as having diabetes mellitus. The diagnosis may be confirmed by a random plasma glucose concentration greater than 11.1 mmol/litre or a fasting plasma glucose concentration greater than 7.0 mmol/litre (previously 7.8 mmol/litre), providing this result can be replicated. Impaired glucose tolerance, now renamed impaired fasting glycaemia, is confirmed by a fasting plasma glucose concentration of 6.1–7.0 mmol/litre.

Classification

The WHO and ADA have also developed a new classification system identifying four types of diabetes mellitus.

Type I is caused by autoimmune or viral destruction of susceptible β cells in the islets of Langerhans in the pancreas, which are responsible for the production of insulin. Their destruction results in no endogenous insulin being produced. Type I usually presents in patients under 30 years of age. Its inheritance is multifactorial. There is a strong genetic association with increased expression of human leucocyte antigens (HLA) DR3 and DR4 found on chromosome 6. The worldwide incidence of type I diabetes mellitus is 0.4%, but it is more common in developed countries.

Hyperglycaemia occurs as a result of reduced peripheral uptake of glucose, which is usually insulin mediated. There is also increased proteolysis, lipolysis and subsequent gluconeogenesis. This leads to massive protein loss and depletion of fat stores, further increasing the plasma glucose concentration. Glucose cannot be used for energy in these circumstances, therefore the liver produces ketoacids as an alternative energy source. This results in acidaemia. Exogenous insulin is vital to maintain glucose and acid–base
homeostasis.

Type II patients have reduced secretion of the active form of the insulin molecule. They have increased amounts of inactive insulin precursors, combined with increased peripheral insulin resistance as a result of impaired glucose transport mechanisms. This also reduces muscle glycogen synthesis. The worldwide incidence is 6.6%. The diagnosis is more common in patients over 40 years of age and in populations that have changed from a traditional to a Western diet and lifestyle. Type II diabetes has a strong familial link, with over 90% concordance between monozygotic twins.

Patients are usually overweight (unlike type I patients who are often thin) and do not have the propensity for acidotic states because they usually have enough insulin to prevent ketoacidosis. They may occasionally present with hyperosmolar non-ketotic coma (HONK). Glycaemic control can be maintained with oral hypoglycaemic agents but exogenous insulin may be used in extreme situations. These diabetic patients are the most susceptible to end-organ disease, therefore good blood sugar control is mandatory.

Type III patients suffer from hyperglycaemia precipitated by drugs (e.g. thiazide diuretics, corticosteroids, β-blockers) or concurrent disease. Associated diseases may include genetic disorders (e.g. Huntingdon's chorea, Down's syndrome, dystrophia myotonica), pancreatic disease (e.g. pancreatitis, haemochromatosis) or endocrine diseases (thyrotoxicosis, acromegaly, Cushing's syndrome). Successful treatment or removal of the cause usually results in normoglycaemia.

Type IV is also known as gestational diabetes. It usually presents during the third trimester of pregnancy and affects about 4% of pregnancies. Detection and treatment are vital to prevent fetal macrosomia. Oral hypoglycaemic agents are teratogenic and subcutaneous insulin is usually needed. Insulin requirements drop suddenly post-partum and normal glucose homeostasis is quickly restored. The mother has an increased risk of developing type II diabetes later in life (30–50% incidence within 10 years).

Long-term complications

Poor blood glucose control can result in acute metabolic disturbance and, if sustained, can cause chronic end-organ damage. The treatment of acute diabetic emergencies is outside the scope of this article.

There are two theories explaining how chronic hyperglycaemia may cause damage at the molecular level.

- Protein glycosylation in which irreversible covalent bonds form between excess glucose and protein compounds, altering their function and interaction with other compounds.
- Polyol pathway in which glucose is metabolized to fructose via sorbitol. Saturation of this pathway produces excess sorbitol, which activates aldose reductase, an enzyme that further enhances sorbitol production. A positive feedback loop is produced. The increased level of sorbitol causes tissue damage. Animal studies using aldose reductase inhibitors have shown promising results in the reduction of end-organ damage but they may be toxic to humans.

The pathological findings associated with chronic hyper-glycaemic end-organ damage are primarily those of micro-vascular disease, particularly affecting the cerebral and coronary vessels. The cardiovascular, neurological, renal and ophthalmic systems are those most commonly affected. Microvascular organ damage may be the main indication for surgery and it also complicates perioperative anaesthetic management.

Cardiovascular: patients with diabetes mellitus have accelerated formation of atheromatous plaques as well as generalized microvascular disease. Perioperative myocardial ischaemia and infarction are more common than in the general population. The risk of life-threatening arrhythmias is greater because the threshold for the initiation of ventricular fibrillation is reduced. Hypertension is common, caused by the loss of vessel elasticity secondary to protein glycosylation. Good blood pressure control can reduce mortality, though β-blockers, thiazide diuretics and calcium antagonists can worsen glycaemic control. Other cardiovascular complications include peripheral vascular disease and cardiac failure.

Neurological: peripheral and autonomic neuropathies are the most common neurological complications of diabetes mellitus. Peripheral neuropathies typically have a symmetrical 'glove and stocking' distribution. The extent of the neuropathy should be documented accurately to prevent medico-legal problems. Up to 40% of type I patients and 17% of type II patients have autonomic neuropathy. A careful history may elicit symptoms but the condition is often asymptomatic and detectable only by screening. Autonomic neuropathy should be suspected if the patient complains of abnormal sweating, bladder dysfunction, diarrhoea or dizziness. Other features may include cardiovascular instability and gastroparesis (potentially causing regurgitation and/or aspiration). Autonomic neuropathy can be confirmed by:

- a drop in postural blood pressure on standing, or absence of increase in diastolic blood pressure after 5 minutes of hand grip
- absence of sinus arrhythmia on ECG or by palpation
- absence of cardiac response to the Valsalva manoeuvre.

Renal: patients with type I diabetes mellitus have the highest incidence of end-stage renal disease and progress most rapidly from microalbuminuria to proteinuria, nephrotic syndrome and eventually chronic renal failure. Strict glycaemic control can delay the onset of microalbuminuria, which signals the inevitable progression to end-stage renal disease. The extent of renal disease can be assessed by preoperative creatinine, urea and electrolyte measurements.

Ophthalmic: blindness may be caused by cataracts or exudative or proliferative retinopathy. Perioperative hypertension can cause vitreous haemorrhage.

Respiratory: problems include a reduction in lung volumes and a decrease in diffusing capacity. Chest infections are common. Obese diabetic patients may demonstrate signs and symptoms of obstructive sleep apnoea (see *Anaesthesia and Intensive Care Medicine* **3:6:** 196).

Stiff joint syndrome: the high incidence of difficult intubations in patients with type I diabetes may be caused by protein glycosylation. Airway assessment may be normal but the inability to perform 'prayer's sign' (approximation of the palmar proximal interphalangeal joints) as well as limited atlantoaxial extension can indicate a potentially difficult intubation.

Infection: hyperglycaemia may result in leucocyte dysfunction. This increases the incidence of wound infection and delayed healing, particularly if the blood glucose is above 14 mmol/litre. Peripheral vascular disease exacerbates poor wound healing. Insulin requirements increase in the presence of infection.

Treatment

Treatment iscovered elsewhere.

Anaesthetic management

The aim of perioperative management is to maintain good blood sugar control. Hypoglycaemia can occur preoperatively following excessive starvation or late cessation of long-acting hypoglycaemic agents. Hyperglycaemia is exacerbated by the metabolic response to surgery. Controlling hyperglycaemia prevents immediate metabolic disturbance and electrolyte abnormalities and reduces the incidence of long-term end-organ damage.

Metabolic response to surgery: metabolic disruption occurs in all patients undergoing surgery, the extent depending on the operation as well as the severity of the underlying disease. The stress response involves the release of catecholamines, cortisol, growth hormone, thyroid hormones and other catabolic hormones. The production and peripheral action of insulin, an anabolic hormone, is decreased, causing an overall rise in blood glucose levels. Metabolic disruption is exaggerated in diabetic patients and may continue postoperatively because peripheral insulin resistance remains high.

Preoperative preparation: patients must be evaluated to assess their current and long-term glycaemic control and the efficacy of their present treatment regimens (Figure 1). Simple bedside tests and glycosylated haemoglobin (HbA_{1C}) levels can assess recent control of blood sugar. An HbA_{1C} level less than 10%, indicates good control over the previous 6–8 weeks. Acute hyperglycaemia is a contraindication to surgery and anaesthesia because it may cause postoperative metabolic disturbance, increased infection, microvascular damage and delay wound healing. Patients must be metabolically stable and assessment may require blood gas analysis if recent diabetic ketoacidosis has been a problem.

Preoperative investigations

- Full blood count – haemoglobin; raised white cell count indicates infection
- Urea and electrolytes – renal function
- Glucose – current glycaemic control
- HbA_{1C} – long-term glycaemic control
- ECG – arrhythmias, ischaemia, previous cardiac events
- Urinalysis – glucose ± ketones

1

Associated complications (cardiovascular, renal, neuropathic) must be actively sought and investigated appropriately. It is particularly important that cardiac disease is excluded and an ECG is mandatory. Autonomic neuropathy must be identified because it may have major anaesthetic implications. Pre-existing renal impairment may affect drug choices. Airway assessment is important to anticipate unexpectedly difficult intubation. Diabetic patients should have operative priority to reduce the starvation period.

Perioperative blood sugar management: the aim is to maintain blood sugar levels at 6–10 mmol/litre. This may be achieved in several ways. Management should include measurement of blood glucose every 2 hours and of electrolytes every 6 hours. The regimen used depends on the type of diabetes mellitus and the extent of surgery.

Type II – for minor surgery in patients with good blood sugar control, short-acting oral hypoglycaemic agents should be omitted on the morning of surgery. Longer-acting medication must be stopped 24 hours before surgery. Blood glucose levels should be monitored closely throughout the perioperative period. Once oral intake has resumed, oral hypoglycaemic medication should be restarted immediately. If the patient is controlled by diet, monitoring blood glucose levels is usually the only requirement. Insulin should be considered in patients with poor glycaemic control. For major surgery, patients should be converted to an insulin regimen and treated as if they had type I diabetes mellitus.

Type I – for minor surgery, patients may follow a 'no insulin, no glucose' regimen provided both carbohydrate and insulin are administered early postoperatively. Postoperative nausea and vomiting must be minimized and blood glucose monitoring is imperative. Alternatively, an infusion of 5% dextrose may be commenced and 50–75% of the patient's normal morning insulin dose given subcutaneously. Both regimens have drawbacks including an increased risk of ketoacidosis and an enhanced stress response. Absorption of insulin from subcutaneous tissues is inconsistent during surgery because skin and muscle perfusion may be altered by other physiological variables. For anything other than minor surgery, insulin and dextrose infusions remain the management of choice. Long-acting insulin should be omitted 24 hours preoperatively, but short-acting preparations may be continued until the morning of surgery. The insulin/dextrose infusion should be commenced concurrently with starvation and continued until oral intake is resumed postoperatively. There are two main insulin/dextrose regimens. In the Alberti regime (Figure 2) insulin is added to a 500 ml infusion bag containing 10% dextrose and potassium. It is a safe regimen because simultaneous infusion of both insulin and dextrose is guaranteed. The disadvantage is that if blood glucose levels are outside an acceptable range a new infusion must be prepared with a different amount of insulin. Insulin is also adsorbed by plastic and glass surfaces. This may be a problem with the Alberti regimen, which has a high volume solution with a low insulin concentration. The alternative approach is to use separate infusions of insulin and 5% dextrose containing potassium (Figure 3). This is much more flexible because the two infusions can be controlled independently. If a single cannula is used for both infusions a one-way valve must be incorporated to prevent insulin entering the dextrose administration set. Ideally, separate cannulas should be used but hypo- or hyperglycaemia may occur if either of the cannulas occludes.

Alberti regimen (Alberti and Thomas, 1979)

500 ml 10% dextrose solution + 10 U insulin + 10 mmol KCl
Run at 100 ml/hour, check blood glucose every 2 hours

- If blood glucose < 5 mmol/litre, use 5 U insulin per bag
- If blood glucose 5–9.9, use 10 U insulin per bag
- If blood glucose 10–14.9, use 15 U insulin per bag
- If blood glucose ≥ 15, use 20 U insulin per bag

2

Insulin sliding scale

5% dextrose + 10 mmol/litre KCl – run at 125 ml/hour
0.9% NaCl + insulin at 1 U/ml

- If blood glucose ≤ 4.9, give 0.5 U insulin/hour i.v.
- If blood glucose 5–14.9, give 2 U insulin/hour i.v.
- If blood glucose 15–19.9, give 4 U insulin/hour i.v.
- If blood glucose ≥ 20, review

3

Postoperative management: the insulin/dextrose infusion regimen should be continued until the patient is able to resume and maintain oral intake. Intravenous administration can be converted into subcutaneous boluses before each meal, with regular blood glucose monitoring. During recovery, insulin requirements reduce and it is recommended that once subcutaneous requirements are less than 20 U/day a normal preoperative regimen may be restarted. Early patient mobilization hastens a return to metabolic homeostasis. This requires attention to adequate analgesia. Treatment of postoperative nausea and vomiting allows an earlier return to a normal diet.

Choice of anaesthetic: the aim is to minimize metabolic disturbance.

Regional anaesthesia has many advantages. A conscious patient permits early detection of hypoglycaemic episodes and reduces the risk of aspiration. Postoperative nausea and vomiting is minimized allowing the patient to return to a normal diet sooner. Regional techniques for pelvic and limb surgery reduce the stress response to surgery, and thus reduce a rise in blood glucose. Hypotensive episodes related to the regional technique may be exaggerated in the presence of autonomic neuropathy and may cause further deterioration of end-organ function. Strict asepsis is vital to avoid infection, especially epidural abscess formation. Regional anaesthesia in patients with peripheral neuropathy is not recommended for medico-legal reasons.

General anaesthesia can mask the signs of hypoglycaemia and therefore requires regular blood glucose measurement. A rapid sequence induction may be required in patients with evidence of autonomic neuropathy to prevent aspiration; difficult intubation should always be anticipated. Hypoxia and hypercarbia may exacerbate the stress response, hypotension may worsen end-organ damage and hypertension increases the risk of vitreous haemorrhage. The stress response may be lessened by the use of high doses of opiates. The resulting respiratory depression and delayed return to consciousness may be confused with hypoglycaemia. Sympathomimetics and diuretics antagonize insulin, while clonidine, monoamine oxidase inhibitors and β-blockers potentiate its action. It is advisable not to use fluids containing lactate (e.g. Hartmann's solution) because metabolic acidosis may be exacerbated; lactate is converted to glucose by gluconeogenesis, further disrupting glycaemic control. Transfusion of packed cells may disrupt glucose homeostasis because citrate promotes gluconeogenesis. Stiff joints require great care with preoperative positioning. Diabetic patients are also at risk from skin trauma, ulceration and nerve injury. ◆

Recognition and Management of Phaeochromocytoma

Andrew K McIndoe

Andrew K McIndoe is Consultant Anaesthetist and Senior Clinical Lecturer in the Sir Humphry Davy Department of Anaesthesia, Bristol Royal Infirmary. He is also the Director of Research and Education at the Bristol Medical Simulation Centre where he has developed a specific interest in human factors and crisis management.

Phaeochromocytomas are tumours of chromaffin cells. The name derives from the observation that catecholamine storage granules in these cells turn brown when stained with chromic acid. Although phaeochromocytomas are thought of primarily as tumours of the adrenal medulla, they occur wherever chromaffin cells are found. 95% occur in the abdomen, of which 85% are in the adrenal gland. The remainder tend to be near the kidney or in the organ of Zuckerkandl. Outside the abdomen they occur in the sympathetic chain, the heart and the posterior mediastinum.

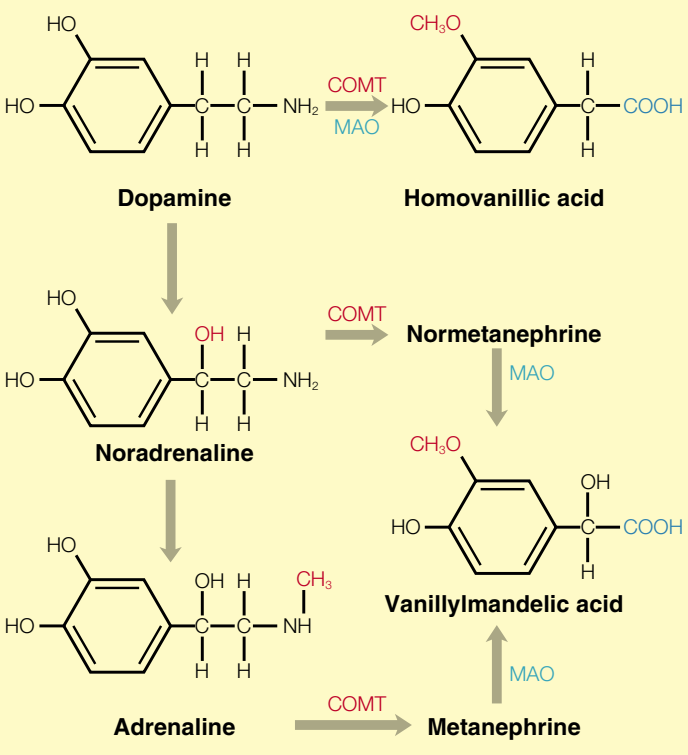
The sympathetic nervous system

The sympathetic nervous system comprises the sympathetic chain (T1–L2), a number of peripheral plexuses and the adrenal medulla. All are supplied by preganglionic cholinergic neurons connecting the CNS to sympathetic effectors derived from chromaffin cells. Chromaffin cells produce noradrenaline, adrenaline and dopamine. The sympathetic chain lies posterior to the aorta on either side of the thoracic column and is made up from the cell bodies and ganglia of most of the chromaffin cells. Postganglionic neurons derived from the sympathetic chain are noradrenergic and innervate vascular smooth muscle, mediating vasoconstriction. More peripheral chromaffin cells are located in the cervical ganglia, carotid bodies, and a number of abdominal plexuses, but most significantly in the adrenal medulla. Typically the normal adrenal medulla contains four to five times as much adrenaline as noradrenaline. Catecholamine secretion is achieved by exocytosis into the blood stream, in response to pain, stress, hypoglycaemia and hypoxia. Chromaffin cells are also present in the remains of the organ of Zuckerkandl located near the inferior mesenteric artery, which is a significant source of catecholamines during fetal development.

Catecholamine biochemistry

The principal catecholamines are adrenaline, noradrenaline and dopamine (Figure 1). All are derived from dietary tyrosine or synthesized from the amino acid precursor phenylalanine. Within the chromaffin cells, tyrosine is hydroxylated to dopa (dihydroxyphenylalanine), which is transported to the nerve terminals. Dopa is decarboxylated to dopamine and accumulates in storage vesicles or granules in the nerve terminal. The membranes of these vesicles contain dopamine β-hydroxylase, which catalyses the conversion of dopamine to noradrenaline. There is no further conversion in the peripheral sympathetic nerve terminals, but in the adrenal medulla noradrenaline is N-methylated to adrenaline in a reaction controlled by phenylethanolamine-N-methyltransferase (PNMT) and facilitated by glucocorticoids. The adrenal medullary catecholamines are stored in granules with ATP. Mg^{2+}-dependent ATPase controls uptake into these granules and inhibits subsequent release.

Catecholamine biochemistry



COMT, catechol-O-methyl transferase
MAO, monoamine oxidase

1

Once released, the amines are rapidly eliminated. Up to 90% of the noradrenaline released at the synapse is taken up again by the presynaptic nerve ending (uptake 1). The process is highly energy dependent and is saturable. It is blocked by cocaine, metaraminol, tricyclic antidepressants and phenothiazines (Figure 2). Noradrenaline is recycled into storage granules or deaminated by mitochondrial monoamine oxidase (MAO). Although circulating catecholamines can also be destroyed by this route, 70% of adrenaline is methoxylated by catechol-O-methyl transferase (COMT) in the liver and kidney (uptake 2) a process that is also saturable. Most of the circulating adrenaline and noradrenaline is destroyed by COMT, therefore measurement of urinary O-methylated derivatives (metanephrines) has traditionally been viewed as a good index of secretion (Figure 1). A small proportion of catecholamines are conjugated with sulphate or glucuronide in the liver, gut and red blood cells.

Catecholamine synthesis and elimination

Facilitation	Inhibition
Synthesis	
Tyrosine hydroxylase	Metyrosine Dopamine Noradrenaline
Storage	
Dopamine β-hydroxylase	Reserpine Guanethidine
Release	
Angiotensin	α_2-receptor stimulation
Ephedrine	Magnesium
Amphetamine	Guanethidine Bretylium
Reuptake	
Noradrenaline	Cocaine Metaraminol Tricyclic antidepressants Phenothiazines
Monoamine oxidase (MAO) breakdown	
Progesterone	Monoamine oxidase inhibitors (MAOIs) Oestrogen
COMT breakdown	Corticosteroids Phenoxybenzamine

2

The overall cardiovascular response to adrenoreceptor stimulation is moderated by the baroreceptors and other reflex mechanisms (Figure 3). Thus, a sudden rise in aortic pressure in response to an α_1-agonist (e.g. phenylephrine) may result in reflex bradycardia and subsequent redistribution of plasma volume. Specific agonists and antagonists at the four adrenoreceptor subtypes are listed in Figure 4.

Adrenoreceptor effects

Receptor	Principal effects
α_1	Vasoconstriction, uterine contraction, increased sweating, decreased insulin release, decreased glucagon release
α_2	Inhibition of further noradrenaline release (presynaptic adenylate cyclase inhibition)
β_1	Chronotropy, inotropy, arrhythmogenicity, renin secretion
β_2	Smooth muscle relaxation in the bronchi, vascular wall, uterus, adipose tissue, lipolysis, insulin and glucagon secretion

3

Adrenoreceptor agonists and antagonists

Agonists	Antagonists
α_1-receptor	
• Phenylephrine • Methoxamine • Adrenaline • Noradrenaline • Isoprenaline (weak)	• Doxazosin • Phentolamine • Phenoxybenzamine • Magnesium
α_2-receptor	
• Clonidine • Adrenaline • Noradrenaline • Isoprenaline (weak)	• Phentolamine • Phenoxybenzamine
β_1-receptor	**β_1- and β_2-receptor antagonists**
• Isoprenaline • Adrenaline • Noradrenaline	• Propranolol • Esmolol • Labetalol • Atenolol
β_2-receptor	• Bisoprolol • Celiprolol (β_1 selective)
• Isoprenaline • Adrenaline • Noradrenaline (weak)	

4

Predisposition

Most phaeochromocytomas (90%) occur sporadically and are benign. However, familial predisposition occurs in multiple endocrine neoplasia type 2 (MEN 2A, 2B and 2C), von Hippel–Lindau disease, neurofibromatosis type 1 (von Recklinghausen disease), and familial carotid body tumours. MEN 2A (Sipple's syndrome) displays autosomal dominant inheritance and is characterized by the association of medullary thyroid carcinoma, phaeochromocytoma and parathyroid hyperplasia. The underlying genetic link seems to be a mutation of the *RET* gene resulting in an oncogene that drives cellular proliferation in the target endocrine organs that make up the MEN 2 triad. These patients often have bilateral adrenal phaeochromocytomas and are more likely to have adrenaline-secreting tumours than sporadic phaeochromocytomas. In von Hippel–Lindau syndrome the mutation is slightly different, resulting in the inactivation of a tumour suppressor gene. Patients can develop bilateral kidney tumours and cysts, phaeochromocytomas, retinal angiomas, pancreatic cysts and tumours, cerebellar or spinal haemangioblastomas, epididymal cystadenomas, and tumours of the inner ear.

Diagnosis

History and physical examination: symptoms are variable. Hypertension is the most common clinical sign. It may be sustained or paroxysmal. Patients also describe episodes of anxiety, excessive sweating, palpitations (both fast and slow) and headache. The presentation depends on the nature of the tumour. Those secreting mainly noradrenaline present with hypertension, headaches and slow, thudding palpitations, whereas those secreting adrenaline present with tachycardias and anxiety attacks. Nausea and vomiting may be a result of excessive dopamine release. Intense vasoconstriction can also give rise to pallor and goose pimples. The symptoms are not specific, only 0.5% of those tested on clinical suspicion with hypertension prove to have a phaeochromocytoma.

Differential diagnosis: it is difficult to distinguish the normally functioning sympathetic nervous system from the episodic overactivity of a phaeochromocytoma because catecholamines tend to be reabsorbed or metabolized quickly following their release. Attempts at measurement of plasma catecholamines give only a brief snapshot of the pharmacological state of the sympathetic system and may give rise to false-negative results. Sensitivity may be improved by detecting the plasma metabolites normetanephrine and metanephrine (Figure 1). The abnormal threshold for normetanephrine is 2.5 pmol/ml and that for metanephrine is 1.4 pmol/ml. Alternatively the 24-hour excretion of urinary catecholamines and metabolites can be measured. The abnormal threshold is over 140 nmol/litre for adrenaline and over 800 nmol/litre for noradrenaline.

Phaeochromocytomas are rare and biochemical screening tests give many false-positive results despite repeat testing. Specificity can be enhanced by follow-up of borderline abnormal patients with a clonidine suppression test. Clonidine is an α_2-agonist and usually causes a decrease in physiological release of noradrenaline from sympathetic nerve terminals. Lack of suppression is suggestive of a phaeochromocytoma in the absence of reuptake inhibitors (tricyclic antidepressants, cocaine, metaraminol, phenothiazines). Alternatively a glucagon stimulation test can be used which, in the presence of a phaeochromocytoma, results in a greater than threefold increase in plasma noradrenaline within 2 minutes of intravenous glucagon administration.

Localization: CT localizes adrenal phaeochromocytomas with a sensitivity of 93–100%. Sensitivity is 90% for extra-adrenal tumours but is slightly higher using MRI. Both techniques have poor specificity, but if there is doubt, nuclear imaging using ^{123}I-metaiodobenzylguanidine scintigraphy enhances the ability to identify and localize the catecholamine source. Extra-adrenal tumours can also be located by selective vena caval sampling for plasma catecholamines and metanephrines or by positron emission tomography for selectively bound radionuclide markers.

Preoperative preparation

Surgical excision can be undertaken safely only when stability has been imposed pharmacologically on the sympathetic system. The main clinical objectives are to achieve stable blood pressure, heart rate and rhythm and to allow time for blood volume to be restored to normal. The over-production of catecholamines can be interrupted, blocked or antagonized at the point of synthesis, release or receptor action (Figures 2–4). Control of blood pressure by β-adrenoreceptor blockade alone may cause hypertension secondary to β_2-blockade or may cause cardiac failure because of the fall in contractility in the face of high afterload. The traditional approach is to institute α-adrenoreceptor blockade and then to add β-adrenoreceptor blockade if necessary.

Oral phenoxybenzamine has been used for many years. It covalently binds to α_1- and α_2-adrenoreceptors. It blocks catecholamine-induced vasoconstriction and catecholamine reuptake (Figures 3 and 4) resulting in β-adrenoreceptor stimulation that manifests as a tachycardia. Therefore, use of phenoxybenzamine usually necessitates the use of adjuvant β-blockade. Preoperative control is good, but postoperatively, patients remain sleepy and may require large amounts of intravenous fluid to maintain blood pressure until the blockade has worn off, despite stopping phenoxybenzamine 24–48 hours before surgery.

Doxazosin is a competitive selective α_1-adrenoreceptor antagonist that can be given as a single daily oral dose of up to 16 mg. Because doxazosin does not block presynaptic α_2-adrenoreceptors, it does not cause a tachycardia and β-blockade is necessary only if the tumour secretes adrenaline. Doxazosin has a longer duration of action than other competitive antagonists (e.g. prazosin) so administering the drug up to and including the eve of surgery allows adequate perioperative cover without the complication of significant postoperative hypotension.

Selective β_1-adrenoreceptor blockade is indicated for patients who have an adrenaline-secreting phaeochromocytoma. It is also likely to be required for those established on phenoxybenzamine preoperatively with a tachycardia induced by α_2-adrenoreceptor mediated reuptake inhibition. Suitable options include atenolol, 100 mg/day, or bisoprolol, 10–20 mg/day.

Having achieved preoperative cardiovascular stability, the main determinant of perioperative risk is the baseline myocardial state of the patient. Chronic exposure to high circulating catecholamine concentrations can result in cardiomyopathy therefore a screening echocardiogram is advisable in addition to an ECG (Figure 5).

General principles of elective phaeochromocytoma surgery

Preoperatively

- Determine where the tumour is and what it secretes
- Investigate myocardial function with ECG and echocardiogram
- Establish α_1-adrenergic blockade to control hypertension (e.g. doxazosin)
- Consider adding β_1-adrenergic blockade to control heart rate or rhythm (e.g. atenolol or bisoprolol)

Peroperatively

- Sedative premedication
- Invasive blood pressure monitoring pre-induction
- Obtund pressor response to intubation at induction
- Central venous pressure (CVP) monitoring (antecubital long line or internal jugular line)
- Maintain anaesthesia with a moderate degree of vasodilatation (e.g. isoflurane)
- Establish adequate surgical analgesia by T9–L1 epidural or opioid infusion
- Control blood pressure surges in response to surgical manipulation with: α-receptor antagonists (e.g. phentolamine, 1–2 mg) magnesium sulphate infusion (therapeutic range 2–4 mmol/litre)
- Control tachydysrhythmias with β-blockade (e.g. labetalol, 5 mg)
- Wind down epidural infusion before final cross-clamp of drainage veins of tumour
- Keep up with fall in CVP with intravenous fluids when pressor effects diminish

Postoperatively

- HDU/ITU care with invasive blood pressure/CVP monitoring until normalized
- Wake up early to minimize hypotension secondary to residual α_1-blockade
- Use posture and intravenous fluids to maintain blood pressure; vasopressors tend to be ineffective

Peroperative management

Adrenalectomy can be performed using an open lateral retroperitoneal approach or by laparoscopic transperitoneal surgery. Open surgery is quicker and less likely to result in surges in catecholamine release, but is more painful postoperatively. Recovery time from a laparoscopic procedure is shorter and patients mobilize within 24 hours and can be discharged within 48 hours. However, they spend longer on the operating table and more marked peaks in catecholamine release are observed during surgical manipulation. Control of these cardiovascular perturbations is the main challenge facing the anaesthetist because they occur regardless of depth of anaesthesia, analgesia and efficacy of central neural blockade. Preoperative preparation with adrenoreceptor antagonists blunts the magnitude and rate of cardiovascular change but does not eliminate the effects of physical manipulation of the tumour. Reliable invasive monitoring of arterial and central venous pressure is essential. Use of epidural analgesia (T9–L1) or opioid infusion (e.g. remifentanil, alfentanil) helps by eliminating noxious stimuli from provoking catecholamine release but more direct antagonists are also required. A general anaesthetic using one of the volatile agents has the advantage of providing some vasodilatation, but in practice this will need to be supplemented by other agents (Figures 2–4).

Magnesium sulphate has several potentially beneficial actions. It is anti-arrhythmic as a result of myocardial calcium channel blockade, regulation of intracellular potassium and ATP activation. It acts as a vasodilator by blocking the adrenoreceptor response to noradrenaline and angiotensin II. It also inhibits catecholamine release from the adrenal medulla and peripheral adrenergic nerve terminals. It is normally presented as a 50% solution in a 10 ml ampoule (500 mg/ml = 2 mmol/ml). The effective therapeutic plasma concentration is 2–4 mmol/litre. This can usually be achieved with an initial loading dose of 40–60 mg/kg intravenously followed by an infusion of 2 g/hour. Side-effects include a prolongation of neuromuscular blockade and inhibition of platelet activity.

Phentolamine is a competitive α_1- and α_2-adrenoreceptor antagonist that can be given intravenously by infusion or in 1–2 mg increments. It acts within one circulation time and can be administered in direct response to observed changes in systemic blood pressure. It is generally presented as a 10 mg/ml preparation in a 1 ml ampoule which should be diluted to a 1:10 solution for clinical use. Side-effects include a tachycardia secondary to presynaptic α_2-blockade.

Labetalol is a combined α- and β-adrenoreceptor blocker. Given in incremental doses of 5 mg it takes about 5 minutes to achieve an effect that can last for several hours. Used intravenously it causes a 7:1 β:α blockade. Therefore an observed fall in blood pressure may be accompanied by a profound fall in heart rate. It makes a useful second-line agent to deal with adrenaline-induced tachydysrhythmias and tachycardias secondary to use of α_2-adrenoreceptor antagonists.

Sodium nitroprusside is a mixed arterial and venous dilator that reduces preload and afterload. It acts by stimulating the formation of cyclic guanosine monophosphate (GMP) that relaxes vascular smooth muscle. Onset time is rapid over a few seconds and its duration is short with a plasma half-life of 3–4 minutes. Cyanide poisoning can occur with infusion rates greater than 2 μg/kg/minute but are unlikely in the short term (less than 24 hours).

Towards the end of the operation one needs to anticipate the sudden exponential drop in blood pressure that usually accompanies application of the final clamp to vessels draining the phaeochromocytoma (Figure 6). Even with the presence of central venous monitoring it can be difficult to predict the final volume status of the patient, because the intermittently high levels of circulating catecholamines during the procedure tend to cause marked changes in central venous filling pressure. This is a time to reduce the hypotensive effect of other agents including the epidural.

Clamping of adrenal vein accompanied by fall in blood pressure during elective laparoscopic adrenalectomy[1]

[1]This fall may be profound in the under-filled, heavily α- and β-blocked patient.

Postoperative management

Postoperative care should be based in a high dependency care area with facilities to monitor and react to continuous invasive blood pressure and central venous pressure changes. Postoperative hypotension is the most commonly encountered problem (Figure 6), because the source of catecholamines has been removed but the effects of adrenergic blockade remain. It can be difficult to treat because pressor agents in standard doses are ineffective. Attention to fluid balance and posture are the most effective interventions. Early extubation should be attempted. An awake reticular activating system helps to maintain blood pressure by stimulating release of noradrenaline from sympathetic nerve endings. Normal secretion of catecholamines from the contralateral adrenal gland will have been suppressed by the phaeochromocytoma, and adrenoreceptors will be blocked and down-regulated for some time. Analgesic requirements depend largely on whether surgery has been open or laparoscopic. Those who have had open surgery probably require continued epidural analgesia, while those who have had laparoscopic surgery tend to require oral analgesia only. Blood glucose should be monitored because hypoglycaemia may occur. Steroid replacement therapy is not usually required unless bilateral adrenalectomies have been performed

Emergency presentation

Phaeochromocytomas may present unexpectedly during coincidental surgery because of their non-specific symptoms and episodic nature (Figure 7). An awareness of the known associations should alert the anaesthetist to the possibility of an underlying phaeochromocytoma when faced with a sudden unexplained severe hypertensive episode, but because most cases are sporadic one needs to keep an open mind. If the diagnosis is suspected on the table, all stimulation should be stopped immediately. If the tumour secretes predominantly noradrenaline, systemic hypertension may be accompanied by a baroreceptor-mediated reflex bradycardia. Peripheries will be cold and pale as a result of vasoconstriction and the patient may have ‘goose bumps’.

[1]Note how ineffective vasodilators (hydralazine and isoflurane) alone were in managing the hypertension. Use of phentolamine provided transient control of blood pressure but also caused a tachycardia that responded to β-blockade. Cardiovascular control was finally achieved with a combination of α-blockade (phentolamine) and magnesium.

7

Myocardial ischaemia may be evident on the ECG and may be complicated by tachydysrhythmias, especially if the tumour secretes adrenaline. Severe hypertension may be accompanied by pulmonary oedema. There is no justification for proceeding with surgical excision in these circumstances, because mortality is unacceptably high without preoperative adrenoreceptor blockade. Control should be attempted with the agents described above (Figure 4) and the operation should be terminated with the minimum of surgical stimulation as quickly as possible. Postoperative intensive care should include cardiac troponin assay and 24-hour urinary catecholamine excretion. The patient can then be re-booked at a later date, having planned and implemented a multidisciplinary approach to the problem. ◆

Airway Trauma in ENT

Anil Patel

Anil Patel is Consultant Anaesthetist at the Royal National Throat, Nose and Ear Hospital, London, UK. He qualified from University College London, and trained in anaesthesia at Guy's Hospital, London.

Airway trauma in ear, nose and throat (ENT) surgery can be broadly categorized as:
- external laryngeal injury caused by blunt trauma or penetrating injuries to the neck
- iatrogenic injury related to intubation trauma, prolonged intubation or tracheostomy.

External laryngeal injury

Patients requiring airway management can be divided into those presenting with obvious respiratory distress requiring immediate intervention to establish a patent airway and effective ventilation and those presenting with no obvious respiratory distress who require careful evaluation and observation. Up to 25% of these patients subsequently require airway intervention.

Immediate intervention for airway control may involve tracheostomy under local anaesthetic for massive cervical and laryngeal trauma, orotracheal intubation or intubation through a large open wound in the airway. Orotracheal intubation should be performed by experienced personnel without the use of cricoid pressure, which may result in cricotracheal separation and loss of airway patency. In this situation, the risk of aspiration is less significant than the potential loss of the airway. Fibre-optic intubation is difficult under these circumstances owing to airway distortion, bleeding and the difficulties of passing a fibrescope past areas of airway damage. It is not recommended.

Orotracheal intubation should be attempted with a selection of small tubes, with straight and curved laryngoscopy blades available. If elevation of the vallecula with a curved blade fails to pull a dislocated epiglottis forward, a straight laryngoscope blade may be required to elevate the epiglottis directly. Oral intubation may cause further laryngeal trauma by forcing debris lower down the airway and worsening laryngotracheal disruption.

No obvious respiratory distress – patients presenting with no obvious respiratory distress require a high degree of suspicion for airway trauma. Preventable deaths occur in up to 10% of patients with airway trauma. Symptoms suggestive of laryngeal trauma include dyspnoea, pain, dysphagia and hoarseness. Examination may reveal abrasions over the anterior neck, upper airway noises resulting from oedema or foreign bodies, stridor, haemoptysis with frothy blood, subcutaneous emphysema, loss of palpable landmarks in the thyroid or cricoid cartilage, and pneumothorax. Careful, gentle assessment should be undertaken to avoid accidental dislodgement of unstable cartilage fragments, which may cause airway compromise. Flexible fibre-optic laryngoscopy identifies oedema, haematomas and vocal fold paralysis caused by recurrent laryngeal nerve injury while CT scans identify laryngeal cartilaginous damage.

Small mucosal lacerations, small haematomas and single non-displaced fractures of the thyroid cartilage can be managed conservatively with close observation. Treatment includes voice rest, head elevation, humidified air to prevent crusting, antibiotics and early steroid use to reduce oedema. Intervention by oral intubation or tracheostomy may be required if airway deterioration occurs.

Iatrogenic airway trauma

Laryngeal trauma from tracheal intubation still occurs despite the change to high volume, low pressure cuffs in patients of all ages. Although most changes are superficial and heal quickly, a few patients develop glottic or subglottic stenosis and present with airway compromise many weeks or months after a period of prolonged intubation. Some patients sustain severe airway damage after relatively short periods of intubation. Early, nonspecific changes in the airway include oedema and superficial ulceration resulting in granulation tissue, which may form firm scar tissue.

Patients who complain of a sore throat and weak voice after intubation may have arytenoid subluxation. Attempts to induce this lesion in cadavers have failed and it has been suggested that the condition is better termed 'post-intubation crico-arytenoid dysfunction'. An understanding and awareness of the factors that predispose to iatrogenic laryngeal trauma is important in reducing morbidity associated with these injuries (Figure 1). ◆

Factors predisposing to intubation trauma

Tube placement
- Emergency intubation by unskilled individuals
- Repeated attempts at intubation
- Improper use of introducers
- Abnormal larynx

Tube characteristics
- External diameter, shape, stiffness and material
- Cuff volume and pressure

Duration of intubation
- No universal agreement on safe period
- Decision for tracheostomy at 5–14 days dependent on general condition
- Longer duration with infants than with adults

General conditions
- Gastro-oesophageal reflux with spillover
- Impaired mucociliary clearance
- Acute or chronic disease states with poor tissue perfusion and hypoxia
- Infection

Anaesthesia for Endoscopic Surgery

Anil Patel

Anil Patel is Consultant Anaesthetist at the Royal National Throat, Nose and Ear Hospital, London, UK. He qualified from University College, London, and trained in anaesthesia at Guy's Hospital, London. His interests include the role of the laryngeal mask airway in ENT surgery, jet ventilation and airway surgery.=

Anaesthesia for endoscopic procedures of the supraglottis, glottis and subglottis requires close cooperation between anaesthetist and surgeon, an understanding of each other's problems and knowledge of specialist equipment. Shared airway procedures are unique in that both anaesthetist and surgeon are working in the same anatomical field. The anaesthetist is concerned with adequate oxygenation, removal of carbon dioxide, maintenance of an adequate airway and the prevention of soiling of the tracheobronchial tree, while the surgeon requires an adequate view of a clear motionless operating field.

Patients vary from young, otherwise fit and well individuals, presenting with voice changes secondary to benign vocal cord pathology (e.g. small nodules, polyps), to elderly, heavy smokers with chronic obstructive pulmonary disease presenting with voice changes, dysphagia and stridor caused by glottic carcinoma. Different anaesthetic techniques are suitable for different patients.

Preoperative assessment

Standard airway assessments to predict the ease of ventilation, visualization of the laryngeal inlet and tracheal intubation should be performed. An assessment of airway pathology and its impact on airway management should be made.

A history of previous endoscopic procedures and outcome should be noted. Dysphagia, best breathing position, breathing pattern during sleep, voice changes and stridor give an indication of the severity of disease. Patients may have no obvious stridor on initial examination but it may become apparent as the patient lies down, changes from their best breathing position or on minimal exertion. Inspiratory stridor is usually associated with lesions above the glottis whereas expiratory stridor is usually seen with lesions below the glottis.

The severity and size of lesions at the glottic level are assessed by direct or indirect laryngoscopy, undertaken by surgeons in an outpatient setting; a photograph of the findings is often recorded in the notes. Information about subglottic and tracheal lesions is provided by chest radiography, CT and MRI.

The size, mobility and location of lesions should be identified before anaesthetizing the patient.

Size of the lesion gives an indication of potential airflow obstruction. Stridor indicates a significantly narrowed airway. In the adult, stridor implies an airway diameter of less than
4.5 mm, but the absence of stridor does not exclude a significantly narrowed airway.

Mobility – very mobile lesions (e.g. multiple large vocal cord polyps or papillomas) can cause airway obstruction following induction of anaesthesia because their mobility and the loss of supporting tone in the larynx can allow them to 'fall' into the airway.

Location – supraglottic lesions, if mobile, can obstruct the airway or make visualization of the laryngeal inlet difficult. Subglottic lesions may allow a good view of the laryngeal inlet but cause difficulty during the passage of a tracheal tube or during jet ventilation.

Foreign body aspiration is most common in children aged 1–4 years and most foreign bodies enter the right main bronchus. The symptoms and signs are relative to the size of the object, its mobility and location. Partial obstruction of the larynx or trachea presents as stridor, dyspnoea, coughing and drooling. Bronchial foreign bodies mainly cause coughing, wheezing, dyspnoea and reduced ventilation on the affected side.

Vocal cord pathology

Nodules are benign lesions of the vocal fold that are usually bilateral and caused by vocal abuse.

Polyps are benign lesions of the vocal fold, common in adults. They are usually unilateral and can be sessile or pediculated, oedematous or angiomatous. The aetiology is multifactorial and includes vocal abuse and trauma. They often require surgery with careful dissection or laser phonosurgery.

Cysts are benign lesions commonly seen in adults. They are caused by obstruction of a glandular duct resulting in a mucous retention cyst. They are often seen in young women, particularly professional voice users, and are treated with careful dissection.

Granulomas are benign lesions induced by healing granulo-matous tissue, which develops after microtrauma. They are usually found on the posterior third of the vocal process following trauma during intubation or extubation. Resection is required if they are large and disturbing breathing.

Papillomas are benign lesions caused by human papilloma virus infection and can undergo malignant transformation. In adults, hoarseness is usually the main symptom while in children airway obstruction can occur. Following laser resection, papillomas can recur and some patients require repeated laser phonosurgery at 3–12-monthly intervals.

Malignant tumours are usually unilateral and occur mainly on the middle third of the vocal fold. 80% are found in men aged 40–65 years. Over 97% of patients are smokers with a high alcohol intake. Treatment depends on tumour staging and involves local resection, radiotherapy or transoral laser resection.

Other lesions are caused by haemangiomas, submucous haemorrhage, Reinkes oedema and chronic laryngitis.

Anaesthetic techniques for endoscopy

Ideal technique: there is no ideal anaesthetic technique for all endoscopy procedures. The technique depends on the patient's general condition, the size, mobility and location of the lesion, the use of a laser and surgical requirements.

The ideal technique would:

- be simple to use
- provide complete control of the airway with no risk of aspiration
- control ventilation with adequate oxygenation and carbon dioxide removal
- provide smooth induction and maintenance of anaesthesia
- provide a clear motionless surgical field, free of secretions
- not impose time restrictions on the surgeon
- not be associated with the risk of airway fire or cardiovascular instability
- allow safe emergence with no coughing, bucking, breath holding or laryngospasm
- produce a pain-free, comfortable, alert patient with minimum hangover effects.

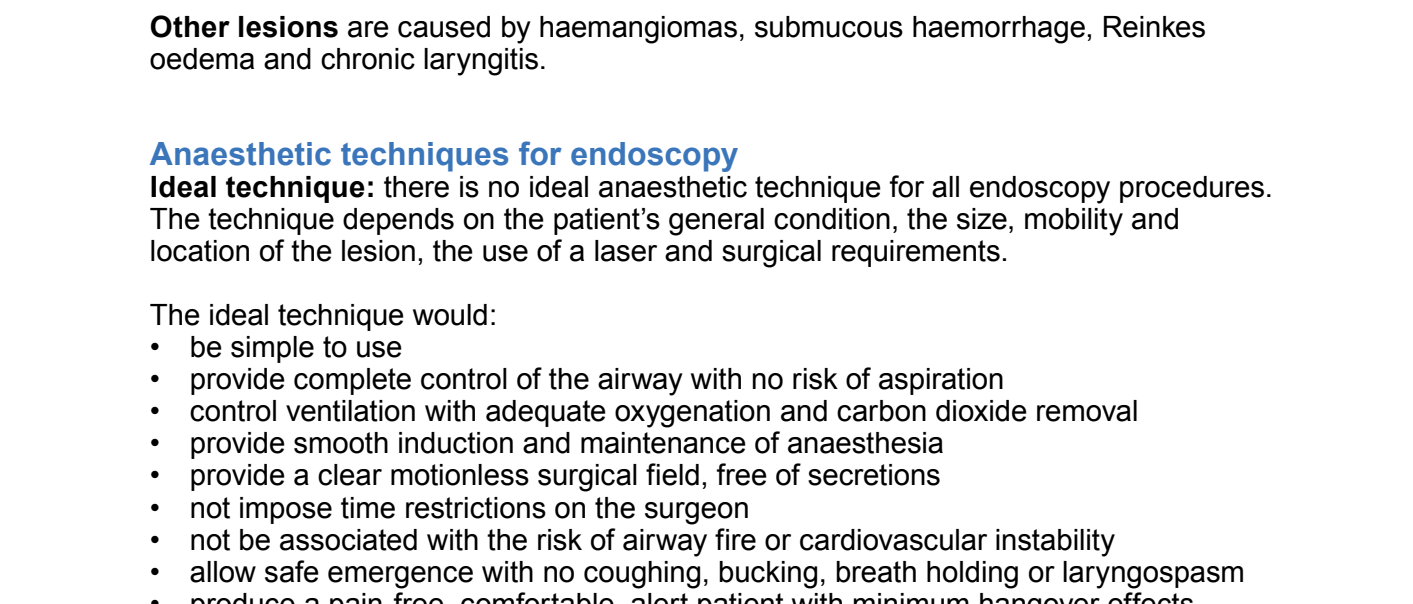
Some of these ideals conflict. The presence of a cuffed tracheal tube provides control of the airway and prevents aspiration but may obscure a glottic lesion and is not laser safe (Figure 1b). A cuffed laser tube provides some protection against laser-induced airway fires but has a greater external diameter to internal diameter ratio and may obscure laryngeal lesions. Jet ventilation techniques require specialist equipment and knowledge and an understanding of their limitations.

Basic technique: following intravenous induction of anaesthesia, mask-bag ventilation is manually confirmed before administration of muscle relaxants appropriate to the length of surgery. Laryngoscopy is undertaken to visualize the lesion, establish laryngoscopy grade and administer topical local anaesthetic (lidocaine (lignocaine)). Confirmation of pathology is important because the disease may have progressed since the last outpatient visit and the anaesthetic plan may have to be changed. Topical local anaesthetic is essential for the supraglottis, glottis and subglottis for cardiovascular stability, reduction of airway reflexes and smooth recovery.

Intubation techniques

Microlaryngoscopy tubes

Microlaryngoscopy tubes have a small internal and external diameter and have been designed specifically for endoscopy procedures because the small external diameter allows the surgeon a good view of the glottis (Figure 1c). Advantages of microlaryngoscopy tubes include control of the airway, the presence of a cuff, which protects against aspiration, and a motionless field for the surgeon. Disadvantages include the inability to use a laser because of the risk of an airway fire, obscuring the posterior commissure area where pathology may be missed, and increased airway resistance allowing spontaneous ventilation for short periods only.

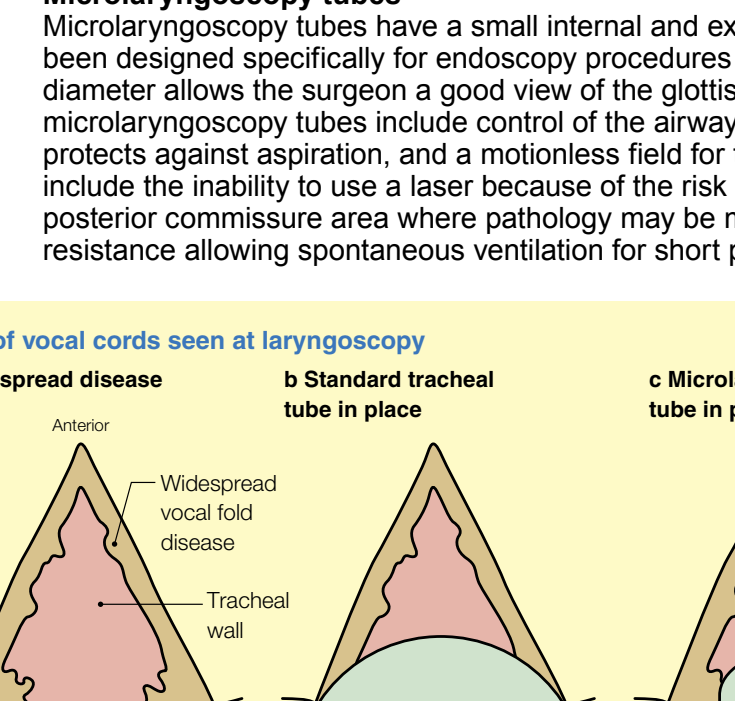


1

Laser tubes

Laser microsurgery of the airway allows precise surgical cutting, coagulation and sealing with little postoperative oedema. Lasers are used for the resection of papillomas, vascular lesions of the vocal cords, granulomas and laryngeal carcinomas. Carbon dioxide lasers are the most commonly used in airway surgery and are targeted towards the glottis by aiming mirrors integral to operating surgical microscopes. The two main hazards from the use of a laser are the risk to operating theatre staff from diverted laser radiation and the risk to the patient from a laser-induced airway fire.

An airway fire occurs only if the three components of the fire triangle are present (Figure 2). To minimize these risks the inspired oxygen concentration should be the lowest that maintains adequate oxygen saturations, and air should be used in preference to nitrous oxide. The potential fuel source should have laser-resistant properties (laser tubes) or be removed (supraglottic jet ventilation technique). The only non-flammable laser tube is the Norton (Figure 3) which is constructed of steel. Most laser tubes have laser-resistant properties, but ignite with sustained laser energy strikes. Laser tubes have greater external diameter to internal diameter ratios owing to their laser-resistant protective coverings and may obscure airway lesions.



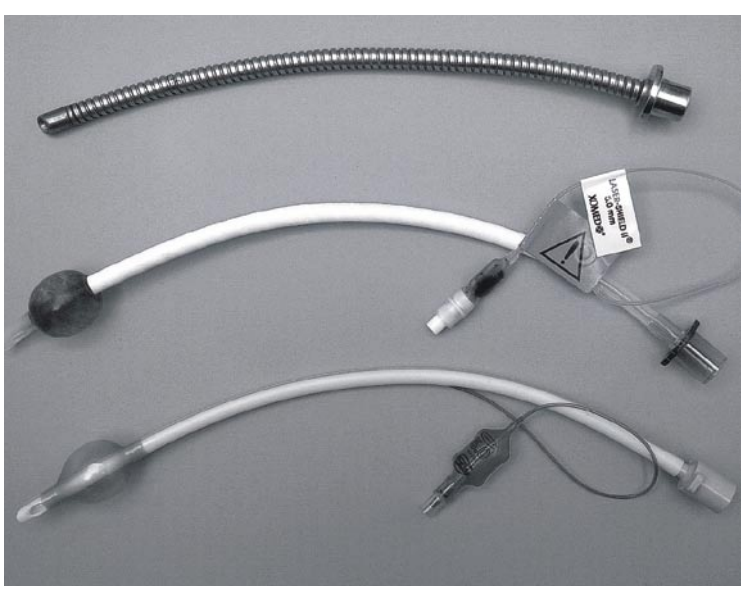
2

Anaesthetists involved in cases using lasers for airway surgery should be familiar with the causes of a laser airway fire, the limitations of laser-resistant tubes and an airway fire drill (Figure 4).

Non-intubation techniques

Spontaneous ventilation technique

Spontaneous ventilation techniques are used in the management of foreign body aspiration and for the dynamic assessment of the airway in patients with, for example, tracheomalacia. The technique allows a clear view of an unobstructed glottis. Anaesthetic management of patients with foreign body aspir-ation should aim to provide adequate oxygenation, a smooth induction, prevention of fragmentation or distal movement of the foreign body, sufficient depth of anaesthesia to prevent coughing, bronchospasm and laryngospasm, and smooth recovery.



3a Metal Norton tube with no cuff. **b** 5.0 mm internal diameter Xomed Laser Shield II. **c** 5.0 mm internal diameter Portex microlaryngoscopy tube.

Airway fire drill

Immediate action simultaneously
- Put out fire – flood field with saline (which must be immediately available)
- Remove energy source – stop laser
- Remove oxidant source – disconnect circuit, stop ventilation, stop gases
- Remove fuel source – extubate and remove burning fragments

Urgent action
- Review airway – ensure no burning fragments
- Oxygenate – 100% oxygen by bag and mask
- Review damage – flexible or rigid bronchoscopy
- Establish airway – re-intubate, laryngeal mask airway or jet ventilate

Assessment
- No airway damage – may proceed with surgery
- Severe airway damage – tracheostomy or oral intubation, ICU admission and controlled ventilation

4

Following inhalation induction with sevoflurane or halothane in 100% oxygen, intravenous access is established at an appropriate depth of anaesthesia, if not already present. When a suitable depth of anaesthesia is reached, laryngoscopy is undertaken and topical local anaesthetic (lidocaine (lignocaine)) administered above, below and at the level of the vocal cords. 100% oxygen is administered by face mask with spontaneous ventilation and anaesthesia continued with inhalational or intravenous (propofol) agents. At a suitable depth of anaesthesia the surgeon undertakes rigid laryngoscopy and bronchoscopy.

Insufflation technique
The insufflation technique requires a spontaneously breathing patient. Insufflation of anaesthetic gases and agents can be via a number of routes, including:
- a small catheter introduced into the nasopharynx and placed immediately above the laryngeal opening
- a tracheal tube cut short and placed through the nasopharynx emerging just beyond the soft palate
- a nasopharyngeal airway
- the side-arm or channel of a laryngoscope.

Insufflation techniques are useful in the removal of foreign bodies, evaluation of airway dynamics (tracheomalacia) and relatively fixed lesions (glottic, subglottic stenosis). Movements of the vocal cords are minimal or absent despite a spontaneously breathing technique provided an adequate level of anaesthesia is maintained. Limitations of insufflation techniques include:
- no control over ventilation
- loss of protective airway reflexes and the potential for the airway soiling
- theatre pollution with volatile agents requiring the presence of high-intensity suction catheters near the mouth.

Insufflation techniques may not be suitable for soft floppy lesions, particularly in the supraglottis or glottis, which may obstruct the airway following the onset of general anaesthesia.

For satisfactory insufflation techniques an adequate depth of anaesthesia is vital. If the depth of anaesthesia is too light, movement may occur, the patient may cough or laryngospasm occur. If the depth of anaesthesia is too great the patient may become apnoeic with cardiovascular instability. Careful observation throughout the procedure, noting movements, respiratory rate and depth, cardiovascular stability and constant observation for unobstructed breathing are vital, with the concentration of volatile anaesthetic adjusted accordingly.

Intermittent apnoea techniques
Intermittent apnoea techniques have been described for the laser resection of juvenile laryngeal papillomatosis, where the presence of a tracheal tube obstructs surgery. Following induction of general anaesthesia and confirmation of ventilation by face mask, muscle relaxants are administered followed by tracheal intubation. The patient is hyperventilated with a volatile anaesthetic agent in 100% oxygen. The tracheal tube is then removed, leaving the surgeon a clear unobstructed immobile surgical field. After an apnoeic period of typically 2–3 minutes, surgery is stopped, the tracheal tube is reinserted and the patient hyperventilated once more. The advantages of the technique are the immobile unobstructed surgical field and the inherent safety in the use of a laser with the potential fuel source (tracheal tube) removed. Disadvantages of the technique include:
- risk of aspiration of blood and debris with the tracheal tube removed
- variable levels of anaesthesia
- interruption to surgery for reintubation
- potential trauma through multiple reintubation.

Jet ventilation techniques
In 1967, Sanders first described a jet ventilation technique using a 16-gauge jet placed down the side-arm of a rigid bronchoscope and relying on air entrainment to continue ventilation with an open bronchoscope. Sanders used intermittent jets of oxygen (rate 8/minute, 3.5 bar driving pressure) to entrain air and showed the technique maintained supranormal oxygen pressure with no rise in the carbon dioxide pressure

Since 1967, modifications to Sanders' original jet ventilation technique have been made for endoscopic airway surgery. Supraglottic jet ventilation describes a technique in which the jet of gas emerges in the supraglottis by attachment of a jetting needle to the rigid suspension laryngoscope (Figure 5). Subglottic jet ventilation involves placing a small (2–3 mm) catheter or specifically designed tube (Benjet, Hunsaker) through the glottis and into the trachea. Transtracheal jet ventilation involves the placement of specifically designed percutaneous transtracheal catheters through the cricothyroid membrane or trachea.

5 Rigid suspension laryngoscope with jetting needle.

As well as modifications to the site at which the jet of gas emerges, changes to the frequency of jet ventilation have been described. High frequency (greater than 1 Hz, 60 breaths/minute) is used with ventilatory rates typically about 100–150/minute. High frequency jet ventilation allows:
- a continuous expiratory flow of air, enhancing the removal of fragments of blood and debris from the airway
- reduced peak and mean airway pressures with improved cardiovascular stability
- enhanced diffusion and interregional mixing within the lungs resulting in more efficient ventilation.

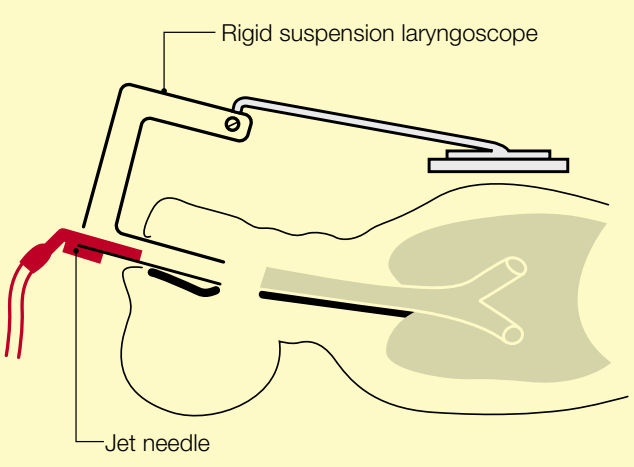
These advantages are of particular importance in patients with significant lung disease and obesity.

A typical jet ventilation technique includes preoxygenation followed by intravenous induction and maintenance with a target-controlled infusion of propofol, supplemented by bolus administration or infusion of alfentanil or remifentanil. At a suitable depth of anaesthesia, manual confirmation of mask ventilation is made before administration of muscle relaxants. Laryngoscopy is undertaken and topical lidocaine (lignocaine) administered. Face mask ventilation is continued with 100% oxygen until the surgeon is ready to site the rigid (suspension) laryngoscope on to which a jetting needle has been attached in preparation for supraglottic jet ventilation. Alternatively, a laryngeal mask airway can be inserted after induction and used to ventilate the patient with 100% oxygen until the surgeon is ready to site the laryngoscope. At the end of surgery, the laryngeal mask airway is reinserted before antagonism of residual muscle relaxation and cessation of intravenous anaesthesia, to facilitate smooth emergence.

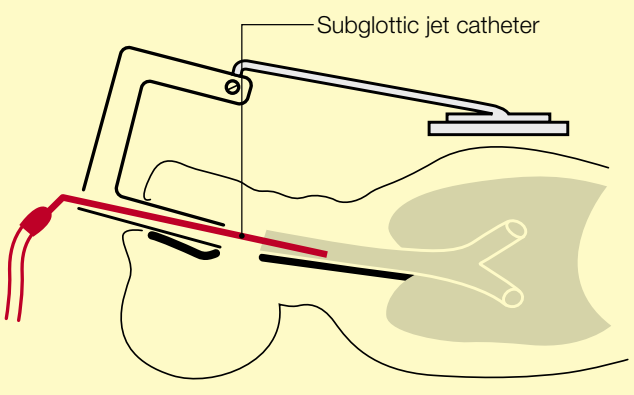
Supraglottic jet ventilation (Figure 6a) is commonly used in endoscopy procedures because it allows a clear unobstructed view for the surgeon with no risk of laser-induced airway fires. In common with all jet ventilation techniques, there is a risk of barotrauma with possible pneumomediastinum, pneumothorax, subcutaneous emphysema and pneumopericardiun. Other problems include:
- gastric distension with entrained air
- malalignment of the rigid suspension laryngoscope or jetting needle resulting in poor ventilation
- blood, debris or fragments being blown into the distal trachea
- vibration and movement of the vocal cords
- inability to monitor end-tidal carbon dioxide concentration.

Jet ventilation

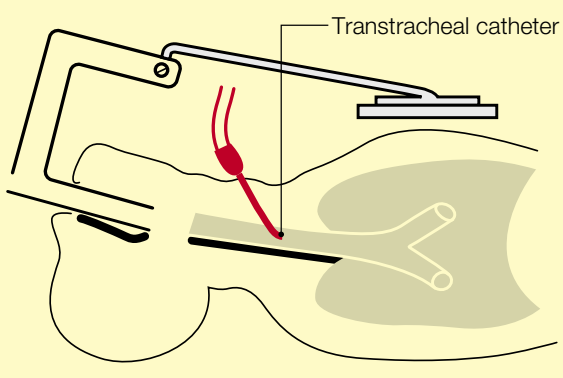
a Supraglottic jet ventilation



b Subglottic jet ventilation



c Transtracheal jet ventilation



6

Subglottic jet ventilation (Figure 6b) allows delivery of a jet of gas directly into the trachea. The technique is more efficient than supraglottic jet ventilation and results in reduced peak airway pressures, no vocal cord motion, a good surgical field and no time constraints for the surgeon in the placement of the rigid laryngoscope. The main disadvantages are the potential for a laser-induced airway fire due to the presence of a potential fuel source within the airway, and a greater risk of barotrauma than in supraglottic jet techniques.

Ventilators incorporating alarms and automatic interruption of jet flow when preset pause pressure limits have been reached (i.e. blockage of entrainment and exhalation have occurred) should be used.

Transtracheal jet techniques (Figure 6c): elective transtracheal catheter placement under local anaesthesia in individuals with significant airway pathology or under general anaesthesia for elective laryngeal surgery has been described. Transtracheal jet techniques carry the greatest risks of barotrauma of all jet ventilation techniques. Other potential problems include blockage, kinking, infection, bleeding and failure to site the catheter. The use of transtracheal jet ventilation for endoscopic surgery of the larynx requires careful evaluation of the potential risks and benefits.

Recovery from anaesthesia

Smooth emergence and recovery from anaesthesia are essential. Some studies show a 10–20 fold increase in reintubation following laryngoscopy or panendoscopy when compared with general surgical re-intubation rates. The recovery profile with a laryngeal mask airway provides smooth emergence from anaesthesia and some groups advocate the exchange of microlaryngoscopy tubes, tracheal and laser tubes for a laryngeal mask airway for recovery. ◆

ENT Emergencies

Richard Semenov

Richard Semenov is Consultant Anaesthetist at the Royal National Throat, Nose and Ear Hospital, London, UK. He obtained postgraduate training at the Middlesex and Royal Free Hospitals. His interests include anaesthesia for ENT surgery and the shared airway.

Ear, nose and throat (ENT) emergencies can cause acute life-threatening situations; they require a calm approach and good leadership skills. Good communication between anaesthetist and surgeon is vital in the management of these patients. This article concentrates on three emergency situations.

Acute epiglottitis

Acute epiglottitis is caused by *Haemophilus influenzae* type B. Epiglottic swelling can cause upper airway obstruction. It is most common in children aged 2–5 years and can progress rapidly from a simple upper respiratory tract infection to acute airway embarrassment. The typical clinical picture is a drooling child, who wants to sit up, with tachypnoea, suprasternal recession and stridor. The absence of a cough helps to distinguish it from laryngotracheobronchitis (croup). Complete airway obstruction may be provoked by pharyngeal examination, intravenous cannulation and excessive excitement. In severe cases, the diagnosis is made on clinical assessment.

The child and parents should be kept calm while experienced anaesthetic, paediatric and ENT help is sought. Anaesthesia should be induced using sevoflurane in 100% oxygen with the patient in the sitting position until tracheal intubation is possible. Induction is usually slow and the apparatus for difficult intubation and the facilities for urgent tracheostomy must be available. Atropine may be given once the intravenous cannula is sited. An oral tracheal tube one size smaller than normal should be used and this can be changed to a nasal tube for increased comfort if intubation is straightforward.

Halothane has been the agent of choice for inhalational induction when a patient's upper airway is partially obstructed. Recently, reports of the use of sevoflurane in the difficult airway have been published. If the airway obstructs completely after reaching a deep plane of anaesthesia, the redistribution of the inhalational agent from the brain to the other body compartments is the primary determinant of time to awakening. Halothane has a higher blood gas solubility, therefore it should redistribute to other compartments more quickly than sevoflurane and the brain concentrations of halothane should fall more rapidly and the patient should regain consciousness faster than with sevoflurane. However, induction with halothane takes longer than with sevoflurane because of its higher blood:gas solubility coefficient, which allows more time for halothane to distribute round the body. The concentration gradient from blood, brain and alveoli to other compartments is therefore lower than with sevoflurane. The blood: tissue solubility coefficient is similar for the two agents. As a consequence, when the airway obstructs, it takes longer to return to consciousness with halothane.

Acute epiglottitis is becoming rare in children, probably because of effective vaccination against *H. influenzae*. The Hib vaccine was introduced in the UK in October 1992. Hib-vaccinated children who develop epiglottitis grow penicillin-sensitive streptococci, making penicillin the first choice treatment, rather than the cephalosporins or chloramphenicol required for *H. influenzae*.

The incidence of acute epiglottitis in adults has increased because of the frequent use of antibiotic agents in childhood with an associated failure to develop immunity against *H. influenzae*. Greater awareness and recognition of the disease may also have played a role. Cases of epiglottitis caused by unusual pathogens are being reported among immunocompromised patients, such as drug abusers.

Obstructed airway in head and neck surgery

If asked about the management of an obstructed airway, many anaesthetic trainees suggest an awake fibre-optic intubation. However, serious complications may be associated with its use. There are three main sites of obstruction:

- supraglottic and glottic lesions causing obstruction
- mid-tracheal obstruction, often secondary to retrosternal goitres and thyroid carcinomas
- lower tracheal and bronchial obstruction, usually from large mediastinal masses (e.g. lymphomas, thymomas, carcinomas).

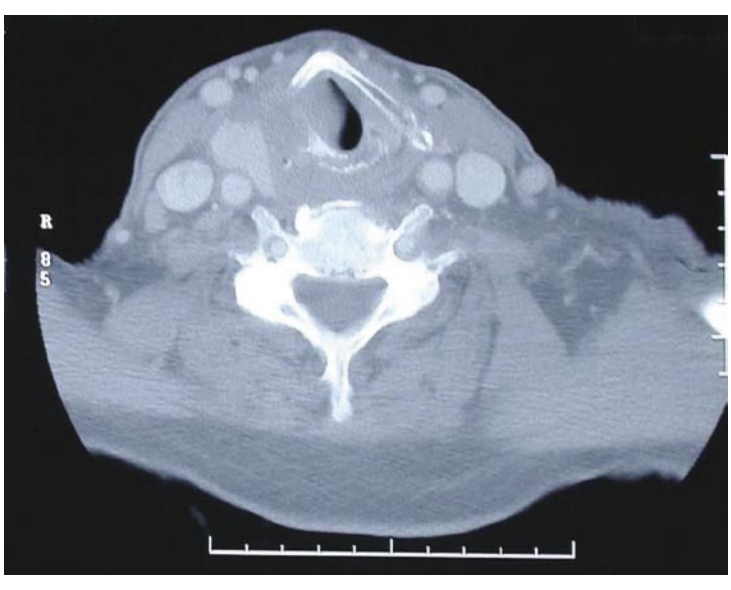
Supraglottic and glottic lesions

Careful preoperative assessment is essential for the management of upper airway obstruction. The implication of stridor is that there is a reduction of airway diameter of at least 50%. Patients often present late owing to the slow-growing nature of the tumours. With severe obstruction there may be difficulty in breathing that wakes the patient at night in a panic. The presence of nocturnal symptoms suggests advanced obstruction. A fibre-optic nasendoscopy will usually have been performed by the ENT surgeon in the outpatient clinic. It does not involve spraying the larynx with local anaesthetic or making contact with the vocal cords, both of which are hazardous and can precipitate complete airway obstruction. A CT scan of the neck is helpful to assess the subglottis and the lower extent of the tumour.

Senior ENT and anaesthetic staff should discuss the case before the patient's arrival in the anaesthetic room. If it is decided to undertake a general anaesthetic a secondary plan should be prepared, in case problems arise, and it should be discussed with the patient. Patients with moderate stridor, in whom intubation is considered possible, should be managed with an inhalational induction in theatre with the ENT surgeon gowned and ready (plan A). A tracheostomy tray and rigid ventilating bronchoscope should be available. Safety lies in the maintenance of spontaneous ventilation, induction takes time and should not be hurried. Difficulty often arises when the patient first loses consciousness. The skill lies in avoiding coughing and subsequent laryngeal spasm. A nasal airway can be helpful.

When anaesthesia is deep enough, laryngoscopy should be attempted and a rapid decision made as to whether a tube can be passed. If a decision is made to intubate, a maximum of two attempts should be made because persistent attempts may result in total obstruction. Correct position should be confirmed with capnography. If it proves impossible to intubate, the surgeon should perform a tracheostomy while the patient maintains spontaneous respiration (plan B). A laryngeal mask airway can be useful to maintain the airway but may prove difficult to insert with a supraglottic tumour.

Patients with severe stridor resulting from a supraglottic or glottic lesion (Figure 1) often come to hospital for the first time as an emergency or have deteriorated following radiotherapy. They should have no sedation and be given a helium:oxygen mixture to improve symptoms. They should have a preliminary surgical airway performed under local anaesthetic. This can be a tracheostomy or an emergency cricothyroidotomy cannula can be placed through the tracheal rings below the level of the tumour to allow subglottic jet ventilation. A formal tracheostomy may be difficult because these patients are often hypoxic, hypercarbic and confused, therefore a short procedure to secure adequate ventilation is often advisable.



1 Glottic stenosis causing stridor.

Mid-tracheal obstruction

With mid-tracheal obstruction the fibre-optic bronchoscope may be useful. The exact site and extent of the obstruction should be defined before embarking on an anaesthetic. A CT scan is essential for lesions of the trachea and bronchi. As in the case of upper airway tumours, the formulation of plan A and plan B is critical. The scan provides a guide to whether a 7 mm tube will pass through the narrowest site of the compression. If this is the case, a conventional induction of anaesthesia can be performed. If there is any doubt, evidence of malignant invasion into the trachea or marked tracheal deviation, an awake fibre-optic intubation is the method of choice, which requires an experienced operator.

Lower tracheal and bronchial obstruction

Patients with symptomless lower tracheal and bronchial obstruction from mediastinal masses can develop unexpected respiratory obstruction during anaesthesia. During spontaneous respiration there is a subatmospheric intrapleural pressure and widening of the airways during inspiration. Administration of a muscle relaxant may alter the support of the bronchial tree and collapse of the airway can occur with positive-pressure ventilation. Tissue biopsy should be performed whenever possible under local anaesthetic and if superior vena caval obstruction is present urgent radiotherapy and chemotherapy may be necessary, even in the absence of a histological diagnosis. A rigid bronchoscope may relieve obstruction. Cardiopulmonary bypass may have to be considered.

The bleeding tonsil

The problems of the bleeding tonsil include:

- stomach full of blood and risk of aspiration
- potential difficult airway, oedematous and obscured by blood
- hypovolaemia
- not yet recovered from a recent anaesthetic.

Anaesthetists should be alert to the possibility of an unsuspected bleeding disorder. A recent episode of tonsillitis makes the procedure technically more difficult and increases the risk of postoperative haemorrhage. There is conflicting opinion as to whether non-steroidal anti-inflammatory drugs used for postoperative pain increase the incidence of bleeding.

Post-tonsillectomy haemorrhage is seldom a catastrophic acute arterial bleed. It is usually a venous or capillary ooze and therefore resuscitation rather than immediate operation is the first management step. The child may have swallowed a lot of blood and hypovolaemia can be severe before the diagnosis is made.

After effective resuscitation, the patient presents further problems in theatre. There is a risk of aspiration of gastric contents (mostly altered blood), and significant amounts of the anaesthetic agents used previously may still be present. Experienced anaesthetic assistance is required. There are two methods of intubation.

- An inhalational induction in the left lateral position, with suction available, the trachea is intubated during spontaneous ventilation. Induction may be prolonged and hindered by continued bleeding. Few have much experience of intubating in this position.
- A rapid-sequence induction and intubation has the advantages of familiarity and rapidity. It should be attempted only if intubation was easy at the initial procedure. Visualization of the larynx may be difficult if there is torrential haemorrhage, two separate suction units should be ready for use.

Nasogastic aspiration should be performed before extubation. Extubation should be performed when the patient is awake and laryngeal reflexes have returned, to minimize the risk of aspiration of gastric contents. ◆

Gas, Tubes and Flows

Kwong Fah Koh

Kwong Fah Koh is Associate Professor in Anaesthesia at the National University, Singapore. He graduated from the National University of Singapore. He trained in anaesthesia in Singapore and did a fellowship in neuroanaesthesia at the National Hospital for Neurology and Neurosurgery, London.

Understanding fluid flows through tubes and airways requires a knowledge of fluid mechanics. Oxygen, air and nitrous oxide are gaseous fluids and largely obey the laws of fluid dynamics.

Gas laws
Gases are described in terms of pressure, volume and temperature. The three are related according to the ideal gas law:

$$PV = nRT$$

where: P is the pressure (kPa), V the volume (ml), T the temperature (Kelvin), n is Avogadro's number (number of moles of a gas in a fixed volume) and R the gas constant (8.3143 J/gm mol/K). A mole of gas contains 6.023×10^{23} molecules and occupies 22.4 litres at standard temperature and pressure (i.e. 0°C and 760 mm Hg).

The ideal gas law incorporates Boyle's and Charles' laws. At a constant temperature, the volume of a given mass of gas varies inversely with its absolute pressure (Boyle's law). At a constant pressure, the volume of a given mass of gas varies directly with its absolute temperature (Charles' law). However, there are no ideal gases because there are significant intermolecular attractions (van der Waal's forces) between gas molecules, therefore constants are added to both the pressure and volume relationship in the ideal gas laws:

$$(P+a/V^2).(V-b) = nRT$$

where a corrects for attraction between molecules and b corrects for the volume occupied by molecules.

In clinical practice, mixtures of gases are used and their behaviour is described by Dalton's law of partial pressures. This states that in a mixture of gases, the pressure exerted by each gas is the same as that it would exert if it alone occupied the container, so the total pressure in a system is a sum of all the partial pressures of the different gases.

Movement of gases
Fluids flow when there is a pressure difference. Hagen–Poiseuille's law states that flow through a horizontal straight tube of uniform diameter is proportional to the pressure gradient and the fourth power of the radius, and is inversely related to the viscosity of the gas and the length of the tube.

$$F = \frac{\Delta P \pi r^4}{8 \mu l}$$

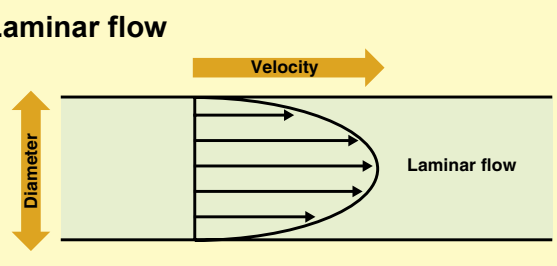
where: F is the flow rate through the tube (cm^3/s), ΔP the pressure gradient, π is 3.14, r the radius of the tube (cm), μ the fluid viscosity (g/cm/s), and l the length of the tube (cm).

The law assumes that flow is laminar. When flow exceeds a critical velocity, the flow velocity profile loses its parabolic profile and becomes turbulent. This occurs when the Reynold's number becomes larger than 4000. Reynold's number is affected directly by flow rate through the tube and density of the gas and is inversely related to viscosity of the gas and the radius of the tube. The higher the number, the more turbulent the flow. Flow is laminar at Reynold's numbers less than 2000.

Flow becomes turbulent when the velocity is high, when there are sharp angles, changes in diameter or multiple branching (Figure 1). This can be seen in the upper airway. During normal respiration, flow in the trachea is usually a mixture of turbulent and laminar flow. If there is an obstruction (e.g. glottic stenosis), the radius of the airway decreases and the flow velocity increases. This accentuates turbulence and gas flow decreases. Such patients often assume an extended neck position to minimize the angles present and increase the upper airway diameter in an attempt to decrease the turbulence and improve gas flow.

Laminar and turbulent flow characteristics

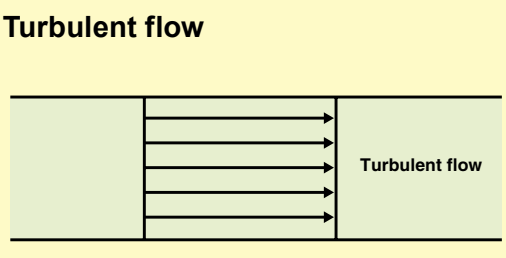
Laminar flow



- Viscosity
- Radius^4
- ΔP^4

Reynold's number < 2000

Turbulent flow



- Density
- Radius^2

$\Delta P^{½}$
Reynold's number > 4000

1

Flow, viscosity and density
The viscosities of common anaesthetic gases are fairly similar but their densities differ greatly (Figure 2). When the airway is narrowed, flow becomes turbulent and the density of a gas assumes greater significance. The density of oxygen is quite close to that of air, but the density of 70% nitrous oxide in oxygen is 60% higher. The density of 80% helium in oxygen is only 30% that of air. During an airway obstruction, using heliox (80% helium, 20% oxygen) can improve gas flow by reducing turbulence. This improved flow can be 1.73 times greater than air or 100% oxygen. Nitrous oxide should be avoided during induction if there is significant airway obstruction.

Density and viscosity of gases at 20°C, 101.3 kPa

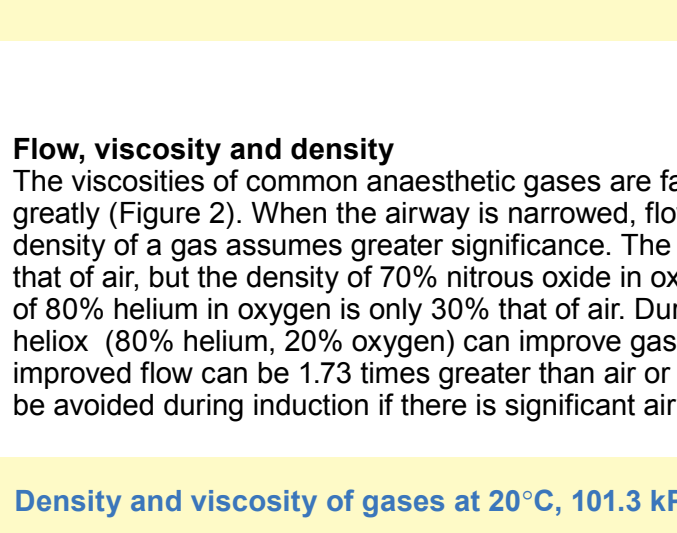
	Viscosity	Density
Air	18.2	1.196
Nitrogen	17.6	1.165
Oxygen	20.4	1.331
Nitrous oxide	14.6	1.831
Helium	19.6	0.166

Air contains 0.04% carbon dioxide with 50% relative humidity

2

Flow through tracheal tubes
The largest possible tracheal tube used to be regarded as the 'correct' size (8 or 9 mm internal diameter). However, larger tracheal tubes cause more trauma to the pharynx, larynx and tracheal wall. Smaller tubes are easier to insert and cause less trauma. Studies have shown that smaller tracheal tubes (6 or 7 mm internal diameter) do not significantly increase airway resistance (Figure 3). Airway pressure is usually measured at the proximal end of the tracheal tube. Because of this, the airway pressure measured is higher when a small tube is used than when a larger diameter tube is used. However, when the intratracheal pressures are measured, they are not significantly higher during the inspiration and expiration phases. Tube sizes of 6 and 7 mm internal diameter are acceptable for positive-pressure ventilation during routine anaesthesia.

Flow rate compared with pressure drop for a range of tracheal tubes



The red line is the suggested upper limit of acceptable resistance for an adult.

3

In intubated patients, mechanical ventilators can overcome impedance to inspiratory flow, but not the impedance to passive expiration. In weak patients, resistance to exhalation through long narrow tubes, compounded by turbulence, can delay weaning. Such patients benefit from a larger tracheal tube or a tracheostomy. The reduced resistance (from using a short, large- bore tube) during expiration minimizes the work of breathing during expiration and thus aids weaning.

Flowmeters
A flowmeter consists of a bobbin in a tapered glass tube. As the bobbin moves upwards, the gap around it increases so that a higher flow is required to support the bobbin. At low flows, the gap between the bobbin and the tube is small so the flowmeter resembles a tube. The flow is laminar and thus is dependent on the viscosity of the gas. At higher flow, the gap is wider and the flowmeter resembles an orifice that has a turbulent character. Gas flow is thus dependent on density rather than viscosity. If oxygen and helium are passed through identical flowmeters, the measurements of flow will be accurate at low flows, because their viscosities are quite close. However, at high flows, the helium will relatively under-read as flow is increased because of its lower density.

Flow through constrictions
The Bernoulli effect describes the fall in pressure at points of constriction, where flow velocity is higher. This effect is seen in devices using the Venturi principle, such as gas nebulizers, some flowmeters and face masks (Ventimask). Jet ventilators force gas through a narrow orifice. The resultant jet creates a low pressure area that causes gas entrainment. When a jet ventilator is used, it is important that the airway is unobstructed during inspiration (to allow entrainment) and expiration (to prevent breath stacking).

Some effects of high gas pressures
Gas density increases in direct proportion to pressure. Air at 10 atmospheres has ten times the density of air at sea level. Thus, the work of breathing at higher atmospheric pressure (e.g. during diving) is greater. The maximum breathing capacity is decreased because density is increased due to increased pressure. To circumvent this problem, helium, with a density one-seventh that of nitrogen is used with oxygen (heliox) at high pressure.

Flowmeters are affected by pressures, because flow is affected by density at higher rates of flow. A flowmeter would read lower at high pressures. ◆

Obstructive Sleep Apnoea

John Ruddock

John Ruddock is Consultant Anaesthetist at the Royal National Throat, Nose and Ear Hospital, part of the Royal Free Hampstead Hospital Trust, London, UK. It is a specialist hospital for ENT and head and neck surgery. He is actively engaged in the diagnosis and treatment of patients with sleep-related breathing disorders.

Adults who are said to have obstructive sleep apnoea (an apnoea-hypopnoea index (AHI) of more than 15 episodes per hour of sleep) have a variety of upper airway conditions. In this article, the term obstructive sleep apnoea (OSA) is used for the occurrence of repeated obstructive episodes over several respiratory cycles. 'Sleep-disordered breathing' is a better general term.

The nature of sleep
The principal function of sleep is to restore the function of the prefrontal cortex, thereby restoring higher centre cognitive activity. This is brought about by the delta (slow) wave activity generated by the cerebral cortex under the influence of centres in the thalamus. This is the EEG activity that characterizes the Rechtschaffen and Kales sleep stages 3 and 4. The delta activity per 30-second sleep epoch in these sleep stages is 20–50% in stage 3 and over 50% in stage 4. Normally 25–40% (2–3 hours) of sleep should occur in these stages. They occur mainly in the first two or three 90-minute sleep cycles. Even small amounts of sleep deprivation result in measurable changes in certain cognitive function tests. Making appropriate responses to unexpected events is particularly impaired and while alertness can be restored by stimulants such as caffeine, these higher centre cognitive functions cannot be restored by stimulants.

To achieve sleep stages 3 and 4 the individual needs to progress through stages 1 and 2 and it is in these lighter sleep stages that airway inadequacy may express itself in sleep-disordered breathing. The progression to deep sleep coincides with the establishment of regular respiration and anything that impairs this regularity, impairs the progression to deep sleep.

Airway maintenance during sleep
The upper airway is maintained by tone in the skeletal musculature of nose, nasopharynx, oropharynx, tongue and larynx. Efferent discharges to these muscle fibres have tonic and phasic components. The phasic components are in synchrony with inspiration. The effect is to brace the airway against a tendency to collapse. (The flaring of the nostrils with intense inspiratory effort is part of this phasic activity.) During sleep, the tonic efferent discharge falls in parallel with the reduction in tone throughout all the skeletal musculature and is at a minimum during rapid eye movement (REM) sleep. The upper airway becomes increasingly susceptible to forces provoking airway narrowing, such as pressure from fat around the pharynx or the collapsing effect of inspiration, which is accentuated when there are pathological conditions, such as nasal obstruction, affecting the upper airway. The airway may become unable to support adequate respiration during sleep. How the brain senses this inadequacy is not known, but the result is the inability to progress to deep sleep.

Compensations for airway impairment during sleep
Airway impairment during sleep is compensated for by posture, respiratory drive, pharyngeal reflexes and sleep disruption.

Posture – normally individuals automatically adjust their sleeping posture to compensate for airway narrowing. They may turn their head to the side, elevate their head to the 'sniffing the morning air' position, turn on their side or lie prone. The afferent loop for this response is unknown. The airway remains patent or is occluded for only a few respiratory cycles until the compensating adjustment in posture has been made. During REM sleep, when the individual is sleeping on their back, the generalized paralysis prevents compensatory changes in posture and OSA events may persist throughout the REM period.

Pharyngeal reflexes – when people with airway narrowing are given a sedative, such as midazolam, 3–5 mg, and propofol, 50–100 mg, their airway may become obstructed if they are lying on their back. Just as in REM sleep, they are unable to move to make appropriate compensatory postural changes. The obstruction persists, but is intermittently relieved, probably because the respiratory drive increases as the carbon dioxide level rises. Local pharyngeal reflexes respond to a negative pressure within the lumen to increase the tone of the airway musculature and these would be stimulated when the force of inspiration increased against the airway obstruction. The afferents for these reflexes may also be within the thorax because airway obstruction leads to negative intrathoracic pressure. In addition, the increased respiratory drive augments the phasic tone of the airway musculature.

Failure to progress in sleep – when progressive airway narrowing during sleep has produced maximal levels of respiratory drive and phasic tone the final measure to preserve adequate respiration during sleep is sleep disruption. Arousal is linked by neural mechanisms within the brain to a certain critical level of respiratory stimulation. The arousal causes the tone in the airway to return and so relieve the airway obstruction. This is the situation in OSA.

Categories of sleep-disordered breathing

Upper airway resistance
Upper airway resistance is an arbitrary term for two typical responses.

- Postural changes, such as head extension, may be inadequate to compensate for airway impairment. An increase in respiratory drive may be required to overcome the resistance and augment the phasic component of tone in the airway musculature. There are no apnoeas, but airflow may wax and wane (hypopnoea) owing to increasing obstruction. There may be paradoxical respiration. The respiratory drive increases until the arousal threshold is exceeded. The arousal causes the tone in the airway to return. The airflow is increased and the snoring is reduced.
- Others have a different response, which may be induced by a lower metabolic rate and cardiac output. In these individuals, the waning airflow seems to be the result of a reduced respiratory drive and any snoring occurs when the airflow increases during the arousal phase. The inference is that airway reduction impairs respiration and leads to a rise in the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) until this has a stimulatory effect on the respiratory centre, which incurs a delay. At a particular level of respiratory stimulation there will be an arousal, hyperventilation and overcompensation. The $PaCO_2$ falls below the respiratory threshold and there is a hypopnoea or central apnoea and the cycle is repeated.

OSA
Effective compensatory reflexes safeguard the airway during sleep and prevent persistent obstruction. Significant OSA occurs when the ability of these reflexes is exceeded. There is a limit to which postural change can aid the situation, the respiratory drive can be at a maximum and the protective pharyngeal reflexes may be impaired.

Mild OSA – in REM sleep, postural changes are obtunded but there are other compensations in response to OSA. There may be a microarousal (momentarily coming out of REM sleep) or REM sleep may be reduced. Commonly, OSA occurs in REM sleep only when the individual is lying on their back; when they lie on their side, they have REM sleep without apnoeas and without desaturations. These individuals desaturate when on their back during each of their three or four REM episodes each night, probably to 70%. Mild OSA does not have an impact on daytime somnolence. In the presence of coronary vascular disease there are probable implications in the postoperative management of people with mild OSA (see rebound REM below). Many people desaturate during REM sleep without having OSA because a reduction in respiratory effort occurs as part of the normal reduction in skeletal muscle tone that occurs during REM sleep.

Moderate OSA – obstructive apnoeas occur in sleep stages 1 and 2 if individuals sleep on their back. There is probably an impairment in the local pharyngeal reflexes. The theory is that pharyngeal mucosal oedema from the repeated trauma of airflow turbulence and actual damage to nerve endings has resulted in the impairment or loss of these protective pharyngeal reflexes. The result is that the airway is obstructed, the carbon dioxide level rises, the oxygen level falls and the respiratory drive increases until the individuals arouse. They suffer repeat arousals, of which they are not usually aware, but sleep is disrupted and progression to deep sleep is impaired. Individuals with moderate OSA who lie on their side may not have obstruction and sleep can progress, though they may show features of 'upper airway resistance'. They may not have severe daytime somnolence.

Severe OSA – patients either obstruct in all sleep positions or remain on their backs throughout the night despite repeated obstructive events. They do not have any sustained delta sleep and REM sleep is usually severely disrupted. These patients are somnolent with severe impairment to their quality of life. Treatment is with nasal continuous positive airway pressure (CPAP). Patients will still obstruct if they do not use CPAP, unless during their treatment period they have lost a great deal of weight. However, treatment eliminates somnolence and their cardiovascular system is not subjected to the strain of repeated episodes of hypertension and tachycardia.

Cardiovascular system – negative intrathoracic pressure during apnoea leads to a fall in systemic blood pressure and heart rate. It also causes increased venous return and stimulation of the baroceptors of the aortic arch and therefore at the end of the apnoea when the arousal results in relief of the airway obstruction, there is a rise in blood pressure and heart rate. This is usually coincident with the nadir in peripheral oxygen levels. The result is severe cardiovascular instability. Cardiac dysrhythmias (supraventricular and ventricular ectopics, atrial fibrillation and periods of complete heart block) often occur in these patients. There is an increase in daytime blood pressure. Essential hypertension in these patients may be refractory to medical treatment until the OSA is treated with nasal CPAP, similarly in patients with upper airway resistance.

Central apnoea
The 'central' event is caused by a reduction in respiratory drive. The most common cause is when an individual enters an episode of periodic respiration as a result of a change in sleep stage or position and there are alternations of hypo- and hyperventilation. They may be a normal event during sleep onset, after an arousal or during REM sleep. Their association with 'upper airways resistance' has been discussed. In addition, central apnoeas may occur when there is respiratory failure – the hypoxic drive during sleep results in hypocapnia and respiratory cycling. Altitude causes similar events. Respiratory drive and airway musculature are affected in patients with brain lesions (e.g. after a stroke). In addition, there is the long-period respiratory cycling of Cheyne–Stokes breathing in which the low cardiac output of heart failure results in a prolongation of feedback.

Mixed apnoea
Some patients have mixed apnoea (obstructive plus central apnoea). They have a central apnoea with an initial patent airway, however, the absence of phasic drive and the presence of surface tension effects from the mucous lining of the airway result in airway closure. Also, pharyngeal reflexes do not operate when there is no respiration. When respiration restarts, the opening of the airway produces a characteristic snore.

OSA

Aetiology: a number of head and neck and neuromuscular pathologies provoke sleep-disordered breathing and may render the individual unable to compensate effectively. The most common aetiology is a history of nasal obstruction that originates in developmental or traumatic abnormality of the nasal airway. Over time the increased respiratory effort required for adequate breathing results in pharyngeal wall collapse, thickening and folding of the mucosa, elongation of the uvula, submucosal oedema and a tendency to breath through the mouth, that restricts the post-lingual airway. In middle age, particularly in men, fat is deposited in the neck and this further compresses the airway. These occurrences are insidious as are their effects on sleep. An individual and resilient sleep pattern is established.

Investigation: a simple sleep study is all that is required, provided it is interpreted with an understanding of what may be happening to the sleep staging. A polysomnogram is unnecessary and impractical for investigating most people. The important parameters of the sleep study are gender, body mass index, Epworth Sleepiness Score, sleep position, snoring events, oxygen saturation, heart rate, abdominal and chest respiratory efforts and airflow. Monitoring leg movements is also useful. In the Epworth Sleepiness Score the patient is asked to score their likelihood of falling asleep on a scale of 0–3 for eight different activities or periods of the day. The maximum score for extreme sleepiness is 24; normal scores are less than 10.

Implications for anaesthesia: few patients have perioperative sequelae due to OSA. Often those at risk are in or approaching the morbidly obese range and appropriate anaesthetic safeguards (e.g. short-acting agents, awake fibre-optic intubation) are used for that reason. However, there are reports of cases in which the anaesthetist has not been prepared for OSA and anecdotal reports of patients, not necessarily obese, who have died during the perioperative period in whom OSA has been implicated.

The confounding factors related to obesity are difficult venous access, difficult airway maintenance, difficult intubation, hypoxia, thromboembolic phenomena and gastro-oesophageal reflux. Apart from these, the focus of concern for adults with OSA is the recovery period. The airway is maintained in these patients by the respiratory drive and the capacity for arousal; the factors that are obtunded by general anaesthetics. The anaesthetic technique must ensure that when the patient is required to maintain their own airway, they will be awake with a good respiratory drive. Appropriate anaesthetic agents to achieve this aim are desflurane and remifentanil.

Preoperative assessment: patients who are likely to have OSA have a history of snoring, sleep apnoea and daytime somnolence. Men are more likely to have the condition than women because of the different distribution of fat tissue in the neck. Obese patients with severe OSA have a reduced functional residual capacity and desaturate profoundly, regularly to 60% throughout the night. A person with OSA who is not obese will not desaturate to this degree. The diagnosis is made from an overnight oximeter recording on an obese patient who is sleeping; conversely the anaesthetist can be reassured by a negative trace. Objective evidence that the patient has been to sleep can be obtained from the heart rate record. If severe OSA is suspected, elective surgery must be deferred. A patient with severe OSA needs to be stabilized on nasal CPAP.

Upper airway resistance and moderate OSA are often present in patients with a history of snoring and sleep apnoea, in those with a thick neck, large tongue or retracted mandible. The recovery position and Guedel airway are likely to be needed until the patient is awake. The need for effective postoperative analgesia in these patients may warrant the use of an oximeter or care in the high dependency unit.

Low body mass index (BMI) and severe OSA – most patients with significant sleep apnoea have a BMI of 30 or more. However, severe OSA can occur in patients with a normal BMI as a result of maldevelopment of maxilla or mandible. If the condition is associated with neurological deficit or motor weakness, hazards for the patient following general anaesthesia include laryngeal incompetence, which could lead to aspiration or respiratory failure.

Mild OSA and 'rebound REM' – all patients have impaired sleep during the immediate postoperative period. For patients with sleep-disordered breathing, this means that the number of hypoxic events will be reduced. In particular, there is inhibition of REM sleep, partly due to the effect of analgesic drugs such as morphine. A person who desaturates during REM sleep may not therefore desaturate during the first few nights after surgery. A few nights later, there may be increased amounts of REM sleep to compensate for the period of deprivation. As a result, the patient may desaturate for long periods in the postoperative period when they will not usually be receiving supplementary oxygen. For most patients, desaturation during REM is probably not hazardous, but where there is coronary insufficiency, it should be avoided by the use of nasal CPAP. The combination of mild OSA and coronary insufficiency may be responsible for postoperative myocardial infarction.

Anaesthesia in severe OSA: a patient with severe OSA who is having surgery to remove nasal polyps to assist nasal CPAP therapy can probably have their airway managed with a flexible laryngeal mask (LMA) in the hands of an experienced anaesthetist. After securing intravenous access and giving an anticholinergic agent, glycopyrrolate, 200 μg, anaesthesia is induced with oxygen and sevoflurane, with or without propofol, 10 mg increments. A Guedel or nasopharyngeal airway may be needed. If airway compromise occurs, suxamethonium, 100–150 mg, may be needed, alternatively if hand ventilation is achieved without suxamethonium, a small amount of atracurium, 25 mg. Remifentanil, 10 μg increments, are given and the flexible laryngeal mask (size 5 males; size 4 females) inserted. Anaesthesia is maintained by ventilating with oxygen, desflurane with or without air or nitrous oxide and by using a remifentanil infusion. If normal levels of $ETCO_2$ (end-tidal carbon dioxide level) are not achieved for a maximum inspiratory pressure of 20 cm H_2O, the use of a tracheal tube needs to be considered.

At the end of the operation the muscle relaxant is reversed and the patient recovered, sitting up, with the flexible LMA and bite guard in place until they are well awake. The LMA is removed, provided adequate levels of oxygen saturation and $ETCO_2$ have been achieved. Patients with nasal packs require nursing in the high dependency unit. Postoperative CPAP intervention requires a full-face mask.

If a tracheal tube has been used for anaesthesia for surgery, then awake extubation with the patient sitting upright is the preferred option with the use of a nasopharyngeal airway or rigid LMA where appropriate. Postoperative analgesia with opiates may need to be withheld and the patient warned about this. Non-opiate analgesia is preferred. Regional anaesthetic techniques are not necessarily indicated because they impact on the strength of respiration. ◆

Percutaneous Tracheostoma

Robert Broomhead

Robert Broomhead is Specialist Registrar in Intensive Care Medicine at the Hammersmith Hospital, London. He graduated from Leeds University and is training in anaesthesia and intensive care medicine on the North West Thames rotation.

Prolonged ventilatory support of intensive care patients using nasal or oral tubes, is associated with a number of problems. Tracheal tubes are uncomfortable and require the patient to be sedated. These tubes are more liable to occlusion (kinking, biting, secretions) and their length and contours make it difficult to pass catheters for effective tracheobronchial suctioning of secretions. Oral tubes can be difficult to secure and constant movement increases the chance of tracheal damage. They also prevent adequate oral hygiene procedures. Nasal tubes are associated with infection in the paranasal sinuses.

Placement of a tracheostomy reduces or removes these problems. It also reduces the dead space and the resistance to, and work of, breathing. The benefits of tracheostomy are outlined in Figure 1 and the complications listed in Figure 2. The decision to perform a tracheostomy is based on an appraisal of the risks and benefits for each patient (Figure 3). Tracheostomy was advocated after 1 week of continued ventilation to avoid subglottic ulceration. Recently, the trend has been towards early placement in patients predicted to have prolonged requirements for ventilatory support, or airway protection.

Advantages of percutaneous tracheostomy

- May be performed in the ICU (removing the hazards of transferring critically ill patients)
- Performed by intensivist/anaesthetist (does not require referral to a surgeon and organization of theatre time)
- Often quicker than open surgical technique
- Fewer postoperative infections
- May be reduced incidence of tracheal stenosis
- Aids weaning from ventilator
- May reduce patient's length of stay in ICU

1

Complications of tracheostomy

Immediate
- Submucosal placement of guidewire and/or dilation
- Cricoid damage
- Trauma to the posterior wall of trachea
- Marked fall in oxygen pressure
- Cardiac dysrhythmia
- Haemorrhage
- Surgical emphysema
- Pneumothorax
- Misplacement of tracheostomy tube into pretracheal tissues
- Occlusion of tracheostomy tube tip against tracheal wall or due to cuff herniation
- Perioperative death

Delayed
- Infection of stoma
- Tracheostomy tube blockage with secretions
- Ulceration of trachea at site of the cuff
- Erosion at stoma site leading to catastrophic bleeding (innominate artery) or tracheo-oesophageal fistula
- Pneumonia

Late
- Granuloma formation in the trachea
- Tracheomalacia
- Tracheal stenosis
- Failure of stoma to close once decannulated

2

Contraindications for percutaneous tracheostomy

- Infection/inflammation at the proposed tracheostomy site
- As a means of emergency airway access
- Uncorrected bleeding diathesis
- Enlarged thyroid gland
- In children
- Burns/trauma to anterior neck
- Difficult anatomy (e.g. obesity, deformity)
- Marked cardiovascular or respiratory instability

3

Consent – percutaneous tracheostomy is usually undertaken on patients who are already sedated and intubated in the ICU and from whom formal consent cannot be obtained. If the patient is sufficiently awake the procedure should be explained to allay anxiety. An explanation should also be given to the relatives.

Technique
All the apparatus required is checked and prepared before the procedure (Figure 4). A tracheostomy tube is selected and checked to ensure that the cuff inflates correctly, and that it fits over a suitable dilator/introducer. A tracheostomy tube of 8.0 mm internal diameter is adequate for most adults and usually fits satisfactorily over a 24 FG dilator.

4

An anaesthetist undertakes responsibility for the anaesthetic, and the management of the airway, partially withdrawing the tracheal tube at the appropriate time. Most units use a fibre-optic laryngoscope or bronchoscope via the tracheal tube during the procedure. This allows visualization of the tracheal puncture site, and the correct position and orientation of the guidewire placed by the operator.

Blood pressure, ECG and oxygen saturation are monitored throughout the procedure. Monitoring end-tidal carbon dioxide is also strongly recommended. The patient is anaesthetized, paralysed and ventilated with 100% oxygen. A positive end-expiratory pressure (PEEP) of 5–10 cm H_2O is generally recommended. Pressure-controlled ventilation may be useful to maintain tidal volumes during withdrawal of the tracheal tube.

The patient is positioned supine with head and neck extended sufficiently to allow identification of the landmarks. This is facilitated by the placement of a pillow or rolled towel under the shoulders. Problems may occur with the final position of the tracheostomy tube as a result of the head and neck being extended too far. The trachea and skin each move to a different extent during extension.

Full surgical aseptic technique is used; the operator should scrub and wear surgical cap, mask, gown and gloves. All personnel should wear eye protection and a mask because the patient's blood and secretions may be blown into the air around the operative site.

The anterior neck and upper chest is cleaned and prepared using an alcoholic chlorhexidine skin preparation solution and the operative area is draped. The cricoid cartilage is identified below the thyroid notch. The position of the second tracheal cartilage is estimated below this. These points may be marked. The area of skin at the intended tracheostomy site is infiltrated with 1% lidocaine (lignocaine) containing 1: 100,000 adrenaline (epinephrine). This provides local analgesia, causes blanching of the area and reduces oozing from skin vessels.

A short horizontal skin incision (about 1.5 cm) is made over the trachea. Some operators advocate blunt dissection in the midline down to the trachea using curved artery forceps. The aim is to identify the space between the first and second (or second and third) tracheal rings, which are the recommended sites of tracheostomy stoma.

At this point, the anaesthetist pulls back the tube to avoid it being transfixed by the needle. Withdrawal requires deflation of the cuff, therefore the ventilator settings will have to be adjusted to maintain adequate ventilation. Withdrawal of the tube is best performed under direct laryngoscopy, until the top of the deflated cuff is visible in the glottic aperture. The palpating finger of the operator can also feel as the tip of the tube passes above the site of intended puncture. Once the tube is withdrawn sufficiently it is secured in this position for the remainder of the procedure.

The Ciaglia Percutaneous Tracheostomy Introducer Set (Cook® Critical Care Products) provides a cannula over a needle, which can be attached to a 5 ml syringe. The anterior wall of the trachea is punctured; confirmation of which is provided by the ability to aspirate air. The syringe may be partially filled with saline, if desired; aspirated air can then be seen to bubble through the saline. The cannula is then advanced off the needle in a caudal direction and a J-tipped guidewire passed through the cannula and down the trachea. The fibre-optic laryngoscope is invaluable in confirming the correct position and orientation of the guidewire. With the guidewire in position, the cannula is removed and the initial puncture site is preliminarily dilated to accept a guiding catheter, over which, either serial dilators, or the *Blue Rhino*® tapering dilator is passed, to enlarge the stoma progressively. Marks on the dilators indicate the limit to which the dilator should be introduced into the trachea. Unnecessary force or incorrect alignment of the dilator during its insertion may result in failure to follow the contour of the guidewire. This can cause kinking of the guidewire increasing the risk of introducing the dilator into the pre-tracheal tissue and causing damage to anatomically related structures.

Once a suitably sized stoma has been created, a previously checked flexible tracheostomy tube is loaded onto a dilator and guided through the stoma into the trachea. The dilator is removed, the cuff inflated and the patient ventilated through the new tracheostomy. Only when ventilation is assured and satisfactory via the tracheostomy should the tracheal tube be removed.

The tracheostomy tube is secured with tape round the patient’s neck with the patient's head and neck flexed to a normal position. Some operators suture the flange of the tracheostomy tube to the skin but this is not essential, may lead to a false sense of security and often results in skin infection at the suture site.

Alternative methods of maintaining the airway

In surgical tracheostomy the surgeon dissects the anatomy and is in control of the airway directly, before the tracheal tube is withdrawn and the stoma is created. In percutaneous tracheostomy, the tracheal tube is withdrawn early in the procedure and maintained in a precarious position until the stoma is created and the tracheostomy tube inserted. Techniques to improve the traditional partially withdrawn tracheal tube method include:

- oxygen insufflation via a catheter at the level of the carina
- use of a microlaryngeal tube inserted to a level beyond the intended stoma site and not withdrawn during tracheal puncture
- laryngeal mask airway
- tracheal tube through a laryngeal mask airway.

Aftercare

A newly created tracheostomy stoma is a surgical wound and should be treated accordingly. High standards of aseptic technique should be maintained during wound dressing. The stoma does not ‘mature’ for 7–10 days. Every effort should be made to ensure that the tracheostomy tube is secured in its correct position and is not being pulled into unsatisfactory angles by the weight of ventilator tubing.

If displacement of the tracheostomy tube occurs within the first few days of creating the stoma, replacing it may be impossible and the attempt may create a false passage. It is much safer to re-intubate the patient and re-establish the tracheostomy under controlled conditions. ◆

Straight Laryngoscopy: Function, Technique and Design

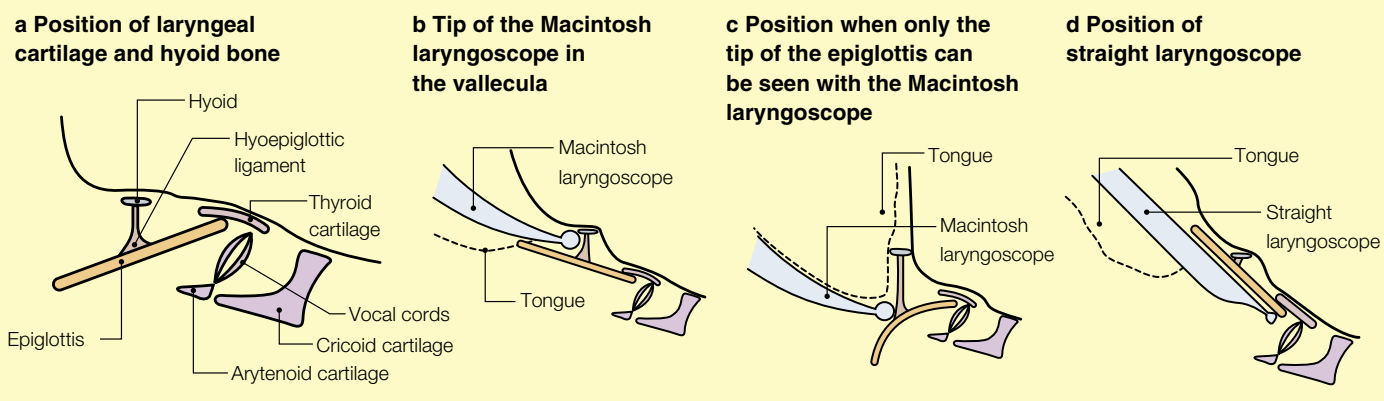
John Henderson

John Henderson is Consultant Anaesthetist at the Western Infirmary, Glasgow, UK. He trained at Glasgow Royal Infirmary, was a fellow in New York and staff anesthesiologist in Boston. He has used awake fibre-optic intubation since 1977. He is Guidelines Project Officer of the Difficult Airway Society.

Tracheal intubation under vision was originally performed with the straight laryngoscope. Curved laryngoscopy with the Macintosh laryngoscope (introduced in 1943) became the standard technique because it was perceived to be less demanding than straight laryngoscopy. There is increasing evidence that tracheal intubation can be achieved under vision with the straight laryngoscope in most patients in whom this is impossible with the Macintosh. Many of the complications of difficult intubation with the Macintosh laryngoscope might be avoided if anaesthetists were skilled in straight laryngoscopy.

Straight laryngoscopy has a good theoretical basis. All laryngoscopes are used to move the tongue to the left and to elevate the epiglottis so that the vocal cords are revealed. The normal relationship of the laryngeal cartilages and the hyoid bone is shown in Figure 1a. Figure 1b shows the tip of the Macintosh laryngoscope in the vallecula, close to the hyoepiglottic ligament. Elevation of the hyoid tensions the hyoepiglottic ligament and thus elevates the epiglottis indirectly. Figure 1c shows the situation where no more than the tip of the epiglottis is seen with the Macintosh laryngoscope. Some of the bulk of the tongue remains trapped between the tip of the laryngoscope and the hyoid bone, and the tip of the laryngoscope cannot enter the vallecula. The epiglottis cannot be elevated and is displaced posteriorly so that it obstructs the potential line of sight of the larynx. Figure 1d shows the position of the straight laryngoscope, introduced from the side of the mouth, in such a patient. The tip of the laryngoscope is posterior to the epiglottis, which is elevated directly. Theoretically, the straight laryngoscope performs better than the Macintosh because of its ability to elevate the epiglottis directly in difficult patients, and to improve the line of sight.

Straight laryngoscopy



1

The technique of straight laryngoscopy is different from the Macintosh, and initial use often proves difficult.

- The laryngoscope is inserted and kept lateral to the incisors. The tip may pass initially into the right pyriform fossa, so that medial movement of the tip is necessary.
- Maximum mouth opening requires more deliberate attention.
- The tip of the laryngoscope is passed posterior to the epiglottis, which is elevated directly.
- Optimum depth of insertion (tip close to vocal cords) requires attention.
- Vector of force applied to the laryngoscope handle is different.

Further information about the technique is available from the Further reading or, in more detail, from the author.

The most widely used straight laryngoscope is the Miller. Passage of the tracheal tube with the Miller laryngoscope can be difficult. The Belscope is angulated to reduce the risk of dental damage. The Henderson laryngoscope shares with the Belscope an atraumatic tip and a light that cannot be dimmed by secretions or soft tissues. The cross-section of the Henderson laryngoscope is designed to facilitate passage of the tracheal tube so that tracheal intubation is integrated with direct laryngoscopy in a single rapid process. Optimal (paraglossal) technique with any of these laryngoscopes has much to offer. Moderate expertise requires 50 or more initial intubations, followed by continuing regular use. ◆

Transtracheal Jet Ventilation

Ali Diba

Ali Diba is Consultant Anaesthetist at the Regional Burns/Plastics and Maxillofacial Hospital in East Grinstead, West Sussex, UK. He qualified from Southampton University. He is an expert in the management of the difficult airway. His interests include critical care of burns patients and infusional anaesthesia.

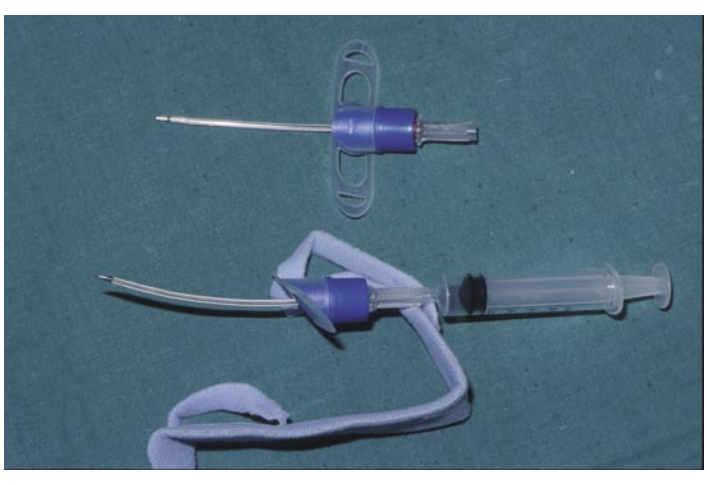
Transtracheal jet ventilation (TTJV), also called needle cricothyroidotomy, is a simple, safe and effective technique for ventilating apnoeic lungs electively or in an emergency. No patient should suffer hypoxic injury as a result of failure to ventilate the lungs without a competent attempt at TTJV having been made. Failure to ventilate still causes death under anaesthesia. An incidence of about 1/10,000 is quoted for failure to intubate associated with failed mask ventilation at anaesthesia.

Using dedicated equipment minimizes the chances of apparatus-related failure. Little experience is necessary, however, familiarity encourages earlier use in an emergency and allows a more confident approach to the difficult airway as a whole, especially if the technique is available as a backup in case of failure of the first strategy for management of the patient's airway. A number of centres worldwide use TTJV electively for peroperative ventilation.

History
In 1967, Sanders demonstrated ventilation of the lungs of anaesthetized patients using high-pressure oxygen at bronchoscopy. Transtracheal ventilation was described in 1971 by Spoerel in India. In 1983, Layman reported TTJV, without complication, in 60 patients with gross pathology requiring oral surgery, using an intravenous catheter inserted through the cricothyroid membrane. In 1985, Ravussin designed a dedicated transtracheal catheter, which remains the device of choice.

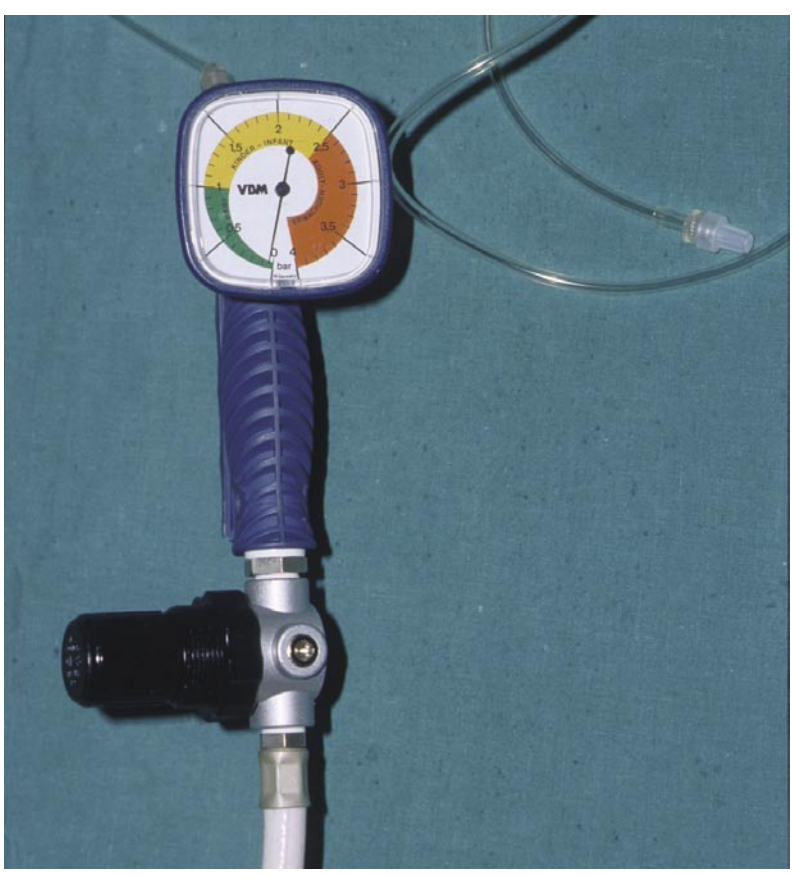
Apparatus
Safety in TTJV depends on intratracheal placement of the catheter. The ability to freely aspirate 'air' from the catheter following insertion is paramount. Conventional plastic intravenous cannulas tend to kink at the skin or within the trachea because of the acute angle between skin entry and tracheal axis which may preclude this safety check and decrease the efficiency of ventilation.

The Ravussin Jet Ventilation Catheter (VBM Medizintechnik GmbH, D-7247 Sulz a.N. Germany) is available in 13 G for adults (Figure 1) and proportionately shorter 14 G and 18 G versions for children and babies. It is made of Teflon, which is stiffer than plastic and is gently curved with an angled connector, which when sitting flush on the skin allows the catheter to point axially down the trachea without kinking. A Velcro strap passed around the neck keeps the whole assembly firmly in place. A 15 mm diameter ISO male connector around the Luer-Lock allows temporary low-pressure oxygen insufflation from a conventional anaesthetic system.



1 Ravussin Jet Ventilation Catheter for adults (13 G).

The TTJV catheter is connected to a high pressure (4 bar) oxygen source through a Sanders injector. A variable outlet pressure version (Figure 2) is used for added safety if the system might be used in children.



2 Variable pressure injector.

A complete TTJV system should be available in all areas where anaesthesia is administered or where unconscious patients may be admitted (Figure 3). It is not feasible to assemble the equipment from disparate items when the need for TTJV is identified in an emergency situation.

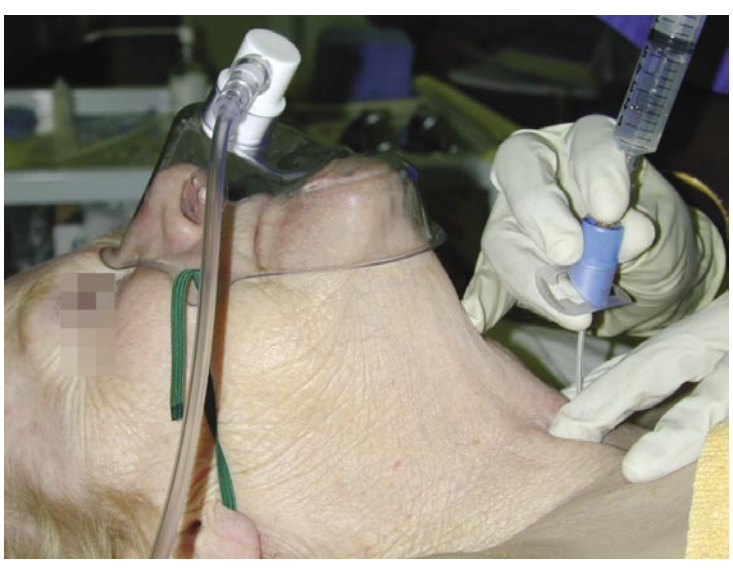
3 Difficult intubation trolley.

Low pressure gas, as delivered from the common gas outlet of an anaesthetic machine (limited by the machine safety pressure relief valve or anaesthetic bag compliance to 320 or 80 cm H_2O) and delivered through a narrow-bore transtracheal catheter will, at best, provide temporary apnoeic oxygenation by providing gas flows of only 200 to 80 ml/s for a 14 G cannula. TTJV requires a high-pressure gas source and implies that adequate gas exchange can be maintained.

For protracted ventilation, high frequency jet ventilators are available that allow the driving pressure, breath rate and I:E ratio to be controlled individually. They can measure end-expiratory intratracheal pressure through the ventilating cannula, thus stopping subsequent breaths if gas egress from the lungs is obstructed.

Technique
The patient's head is positioned as if for a tracheostomy with head and neck extension. The trachea is most easily approached percutaneously through the cricothyroid membrane, though lower cartilaginous interspaces are also practicable. The membrane is best identified with the fingertip and nail and may be marked. An intradermal bleb of local anaesthetic should be administered in the conscious patient, and this syringe and needle can also be used as a seeker to confirm correct identification by easy passage though the membrane and aspiration of air. Intratracheal lidocaine (lignocaine) is not essential because the catheter tends not to irritate the airway.

A 5 ml syringe is attached to the catheter/needle assembly which is inserted in a slight caudad direction with negative pressure maintained on the syringe plunger (Figure 4). A slight 'give' followed by further easy passage and aspiration of air signifies entry into the trachea. The catheter should advance easily off the needle, which is then removed (Figure 5). Further free aspiration of air from the catheter and a perfect end-tidal carbon dioxide trace on gas sampled from the catheter in the breathing patient confirm its position (Figure 6). The injector is then connected using Luer-Lock tubing and a single test breath should be administered to test the integrity of the system. The awake patient usually coughs at this stage, and all patients must be carefully observed for chest deflation after each breath. If air cannot be aspirated from the catheter it must be resited.



4 Needle insertion.

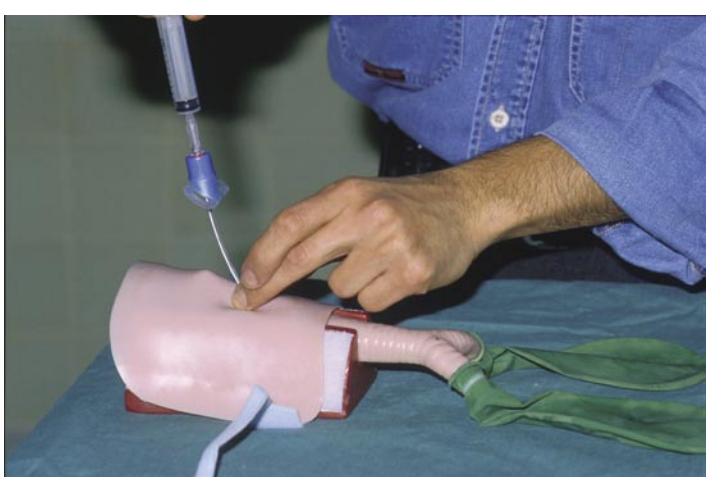
5 Withdrawal of cannula.

6 Checking catheter position.

In the elective situation anaesthesia can be induced, and jetting may proceed with the following provisos. 'Pre-oxygenation' guards against desaturation in the interval between induction of anaesthesia and the onset of paralysis and jet ventilation. Neuromuscular paralysis ensures there is no jetting against a forcibly closed glottis risking barotrauma.

Appropriate craniocervical extension and/or jaw thrust allows an adequate expiratory airway in most patients, even those with obstructing glottic lesions. An oral, nasopharyngeal or laryngeal mask airway (LMA) may also be needed. There is no record of a patient needing a second needle for gas escape, though this remains an option. It is important not to ventilate while the airway contains anything that may occlude the upper airway (e.g. the passage of a tracheal tube over a fibre-optic endoscope).

A mannequin or dummy neck can be used to practise the technique (Figure 7).



7 Practising the technique on a dummy neck.

Applications
TTJV, using a small diameter cannula, is preferable to tracheostomy in an emergency because it is faster and simpler to perform and involves fewer complications.

Assuming the anterior neck can be accessed in an elective patient in the absence of significant overlying tissue swelling or infection, TTJV may be indicated as an interim manoeuvre (surgical access for tracheostomy is not impeded by TTJV) or as the definitive airway management technique. The categories are not mutually exclusive.

Emergency/resuscitation: TTJV can be used in the 'can't ventilate, can't intubate' situation; where there is failure to intubate the trachea and established failure to ventilate the lungs by other means (such as face mask or LMA) owing to abnormal anatomy, trauma or disease.

Elective: TTJV alone is appropriate for airway management for suspension microlaryngoscopy, endoscopy, tracheal surgery, or laser surgery of the airway.

If there is uncertainty about the ability to maintain airway competence following induction of anaesthesia TTJV may be used as an alternative to awake intubation. Siting a TTJV catheter in the awake patient secures the ability to ventilate the lungs following induction. This does not require confidence with local anaesthetic techniques or patient cooperation and allows safe, unhurried and comfortable airway instrument-ation for patient and anaesthetist. In children with orofacial tumours for example, the cannula may be sited under ketamine sedo-analgesia allowing fibre-optic intubation under general anaesthesia with muscle relaxation. This combination constitutes a powerful technique.

TTJV may be used as an alternative to a surgical airway if fibre-optic intubation is inapplicable, for example because of airway soiling by blood or obstructing laryngeal tumours with 'pinhole trachea'. Awake tracheostomy is a difficult procedure even for the experienced head and neck surgeon; it may be impossible in the patient needing to sit to struggle to breathe or spit out blood. Siting a TTJV catheter is easier and permits tracheostomy or tumour resection to be carried out under general anaesthesia. Debris and blood tend to be blown out of the oropharynx.

Complications
The most common problem is failure to cannulate the trachea. Use of curved cannulas and other manoeuvres aimed at getting the catheter to lie axial to the trachea tend to make cannulation more difficult, but ultimately increase safety and success.

There are no reports of problematic haemorrhage, though TTJV is not advised if there is involvement of the anterior neck or trachea in vascular malformations. A small dried rivulet of blood in the trachea on endoscopy is not uncommon following catheter insertion.

The sequence of barotrauma, pneumothorax, pneumo-mediastinum and subcutaneous emphysema usually follows failure to ensure a clear expiratory pathway during surgical instrumentation and is more common in children. Meticulous technique, a high index of suspicion and prompt treatment mitigate against this complication becoming a catastrophe.

A dry cough is often reported after TTJV. The tiny puncture site normally seals on removal of the catheter. Pressure should be applied to the site to prevent subcutaneous emphysema.

There are no specific recognized late complications of perioperative TTJV. ◆

Clinical Governance

Gregor Imrie
P G M Wallace

Gregor Imrie is Specialist Registrar in Anaesthesia at the Western Infirmary, Glasgow, UK. His subspecialty is intensive care medicine.

P G M Wallace is Consultant Anaesthetist at the Western Infirmary, Glasgow, UK. He is President of the Association of Anaesthetists of Great Britain and Ireland and past President of the UK and Scottish Intensive Care Societies.

Britain's National Health Service (NHS) was constituted in 1948 as a universal system, funded predominantly by taxation, to provide healthcare without financial barriers to access. At its inception it was essentially a paternalistic service where the professionals delivering the care defined the needs of patients and set up services to meet those needs. The expectation was that high individual professional integrity and competence would lead to a high quality service. This system served the country well for several decades, however, various attempts have been made by successive governments to improve the NHS. These initiatives have been driven by rising public expectations over the lifetime of the service. In recent years, added impetus for change has developed as a consequence of high profile failures within the NHS (e.g. paediatric cardiac surgery in Bristol).

Clinical governance is the centrepiece of the latest government initiative aimed at improving the NHS. It was first described in the White Paper of 1997 *The New NHS*. It builds on several previous national quality initiatives (Figure 1). While high individual professional standards remain essential for a good quality service, clinical governance aims to instil an overall ethos of corporate responsibility to improve quality of care in the NHS.

History of national quality initiatives

Resource management	1980s
Medical audit	1989
Patient's Charter	1993
Clinical guidelines	1993
Clinical effectiveness	1995
Clinical governance	1997

1

Definition

Almost anything done under the name of quality in the NHS may now come under the clinical governance umbrella. As a result of a lack of an intuitive meaning to the term, and partly owing to its enormous scope, it has proved difficult to give a clear definition of clinical governance. The most widely used definition, and the one quoted by government agencies is 'Clinical governance is a system through which NHS organizations are accountable for continuously improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish'.

Alternatively, in 1998, Sam Galbraith MP gave a statement, which touches on the role of clinical governance in meeting the rising public and political expectations of the NHS. 'Clinical governance is the vital ingredient that will enable us to achieve a health service in which the quality of healthcare is paramount. The best definition that I have seen of clinical governance is simply that it means corporate accountability for clinical performance. Clinical governance will not replace professional self-regulation and individual clinical judgement, concepts that lie at the heart of healthcare in this country. But it will add an extra dimension that will provide the public with guarantees about standards of care.'

A more succinct definition is 'Clinical governance is corporate responsibility for clinical performance'.

Responsibility

Clinical governance applies to all patient services in the NHS. The statutory duty to seek quality improvement through clinical governance rests with Trust chief executives. The government's aim is to ensure that quality of care is as important as financial matters at Trust board level. Trust chief executives are now expected to:

- ensure a culture in which the highest standard of clinical care is the responsibility of everyone in the organization
- introduce structures and processes that allow this to happen.

These duties are considerable and delegation is required. A degree of local discretion is allowed in how this is achieved but a common model is as follows.

- Individual doctors remain responsible for their clinical decisions.
- Departmental heads and clinical directors have responsibility for quality of care in their directorate and they report on quality issues to a clinical governance committee.
- This committee assumes oversight of the clinical governance activities of the Trust. It should ensure that the appropriate structures for clinical governance are in place and that they work well.
- The clinical governance committee reports directly to the Trust board and chief executive.
- Trusts are assessed by the national bodies described below.

Key components of clinical governance at Trust level

It is hoped that by adherence to the key tenets of clinical governance (reviewed below) at a local level, Trusts will have well trained and motivated staff producing safe and effective evidence-based care; and as a consequence of good communication, patients will be well informed and involved in the decisions regarding their care.

Education, training and professional development of staff: good quality healthcare depends on the quality of staff. Time should be set aside for staff education, training and continuing professional development. This has important resource implications for Trusts.

Evidence-based clinical practice: Trusts should ensure that the care they deliver is based on the best available evidence. Systems should be in place for receiving, distributing and implementing evidence-based guidelines as they are published. Adherence to evidence-based practice must be audited (see below).

Clinical audit requires:

- structured review by clinicians of their practice and results against agreed standards
- sharing of audit results across clinical teams
- modification of care as dictated by the results of audit
- remonitoring to ensure quality of care has improved.

Trusts should ensure that good audit systems are in place. This requires investment in information technology systems and extra staff to facilitate the process.

Risk management: Trusts must have established protocols to identify adverse events. A blame-free culture in which to report adverse events should be cultivated. Structures to allow identification of patterns, and the initiation of prompt change should be in place. Risk management within Trusts should be pro-active and lessons painfully learnt in other parts of the health service should be applied locally. Risk management staff may be useful in designing systems to minimize risk. Trusts should also aim to reduce problems and complaints by means of good communication.

Communication with patients and relatives: poor communication is regularly highlighted as a cause of patient dissatisfaction. Trusts should provide training in communication skills for their staff and ought to factor in the time required for good communication when planning staffing levels. The development and provision of information leaflets can aid staff in this activity. Trusts should encourage comments and suggestions from patients and relatives regarding the services they provide and institute change as necessary.

Complaints procedures: there should be accessible, well-publicized complaints procedures available to patients and relatives. Good clinical governance requires thorough investigation of complaints in an environment that is supportive of the staff involved.

Tackling poor clinical performance: while only a part of clinical governance, this is the area most associated in doctors' minds with the concept. It has been widely recognized that the pre-existing regulatory systems have, on occasion, failed to detect and correct poor clinical performance at an early stage. Extensive new national regulatory measures are being developed to reduce this problem. Despite these measures it remains probable that other doctors in a department will be the first to note a colleague's poor performance or conduct. Anaesthetic departments should aim to be vigilant in detecting, correcting and supporting their poorly performing members. If good structures are in place it may be possible to correct poor performance before it has a major impact on standards of care. The Royal College and the Association of Anaesthetists have published useful guidance for departments in this area.

Support structures for clinical governance: Trusts should have a simple clinical governance chain of command so there is clarity about who is doing what within the Trust. Clinical governance support staff have in the past been appointed in a rather scattergun fashion (e.g. separate staff for clinical audit, risk management and clinical effectiveness). Such staff should be integrated into a single clinical governance department to increase their effectiveness.

Major national components

With the inception of clinical governance a significant regulatory and support industry has developed. These structures are not fully established and continue to evolve. The major organizations with associated websites are listed in Figure 2. Their present roles are described below.

Organizations with major roles in clinical governance

• General Medical Council Revalidation	www.gmc-uk.org www.revalidationuk.info
• Royal College of Anaesthetists	www.rcoa.ac.uk
• Association of Anaesthetists of Great Britain and Ireland	www.aagbi.org
• Department of Health Appraisal National Service Frameworks Clinical Governance Support Team	www.doh.gov.uk www.appraisaluk.info www.doh.gov.uk/nsf www.cgsupport.org
• National Clinical Assessment Authority	www.ncaa.nhs.uk
• National Institute for Clinical Excellence	www.nice.org.uk
• Commission for Health Improvement	www.chi.nhs.uk
• National Patient Safety Authority	www.npsa.org.uk
• Scottish Intercollegiate Guidelines Network	www.sign.ac.uk
• Health Technology Board for Scotland	www.htbs.co.uk
• Clinical Standards Board for Scotland	www.clinicalstandards.org
• Clinical Resource and Audit Group	www.show.scot.nhs.uk/crag
• Clinical Resource Efficiency Support Team	www.n-i.nhs.uk/crest

2

Appraisal

Appraisal was introduced by the Department of Health with the support of the medical profession in April 2001. On an annual basis, trained appraisers will review the activities of the doctor being appraised; agree with him key objectives for the following year and outline the doctor's requirements of his employer to allow him to achieve these objectives.

The main objective of appraisal is to encourage continuing professional development but it also incorporates elements of performance review. The appraisal is based around the main tenets of the General Medical Council document *Good Medical Practice*.

All consultants in England should have undergone appraisal by April 2002. This deadline was not met, but following the completion of consultant appraisal it is planned to introduce appraisal for all other grades of NHS doctor.

General Medical Council (GMC) and revalidation

The GMC was set up in 1858 and its regulatory role in maintaining standards in the medical profession is long established. More recently, disquiet has been expressed by the profession, government and the public that the GMC could be more effective. In response, the GMC has examined its structures and proposes to develop an additional regulatory system for doctors. The GMC plans that all doctors will have to demonstrate, on a regular basis, that they remain fit to continue in medical practice – a process it has termed revalidation.

Revalidation involves an assessment against a standard fit-ness to practise and will result in the renewal or withdrawal of a doctor's licence to practise medicine after each revalidation process. Revalidation will take place every 5 years. The full details of revalidation are yet to be decided. As appraisal and revalidation will be based largely on the same sources of information, appraisal summaries are likely to be used in the revalidation process.

Government and the GMC expect the legislation to make revalidation mandatory to be passed in December 2002. If pilot schemes are successful revalidation will commence 2 years after this date.

The medical Royal Colleges

The individual Royal Colleges have long guided and supervised consultants and trainees in achieving and maintaining high standards – activities that now come under the clinical governance umbrella.

The Royal College of Anaesthetists, often in conjunction with the Association of Anaesthetists of Great Britain and Ireland, has been active in this regard. Major examples of their clinical governance activities include:

- assessment of trainees' core competencies as they progress through training
- the good practice guide for departments of anaesthesia
- publication of guidelines for anaesthetic practice
- an obligatory continuing educational and professional development programme for consultants
- publication of patient information materials (e.g. on pain relief in labour)
- support for critical incident reporting.

The new clinical governance ethos should put more weight behind College initiatives. In theory, as a result of clinical governance, managers will be more willing to fund the quality of care and safety measures that the College advocates (e.g. the removal of anaesthetic machines that can deliver a hypoxic mixture).

National Clinical Assessment Authority (NCAA)

The NCAA was established in April 2001 as a support service for employers of doctors whose performance is giving cause for concern. Its budget for 2002–2003 is £10.1 million.

The NCAA will consider referrals from employers (or self-referrals by doctors) on the full range of potential performance difficulties (i.e. clinical, behavioural and health matters). When a referral is received, the NCAA will:

- offer support and advice aiming for a local solution
- if this fails it will move to a formal assessment of the doctor's performance
- after assessment, a plan of action is recommended which might involve, for example, re-education or a change in working environment
- while it would hope to facilitate local resolution of problems, appropriate referral will be made if its assessment reveals matters that require investigation by the GMC or CHI.

Formal assessment of doctors began only in April 2002 and the role of the NCAA is not yet fully established. However, it does appear to have the advantage of being a 'half-way house' where problems can be identified and tackled at an early stage before a major breakdown in quality of service occurs or before suspension and referral to the GMC become mandatory.

National Institute for Clinical Excellence (NICE)

NICE was set up in April 1999. Its budget in the tax year 2001–2002 was £10.6 million. It is the main national facilitator for clinical governance issues. The functions of NICE are to:

- issue guidance on the full range of health technologies including drugs, medical devices and surgical techniques
- produce guidelines on the management and care of specific conditions
- oversee the four confidential inquiries (Confidential Inquiry into Maternal Deaths, Confidential Inquiry into Stillbirths and Deaths in Infancy, National Confidential Inquiry into Perioperative Deaths, Confidential Inquiry into Homicide by People with Mental Illness)
- advise on audit methodology and in particular to advocate audit of how well the advice it gives is adhered to.

The guidance produced by NICE is based on cost and clinical effectiveness. Adherence to its advice should contribute to an improvement in standards of care nationally and reduce regional variations in care.

National Service Frameworks (NSF)

The Department of Health instituted a rolling programme of NSF in 1998 as part of the clinical governance initiative. NSF set national standards to be attained in a particular area. There are, for example, NSF for coronary heart disease and for the elderly. They are broad in scope and of strategic importance. Usually only one new framework is published a year. They aim to drive improvement in standards of care across the country. NSF can impact on anaesthetic services by setting objectives that departments need to plan for and accommodate, for example the Older People NSF states that patients with fractured hips should have repair carried out by experienced staff within 24 hours of admission.

Commission for Health Improvement (CHI)

The CHI was established in November 1999 as the principal regulator of the clinical governance initiative in England and Wales. Its budget in the year 2001–2002 was £24.5 million. Its main roles are to:

- assess every NHS organization on a 4 yearly basis by means of a detailed clinical governance review, the results of which are published
- monitor the implementation of the national guidelines produced by NICE and NSFs
- investigate system failures within the NHS at local, regional and national level. One of CHI's strengths is that its reports achieve national prominence, particularly when they include adverse findings. They are a strong impetus to improvement when services are found wanting. CHI's recommendations have to be enforced by Health Authorities and the National Assembly of Wales.

Clinical Governance Support Team (CGST)

The CGST was established in September 1999 to support the implementation of clinical governance across the NHS in England. To date it has educated 400 teams from NHS organizations on clinical governance issues under its Clinical Governance Development Programme. Among other activities, it publishes on its website the details of successful local clinical governance schemes, and operates a Trust board level development programme.

National Patient Safety Authority (NPSA)

The NPSA was established in July 2001 to provide national leadership on patient safety and adverse event reporting. Its budget for 2002–2003 is £15 million. It will establish and operate a mandatory national system for reporting adverse events and near misses. This information will be collated and distributed to allow the early initiation of preventative measures throughout the NHS. It is hoped by these means to prevent recurrence of tragedies such as the intrathecal injection of vincristine (at least 13 patients are known to have died or been paralysed since 1985).

Organizational variations in the UK

- Appraisal, under the auspices of the Department of Health, applies to doctors in England. Similar appraisal systems are being instituted in the rest of the UK.
- The GMC and the Royal College of Anaesthetists operate throughout the UK.
- NICE, CHI and the NPSA operate in England and Wales. NSFs apply to England.
- The CGST and NCAA apply to England only, but it is probable the Welsh Assembly will accept their roles.
- In Scotland, though there is not an exact duplication of systems, similar roles to CHI and NICE are performed by the Clinical Standards Board for Scotland, aided by the Scottish Intercollegiate Guidelines Network, the Health Technology Board for Scotland, and the Clinical Resource and Audit Group. In 2003, these bodies, with the exception of the Scottish Intercollegiate Guidelines Network, together with the Scottish Health Advisory Service and the Nursing Midwifery Practice Development Unit will amalgamate to form NHS Quality Improvement Scotland.
- In Northern Ireland, the Clinical Resource Efficiency Support Team has published guidelines and audited services since 1988. An extensive review of health service provision is nearing completion which may lead to the introduction of further clinical governance measures. ◆

Consent: Ethical Considerations

Nick Pace

Nick Pace is Consultant Anaesthetist at Western Infirmary, Glasgow. He qualified from Glasgow University and trained at the Glasgow Western and Royal Infirmaries, University Hospital of South Wales and Parkland Memorial Hospital, Dallas, Texas. His interests include airway management and anaesthesia for renal and adrenal diseases. He is currently completing a PhD in medical law.

The relationship between doctor and patient is not uniform. Ethical codes of conduct and laws of consent, confidentiality and negligence vary according to the role played by the doctor and the objective of the contact between patient and doctor.

- In the therapeutic model the relationship is therapeutic and the doctor's main objective is the well-being of the patient and improvement in that patient's health.
- In the research model the relationship changes and the doctor's aim is the accumulation of medical knowledge. The benefits are designed to aid future patients, though there is potential for the research subject to obtain benefit.
- In the relationship between an occupational health doctor and a patient, the doctor's duty is to his employer and not necessarily to the patient.

Rapid developments in medicine have been accompanied by a tendency for patients to ask for greater involvement and control over what happens to them. Physicians and other healthcare professionals do not have a right to do anything to patients without their consent because the right to consent to or to refuse treatment is grounded in the ethical principle of respect for autonomy. A feature of our society is the emphasis on the value and dignity of the individual. Principles of inherent natural rights dictate that a competent person should decide what happens to his or her body. All medical codes of ethics now hold that physicians must obtain the informed consent of patients and subjects before undertaking procedures.

Informed consent

The concept of informed consent needs clarification. Various commentators have reduced the concept to shared decision-making between doctor and patient, so that informed consent and mutual decision-making are identical ideas. The British Medical Association, for example, states that the relationship between doctor and patient is based on the concept of partnership and collaborative effort. Decisions should be made through frank discussion, in which the doctor's clinical expertise and the patient's individual needs and preferences are shared, resulting in the selection of the best treatment option. Patients are therefore actively involved in deciding what is to be done to them.

For the patient's consent to be a valid authorization for the professional to proceed, it must be based on understanding and must be voluntary. Because of the unequal distribution of knowledge between professionals and patients the principle of respect for autonomy entails that professionals have a prima facie obligation to disclose information, to ensure understanding and voluntariness, and to foster adequate decision-making. Thus, the information component can be said to consist of adequate disclosure followed by the understanding and comprehension of what is disclosed. The consent component, in turn, refers to a voluntary decision-making process which is followed by authorization. Therefore, informed consent can be analysed in terms of the elements in Figure 1.

The elements of informed consent

Threshold element
- Competence

Information elements
- Disclosure of Information
- Understanding of information

Consent elements
- Voluntariness
- Authorization

1

Competence

Competence is a precondition of being able to give consent. It is closely tied to autonomy. Law, medicine and to some extent philosophy presume a context in which the characteristics of the competent person are also the properties possessed by the autonomous person. Although autonomy and competence are different in meaning (autonomy meaning self-governance and competence meaning the ability to perform a task), the criteria of the autonomous person and of the competent person are strikingly similar. Thus an autonomous person is necessarily a competent person. A person is thus generally competent to authorize or refuse to authorize an intervention if and perhaps only if that person is autonomous.

Disclosure

There is a requirement for doctors to inform the patient about the material risks of a planned procedure or intervention. However, the patient is not compelled to accept or refuse the treatment that is offered. The patient should be allowed to choose the type and scope of treatment and to base this choice on adequate information about success rates and risks. It is impossible for a health professional to give all available information to the patient. It is not the doctor's role to provide a list of alternatives from which the patient selects options, according to their need and desires. Ideally, the doctor should inform the patient about any risks in the treatment that may be particularly important to that patient, as well as explaining the risks and benefits of alternatives and of non-treatment. Without an adequate transfer of information from doctor to patient there is insufficient information for decision-making. However, the professional's own perspective, opinions and recommendations are often essential for the patient's deliberation, as well as for mutual understanding.

Professionals are generally obliged to disclose a core set of information. This includes:

- those facts or descriptions that patients or subjects usually consider material in deciding whether to refuse or consent to the proposed intervention or research
- information the professional believes to be material
- the professional's recommendation
- the purpose of seeking consent and the nature of consent as an act of authorization.

Despite these general recommendations, controversy surrounds the issue of what should be disclosed about a procedure's risks and negative consequences, as well as about the nature and purpose of the procedure, its benefits and alternative procedures. Should a health professional discuss all the alternatives, including those considered too risky? For example, consider an operation in which a Tenckhoff catheter is inserted into the abdomen to allow peritoneal dialysis in a patient with renal failure. Several anaesthetic techniques may be used to allow this operation to proceed including general anaesthesia, infiltration of local anaesthetic by the surgeon, or an epidural or spinal anaesthetic administered by the anaesthetist. If the general anaesthetic option is taken, should one insert a laryngeal mask airway (LMA) or intubate the patient? If an LMA is inserted, should one use muscle relaxants? Time does not allow a detailed discussion of all the available options with the patient. Thus, the usual attitude is to discuss none of the options, possibly infringing the requirement for information disclosure and thus infringing the patient's autonomy. However, a recent personal audit has shown that patients require very little information from their anaesthetist. Indeed, the most common preoperative question concerned the duration of the anaesthetic. Despite this, it is clear that the more serious the risk or harm done to the person the greater the degree of information required. The legal standards that govern disclosure of information are discussed on page 426.

Understanding

Informed consent implies a duty to disclose information; however, it may be better to use the term comprehend because the information disclosed may not be understood. Increasingly, the ethical focus is changing from the doctor's obligation to disclose information to the quality of a patient's or subject's understanding and consent.

Understanding, therefore, is a more important element than disclosure and arguably the most important element in the process of obtaining informed consent. The key to effective communication, understanding and decision-making is participation by patients in an exchange of information. Ordinarily, a professional has only limited insight into the distinct values, fears, hopes and information needs of others. Asking questions, eliciting the concerns and interests of the patient, and establishing a climate that encourages the patient to ask questions may be more important to the person's understanding than a mass of disclosed information.

Clinical experience and empirical testing indicate that patients exhibit wide variations in their understanding of information about diagnoses, procedures, risks and prognoses. For example, in one study up to 44% of postoperative patients who signed consent forms were unaware of the exact nature of the procedure they had undergone. This also highlights the dubious usual practice of allowing the most inexperienced member of the surgical team to explain the operation to the patient and 'get consent'.

Although some patients are calm, attentive and eager for dialogue, others are nervous or distracted in ways that impair or block understanding. Many conditions, other than lack of sufficient information, can limit their understanding, such as illness, irrationality and immaturity.

It has been argued that patients cannot comprehend enough information or appreciate its relevance sufficiently to make informed decisions about medical care. Ingelfinger stated that 'the chances are remote that the subject really understands what he has consented to'.

There may be many reasons for this. Doctors and patients may use the same word but it may have different meanings to them. Fasting, for example, may mean to the patient 'do not take any food', thereby allowing them to drink as much liquid as they like. Enabling a patient to comprehend and appreciate risks and benefits can be a formidable task. It can be difficult for patients to appreciate the projected expectations of, for example, pain in labour or following surgery.

Patients presenting at antenatal clinics often state they wish to have a completely natural childbirth. This is clearly documented in the case notes, with the staff forbidden to use painkillers or epidural injections. However, once the contractions (and pain) set in, all that was previously stated is quickly forgotten and pain relief demanded. In this situation, can the previous refusal (illustrating respect for autonomy) be overridden? Let us assume for a moment that severe pain can make one's choices irrational and hence make one incompetent (a debatable point). It could be claimed that, because of the pain, the patient is no longer able to make a rational decision and, from a respect for autonomy, the healthcare staff should not administer painkillers. In such a situation, clearly, the principles of beneficence (do good) and non-maleficence (do not cause harm) would overcome any principle for respect for autonomy, leading to painkillers or an epidural being administered, to the obvious comfort of the patient. The point is that it may be difficult for patients to appreciate the nature and degree of pain in advance and thus they cannot fully understand what they are refusing.

Similar arguments can be applied to the appreciation of risks. The general public has a poor understanding of the probabilities of something occurring. Indeed, preferences can be affected simply by framing outcome in terms of probability of survival instead of probability of death, described as a cognitive illusion. If a misconception occurs regarding a particular risk which is material to decision-making, it implies that adequate understanding was not attainable and thus an autonomous authorization was not given. Even the amount of information that can be meaningfully processed is limited. Information overload may be as likely to lead to uninformed decisions as failure to disclose. This is the reason research ethics committees request research information sheets to be as short as possible and written in layman's terms.

Thus, the requirement of an ideal standard of full disclosure and full understanding cannot be attained. However, because actions are never fully informed, voluntary or autonomous, it does not follow that these actions are never adequately informed, free, or autonomous. It is clear that understanding does not need to be full or complete, because a substantial grasp of central facts and other descriptions is often sufficient.

It is also interesting to note what Beauchamp and Childress claim would be ethically acceptable if a patient has an unreasonable belief. For example, a patient may refuse a life-saving operation because of an irrational belief that he or she will die under anaesthesia, based on the fact that a relative died in similar circumstances. There may be overwhelming medical evidence that such a belief is unjustified. 'The position does not imply that we should never coerce patients or subjects to change their beliefs or to process information differently. If a patient's or subject's autonomy is limited by his or her ignorance, as in the case of a false belief a patient has difficulty in surrendering, it may be legitimate and even obligatory to promote autonomy by attempting to impose the information on a patient who finds it unwelcome. And if this proves impossible, the principles of beneficence and non-maleficence may still justify overriding the patient's non-autonomous choices.'

Voluntariness

Voluntariness is the condition of a patient being independent of manipulative and coercive influences exerted by others in order to control that person. There are degrees of influence and three primary categories have been described: coercion, manipulation, and persuasion. Coercion occurs when one person intentionally uses a credible and severe threat of harm or force to control another. This entirely compromises autonomy.

At the other end of the spectrum lie weak forms of influence such as rational persuasion. Here a person is convinced to agree to something through the merit of reasons advanced by another person. Such situations are probably common in the doctor–patient relationship. Manipulation means getting people to do what the manipulator wants by means other than coercion or persuasion. For the purposes of decision-making in healthcare, the most important form of manipulation is informational manipulation, a deliberate act of managing information that successfully influences a person by non-persuasively altering the person's understanding of a situation and thereby motivating the person to do what the agent of influence intends. Some forms of informational manipulation are incompatible with informed consent. For example, this could occur if clinicians withhold information not because of non-maleficence but to manipulate patients into agreeing to their recommendations.

It is easy to inflate the threat of control by influence beyond its proper significance. Most decisions in life are made in the context of competing influences, such as wants, needs, familial interests, legal obligations and persuasive arguments. Although significant, these influences may not be controlling to any substantial degree.

From a clinician's point of view, although there is an obligation to abstain from controlling influences, there can be occasions when doctors are blameworthy if they do not attempt to persuade resistant patients to pursue treatments that are medically essential. This reasoned argument may be vital to ensuring understanding and should never be considered an unjustified form of influence.

The future

The issue of informed consent within medical practice is coming to the fore as the balance of power in the doctor–patient relationship moves relentlessly towards patients. Doctors will have to learn to inhabit the complicated world in which philosophers feel comfortable. The question whether contemporary medicine and research should always be held to the standard of autonomous decision-making is not easy to answer. Respect for patient autonomy is generally regarded as one of the central ethical principles in medical practice. Many would claim a moral imperative of respecting human autonomy in almost all circumstances, and that failing to respect the autonomy of competent people is to inflict harm on them that is just as morally unacceptable as direct physical or mental harm. However, making respect for autonomy a trump moral principle, rather than one principle in a system of principles, places an inappropriately high premium on autonomy. It is not the only principle and should not be overvalued when it conflicts with other values. In certain situations it may take on a secondary importance and other moral principles may outweigh it. However, it is clear that such situations are limited. ◆

Consent and Malpractice Litigation

Nick Pace

Nick Pace is Consultant Anaesthetist at Western Infirmary, Glasgow. He qualified from Glasgow Univeristy and trained at the Glasgow Western and Royal Infirmaries, University Hospital of South Wales and Parkland Memorial Hospital, Dallas, Texas. His interests include airway management and anaesthesia for renal and adrenal diseases. He is currently completing a PhD in medical law.

Malpractice litigation has numerous functions. It provides an incentive to practitioners to maintain a high standard of care, though the law is mainly concerned with guaranteeing that a minimal level of competence is achieved. It allows injured parties to bring a malpractice action as a way of gaining retribution against health professionals, who they believe, need to be punished for harming them. It may also lead to compensation. One of the most important reasons that leads to a legal action being brought is a quest for an explanation of what went wrong.

To win a negligence case the plaintiff (i.e. the patient) is required to prove three things:

- that a duty of care existed and the professionals sued were responsible for the victim's care at the time of the mishap
- that the professionals failed to reach the accepted standard of practice required by law
- that the injuries they suffered were caused by the failure to practise properly. If successful, the patient is entitled to damages.

Duty of care

Establishing a duty of care is not usually a problem when patients are in hospital. The anaesthetist is clearly responsible and has a duty of care to the patient being anaesthetized. However, there are limits to duty of care. For example, in the UK, professionals who pass a road traffic accident have no legal obligation to stop and assist anybody who has been injured, though they may have a professional obligation to do so.

Accepted standard of practice

In most cases of medical negligence the key question is whether the professional failed to reach the standard of care required of them by law. That standard was first established in Scotland in the case of Hunter v. Hanley (1955) and 2 years later in England in the case of Bolam v. Friern HMC (1957). In the Hunter case a hypodermic needle broke during an injection and the plaintiff alleged failure to use a suitable needle. The Bolam case concerned the failure of use of muscle relaxants to control the violent convulsions and spasms during ECT. In both cases it was held that a doctor was not guilty of negligence if he acted in accordance with a practice accepted as proper by a responsible body of medical men skilled in that particular art. In other words, doctors are judged against the standards of their peers. Therefore, if experts from the defendant's profession are prepared to accept that the actions were proper, the negligence claim will fail. The experts merely have to regard the defendant's actions as being within the range of acceptable practice. This means a minimal level of acceptable practice, not what the expert would have liked to happen.

This implies that medical experts establish the standard of care and not the courts, with determination of the legal duty being left to the judgement of doctors. However, there are suggestions that the law is slowly moving away from this view. In the case of Sidaway v. Bethlem Royal Hospital Governors (1985; discussed later) the court reserved the right to decide that even standard practice may be negligent. Similarly, the recent court of appeal case of Bolitho v. Hackney HA (1993) indicated that judges are becoming less reluctant to set standards for doctors. Here Farquaharson noted the possibility of an accepted medical practice being held to be negligent because it put the patient unnecessarily at risk.

Current interpretation seems to be that the fundamental principle is that medical negligence is to be judged against the standards of the medical profession through the evidence of medical experts. This expertise is to be overridden when the medical experts hold views that the judges believe no reasonable doctor could hold.

The rule of acceptable practice applies to other areas of practice. For example, when professionals attempt to do something that they are not qualified to do, the failure to refer the patient to someone properly skilled may be negligence (Wilsher v. Essex AHA, 1996). The development of hospital policies may also have a significant impact on the way in which the standard of care is defined. It is easier to prove that health professionals have been negligent if they have failed to follow policies or protocols. Such protocols are usually designed to clarify acceptable practice and guard against risks by incorporating suitable safeguards. However, a departure from such a guideline or policy does not automatically mean that the person is negligent. It suggests that unless the circumstances indicate that there were good reasons for departing from the usual practice the professional will be found liable. Failing to provide such a justification indicates negligence.

In certain cases, the fact that a particular accident happened is held to be so obviously negligent that it requires the defendants to rebut the presumption that they were in breach of their duty. This maxim, *res ipsa loquitur* (the mishap is said to speak for itself), can be of particular significance in cases were the treatment is complex or the plaintiff is unconscious and is thus of particular importance to anaesthetists. In Saunders v. Leeds Western Health Authority (1985), a 4-year-old child suffered a cardiac arrest during an operation to correct a congenitally dislocated hip and became quadriplegic, mentally retarded and blind. At the trial, evidence was given that the heart of a fit child does not arrest under anaesthesia if proper care is taken. The plaintiff did not need to show what act or omission had caused the arrest. The defendants' explanation of a paradoxical air embolism was rejected and the court found in favour of the plaintiff. The defendants had been negligent.

Cause of the injuries

The third step in proving a negligence claim is showing that the failure to provide a satisfactory standard of care was the cause of the victim's injuries. Unless this can be proved, the claim will fail, even if the defendants were clearly at fault. Where the injury is caused by the care a health professional gives, such as severing a nerve during the course of an operation, it is easy to show that the professional's actions caused the injury. However, it is more difficult in cases in which the patient claims their underlying complaint should have been cured or alleviated but was not. Often it cannot be proved that the patient's injuries were not a result of natural causes, such as the underlying medical problems or an unavoidable accident.

Criminal charges

In most circumstances, malpractice is the concern only of the civil law. However, in extreme cases there may also be criminal implications. For example, if a mistake causes the death of a patient, the health professional could be prosecuted for manslaughter. For this to occur, there must have been gross negligence not merely negligence. A recent determination has been that of the anaesthetist Dr Adomako in the House of Lords. He failed to notice that for over 4 minutes a tracheal tube had become disconnected during an operation under general anaesthetic. An alarm sounded but the connection of the tube was not checked until the patient had suffered a cardiac arrest. One expert prosecution witness stated that a competent anaesthetist should have spotted the problem within 15 seconds. The defendant accepted that he had been negligent, but denied that he was grossly negligent so as to be guilty of involuntary manslaughter. The House of Lords held that the question of whether the degree of culpability was such that the anaesthetist should be liable to criminal sanctions was a matter for the jury. It also approved tests from earlier cases that adopted a suggestion that gross negligence describes cases where the defendant has shown such disregard for the life and safety of others as to deserve punishment. This focuses attention on the recklessness of the professional's behaviour, that is, the failure to concentrate on the patient's interests. Thus, where health professionals have shown an obvious indifference to the risks to the patient, they may be charged with manslaughter.

Consent

A more contentious area regarding malpractice litigation arises when dealing with issues of consent. The consent of the patient legalizes medical examination and treatment. Significant case law has arisen owing to doctors failing to communicate adequately with their patients, either because there had been no proper consultation before treatment or because the medical practitioner failed to disclose the risks inherent in the proposed treatment.

If an individual wants to buy a car, the vendor is not obliged to point out defects in the car. If specifically questioned, the vendor commits fraud if he answers dishonestly, but he is not obliged to volunteer information that may be detrimental to the sale. On the other hand, the relationship between patient and doctor is one known in law as a 'fiduciary relationship.' Any person such as a physician, attorney, priest or other who enters into a relationship of trust and confidence with another has a positive obligation to disclose all relevant facts. The essence of a professional relationship is that the professional knows more about his subject than the person who seeks his help, therefore an affirmative duty of disclosure has always existed.

Patients need to be given a clear explanation of any treatment proposed, including any risks and alternatives, before they decide whether they agree to the treatment. Although consent, expressed or implied, must be given in most cases before treatment is lawful, this does not mean that consent needs to be fully informed. Indeed, the author does not believe that 'fully informed consent' can ever be achieved. Lord Donaldson has pointed out that consent plays two quite different functions in the doctor–patient relationship. One, which he called the legal function, is to provide a legal justification for care. Without such consent health professionals would commit a crime (battery) and a tort (trespass to the person) when they touch their patient. The other function, termed clinical by Lord Donaldson, is to secure the patient's trust and cooperation. This aspect of consent may involve more extensive counselling on the implications, risks and side-effects of treatment than the laws of trespass and battery require.

Battery

A battery is an intentional or reckless unlawful application of force to another person and is a crime as well as a tort at common law. Theoretically many procedures a doctor performs might be batteries (e.g. injections, surgery, manipulations) if done without the consent of the patient. The touching of a person in this manner without consent violates an individual's right of self-determination and constitutes an act of trespass to the person.

The main importance of battery lies in its role in emphasizing that patients are entitled to refuse the care provided by health professionals. They have a right to refuse treatment. In the words of Justice Cardozo from 1914: 'Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without the patient's consent commits an assault.'

The common law has long recognized the principle that every person has the right to have his bodily integrity protected against invasion by others. The seriousness with which the law views any invasion of physical integrity is based on the strong moral conviction that everyone has the right to self-determination with regard to his body.

The distinction between an action based on battery and one for negligence is important. Battery, which is a non-consensual touching, is itself a legal wrong, whether or not any specific damages can be shown to result. Thus, a patient may bring a successful action for battery even when the procedure that was carried out without consent was clearly for his or her benefit. By contrast, in negligence, in addition to showing that the professional fell below the required standard the patient must prove that some damage resulted. This means a patient will lose their case if the procedure benefited them or where the carelessness of the professional did not cause the damage.

Lawyers acting on behalf of patients have argued that, if the patient's consent for an operation or a mode of treatment was given on the basis of inadequate information, either of the risks of the treatment or of the extent of the treatment, the case should be heard in battery and thus have a right to compensation under the laws of battery. However, the UK courts have been intolerant of attempts to try these cases under the laws of battery. Any such attempt has been seen as a device to side-step difficulties in sustaining an action for negligence based on failures to communicate proper information, and the courts have been consistent in holding that actions for battery should play a limited role in healthcare law. Although this position has been criticized, it is unlikely to be altered in the foreseeable future. As a result, battery can normally be successfully alleged only when there was no consent to the procedure. This usually occurs when there has been a blatant error by healthcare staff, such as when the wrong leg is amputated, or when no consent was obtained. Liability in such cases is virtually always admitted and usually settled out of court. In the case of Allan v. New Mount Sinai Hospital (1980) the patient told the anaesthetist not to use the left arm for injections. Unfortunately, the anaesthetist forgot this, and the injection into the left arm leaked out causing tissue damage. The patient successfully sued under an action for battery.

Disclosing information

On the other hand, it is clear that if professionals fail to counsel patients in a way recognized by their peers as appropriate they may be negligent. Thus, patients who allege that they have been given insufficient information must argue that the professionals have been negligent in carrying out their duty to advise them about the decision. This means that this important aspect of consent is governed by the same principles that apply to ordinary malpractice cases. Furthermore, the extent and quality of information that should be provided depends on whether the standard is based on the patient's expectations, that is a patient standard, or on a professional standard.

The professional standard test is the standard of disclosure that the profession would be expected to tell the patient, that is, in accordance with the Bolam test or Hunter v. Hanley. If a responsible body of medical opinion would not have disclosed what was not disclosed by the defendant the doctor would not be found guilty of negligence. Thus, even a significant minority of doctors in agreement will leave the plaintiff in difficulties.

Lord Scarman has attacked this reasoning. Although he would permit the medical experts to establish the standard of care in relation to diagnosis and treatment, he found it unacceptable in relation to informed consent. He has commented that the law's standard is, in effect, set by the medical profession. If a doctor can show that his advice or his treatment reached a standard of care that was accepted as adequate by a respectable and responsible body of medical opinion he cannot be made liable in damages if anything goes wrong. It is a totally medical preposition erected into a working rule of law.

The patient-centred standard, on the other hand, can be subdivided into two, the particular patient standard and the prudent patient standard, corresponding to subjective or objective standards.

The particular patient (subjective) test defines what the plaintiff would have done if notified of all relevant facts. This test suffers from the use of hindsight and since the relevant facts exist only in the mind of the individual an accusation is hard to refute. However, it is a desirable standard in so far as it embodies personal factors, including many that are non-medical, which might affect a particular person's decision.

The prudent patient test requires the plaintiff to establish that a reasonable person would not have undergone a recommended procedure after having been advised of all significant risks. This suffers from the impossibility of defining a reasonable person for each case. However, it appears fair to both sides in that a reasonable doctor and a reasonable patient are meeting on comparable terms.

Other views: if the Bolam test is assumed to be representative of the current law, the doctor would have to warn of all risks that a responsible body of medical opinion considers the patient should be warned of, as opposed to every possible risk. The British Medical Association (BMA) claims that how much or how little is considered adequate varies with each patient. 'It must also be a matter of clinical judgement and the standards set by other doctors. From an ethical viewpoint, the criteria should be as much information as the patient needs or desires. It is interesting to note that in the Bolam case, the law set the level at the standard adopted by the medical profession and a doctor who gives as much detail as a recognized body of medical opinion considers appropriate would be unlikely to be held liable in law.'

It is interesting to note that the BMA considers it unlikely doctors would be held liable in law. The reason for this is that Bolam has been softened by various statements made in cases such as Sidaway v. Bethlem Royal Hospital Governors (1985). In this case the plaintiff suffered from persistent pain in her arms. Preoperatively the surgeon decided that an operation to relieve pressure on the fourth cervical nerve root was required. During the course of the operation the patient's spinal cord was damaged and she suffered severe disability. She sued the hospital and the surgeon, not for negligence in performing the operation, but for failing to warn her of the risk of damage to the spinal cord. Evidence was presented at the trial that this risk was less than 1%. Medical witnesses stated that, in keeping with a practice common to other neurosurgeons, they would also not mention the risk of paralysis or death in order not to frighten the patient. The trial judge therefore dismissed the claim.

The Court of Appeal affirmed the trial judge's view that the law in relation to failures in diagnosis and treatment also applied to failures in the realm of advice. Lord Donaldson, the Master of the Rolls, reviewed the leading transatlantic cases giving rise to the prudent patient test in the doctrine of informed consent, but declined to incorporate those principles: '…what information should be disclosed and how and when it should be disclosed is very much a matter for medical judgement, to be exercised in the context of the doctor's relationship with a particular patient in particular circumstances. It is for this reason that I would reject the American formulation of the duty by reference to a 'prudent patient test'.'

However, the adoption of the medical standard implicit in Bolam was not seen by him as abdicating responsibility to the medical profession. The practice held by the body of responsible practitioners had to be one that was rightly and properly held, and the court would not: 'stand idly by if the profession by an excess of paternalism denies their patients real choice.' In the same case, Lord Justice Browne-Wilkinson formulated a proposition that a doctor was under a duty to disclose to the patient information relevant to the decision the patient would have to take.

It is therefore clear that the courts and medical literature in the UK have suggested that disclosure is the key item and chief condition in the act of giving an informed consent. This allows medical authority and physician responsibility to take preference over patient autonomy. This is not in keeping with the meaning of informed consent which is better analysed in terms of autonomous authorization. Furthermore, good practice is not necessarily interchangeable with the legal minimum. However, it is very clear that the UK, when considering standards of information disclosure, differs significantly from other jurisdictions, such as Australia, Canada and the USA. Indeed, the position is at odds with that in most other common law countries and is notably isolated within the European Community. ◆

Ethics of Research

W Graeme Hilditch
Nick Pace

W Graeme Hilditch is Specialist Registrar working as a Clinical Lecturer in Anaesthesia at the University of Glasgow, UK. He qualified from Glasgow University and trained in anaesthesia in the West of Scotland. His research interests include preoperative assessment and information technology.

Nick Pace is Consultant Anaesthetist at the Western Infirmary, Glasgow. He qualified from Glasgow University and trained at the Glasgow Western and Royal Infirmaries, University Hospital of South Wales and Parkland Memorial Hospital, Dallas, Texas. His interests include airway management and anaesthesia for renal and adrenal diseases. He is a member of the British Transplant Society's Ethics Committee, and is currently completing a PhD in medical law.

Research is vital in improving the health and healthcare of the population; patients have the right to expect the best available prophylactic, diagnostic and therapeutic methods. At present, research involving human participants is not governed by legislation, but doctors involved in research have an ethical duty to show respect for individual rights and follow good research practice.

Patients want to receive the best possible treatment based on evidence derived from previous clinical trials. It could therefore be argued that there is an obligation on current patients to participate in the procurement of this evidence for future patients. However, the interests of the research subject are paramount. Even if research may lead to advances in medical knowledge, the outcome may not justify the risk to the participants. Respect for human life and individual autonomy of the research participant is the primary aim of the ethical review of research.

Ethical approval

All human research should follow ethical principles and be approved by an ethics committee. Ethical review of medical research has had a protracted development since World War II following the inhumane procedures carried out by Nazi doctors in the name of medical research. At the Nuremberg trials, 23 doctors were convicted and the exposure of their deeds led to adoption of the first internationally recognized code of medical ethics, the Nuremberg Code. The rights of research subjects were highlighted in the code, in particular the right of an individual to withdraw from a study at any time.

The formation of ethical review by committee followed the World Medical Association Declaration of Helsinki in 1964, the publication of Pappworth's *The Human Guinea Pig* in the UK and Beecher's *Experimentation in Man* in the USA. They all added weight to the discussion of the ethics of clinical trials, creating a framework for the principles for biomedical research. The Royal College of Physicians issued reports in 1967 and 1973, making various recommendations for the setting up and structure of ethical review committees. In 1975, the Department of Health and Social Security produced guidance, though the resulting system was varied in quality.

In 1991, a revised set of guidelines was issued by the Department of Health reconstituting all Research Ethics Committees (REC) to a standardized structure. Every health district required a local REC and detailed guidance on their composition and function was given. These RECs are convened to provide independent advice to participants, researchers, employers and care organizations on the extent to which proposals for research studies comply with recognized ethical standards. The purpose in reviewing study proposals is to protect the dignity, rights and safety of research participants. In addition, RECs have an obligation to society and researchers to encourage research that will improve healthcare and health.

The International Conference on Harmonization of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH Guidelines) was established in 1990 as a joint regulatory project to improve the efficiency of the process for developing and registering new medical products in Europe, Japan and the USA. The guidelines describe internationally accepted principles and practices for the conduct of individual clinical trials and overall development strategies for new medical products.

Aim of research

Research is often categorized as therapeutic or non-therapeutic, though this is increasingly challenged. In therapeutic research, the subject may benefit from being involved in the research project. In non-therapeutic research there is no clinical benefit to the subject. The distinction is useful when discussing ethical issues and is one of a number of factors that RECs consider.

The aim of research is the generation of knowledge, not the improvement of the health of the research subject, though it may lead to this. Research must be capable of identifying and confirming improvements in clinical management, however small, or improving medical knowledge. Research is justified only if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research. Duplicate or redundant research is unethical because it involves finite risk to the participant with no beneficial outcome. The REC must reassure itself that the research project will lead to a meaningful result. Pre-recruitment statistical analysis must show, for example, that sufficient numbers of participants will be recruited to allow valid results to be produced.

The risks involved with research apply to the participant during the research period. The benefits accrue to future patients if the therapy or diagnostic test being researched is then implemented. This unequal distribution of risk (to the subject) and benefit (to future patients) requires the protection of the research participant who may receive no benefit from the research. The REC must be satisfied that the risks to participants are minimized. However, significant risks may be acceptable under certain circumstances. For example, patients who are critically ill may participate in research involving novel treatment despite known or suspected serious side-effects.

In non-therapeutic research it is essential that all risks should be mentioned and all foreseeable risks kept as low as possible. Potential benefits must greatly outweigh the risks of participation. Although it may be possible to define risk, whether the balance between risk to the individual and the benefit to others is acceptable is difficult to determine. Often the balance is subjective and some suggest the research subject could make the decision. However, this is unethical for several reasons. The REC has more experience and access to advice and knowledge than research subjects and is better able to assess the degree of risk. Also, research subjects may feel they owe a duty to the researchers looking after them and thus subtle coercion may come into play (see later). The REC can come to a collective judgement using individual expertise rather than individual judgement. Furthermore, the cumulative experience of the REC allows identification of serious risks. It is essential to ensure that involvement in the research project is not contrary to the subject's interests.

Consent

Ethical review of research not only considers what risks are acceptable but also ensures that the participants' autonomy is respected. Proper mechanisms for consent must be in place. The principles governing consent are provision of sufficient information to allow choice and freedom to decide without influence from the researcher.

Each participant must be adequately informed of the aims, methods, anticipated benefits, and the potential risks of the study. The participant must be informed of the right to abstain from participation in the study or to withdraw participation at any time without reprisal. Once the researcher has ensured that this information has been understood the participant's freely given informed consent must be obtained. This presents a problem in some areas of research, namely, day surgery, emergency medicine and ICU.

Day surgery: the time available for consent is restricted and there is inadequate opportunity for the patient to process the information, reflect on the risks and benefits, and discuss the proposals with relatives. Efforts should be made to discuss the research with the patient before the day of surgery, allowing formal written consent to be obtained on their arrival for surgery. This may increase the workload for the researcher but failure to do this is deemed by some RECs to be unethical.

Emergency medicine: obtaining consent in emergency medicine and ICU is further compromised because patients are unable to comprehend the information provided owing to their clinical condition. Treatment that is part of a research project may be permitted if the risks of the treatment being studied are not thought to be greater than standard treatment. This causes an ethical dilemma. The benefit to future patients must be balanced against the risks to the research participant and the protection of autonomy. There are no rules governing this balance and individual RECs must assess each study individually. However, it is generally accepted that it is ethical to involve adults who lack capacity, such as in the ICU, in therapeutic research. The situation for non-therapeutic projects is less clear and potentially illegal in England and Wales, though probably not in Scotland through a recent law giving relatives the right to consent on behalf of their incompetent relative. Paradoxically, it is increasingly regarded as ethical throughout the UK, provided certain safeguards are applied. RECs have a major part to play in such decisions and researchers are strongly urged to seek their views.

Recruitment

During recruitment, principles of consent, provision of information and freedom to decide, can be compromised because of the vulnerability of participants. During illness, comprehension and decision-making can be difficult. The research subject can be influenced by a desire to show gratitude and obligation to the doctor, which may make them susceptible to pressure from the researcher, however unintentional. This sense of gratitude can also prohibit a patient's voluntary withdrawal from the research. A suggestion to the patient that they will benefit by participating in research may be an inducement to participate. During recruitment, patients must be protected from pressure to participate and reassured if they decide to refuse participation. Any issues that arise during the research must be addressed and the imbalance of power between researcher and participant minimized.

Despite these problems, it is ethical to recruit from vulnerable groups. The vulnerability of different groups must be anticipated, recognized and taken into consideration by the researcher during recruitment. Participants must be correctly identified and exclusion criteria established. Efforts must be made to ensure that the research could not be carried out on a less vulnerable group. This is a general moral requirement for all research and precludes individuals who are less mature, frail, severely ill or confused from participating in research unless there are special circumstances.

Ethical errors

All research must be based on a properly developed protocol that has been approved by an REC (Figure 1). The aims, design, and methodology of the study must be justifiable, verifiable, scientifically valid and ethical.

Basic components of a Research Ethical Committee proforma

Purpose of the study
- Background of the work
- Information to be obtained
- Proposed benefits

Details of the procedure
- Explain how the study will be executed
- Duration of research
- Treatment allocation
- Procedures undertaken

Recruitment
- Age range of participants
- Principal inclusion and exclusion criteria
- Minimum number of subjects and justification for these numbers, with power calculations where appropriate
- How patients will be approached

Trial products
- Description of all drugs used, stating their known pharmacology, side-effects and toxicity
- If a new drug is to be used, a copy of the Clinical Trials Certificate or Clinical Trials Exemption Certification from the Committee on Safety of Medicines must be included
- List approved and new indications

Patient information
- Purpose of study, nature of procedure, discomfort and possible risks in terms that the subject can understand

Consent
- A standardized form should be used

Finances
- All sources of support for the work should be stated including details of all payments to be made to investigators, patients and healthy volunteers

The aims of the study determine the benefit, and therefore, must be clear, focused and reflected in the study design. The temptation to obtain as many answers as possible from the same number of participants can lead to serious methodological problems. The normal level of statistical significance is that there be no more than one chance in twenty that a given result is due to random variation. Clearly, the more outcomes that are measured the greater the chance that the researchers will identify a false-positive observation. Poor methodology is unethical because it subjects participants to risk for possibly invalid results.

Control groups

Research is susceptible to bias. The outcome measured can be influenced by participant characteristics that are independent of the process being tested. The variability of different individual patients must be overcome by using controls. These are research participants who are closely matched to those in whom the new treatment is being investigated. Thus, variables such as age, weight and diet are similar in both groups; the only difference is the therapy and therefore any difference between the groups can be assumed to be due to the therapy.

An ethical dilemma presents if the control group also requires treatment. This is overcome by giving this group the best current therapy and comparing its benefits, risks and effectiveness to the new treatment. This does not exclude the use of placebo or no treatment in studies where no proven method exists. No trial design should prevent a patient who needs active treatment from receiving it, though the trial therapy may be less effective than the standard treatment.

To eliminate bias, the allocation of controls and study patients must be done in a manner that reduces the introduction of un-recognized but influential factors. The researcher should not choose the controls but use a valid method of randomization.

Blind procedures

Researchers and subjects must be prevented from introducing their own expectations and hopes, which could influence outcome. The effects of a placebo are well documented. Similarly, researchers may be influenced during the measurement of the effect if they know which treatment has been given. Therefore, it is important that neither the researcher nor the subject knows to which group subjects have been allocated. Blinding of patients and researchers is crucial if bias is to be minimized and the results of a trial accepted. It is essential that randomization, the nature of the process and reasons for it are mentioned to the research subjects before their consent (contrary to the Zelen design). In a double-blind trial neither the researcher nor the subject knows whether the subject is receiving treatment or is in the control group.

The ethical problem with randomization and blinding is that the standard treatment is no longer prescribed by the doctor to the patient, but is chosen by a random decision process. The normal doctor–patient relationship is thereby compromised. This problem can be intensified if the clinician is blinded and unaware of the treatment the patient is receiving. If the patient subsequently becomes worse than expected during a trial, it is the responsibility of the researcher to provide a quick and effective means for withdrawal from the study and identification of the treatment received.

Sample size

Essential to the planning of a randomized trial is estimation of the required sample size. The investigator should ensure that there is sufficient power to detect, as statistically significant, a treatment effect. If a trial with negative results has insufficient power, a clinically important effect may be ignored or taken to mean that the treatment under study made no difference. Such a trial may be scientifically useless, and deemed unethical because patients may be put at risk with no apparent benefit. Likewise, studies that are too large are unethical because they involve supernumerary participants and incur unnecessary costs.

Placebos

Care should be taken in the use of placebos. Section 29 of the revised declaration of Helsinki states that ‘the benefits, risks, burdens and effectiveness of a new method should be tested against those of the best current prophylactic, diagnostic and therapeutic methods. This does not exclude the use of placebo, or no treatment, where no proven prophylactic, diagnostic or therapeutic method exists.’

This is highly contentious and seems to rule out some vital uses of placebo-controlled trials in areas where proven treatment already exists. However, failure to use placebos may occasionally reduce the reliability of trial conclusions and increase the proportion of wrong decisions. Placebo-controlled trials are generally more reliable, providing their own check of internal validity and more conclusive proof of efficacy. Using placebos does not mean that the subject receives no treatment, because other medications are permitted in both groups. Rescue medication is also prescribed for specific circumstances.

Epidemiological research

Epidemiological research and disease registers involve collecting and analysing data from large numbers of patients, often without identifying individuals or their clinical involvement. The main aim is the investigation of the incidence and prevalence of diseases, often determining environmental and social factors. This is vital to protect and enhance public health. However, the investigators are bound by the principles of respect for the patient’s autonomy. Records made for one purpose (e.g. anaesthetic charts) should not usually be disclosed for another purpose without the patient’s consent.

The Data Protection Act 1998 requires researchers to make sure that patients are clear how their personal health information may be used and to give them an opportunity to opt out. The Act does not require the use of formal consent forms or signatures from patients before information is shared. However, the Act does require reasonable steps to be taken. A summary of the main principles of the Act is given in Figure 2.

Data Protection Act and Caldicott Guardians

Data Protection Act 1998
This brings into UK law European Directive 95/46/EC on the processing of personal data. It came into effect on 1 March 2000 and, in comparison with the 1984 Act, it is concerned with both records on paper and records held on computers. The act is based on eight principles

1. Personal data shall be processed fairly and lawfully
2. Personal data shall be obtained only for one or more specified and lawful purposes, and shall not be further processed in any manner incompatible with that purpose or those purposes
3. Personal data shall be adequate, relevant and not excessive in relation to the purpose or purposes for which they are processed
4. Personal data shall be accurate and, where necessary, kept up to date
5. Personal data processed for any purpose or purposes shall not be kept for longer than is necessary for that purpose or those purposes
6. Personal data shall be processed in accordance with the rights of data subjects under this Act
7. Appropriate technical and organizational measures shall be taken against unauthorized or unlawful processing of personal data and against accidental loss or destruction of, or damage to, personal data
8. Personal data shall not be transferred to a country or territory outside the European Economic Area unless that country or territory ensures an adequate level of protection for the rights and freedoms of data subjects in relation to the processing of personal data

Caldicott Guardians
In 1997, the Caldicott Committee reported on its review of information that identifies NHS patients.

Following the recommendations, a new system of data protection officers, ‘Caldicott Guardians’, was established.

Each Health Authority, Trust and Primary Care Group required a guardian to agree and review internal protocols for the protection and use of identifiable information obtained from patients

2

Systems of information collection should be constructed to balance public need and the rights of privacy of the individual. Consent should be obtained where practical, with anonymization of data if possible. However, data that have been encoded are regarded by the Data Protection Act as personal if the key for decoding remains in existence. Thus, coded data fall within the Data Protection Act and the researchers’ ethical responsibility, even if the key is not readily available to the researcher. If full anonymization is impossible, the use of pseudonymous data (creating codes and restricting access to them) should be considered, though this can still be interpreted as personal data.

The issues of consent and anonymization are complex, and uncertainties about the interactions between researchers, data protection officers, RECs and the new Caldicott Guardians are not yet clarified. ◆

Jehovah's Witnesses

Manfred Staber
Nick Pace

Manfred Staber is Specialist Registrar at the Western Infirmary, Glasgow, UK. He qualified from the Technical University in Munich, Germany. He trained in anaesthesia and intensive care in Germany, Australia and the UK. His research interests include trauma and critical care.

Nick Pace is Consultant Anaesthetist at the Western Infirmary, Glasgow. He qualified from Glasgow University and trained at the Glasgow Western and Royal Infirmaries, University Hospital of South Wales and Parkland Memorial Hospital, Dallas, Texas. His interests include airway management and anaesthesia for renal and adrenal diseases. He is a member of the British Transplant Society's Ethics Committee, and is currently completing a PhD in medical law.

The Jehovah's Witness Christian movement was founded in the north-eastern USA about 120 years ago. There are more than 5.9 million Jehovah's Witnesses in over 230 countries. The headquarters of the church organization, the Watchtower Bible and Tract Society, is based in Brooklyn, New York. In general, Jehovah's Witnesses are obliged to refuse blood transfusions or other blood-based products. This is based on the prohibition of the consumption of blood as outlined in the Bible (*Genesis* 9:3–4, *Leviticus* 17: 11–12 and *Acts* 15: 28–29). Accepting banned blood products is a serious offence and may lead to excommunication and 'enforced shunning'. This leads to social isolation because friends and family are instructed to avoid the 'offender's company'.

Changes in policy

Vaccinations for Jehovah's Witnesses were banned from 1929 to 1952, as were organ transplants from 1967 to 1980. The policy of refusal of blood dates back to 1945 and was enforced in 1961 with the threat of judicial sanctions and excommunication.

In June 2000, the Watchtower Society announced a change in procedure for 'offenders' and in the 'blood policy'. If through personal choice members accept blood transfusion they automatically disassociate themselves from the religion. If they repent, spiritual support is offered with the possibility of redemption. In other words, members resign from the religion rather than being expelled by a judicial committee.

The more important change from the medical community's view is the expansion in what are acceptable blood products. The ban on primary components (defined as red and white blood cells, platelets and plasma) and whole blood is still upheld. However, it now appears that the Society permits the use of all fractions of so-called 'primary components', the so-called 'secondary components'. At what point a primary blood product becomes a secondary product is open to debate and becomes an individual decision. It appears that nearly all components can be transfused as long as they are given piecemeal or processed (e.g. albumin, all clotting factors, immunoglobulins). Red cells stripped of their outer membrane may be transfused in the form of haemoglobin transfusions. Haemoglobin-based blood substitutes have entered phase 3 clinical trails and may become an acceptable treatment. Bone marrow transplants and the use of peripheral stem cells for autografting are often considered as transplants rather than infusions of primary blood products.

The current blood policy is confusing and complex and not every Jehovah's Witness is aware of the official position of the Watchtower Society. Therefore, in most major cities, Jehovah's Witness Hospital Liaison Committees have been set up to resolve these medical issues. An anonymous group within the Jehovah's Witnesses is trying to reform the blood policy of the Watchtower Society. Until this happens, more premature and avoidable deaths will occur.

Informed consent

As with any other competent adult, Jehovah's Witnesses are entitled to accept or refuse treatment or even only certain aspects of it (e.g. the administration of blood products). Many Jehovah's Witnesses leave copies of detailed healthcare advance directives (a living will concerning all kinds of personal matters) with their general practitioner, family and friends. In addition, Jehovah's Witnesses may carry a signed advanced directive declining blood in all circumstances and releasing the treating doctor from liability for the consequences. Doctors who knowingly give the patient blood despite the presence of an advanced refusal are likely to be held guilty of assault.

Each Jehovah's Witness must decide individually if he or she can accept the blood-derived products mentioned above. Doctors should discuss acceptable treatment, and the medical consequences of not receiving blood products, with the patient.

Blood transfusion

Jehovah's Witnesses believe that blood removed from the body should be disposed of. They object to techniques involving intra-operative blood collection, storage and haemodilution. However, provided the extracorporeal circulation is uninterrupted, many Jehovah's Witnesses agree to autotransfusion as a continuous blood salvage with reinfusion (e.g. during cardiac bypass). Isovolaemic haemodilution may be performed provided a closed continuous loop is maintained. Even epidural blood patches may be accepted provided the injecting syringe remains connected to the circulation. A long extension line from the venous cannula to the syringe and injection via a three-way tap into the epidural space maintains continuity. The use of pre-donation, storage and re-transfusion of blood is unacceptable.

Emergency situations

If a patient is incapable of giving consent (e.g. following trauma) and his or her views as a Jehovah's Witness are unknown, life-saving transfusions should not be delayed. This intervention is not subject to the religion's sanction or judicial process because the individual has not conscientiously accepted blood. If time permits, the patient's relatives or general practitioner can be contacted to establish the patient's views, though they do not have a legal right to refuse transfusions in England and Wales. However, the law in Scotland may be changing shortly, giving relatives legal authority to make treatment decisions. Evidence must be provided, for example in the form of an advance directive, that the patient would not accept blood even if that resulted in death. An advance directive is legally binding, but concerns have been raised because it is often unclear if, at the time of signing, the person was adequately informed of the risk and benefits of blood transfusion and the obligation to comply with church rules may have influenced their decision.

Child of Jehovah's Witness

In the UK, children under the legal age of consent, but capable of understanding the issues, can refuse transfusion without the consent of the parents or legal guardian, though the legal standing of such a refusal is unclear. If blood transfusions are required for an elective procedure and the parents refuse to consent, it may be necessary to apply to a court to make the child a ward of court. At this stage, a second opinion should testify that the child's life or long-term wellbeing is in danger unless it receives blood products during the proposed procedure. A court decision may become necessary to clarify who can give lawful consent, for example, if the child opposes the parental decision or if the parents are divorced and have different views.

In an emergency with the immediate requirement for blood transfusions, there is insufficient time to wait for a court order and blood should be transfused irrespective of the parent's wishes. A second medical opinion, confirming the necessity of immediate requirement for blood should be documented. The courts are highly likely to uphold the decision of the doctors.

Managing Jehovah's Witnesses

Anaesthetists and refusal to treat: in the elective situation individual anaesthetists may decide not to get involved in the care of a Jehovah's Witness, but in an emergency they are obliged to provide appropriate care and to respect the wishes of the patient if known.

Preoperative management: a preoperative consultation should be done early, before the planned procedure, to discuss and document acceptable treatment. Private consultations may be necessary because peer pressure is exerted on members to refuse transfusions. If a Jehovah's Witness accepts blood transfusions it is essential to maintain medical confidentiality. It is important to avoid transfusions during visiting hours and to keep fluid and prescription charts away from the patient's bedside. Access to medical notes should be restricted to the treating medical team. These precautions allow patients to remain silent about the medical treatment if they wish and avoid sanctions or disassociation from the church. Agreed procedures should be signed by the patient and kept in the medical records. Failure to respect the patient's wishes is unlawful and ethically unacceptable and may lead to criminal or civil proceedings. Preoperative anaemia is an important determinant of operative outcome, particularly in patients with underlying ischaemic heart disease. Anaemia should be investigated and treated. The use of iron tablets combined with erythropoietin is effective.

Intra-operative management: surgery under regional anaesthesia can be associated with major blood loss, especially in obstetrics. Confronted with major haemorrhage and the need for urgent transfusion, Jehovah's Witnesses may accept life-saving blood products. This change of consent has to be accepted and life-saving transfusion given, even if the patient had sedation and may not strictly meet the legal standards to give informed consent. Any change in the pre-existing consent should be documented and witnessed in the notes.

Managing anaemia and blood loss: haemoglobin levels of 8–10 g/dl are safe, even in the presence of cardiorespiratory disease. Critical levels of oxygen delivery in fit, healthy and resting adults are reached at about 5 g/dl. For elective procedures, a course of vitamin K, iron, folic acid and erythropoietin can be given. Strategies to reduce intra-operative and postoperative haemorrhage include cell savers and the use of antifibrinolytic drugs (e.g. tranexamic acid, aprotinin). Desmopressin (DDAVP) a synthetic analogue of antidiuretic hormone (ADH) may be used to control bleeding associated with acquired disorders of haemo-stasis, including chronic renal failure and liver diseases and some platelet disorders. In addition, elective ventilation, paralysis and sedation minimize oxygen consumption. Hyperbaric treatment, perfluorochemicals and active cooling have been described, though the latter may impair homeostasis. Recently, Sn-meso-porphyrin, a potent inhibitor of haeme oxygenase, has been used as therapy for severe hyperbilirubinaemia in Jehovah's Witness newborns as an alternative to exchange transfusions. ◆

Transplantation Ethics

John Crawford
Lisa Manchanda
Nick Pace

John Crawford is Consultant Anaesthetist at the Western Infirmary and Gartnavel General Hospital, Glasgow. He qualified from Glasgow University Medical School, with postgraduate training in Scotland and Singapore, and has an honours degree in sports physiology. His interests include the history of organ transplantation, and the ethics of non-heart-beating organ donation.

Lisa Manchanda is Specialist Registrar in the West of Scotland School of Anaesthesia. She qualified from Glasgow University Medical School. Her interests include pain management and the ethical aspects of anaesthesia.

Nick Pace is Consultant Anaesthetist at the Western Infirmary, Glasgow. He qualified from Glasgow University and trained at the Glasgow Western and Royal Infirmaries, University Hospital of South Wales and Parkland Memorial Hospital, Dallas, Texas. He is a member of the British Transplant Society's Ethics Committee, and is currently completing a PhD in medical law.

There have been ethical dilemmas about transplantation since the first successful human kidney transplant in 1954. That transplantation proceeded in the belief that the psychological benefit of live donation outweighed the unknown outcome. Advances in transplant biology and technology have produced new ethical issues. These vary between individuals, countries and cultures, but many arise owing to the scarcity of suitable donor organs.

Allogenic (same species but different genetic constitution) solid organ transplantation is now an established treatment for end-stage organ failure (kidney, heart, lung, liver, pancreas), and a successful transplant results in improved duration and quality of life for the recipient. Unmet demand means patients die waiting for heart, lung and liver transplants because there are no alternative treatments. The success of long-term renal replacement therapy creates growing waiting lists for renal transplantation.

Most societies, and the main religions, accept that organ donation and transplantation is justified by the good it brings.

Transplant organ supply

Brainstem death

Brainstem death (BSD) is a product of modern intensive care. The concept is now well established in most societies. Acceptance took place in several stages and was central to the development of transplantation. In the UK, BSD heart-beating donors have been the main donors since the mid-1970s. Maintaining ventilation and circulatory support on these dead patients allows time for discussion with relatives, screening of donor, and a controlled approach to organ retrieval, allowing the use of the kidneys, heart, lungs, liver and pancreas with short warm ischaemic times.

BSD criteria provide an important demarcation between medical care for the patient (including the determination of death) and the separate involvement of transplant teams. Despite this, there is often discomfort at performing a 'lethal' operation on a body with 'signs of life' even though they are secondary to techno-logical interventions.

Some cultures hold beliefs about death that make it difficult to equate brain death with death. Organ harvesting from BSD donors was not permitted in Japan until 1997 because of the belief that death was not complete until funeral rituals were concluded. This was combined with a loss of trust in the medical community when the initial heart harvest led to a murder charge. Japanese citizens may now elect to permit their death (for the purposes of organ donation) to be elicited using BSD criteria.

Anencephalic donors

It has been suggested that brain death could be extended to anencephalic infants who could become organ donors byplacing them in a special category of death. This might be justified by prolonging life for the recipients, however, anencephalic infants have a functioning brainstem and are not brain dead. Moreover, transplanted organs from anencephalic infants have not worked well. Altering the definition of death in specific cases may also present risks to other patients (e.g. those in a persistent vegetative state).

Elective ventilation

In 1988, the Royal Devon and Exeter Hospital developed an elective ventilation protocol. Dying patients in deep irreversible coma were transferred to the ICU to allow artificial ventilation to be instituted immediately after respiratory arrest. This support continued until brainstem death ensued. The purpose was to increase the donor pool and optimize the condition of organs in preparation for transplantation. Strong arguments have since been made that it was wrong to prolong life and alter the mode of dying only for the benefit of others. The practice also risked patients entering a vegetative state. This practice was abandoned and the Department of Health forbids it. Treating patients for the purposes of organ donation rather than for their benefit risks charges of assault under the Criminal Offences Against the Person Act 1861. Calls for permissive legislation in this area, with patient consent given through an advance directive, must also be balanced against possible damage to the existing BSD programme from loss of public trust.

Non-heart-beating donors

Non-heart-beating donors are being increasingly considered as an important source of organs because demand is unmet by BSD donors. Non-heart-beating donors are declared dead after the irreversible cessation of circulation and respiratory function.

Irreversible brain damage

Patients with profound irreversible brain damage (not BSD) for whom continued support is considered futile by relatives and doctors often have life-sustaining treatment removed and die soon afterwards. In such cases it is possible to harvest organs in controlled conditions (with short warm ischaemic times) shortly after circulatory arrest, with the consent of the patient or relatives. Contentious issues include *pre mortem* placement of femoral catheters and *pre mortem* administration of drugs (e.g. heparin, phentolamine) to optimize retrieved organ function that cannot benefit the patient and may cause harm.

Patients dying in hospital

Other patients dying in hospital may also be potential donors but in a less controlled manner (e.g. death following resuscitation). Delay caused by lack of prior consent has sometimes led to measures such as *post mortem in situ* cooling of the body via percutaneous catheters until relatives are contacted and consent to harvest obtained. Is it justifiable to perform these extraordinary procedures without consent in order only to benefit others? Some argue there is an obligation to help others and such actions offer the family this chance. The limited time in which consent and harvest must be carried out risks misunderstandings. When has irreversible cessation of circulation occurred? Is prolonged resuscitation necessary first, or always ethical itself? Should there be a minimum period between the declaration of death and harvesting? The traditional loose definitions and timings of cardiac death are challenged in the context of non-heart-beating donors. The conflicting interest of reducing warm ischaemic damage must not influence good medical care (appropriate resuscitation, care and respect for the dying) and it is clear that there must be transparent separation between the medical and transplant teams. Likewise the transplant community should avoid any changes in definitions of death. It has been suggested that such a programme should only follow education of, and general acceptance by, the community in which it is to operate. Donor and family wishes and values must be taken into account at all times.

Poor graft survival from so-called marginal donors is also a concern, and the recipients must be made aware of differences in outcome from different sources. Recent evidence suggests that kidneys retrieved with warm ischaemic times of about 30 minutes (with no percutaneous cooling), have delayed initial function but similar long-term survival to those obtained from heart-beating cadavers.

Executed prisoners

In some countries, organs are retrieved from prisoners after execution. This is condemned by many, as is the involvement of physicians. Others argue that it is immoral not to use such organs if they exist, given the benefit they can provide.

Living donors

Before BSD criteria were accepted, living donors provided many kidneys for transplant. Living donation (kidney, liver lobe and lung lobe) has increased as cadaveric organs remain scarce. In Norway and the USA, about 50% of kidney transplants involve living donors compared with 27% in the UK (2001). The benefits to the recipient include reduced waiting time, scheduled procedure, healthy donor organ, reduced cold ischaemic time and longer graft survival. The main benefits to the donor are psychological.

The risks of morbidity and mortality to the donor vary depending on the organ (or partial organ) donated. The magnitude of these risks should alter the way in which decisions are made. Adult-to-adult transplantation of the right liver lobe has a donor mortality of about 1%, while kidney donation has a mortality of 0.03%. The risk to the donor may contradict the obligation to cause no harm. The donor must be aware of all risks and alternatives, and allowed an informed decision free from coercion. The doctrine of free consent allows this non-therapeutic surgery provided the consequences are not against the public interest. What role does the transplant community have in deciding if the risks are unacceptable to a particular donor? It is also worth considering the benefits that individuals and institutions gain from running such programmes and the distinction between allowing a person to risk harm and actively encouraging it.

Living emotionally related donors are not related by blood but by a close relationship such as friendship or marriage. The reward of seeing the recipient in better health is thought to justify their altruistic and risky donations. Most countries permit such donations.

Living unrelated donors: in the USA there have been recent cases of unrewarded altruistic kidney donation from live donors to unknown recipients. They are also known as 'undirected' donors. Concerns include difficulties in accepting that a true understanding of risk has been made; and what should be done if conditions are attached.

Consent for cadaveric organ donation

Opt in: in the UK, individuals are asked to register their intention to be an altruistic donor to society on the NHS donor register. The number of donors from this pool has diminished owing to improved road safety and a shortage of neurosurgical facilities. Over the last 10 years, the 20% reduction in the number of cadaveric organ donors has been matched by a 3% increase per year in patients listed for transplantation. The UK cadaveric kidney transplant rate of 24/1 million population is about half that required to service the waiting list. Spain achieves about 48 cadaveric kidney transplants per 1 million population. The current opt-in system may fail the utilitarian principle of maximizing benefits for society because about half of potential donors fail to become donors.

Opt-out – presumed consent: an alternative strategy of presumed consent assumes an individual wants to donate unless they have 'opted out' by previously registering an objection. An individual's silence is equated with assent whereas there may be a lack of understanding or ambivalence. 'Opt-out' laws, with registers that can be accessed quickly, have advantages in permitting early cooling of potential non-heart-beating donors. Presumed consent laws are accompanied by an obligation to ensure widespread understanding in society and ease of opting out.

Consent from relatives: many countries using 'opt-in' or 'opt- out' systems still seek consent from relatives. Allowing relatives to veto wishes made by a potential donor offends the principle of self-determination. Donor rates may not be increased in 'opt- out' countries taking this 'softer' approach. Countries taking less account of relatives' wishes may demonstrate higher rates but this may not be transferable to other countries without risking loss of trust.

Required request: failure to ask the relatives of suitable donors because of discomfort or antipathy may be a common reason for losing organs, resulting in policies of 'required request'. Disconnecting a ventilator from a BSD individual without making inquiries into the possibility of their organs being used for transplantation is thereby identified as unethical. The individual's and family's right to donate may be denied, and the potential benefit to society lost if relatives are not approached. In the USA, financial penalties have been used to enforce this approach.

Conditional donation occurs when agreement to donation is made dependent on who may receive the organs. A recent UK case involved relatives stipulating the skin colour of the recipient; the conditions were accepted and transplantation proceeded. Review by the Department of Health ruled that organs should not be allocated on the basis of race and that such practice would breach the Race Relations Act 1976. Organs should be accepted when freely given, as a gift, to society. Society has not extended to the donor or their family the right to decide who receives it.

Rewards for donation

Commercialization of organ transplantation is illegal in most countries, however, trade in organs occurs. This may seem unethical and distasteful to those in developed countries, especially those not exposed to a market healthcare system. It may be socially accepted in some countries without a cadaver transplant programme. An individual may argue it is his or her right to sell their organs and undergo non-therapeutic surgery while knowing and understanding the risks. To prevent such transactions may be paternalistic and attack autonomy. The financial pressures to sell may be as important as other moral pressures such as donating an organ within the family. Altruistic donation may be unable to meet demands and the alternative for the recipients may be death. However, the facts suggest that hospitals and doctors undertaking this provide poor quality grafts and poor continuing care, and thus exploit donor and recipient. Such rewarded donation may inhibit the development of sustainable transplant programmes. It is also clear that organ tourists visit poorer countries for transplantation.

Compensation: the boundary between sale and other rewards such as compensation may be blurred. Living donors in the USA are entitled to receive compensation for loss of earnings and expenses. In the USA, the introduction of ethical incentives (Figure 1) to increase living and cadaveric donation has been suggested. There have also been arguments for regulated reward systems to benefit donors and increase organ quality. However, this undermines the principle that one should not sell one's body, and would promote organs as products for sale. Some argue that non-commercialism of the body is paramount and commercialization can never be justified even if it increases the number of organs for transplant. Others point out that payments are often made for blood and gametes.

Proposed 'ethical incentives'

- Medals of honour for bereaved families
- Reimbursement of funeral expenses
- Allowing regulated organ exchanges
- Donors receive highest priority if organ failure develops
- Donor insurance in case of morbidity/mortality

1

Should ICUs be given bonuses or other incentives, in an effort to encourage requests to relatives for organ donation? Does this differ from penalizing them for failing to make a required request?

Access to transplantation

The corollary of demanding that cadaveric organs be unconditionally donated to society is that a just system must exist to distribute this scarce resource.

Access: in the UK, geographical differences in the referral rates for liver transplant may reflect true differences in referral practice and thus inequitable access. Likewise, not all patients may have the same access to living donor programmes. In some health systems, funding for lung transplant is dependent on health insurance. Thus the lung is effectively donated to the part of society that can afford insurance. Without equity of access it could be argued that the best allocation schemes are unjust.

Allocation: UK Transplant controls organ allocation in the UK. Other countries have similar organizations. They aim to maximize overall benefit while meeting individual need in a fair and unbiased way (efficacy, utility, equity, urgency). The exact system differs with organ but includes blood group, and scoring systems for tissue matching, age, urgency of transplantation and location.

To what extent should prognosis after transplantation be taken into consideration? Should continuing alcohol, or other drug misuse be a contraindication for organ transplantation or alter position on a waiting list? Should young recipients have priority? What should be done about differences in outcome that are race dependent? Equity would stress that these factors not be taken into account, but what about using scarce organs for new indications with unknown efficacy? The balancing of utility with justice is a duty for all of society and not just for the transplantation community. It is essential that the criteria for organ allocation are transparent and debated by the public.

Legislation and the Regulation of Transplantation

In the UK, the Human Tissue Act 1961 and the Human Organ Transplants Act 1989 govern organ donation and transplantation.

The Human Tissue Act 1961 allows the person in lawful possession of a body to authorize the removal, from the body, of any part that the person wished to be used for therapeutic, education or research purposes. If no such wish was made then the person lawfully in possession may still authorize such removal, after having made reasonable enquiries that there is no reason to believe that the deceased had expressed an objection or that the surviving spouse or any relative objects.

The Human Organ Transplants (HOT) Act 1989 permits anyone suitable to donate all or part of a vital organ to a close blood relative. It was enacted to regulate transplantation of living donor organs after a scandal involving the purchase of kidneys from Turkish living donors. The Unrelated Live Transplant Regulatory Authority (ULTRA) was set up under this Act to approve all transplant operations involving a living donor who is not a close blood relative of the recipient. The purpose is to ensure that no payment is involved, other than expenses, and that full understanding and consent is obtained without coercion. The process includes the donor being interviewed by an independent assessor. The HOT Act does not apply to transplants of regenerative tissues.

Other legal issues

Domino transplants require ULTRA approval. This refers to organs becoming available from a recipient during a transplant procedure which could be used for someone else (e.g. a healthy heart, during a heart–lung transplant). The necessity for ULTRA approval in domino transplants has been questioned because the opportunity for organ trafficking is effectively non-existent. However, this would require an amendment of the HOT Act.

Paired exchange involves one donor/recipient pair donating to, and receiving from, another donor/recipient pair to resolve tissue incompatibilities, which would prevent transplant within a pair. A variation is an incompatible living donor donating to the general recipient pool in exchange for their relative going to the top of the cadaveric waiting list. In the UK, these swaps are forbidden because they involve elements of coercion (e.g. I will donate only if X receives) while the HOT Act supports only altruistic donation.

Xenotransplantation is transplantation between different species. It offers the possibility of unlimited organ supply. Failed attempts have been made with great controversy, and remain experimental. Immunological problems remain the main barrier to efficacy. The collective risk of trans-species infection is currently considered greater than the potential benefits to individuals and has led to a moratorium on further xenogeneic organ transplants by the UK Xenotransplantation Interim Regulatory Authority (UKXIRA). There is a wide diversity of opinion on the issue of animal rights and welfare. One opinion is that animals are not people and have no value in their own right and human needs should be given precedence because of our special moral status. A counter-argument is that we are animals ourselves, part of nature, not set apart from it and that animals have their own rights as sentient beings. ◆

Chloroform à la reine

Neil Adams

Neil Adams is Consultant Anaesthetist at the West Suffolk Hospitals Trust, Bury St Edmunds, UK. He qualified from Oxford University and St Thomas' Hospital, London, and trained in anaesthesia in Nottingham, Canada and Cambridge. His historical interests include the social aspects and reaction to the introduction of anaesthesia.

On Thursday 7 April 1853, John Snow administered chloroform to Queen Victoria during the birth of Prince Leopold, hence the expression, 'chloroform à la reine.' The three casebooks of John Snow survive in the library of the Royal College of Physicians in London and document his activities as an anaesthetist from 1848 to 1858. The late Dr Richard Ellis transcribed these books as a supplement to *Medical History.* The use of chloroform by Queen Victoria is described in Snow's own words. Ellis notes the particular care Snow took with this entry and the possible slip of the pen (marked with an asterisk) where the word 'after' should have appeared.

Administered chloroform to the Queen in her confinement. Slight pains had been experienced since Sunday. Dr Locock was sent for about nine o'clock this morning, stronger pains having commenced, and he found the os uteri had commenced to dilate a very little. I received a note from Sir James Clark a little after ten asking me to go to the Palace. I remained in an apartment near that of the Queen, along with Sir J Clark, Dr Ferguson and (for the most part of the time) Dr Locock till a little a(*) twelve. At a twenty minutes past twelve by a clock in the Queen's apartment I commenced to give a little chloroform with each pain, by pouring about 15 minims by measure on a folded handkerchief. The first stage of labour was nearly over when the chloroform was commenced. Her Majesty expressed great relief from the application, the pains being very trifling during the uterine contractions, and whilst between the periods of contracting there was complete ease. The effect of the chloroform was not at any time carried to the extent of quite removing consciousness. Dr Locock thought that the chloroform prolonged the intervals between pains, and retarded labour somewhat. The infant was born at 13 minutes past one by the clock in the room (which was 3 minutes before the right time); consequently the chloroform was inhaled for 53 minutes. The placenta was expelled in a very few minutes, and the Queen was cheerful and well, expressing herself much gratified with the effect of the chloroform.

With regard to the historical context of this case, it is possible that two myths have passed down through history. Firstly, was the doctrine of a campaign opposing the use of chloroform in midwifery and surgery by the Church. This idea arose after the publication in 1848 by Sir James Young Simpson of *The Answer to the Religious Objections Advanced Against the Employment of Anæsthetic Agents in Midwifery and Surgery.* Secondly, was the idea that the use of chloroform by Queen Victoria provided an impetus to the general acceptance of the use of anaesthesia in midwifery. For example, Cartwright states that it was the acceptance of the Queen herself that changed the minds of the opponents, while Longford's biography of Queen Victoria states "It was fitting that the battle royal should be won forDr Simpson by the Queen herself."

Queen Victoria photographed by Charles Clifford.
©National Portrait Gallery.

In examining the use of chloroform by Queen Victoria, Connor and Connor throw considerable doubt on the claim of public acceptance following the Queen's usage, noting that the event was largely ignored by the lay newspapers, and that Snow's own obstetric practice did not increase proportionately after April 1853. Turning to religious objection, again much doubt exists because no single piece of evidence has yet been found in contemporary religious writings confirming such opposition.

Snow's services were to be required at the Palace, once again, on Tuesday 14 April 1857 to administer chloroform to Queen Victoria in her ninth confinement for the birth of Princess Beatrice. ◆

Curare, and Griffith and Johnson's use in 1942

Neil Adams

Neil Adams is Consultant Anaesthetist at the West Suffolk Hospitals Trust, Bury St Edmunds, UK. He qualified from Oxford University and St Thomas' Hospital, London, and trained in anaesthesia in Nottingham, Canada and Cambridge. His historical interests include the social aspects and reaction to the introduction of anaesthesia.

Curare appears in European writing as early as 1516, when Peter Martyr d'Anghera described the arrow poison of the South American Indians. In 1595, Hakluyt also describes it in his work on Sir Walter Raleigh's voyage to South America.

The explorer Waterton brought a curare extract back from the Amazon and in 1814 demonstrated, with the help of Sir Benjamin Brodie and Mr Sewell of the London Veterinary College, that its paralysing effects were transient. They injected a curare extract into a she-ass and kept it alive by ventilation of the lungs with a bellows inserted into the animal's windpipe through a tracheotomy.

The attempted use of curare in clinical practice goes back at least as far as 1858, when Sayres and Burrall attempted, unsuccessfully, to use the drug locally to treat tetanus. Beigel described the clinical effects in man in 1868, using calabash curarine. In 1935, Harold King, working with Sir Henry Dale, isolated the pure curare alkaloid from a specimen in the British Museum, but it took until 1943, for Wintersteiner and Dutcher, working in the laboratories of Squibb, to demonstrate that the curare alkaloids could be extracted from the plant *Chondrodendron tormentosum*. Squibb then went on to produce the first commercial preparation of curare under the trade name *Intocostrin*.

Squibb were able to manufacture the drug in a known strength by the 'rabbit head drop test' being calculated from the smallest amount that would cause a rabbit's head to drop without affecting respiration. The first clinical use was in Omaha, Nebraska, where McIntyre and Bennett were assessing the effect of intravenous *Metrazol* to produce convulsions in the treatment of schizophrenic patients. The violence of the convulsions caused 50% of the patients to suffer spinal compression fractures, but a small dose of *Intocostrin* significantly reduced the fracture rate.

Samples of *Intocostrin* were sent to Professor Rovenstine at Columbia Medical School, where his assistant E M Papper spent the night resuscitating the two patients who received the drug. This led Rovenstine to believe that *Intocostrin* was not safe for clinical use. Cullen, in Iowa, used the drug on dogs, but bronchospasm ensued and he came to the same conclusion as Rovenstine.

Harold Griffith, Professor in Montreal, was approached by Squibb's medical representative, Lewis Wright. He reviewed the work of McIntyre and Bennett, including a film they had made. Noting that the psychiatric patients had not died, he reasoned that the worst possibility was to ventilate a paralysed patient, a technique with which he had gained confidence under the training of Ralph Waters in Madison, Wisconsin (with whom, interestingly, Rovenstine and Cullen had also worked). Griffith agreed to try the drug.

Harold Randall Griffith 1894–1985.
© Osler Library of the History of Medicine, Montréal, Québec, Canada.

On 23 January 1942, Griffith and his assistant Enid Johnson, used *Intocostrin* on a 20-year-old man undergoing appendicectomy. The result is reported as dramatic, the abdominal muscles were completely relaxed, and the surgeon was able to remove the appendix with ease. The anaesthetic record survives, intact, in the Sir William Osler Library in Montreal.

Remarks: *Intocostrin, Squibb (Curare) 3.5 cc given intravenously in 1½ minutes as operation started – no appreciable effect on pulse or respiration. After 5 minutes another 1.5 cc of Intocostrin given. Apparently complete relaxation of abdominal muscles resulted and continued for 20 minutes, during which time cyclopropane was lightened. At the end of this period muscle tone returned, probably from wearing off of curare effect. Cyclopropane was then increased in concentration and anaesthesia continued in the usual way. There was no demonstrable change in pulse, blood pressure or respiration*

.

Shortly afterwards, Griffith and Johnson submitted a series of 25 cases of the use of curare to the journal Anesthesiology and so began a new chapter in the history of anaesthesia. ◆

Punch Drunk

Neil Adams

Neil Adams is Consultant Anaesthetist and Clinical Director, Surgical Services, at the West Suffolk Hospital, Bury St Edmunds, UK. He qualified from Oxford University and St Thomas' Hospital, London, and trained in anaesthesia in Nottingham, Canada and Cambridge. His historical interests include the social aspects and reaction to the introduction of anaesthesia.

Following the introduction of inhalational anaesthesia in 1846, it did not take long for the humorous possibilities to be explored. The cartoon shown here and nine articles appeared in *Punch* during 1847 and 1848.

Given that society in 1846 was very different from that of today, with child labour, slavery in America, and literacy rates of about 20% in some socioeconomic groups, it is interesting to see that a humorous perspective was already well developed.

WONDERFUL EFFECTS OF ETHER IN A CASE OF SCOLDING WIFE

Patient – "This is really quite delightful – a most beautiful dream"

Animal rights

Clearly concerned for the welfare of animals in 1847, *Punch* reports that the inhalation of ether had been resorted to professionally by various pork butchers with great success. "The chief difficulty they experienced had consisted of the opposition of the patient; but when the natural obstinacy of the pig had been overcome, and he had been persuaded to inhale the ether, he had been killed with comfort to himself, and without disturbance to the neighbourhood." Other uses reported include the opening of oysters, and the skinning of eels.

Punch noted that in France, bees had been etherized so as to be able to take their honey while they were in a state of inaction, without the necessity of destroying their lives. The article extrapolates to find a method of etherization that would render John Bull insensible to the operation of income tax!

Stages of anaesthesia

An article of 1847 suggests that the first description of the stages of anaesthesia may not be from Snow or Guedel, but from a fictional character, Cimabue Potts, a historical painter.

Potts writes: ''Sir – I have imbibed ether, and shall continue to do so till I have painted a work destined for immortality, which I confidently expect to do next week. I subjoin what I remember of my feelings during the ethereal state.

First stage: Imagined myself in Rome, in company with Rafaelle, Mr. Etty (RA), and the editor of *Art-Union*, the latter in chains, and trampled upon by us in succession (you are aware that I have been the butt of his malignant criticism for years).

Second stage: Felt immortal, and was congratulated by the daily and weekly papers.

Third stage: Produced an historical picture, 25 feet by 15, representing the discovery of the dead body of Harold after the Battle of Hastings; received the premium of £700 from the Fine Arts Commissioners, and was dragged home by the populace in my own carriage!

Last stage: Recovered and found myself, with the bladder empty, in the Goose and Gridiron."

Politics

The absence of items in *Hansard* suggests that Parliament was indifferent to the introduction of anaesthesia. The *Times*, reporting from an article in *Punch* points out political possibilities.

"However desirable this invention may be in a surgical point of view, we have every hope that it will soon be applied to the more delicate operations of politics. How useful would it have been during the last session, when the Conservative body had to undergo the painful process of the cutting off of so many members! Had the new process been known, the political amputations might have taken place without any pain. Considering the frequent severings that Sir Robert Peel has been obliged to undergo, and the numerous occasions upon which he will again most probably feel it necessary to submit to amputations, the new process must be most welcome. As the plan is calculated to prevent pain in all cases of removal, we should recommend its being tried on the next occasion of a removal from office by Her Majesty's Ministers. This has always been a most distressing operation, from the suffering it has inflicted on the parties concerned; and all the friends of humanity must be delighted at the prospect there is of its becoming an entirely painless proceeding." ◆

The Royal Humane Society Resuscitation Guidelines – 1774

Neil Adams

Neil Adams is a Consultant Anaesthetist and Clinical Director, Surgical Services, at the West Suffolk Hospital, Bury St Edmunds. He qualified from Oxford University and St Thomas' Hospital, and trained in anaesthesia in Nottingham, Canada and Cambridge. His historical interests include the social aspects and reaction to the introduction of anaesthesia.

It is impossible to define when the techniques of resuscitation began. They may have ancient origins, for example, there is archaeological evidence of trephining – removing a piece of bone from the skull. Another example is found in the Bible, the Second Book of Kings, Chapter 4, verses 34 and 35, in which the Prophet Elijah is described as bringing back the dead child of the Shunamite woman by warming and mouth-to-mouth resuscitation. In this long history, the work of the Royal Humane Society is fascinating.

In the 18th century, drowning was one of the main causes of death following the development of the canal system as a means of transport. In the UK, the Royal Humane Society had its origins in a meeting held on 18 April 1774 at the Chapter Coffee House, St Paul's Churchyard, London, between Dr William Hawes and Dr Thomas Coggan. Each invited 16 of their friends to help found the Society. Initially 'The Society for recovery of persons apparently drowned', this became 'The Humane Society' in 1776 and 'Royal' in 1787.

The remarkable instructions of the Society as to how revival of the apparently dead may be achieved are printed below. Figure 1 shows the apparatus of the Society; this example is kept in the Museum of the Association of Anaesthetists.

1 The apparatus used by the Royal Humane Society. © The Association of Anaesthetists of Great Britain and Ireland.

Cautions

1 Lose no time

2 Avoid all rough useage

3 Never hold the body up by the feet

4 Nor role the body on casks

5 Nor rub the body with salt or spirits

6 Nor inject tobacco smoke or infusion of tobacco

Restorative means

Send quickly for medical assistance: but do not delay the following measures.

i Convey the body carefully, with the head and shoulders supported in a raised position, to the nearest house.

ii Strip the body, and rub it dry, then wrap it in hot blankets and place in a warm bed in a warm chamber.

iii Wipe and cleanse the mouth and nostrils.

iv In order to restore the natural warmth of the body:
- 1 Move a covered warming pan over the bed.
- 2 Put bladders or bottles of hot water, or heated bricks to the pit of the stomach, the armpits, between the thighs, and to the soles of the feet.
- 3 Foment the body with hot flannels, but if possible,
- 4 Immerse the body in a warm bath, as hot as the hands can bear without pain, as this is preferable to the other means for restoring warmth.

v In order to restore breathing, introduce the pipe of a common bellows (where the apparatus of the Society is not available) into one nostril, at the same time drawing downwards and pushing gently backwards the upper part of the windpipe, to allow more admission of air; blow the bellows gently, in order to inflate the lungs, till the breast be a little raised and make a moderate pressure with the hand upon the chest. Repeat the process till life appears.

vi Inject into the stomach, by means of an elastic tube, half a pint of warm brandy and water, or wine and water.

vii Apply sal volatIle or hartshorn to the nostrils.

If apparently dead from noxious vapours etc.

1 Remove the body into a cool fresh air.

2 Dash cold water on the neck and face and brush frequently.

3 If the body be cold, apply warmth as recommended.

4 Use the measures recommended for inflating the lungs.

5 Let electricity (particularly in accidents from lightening) be early employed by a medical assistant.

Some of these themes would be familiar to those engaged in resuscitation in the 21st century, demonstrating a repeated historical cycle of methods discovered, then forgotten, then re-discovered. ◆

Anaesthetic Records

Tim Peachey

Tim Peachey is Consultant Anaesthetist at the Royal Free Hospital, London, UK. He qualified from King's College Hospital, London. His clinical interests include liver transplant and cardiac anaesthesia. His research interests include computerized record-keeping systems.

For almost as long as anaesthetics have been given, a comprehensive system of recording their conduct and effect has been emerging. When John Snow was practising anaesthesia in the 1850s he kept comprehensive notes on the conduct of his anaesthetics in a notebook. Although less systematized than 'modern' anaesthetic records this approach had the advantage that all the records were in a central location and were available for review. Contrast this with today's method of filing anaesthetic records among a plethora of other documents in a case file. All anaesthetists are aware of the limitations of the modern approach, the usefulness of each record, for tracing the anaesthetic history is dependent on the availability of the case file and a record having been filed. Even in Snow's time, the anaesthetic records contained histories of previous anaesthetic episodes. In the search for a good record-keeping solution, the merits of manual and computer-based systems should be considered.

Purposes of the anaesthetic record

Anaesthetics are probably documented to a greater degree than any other aspect of medical practice. Manual systems of data recording, document the effects of anaesthesia and surgery on the patient at a time resolution typically 12-fold greater than that of manual data recording systems in critical care units. The purpose of such detailed record keeping is multiple. Several authors have tried to define the optimum content of the anaesthetic record, but its format has remained a matter of local preference and has not been standardized. Various functions have been agreed by a number of authors.

Facilitating clinical care during anaesthesia – in designing, or compiling an anaesthetic record, the facilitation of clinical care should be the primary consideration. Although records from two centres are seldom the same, most have similar features. All are based on a time-based chart of physiological observations, drug and fluid administration, events and notes. All should contain information about the patient and their preoperative status together with an operative procedure description (proposed and actual). Most records contain elements of a preoperative checklist and all contain some description of the anaesthetic methodology or technique. As the chart is created during anaesthesia, patterns of response may emerge and trends may be noted. An ideal record should contain all the information required for another anaesthetist to continue the conduct of anaesthesia safely, though this goal is seldom achieved in practice. It follows that the recording of adverse events is as important, if not more important, than recording a series of normal values. However, adverse events are less likely to be recorded than normal occurrences. Other features may be included, which are specifically designed to improve care or avoid an adverse outcome, for example a tick box labelled 'Throat pack removed'.

Augmenting the handover processes – the handover of any anaesthetized or recovering patient from one person to another is a potentially hazardous process break. There are protocols for the handover of patients in post-anaesthesia care areas or recovery rooms and recent guidance has been issued in the UK. The presence of an anaesthetic record does not diminish the obligations of anaesthetists in this regard; a well-kept record should answer most questions that arise during the care of the patient.

Advising the providers of future care – implicit in the safe conduct of anaesthesia is the ability to predict difficulties in management or the likelihood of adverse outcomes. One of the most valuable pieces of information sought from patients in preoperative assessment is their anaesthetic history, particularly any previous problems. A previous anaesthetic record greatly assists in planning another episode of care. A section of the record that documents warnings to future care providers has been advocated. Also, the certain knowledge that a patient is straightforward to intubate is of much greater value than the patient's own recollection of there having been no problems with a previous anaesthetic.

Informing statistical processes – collective sets of anaesthetic records may be used to assess the quality of care offered by a group of anaesthetists as well as providing activity data that may be useful in service planning. Anaesthetics are administered in huge numbers, with a low risk of a negative outcome. The serious adverse effects of anaesthesia are now so rare that their prediction and assessment of probability is difficult. Variations in outcome are subject to a large number of variables, the individual effects of which may be quite subtle. For example, the number of variables that affect the rate of postoperative nausea and the uncertainty that any one approach to the problem will be effective may make the analysis of anaesthetics in large numbers desirable.

Reviewing clinical care – anaesthetic records are the only method by which the quality of anaesthetic care can be evaluated after the passage of time from the episode. Memory of events deteriorates, therefore accurate documentary evidence is essential if retrospective reviews of care are to be possible. Many of these reviews are for clinical audit and clinical governance but some records will be used for complaint investigation and even litigation. Poorly kept and incomplete records may be eliminated from group audits, but such records will reflect poorly on the standard of care delivered when subject to legal scrutiny.

Optimum content

The anaesthetic record set suggested by the Royal College of Anaesthetists is shown in Figure 1. Recommendations from the Australia and New Zealand College of Anaesthetists are similar, but slightly broader in scope, less detailed and emphasize the recording of problems and their management. Documentation of the name of the supervisor and the level of supervision, when trainees are administering anaesthesia, is advocated.

The list in Figure 1 is not an exhaustive account of everything that could be included, but offers sound guidance. The inclusion of information regarding the checking of anaesthetic equipment is controversial. An anaesthetic record that contains the question 'Anaesthetic machine checked – Yes / No' is most unlikely to be answered in the negative. Nor can it be inferred from looking at a given record that the equipment was checked immediately before the anaesthetic in question. The documentation of critical incidents (especially those where no harm results) in the anaesthetic record has not been widely adopted, nor, in the author's opinion, is it likely to be in the near future. In the UK, printed anaesthetic records vary considerably from the suggested record set.

Suggested anaesthetic record set [1]

Pre-operative information
Patient identity
- Name/ID no./gender
- Date of birth

Assessment and risk factors
- Date of assessment
- Assessor, where assessed
- Weight (kg) (height (m) optional)
- Basic vital signs (blood pressure, heart rate)
- Medication (including contraceptive drugs)
- Allergies
- Addiction (alcohol, tobacco, drugs)
- Previous general anaesthesia, family history
- Potential airway problems
- Prostheses, teeth, crowns
- Investigations
- Cardiorespiratory fitness
- Other problems
- ASA grade ± comment

Urgency
- Scheduled – listed on a routine list
- Urgent – resuscitated, not on a routine list
- Emergency – not fully resuscitated

Peroperative information
Checks
- Nil by mouth
- Consent
- Premedication, type and effect

Place and time
- Place
- Date, start and end times

Personnel
- All anaesthetists named
- Qualified assistant present
- Duty consultant informed
- Operating surgeon

Operation planned/performed
Apparatus
- Check performed, anaesthetic room, theatre

Vital signs recording/charting
- Monitors used and vital signs (specify)

Drugs and fluids
- Dose, concentrations, volume
- Cannulation
- Injection site(s), time and route
- Warmer used
- Blood loss, urine output

Airway and breathing system
- Route, system used
- Ventilation: type and mode
- Airway type, size, cuff, shape
- Special procedures, humidifier, filter
- Throat pack
- Difficulty

Regional anaesthesia
- Consent
- Block performed
- Entry site
- Needle used, aid to location
- Catheter yes/no

Patient position and attachments
- Thrombosis prophylaxis
- Temperature control
- Limb positions

Postoperative instructions
- Drugs, fluids and doses
- Analgesic techniques
- Special airway instructions, including oxygen
- Monitoring

Untoward events
- Abnormalities
- Critical incidents
- Preoperative, peroperative, postoperative
- Context, cause, effect

Hazard flags
- Warnings for future care

[1]Reproduced with permission from the *Royal College of Anaesthetists Newsletter* 1997; **36**

Manual records

About 10% of an anaesthetist's time is spent making records during anaesthesia. This might be regarded as time that could have been spent being more vigilant, considering options for the patient, or planning ahead, but the act of record keeping probably ensures that the anaesthetist has mentally registered the values of the parameters he is recording. Attention to the chart may make the detection of trends more likely. However, when critical events occur, the first task that is lowered in priority is record keeping. The value of an anaesthetic record after a critical event may be seriously compromised by inaccuracies in time and recorded values. One study (using simulation) found that over 20% of values recorded during critical incidents were in error by at least 25% and some by 100%. The variability between recorded values and actual values has been known for some years, as has the tendency for real data to be smoothed before they are recorded, so that extreme values and sudden changes are attenuated. It is perhaps not surprising that we feel the desire to make things look good but every anaesthetist knows that most patients have some measurable physiological disturbance during the course of an anaesthetic. The lack of objective evidence for this is a failure of documentation rather than reflection of reality. If records are misfiled, lost or inaccessible the value of keeping them is largely negated.

Computerized records

Computerized anaesthetic records have been in use for over 20 years and commercial systems have been available for at least 10 years, but they have yet to gain widespread acceptance. The medical profession is now embracing electronic patient records but anaesthesia has been passing up the opportunity for at least 10 years. This may be due to the perception among hospital managers that anaesthesia is expensive enough as it is and that computerized record-keeping systems do not save money. (Failure to save money has been a feature of most medical informatics projects and is a poor test of benefit.) The profession has also been slow to accept the benefits of such systems and associates some risk with their adoption. Computerized recording systems offer a number of benefits. They are more accurate than manual data recording systems and offer more detailed data collection for no additional effort. Some systems can now offer documentation of an anaesthetic, even for the shortest of cases, in less time than it takes to write it down. However, there is a perception that the accurate recording of data and the possible recording of monitoring artefacts, may make the defence of the conduct of anaesthesia more difficult. In a sense this is illogical because physiological variability and monitoring artefacts are normal occurrences during anaesthetic practice, not faults of individual anaesthetics or anaesthetists. However, because anaesthetists do not generally record them, this is difficult to prove. Perhaps the most persuasive argument in favour of computerized systems is that all records are kept by the anaesthetic department in a central store and can be recovered instantly for reference, collective statistical analysis, comparison, quality control, transmission to other interested parties or for defence.

Legal aspects

The law does not prescribe any particular format or content for an anaesthetic record. In fact, there is no statutory requirement for a record to be kept. Common law, however, provides that the standard of care offered to a patient has to be higher than 'that which could not be condoned by a reasonable body of one's peers' (the Bolam principle). Therefore, as most anaesthetists keep records, it must be regarded as required in common law to do so. Powers has stated: 'As a matter of evidence, medical records do not prove themselves any more than a newspaper article is proof of the facts to which it relates'. It would seem reasonable though, to assume that a record compiled electronically by automatic collection of data from a vital signs monitor would gain higher standing as evidence of fact than a manual set of notes that are known to suffer from inaccuracies in transcription. While the possibility of tampering with computerized data exists, in reality it is highly unlikely. If an anaesthetic is properly conducted and accurately recorded, it is difficult to see how the anaesthetist's legal position could be damaged by this, almost incontrovertible, evidence. The strength of such evidence is related to the likelihood that a set of data fit with each other and with the story they are asked to support. Figure 2 shows data taken from a real case record. The fall in end-tidal carbon dioxide associated with a period of hypotension, and the subsequent after-drop in temperature fit well with sudden massive blood loss and fluid resuscitation. ◆

Clinical Service and Audit

Ranjit Verma

Ranjit Verma is Consultant Anaesthetist at the Derby City General Hospital. He qualified from the University of Manchester and is the Honorary Secretary and Chairman Elect of the Society for Computing and Technology in Anaesthesia (SCATA) and a council member of the Association of Anaesthetists of Great Britain and Ireland (AAGBI).

The purpose of audit is to provide an efficient, safe and reliable healthcare service that offers the best quality patient care achievable under the circumstances. By looking critically at the processes, mechanisms and quality of healthcare delivery, areas of deficiency can be identified and improvements made or remedial action taken. To facilitate this, various organizations have been formed and many processes created. National Health Service (NHS) Trusts are now required to implement these processes and can be severely penalized if they fail to comply with them.

Patient expectations have also changed following a series of highly publicized events including problems at the Bristol surgical cardiac unit, which resulted in two surgeons being struck off the medical register in 1998 and Dr Harold Shipman's conviction for murder in January 2000. Therefore, it is imperative that a culture of self-examination, accountability and openness is established and becomes part of normal clinical practice.

King's Fund Organizational Audit

King's Fund is an independent charitable organization that was founded in 1897. Its aims are to support health, mainly through improving the quality of health and social care services. It supports research, addressing issues relating to funding of the NHS and the inequalities of access to healthcare, and promotes development work in service provision, such as implementing clinical effectiveness, better services to carers and education in NHS management.

In 1989, it launched a project called the King's Fund Quality Programme, which looked at the quality of healthcare delivery in NHS hospitals based on specified standards. In 1990, this became the King's Fund Organizational Audit and most organizations delivering healthcare, both NHS and private, subscribed to its standards. In 1998, the King's Fund Organizational Audit was relaunched as the Health Quality Service.

Health Quality Service

The Health Quality Service is an independent charitable organization and is the successor to the King's Fund Organizational Audit. It gained accreditation from the UK Accreditation Services as an ISO9002 certified body in 1999. This means that it can award ISO9002 certification to health organizations that fulfil its criteria. It has developed accreditation criteria for acute hospitals, community, mental health, learning difficulties, palliative care and hospices. Its programme for accreditation is voluntary and several NHS Trusts and many private hospitals subscribe to its quality standards.

Audit Commission

The Audit Commission was first established in 1983 to regulate auditors of local authorities in England and Wales. In 1990, its role was extended to include the NHS. Its remit now covers over 13,000 bodies who, between them spend nearly £100 billion of public money annually. The Audit Commission is an independent body which appoints auditors to assess and monitor the way the money is spent and to determine if the various bodies get value for money. Its most recent project involving clinical services is the Acute Hospital Portfolio. This is a collection of audits available for auditors to undertake at acute hospitals. They focus on key service areas or resources within the Trusts. Each year the Commission plans to select up to four topics from the portfolio to survey across all the Trusts in England. The topics are clinical and non-clinical.

National Institute for Clinical Excellence (NICE)

NICE was established as a Special Health Authority of the NHS in 1999. Its purpose is to provide authoritative, robust and reliable guidance on current 'best practice' to patients and their carers and to health professionals and the general public. Projects are undertaken at national level and evaluated by a panel of experts, which includes NHS professionals and members of the lay public, including clinical professionals, patient and carer representative groups, NHS managers, members from industry and research bodies and from the Royal Colleges and professional societies and associations. NICE produces three types of guidance.

Technology appraisals are independent reviews of the clinical usefulness and cost-effectiveness of specific technologies such as the use of a drug, equipment, diagnostic technique, surgical procedure or health promotion activity. Technology appraisal can take up to 12–14 months to produce.

Clinical guidance is produced for healthcare professionals and patients to help them make the right decisions about healthcare in specific clinical circumstances. These guidances are intended to be used in conjunction with current knowledge to help make the right decision for a given scenario. Clinical guidance can take about 2 years to produce.

Interventional procedures relate to the efficiency or effectiveness of new procedures, for example the use of a new surgical technique and its implications in the wider context.

Commission for Health Improvement (CHI)

CHI was launched by the Government in April 2000 aimed at improving the quality of patient care in the NHS. One of its most significant aspirations is to abolish the inequality of standards that exists throughout the NHS. CHI aims to achieve this by undertaking clinical governance reviews, by visiting every NHS Trust and Health Authority including Primary Care Groups, Local Health Groups and General Practices in England and Wales on a rolling programme every 4 years. It investigates any serious failures and checks that the NHS is following national guidelines. It makes its findings public. A typical review takes 17 weeks and has clear objectives and deadlines, which include consultation, data collection and analysis.

Commission for Healthcare Audit and Inspection (CHAI)

CHAI is the next step in the Government's plans to monitor quality of healthcare delivery in the NHS and is planned to be implemented by 2004. It will have appropriate legislation from Parliament and its purpose is to inspect every part of the NHS and private healthcare. It will monitor and review the quality of healthcare delivery and assess how well the NHS is using its funds. It will report to Parliament. It will take over all of CHI's current functions and the National Care Standards Commission's (NCSC) responsibilities for inspecting the private health sector. The Audit Commission's value-for-money studies relating to healthcare, as well as some of its other functions, will also come under CHAI's umbrella, and it will be responsible for a star rating system for NHS hospitals and for instigating special measures in those organizations that fail.

The NHS Litigation Authority (NHSLA)

The NHS Litigation Authority is a Special Health Authority that handles claims and indemnifies NHS bodies in respect of both clinical negligence and non-clinical risks. Clinical negligence claims are handled through the Existing Liabilities Schemes for pre-1995 claims, and the Clinical Negligence Scheme for Trusts for incidents after April 1995.

The incidence of claims against clinical negligence continues to rise. In 1999/2000, the NHS spent £386 million in settling negligence claims and it is estimated that the net value of claims outstanding against the NHS alleging clinical negligence is about £2.6 billion. There is also an estimated liability of a further £1.3 billion for negligent episodes that are likely to have occurred, but for which claims have not yet been received. On average, claims take over 5 years to resolve and there were 23,000 claims outstanding in 2002.

Clinical governance

Clinical governance strives to improve and assure a high standard of clinical practice. It was first described by the Government in 1998 as 'a new system in NHS Trusts and primary care to ensure that clinical standards are met, and that processes are in place to ensure continuous improvement, backed by a new statutory duty for quality in NHS Trusts'. The responsibility for clinical governance rests with the chief executive of each Trust, but it is usually implemented jointly by consensus between senior management and clinicians. The process is open to public scrutiny and every clinician is required to take part. It is a multifaceted process and involves participation in several activities such as clinical audit, education and training, research and development and risk management.

Evidence-based medicine

Evidence-based medicine is a process of systematically reviewing, appraising and using clinical research findings to aid the delivery of optimum clinical care to patients. It is seen as increasingly important in assuring clinical effectiveness in terms of treatments and of cost-effectiveness. Evidence is gathered from existing sources such as research and scientific reviews, and is subjected to a critical appraisal. Critical appraisal is a method of assessing and interpreting the evidence by systematically considering the validity, results and relevance to the problem being considered. Following the appraisal process, evidence-based guidelines are produced and disseminated for implementation.

Clinical effectiveness

Clinical effectiveness is the extent to which specific clinical interventions do what they are intended to do (i.e. maintain and improve health and maximize health gain from available resources). It consists of obtaining evidence (e.g. from journals, national guidelines or other sources), implementing changes based on the evidence, and assessing the effect of the changes.

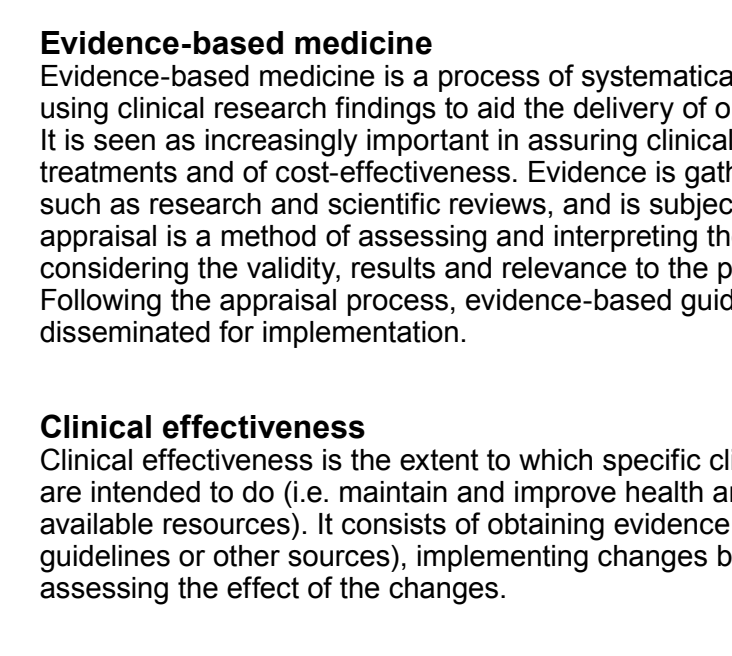
Risk management

No activity is without risks. In healthcare delivery there can be risks to the patients, to the practitioners and to the organization providing the healthcare service. Risk management is a process that tries to keep these risks to a minimum. If things go wrong, the process attempts to find out why and ensures that it does not happen again. A risk management strategy should ensure a safe working environment. Training should be appropriate for the tasks being undertaken and untoward or critical incidents should be easily identified and reported. There should be an effective claims management mechanism in place.

Clinical audit

The NHS Executive defines clinical audit as 'the systematic critical analysis of the quality of healthcare, including the procedures used for diagnosis, treatment and care, the use of resources and the resulting outcome and quality of life for patients. It embraces the work of all healthcare professionals'.

Clinical audit can be retrospective, prospective or related to significant events. It is a cyclical process in which standards are agreed and data collected. Analysis of the data shows if the standards are being met. If not, changes are planned and implemented and data collected for a second time and analysed to see if any improvements have resulted from these changes (Figure 1). It is important to realize that data are collected and analysed on two occasions. The first data collection is to establish the current position and the second is to see if any improvements have been made. The audit process should allow sufficient time for the changes to take effect and it may be necessary to repeat the audit cycle several times before the benefit is seen.



1

Clinical audit is likely to be successful if it is done voluntarily rather than being imposed. The topic selected should be relevant and potentially beneficial to the patient or to the organization and amenable to improvement. The whole process should be trans-parent. The criteria being measured should be meaningful and clearly defined. The standard against which the criteria are measured should be realistic and based on what is right for the local circumstances. Careful planning of how the audit will be done is critical and the methodology should be kept as simple as possible. Only data that are relevant to the topic should be collected (collection of superfluous data is time-consuming and wasteful). Data collected for clinical audit, unlike clinical research, is not usually subjected to rigorous statistical techniques, simple percentages are usually sufficient.

If the first run shows that the stipulated standards have been met, it is important to consider if this is because the performance is genuinely satisfactory or whether the standards were set too low. If the analysis shows that standards are not being met, changes need to be agreed and implemented and the process repeated to see if the changes have achieved an improvement.

PDSA (Plan, Do, Study, Act) cycle

The PDSA cycle (Figure 2) is a tool for bringing about change in an organization by breaking it down into small manageable elements. It consists of looking at small areas to see if improvement can be made to benefit the whole. Large numbers of individuals involved in small, simple PDSA cycles are more productive in terms of seeing the process through and instigating minor changes that make a significant difference to the whole.

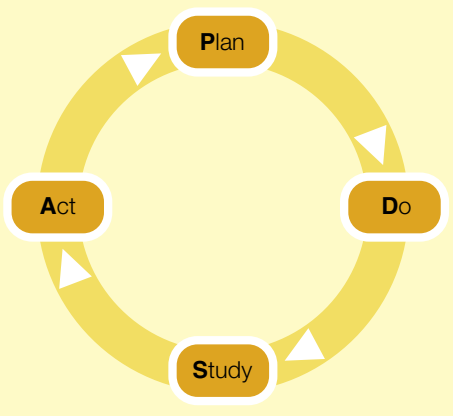
Plan – a small area of perceived benefit is identified by any individual working in a given environment. A change in working practice is planned with clear objectives in mind. It is important to be aware of who might be affected by this change.

Do – the plan is executed over a short period of time. Careful documentation and unexpected observations are recorded. Analysis of the results as they are collected may be started.

Study – the analysis is completed and results compared with predictions.

Act – if the original precept is justified, the proposed changes are incorporated as a matter of policy and disseminated throughout the organization. If there is no significant gain, the cycle may be repeated or the idea for that particular change dropped.

The PDSA cycle



2

Informatics

The Government has committed itself to an expenditure of £1 billion over a 7-year period to modernize the NHS inform-ation technology (IT) infrastructure. The programme, which was started in 1998, focuses on five main areas:

- NHS Direct
- NHS Net
- National Booked Admissions Project
- National Electronic Library for Health (NeLH)
- Electronic Health Record.

All Trusts have been building up their IT infrastructures to enable them to exploit these developments. As these technologies come on stream it should make audit of clinical services easier, simplifying data collection, analysis and report generation. The use of e-mail to facilitate communications in the NHS is already well established. Medline and Embase offer excellent electronic access to peer journals while the Cochrane Collaboration, through their network of collaborative review groups, provide objective reviews of various topics to enable healthcare professionals to improve clinical management of patients. ◆

Communication: Health Records

Roger M Tackley

Roger M Tackley is Consultant Anaesthetist at Torbay Hospital, Torquay. He is devoting increasing amounts of time to developing electronic patient record systems for the South West region. He has been involved in the NHS Clinical Terms Project, Headings Project and Maternity Data Care Project, and is currently the Chairman of the Society for Computing and Technology in Anaesthesia.

Treating and caring for patients usually involves a team of clinicians who work different shifts and may work in different locations. Unless there are good methods of communication, clinical care will be delayed or compromised. The limitations of holding health records on paper are becoming more obvious as the throughput of patients increases, staff work shorter shifts with more handovers, patients demand access to their records and new rules for confidentiality are introduced. In response to this, the NHS published *Information for Health* in 1998, which outlined its plans to computerize hospitals and the benefits that would follow to patients, staff and public. A key target is that all acute hospitals will have an Electronic Patient Record by 2005. This was supported by another White Paper in July 2002 entitled *Delivering 21st century IT support for the NHS*.

Health records

The importance of clinical records is often underestimated. According to the Audit Commission report *Setting the Record Straight* in 1995, clinicians spend at least 25% of their time recording, reading or manipulating information. Health records are kept for several reasons.

Record care given – to monitor progress and reaction to different treatments. It also records what has been explained to the patient.

Communication – information is shared among the clinical team and, increasingly, with the patient.

Source of data for aggregate analysis – information for audit and clinical governance is often extracted manually from notes.

Archive – notes are kept as an historical record.

Legal record – notes are often used to support or refute complaints and medico-legal actions.

Standards for clinical record keeping: guidelines for record keeping have been developed by The General Medical Council (GMC) (Figure 1), the Clinical Negligence Scheme for Trusts (CNST), Royal College of Anaesthetists Good Practice Guide (Figure 2), CASPE Accreditation and Development of Health Records and many other clinical bodies. It is the clinician's responsibility to keep good records because so much depends on them. The NHS Litigation Authority uses the standards developed by the CNST to accredit hospitals into different categories of medico-legal risk. This affects the insurance premium each Trust has to pay. It is clear from the standards (see NHSLA web site) that there is less risk, for instance, when different clinical disciplines all use the same health record.

GMC Good Medical Practice 2001 (extract)

In providing care you must:

- 'keep clear, accurate, and contemporaneous patient records which report the relevant clinical findings, the decisions made, the information given to patients and any drugs or other treatment prescribed'
- 'keep colleagues well informed when sharing the care of patients'

1

RCA Good Practice Guide 1998 (abbreviated)

'The record must be such that if another doctor were required to take over the case this record would give him/her systematic and ready access to all the information required'

Points to include

- Basic data: names of surgeon(s) and anaesthetist(s), date, proposed operation
- Patient identification: name, age, gender, hospital number
- Preoperative assessment: relevant history, physical examination, drugs, allergies
- Anaesthetic technique
- Intravenous drugs administered
- Relevant equipment monitoring
- Patient monitoring used: recommendations of the Association of Anaesthetists
- Physiological variable recorded: not less frequently than every 15 minutes
- Fluid balance: evidence of venous cannulation and record of fluids
- Postoperative pain relief: clear and appropriate postoperative analgesic orders
- Other postoperative instructions
- Critical incidents and complications must be accurately documented
- Handover from one anaesthetist to another should be noted

2

Archiving NHS records: in the UK, there are statutory requirements for how long health records must be kept. In the case of hospital records some examples are:

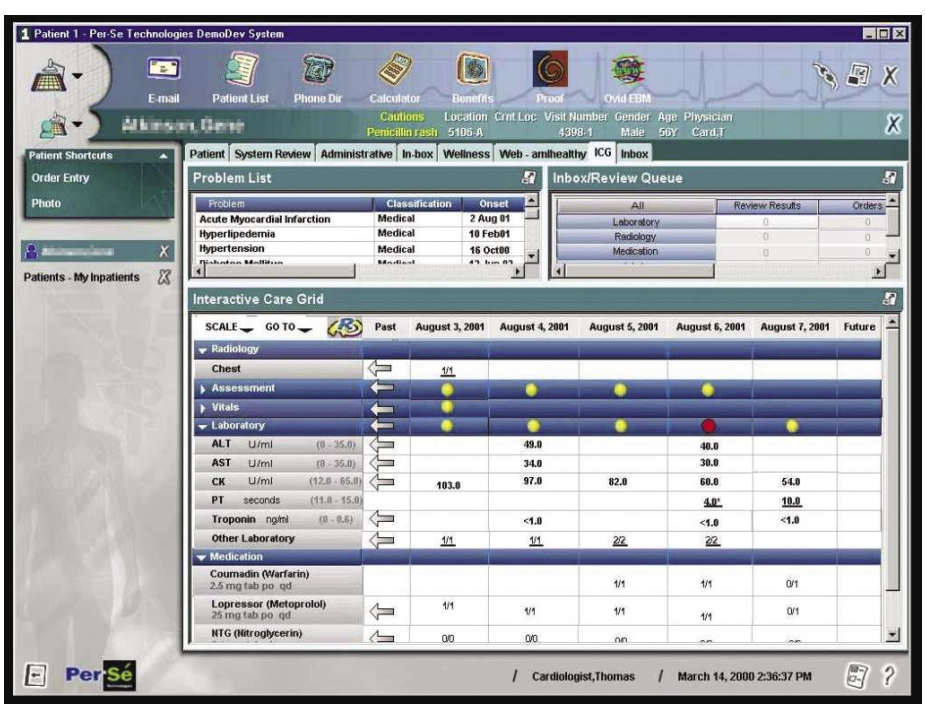
- 8 years, in general, unless specified below
- children – up to 25th birthday
- donor records – 11 years post-transplantation
- maternity – 25 years
- mentally disordered – 20 years after last treatment
- patients in clinical trials – 15 years after end of treatment
- litigation – 10 years
- audit documents – 2 years
- theatre registers – local decision in consultation with health professionals.

Electronic patient records (EPR)

The NHS defines EPR as 'A record containing the patient's personal details (demographics), their diagnosis or condition, and details about the treatment/ assessments undertaken by a clin-ician. Typically it covers the episodic care provided mainly by one institution.' In practice, there are separate EPRs for a patient in a number of Trusts, GP surgeries and specialist clinical systems (e.g. anaesthetic record keeping systems). The NHS has defined six levels for EPR; each builds on the previous level:

- clinical administrative data
- integrated clinical diagnosis and treatment support
- clinical activity support
- clinical knowledge and decision support
- specialty specific support
- advanced multimedia and telematics.

Telemedicine allows clinicians in remote areas to access expert advice from specialists. Other multimedia applications allow the storage of video or sound clips in the patient's notes. Well-designed EPR screens allow a user-defined composite view of patient information. Figure 3 shows a problem list, an in box of current messages and a timeline summary of clinical results. The screen is interactive so the clinician can click on any item and find more details, and if security allows, edit or add further orders.



3 Example of electronic patient record screen.

Electronic health record (EHR)

The NHS defines EHR as 'the concept of a longitudinal record of patient's health and healthcare – cradle to grave. It combines the information about patient contacts with primary healthcare as well as subsets of information associated with the episodic elements of care held in EPRs'. EHRs will probably follow the introduction of EPRs; pilot sites are expected to be running by 2005.

The use of an EHR is epitomized in the following scenario. There is an emergency admission of a confused, semiconscious patient with abdominal pain following a road traffic accident. Using the details found in his wallet, it is realized that he is not on the hospital patient administration system, and so the EPR software is used to access the National Strategic Tracing Service (NSTS) to obtain his NHS number. Doctors treating this patient will then have access to the EHR and using the patient's NHS number can look up his:

- current medication (e.g. insulin)
- current diagnoses (e.g. diabetes, porphyria, angina)
- previous contacts – shows current GP and last admission to hospital.

It is then possible to contact the last hospital for details of any previous anaesthetic and possibly obtain an electronic reply. Even without it, the anaesthetist is forewarned about many aspects that improve the patient's care.

Clinical language

If information is to be shared, clarity is essential. To share information, clinicians must use the same language. For instance, there are many ways of recording a prolonged suxamethonium effect:

- suxamethonium apnoea
- sux apnoea
- scoline apnoea
- prolonged succinylcholine block
- dual block.

All of which can be further confused by spelling mistakes. This problem is exacerbated by the use of computers, which are very good at legible recording and rapid display, but can interpret only what they have been programmed to recognize. Therefore a search for all the 'scoline apnoeas' will not automatically find the 'sux apnoeas'. To improve communication between disciplines and to allow computerization of health records a comprehensive, but flexible, set of terms must be used.

Statistical classifications

For many years, the NHS has been compiling statistics based on diagnoses and operations recorded during a hospital admission. For accuracy, there are strict rules about which codes must be used for which concepts. The International Classification of Diseases (ICD, now in version 10) and the Office of Population Censuses and Surveys (OPCS) classification of operations and procedures (version 4) have been used for many years to code diagnoses and operations which are then sent to the Department of Health hospital episode statistics (HES) department for aggregation.

One disadvantage of these classifications is that the terms used are often unsuitable for clinical use; for example, 'Epidural anaesthetic using sacral approach', 'Biopsy of cerebellum NEC'. Despite this, many electronic systems incorporate these terms and expect clinicians to use them. Another disadvantage is that OPCS4 (about 7000 terms) does not include procedures for nursing or physiotherapy, and is revised so seldom that newer techniques have to be included as OS (otherwise specified). ICD10 (about 11,000 terms) includes very few symptoms and signs so that it is impossible to record a full clerking or nursing assessment.

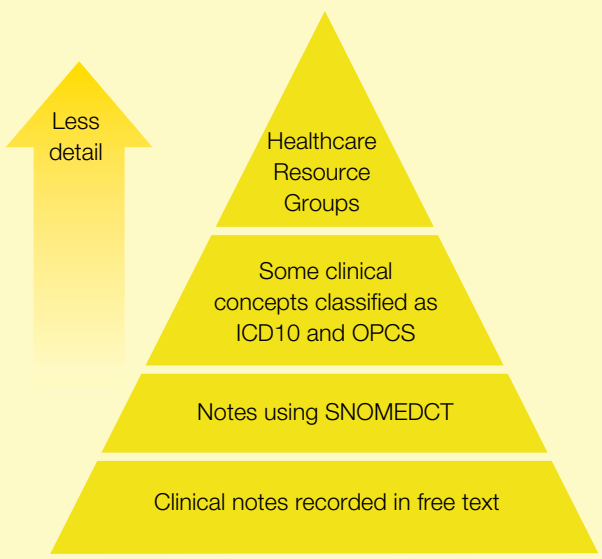
Clinical terminologies

In the UK, over half of GPs use computerized record systems. They need to be able to record symptoms and signs, treatments and operations. In the 1980s, a GP called Dr Read developed a coding system that covered most of what a GP needed to record. This was bought by the Department of Health in 1990 and expanded to include what hospital clinicians needed. The resulting clinical terms (CTV3) were comprehensive (nearly 300,000), but at the time too complex for most system suppliers to take on.

In 1999, the NHS formed an alliance with the College of American Pathologists to merge CTV3 with SNOMEDRT (Systematized NOmenclature for MEDicine Reference Terminology), a terminology in use in the USA. The NHS expect that this new terminology (SNOMEDCT) will be in use in clinical systems by mid-2003. Being an international terminology there are many advantages to clinical system suppliers in using it. SNOMEDCT has 325,000 concepts and over 800,000 terms including synonyms and so it has to be used in a computerized environment.

SNOMEDCT maps to other coding systems (e.g. ICD10 and OPCS4) which means that even if clinical information is recorded only in SNOMEDCT, it can be semi-automatically mapped to other classifications, saving many hours of coding work. Figure 4 shows the progression from recording notes in free text, which is unreliable to analyse, to using SNOMEDCT which allows recording of clinical detail in a reproducible format, and then classifications (e.g. OPCS4) which can be used to generate Healthcare Resource Groups for management purposes.

Aggregation of clinical terminology



Abbreviations: ICD, International Classification of Diseases; OPCS, Office of Population Censuses and Surveys; SNOMEDCT, Systematized Nomenclature for Medicine

Team working

Communication with other members of the clinical team may be by sharing the health record, by correspondence or by conversations (face to face or by telephone). The members of the clinical team may be based on one site but more often are not. Each discipline tends to use their own structures for recording patient assessments; for example, doctors use history and examination headings and nurses use activities of daily living. In order to share information effectively, there must be a structured handover. This may be face to face, but often staff are too busy to do this for all patients. It is recommended that clear summaries of the patient's problems and progress are kept so that any clinician can quickly understand the relevant issues.

Laurence Weed has written many papers on the benefits of Problem Oriented Medical Records. Out of this has come the concept of a shared problem list which is much easier to maintain in an electronic patient record, and is accessible to all authorized staff, at any time and simultaneously if necessary.

Structured notes and discharge summaries

Many studies have shown that doctors prefer to use semi-structured notes for clerking, discharge summaries and anaesthesia. They speed the entry of information, reduce omissions and make it easier to find important facts. GPs prefer to receive discharge summaries set out with sections for: reason for admission, diagnoses, investigation results, operations performed and drugs on discharge. As yet there are no standard headings but the National Headings project (see NHSIA website) has proposed a set that has worked well in many pilot sites and should be used as guidance when designing any structured clinical notes. ◆

Confidentiality and Security of Information

David Jones

David Jones is Consultant Anaesthetist at the Royal Gwent Hospital, Newport, Wales. He qualified from Manchester University and trained in anaesthesia in Birmingham and Cardiff. He gained an MSc in medical informatics at the University of Wales, Cardiff. His interests include day-case anaesthesia, diving medicine and informatics.

Keeping patient information confidential is not a new issue (it is one of the professional responsibilities placed on doctors by the GMC), but because of the rapid rise in electronic processing it has acquired greater emphasis. In addition, there has been increasing dependence on information technology in healthcare and a greater need for information to be made more widely available. To address the consequent security implications, the UK government has produced new guidelines and there have been changes to the law. While much of the provision of security may lie at a corporate level, individual health workers have obligations dictated by these guidelines and laws.

Information security is about preserving confidentiality, integrity and availability of information (Figure 1). Security can never be perfect and there is an element of mutual incompatibility with this triad. Making information more easily available, even for authorized access, can compromise confidentiality and the more the information is made available by accessing, updating and transmitting, the more likely its integrity may suffer. Failure of these three principles can cause problems. Service disruption can occur if vital data are unavailable; there can be loss of privacy; patient harm can result if vital information is incorrect or unavailable, and financial loss can be incurred with the replacement of lost equipment and information. There are also the wider issues of falling foul of the law and loss of public confidence.

Information security

- **Confidentiality** a ‘for your eyes only’ principle, access is confined to those who have authority
- **Integrity** relates to the preservation of information in the form that it was recorded
- **Availability** involves ensuring that information can be provided to the right person when required

1

Department of Health directives

In the UK, a number of government documents relate to information technology. The most relevant are the Department of Health’s prescription for the future use of information technology *Information for Health* and the more technical *Building the Information Core*. They describe computer systems using lifelong electronic records, and are available round the clock to health workers in all disciplines across the whole NHS. The security implications of this are recognized in the documents. It is acknowledged that patients must be made aware of the intention to share information and their objections respected and that all systems should have access controls to preserve confidentiality and adhere to legislation.

Growing confidentiality problems led to the government convening a committee chaired by Dame Fiona Caldicott with the purpose of reviewing the confidentiality issues of patient-identifiable information. This Caldicott Committee identified principles of good practice that NHS Trusts are obliged to adopt for all information flows. Each Trust is required to appoint a Caldicott Guardian, a board-level healthcare professional, whose role is to supervise the production and execution of local policies ensuring confidentiality. Every use of patient-identifiable information must be justified and where possible excluded in information flows. Trusts are responsible for ensuring that only those with authorization and a need to know should have access and even then only to those items that they need to see. Trusts must regularly review their practice and institute appropriate security, ensuring that all uses of information are legal and that those with access are aware of their responsibilities and legal obligations.

Legislation

The 1998 Data Protection Act came into force in the UK on 1 March 2000, replacing the 1984 version and incorporating the 1990 Access to Health Records Act. It defines data processing as collecting, using, modifying, storing and disclosing information. It uses the terms data controller to describe those responsible for processing information and data subject as the person whose information is recorded. It is designed to protect individuals by preventing misuse of their personal information and defines situations in which those who process personal information should register their use. It applies to living persons; the 1990 Access to Health Records governs access to records of the dead.

The Act uses the word ‘data’ where the word ‘information’ might be preferable. In precise terms ‘data’ is a pure collection of values or terms without meaning and as such has no confidentiality issue. Information is data with meaning. I have used the word ‘data’ where it is used in reference to the Act. The Act has eight principles.

Data shall be obtained and processed fairly and legitimately – the criteria given for fairness are that the common law duty of confidence is complied with and that the data subject was not misled into providing information. The data subject should be aware of how the information will be used and who will use it. To be legitimate, either consent must be given or there must be a valid reason as described by the Act. Two schedules define valid use (schedules 2 and 3). Schedule 3 describes the use of sensitive information such as health records, defined by the Act as information relating to the physical or mental health or condition of an individual which have been made by or on behalf of a health professional in connection with the care of that individual.

Data shall be obtained only for specified and lawful purposes – the information cannot be used for a purpose other than that specified without consent of the data subject.

Data shall be adequate, relevant and not excessive – pro-cessed information must be sufficient to perform the specified task but no more than the minimum required data items must be used.

Data shall be accurate and where appropriate up to date – it is a duty of the controller to take reasonable steps to ensure information remains accurate.

Data shall be kept for no longer than necessary – they should be retained only for the duration of the specified purpose.

Data shall be processed according to a data subject’s rights – subjects have a right to see what is recorded about them (subject access), though the Act provides an exception if awareness could be considered harmful to their physical or mental health. For a small fee (£10; though documents such as radiographs can cost up to £50) they are entitled to a description of the information, its purpose, who may use it, a copy in a form they can understand (but not the original) and how it was obtained. Where processing contravenes the Act a subject has the right to prevent processing and demand rectification. There is a right to control use of data where it is used for automated decision making, for instance, where patients may be placed on a waiting list. In such circumstances they have a right to demand a manual analysis. The Information Commissioner, formerly known as the Data Protection Registrar (currently Elizabeth France), can be asked to make an assessment if there is a dispute and, where appropriate, take action against the data controller.

Data shall be protected by appropriate security – the Act does not define appropriate. There is considerable scope for interpretation of what is reasonable.

Data shall not be transferred without adequate protection – this principle governs international transfer. Personal data must not be transmitted ‘unless that country or territory ensures an adequate level of protection of the rights and freedoms of data subjects in relation to the processing of their personal data.’

Consent

The Data Protection Act does not require consent for using personal information in healthcare. The important criterion is that the data controller can show that the specified purpose could not readily be achieved without its use. In any other instance, anonymized information should be used or explicit informed consent obtained from the data subject. The Commissioner interprets healthcare quite broadly to include preventative medicine, medical diagnosis, medical research, the provision of care and treatment, and the management of healthcare services. If patient information is disclosed to others, the data controller has a duty to ensure that those to whom the information is disclosed have the same justification. Because of the proposed wider use of health records in the NHS and potential disclosures the safest option would be to obtain explicit consent to that wider use. While Trusts generally produce leaflets for patients on the use of health records, obtaining explicit informed consent does not seem the norm.

The Act defines other valid processing purposes which could apply to doctors: for the performance of a contract; where required by statute (e.g. infectious disease notification); and circumstances that are considered to be for the greater public good. The latter is open to interpretation. There are many potential consequences of the Act that have yet to be tested in Court. For their own protection, health service employees who record and use patient information should ensure they do so within local guidelines based on Caldicott recommendations, which are governed by the law. These guidelines will develop as the NHS implements technological strategies.

The Computer Misuse Act 1990 protects information systems from the acts of individuals. It makes it an offence to access a computer system without authority and an offence to cause modification to that system.

Other laws relate to information security, but the two described above are the most relevant.

Security measures

Security breaches fall into three categories:

- denial of access
- unauthorized disclosure
- unauthorized destruction or modification of data.

Appropriate countermeasures to deal with these issues require resources, and their cost has to be considered relative to the cost of the assets to be protected and the risk of harm.

Theft prevention is a major security problem in any large organization and loss of equipment is a common cause of denial of access. Controlling physical access to secure areas by ensuring locks are used is essential. There is a need for a cultural change in the NHS where open access to areas that should be secure has been the norm.

Information security covers all communication, even what is spoken, therefore general office security must cover information given over the telephone or sent by fax, in both cases the recipient may not be the intended person. Media containing confidential information should be locked away and sensitive documents shredded when no longer needed.

Network security

Access to hospital systems is generally made over a network and the logging in process attempts to restrict access to those authorized. Each user has a user name provided by the system administrator. This identifies the user to the system for the purpose of determining to which parts of the network and to which processes the user has valid access. This can also offer accountability because an automated system log records the actions of individual users. User names are not secret and a password is also used to authenticate an individual. The password is provided by the system initially, but should be changed to the user’s choice as soon as possible. User names and passwords should not be shared; each user must have their own.

There are some simple basic rules for the choice and use of passwords. Passwords should be memorable and not a random sequence of characters; they should be kept secret and not written down. Personal details such as family member names are too easily guessed. Ideally they should be eight characters or more in length and contain at least one non-alphabetic character. Passwords should be changed from time to time and always changed if compromised. Some of these rules, particularly those relating to length, characters used and the frequency of changes may be enforced by the system.

Different processes, accessible via the same network, may require additional user identification and passwords, though sometimes a single log in provides access to all. The former is more secure, but the latter is more convenient. Users are required to log out of systems when finished and this should be done when leaving the computer to avoid unauthorized access. Monitors should face away from public areas and have a facility for screen blanking or a screen-saver to protect information from prying eyes.

E-mail communications can be read on any of the servers on the electronic route from sender to receiver and therefore are not very secure. Patient-identifiable information should be encrypted in e-mails. The NHS began rollout of encryption tools in March 2002.

Privacy enhancing technologies (PETs)

Access control and encryption are examples of PETs. The term has also been associated with features designed to protect identities that substitute identifiers such as names, addresses and registration numbers with pseudonyms. If it is never necessary to know the identity of the individuals to whom personal data relates, then all personal identifiers should be removed. However, this can lead to problems if future cross-references are needed. Pseudonymization is the process by which pseudonyms replace the true personal identifiers. The latter are not discarded but retained in a secure part of the computer system allowing the original data to be retrieved if appropriate. Normally, only the pseudonyms are visible which allows administrative tasks to be performed on the data by those who have no need to identify an individual patient. It could allow researchers to make more extensive use of medical records without confidentiality becoming an issue.

Logbooks and private practice

The greatest problem for individual doctors is managing the security of patient information that they have sole control of, such as their personal logbooks and private practice accounts. A complete logbook database is often carried around, in many cases on a portable computing device, which is easy to lose. The easiest and safest way to achieve confidentiality is to remove all patient identifiers, although this precludes cross-referencing to other information or authentication of individual records later.

Maintaining a copy of the database is essential; it is surprising how often no backup of essential documents exists. Backup floppy disks or CDs should be verified as a true copy and kept secure. Electronic logbooks have an advantage over paper logbooks because they can be protected by a password and encryption. Therefore, even if others obtain access to the device, the information can be kept secure.

There is no guaranteed way to avoid viruses, but the worst of their effects, destruction of information, can be resolved by having backups. The risks can be reduced by using anti-virus software, which must be used regularly and kept up to date.

Research

In the UK, patient information processed for the purposes of medical research has some exemptions from the Data Protection Act, provided it is not processed to support measures or decisions relating to an individual patient or in such a way that they may suffer damage or distress. These exemptions are that personal data may be kept indefinitely and data may be processed further, provided this is for research purposes. In addition, subject access is not obligatory provided an individual patient will not be identified in the results of the research.

Doctors who independently use databases containing patient-identifiable information must notify the Information Commissioner of that use. This can be done on-line ***(http://www.dpr.gov.uk/notify/4b.html)*** or by telephone (01625 545740) at a cost of £35 per annum. The doctor has an obligation to ensure that patients know what is recorded, who will use it and for what purpose. The duty of confidence requires that reasonable steps are taken to keep information secure. ◆

Databases

John Fairfield

John Fairfield is Consultant Anaesthetist at the Leeds Teaching Hospital NHS Trust. He specializes in anaesthesia for spinal surgery, orthopaedics and trauma. He is adviser to the Trust on clinical informatics and has lectured widely on the subject. He is Clinical Governance Reviewer for the Commission for Health Improvement.

A database is any collection of data or information, that is specially organized for rapid search and retrieval by a computer (Figure 1). Databases are built to facilitate the storage, retrieval, modification, and deletion of data in conjunction with various data-processing operations.

Database

One or more large structured sets of persistent data, usually associated with software to update and query the data. A simple database might be a single file containing many records, each of which contains the same set of fields where each field is a certain fixed width.

A database is one component of a database management system.

Source: The Free On-line Dictionary of Computing, © 1993–2003 Denis Howe (http://wombat.doc.ic.ac.uk/)

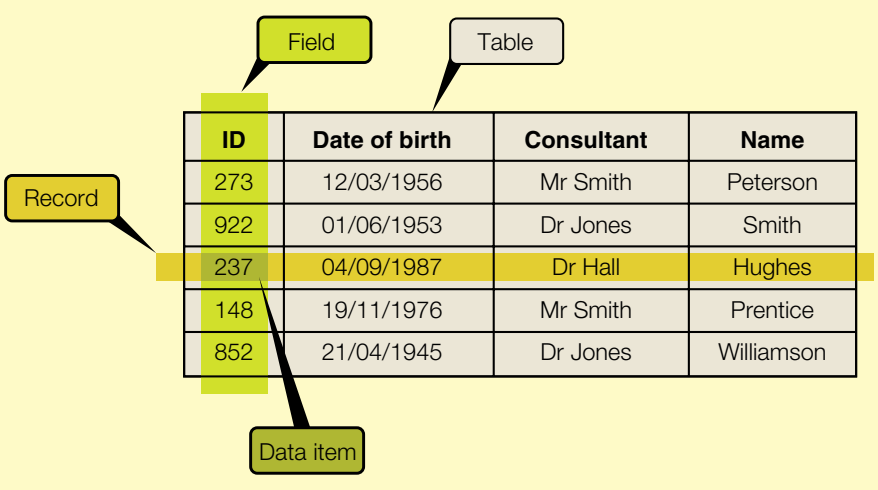
1

A database consists of a table or set of tables. The information in the tables may be broken down into records, each of which consists of one or more fields. Fields are the basic units of data storage, and each field typically contains information pertaining to one aspect or attribute of the object described by the database. Using keywords and sorting commands, users can rapidly search, rearrange, group and select the fields in many records to retrieve or create reports on particular aggregates of data.

Databases are designed to manage and manipulate structured information. For example, the telephone book contains several items of information (name, address, telephone number) about each telephone subscriber in a particular area. Each subscriber's information takes the same form. In terms of a database, the telephone book is a table, which contains a record for each subscriber. Each subscriber record contains three fields: name, address, and telephone number. The records are sorted alphabetically by the name field, which is called the key field.

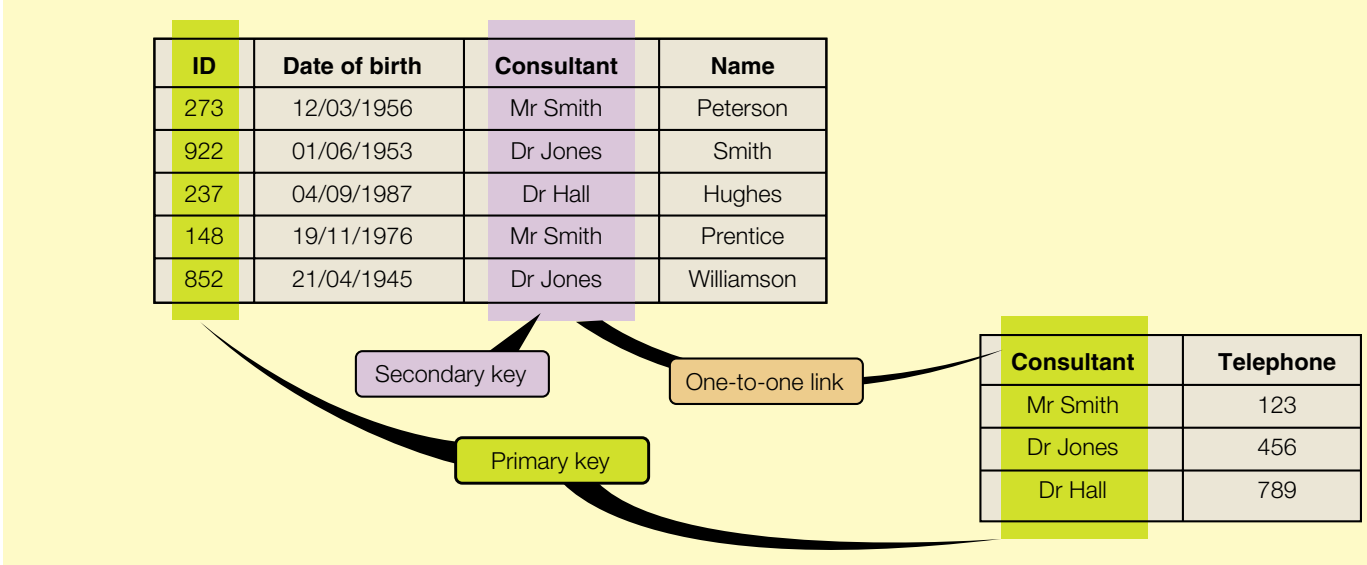
Figure 2 shows a small section of a table from a medical database used to store a list of patients and their doctor; the table, a field, record and data item are marked. It can be seen that a table is basically a collection of data with a name. The name is usually equivalent to some object (e.g. patient, resource, procedure). One of the main features of a database table that differentiates it from a spreadsheet is that each record must be unique. The specific field (or in some cases combinations of fields) that guarantees that uniqueness is known as the primary key (Figure 3). It is inevitable therefore that the primary key must be unique.

Components of a database table



2

Extra fields and links



3

If it is necessary to store more information in the database, it is possible to increase the number of fields in the table. In the medical database, for example, the telephone number that each patient needs to call to contact their doctor could be added as an extra field (Figure 3). The use of a database using only a single table to contain all the data is known as a flat file database. Although adding extra fields is simple, it can lead to problems. The most important of which is data duplication, for example each doctor and their telephone number occurs in the table many times. Therefore, there is an increased need for storage space that can become significant in large tables and cause slowing of the system. Also, if a doctor changes their telephone number, all the entries in the table must be changed. A more efficient solution is to add a new table containing the names of the doctors and their telephone numbers, then to link the new table to the original one as shown in Figure 3. Each table has its own primary key, and the primary key of the subsidiary table is linked to a secondary key in the master table.

Databases with linked tables, some of which are related to other tables, are known as relational databases. The process of moving data into separate related tables is known as normalization. In real-life databases the number of tables often increases dramatically. One of the most important aspects of database design is deciding which fields should go into which table. Normalization and object modelling facilitate this process.

The object that the table as a whole represents (i.e. what its name stands for such as 'doctor') plays some part in determining the fields, however, the fields must be subjected to a formal process known as normalization to ensure whether they should be included in the table or would be better included in a different one. If the tables are designed from an object model they are often already normalized.

Object modelling

The purpose of modelling is to provide a description of a system of some type. It is a method for distilling the associations between 'things', and requires a good understanding of the real-world system that the database is attempting to represent. The model requires only enough detail to describe the processes and the information to be represented and it is always context specific. In database modelling terms, a hospital patient is a different entity from the doctor, the finance manager and the hospital chaplain.

Normalization ensures that a database can work. Anyone can come up with all sorts of tables and sets of fields within each of them, but this is ineffective if the data are not structured in the correct way. A relational database is designed to work with normalized data and if presented with non-normalized (i.e. unstructured) data it will fail to work correctly.

Normalization has its origins in mathematical set theory. It was first developed by Edger Codd in the late 1960s, it is a process that consists of several clearly defined stages and requires an understanding of functional dependency. Data are said to be in first, second, third, etc. form indicating how structured they are. Data in first normal form are said to be less normalized than those in second normal form which, in turn, is less normalized than those in third normal form. Data can be in one of these normal forms or be made to conform to one of them by applying a number of strategies, which usually involves splitting a table up into several smaller ones.

It may sound as if something as technical as normalization should be left firmly in the hands of experts (often referred to as knowledge domain experts) however, it is important that data normalization is undertaken by someone who understands database design as well as the data and their relationships in the real world. Normalization applied by data processing staff is often done badly, because it depends on a detailed understanding of the data used by the organization and such an understanding is seldom held by these staff. Rather, the data are best understood by managers and users who work with the data on a day-to-day basis. To them, normalization represents 'common sense'.

The definitions of the forms of normalization are beyond the scope of this article but are well explained at the web site of DataModel.Org (http://www.datamodel.org/DataModelReference.html) and in several of the books listed in the Further Reading.

As a result of normalization, the number of tables is often increased dramatically. This process of increasing the number of tables, but not the number of fields, should not be seen as increasing the complexity of the database, but the opposite. After normalization, tables are simplified in terms of conceptual clarity (the tables often relate more closely to real-world objects) and database operations (updating, deleting and searching).

Database management systems

If a database is a collection of data in its component tables then the computer program that organizes and manipulates the database is a Database Management System (DBMS). Many computer programs called databases are in reality DBMSs, for example Access (®Microsoft Corporation), FileMaker Pro (®FileMaker, Inc.) and Paradox (®Corel Corporation) are designed to work on desktop computers while Oracle (®Oracle Corporation) and SQLServer (®Microsoft Corporation) are designed to work in a networked environment.

A DBMS:
- contains metadata (the structure of the data)
- allows actions to be performed on the data (e.g. adding, editing, deleting, sorting)
- supports queries
- produces reports based on queries.

Queries and reports

Queries are the main way users retrieve database information. Typically, the user provides a string of characters and the computer searches the database for a corresponding sequence and provides the source materials in which those characters appear. A user can request, for example, all records in which the contents of the field for a patient's last name is the word Smith. More complex queries can be constructed, for example to list all patients who failed to attend Dr Smith's outpatient clinic in the last 6 months.

Most DBMSs use a standard system called Structured Query Language (SQL) to query their tables, although most provide a graphical interface to generate the SQL itself. SQL resembles many programming languages, and is a structured form of English. For example, the SQL to find which of Dr Smith's patients did not attend would look something like:

```
Select * from patients
where surgeon = Smith
and clinic date >( now()-183)
and DNA = True
```

The result of the query is placed into a new answer table.

Having performed a query to select the data required, DBMSs have the ability to format the data in the answer table, together with many other complex elements such as other text and graphics, to produce a report that is easier to use than the raw data. In the example given above it could be used to produce letters to send to the patients who failed to attend giving them a new clinic appointment. ◆

Computers let you make more mistakes faster than any other invention in human history, with the possible exception of handguns and tequila

Knowledge Management

Chris Barham

Chris Barham is Consultant Anaesthetist at the Queen Victoria Hospital, East Grinstead, West Sussex. He is Chairman of the Society for Computing and Technology in Anaesthesia. He trained at King's College Hospital, London. His interests are information technology, difficult airway problems and anaesthesia for maxillofacial and plastic surgery.

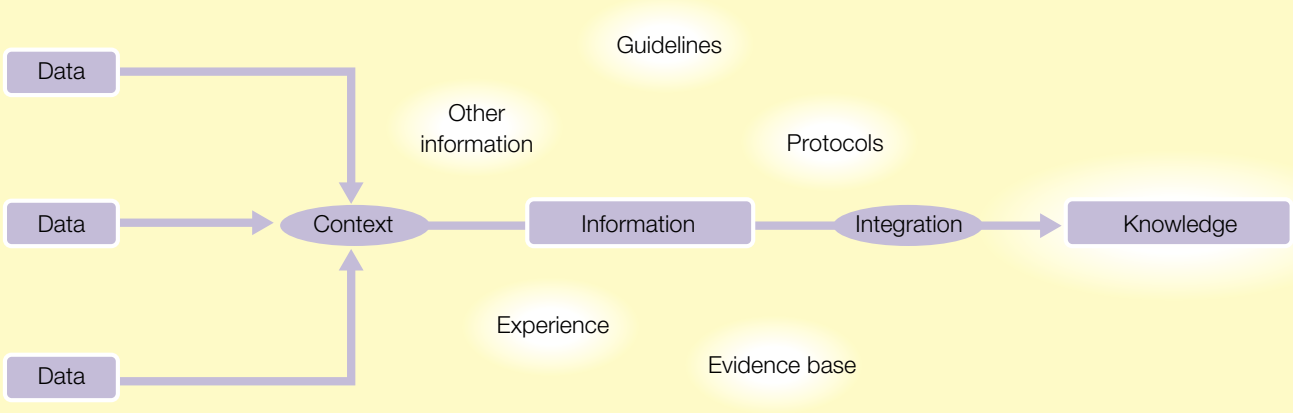
A little learning may be 'a dang'rous thing', but our problem today is a seemingly limitless supply of information.

Data: an item of data (a datum) consists of a label and a value. Thus, pulse = 80, systolic blood pressure = 120 are data. They convey facts, but tell you little unless you know their context.

Information: if the above data are known to be from an adult, ASA 1 patient this provides information. Clearly the information would be different if the data were from a neonate.

Knowledge can be defined as the information one has acquired through learning or experience. This implies conscious awareness and is the result of processing information and assimilating it with other information from the environment. For example, the doctor may decide to treat hypertension based on information on the patient, the likely pathology, the pharmacology of antihypertensive drugs and many other factors. All these integrate to produce knowledge (Figure 1).

Decision-making process



1

Knowledge may be explicit (e.g. guidelines, protocols, evidence base) or tacit (e.g. experience, intuition). The former may be written down, but the latter is more difficult to record because it is 'in the head'. In time, it may be codified, and so become explicit, for example, the development of algorithms to manage difficult airway problems.

This process of making tacit knowledge explicit is used in decision support. This may be any method that takes input information about a clinical situation and then produces inferences that can assist practitioners in their decision making. For example, a prescribing system might present advice based on information about the patient and the drugs. It may alert one to potential hazards or interactions, and suggest alternatives. It may tell you things you already know, but it will not overlook or forget things, as we are prone to do.

Wisdom is required for knowledge to be useful practically. This is the ability to make sensible judgements and decisions based on one's knowledge, experience, prudence and common sense.

Knowledge acquisition: the two main sources are the spoken word and books, but some others are shown in Figure 2. The textbook is accessible but expensive and quickly becomes out of date. This journal combines the accessibility of a textbook with currency of information.

Sources of knowledge acquisition

- Books
- Lectures
- Multimedia
- Ask a colleague (Phone a friend)
- Survey (Ask the audience)
- Guidelines
- Journals
- Internet

2

Problem-based learning: using a problem-based approach to learning influences the recall and application of knowledge. The method is based on using a problem (real or simulated) and access to the knowledge required for its solution. Context is also important – if the environment is real, knowledge retrieval is better. Thus, learning in the operating theatre is better than using a simulator, but that is better than the classroom. Learning is most effective when we have access to answers to questions at the point of patient care. A useful strategy is to develop a personal mission statement for learning, based on what we need to know and what we are happy to look up.

Information for patients: patients are expressing an increasing desire for information. The implicit trust placed in the medical profession has been dented in recent years, and concerns have led patients to search for their own information. They seek it from a variety of sources, including family and friends, chemists, NHS Direct, the Internet and medical consultations. The Royal College and Association of Anaesthetists has recently developed a series of information sources on anaesthesia for patients (www.youranaesthetic.info).

Information technology: the Internet is a source of knowledge, and the worldwide web has become the most accessible source of information for many. Email has also revolutionized information exchange, but it is important to be aware of the security and confidentiality implications. Email discussion lists can be a useful means of rapidly seeking the views of a number of colleagues.

Most hospitals now have an intranet, which is a mini-Internet accessible only within the organization. It can provide access to locally developed information, for example policies and guidelines. The NHS is committed to giving desktop access to all clinicians, but this has yet to be achieved. To the anaesthetist, the 'desktop' means the anaesthetic machine as well as the office. ◆

(This is the first of a series of 10 articles on *Knowledge for the Clinician* published in the succeeding issues of the journal.)

Secondary Uses of Clinical Information

John Fairfield

John Fairfield is Consultant Anaesthetist at the Leeds Teaching Hospital, NHS Trust. He specializes in anaesthesia for spinal surgery, orthopaedics and trauma. He is adviser to the Trust on clinical informatics and has lectured widely on the subject. He is Clinical Governance Reviewer for the Commission for Health Improvement.

Information about patients is collected in huge quantities in the health service. Although some of this information is general (e.g. patient demographics) most is clinical, relating to the patient's medical condition. This information is stored in a host of systems, some paper based and some electronic. Much of the information is duplicated.

The primary use of this information is to aid the management of the healthcare of the patient to whom it relates; to achieve a diagnosis and then to plan and provide treatment for the patient. Uses for the data that are not concerned with the day-to-day management of an individual patient's illness are termed 'secondary uses of clinical information'. In general, these are the use of personal information for the benefit of the community (in its widest sense) rather than the individual. They include:

- planning services at local, regional and national levels
- record keeping for legal reasons
- teaching (including logbooks)
- performance management
- adverse incident and risk management
- complaints and litigation
- research
- audit
- clinical governance, including benchmarking of performance of individuals, teams, hospitals and regions.

Data aggregation

Many, though not all, of the secondary uses of clinical inform-ation use data that have been aggregated (data that relate to many patients or have been taken from many sources). For example, when estimating the number of deaths following myocardial infarction (MI), the data may be taken from many patients, in many hospitals, following MI from a number of different aetiologies. This aggregation can be used to define prognosis, to measure performance, and for research. However, data aggregation is prone to many problems.

Case-mix – in order for the results of the aggregation to be accurate it is important that all the cases are similar. For example, the mortality following MI complicated by left ventricular failure is different from uncomplicated MI, and it is relatively easy to separate these two groups. It is harder to understand the difference in mortality following MI in patients treated by two cardiologists, unless one knows that one of the cardiologists has a special interest in diabetic patients.

Data collection – using the example of MI, it might seem simplest to use data from death certification, but this is prone to error. Following MI, many patients die from heart failure, if only patients whose primary cause of death is recorded as MI are included in the data, then those suffering MI followed by heart failure will be missed. If heart failure as the primary cause of death is used, then many patients who suffered heart failure without MI will be included. The diagnosis at the time of admission could be used, but many patients have the diagnosis of chest pain made on admission, only to have MI confirmed later. The number of patients whose diagnosis is obscure on admission varies between hospitals, invalidating comparison between them.

Using different terms for the same clinical entity – the potential for confusion is clear if one doctor in a hospital records all MIs as 'myocardial infarction' but another uses 'coronary thrombosis'. It would be difficult to store the full English or Latin name of every diagnosis and operation. For example, myocardial infarction could be spelt incorrectly, other words having the same meaning could be substituted, or the doctor's handwriting could be difficult to read. Even if there was unlimited capacity to retain and search text, it would be impossible to take account of all the possible descriptive variables that clinicians might use.

Coding

The problem of multiple clinical terms, and that of recording the correct primary diagnosis, is addressed by using sets of alphanumeric codes. In the UK, the diagnosis is coded using the International Classification of Diseases, 10th revision (ICD10). The code for myocardial infarction is I21.9. These codes use less space, are easier to search and are specific for each disease or diagnosis. ICD also allows certain codes to be paired to convey more information. Operations and procedures are coded using the Office of Population Censuses and Surveys Tabular List of the Classification of Surgical Operations and Procedures; normally referred to as OPCS4. In OPCS4, percutaneous transluminal balloon angioplasty of the aorta is neatly reduced to L26.1.

Hospital Episode Statistics

Each NHS hospital is required to return data about each patient treated to the Department of Health. This data set forms the basis of the Hospital Episode Statistics (HES) system, which is a powerful database containing personal, medical and administrative details of all patients admitted to, and treated in, NHS hospitals in England. This information has a host of uses including:

- policy development
- illustrating variations in health status and health delivery through time and across geographical areas
- production of comparative statistics to assist in performance management
- medical research – HES contains information of use to clinicians and others who are developing new treatments, investigating causal factors and monitoring trends.

Some technical terms

Benchmarking
The process of measuring the results of a service at a known point and position and then evaluating that point-position on a comparative basis with other similar services on an appropriate and repeatable basis

Case-mix
The mix of people, patients, treatments or services. It is used to understand the needs, provision and resource uses associated with healthcare

Core Data Sets (CDS)
The core information that health professionals need to exchange and share about the treatment of a patient with a specific condition (e.g. the national cancer data sets)

Cochrane Library
An electronic publication designed to supply high quality evidence to inform people providing and receiving care, and those responsible for research, teaching and funding and administration at all levels. It is an international endeavour that prepares, maintains and promotes the accessibility of systematic reviews of the effects of healthcare interventions

Electronic Health Record (EHR)
The concept of a longitudinal record of a patient's health and healthcare – from birth to death. It combines both the information about patient contacts with primary care as well as subsets of information associated with the episodic elements of care held in EPRs

Electronic Patient Record (EPR)
Contains a patient's personal details (e.g. name, date of birth), their diagnosis or condition, and the details about the treatment/ assessments undertaken by a clinician. Typically covers episodic care provided mainly by an institution

Health Benefit Groups (HBG)
A method of linking health needs with service delivery and the expected health benefit to assist in health needs assessment and planning service delivery

Healthcare Resource Groups (HRG)
A way of grouping the treatment of patients to allow analysis of the appropriateness, efficiency and effectiveness of care. It is based on clinically meaningful hospital inpatient episodes and the level of resources

Informatics
Covers all aspects of information management, information systems and information technology for professional practice

Information management (IM)
The way in which data and information are collected, stored, processed and used

Information technology (IT)
The equipment and the mechanics of information systems

Performance Assessment Framework (PAF)
A group of 6 areas (health improvement, fair access, effective delivery of appropriate healthcare, efficiency, patient and carer experience, outcomes of healthcare) by which the performance of all NHS Trusts is measured

Tables summarizing the data are published annually by the Department of Health and are available from the NHS Executive web site. The records are collected from all hospital providers in England (Scotland and Wales have their own systems) and are amalgamated annually. There are 40 items of information (fields) (Figure 1), including some of the patient's personal details (e.g. age, gender, place of residence), information about their admission to hospital (e.g. elective or emergency) and11 fields provide clinical data (e.g. diagnoses and details of any operations).

Some data fields in the Hospital Episode Statistics

Dates
- When admitted
- When operated on
- When discharged

Cause of accident
- E-codes (ICD10)

Hospital Episode Statistics numeric codes
- Method of admission
- Method of discharge

Surgical procedures
- OPCS4 codes

Provider and area codes
- Hospital Unit or Trust
- Health Authority
- Area of residence

Periods in days
- Duration of episode
- Waiting time

Diagnosis
- ICD10 codes

1

Diagnostic analysis

When using systems such as HES to provide answers to questions such as: "How many in-patients were diagnosed as suffering from MI during 2001?" it is necessary, for the sake of consistency, to use common standards when deciding which episodes to count. Also, it is important to qualify answers with an explanation of how the figures were produced. In some cases it may be impossible to give an answer because, in HES for example, information is divided into consultant episodes, it does not deal directly in 'patients' or 'stays in hospital'. Each record has space for seven separate diagnoses, which can present another problem. Unless the questioner specifically demands something different, it is standard to look only at the primary diagnosis field of those episodes that finished during the year. Counting finished episodes includes some patients who were admitted the previous year, but this is counterbalanced by those who remain in hospital until the following year. It is important to understand, for example, that if a patient's primary diagnosis was heart failure, but they also suffered a MI, the MI will be missed if only the primary diagnosis field is searched.

NHS Performance Assessment Framework

One of the uses of HES data is to generate the information used to produce indicators of the quality and effectiveness of NHS Trusts. This is known to the NHS as the NHS Performance Assessment Framework (PAF) and to the media as league tables. It enables Hospital Trusts to assess and compare their performance against a range of measures. It has four areas:

- clinical effectiveness and outcomes
- efficiency
- patient/carer experience
- capacity and capability.

Of most relevance to HES data are the measures relating to clinical effectiveness and outcomes (Figure 2). Bearing in mind the problems associated with using aggregated data, with coding some diagnoses and procedures, and with the variable quality of the information systems in parts of the NHS, it is easy to see how the performance for individual Trusts is easily misrepresented. ◆

NHS Performance Assessment Framework for acute Trusts, clinical components

i Percentage of patients discharged to usual place of residence within 56 days of emergency admission to hospital with a stroke, aged 50 and over (age and gender standardized)

ii Percentage of patients discharged to usual place of residence within 28 days of emergency admission to hospital with a hip fracture, aged 65 and over (age and gender standardized)

iii Emergency readmissions to hospital within 28 days of discharge (all ages), as a percentage of live discharges (age and gender standardized)

iv Emergency readmissions to hospital within 28 days of discharge following treatment for a fractured hip, as a percentage of live hip fracture discharges (age and gender standardized)

v Emergency readmissions to hospital within 28 days of discharge following a stroke, as a percentage of live stroke discharges (age and gender standardized)

vi Deaths within 30 days of surgery for non-elective admissions to hospital, per 100,000 patients (age and gender standardized, includes deaths in hospital and after discharge)

vii Deaths within 30 days of a coronary artery bypass graft, per 100,000 patients (age and gender standardized, includes deaths in hospital and after discharge)

viii Deaths within 30 days of emergency admission to hospital with a hip fracture, of patients aged 65 and over, per 100,000 patients (age and gender standardized, includes deaths in hospital and after discharge)

ix Deaths within 30 days of coronary artery bypass graft, per 100,000 patients (age and gender standardized, includes deaths in hospital and after discharge)

Telemedicine

Sophie M Jones

Sophie M Jones is Research Registrar in Plastic Surgery at Salisbury District Hospital, Wiltshire, UK. She qualified from Oxford University and UMDS before completing her surgical training in Norwich. She was involved in the development of a telemedicine system at the Queen Victoria Hospital, East Grinstead, and carried out research in this field.

Telemedicine is the assessment and review of patient information (history, examination or investigations) by a health professional who is separated temporally and/or spatially from the patient. It is 'the practice of medicine from a distance'; from the Greek *tele* meaning far.

Telemedicine is not new; it has been practised since the invention of the telephone. However, the development of technology, specifically the Internet, has increased the means whereby information can be acquired and transmitted over large distances. Virtually any information relevant to patient treatment can now be shared with colleagues over large distances in a short time. Telemedicine diminishes inequalities in service provision, improves access to healthcare and reduces costs.

Components of telemedicine

Telemedicine requires communication between two or more sites. The fundamental components of a telemedicine system are means of information capture, transport and display.

Information capture: in the medical consultation it is essential to ensure privacy and security of data using technology that is accurate, reliable and simple to use. Generally, the patient's informed consent is necessary, particularly if identifiable information (e.g. a recognizable photograph) is to be transferred. There are no standards for photographic technique and referring practitioners receive little or no training in clinical photography. However, modern digital cameras are easy to use and attention to detail can result in excellent images (Figure 1).

Digital images taken by staff and transmitted for expert opinion.

1

Information transmission: telemedicine can be practised almost anywhere, given the right equipment. Satellite systems enable access from the most remote locations. Most systems use telephone networks, digital networks (e.g. Integrated Services Digital Network (ISDN), Local Area Networks (LANs), Global System for Mobile communications (GSM), mobile phones, asynchronous transfer mode (ATM)) or the Internet. Fast, sophisticated and automated telemedicine using intuitive interfaces and powerful information management systems is possible using these methods of transmission and current technology. However, simple telemedicine systems can be just as effective.

Most systems use some form of encryption or exclusive LANs to transmit data securely. In the UK, the NHSnet is an exclusive intranet which allows communication across the National Health Service (NHS) while providing maximum security of its contents. However, no system is completely safe against intruders.

Information display: software used to display the information should be accurate, reliable and simple to use. Images can be displayed in a variety of formats; the most common are BMP and JPEG files. JPEG files are smaller than most others, containing about 300 kB. This is important because the number of pixels used for each image influences its quality and size and therefore the download time of each file. Having conveyed the information to an expert, the referring doctor can receive an opinion in real-time or store-and-forward. In real-time telemedicine at least two individuals communicate synchronously using a video-conference or a telephone call (e.g. telepsychiatry). Store-and-forward telemedicine (Figure 2) refers to the transfer of pre-recorded information that can be assessed in a time-independent fashion (e.g. teledermatology, teleradiology).

2 Using a store-and-forward telemedicine system.

History

Telemedicine has been in existence through radio and telephones since their invention. One of the earliest examples of modern telemedicine was the monitoring of astronauts' physiological functions (blood pressure, respiratory rate, ECG and temperature) by the US National Aeronautics and Space Administration (NASA) in the late 1960s. Also in the USA, in 1967, doctors were invited to bring radiographs to Logan Airport in Boston where they were scanned by a black-and-white camera and transmitted to a video monitor in the radiology department of Massachusetts General Hospital. Physicians could then discuss the case by telephone.

The first real-time interactive link was also set up in 1967 between the Nebraska Psychiatric Institute in Omaha and the Norfolk State Hospital (112 miles apart). The first use of satellite communications took place in 1976 when the Communications Technology Satellite *Hermes* was launched by NASA as part of a joint project with Canada's Department of Communications to serve remote areas of Canada; it was used in several telemedical studies. Telemedicine continues to play an important role in Canadian Healthcare (NORTH Network, Ontario).

Cost

Implementation of telemedicine systems has been resisted partly because of the cost of purchasing the hardware. However, with the advancement of technology, costs have fallen. Setting up a telemedicine system is now cheaper and running costs are relatively low, especially for store-and-forward systems.

Education

Telemedicine enables fast and easy access to medical information and guidance. Initially, the quality of health information on the Internet was poor, but the quality and quantity has increased over the last few years and much of it is available to health consumers as well as clinicians. The Internet allows clinicians to keep up to date with the latest medical advances, consult online textbooks and share clinical problems. Increasing numbers of hospital departments and universities arrange interactive tutorials and case discussions via videoconference. Patients can access information online about their disease, its management, research trials and support groups.

Legal challenges

The medico-legal implications of telemedicine have been debated extensively. Most legal and ethical issues are similar to those in general medicine (e.g. security of data, confidentiality, risk). The specific implications of telemedicine will be revealed by litigation as they arise. The Health Guidance Note on Telemedicine published by NHS Estates states that the medico-legal issues are not fully resolved.

Research

The Telemedicine Information Exchange (TIE) (http://tie.telemed.org) is a US-based database of current research in telemedicine throughout the world. In the UK, the Telemedicine Information Service (TIS) (www.tis.bl.uk) monitors current research and is a good source of information.

Implementation

Implementation of telemedicine into routine health services has been impeded by lack of scientific evidence about its clinical and cost effectiveness. The British government stated that, without such evidence, telemedicine will not be introduced widely. The Information Technology departments in UK hospitals are also ill-equipped to cope with the exponential advancements in medical technology. The integration of telemedicine into mainstream conventional healthcare is one of the greatest challenges facing the NHS over the coming years. If met, it will change our way of thinking about the delivery of primary and secondary care in the next millennium.

Telemedicine holds the promise of improving access to healthcare, especially in areas where there are geographical barriers. It is evolving into a valuable, but underused, resource for the delivery of healthcare to patients at a distance, particularly where patient transport is impractical, expensive, complicated, and/or urgent. Progress in its use has been slow, it is only in the last few years that telemedicine has moved from development and evaluation of prototype systems to use in clinical practice. Today, over 250,000 telemedicine consultations are generated annually in military and civilian health delivery systems. Thus, slowly but surely, telemedicine is advancing and changing the practice of medicine. ◆

Working Clinical Systems

Anthony P Madden

Anthony P Madden is Consultant Anaesthetist in the North Bristol NHS Trust. He qualified from Oxford University and St Bartholomew's Hospital, London. He trained at St Bartholomew's, Great Ormond Street and St Thomas' Hospitals, London. He has a special interest in electronic patient records.

Computerization of healthcare is unavoidable. All clinicians, including anaesthetists, need to understand what computers can do for them, and what may be involved in the procurement and implementation of such systems.

In the UK, the NHS has a clear vision and strategy for the implementation of clinical computer systems, which is set out in documents such as *Information for Health*, the *NHS Plan*, *Delivering the NHS Plan*, the *Wanless Report*, and the *National Specification for Integrated Care Records Service*.

The problem for clinicians worldwide has been that until recently most of the effort that has gone into computerization of healthcare has been aimed at supporting departmental functions (e.g. pathology, radiology, pharmacy) or at supporting the political need for information about the performance of publicly funded healthcare systems, including the need for clinical governance.

Why computerize?

There are four main reasons for introducing computers into clinical practice.

- Paper-based clinical data recording cannot effectively support new models of care.
- Often the information contained in paper records is not available to clinicians when they need it.
- Paper is an inefficient way of providing the information needed for clinical governance.
- Paper processes cannot support clinical decision-making in the way that computers can.

The way healthcare is provided is constantly evolving. The introduction of ambulatory centres or diagnostic and treatment centres, remote from the main hospital, and the requirement that patients should not have to travel long distances for a consultation, means that clinicians have to travel and may see the same patient in different places on different occasions during a single episode of care. In this system, there is considerable risk of paper records going astray and not being available when needed. Computerization can solve this problem, as well as the associated processes of booking the patient into outpatient clinic and operating theatre slots, ordering tests, scheduling transport, booking a bed, transmitting test results, keeping their GP informed and ensuring the patient is not lost to follow-up (Figure 1).

Some reasons for implementing electronic patient records (EPRs)

"…making the fundamental and lasting changes that will have a major impact on patient safety is much more difficult than simply installing new technologies…We must re-examine all that we do and redesign our many and complex systems to make them less prone to human error"
Editorial, *BMJ*, 18 March 2000

"If we managed travel like we manage healthcare then travel agents would book flights on the basis of the flight schedules they could remember"
Lawrence L Weed

Paper clinical notes are "poorly legible, ill-structured, bulky and untidy"
***Audit Commission*, 1995**

Anyone who has spent time trawling through a pile of paper clinical records trying to extract data for clinical audit will know that this is an inefficient way to gather data for clinical governance and for central government returns. Paper cannot advise, guide, or support clinical decision making in an active way. There is no guarantee that the relevant paper document will be available when needed, for example, a hospital protocol for the management of insulin-dependent diabetics undergoing surgery. Computerization can help.

Classification of modern EPR systems

There is no accepted single classification of electronic patient record (EPR) systems. Systems have a variety of origins and most are undergoing constant development. User interfaces are being changed, and in some cases the underlying databases and data structures are evolving. All this makes classification difficult. No single EPR system can do everything, so a useful primary classification for the core functions of a modern system is into:

- integrated
- interfaced 'best of breed' solution.

Even this is slightly false because it begs the question of what functions are 'core' and what are not. An integrated EPR will need interfaces to secondary or feeder systems (e.g. pathology, radiology) and these interfaces are typically managed by an integration engine that translates the output of one system (e.g. pathology) into a form that is 'understood' by the EPR or *vice versa*. HL7 is an international standard for transmitting such structured messages, but some manufacturers have enhanced the standard so that a degree of translation is required.

A secondary classification is:

- designed from scratch using modern technology
- based on fundamentally old technology with a user front end that has been updated over the years
- developed from a patient administration system or a departmental system (e.g. pharmacy).

All modern EPR systems are patient-centric. This means that when a user logs on to the system the first thing they do is identify the patient or patients in whom they are interested. This contrasts with older systems, in which a user typically logs in to the functional area of interest (e.g. patient administration, radiology, pathology) and then identifies the patient. A system that is not patient-centric cannot provide the integration of appointment scheduling, bed management and clinical functions demanded of a modern system.

In terms of technical architecture, modern systems are either based on a 'client-server' model (where the EPR software resides on the user's PC) or a 'thin client' model (where all the processing is performed on a central server). The clients in this environment typically use a web browser for the user interface. This may run on a relatively lowly specified PC, or on a personal desktop assistant (PDA), tablet or laptop device. Screen size can be a problem with PDAs because it is impossible to display all the required information on a screen with a diagonal of 8–10 cm. Thin client environments are theoretically easier to maintain because enthusiastic users cannot interfere with the EPR software and thin client devices can be cheaper to buy than a conventional well-specified PC. The network bandwidth may also be less demanding. However, 'client-server' architecture can be set up to run in a thin client mode using special software. This may be useful for running these applications in places that are remote from the main hospital, such as primary care health centres or community hospitals.

Core EPR functions

The main EPR functions are:

- patient administration
- scheduling and tracking
- clinical documentation
- order communications, including laboratory and radiology requests and results, pharmacy and electronic prescribing
- clinical decision support
- analysis.

Jargon buster

ADT	Admissions, discharges and transfers, see PAS
AIMS	Anaesthetic Information Management System
Arden syntax	A programming language for medical logic modules/sophisticated clinical decision support
DICOM	A communication standard for handling digital images, mostly relevant to diagnostic imaging (e.g. radiographs)
EHR	Electronic Health Record, a term introduced in IfH and now superseded by ICRS. The concept of a cradle-to-grave record of health and healthcare maintained in the primary care arena
EPR	Electronic Patient Record. Superseded by ICRS but still in common use. The electronic equivalent of the hospital notes folder but with added functions
GUI	Graphical User Interface (e.g. Microsoft Windows)
HL7	Health Level 7. A standards group in the USA. Often used in the context of 'structured messages' used to send clinical information between computer systems (e.g. EPR and RIS)
HTML	Hypertext Markup Language. The language of the World Wide Web. A small subset of SGML
ICRS	Integrated Care Records Service. A new term encompassing the concepts of both EPR and EHR
IfH	*Information for Health*. The UK Government's Information Strategy for the NHS for the period 1998–2005. Updated in *Building the Information Core*
LIMS	Laboratory Information Management System. Computer system used to manage laboratory processes and outputs
LIS	Local Implementation Strategy for IfH
Order Comms	Order communications. The electronic equivalent of 'requesting' a radiograph or blood test or almost anything else that may be required for a patient (e.g. a theatre slot, dietetic advice)
PACS	Picture Archiving and Communication System. Uses DICOM standard. Electronic store for digital images, mostly diagnostic
PAS	Patient Administration System. Deals with appointments, waiting lists, admissions, discharges, transfers and provides information for Government returns regarding hospital activity
PDA	Personal Desktop Assistant. A handheld computer designed to be used in conjunction with a desktop PC (e.g. Palm or Pocket PC devices)
RIS	Radiology Information System. Computer system used to manage radiology processes and outputs
SGML	Standard Generalized Markup Language, a page markup language that was initially developed in the late 1960s by the US Graphic Communications Association to permit the electronic transfer of page formatting and layout instructions from publishers to printers. Adopted as an international standard in 1986
UML	Universal Modelling Language. A technique for modelling processes that is universally applicable and facilitates the subsequent computerization of those processes
URL	Universal Resource Locator. An internet address (e.g. www.doh.gov.uk/ipu). Also used to identify 'resources' such as PCs or printers on a local area network
XML	Extensible Markup Language. A subset of SGML. More flexible than HTML. Can be used to transmit structured messages (e.g. pathology results)

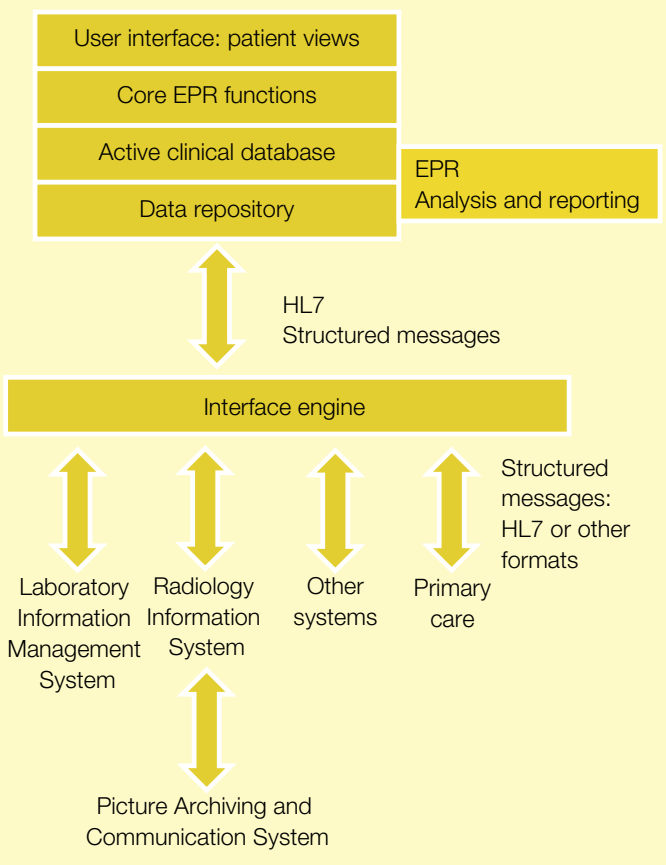
Most modern EPRs have weak areas and none that the author is aware of does everything really well, despite the claims of the software companies. Most have a comprehensive set of patient administration system (PAS) functions, and nearly all have good order communications functionality, though electronic prescribing can be a weakness, largely because the software has not yet been fully developed and tested in clinical use. The ability to document clinical findings and record clinical observations varies from system to system. Active decision support is an area that all companies recognize as something that must be supported, though most require work to be done during implementation to tailor the decision support module to local needs. Analysis is best performed on an off-line copy of the database, because running reports on the active copy can result in unacceptably slow response times for clinical users.

Some EPRs have scheduling and tracking functions integrated into their core, thus permitting a close link to order communications, PAS and care pathways. This close linkage is not easy if patient scheduling and tracking functions are provided by a separate system that has to be interfaced to the EPR. Laboratory information management system (LIMS) and radiology information system (RIS) functions are also sometimes available as part of the core, though it is more common for these to be provided separately and interfaced to the EPR (Figure 2). PACS is always separate.

Modernization

Most clinicians can think of ways to improve the service they provide. The jargon term for this is business process re-engineering, and when it involves the re-design of clinical processes it needs a formal process to ensure that patients are not put at greater risk.

Technical structure of a typical electronic patient record (EPR)



2

Process re-engineering is an essential component of implementing an EPR, and the stages comprise:

- analysis of the existing process
- design of the new computerized process
- configuring the EPR to deliver the new process
- testing the software and running clinical scenarios *in vitro* before going live
- piloting the new clinical processes in a limited clinical area (e.g. a single ward or department) with careful supervision and collecting audit data if applicable
- formally reviewing the outcome of the pilot and making changes if necessary
- rolling out the new process and the EPR to other clinical areas.
  All this requires input from clinicians if it is to work well.

Anaesthetic considerations

Information for Health specified six levels of increasing sophistication of EPRs. NHS hospitals have some flexibility in choosing which functions in which of the six levels they implement and when. However, there are target dates for the implementation of some functions (e.g. electronic prescribing).

The data recording and reviewing requirements of anaesthesia are similar to those of many other specialties. Preoperative assessment and investigation, intraoperative recording of physiological data and drug and fluid administration, along with details of anaesthetic technique, and postoperative data recording are not fundamentally different from the processes that are undertaken by clinicians in many other specialties. EPRs should be able to handle these requirements, though special anaesthetic screens may need to be designed when the EPR is being configured following the analysis phase and before piloting the system in a clinical environment.

Automatic downloading of physiological data from anaesthetic monitors has been technically possible for many years. Difficulties encountered in linking all the different devices in use in a typical anaesthetic department to an AIMS, and the fact anaesthesia is now so safe (making the economic justification weak) may explain why these systems are not more widely available.

It is likely that the small number of AIMS manufacturers will be squeezed as equipment manufacturers provide devices with outputs that comply with international communication standards and protocols, and EPRs are provided with the ability to incorporate the data streams from critical care monitors using ‘plug and play’ technology. ◆

Acid–Base and Blood Gas Analysis

Peter J McQuillan

Peter J McQuillan is Consultant in Intensive Care at the Queen Alexandra Hospital, Portsmouth, UK. He qualified from Newcastle and trained in intensive care and anaesthesia in Newcastle, Dunedin (New Zealand), Oxford, Portsmouth, Southampton and Perth and Melbourne (Australia). His interests include quality of acute care.

Acid–base homeostasis is important because protein structure and function, ionic dissociation and all chemical reactions are pH dependent. Whereas plasma sodium is controlled within a few mmol/litre, $[H^+]$ is controlled within a few nmol/litre. Acid load comes from both respiratory sources (i.e. carbon dioxide via carbonic acid) amounting to 15–20,000 mmol H^+/day, and metabolic sources (i.e. metabolism of sulphates, phosphates, nitrates, lactate and ketoacids; 40–80 mmol/day). Acute changes in acid–base state are minimized by buffering systems (which minimize the change in $[H^+]$) and other compensatory mechanisms, before excretion of acids or alkalis.

Definitions

$$pH = -\log[H^+] = \log \frac{1}{H^+}$$

(p stands for power from German *Potenz*)

- pH is the negative logarithm (i.e. the logarithm of the reciprocal) of the hydrogen ion concentration. In a logarithmic scale, a unit change in pH represents a 10-fold change in H^+ concentration.
- Normal ranges: pH = 7.34–7.43 (i.e. ≈ 7.40); H^+ = 46–37 nmol/litre (i.e. ≈ 40 nmol/litre)
- Figure 1 gives the rule of thumb for interconversion of pH and $[H^+]$
- Acidaemia/alkalaemia occur when pH or H^+ are outside the normal range.
- Acidosis/alkalosis are the processes tending to produce an acidaemia/alkalaemia.
- An acidosis or alkalosis may exist in the absence of an acidaemia/alkalaemia if:
  - the primary process is not sufficiently severe to change pH beyond the normal limits
  - compensation may have occurred to bring pH back within the normal range
  - mixed processes alter pH in different directions.

A rule of thumb for easy translation between pH and H^+

$[H^+]$ nmol/litre	$[H^+]$ nmol/litre	pH
10^{-7}	100	7.00
$10^{-7.2}$	63	7.20
$10^{-7.3}$	50	7.30
$10^{-7.4}$	40	7.40
$10^{-7.5}$	32	7.50
$10^{-7.6}$	25	7.60
$10^{-7.8}$	16	7.80

If pH =7.ab and H^+ = cd, then ab+cd ≈ 83
pH 7.23 => H^+ = 83 – 23 = 60
H^+ = 25 => pH = 7.(83–25) = 7.58
The error is small and inconsequential for clinical purposes between pH 7.1 and 7.6.

1

Henderson and Hasselbalch equation

This equation describes the relationship between concentrations of dissociated and undissociated acid or base, dissociation constant and pH. The carbonic acid system is of fundamental importance. The reaction of carbon dioxide with water forms carbonic acid, which dissociates to form bicarbonate and hydrogen ions:

$$CO_2 + H_2O \rightleftarrows H_2CO_3 \rightleftarrows H^+ + HCO_3^- \qquad 1$$

Henderson noted that according to the law of mass action:

$$\frac{[H^+][HCO_3^-]}{[H_2CO_3]} = k \quad \text{where k is a constant}$$

$$\Rightarrow 24.\frac{40\ (\text{mm Hg})}{24} = 180.\frac{5.3(\text{kPa})}{24} = 40\ \text{nmol/litre}$$

This simple formula allows the validity of blood gas results to be checked easily.

Hasselbalch took the logarithm of the reciprocal to produce the classical Henderson–Hasselbalch equation:

$$= pK_a + \log \frac{HCO_3^-}{0.03 \times PaCO_2\ (\text{mm Hg})} \quad \text{or} \quad \frac{HCO_3^-}{0.23 \times PaCO_2\ (\text{kPa})}$$

The pK_a value at 37°C is 6.1. Thus pH depends on the ratio of bicarbonate to carbonic acid or the ratio of bicarbonate to dissolved carbon dioxide. Changes in pH or H^+ occur through a change in this ratio. Compensatory mechanisms exist to return this ratio towards 20.

Alterations to pH

'Metabolic' processes change HCO_3^-, which alters the numerator and hence the pH.

Metabolic acidosis

$$pH = 6.1 + \log \frac{HCO_3^-}{0.23 \times PaCO_2} \qquad \downarrow\downarrow \ \downarrow$$

The primary change is a fall in bicarbonate (acidosis, metabolic). Compensation produces a fall in $PaCO_2$ to return the ratio (and pH) towards normal.

Respiratory compensation occurs quickly in spontaneously breathing patients. Ventilated patients may have ventilation limits imposed, thereby precluding adequate compensation. A patient with diabetic ketoacidosis may develop a $PaCO_2$ of 1.7 kPa to compensate: intubation and ventilation requires the use of a high minute volume to maintain the compensated state.

Metabolic alkalosis

$$pH = 6.1 + \log \frac{HCO_3^-}{0.23 \times PaCO_2} \qquad \uparrow\uparrow \ \uparrow$$

The primary change is a rise in bicarbonate (alkalosis, metabolic). Compensation produces a (small) rise in $PaCO_2$ to return ratio (and pH) towards normal. This hypoventilatory ability is very limited in humans.

'Respiratory' processes change $PaCO_2$, which alters the denominator and hence the pH.

Respiratory acidosis

$$pH = 6.1 + \log \frac{HCO_3^-}{0.23 \times PaCO_2} \qquad \uparrow \ \uparrow\uparrow$$

The primary change is a rise in $PaCO_2$ (acidosis, respiratory). Compensation produces a rise in bicarbonate to return the ratio (and pH) towards normal.

An acute rise in $PaCO_2$ moves Equation 1 to the right prod-ucing an increase in HCO_3^- (as H^+ is buffered by haemoglobin) as a change in equilibrium of the reaction, rather than a compensation. Chronically, renal retention of HCO_3^- is a compensatory process taking hours to days. The expected level of HCO_3^- can be calculated using the formula in Figure 2 giving an indication of the acuteness of the process. If the HCO_3^- is other than the predicted value (for acute or chronic change), another process must be involved.

Respiratory alkalosis

$$pH = 6.1 + \log \frac{HCO_3^-}{0.23 \times PaCO_2} \qquad \downarrow \ \downarrow\downarrow$$

The primary change is a fall in $PaCO_2$ (alkalosis, respiratory). Compensation produces a fall in bicarbonate to return the ratio (and pH) towards normal.

Compensatory mechanisms move the pH back towards normal but seldom completely normalize it.

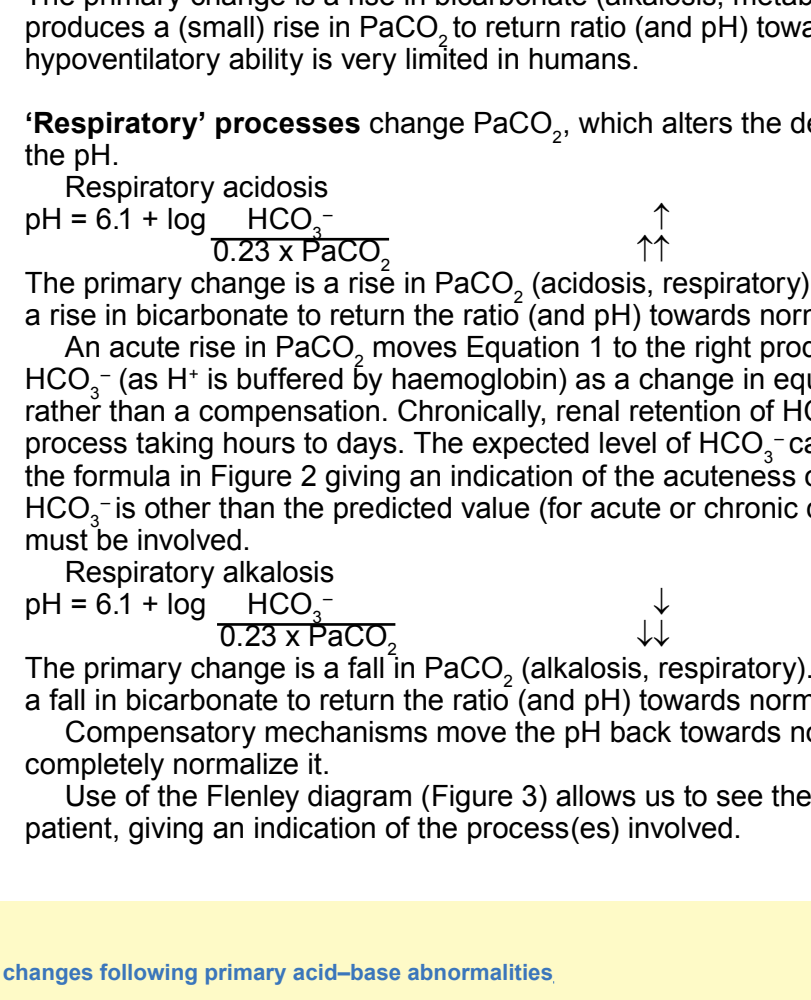
Use of the Flenley diagram (Figure 3) allows us to see the acid–base status of the patient, giving an indication of the process(es) involved.

Expected changes following primary acid–base abnormalities

kPa	Standard base excess (SBE) (mmol)	ΔHCO_3^- (mmol)	$\Delta [H^+] / PCO_2$	pH
Respiratory acidosis: acute	$\Delta SBE = 0\ \Delta PCO_2$	$\Delta HCO_3^- = 0.75\ \Delta PCO_2$	$\Delta[H^+] = 5.5\ \Delta PCO_2$	$0.06\ \Delta PCO_2$
Respiratory acidosis: chronic	$\Delta SBE = 3\ ^*\Delta PCO_2$	$\Delta HCO_3^- = 3\ \Delta PCO_2$	$\Delta[H^+] = 2.3\ \Delta PCO_2$	$0.023\ \Delta PCO_2$
Respiratory alkalosis: acute	$\Delta SBE = 0\ \Delta PCO_2$	$\Delta HCO_3^- = 1.5\ \Delta PCO_2$	$\Delta[H^+] = 5.5\ \Delta PCO_2$	$0.06\ \Delta PCO_2$
Respiratory alkalosis: chronic	$\Delta SBE = 3\ ^*\Delta PCO_2$	$\Delta HCO_3^- = 4\ \Delta PCO_2$	$\Delta[H^+] = 2.3\ \Delta PCO_2$	$0.023\ \Delta PCO_2$
kPa	**PCO_2 (kPa)**	**PCO_2 (kPa)**	**PCO_2 (kPa)**	**pH**
Metabolic acidosis	$\Delta PCO_2 = 0.13\ \Delta SBE$	$\Delta PCO_2 = (0.17\ ^*\ HCO_3^-) + 1$	$PCO_2 = -0.1H^+ + 9.3$	$7.(\ HCO_3^- + 15)$
Metabolic alkalosis	$\Delta PCO_2 = 0.08\ \Delta SBE$	$\Delta PCO_2 = (0.1\ ^*\ HCO_3^-) + 2.8$	$PCO_2 = -0.2H^+ + 13$	$7.(\ HCO_3^- + 15)$

2

Flenley diagram



Plotting the measured parameters of H^+ (or pH) against PCO_2 allows a graphical illustration of the observed acid–base status and the processes involved.

3

Metabolic acidosis and acidaemia

Blood contains anions (negatively charged) and cations (positively charged) and electrical neutrality dictates that:

$$(Cl^- + HCO_3^- + \text{albumin}^- + \text{phosphate} + \text{sulphate} + \text{lactate} + \text{ketones}) = (Na^+ + K^+ + Ca^{2+} + Mg^{2+})$$

If we measure only Na^+, Cl^- and HCO_3^- and UC^+= unmeasured cations and UA^- = unmeasured anions, the above equation becomes:

$$Na^+ + UC^+ = Cl^- + HCO_3^- + UA^-$$

$$\text{The anion gap (AG)} = Na^+ - (Cl^- + HCO_3^-)$$
$$= UA^- - UC^+ = < 12\ \text{mmol/litre}$$

Another version of the formula uses Na^+ and K^+ with a normal value of ≈ 15 mmol/litre. Hypoalbuminaemia reduces the AG and can be corrected using the formula AGc = AG – 0.25 (normal – actual albumin).

A metabolic acidosis involves a primary fall in HCO_3^-. Assuming there is no change in cations, the fall in HCO_3^- must be balanced by either an increase in UA^- or Cl^-.

High anion gap metabolic acidosis: an increase in UA^- implies a gain of acid. $Na^+ - [Cl^- + \downarrow HCO_3^-]$ implies an increase in AG. HCO_3^- falls and Cl^- is unchanged, UA^- is increased.

The causes include:

- lactic acidosis
- ketoacidosis (diabetes, alcohol, starvation)
- renal failure
- salicylates, ethanol, methanol, ethylene glycol.

Normal anion gap metabolic acidosis: normal AG plus increased Cl^- implies a loss of HCO_3^-.
$Na^+ - [\uparrow Cl^- + \downarrow HCO_3^-]$ means a normal AG with no change in unmeasured anions.
The causes include:
- gain of acid (ammonium chloride ingestion; lysine, arginine HCl in TPN)
- reduction in renal H^+ elimination (renal tubular acidosis (type 1, distal or type 4, hypoaldosteronism))
- an increase in HCO_3^- loss which may be gastrointestinal (diarrhoea, ileostomy, ureteroenterostomy) or renal (carbonic anhydrase inhibitors: acetazolamide, renal tubular acidosis (type 2, proximal) or renal tubular damage).

Metabolic alkalosis

Generation of a metabolic alkalosis is associated with a net gain of HCO_3^- via:
- loss of acid via gastrointestinal or renal routes
- administration of HCO_3^- or its precursors (e.g. citrate in blood, lactate or acetate in haemofiltration fluid)
- loss of fluid with disproportionately more Cl^- than HCO_3^-: sometimes called a contraction alkalosis, a decrease in extracellular volume with little HCO_3^- loss leads to an increase in $[HCO_3^-]$ and hence a metabolic alkalosis.

Maintenance of metabolic alkalosis requires impairment of renal HCO_3^- excretion because the kidney normally excretes HCO_3^- easily. This may occur in
- hypovolaemia
- potassium depletion
- mineralocorticoid excess
- hypercapnia.

Metabolic alkalosis may be:
- saline (Cl^-) responsive (urinary $Cl^- < 10$ mmol/litre) due to vomiting, chloride diarrhoea, diuretics or alkali ingestion
- saline (Cl^-) unresponsive (urinary $Cl^- > 10$ mmol/litre) due to mineralocorticoid excess, potassium depletion or renal Cl^- wasting (Bartter's syndrome)

Interpreting blood gases

Only PaO_2, $PaCO_2$ and $[H^+]$ or pH are measured in blood gas analysers. $PaCO_2$ defines the magnitude of the respiratory component but there is debate about the usefulness of the derived variables that describe the metabolic component (bicarbonate, standard bicarbonate, base excess and standard base excess (SBE)). This is in part because changes in $PaCO_2$ alter bicarbonate. The following system may be useful in assessing acid–base status.
- Is the pH normal, acidaemic or alkalaemic?
- pH or $[H^+]$ in normal range suggests one of the following:
  – no acid–base disorder exists
  – two or more disorders tending to offset pH or $[H^+]$ in opposite directions
  – partial compensation has occurred.
- Does the $PaCO_2$ change in the direction that would explain the pH change?
  – if it does then there is (at least) a respiratory abnormality.
  – if not, there must be a metabolic abnormality driving the pH change.
- Does HCO_3^- change in the direction that explains the pH change?
  – if it does there is a metabolic abnormality.
  – if not and it changes in the same direction as the change in $PaCO_2$ then it may represent a compensatory change.
- After identifying the primary or major abnormality ($\Delta PaCO_2$ for respiratory or ΔHCO_3^- for metabolic), what value would you expect for the other component if this were the only acid–base abnormality present (Figure 2)? If the value is different from the predicted value there must be another abnormality (i.e. a mixed picture). Alternatively, if an acute respiratory abnormality exists, are the actual and predicted pH or $[H^+]$ the same? If not, another metabolic abnormality exists.
- In a metabolic acidosis, the anion gap helps to identify the cause. If the deviation in the HCO_3^- from normal is different from the change in the anion gap from normal, another abnormality may exist.

Stewart physicochemical approach of acid–base balance

Stewart suggested changes in $[H^+]$ occur from dissociation of water into H^+ and OH^- rather than additions of acid or alkali. This dissociation potentially produces an inexhaustible source of H^+ and is bound by the laws of physical chemistry, in particular the principles of electroneutrality and of the conservation of matter. Three independent fundamental determinants of $[H^+]$ are the strong ion difference (SID), $PaCO_2$ and the total weak acid concentration (A_{TOT}). Stewart pointed out that the correlation of HCO_3^- with metabolic changes in $[H^+]$ is not evidence of causation, any more than the ECG changes in myocardial infarction represent the cause.

A strong ion is one that is (nearly) completely dissociated. SID is the net charge balance of all strong ions in solution, i.e. $(Na^+ + K^+ + Ca^{2+} + Mg^{2+}) - (Cl^- + lactate^-) =$ 40–42 nmol/litre = apparent SID (SIDa). This is similar to the old 'buffer base' concept. Neither H^+, nor HCO_3^- are strong ions. Weak acids, A^- (albumin and phosphate) contribute the remaining charge to satisfy electroneutrality. A rise in SID causes less water dissociation and an alkalosis and a fall in SID produces greater dissociation and an acidosis (Figure 4).

SID ↓
↓

$H_2O \rightleftarrows H^+ + OH^-$

↑

SID ↑.

Effect of strong ion difference on pH due to dissociation of water

Acute Liver Failure

Kevin E J Gunning

Kevin E J Gunning is Director of the John Farman Intensive Care Unit, Addenbrooke's Hospital, Cambridge, UK. He qualified from St Bartholomew's Hospital, London, and after obtaining his FRCS, trained in anaesthesia in London. His current interests include audit and training in intensive care.

Acute liver failure (ALF) is an uncommon condition characterized by jaundice, coagulopathy and encephalopathy in a patient with previously normal liver function. In the USA, there are 2000 cases a year and in the UK there are 400. The main aims of treatment are the control of cerebral oedema and supportive management of multiple organ failure until hepatic regeneration occurs. Sepsis and cerebral oedema are the main causes of death.

Aetiology – in the UK, paracetamol (acetaminophen) overdose is the most common cause (70%) of ALF, but worldwide it is viral hepatitis (Figure 1).

Pathology – there is centrilobular necrosis of hepatocytes with activation of macrophages and liberation of cytokines, specifically tumour necrosis factor and interleukins 1 and 6.

Causes of acute liver failure

- Infection (hepatitis A, B, C, E, non-A non-B, cytomegalovirus, herpes simplex virus, Epstein–Barr virus, varicella)
- Drugs (paracetamol (acetaminophen), isoniazid, monoamine oxidase inhibitors (MAOIs), non-steroidal anti-inflammatory drugs (NSAIDs), halothane, Ecstasy, gold, phenytoin)
- Metabolic (Wilson's disease, Reye's syndrome)
- Cardiovascular (Budd–Chiari syndrome, ischaemic hepatitis)
- Miscellaneous (acute fatty liver of pregnancy, lymphoma, amanita phalloides, herbal medicines)

1

Clinical presentation

ALF usually presents with malaise, nausea and jaundice. The interval between the onset of jaundice and the onset of enceph-alopathy depends on the aetiology and is used to classify ALF:

- hyperacute liver failure (7 days between onset of jaundice and encephalopathy)
- acute liver failure (8–28 days)
- subacute liver failure (5–12 weeks).

This classification has implications for the prognosis and incidence of cerebral oedema, which is more common in hyperacute failure. As liver failure progresses, encephalopathy becomes the characteristic feature. The grading of encephalopathy is described in Figure 2. The mechanism of encephalopathy is not fully understood. Ammonia, false neurotransmitters and endogenous benzodiazepine ligands that enhance the effect of the inhibitory transmitter γ-aminobutyric acid have been proposed as causes.

Grades of encephalopathy

- Grade I: altered mood, impaired concentration and psychomotor function, rousable
- Grade II: drowsy, inappropriate behaviour, able to talk
- Grade III: very drowsy, disorientated, agitated, aggressive
- Grade IV: coma, may respond to painful stimuli

2

Diagnosis and investigations

There is no specific diagnostic test for ALF, however specific tests to identify the cause may include:

- viral serology for the hepatitis viruses
- plasma caeruloplasmin and 24-hour urinary copper to diagnose Wilson's disease
- hepatic ultrasound to demonstrate hepatic vascular occlusion in Budd–Chiari syndrome.

There will be elevation of:

- serum bilirubin (a level over 300 μmol/litre implies severe disease)
- plasma aspartate aminotransferase (AST) and alanine amino-transferase (ALT) reflecting hepatocellular damage
- prothrombin time (PT) (used as an indicator of the severity of the disease). Other common abnormalities are hypoglycaemia, hyponatraemia, hypomagnesaemia, respiratory alkalosis and metabolic acidosis.

Management

Paracetamol (acetaminophen) overdose results in the accumulation of the hepatotoxic metabolite N-acetyl-p-benzoquinonimine which is normally inactivated by conjugation with glutathione. N-acetylcysteine should be given as soon as possible after the overdose according to the standard treatment nomogram, to re-plenish hepatic stores of glutathione. The management of patients who meet the clinical indicators of poor prognosis (Figure 3) should be discussed with a regional liver centre and they should be transferred urgently for transplant assessment. Elective intubation and ventilation should be considered before transfer for patients with Grade II encephalopathy and it is mandatory for patients with Grade III or IV encephalopathy. The patient should be transferred with full monitoring by experienced personnel.

King's College Hospital criteria for liver transplant-ation in acute liver failure

Paracetamol (acetaminophen) overdose

- H^+ > 50 nmol/litre

Or all of the following:

- Prothrombin time > 100 seconds
- Creatinine > 300 μmol/litre
- Grade III–IV encephalopathy

Non-paracetamol (acetaminophen)

- Prothrombin time > 100 seconds

Or three of the following:

- Age < 10 years or > 40 years
- Prothrombin time > 50 seconds
- Bilirubin > 300 μmol/litre
- Time from jaundice to encephalopathy > 2 days
- Non-A, non-B hepatitis, halothane or drug-induced acute liver failure

3

The basis of intensive care management is to provide support for failing organs while allowing time for hepatic regeneration.

- Omeprazole or ranitidine are given as prophylaxis against gastrointestinal bleeding.
- Early enteral nutrition is recommended but there is no need to restrict protein or calories.
- Hypoglycaemia is common and an infusion of 10% glucose should be administered to keep the blood glucose level above 3.5 mmol/litre.
- Agitated or aggressive patients may need ventilation to enable care to be given.

Those with grade III or IV encephalopathy should be electively ventilated, because of the risk of cerebral oedema.

- High levels of positive end-expiratory pressure (PEEP) should be avoided because they may increase hepatic venous pressure and intracranial pressure (ICP).
- Pulmonary complications such as acute respiratory distress syndrome, aspiration or pneumonia occur in 50% of cases.
- Cardiac output is high (> 5.0 litre/minute) in 70% of cases, with a reduced systemic vascular resistance. Relative hypotension is therefore common and should be treated by volume loading with colloids. A pulmonary artery catheter or PiCCO should be inserted to guide therapy. Vasopressors (e.g. noradrenaline (nor-epinephrine)) may be needed to maintain mean arterial pressure, despite adequate volume replacement.
- N-acetylcysteine may be beneficial in the management of ALF even if paracetamol (acetaminophen) is not the cause. The evidence is conflicting, but it has been shown to increase cardiac output and oxygen delivery and is given as a loading dose of 300 mg/kg followed by an infusion of 150 mg/kg/hour.
- Coagulopathy is a major feature of ALF, because the liver synthesizes all the coagulation factors apart from factor VIII. Sepsis, reduced protein C and antithrombin III levels contribute to low- grade disseminated intravascular coagulation (DIC). The PT is a good measure of the severity of the disease and should not be corrected unless the patient is actively bleeding. Thrombocytopenia should be corrected if the platelet count falls below 50 x 10^9/litre.

Infection

Infection is common as a result of neutrophil and Küpffer cell dysfunction and sepsis is the cause of death in 11% of cases. Bacterial infections with Gram-positive organisms are seen in the first week and fungal infections after 2 weeks. The usual signs of infection (e.g. pyrexia, leucocytosis) may be absent and infection surveillance must be rigorous. Prophylactic fluconazole, 100 mg/day, should be started.

Cerebral oedema

Cerebral oedema develops in 80% of patients with Grade IV encephalopathy and is the cause of death in about 30–50% of patients with ALF. There is now evidence to suggest that it is the result of the high level of ammonia, which leads to an increase in the synthesis of intracellular cerebral glutamine. This increases osmotic pressure in astrocytes, resulting in cerebral oedema. The patient should be nursed with a 20° head-up tilt to improve cerebral perfusion pressure; there should be minimal intervention to prevent surges in ICP. Hyperventilation should be avoided and the $PaCO_2$ should be maintained at 4.7–5.2 kPa. Systolic hypertension and sluggish pupillary responses are the most reliable clinical signs of raised ICP, which should be treated with an intravenous bolus of mannitol 20%, 0.5 g/kg, which takes 20–60 minutes to act. The boluses may be repeated provided that the serum osmolality is less than 320 mOsmol/litre.

Some centres measure ICP using extradural, subdural or parenchymal monitors. However, the benefits must be balanced against the risk of haemorrhage, which occurs in about 15%. Coagulation should be corrected before the insertion of the monitor. Cerebral perfusion pressure should be maintained above 60 mm Hg. Thiopental (thiopentone) as a 50 mg bolus or an infusion of 50 mg/hour can be used to treat intractable intracranial hypertension, but may cause a fall in systemic blood pressure and a reduction in cerebral perfusion pressure. Moderate hypothermia (32–33°C) reduced ICP in one study.

Renal failure

Renal failure occurs in 70% of patients after paracetamol (acet-aminophen) overdose due to its nephrotoxic effect. Sepsis and hypovolaemia also contribute to renal failure. Haemodiafiltration may be necessary to maintain fluid balance and to correct hyponatraemia, hyperkalaemia and acidosis. A lactate-free replacement fluid should be used, because the failing liver can not clear lactate.

There has been considerable research into the development of an artificial liver. Trials of systems using extracorporeal perfusion of blood through columns of hepatocytes, or dialysis against an albumin-coated membrane have been undertaken, but most studies are small and experimental.

Prognosis

Overall survival with medical treatment is 10–40%. The prognosis depends on the aetiology and is best after paracetamol (acetaminophen) overdose and hepatitis A, and worst for non-A, non-B hepatitis and idiosyncratic drug reactions. The time to the onset of encephalopathy also affects prognosis, hyperacute failure has a 35% survival and subacute failure has a 15% survival. The outcome from transplantation for ALF is improving and is now 65–75%. ◆

Acute Lung Injury and the Acute Respiratory Distress Syndrome

Matthew E J Callister
Timothy W Evans

Matthew E J Callister is Wellcome Research Fellow at the Unit of Critical Care, National Heart and Lung Institute, London, UK.

Timothy W Evans is Professor of Intensive Care Medicine at Imperial College School of Medicine and Clinical Director of Intensive Care Medicine at the Royal Brompton and Harefield NHS Trust, London.

Acute lung injury (ALI) and its extreme manifestation, the acute respiratory distress syndrome (ARDS), complicate a wide variety of medical and surgical conditions. Mortality remains high (40–70%) and survivors often require extensive periods of intensive care, representing a considerable clinical and fiscal burden.

ALI and ARDS are defined by refractory hypoxaemia associated with lung inflammation and increased pulmonary vascular permeability. The commonly accepted radiological and physiological criteria were first established at an American–European Consensus Conference in 1993 (Figure 1). ALI and ARDS were defined as separate, yet related, states on a pathophysiological continuum of pulmonary damage. Standardization of the criteria required to diagnose these conditions greatly facilitated the design of clinical trials allowing comparison between patient groups in various studies. However, these definitions take no account of the prognostic significance of the precipitating condition, and fail to specify the ventilatory strategy to be used when the presence and severity of hypoxemia are established. It is also increasingly recognized that individual interpretation of chest radiographs can vary widely, even among experienced clinicians. The Consensus Conference therefore met again in October 2000 to address these concerns in revised criteria.

Definitions of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS)

- Appropriate clinical setting with one or more recognized risk factors
- New, bilateral, diffuse, patchy or homogeneous pulmonary infiltrates on chest radiograph
- No clinical evidence of heart failure, fluid overload, or chronic lung disease (pulmonary artery occlusion pressure < 18 mm Hg)
- PaO_2:FiO_2 ratio of < 40 kPa (< 300 mm Hg) for ALI or < 26.6 kPa (< 200 mm Hg) for ARDS

1

Incidence and aetiology
Historically, the incidence of ARDS is estimated as 1.5–75 cases per 100,000 population. However, the only study to use the 1993 consensus criteria to define ALI and ARDS using a prospective cohort study identified 17.9 and 13.5 cases of ALI and ARDS, respectively, per 100,000 population. Many serious medical and surgical conditions may precipitate ALI/ARDS, not all of which involve the lung (Figure 2). Prognosis depends in part on the nature of the precipitating insult. Thus, trauma-induced lung injury is associated with a more favourable outcome than that precipitated by sepsis. The presence of multiple risk factors further increases the likelihood of developing ARDS, as do co-morbid factors such as chronic alcohol abuse. A recent study has suggested that a history of diabetes reduces the risk of developing ARDS in patients with septic shock.

Causes of acute lung injury and acute respiratory distress syndrome

Pulmonary causes
- Pneumonia
- Aspiration of gastric contents
- Inhalational injury
- Hypoxia/reperfusion injury
- Fat emboli
- Pulmonary contusion
- Near-drowning

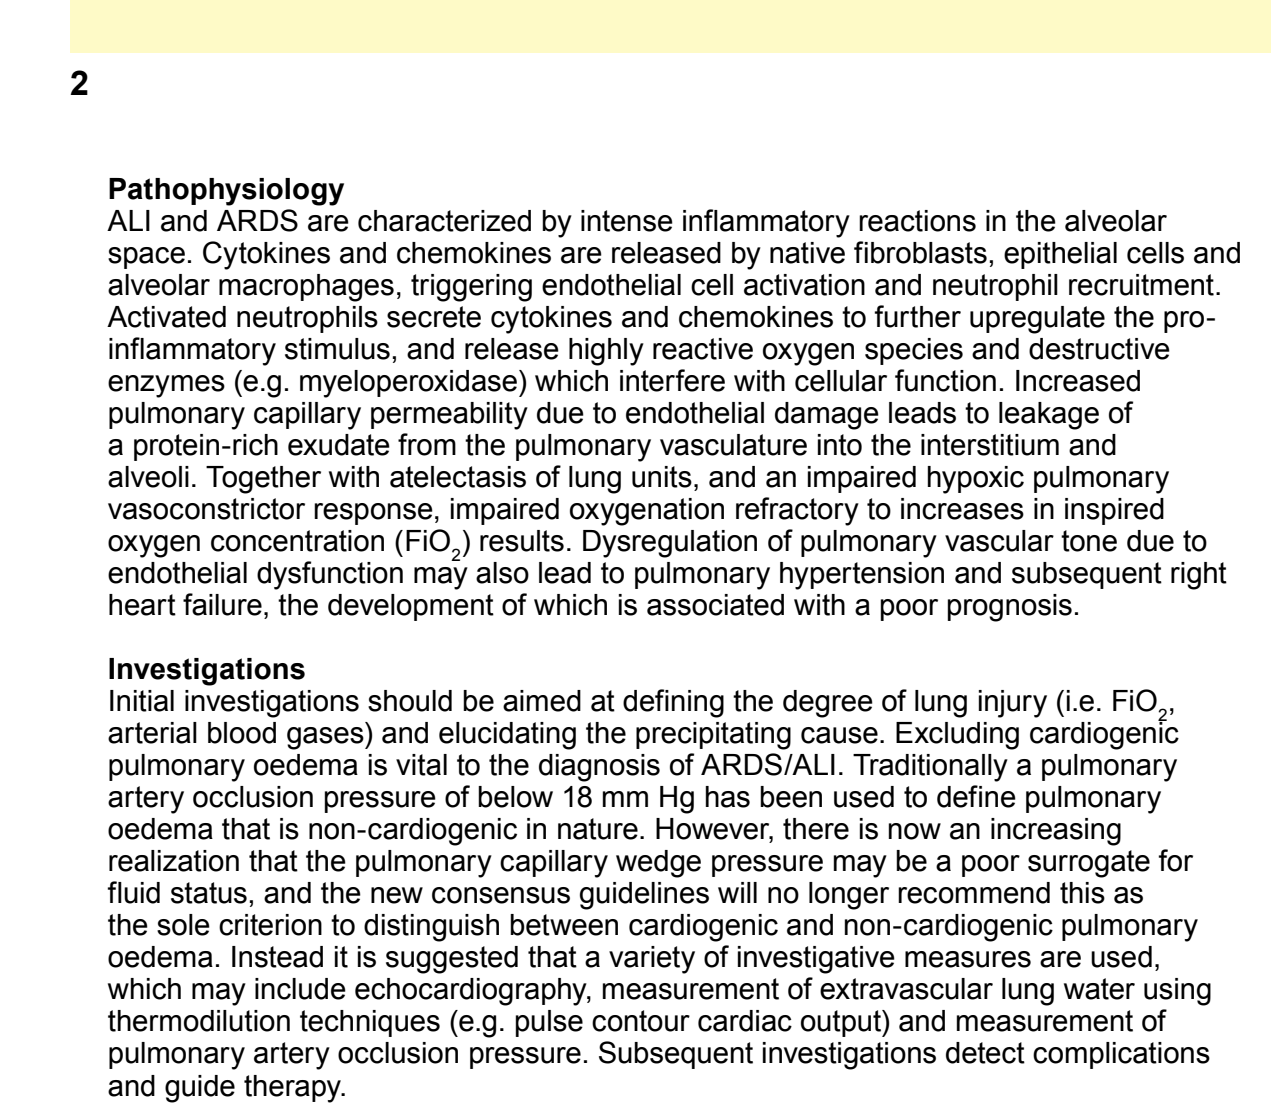
Non-pulmonary causes
- Sepsis
- Severe trauma
- Cardiopulmonary bypass
- Massive transfusion
- Drug overdose
- Acute pancreatitis

2

Pathophysiology
ALI and ARDS are characterized by intense inflammatory reactions in the alveolar space. Cytokines and chemokines are released by native fibroblasts, epithelial cells and alveolar macrophages, triggering endothelial cell activation and neutrophil recruitment. Activated neutrophils secrete cytokines and chemokines to further upregulate the pro-inflammatory stimulus, and release highly reactive oxygen species and destructive enzymes (e.g. myeloperoxidase) which interfere with cellular function. Increased pulmonary capillary permeability due to endothelial damage leads to leakage of a protein-rich exudate from the pulmonary vasculature into the interstitium and alveoli. Together with atelectasis of lung units, and an impaired hypoxic pulmonary vasoconstrictor response, impaired oxygenation refractory to increases in inspired oxygen concentration (FiO_2) results. Dysregulation of pulmonary vascular tone due to endothelial dysfunction may also lead to pulmonary hypertension and subsequent right heart failure, the development of which is associated with a poor prognosis.

Investigations
Initial investigations should be aimed at defining the degree of lung injury (i.e. FiO_2, arterial blood gases) and elucidating the precipitating cause. Excluding cardiogenic pulmonary oedema is vital to the diagnosis of ARDS/ALI. Traditionally a pulmonary artery occlusion pressure of below 18 mm Hg has been used to define pulmonary oedema that is non-cardiogenic in nature. However, there is now an increasing realization that the pulmonary capillary wedge pressure may be a poor surrogate for fluid status, and the new consensus guidelines will no longer recommend this as the sole criterion to distinguish between cardiogenic and non-cardiogenic pulmonary oedema. Instead it is suggested that a variety of investigative measures are used, which may include echocardiography, measurement of extravascular lung water using thermodilution techniques (e.g. pulse contour cardiac output) and measurement of pulmonary artery occlusion pressure. Subsequent investigations detect complications and guide therapy.

Chest radiography is easy to perform and may help in the detection of barotrauma or superadded infection. However, CT of the thorax is more sensitive for detecting pneumothoraces, pleural collections or pulmonary infiltrates, and is increasingly used as a routine investigation in ALI and ARDS. CT has also contributed to the understanding of the pathophysiology of ARDS by demonstrating patchy involvement of lung parenchyma rather than the homogeneous appearance seen on chest radiographs (Figure 3). Attempts have been made to use CT to predict responsiveness to interventions, one study correlating a response to inhaled nitric oxide with CT evidence of alveolar recruitment following increased positive end-expiratory pressure (PEEP).



Chest radiographs and CT scans for two patients with established acute respiratory distress syndrome. The radiographs show characteristic ground-glass shadowing bilaterally. Both CT scans demonstrate areas of interstitial ground-glass shadowing (w) with dense opacification (x) in the dependent regions. Patient 2 has extensive barotrauma and a pneumothorax (y) and an intercostal drain (z) are seen on the CT.

3

Fibre-optic bronchoscopy is often used to obtain microbiological samples to rule out pulmonary infection. Analysis of bronchoalveolar lavage fluid can also provide information concerning neutrophil infiltration and cytokine levels, which may have implications for prognosis.

Management

Treatment of the precipitating condition and the complications of ventilation (e.g. barotrauma, nosocomial infection) are essential in managing ALI and ARDS.

General supportive measures
Nutrition: adequate nutrition introduced early in the clinical course is now regarded as crucial to the management of patients with ARDS. Whenever possible, nutrition should be administered via the enteral route, and the use of prokinetic drugs, avoidance of agents that impair gastric emptying (e.g. dopamine) and the use of post-pyloric feeding tubes can help to achieve this. Recent research has suggested that feeds rich in certain fatty acids and antioxidants may be of benefit in ARDS, presumably via changes in the host immune response. Eicosapentaenoic acid (EPA) modulates production of pro-inflammatory eicosanoids, and γ-linoleic acid (GLA) may suppress production of leukotrienes while being metabolized to prostaglandin E_1. A recent randomized controlled trial of feeds supplemented with EPA/GLA in patients with ARDS has shown improvements in oxygenation, and shorter periods of ventilation and ICU stay. Further investigation in this area is required.

Fluid management: pulmonary oedema in ALI/ARDS is caused by increased pulmonary vascular permeability in the face of 'normal' pulmonary capillary pressures. Several studies have shown an association between a persistent positive fluid balance and poor outcome in ARDS, but it is not clear whether this represents administration of unnecessary fluid or greater haemodynamic instability in a group with a pre-existing poor prognosis. One clinical trial has shown that patients managed using the more restrictive of the two had shorter periods of ventilation and reduced ICU stays.

Ventilation and gas exchange

Protective ventilatory strategies: most patients with ARDS require mechanical ventilatory support to achieve adequate gas exchange. One study indicated that satisfactory oxygenation can be achieved in a proportion of patients by using positive pressure ventilation applied via a face mask, however, most patients require tracheal intubation.

The traditional strategies of ventilation used in these patients may have contributed to the propagation of lung injury. Experiments in animals showed that ventilation using large tidal volumes caused disruption of the pulmonary epithelium and endothelium, lung inflammation and impaired oxygenation. Excessive stretching of the lung parenchyma together with cyclical opening and closing of damaged lung units is thought to generate pro-inflammatory mediators, which exacerbate pulmonary damage, and if disseminated into the systemic circulation also contribute to the development of distant organ failure to which many patients succumb. As a result, ventilatory strategies now aim to limit the shear forces applied to the lung parenchyma, and reduce the cyclical recruitment and derecruitment of alveolar units. Thus, tidal volumes are set at lower levels than have traditionally been thought necessary. This reduces carbon dioxide clearance, often resulting in a respiratory acidosis. A large multi-centre trial in the USA has shown a convincing reduction in mortality (from 40% to 31%, p = 0.007) associated with this approach (using tidal volumes of 6 ml/kg) compared with conventional (12 ml/kg) ventilation.

High levels of PEEP can also be used to ensure recruitment and retention of damaged lung units. PEEP can also be transiently increased in a step-wise manner to high levels (e.g. 35–40 cm H_2O) before step-wise reduction to a maintenance level above the lower inflection point of the pressure–volume curve. CT images during such manoeuvres have demonstrated recruitment of atelectatic regions especially in dorsal areas of the lung, which remain inflated after the PEEP is reduced, with an associated improvement in gas exchange. A large multi-centre trial in North America is currently investigating the effect of different levels of PEEP and transient recruitment manoeuvres on outcome following ARDS.

Prone positioning: mechanical ventilation in the prone position is often used in the management of patients with ARDS. About 60% of patients respond with significant improvements in gas exchange, which may persist after the patient is returned to the supine position. Response cannot be predicted, therefore a trial period is often used to identify patients who are likely to benefit. There have been no controlled studies to establish whether this technique is associated with an improved outcome, although a large (over 300 patients) Italian study is soon to report.

Extracorporeal gas exchange is performed using veno-arterial bypass and can be used in the absence of conventional forms of ventilation as the sole mechanism of gas exchange, or coupled to mechanical ventilation (in which case its principal function is to enhance carbon dioxide clearance). Neither of the two randomized trials of extracorporeal gas exchange carried out to date revealed a survival advantage. An increased understanding of the most appropriate way to ventilate patients with severe ARDS is likely to lead to this technique being used less often.

Novel ventilatory techniques

High-frequency ventilation (HFV) is a mode of mechanical ventilation that employs rapid respiratory rates (more than four times those used in conventional techniques). Tidal volumes are reduced, and are often smaller than the anatomical deadspace. The two modes of HFV most widely used are high-frequency jet ventilation (HFJV) and high-frequency oscillator ventilation (HFOV). HFJV involves the intermittent delivery of high-pressure gas jets into the tracheal tube. However, optimal gas warming and humidification are difficult to achieve, leading to problems with airway secretions and debris, which coupled with a reliance on passive expiration can lead to air trapping. HFOV involves the delivery of a continuous distending pressure to the tracheal tube, which is then modified by the movement of a vibrating loudspeaker. Humidification and warming of the fresh gas flow are easier to achieve, and an active expiratory phase leads to less gas trapping. The only randomized controlled trial of HFJV in patients with severe acute respiratory failure did not show a significant improvement in gas exchange or a survival benefit. However, recent evidence suggesting that low tidal volumes reduce ventilator-associated lung injury, and that high levels of continuous airway pressure (PEEP) improve recruitment and retention of lung units, has renewed interest in HFV (especially HFOV) as an appropriate mode of ventilation in ARDS.

Liquid ventilation involves filling the lungs with biologically inert fluids called perfluorocarbons through which oxygen and carbon dioxide readily diffuse. Ventilation occurs either through a specialized ventilator, or if the lungs are only partially filled (partial liquid ventilation) by using a conventional ventilator. The results of a phase II study of partial liquid ventilation in patients with ARDS are awaited.

Pharmacological therapies

Vasoactive agents: nitric oxide is an endogenous vasodilator, which can be given by inhalation at concentrations up to 20 parts per million. It has been shown to improve oxygenation in ALI and ARDS through effects on ventilation–perfusion matching, and to decrease pulmonary vascular resistance. Only a proportion of patients with ARDS benefit from nitric oxide and randomized controlled trials in patients with ALI and ARDS have failed to show an improvement in mortality or a reduction in the duration of mechanical ventilation. Improvements in oxygenation are transient, disappearing after 24 hours of therapy.

Prostacyclin (PGI_2) is another endogenous vasodilator that may have beneficial effects in ARDS. Like nitric oxide it is thought to redistribute pulmonary blood flow to ventilated lung units, thus improving ventilation–perfusion matching. A sequential trial of nitric oxide and PGI_2 in patients with ARDS showed the two treatments to have identical effects on oxygenation and shunt flow, but as PGI_2 is easier to monitor and deliver than nitric oxide, it is often used in its place.

Surfactant supplementation has proved effective in neonatal respiratory distress syndrome, and surfactant deficiency and dysfunction has been demonstrated in adult patients with ARDS. A number of randomized controlled trials have failed to demonstrate an effect on either mortality or length of ventilation or ICU stay. More recently, a smaller trial has shown a survival benefit following use of bovine surfactant, but further large-scale trials are necessary.

Antioxidants: oxidative stress is thought to be central to the pathogenesis of ARDS. Alveolar macrophages and recruited activated neutrophils release highly reactive oxygen species, which cause injury through interactions with proteins, lipids and DNA. It is thought that excessive production overwhelms the endogenous antioxidant systems that normally regulate the redox state within the lung. Attempts have therefore been made to introduce antioxidants to redress this balance, in particular using N-acetylcysteine, but none has shown a survival benefit nor a reproducible effect on pulmonary physiology.

Anti-inflammatory agents: ketoconazole is an imidazole used primarily for its antifungal effects, but which also has immune modulating functions that may be of benefit in preventing the development of ARDS. Although a large multi-centre trial showed that ketoconazole had no effect on mortality or duration of ventilation in patients with established ALI or ARDS, two smaller studies in critically ill surgical patients demonstrated a significant reduction in the incidence of ARDS.

Corticosteroids have been used to treat ARDS since the 1960s. However, several multicentre trials in the 1980s failed to show a beneficial role for corticosteroids, either in the prevention of ARDS in at-risk groups or in the treatment of established ARDS. Recent meta-analyses have concluded that corticosteroids do not improve, and may worsen, mortality in patients with sepsis (a high-risk group for ARDS). However, despite this evidence, there has been a recent resurgence in enthusiasm for the use of corticosteroids in the late (fibroproliferative) phase of ARDS. The only controlled data to support such therapy randomized patients on day 7 of ARDS to receive methylprednisolone or placebo for 32 days. Despite the small numbers of patients studied (24), there was an impressive reduction in ICU and hospital mortality (p = 0.002 and p = 0.03, respectively) associated with corticosteroid use. However, care must be taken to exclude continuing infection before the introduction of corticosteroids in this setting.

Prognosis and future developments

Few interventions in ALI and ARDS have been demonstrated to improve outcome. This may be, in part, because only about 5% of patients die as a result of respiratory failure, and thus therapies that improve oxygenation or other ventilatory parameters are unlikely to impact significantly on mortality. The heterogeneity of patients entered into trials as a result of the broad definitions of ALI/ARDS may preclude the demonstration of outcome benefit. New definitions of ALI/ARDS and an increasing focus on aetiological subgroups of patients are needed.

Despite this, an improvement in the outcome of ARDS in single centres has been reported in recent years, one study reporting a reduction in mortality from 66% to 34% over the years 1990 to 1997. Large-scale clinical trials (coordinated by the ARDS network in North America) are investigating the use of late steroids, the optimal settings of PEEP, and the effects of recruitment manoeuvres in ARDS. There is also increasing interest in genetic polymorphisms that may predict susceptibility to develop these conditions and thus allow early identification of high-risk patients.

Acute Pancreatitis

Tony Pickworth

Tony Pickworth is Consultant in Anaesthesia and Intensive Care Medicine at the Great Western Hospital, Swindon, UK. He qualified from Emmanuel College, Cambridge, and Merton College, Oxford, and trained in anaesthesia in Stoke-on-Trent and East Anglia. He is an examiner in physiology for the MRCS (London). His particular interests are ventilation strategies and sedation for intensive care.

Aetiology and pathogenesis

Acute pancreatitis is an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems.

Gallstones and high alcohol intake are associated with about 80% of cases. 10% of cases are idiopathic. Other causes include:

- hypertriglyceridaemia
- hypercalcaemia
- trauma
- endoscopic retrograde cholangiopancreatography (ERCP)
- drugs (e.g. sodium valproate, tetracycline, thiazides, furosemide (frusemide)).

The incidence of acute pancreatitis appears to be rising. Figures as high as 200/1,000,000 population have been quoted; a ten-fold increase since 1970. High alcohol intake accounts for much of this rise. The disease is most common in women aged 50–60 years.

The cellular mechanisms involved in the development of acute pancreatitis are unclear, however, a key step appears to be intra-acinar activation of trypsinogen. This causes activation of other enzyme systems including lipase, phospholipase A2, elastase, chymotrypsin and the kallikrein-kinin system, resulting in fat and tissue necrosis, coagulation, vascular damage, haemorrhage, oedema formation and inflammation.

Diagnosis and assessment of severity

The clinical presentation is of rapid onset of upper abdominal or back pain, vomiting, fever and tachycardia. Occasionally Grey Turner (bruising in the loin) and Cullen (bluish discoloration near the umbilicus) signs may be present. In about 80% of cases the course is mild and resolves spontaneously.

Diagnosis is most commonly made using serum amylase estimation, though there are limitations to its specificity and sensitivity. The serum lipase level is more accurate and a better marker for alcoholic pancreatitis. However, the laboratory measurement of lipase was, until recently, more complicated and it is not available in many centres.

Assessment of severity – the most common scoring systems are those of Ranson and Glasgow (or Imrie). The criteria for the Glasgow system are:

- patient aged over 55 years
- white blood cell count over 15 x 10^9/litre
- serum glucose over 10 mmol/litre
- serum urea over 16 mmol/litre
- partial pressure of oxygen in arterial blood (PaO_2) less than 60 mm Hg (8.6 kPa)
- serum calcium less than 2 mmol/litre
- serum albumin less than 32 g/litre
- serum lactate dehydrogenase over 600 units/litre
- serum aspartate transaminase over 100 units/litre.

Three positive criteria within 48 hours indicate severe disease. The disadvantage of the above systems is that data collection is not complete until 48 hours after patient admission. Evidence suggests that APACHE II (Acute Physiology and Chronic Health Evaluation) scoring at 24 hours is at least as accurate.

Biochemically, C-reactive protein (CRP) is a useful test to assess severity, but only 72 hours after disease onset. An earlier marker is urinary trypsinogen activation peptide (TAP) which is valuable at 24 hours. It has an 86% sensitivity for identifying patients who will develop severe disease.

Imaging may be necessary to diagnose the disease or its cause. Ultrasound is useful in suspected pancreatitis only for diagnosing gallstones. Contrast CT scanning is the imaging procedure of choice to diagnose and monitor acute pancreatitis.

Management

General care: the basis of management is:

- bed rest
- analgesia
- intravenous fluids
- withholding of oral intake
- support of failing organ systems
- identification of severe cases
- identification of complications.

In episodes with complications, or those predicted to be severe, the patient should be managed in a critical care area. Physiological supportive care is required because systemic inflammatory response syndrome (SIRS) or multiple organ failure may result.

Specific therapies include:

- aprotinin
- glucagon
- somatostatin
- octreotide
- gabexate mesilate (an antiprotease agent)
- fresh frozen plasma
- lexipafant (an inhibitor of platelet activating factor)
- peritoneal lavage.

None of these have any impact on the mortality rate, though there is weak evidence that lexipafant, commenced within 48 hours of disease onset, can reduce complications and organ failure.

Nutrition: in severe or prolonged cases total parenteral nutrition is commonplace. Total parenteral nutrition seldom causes release of pancreatic enzymes, except when there is a high lipid load. Enteral nutrition promotes pancreatic enzyme production unless feed is delivered into the jejunum or below. Elemental feeds seem to stimulate the pancreas even if delivered directly to the jejunum, whereas standard feeds do not.

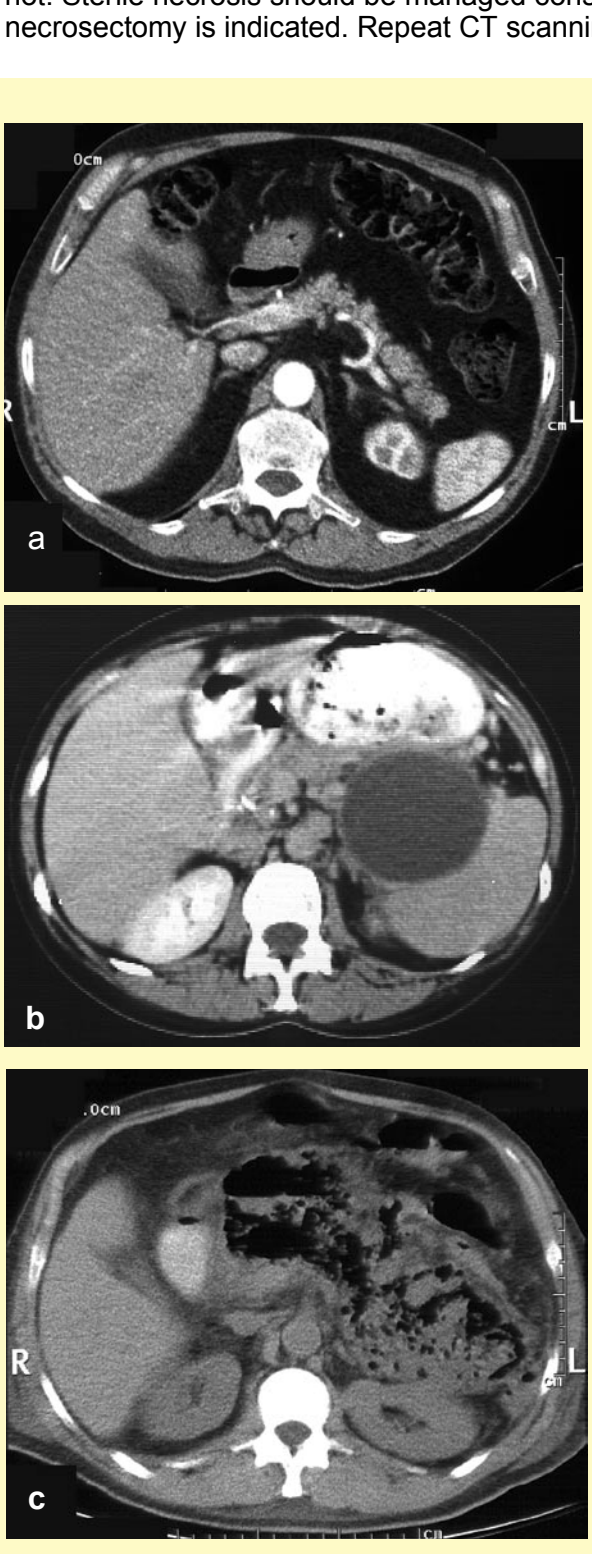
ERCP and sphincterotomy may be necessary in the case of gallstone pancreatitis even in the acute phase of the illness. It is recommended if there is evidence of obstructive jaundice, or for severe pancreatitis with gallstones that does not settle within 72 hours.

Complications: the main complications of pancreatitis are:

- infection and/or abscess formation
- pancreatic necrosis
- multiple organ failure
- hypocalcaemia
- pseudocyst formation
- chronic pancreatitis.

The mortality from infected severe pancreatitis is over 50%. There is evidence to support the use of prophylactic antibiotics in severe pancreatitis. Where there is proven infection, but a specific organism is unknown, treatment with imipenem, 500 mg 8 hourly, is suitable, because of its spectrum and pen-etration into pancreatic tissue.

CT scanning is used to recognize abscess or pseudocyst formation or necrosis (Figure 1). Even if a CT scan is not required for diagnostic purposes, it should be performed 3–10 days after the start of a severe attack. If signs of necrosis are seen, a fine needle aspirate of the pancreatic fluid is indicated to identify whether the tissue is infected or not. Sterile necrosis should be managed conservatively but, if there is infection, open necrosectomy is indicated. Repeat CT scanning is recommended every 1–2 weeks.



a Normal pancreas (CT with contrast);
b Inflamed pancreas with pseudocyst;
c Extensive pancreatic necrosis with gas trapping (emphysematous pancreatitis).

1

Acute respiratory distress syndrome and multiple organ failure are common sequelae of severe pancreatitis and require supportive care. Specifically, hypocalcaemia may result, owing to hypoalbuminaemia, abnormal parathyroid activity, or form-ation of intraperitoneal soaps with released free fatty acids. Other metabolic complications include hyperlipidaemia and hyperglycaemia.

Prognosis and further management

80% of cases are mild attacks that settle in a few days with conservative management. Mortality in such cases is less than 2%. In severe cases, mortality is about 10% overall; 20% where there is necrosis and over 50% with infected necrosis. Data from the Intensive Care National Audit and Research Council case-mix programme indicate a hospital mortality of 44% for patients with pancreatitis admitted to ICU.

Although the spectrum of severity is similar with different aetiology, there may be a difference in outcome. If pancreatitis is associated with alcohol there is often evidence of chronic fibrosis and inflammation, but with acute biliary pancreatitis the gland usually returns to histological normality. Gallstone pancreatitis is likely to recur if the stones are not treated, and it is recommended that cholecystectomy and clearance of the common bile duct is performed within 4 weeks of the attack. ◆

Acute Renal Failure and Renal Replacement Therapy in the ICU

Sara Blakeley
Gary Smith

Sara Blakeley is Specialist Registrar in Portsmouth, UK. She qualified from Southampton University and is training in intensive care medicine and nephrology. Her particular interest is critical care nephrology.

Gary Smith is Consultant in Intensive Care Medicine at Portsmouth Hospital NHS Trust and Honorary Senior Lecturer in Critical Care in the School of Postgraduate Medicine at the University of Portsmouth. After qualifying from the University of Southampton, he trained in anaesthesia and medicine in the South of England and at Yale University, USA. His main interests are multiprofessional education, cardiopulmonary resuscitation and pre-hospital trauma care.

Acute renal failure (ARF) is a sudden and sustained fall in the glomerular filtration rate (GFR) associated with a loss of excretory function and the accumulation of metabolic waste products and water. It leads to rising serum urea and creatinine, usually with a fall in urine output. Definitions such as a doubling of the serum creatinine or daily urine volumes of less than 400 ml have been used as diagnostic markers for ARF. The absence of a universally accepted definition for ARF makes determining its incidence difficult, but up to 10% of all patients admitted to the ICU receive some form of renal replacement therapy.

Patients with hospital-acquired ARF are more likely than those with community-acquired ARF to be admitted to ICU. In critically ill patients, renal failure is often a component of multiple organ failure, and its aetiology is likely to be multifactorial. Different incidence rates between ICUs are a reflection of their case-mix as well as different attitudes to renal replacement therapy. Renal failure in patients on the ICU is unlikely to resolve with conservative management; up to 70% of patients with ARF require renal replacement therapy. In many cases this is started within 24 hours of admission to the ICU.

The main causes of ARF (Figure 1) can be categorized as pre-renal, intrinsic or obstructive.

Mortality – in ICU, ARF alone has a mortality of 20–30% but this rises if another organ failure exists. When associated with ARF, failure of two organs leads to death in about 50% of patients, rising to over 90% if ARF accompanies three or more organ failures.

Outcome – following discharge from the ICU, about 70% of those who have developed ARF recover renal function completely. 5–10% of patients with previously normal renal function remain on long-term renal replacement therapy. The figure is much higher (about 30%) if there is a background of pre-existing renal impairment.

Causes of acute renal failure on the ICU

Pre-renal (renal hypoperfusion)
- Intravascular volume depletion (e.g. dehydration, blood loss, redistribution of fluid between body compartments)
- Severe hypotension (e.g. sepsis, drugs)
- Reduced cardiac output (e.g. pump failure post myocardial infarction, myocardial ischaemia)

Intrinsic renal failure
- Acute tubular necrosis (ATN)
  Ischaemic (the extreme end of pre-renal failure, also seen with pancreatitis, burns, sepsis)
  Exogenous toxins (e.g. radiocontrast, nephrotoxic drugs – usually occurs on a background of volume depletion, sepsis or pre-existing renal impairment)
  Endogenous toxins (e.g. rhabdomyolysis, massive haemolysis, tumour lysis syndrome)
- Hepatorenal syndrome
- Acute glomerulonephritis/interstitial nephritis (with multi-system involvement)
- Increased intra-abdominal pressure
- Vascular (e.g. malignant hypertension, atheroembolic conditions)

Obstructive renal failure
- Unusual to be main cause of acute renal failure on the ICU

Renal replacement therapies

In an ICU, renal replacement therapies can be categorized as continuous or intermittent. In the UK, continuous therapies predominate (Figure 2). There are few randomized controlled trials comparing intermittent with continuous therapies, but continuous renal replacement therapy (CRRT) is associated with reduced mortality. CRRT usually involves the removal and return of blood through a single cannula placed in a large vein (veno-venous therapy); arteriovenous therapies are seldom used. CRRT causes less haemodynamic instability, because fluid removal is slower and there is time for fluid to re-equilibrate between body compartments.

Continuous renal replacement therapies used on ICUs

Mode of therapy	Principal method of solute clearance
Continuous veno-venous haemofiltration (CVVH)	Convection
Continuous veno-venous haemodiafiltration (CVVHDF)	Convection and diffusion
Continuous veno-venous haemodialysis (CVVHD)	Diffusion
Slow continuous ultra-filtration (SCUF)	Fluid removal by ultrafiltration
High flux dialysis (HFD)	Convection and diffusion

Principles of CRRT

In CRRT, solutes are removed from blood by diffusion or convection. Different processes remove different sized molecules (Figure 3).

Diffusion is the movement of solutes down a concentration gradient across a semipermeable membrane. This is the main physical process occurring during haemodialysis. Solutes (e.g. urea, creatinine) cross the dialysis membrane from the blood to the dialysis fluid compartment. Fluid in the dialysis compartment moves in a counter-current direction, thereby maintaining a concentration gradient. It is also possible for solutes (e.g. bi-carbonate) to move in the opposite direction (e.g. from dialysate to blood).

Convection – if a pressure gradient is set up across the dialysis filter, water is pushed across the membrane and carries dissolved solutes with it; this is known as the solvent drag. The movement of fluid across the membrane as a result of this transmembrane pressure is ultrafiltration, and the fluid produced is ultra-filtrate. The process by which solutes move across the membrane is convection.

Size of molecules cleared by continuous renal replacement therapies (CRRT)

Type of molecule	Size	Example	Mode of removal
Small	< 500 Da	Urea, creatinine, amino acids	Convection, diffusion
Middle	500–5000 Da	Vitamin B_{12}, inulin, vancomycin	Convection better than diffusion
Low molecular weight proteins	5000–50,000 Da	β_2 microglobulin, cytokines, complement	Convection or absorption (on to filter)
Large proteins	> 50,000 Da	Albumin	Only minimal removal by standard CRRT

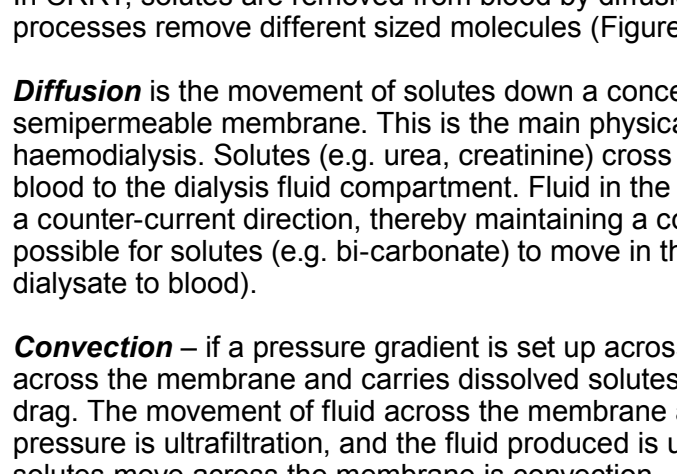
Da = Daltons

Types of CRRT

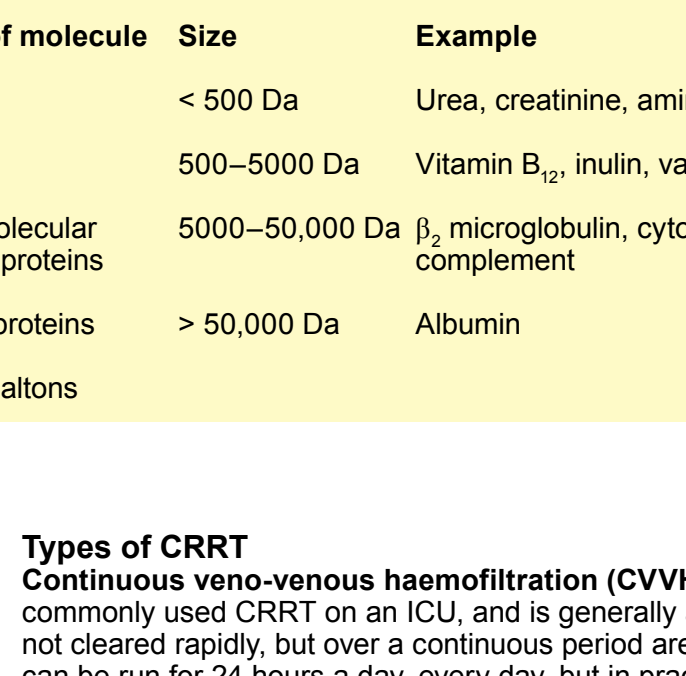
Continuous veno-venous haemofiltration (CVVH) (Figures 4a and 5) is the most commonly used CRRT on an ICU, and is generally a continuous process. Solutes are not cleared rapidly, but over a continuous period are cleared efficiently. The process can be run for 24 hours a day, every day, but in practice it is often run for 24–72 hours at a time. 'Down time' occurs to change the filter (either electively or because the filter has clotted) or for procedures to take place. It is stopped when there is evidence of a return of renal function.

Types of continuous renal replacement therapies

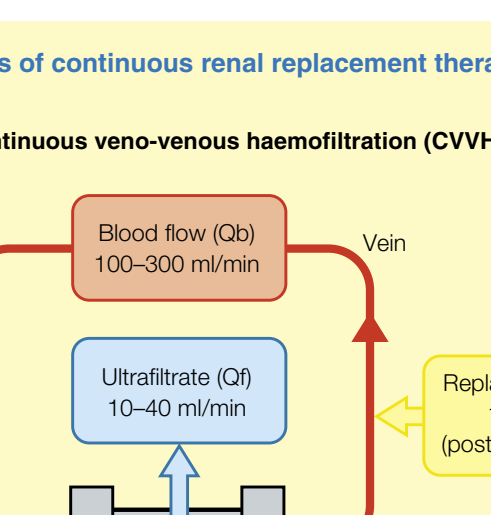
a Continuous veno-venous haemofiltration (CVVH)

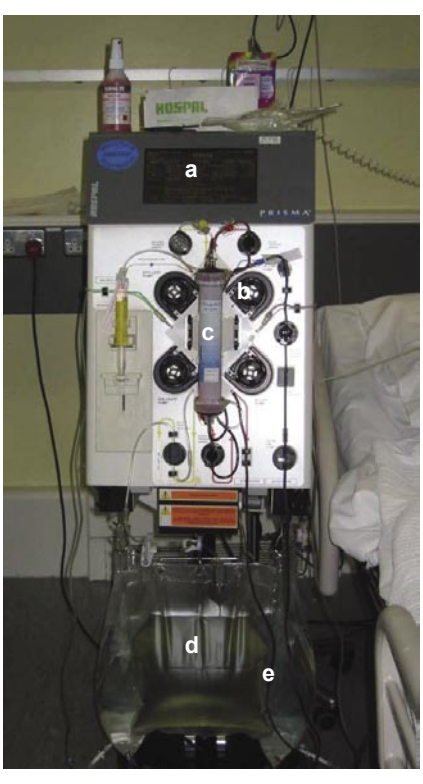


b Continuous veno-venous haemodiafiltration (CVVHD)



c Slow continuous ultrafiltration (SCUF)





5 The Prisma (Hospal) continuous renal replacement therapy machine. **a** Information screen; **b** four pumps (dialysate, blood, replacement fluid, effluent); **c** filter; **d** effluent bag; **e** replacement fluid.

Blood is usually pumped through the dialysis circuit at the highest achievable flow rate (100–200 ml/minute); this depends on the quality of vascular access and the patient's haemodynamic state. A specialized, sterile fluid (replacement fluid) replaces the large volume of ultrafiltrate removed. There is no consensus on how long or how fast haemofiltration should be undertaken, but an ultrafiltration rate of at least 35 ml/kg/hour has been associated with improved survival compared with 20 ml/kg/hour. In practice about 2 litres of ultrafiltrate are removed each hour. Either all or part of the ultrafiltrate is replaced depending on the desired overall fluid balance.

Continuous veno-venous haemodiafiltration (CVVHD) (Figure 4b) is similar to CVVH but combines diffusion and convection. Blood and dialysate fluid are circulated in a counter-current fashion. As with CVVH, a transmembrane pressure is applied, producing large volumes of ultrafiltrate. Replacement fluid is reinfused at a rate dependent on the volume of fluid to be removed.

Haemodialysis almost exclusively uses diffusion to remove solutes from plasma but can be combined with ultrafiltration to remove fluid. As with CVVHD, blood and dialysis fluid are circulated in a counter-current fashion, but no replacement fluid is reinfused. This treatment is generally performed intermittently for patients with end-stage renal failure needing chronic dialysis. It can be performed continuously on the ICU, but its use is not widespread.

Ultrafiltration can be applied alone as a slow and continuous therapy, termed slow continuous ultrafiltration (SCUF) (Figure 4c). Ultrafiltrate is formed at a rate of less than 300 ml/hour and replacement fluid is not infused. It can be useful when there is volume overload, but no solute accumulation (e.g. congestive cardiac failure).

Continuous high flux dialysis uses a highly permeable dialysis membrane with blood and dialysate circulating in a counter-current fashion. The production of ultrafiltrate is controlled by pressure, and is reinfused by backfiltration in the blood system, therefore a separate replacement fluid is not needed. This process is seldom used on the ICU.

Indications for starting renal replacement therapy

It is better to start renal replacement therapy early rather than wait for complications of ARF to develop (Figure 6). Fluid balance is a major stimulus for starting CRRT in critically ill patients because large volumes of daily intravenous fluids are required to maintain intravascular volume, and for drug delivery and nutrition.

Indications for starting renal replacement therapy

Indication	Comments
Anuria or oliguria	Urine volumes < 200 ml/12 hours
Hyperkalaemia	Serum potassium persistently > 6.5 mmol/litre
Severe acidaemia	pH < 7.1
Serum urea > 30 mmol/litre or creatinine > 300 μmol/litre	Values are not absolute, only a guide
Refractory fluid overload	Especially if compromising lung function
Uraemic complications	Encephalopathy, pericarditis, neuropathy or myopathy
Temperature control	Hyper- or hypothermia
Drug overdose	See Figure 7
Sepsis	

Convection removes low molecular weight proteins of 5000–50,000 Da. Many of the septic mediators (e.g. cytokines, complement) lie within this group. These mediators are absorbed onto the filter membrane and so removed. Interest surrounds the use of high volume haemofiltration to remove these inflammatory mediators to improve outcome from severe sepsis. High volume filtration is defined as ultrafiltration of over 2 litres/hour, and there is evidence that filtrate volumes up to 6 litres/hour are associated with a significantly lower mortality in septic patients.

Vascular access

Most renal replacement therapy is veno-venous in nature, therefore vascular access is usually via a double-lumen vascular catheter placed in a central vein. Blood is withdrawn from the proximal lumen ('arterial side') and returned through the distal lumen ('venous side').

The site of insertion is determined clinically, because critically ill patients often have other central venous catheters in place. The subclavian route is usually avoided in patients who may need an arteriovenous fistula for long-term haemodialysis, because the incidence of subclavian vein stenosis following cannulation is high.

Blood flow through the catheter should be good. Poor access should not be treated by reducing blood flow rates, because this leads to ineffective solute clearance.

Dialysis filters

As blood comes into contact with the filter (membrane) surface, complement and leucocytes can become activated, triggering the coagulation cascade and inflammatory pathways. The degree of activation is variable with some filters having more 'membrane biocompatibility' than others (more biocompatibility means less activation). It is suggested that biocompatible membranes are associated with an improved outcome from ARF, but the evidence is not robust.

Filter membranes are either cellulose-based or synthetic. Cellulose-based filters (e.g. cuprophane, cellulose acetate) are very thin and strongly hydrophilic. They are generally low flux membranes and are poor at removing middle molecules. Synthetic filters (e.g. polysulfone, polyamide, polyacrylonitrile) are high flux membranes and are generally more biocompatible than cellulose membranes. The flux of a membrane refers to its hydraulic permeability and how much convective transport can take place across it. Most filters used for CRRT are synthetic, high flux membranes with a surface area of 0.6–1.2 m^2.

Replacement fluid

A sterile replacement fluid replaces the ultrafiltrate removed by haemofiltration and haemodiafiltration. The fluid is infused either before the filter (pre-dilution) or into blood leaving the filter (post-dilution). Pre-dilution lowers the haematocrit of blood passing through the filter thus reducing anticoagulation requirements, but leads to a 10% reduction in solute clearance.

The main buffers in replacement fluid are lactate or bicarbonate. Many critically ill patients already have a lactic acidosis or are unable to handle lactate appropriately. In these patients, a paradoxical worsening of the acid–base balance may be seen with a lactate buffer.

The concentration of sodium, potassium and glucose in the replacement fluid can be varied depending on the clinical need. However, the fluid does not contain phosphate or amino acids and these may have to be supplemented.

Anticoagulation during renal replacement therapy

During CRRT, blood is continually in contact with the circuit tubing and the filter, with consequent stimulation of the coagulation cascade. Recurrent clotting of the circuit renders treatment inadequate and is a drain on nursing and financial resources.

Often, CRRT can be performed in critically ill patients without the use of anticoagulants because they often have deranged clotting, thrombocytopenia or both. Anticoagulation-free CRRT is made easier with good venous access, good blood flow rates and pre-dilution.

If anticoagulation is required, unfractionated heparin at doses that do not alter the activated partial thromboplastin time (e.g. 5–10 IU/kg/hour) can be used. Full systemic heparinization is seldom needed. Other options include low-molecular-weight heparin, recombinant hirudin, regional heparinization and the use of prostacyclin. The latter inhibits platelet aggregation but has no effect on coagulation parameters. Its side-effects include vasodilatation, but this is seldom a contraindication, even in patients with an unstable cardiovascular system.

Pharmacokinetics on CRRT

The high flux haemofilter membranes used in CRRT are per-meable to most non-protein-bound drugs (Figure 7). While receiving CRRT, the doses of drugs should be given on the assumption that the GFR is 10–50 ml/minute. When a patient with ARF is not receiving renal replacement therapy, the GFR should be assumed to be less than 10 ml/minute. With pre-dilution, the concentration of the drug entering the membrane is reduced by dilution. During CRRT, the highest drug clearances occur with drugs that are not protein-bound or when post-dilution is used. ◆

Pharmacokinetics

Drugs removed on haemodialysis
- Salicylates
- Methanol
- Barbiturates
- Lithium
- Aminoglycosides
- Cephalosporins

Drugs not removed on haemodialysis
- Digoxin
- Tricyclic antidepressants
- Phenytoin
- Benzodiazepines
- β-blockers
- Oral hypoglycaemic agents

Antibiotic Prescribing in the ICU

Richard Brindle

Richard Brindle is Consultant Microbiologist and Infection Control Doctor at Portsmouth Hospitals, Portsmouth, UK. He qualified from Southampton University and trained in general medicine and microbiology in Coventry, the London School of Hygiene and Tropical Medicine, and Oxford. His interests are in hospital-acquired infections and tropical diseases.

Choosing an appropriate antibiotic

Patients in the ICU displaying signs of sepsis belong to one of the following categories:

- infected with a known organism from an identified site
- infected with a known organism from an unidentified site
- infected, but no causal agent has been identified
- uninfected.

Occasionally the clinical signs of an infection suggest the causal organism and the appropriate antibiotic. However, the choice of antibiotic is often guided by the results of microbiological investigation. Ideally, specimens for culture should be taken before antibiotics are given. Appropriate specimens include:

- blood cultures (preferably from different sites)
- urine
- respiratory secretions (non-bronchoscopic lavage samples are preferred)
- wound swabs or aspirates from skin lesions
- drain, fistula or other fluids or pus
- other relevant specimens.

Cultures should be repeated every few days, even if the patient is improving or stable. This allows empirical therapy to be rationalized and provides information about patterns of resistance.

If the organism is known, a decision can be made about the most suitable antibiotic, the most appropriate dose and dosing schedule, the ideal duration of therapy and the need for adjunctive therapy. If the source of infection is unknown, the site can often be suggested on the basis of an organism isolated from blood (Figure 1).

Correlation between organism and site of infection

Isolate from blood	Likely sites	Action
Staphylococcus aureus	Infected intravenous line site Deep sepsis (abscesses) Endocarditis	Remove source, if possible, and give at least 14 days' therapy All *S. aureus* infections need treating
Staphylococcus epidermidis (coagulase-negative *Staphylococcus*)	Contaminant Colonized lines (venous and arterial) Infected prosthesis	Remove source Treating colonized tunnelled lines may be successful
Enterococcus spp.	Colonized lines Intra-abdominal sepsis Endocarditis	Remove source Drain collection Treat, if source cannot be removed
Coliforms	Urinary tract Gall bladder Intra-abdominal sepsis Lines Chest	Treat Drain any collections Remove lines
Anaerobes	Intra-abdominal sepsis Necrotizing cutaneous infections	Drain collection Debridement Treat
Pseudomonas aeruginosa urinary catheter)	Colonized lines Urinary tract Chest	Remove source if possible (line or Treat
Yeasts	Colonized lines Intra-abdominal sepsis Urinary tract	Remove source Drain collection and give at least 14 days' therapy

Antibiotic combinations

Combinations of antibiotics are recommended when:

- the cause of the infection is unknown
- multiple bacteria are involved
- resistance develops easily on monotherapy
- the outcome is known to be improved with combinations of antibiotics.

The most common ICU situation in which combination therapy is appropriate is in the treatment of ventilator-associated pneumonia (VAP). This is characterized by the onset of an inflammatory response, radiographic changes, purulent secretions and hypoxaemia after a patient has received positive-pressure ventilation for a few days. The organisms causing VAP are varied and depend on the patient's previous pulmonary history and previous use of antibiotics. Late onset VAP is generally caused by *Pseudomonas aeruginosa* or *Staphylococcus aureus*. Most UK hospitals have high levels of methicillin-resistant *S. aureus* (MRSA), therefore a high proportion of *S. aureus* VAP is caused by MRSA. Consequently, when empirical therapy for VAP begins it should include an agent directed against both *Ps. aeruginosa* and MRSA.

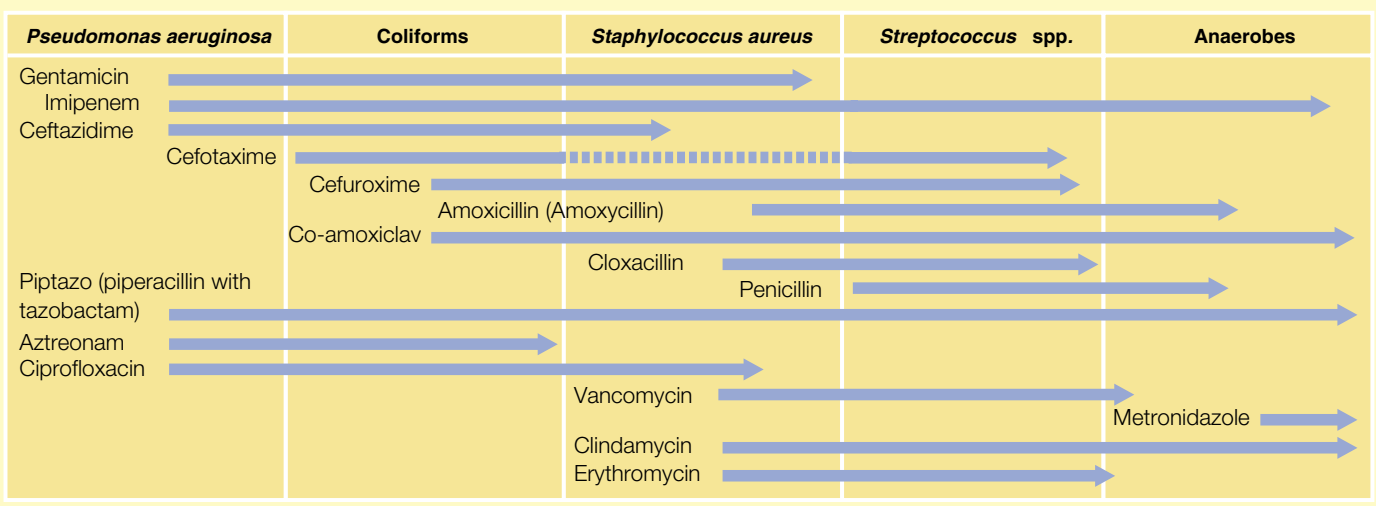
While the development of vancomycin resistance by MRSA with monotherapy is rare, the development of resistance to anti-pseudomonal antibiotics while taking anti-pseudomonal monotherapy is common. One way of reducing resistance developing in *Ps. aeruginosa* is to use two anti-pseudomonal antibiotics, of different classes.

Combinations of antibiotics are also of value when resistance is high or unpredictable and they ensure that at least one anti-biotic will be effective. Antibiotic combinations can also be more effective than monotherapy, for example an aminoglycoside and acylureidopenicillin (azlocillin or piperacillin) in the treatment of *Ps. aeruginosa* infections. However, the risk of toxicity increases with the number of antibiotics used and, if adequate levels of both antibiotics are not maintained, resistance to one agent can develop. This is commonly seen with rifampicin and *S. aureus* infections.

Broad-spectrum and narrow-spectrum antibiotics

Most antibiotics used as empirical therapy in the ICU have a broad antibacterial spectrum which is useful if the cause of sepsis is uncertain. However, broad-spectrum agents are generally more expensive, have significant effects on the patient's normal flora and are more likely to lead to *Clostridium difficile*-associated diarrhoea, fungal overgrowth and colonization with resistant organisms. Therefore, it is sensible to change to a narrow-spectrum agent as soon as possible, though whether this reverses the effect of an initial broad-spectrum agent is uncertain. Figure 2 illustrates the spectrum of activity of commonly prescribed antibiotics.

Spectrum of activity of some antibiotics



Only vancomycin or teicoplanin are suitable for empirical treatment of *Staphylococcus epidermidis* (coagulase-negative *Staphylococcus*) and methicillin-resistant *Staphylococcus aureus* (MRSA). Bacteria such as meningococci, *Haemophilus*, *Listeria*, enterococci and the 'atypicals' do not fit neatly into the scheme.

Selective decontamination of the digestive tract

There is strong evidence that by reducing the bacterial load on a patient on admission to the ICU, infection can be reduced. This can be accomplished using broad-spectrum antibiotics and antifungals and seems to be particularly effective following trauma. The regimen should include antibiotics active against resistant enterobacteria, *Ps. aeruginosa* and MRSA. However, there is a reluctance to use the limited armoury of antibiotics as prophylactic agents, despite the lack of evidence that selective decontamination has increased superinfection with resistant organisms.

Early and late infections

The acquisition by patients of ICU flora is a function of their length of stay in the ICU and, more importantly, their previous antibiotic treatment. Many patients admitted to ICU will have received antibiotics and most ICU patients receive antibiotics at some stage during their stay, and will also have been in hospital for some time before admission to the ICU. For example, respiratory specimens from a patient admitted directly to the ICU with a community acquired pneumonia may contain *Streptococcus pneumoniae*. Treatment with a narrow-spectrum antibiotic is characterized by initial clinical improvement, however, if assisted ventilation continues beyond a few days, this flora is commonly replaced by ICU flora and the development of VAP.

Sites of infection

Line-associated sepsis and bacteraemia is common in the ICU. Blood or intraluminal cultures identify the organism. Catheters impregnated with antibiotics or antiseptic reduce the infection rate, but are more expensive than standard ones. If the catheter entry site is infected, or cultures from the line are positive, the line should be removed. *S. aureus* or yeast blood infection associated with a line require therapy and are absolute indications for line removal. Bacteraemia associated with other organisms generally resolves following line removal.

VAP therapy may need to be continued for as long as the patient is mechanically ventilated. Empirical therapy is discussed above.

Intra-abdominal sepsis – infection seldom resolves without drainage and corrective surgery. Antibiotics such as co-amoxiclav or the combination of cefuroxime and metronidazole are generally adequate in community-acquired infections with early surgery. If the patient has been in hospital and taking antibiotics for more than a few days, a broader spectrum antibiotic (e.g. piptazo, imipenem) is recommended.

Urinary tract – though a high proportion of ICU patients are catheterized, and the bladder urine may become colonized, the urinary tract is seldom the source of clinical infection, if catheter patency is maintained. Candiduria is relatively common but may be a reflection of colonization or a sign of candidaemia.

Diarrhoea

The widespread use of broad-spectrum antibiotics is a significant cause of diarrhoea. *C. difficile*-associated diarrhoea and colitis need early recognition and treatment, because infection may require colectomy. The current endemic strains of *C. difficile* are resistant to most antibiotics and this allows their preferential survival. Withdrawal of antibiotics may allow resolution but, if diarrhoea persists, it should be treated with metronidazole (oral or nasogastric is preferred). If the diarrhoea does not resolve, or has developed while taking metronidazole, oral vancomycin should be administered.

Dose

It is important to use appropriate doses because too little antibiotic may not have a therapeutic effect and allows resistant organisms to persist; too much antibiotic may cause toxicity. Dose needs to be individualized and knowledge of the mode of excretion is vital. In general, the highest dose that is safe to use should be administered.

Duration

The duration of antibiotic therapy depends on the organism isolated, its source and the clinical response. Studies of relapse and complications suggest a minimum of 2 weeks' therapy for *S. aureus* and *Candida* spp. blood infections, but there are few data on minimum duration of therapy for other ICU-acquired infections. The duration of therapy for VAP depends on the clinical and laboratory response. Antibiotics should be reviewed after 5 days' therapy. Some patients, particularly with MRSA pneumonia, may require repeated courses. If there is a poor clinical response, the antibiotics should be stopped for 12 hours and cultures taken; a new empirical treatment can then be commenced. ◆

Assessment and Stabilization of the Critically Ill Patient Outside the ICU

Gary Smith

Gary Smith is Consultant in Intensive Care Medicine at Portsmouth Hospitals NHS Trust, and Honorary Senior Lecturer in Critical Care in the School of Postgraduate Medicine, University of Portsmouth, UK. He qualified from Southampton University Medical School and trained in anaesthesia and medicine in the South of England and Yale University, USA. His interests include the organization of intensive care services, outcome prediction and the training of doctors, nurses and paramedics.

ICU medical staff are often required to assess and stabilize patients referred for ICU admission. They may also be asked to assess patients for the following reasons:

- difficult venous access
- analgesic techniques
- fluid balance
- tracheostomy care
- inter-hospital transfer
- intra-hospital transfer to a high dependency unit or the operating theatre
- as a member of the cardiac arrest or medical emergency team.

The assessment and stabilization of all such patients follows similar lines, but this contribution focuses on the patient who is referred and accepted for ICU admission.

Referral process

ICU referrals are traditionally made by doctors; however, they are increasingly being made by nurses and physiotherapists acting on guidelines (e.g. physiological abnormalities) previously agreed with ICUs. The ICU staff require a range of referral details (Figure 1). If the patient has a potentially life-threatening illness, the caller should be given simple instructions regarding therapy to be undertaken before the ICU team arrives. Before leaving to assess the patient, the ICU doctor should share the collated data with the senior ICU nurse and check whether an ICU bed is available.

Information required during referral to the ICU

- Patient's name
- Patient's gender
- Patient's age
- Current location of patient
- Date of referral
- Time of referral
- Name, grade and contact details of person making the referral
- Whether the referral has been discussed with the consultant responsible for the patient's care
- Whether the referral has been discussed with the patient or the patient's relatives, and their wishes
- The patient's diagnosis and prognosis
- Relevant past medical history
- Relevant social history, including quality of life
- Patient's current condition, especially vital signs, urine output
- Patient's current therapy, especially fractional inspired oxygen concentration, fluid therapy, drugs
- Patient's current monitoring
- Presence of intravenous lines and central venous access
- Presence of a nasogastric tube, wound drains or thoracocentesis tubes
- Results of recent laboratory investigations
- Patient's resuscitation status
- Any agreed limitation of therapy

1

ICU retrieval team

In some ICUs, a dedicated retrieval nurse attends the patient with the ICU doctor, in order to provide expert assistance. He/she can also support the patient during stabilization and transfer, and provide an initial contact for the patient's family. The ICU team usually takes the necessary stabilization drugs and equipment to the patient's bedside, possibly attached to the patient's stretcher.

Assessment and stabilization

Traditional history-taking and examination is often inappropriate when attending critically ill patients, where life-saving measures must often precede diagnosis. Initially, assessment and stabilization occur together, focusing on the rapid detection and simultaneous treatment of potentially life-threatening emergencies. Simple questions to the patient can establish whether the patient has a patent airway, is breathing and perfusing his/her brain. Patients who can speak only in short sentences, or with one or two words at a time, are usually in extreme respiratory distress and at risk of sudden respiratory arrest. As stabilization proceeds, important aspects of the patient's medical history can be obtained from ward staff, the patient's case notes and charts (e.g. temperature, pulse, respiration, blood pressure, neurological observation chart, fluid balance, drug prescription chart) or the patient's family. Co-morbid conditions may have a significant impact on the response to critical illness.

Throughout the period of assessment and stabilization, the ICU team should observe good hygiene and infection control measures. In order that patients are examined properly, full exposure may be necessary. This should be done in a way that respects the dignity of the patient and prevents heat loss.

Airway

Assessment of airway patency involves the steps given in Figure 2. If the airway is obstructed, immediate clearance is mandatory before assessing breathing. Simple adjuncts (e.g. oropharyngeal or nasopharyngeal airway) suffice initially, but tracheal intubation under general anaesthesia is usually required in the critically ill. Anaesthetic agents invariably reduce cardiac output and vascular resistance, therefore a 200–500 ml fluid bolus should be given before induction. Occasionally, vasoactive drug infusions (e.g. adrenaline (epinephrine), noradrenaline (norepinephrine), dobutamine) are also required. In extremely rare circumstances, a surgical airway is required. In all patients, a chest radiograph should be undertaken as soon as possible to confirm correct tracheal or tracheostomy tube placement.

Assessing airway patency

Look for

- Foreign bodies, secretions or blood within the mouth
- Obstruction of the pharynx by the tongue
- Use of the accessory muscles of respiration
- Chest expansion
- Paradoxical breathing

Listen for

- Abnormal upper airway sounds (e.g. stridor, gurgling, snoring); if obstruction is complete, breath sounds will be absent

Feel for

- Expired air

2

Breathing

Breathing is assessed as described in Figure 3. Unilateral chest movement suggests underlying unilateral disease (e.g. pneumothorax, pneumonia, effusion). A high (> 20), or rapidly rising, respiratory rate usually indicates severe illness or impending deterioration. Small pupils may reflect excessive opiate administration.

Respiratory interventions are often based on clinical signs rather than arterial blood gas analysis. All critically ill patients must receive oxygen via a face mask with a reservoir bag or bag–valve–mask manual resuscitator, sufficient to maintain a minimum peripheral saturation of haemoglobin by oxygen of 90% (arterial oxygen tension = 8 kPa). Inadequate minute volume requires assisted ventilation, possibly with intubation. Positive end-expiratory pressure may be required. Pneumothoraces or large pleural fluid collection should be treated using tube thoracocentesis. Wheezing should be treated with inhaled bronchodilators. If the patient is in pain, initiation of an appropriate analgesic regimen may improve ventilation.

Assessing breathing

Look for or observe

- Cyanosis
- Chest deformity
- Respiratory rate, pattern and depth
- Equality of chest expansion
- Fractional inspired oxygen concentration
- Peripheral saturation of haemoglobin by oxygen
- Jugular venous pressure
- Abdominal distension

Listen for

- Wheeze, crackles, bronchial breathing
- Bilateral breath sounds

Feel for or palpate

- The position of the trachea
- Chest wall (for surgical emphysema or crepitus)
- Depth and equality of movement on each side of the chest

Percuss

- To elicit dullness or hyper-resonance

3

Circulation

Lung or pleural pathologies (e.g. tension pneumothorax) that can compromise the circulation, should have been treated during the respiratory system assessment. Figure 4 describes how to assess circulation. In shock, the blood pressure may be normal, because compensatory mechanisms increase peripheral resistance as cardiac output falls. A low diastolic blood pressure suggests vasodilatation (as in sepsis). A narrowed pulse pressure suggests vasoconstriction (cardiogenic shock or hypovolaemia). A thready pulse suggests poor cardiac output; a bounding pulse may indicate sepsis. The presence of a carotid or radial pulse implies systolic blood pressures are greater than 70 and 90 mm Hg, respectively.

The nature of cardiovascular resuscitation is determined by the cause, but should be directed at replacing fluid, controlling haemorrhage and restoring tissue perfusion. Massive or continuing haemorrhage and cardiac tamponade (diagnosed by hypotension, raised jugular venous pressure, muffled heart sounds, cardiomegaly on chest radiography, or electromechanical dissociation) are life-threatening conditions and must be treated urgently. Massive or continuing haemorrhage requires transfusion and may require urgent resuscitative surgery. Cardiac tamponade requires pericardiocentesis or pericardiotomy. All critically ill patients require at least one large (16 G) cannula, preferably two, placed in large veins.

Hypovolaemia contributes to circulatory dysfunction in almost all medical and surgical emergencies. Fluid challenges of warmed crystalloid should be given over 5–10 minutes to all patients, as follows:

- 10 ml/kg in normotensive patients
- 20 ml/kg in hypotensive patients
- 5 ml/kg in patients with known cardiac failure, in whom closer monitoring should be initiated (listen for crepitations after each bolus, consider a line).

The goal of therapy is to improve tissue perfusion. Although blood flow is more important than blood pressure, a minimum mean blood pressure of 70 mm Hg should be sought (higher in hypertensive patients). If perfusion does not respond to fluids alone (i.e. central venous pressure rises after fluid boluses without evidence of improved cardiac output), vasoactive drugs such as dobutamine, > 5 μg/kg/minute, adrenaline (epinephrine),> 0.05 μg/kg/minute, or noradrenaline (norepinephrine), > 0.05 μg/kg/minute, should be commenced.

Reassessment of circulatory status is essential. If there is no improvement, the fluid challenge can be repeated. In a few patients, fluid administration leads to cardiac failure. If this occurs, fluid administration should be stopped and vasoactive drugs (see above) commenced.

Disability
Rapid assessment of a patient's neurological status involves:
- examining the pupils (size, equality, reaction to light)
- the 'AVPU' system (A, alert; V, responds to vocal stimuli;P, responds to painful stimuli; U, unresponsive).

Common causes of unconsciousness include profound hypoxaemia, hypercapnia, cerebral hypoperfusion, hypoglycaemia or recent administration of sedatives, analgesics or anaesthetic drugs. Reversible causes should be treated immediately. Spontaneously breathing, unconscious patients are at risk of airway obstruction and aspiration of secretions, vomit or blood. Consequently, unconscious patients are better nursed in the lateral recovery position until intubated.

Assessing circulation

Look for or observe
- Conscious level
- Capillary refill (normally < 2 seconds)
- Colour and temperature of digits (cyanosed, pale, cold and clammy in shock)
- Venous filling (including jugular venous pressure)
- Urine output
- Nasogastric, stoma or drain output
- Evidence of concealed or overt haemorrhage

Listen for
- Heart sounds
- Blood pressure (systolic, mean, diastolic); note patient's normal values

Feel for or palpate
- Presence, rate, quality, regularity and equality of peripheral and central pulses

End of the initial assessment and stabilization period
At the end of the initial assessment, the patient should be showing signs of improvement. The following minimum monitoring devices should already be attached or inserted:
- pulse oximeter
- capnograph (if intubated)
- ECG
- blood pressure measurement (usually invasive).

Other devices that may be used include: urinary catheter, central venous catheter, nasogastric tube, and pulmonary artery catheter. Before moving the patient from the ward, the patient's oxygen saturation in arterial blood, heart rate, blood pressure, central venous pressure, end-tidal carbon dioxide tension, ventilator settings and performance should be noted. Actions taken during stabilization should be documented in the patient's notes. All invasive devices should be firmly secured to the patient. The patient should be sedated to an appropriate level for transfer; muscle relaxation may be required. Finally, the ICU should be notified of the impending arrival of the patient.

Brainstem Death

Suzie J Tanser
Gary B Smith

Suzie J Tanser is Specialist Registrar in Anaesthesia, Royal Navy – Southampton General Hospital. She qualified from St Bartholomew's Hospital, London, then joined the Royal Navy. She trained in anaesthesia and intensive care in Plymouth, Exeter, Portsmouth, Southampton and London and completed advanced training in intensive care in 2001.

Gary B Smith is Consultant in Intensive Care Medicine at Portsmouth Hospital NHS Trust and Honorary Senior Lecturer in Critical Care in the School of Postgraduate Medicine at the University of Portsmouth. After qualifying from the University of Southampton, he trained in anaesthesia and medicine in the South of England and at Yale University, USA. His main interests are multiprofessional education, cardiopulmonary resuscitation and pre-hospital trauma care.

Death has traditionally been diagnosed using the triad of Bichat – 'the failure of the body as an integrated system, associated with the irreversible loss of circulation, respiration and innervation'. However, the development of techniques to maintain respiration and circulation artificially, and the fact that dead patients may look alive, have a heart beat and feel warm, has led to conceptual and practical problems with the diagnosis of death.

The brainstem comprises the midbrain, pons and medulla oblongata. It contains the respiratory and cardiovascular centres and integrated sensory and motor functions. It is necessary for spontaneous respiration, consciousness and cortical activation. Death of the brainstem is equivalent to death of the individual, even if heart, lung and spinal cord function persist. Eventually all organs fail and asystole occurs. There has never been a documented recovery following properly conducted brain death testing that indicated brainstem death. It is agreed that permanent functional death of the brainstem constitutes brain death and, once this has occurred, further artificial support is fruitless and should be withdrawn. It is good medical practice to recognize when brain death has occurred and to act accordingly, sparing the relatives from futile hope and freeing valuable intensive care resources.

Incidence and aetiology

Up to 10–15% of deaths in UK ICUs are brainstem deaths. In adults, the most common primary diagnoses are trauma and intracranial haemorrhage; in children, they are trauma and the anoxic encephalopathies (e.g. drowning). Other causes include intracranial malignancy, intracranial abscesses, hydrocephalus and meningitis. Cardiac arrest may lead to brainstem death, but more often, leads to a persistent vegetative state.

Diagnosis of brainstem death

The UK code for the diagnosis of brainstem death was defined by the Conference of Medical Royal Colleges in 1976 and has been updated subsequently. The three stages of diagnosis are preconditions, exclusions and clinical testing.

Preconditions

- The patient is in an unresponsive coma.
- The patient's condition is due to irreversible brain damage of known aetiology.

Exclusions

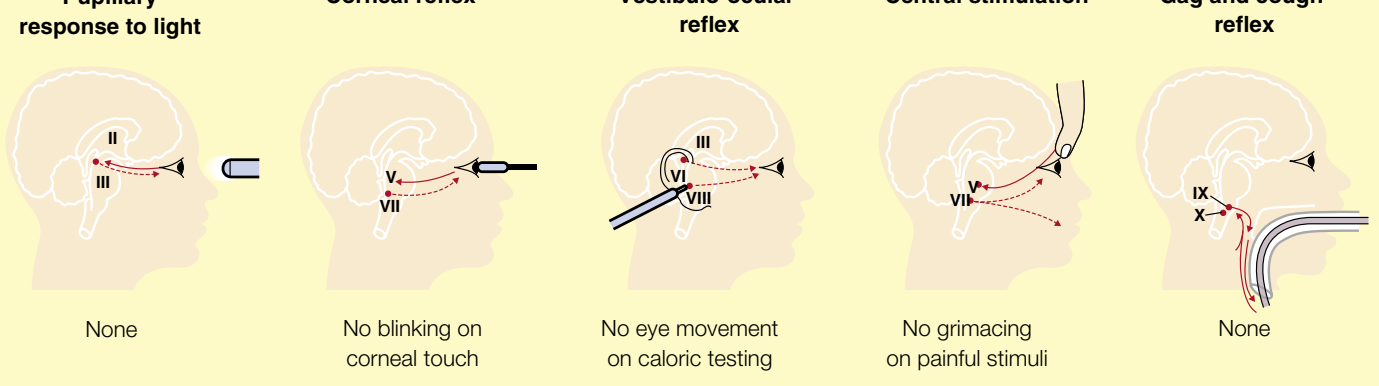
All the following reversible causes must be excluded:

- drugs (e.g. narcotics, hypnotic, tranquillizers, muscle relaxants)
- primary hypothermia (core temperature must be above 35°C)
- circulatory (including recent circulatory arrest)
- metabolic (e.g. hyponatraemia, hypoglycaemia)
- endocrine (e.g. hypothyroid state).

Clinical tests

- Clinical tests are performed by at least two doctors (one a consultant, the other at least 5 years' post registration) who are unconnected with the family and, if organ donation is an option, the transplant team.
- These tests are repeated twice by both doctors either indep-endently or together. The time interval is not specified.
- The tests involve reflexes involving the brainstem (Figure 1) and an apnoea test. There should be no pupillary response to light, no corneal reflex, no vestibulo-ocular reflex, no motor response to central stimulation, no gag and cough reflex and no spontaneous breathing.

Clinical tests for brainstem death



1

Pupillary response to light – the pupils do not respond directly or consensually to sharp changes in light intensity. This tests cranial nerves II (afferent) and III (efferent).

Corneal reflex – there is no response to direct stimulation of the cornea. This tests cranial nerves V (afferent) and VII (efferent). Care should be taken to avoid damage to the cornea. Gentle pressure using a cotton bud is the preferred method.

Vestibulo-ocular reflex – there are no eye movements following slow injection of 20 ml of ice-cold water over 1 minute into each external auditory meatus in turn. A normal response is deviation towards the stimulus. Before this a visual inspection of each tympanic membrane must be made to ensure clear access. Local injury or disease does not invalidate the diagnosis. This tests cranial nerves VIII (afferent) and III, IV and VI (efferent).

Motor response to central stimulation

- No motor response within the cranial nerve distribution to sustained painful stimuli to limbs or the supraorbital notch. This tests cranial nerves V (afferent) and VII (efferent).
- Spinal reflexes may occur after stimulation of the trunk or extremities. Occasionally these can be dramatic, such as back arching or extensor posturing (Lazarus' sign). These movements may be upsetting but since they originate below brainstem level, they do not rule out the diagnosis of brainstem death.
- No reaction should be seen following painful stimulation in the cranial nerve distribution.

Gag and cough reflex – there is no contraction of the soft palate when stimulated or response to bronchial stimulation. This tests cranial nerves IX and X.

Spontaneous breathing – this tests the ability of the patient's brainstem to initiate spontaneous respiration. Before testing, the following should occur:

- preoxygenation of the patient with 100% oxygen for 10 minutes
- the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) should be allowed to rise to 5 kPa (40 mm Hg) or above.

To test the function of the respiratory centre:

- the patient is disconnected from the ventilator
- oxygen at 6–10 litres/minute is insufflated into the trachea using a catheter (to maintain adequate oxygenation)
- the $PaCO_2$ is allowed to rise to over 6.65 kPa (50 mm Hg) – this requires arterial blood gas analysis
- the lack of spontaneous respiratory effort is confirmed.

Following apnoea testing, the patient is reconnected to the ventilator if:

- only one set of brainstem function tests has been completed
- two sets of tests have been completed, which show lack of brainstem function and the patient is to become an organ donor.

Time of death

The legal time of death is the time of completion of the first set of brainstem tests. Death is certified after completion of the second set of tests, regardless of when active support is withdrawn.

Special circumstances

Neonates and young children – clinical brainstem tests alone cannot be applied to children with a conceptual age of less than 52 weeks or less than 2 months post-term delivery. Ancillary testing such as cortical electrical activity (EEG), sensory evoked potentials (SEP), evaluation of brain blood flow (cerebral angiography, radionuclide scanning or Doppler ultrasonography) or MRI has been suggested, but no tests are foolproof. Therefore, no single method should be relied on and any clinical or ancillary test used should be repeated two or three times over a period of up to 24 hours.

Respiratory disease – apnoea testing may be invalid in patients with chronic pulmonary disease and carbon dioxide retention. For such patients, their usual $PaCO_2$ levels should be taken as baseline and the $PaCO_2$ allowed to rise during apnoea testing to at least 2 kPa above baseline or until a respiratory acidaemia can be demonstrated. Oxygen supplementation should be reduced accordingly.

Inability to apply clinical criteria – in some cases, such as severe facial trauma, profound metabolic or endocrine disturbances, it may be impossible to apply all the preconditions, exclusions or clinical tests. Under these circumstances, all possible tests should be completed and supplemented with the additional tests described below. Great care should be taken under these circumstances when declaring death because the additional tests have not been legally validated in the UK.

Additional tests

Cerebral angiography – a selective four-vessel angiography is done with contrast media injected into both the anterior and posterior circulation. A minimum mean arterial pressure of 80 mm Hg is required for this test. In brain death, no intracranial perfusion other than occasional filling of the superior sagittal sinus is seen.

Radionuclide scanning – a radioactive-labelled substance that readily crosses the blood–brain barrier can be used to image parenchymal uptake activity. In brain death there is lack of uptake into parenchymal tissues.

Transcranial Doppler ultrasonography – the intracranial arteries can be insonated using a 2 MHz pulsed Doppler instrument. Absent diastolic flow has been reported in brain death. However, interpretation of these tests can be difficult.

Neurophysiological tests – the electroencephalogram (EEG) can be a useful confirmatory tool especially in young children. It should not be used in isolation, because it does not adequately assess brainstem function. Auditory and sensory evoked potentials have also been used.

Social and religious issues

The concept of brainstem death is difficult for many relatives and has been made more so by media reporting of so-called medical errors. It should be emphasized that brainstem death is irrefutably death and the act of switching off the ventilator is not 'killing the patient' but merely ceasing to ventilate a corpse.

Allowing relatives to witness the brainstem tests may help them to understand that death has occurred. However, witnessing the spinal reflexes tests may cause distress and it is important to explain the process continually throughout the testing.

Some religious groups (e.g. Orthodox Jews) do not believe in the concept of brainstem death and may refuse to allow withdrawal of ventilatory support, which they consider to be tantamount to murder. Published data indicate that asystole results within days of brainstem death. Therefore, to respect religious or cultural sensitivities, it may be appropriate to wait for asystole to occur before certifying death. ◆

Cannulation of Central Veins for Resuscitation and Monitoring in the ICU

Carl Waldmann

Carl Waldmann is Consultant Anaesthetist and ICU Director of the Royal Berkshire Hospital, UK. He qualified in medicine from Cambridge University and the London Hospital and trained in anaesthesia in the RAF. His main interests are the setting up of ICU follow-up programmes, and head injury management in a district general hospital.

Central venous catheters (CVCs) are integral to current medical practice, but complications are associated with their insertion. Placement of CVCs used to be the preserve of surgeons using general anaesthesia but the success rate was only about 75% and the vein was compromised for future use. The introduction of the percutaneous method led to uncontrolled use of CVCs by a variety of inadequately trained staff with serious, potentially avoidable, complications that were sometimes fatal. Recent advances in CVC manufacture, better training in insertion techniques, the use of ultrasound, the development of hospital nutrition teams, and the increasing involvement of interventional radiologists in the ICU should all ensure that CVC placement becomes safer. Interventional radiologists should be more involved in the management of ICU patients because they are familiar with ultrasound and fluoroscopic techniques, have extensive experience with advanced catheter and guidewire techniques, and are adept at retrieving catheters or parts of catheters inadvertently lost within the vascular system.

Figure 1 lists the indications for using CVCs. Originally CVCs were of fine bore, but newer, wide-bore, high-flow, central venous pressure lines and pulmonary artery catheter introducers permit rapid volume replacement. Multilumen catheters allow concurrent CVP monitoring and multiple drug infusion.

Indications for central venous catheterization

- Replacement of circulating volume
- Haemodynamic monitoring
- Monitoring of jugular bulb venous oxygen and mixed venous oxygen saturation
- Administration of vasopressors
- Repeated or frequent blood sampling
- Parenteral nutrition
- Chemotherapy
- Insertion of pacing wires or pulmonary artery catheters
- Endoluminal intervention (e.g. endocardial biopsy)
- Haemofiltration

1

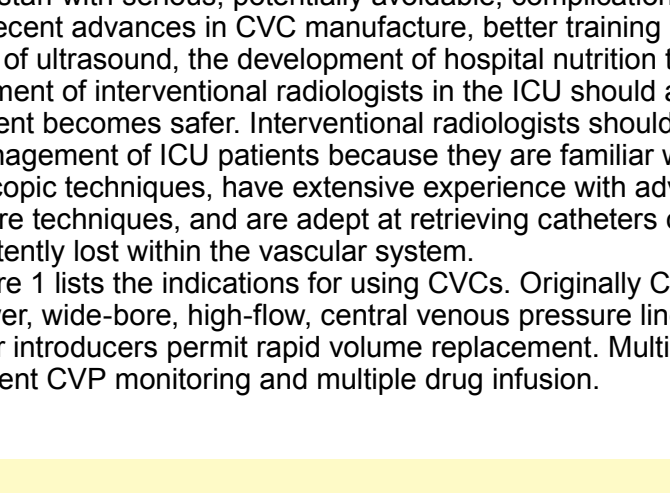
Insertion

In general, internal jugular, subclavian and femoral veins can be cannulated using standard anatomical landmarks (Figure 2).

The technique most often used was described by Seldinger in 1953. A small needle is inserted through the vein wall, a wire guide is advanced through the needle into the vein and the needle replaced by a dilator over the guide. A small incision is made close to the wire and the dilator replaced by the catheter. After cannulation of the internal jugular vein and subclavian vessels a chest radiograph should be taken to confirm correct CVC positioning and to ensure there is no pneumothorax.

Access sites of choice

1. High internal jugular
2. External jugular
3. Low internal jugular
4. Supraclavicular
5. Infraclavicular



a Clavicle
b 1st rib
c Suprasternal notch
d Sternal angle
e Right atrium
f External jugular vein
g Internal jugular vein
h Subclavian vein
i Left innominate vein
j Superior vena cava
k Suggested catheter tip positioning zone

2

Femoral vein
The most common use of the femoral vein in an ICU is for placement of a double-lumen haemofiltration line. Traditional teaching suggests that the femoral vein lies medial to its artery. However, ultrasound studies have demonstrated that the artery and vein do not always lie side by side; the degree of overlap between vessels varies between patients and sides. It is recommended that the femoral vein should be accessed just below the inguinal ligament and that ultrasound-guided placement should be used in patients with difficult anatomy, coagulopathy or peripheral vascular disease.

The femoral approach is usually used only when central access is unfeasible by other routes, and usually only as a short-term expedient. The route is impractical for mobile patients. Other concerns are thromboembolism and groin sterility.

Subclavian vein
The subclavian vein is the most comfortable cannulation site for patients, and is the best for long-term parenteral nutrition, pacing wires and Hickman lines. However, there are significant concerns because of the proximity of the subclavian vein to the subclavian artery (pressure cannot be exerted here if the artery is punctured), lung (risk of pneumothorax) and, on the left, the thoracic duct. Successful placement may be impossible unless the patient is placed head-down, which they may not tolerate.

Various approaches have been described. The author prefers infraclavicular puncture with a small needle introduced 2 cm inferior to the junction of the middle and medial thirds of the clavicle (see Figure 2). The needle is advanced medially in the direction of the suprasternal notch in a horizontal plane.

Internal jugular vein
Cannulation of the internal jugular vein may be difficult in obese patients or those with goitre or neck rigidity. This route, especially the high approach, is favoured for cannulation in the ICU because the insertion site is distant from the lung apex and haemorrhage from an inadvertent puncture of the carotid artery is easily controlled. However, damage to the brachial plexus, phrenic nerve and sympathetic chain are possible.

There are several well-described approaches to the internal jugular vein (see Figure 2). Success is increased by positioning the patient head-down with a pillow under the shoulders. The needle is inserted laterally to the palpated carotid artery, under the clavicular head of the sternomastoid at the apex of the posterior triangle. It is directed caudally and anteriorly towards the ipsilateral nipple. Normally the internal jugular lies anterior and lateral to the carotid artery; however, it may be unilaterally absent in up to 2.5% of patients. In 5.5% of patients the internal jugular lies outside the path predicted by anatomical landmarks.

Coagulopathy
Although insertion of CVCs in the presence of a coagulopathy is a relative contraindication, a recent series of 658 cannulations in patients with liver disease and coagulopathy demonstrated a low incidence of haemorrhagic complications. The presence of a raised international normalized ratio alone is not a contraindication to CVC insertion, and there is little evidence that transfusion of fresh frozen plasma is required before insertion. Nevertheless, caution is recommended in patients with combined coagulopathies, thrombocytopenia, or those on haemofiltration.

Aids to successful CVC insertion

Correct positioning of a patient, and the use of various manoeuvres, during central vein cannulation may increase the chances of success. The diameter of the internal jugular vein can be increased by using a Valsalva manoeuvre, abdominal binder and increasing head-down tilt. Carotid artery palpation and full neck extension reduce the vein's diameter.

Venography reduces the number of attempts to insert CVCs in patients with occluded or absent central veins.

Hand-held Doppler probes avoid multiple attempts in patients with unilateral absence or narrow diameter veins.

Portable ultrasound machines – the use of two-dimensional (B-mode) ultrasonography allows visualization of the anatomy both before and during cannulation. 100% success has been reported if a portable ultrasound machine is used as a 'bale-out' technique after failed attempts at 'blind' cannulation. It has recently been suggested that blind attempts at venous cannulation should be replaced by ultrasound-guided techniques. The use of a longitudinal view enables the operator to monitor the passage of the needle throughout the procedure as the needle enters the vein.

Complications
Complications may occur in up to 10% of central vein cannulations. Common complications are listed in Figure 3.

Complications of central venous catheterization

Local complications
- Failure to cannulate
- Arterial puncture
- Haematoma
- Local infection
- Thrombosis of vessel

Distant complications
- Perforation
- Haemorrhage
- Cardiac tamponade
- Pneumothorax
- Arrhythmias
- Damage to thoracic duct (subclavian)
- Brachial plexus damage (subclavian)
- Air embolism
- Catheter embolism
- Thrombus formation
- Bacteraemia, sepsis
- Respiratory obstruction

3

Line infection: catheter-related infections are potentially avoidable, yet account for about 25% of all nosocomial infections and 50% of nosocomial bloodstream infections in ICU patients. Consequently, there is considerable interest in determining whether CVCs need to be changed regularly in ICU patients, even in the absence of evidence of infection, and whether they should be changed routinely when an ICU patient has a persistent fever.

Recent data demonstrate that removal of the CVC in patients with suspected line infection is unnecessary in up to 90% of cases. In the absence of obvious infection at the skin entry site, one expedient would be merely to change the line over a guidewire with antibiotic cover and await microbiological advice following culture of the removed CVC tip. Replacement of the second catheter is recommended if the first is found to be significantly colonized. However, the first CVC is still often unnecessarily sacrificed to enable the diagnosis of catheter-related sepsis. To avoid this, using the very sensitive and specific technique of endoluminal brushing may be an alternative. The use of endoluminal brushing is regarded as safe and simple and eliminates the need for recatheterization with its attendant complications. This is particularly important in patients with long-term Hickman lines.

Catheter-related sepsis may also occur in the absence of pyrexia, leucocytosis and localized erythema at the insertion site. Line removal may be essential if severe systemic illness is to be avoided. Regular bacteriological surveillance with endoluminal brushing or by a technique known as 'time to positivity of hub-blood versus peripheral blood cultures' (in this technique an earlier positivity of central compared with peripheral venous blood cultures may be associated with catheter-related bacteraemia) may prove to be useful surveillance methods.

The incidence of bacteraemia due to infected CVCs has been estimated at 5.3 episodes per 1000 catheter days (ranging from 2.8 in cardiac surgical patients to 12.8 in patients in the burns units). The organism most commonly cultured is coagulase-negative *Staphylococcus*, though *Candida* is often reported. Colonization of lines may be associated with death, morbidity and a prolonged hospital stay. The essential elements of a strategy to prevent CVC-related infections include barrier precautions during insertion, strict aseptic technique during manipulation of lines, avoiding systematic change of dressings and catheters, and continuous surveillance.

Advances in catheter design

Material: the use of polyurethane virtually eliminates kinking. Soft catheter tips prevent vessel perforation.

Adjustable hubs permit the insertion distance to be altered after chest radiograph checks have been performed. In adults, the use of 15 cm CVCs often eliminates the need for hubs if the internal jugular vein site is used. Suturing the hub may not always ensure that a CVC is securely sited; it is preferable to suture the catheter itself.

Multilumen catheters reduce the possibility of drug interaction and bolusing of vasoactive drugs, allow rapid volume replacement and permit the introduction of a pulmonary artery catheter through the same catheter, thereby reducing the need for more than one venous puncture.

Heparin and antibiotic coating: non-thrombogenic lining of CVCs was described in 1971 as a method of preventing catheter blockage by fibrin deposits and avoiding bacterial growth on catheters. Some catheters are now coated with a combination of antimicrobial agents (e.g. minocycline, rifampicin) and heparin.

Cardiac Arrhythmias in the Critically Ill

Kirsten J C Richards
Andrew T Cohen

Kirsten J C Richards is Specialist Registrar in General Medicine at St James's University Hospital, Leeds, UK. She qualified from Sheffield University and trained in general and emergency medicine in Sheffield and Leeds. She has also worked in intensive care medicine in Leeds. Her interests lie in acute and intensive care medicine.

Andrew T Cohen is Consultant in Anaesthesia and Intensive Care in the 14-bedded ICU at St James's Hospital, Leeds, UK. He is an examiner for the final FRCA and chairs the Trust Drug and Therapeutics Committee.

Cardiac arrhythmias are a common cause of potentially life-threatening, haemodynamic compromise in critically ill patients. This article describes a systematic approach to the management of the four general characteristics of arrhythmia – broad or narrow complex and tachycardia or bradycardia – because it is important to treat the patient and the general type of rhythm rather than considering each disturbance in detail.

Factors that predispose to the development of arrhythmias in peri-operative or critically ill patients include:

- cardiac disease
- hypoxia and hypercarbia
- electrolyte imbalance (particularly hypo- or hyperkalaemia, hypomagnesaemia)
- hypovolaemia
- extremes of temperature
- elevated catecholamine levels (endogenous and exogenous)
- pulmonary artery catheterization
- systemic inflammation (e.g. systemic inflammatory response syndrome)
- drugs.

Successful management should be approached in stages:

- rapidly assess the haemodynamic status of the patient
- identify the origin of the arrhythmia
- correct predisposing factors (e.g. hypoxia, electrolyte imbalance)
- consider specific therapy (e.g. drugs, DC cardioversion)
- prevent further arrhythmias.

Identification of the arrhythmia

A 12-lead ECG should be performed before treatment in all cases of arrhythmia except pulseless rhythms occurring during cardiac arrest. Identifying the precise rhythm is unnecessary but it is important to determine whether the complex width is narrow or broad, whether the patient is haemodynamically compromised, and in certain situations, whether the patient has known underlying structural heart disease.

A pulseless narrow complex tachycardia should be treated as pulseless electrical activity (electromechanical dissociation) if the rate is less than 200 beats per minute (bpm). However, if the rate is greater than 200 bpm, the initial treatment should be synchronized DC cardioversion (100 J, 200 J, 360 J). The Resuscitation Council (UK) Advanced Life Support guidelines for pulseless electrical activity should be followed if there is no response to initial DC cardioversion.

If a pulse is present, determine whether the rhythm is a tachycardia (> 100 bpm) or a bradycardia (< 60 bpm) and whether the complexes are broad (> 0.12 second) or narrow (< 0.12 second). Examples of the four types of arrhythmia are given in Figure 1.

Types of arrhythmia

Narrow complex bradycardias

- Sinus bradycardia
- Slow atrial fibrillation
- Mobitz type II heart block

Broad complex bradycardias

- Sinus bradycardia with pre-existing bundle branch block
- Mobitz type III heart block (complete heart block may be present if the ventricular rate is 30–40 bpm with complete dissociation of atrial activity)

Narrow complex tachycardias

- Irregular: atrial fibrillation
- Regular: supraventricular tachycardia (e.g. atrial tachycardia, atrial flutter, junctional tachycardia, supraventricular tachycardia with accessory pathway)

Broad complex tachycardias

- Ventricular tachycardia
- Supraventricular tachycardia with aberrant conduction (pre-existing inter-ventricular block)

1

Management of arrhythmias

Drug treatment
All antiarrhythmic drugs are also potentially rhythmogenic.

Electrolytes

Potassium – hypokalaemia commonly causes arrhythmias, especially ventricular tachycardia (VT). Patients at particular risk of hypokalaemia include those taking diuretics, post-operative patients, patients undergoing treatment for diabetic ketoacidosis, and those receiving intravenous fluid replacement therapy. An infusion of potassium chloride, 60 mmol in 60 ml normal saline, should be given via central access at a maximum rate of 30 mmol/hour.

Magnesium – magnesium deficiency tends to occur concurrently with hypokalaemia. Magnesium correction should be considered in all patients with VT. Intravenous magnesium sulphate, 2.5 g (5 ml 50%), should be given over 30 minutes. In patients with shock and refractory ventricular fibrillation (VF) an initial dose of magnesium sulphate, 1–2 g (2–4 ml 50%) may be given peripherally over 1–2 minutes.

Other antiarrhythmic drugs are listed in Figures 2 and 3.

Antiarrhythmic drugs

	Uses	Dose	Important side-effects
Adenosine • Blocks specific cardiac receptors • Slows conduction across AV node • Slows rate • Very short half-life (8–10 seconds)	• Terminates SVT • Facilitates diagnosis • Differentiation of broad complex SVTs from VT Identification of arrhythmia by revealing the underlying atrial rhythm (e.g. atrial flutter/ fibrillation/tachycardia)	6–12 mg via central access or large peripheral vein (can repeat 12 mg x 3) Immediately flush with saline. Monitor patient in a high dependency setting throughout administration. Reduce initial dose to 3 mg in heart transplant patients who are more sensitive to adenosine and to 0.5–1 mg in patients receiving dipyridamole. Effects are antagonized by theophylline and coffee	• Bradyarrhythmias • Bronchospasm (should be administered in high dependency facility and used with extreme caution in asthmatics) • Transient chest tightness, nausea, flushing • Avoid in heart block and sick sinus syndrome
Amiodarone • Blocks repolarizing potassium channels • Prolongs AP, refractory period and QT interval • Long half-life (50 days) • Minimally negatively inotropic	• Refractory VF • Pulseless VT • Haemodynamically stable VT, SVT and AF	• Refractory VF/pulseless VT: 300 mg in 20 ml 5% dextrose • Stable tachyarrhythmias: 150 mg in 20 ml 5% dextrose over 10 minutes, or 300 mg in 100 ml 5% dextrose over 1 hour followed by maintenance infusion of 900 mg in 250 ml 5% dextrose over 23 hours • Ideally use central access but large-bore peripheral vein may be used	• Hypotension, photosensitivity, slate-grey skin discoloration, corneal microdeposits, peripheral neuropathy, bradycardia, conduction disturbances of thyroid and liver, dysfunction of pulmonary and retroperitoneal deposits • Decrease digoxin and warfarin doses • Avoid in heart block
Atropine • Antimuscarinic • Blocks vagus nerve	• Bradyarrhythmias • Asystole	• 0.5–1 mg i.v., increasing to a maximum total dose of 3 mg	• Tachycardia, constipation, reduced bronchial secretions, urinary retention, dilated pupils
Digoxin • Cardiac glycoside • Inhibits Na/K-ATPase • Increases intracellular calcium • Increases vagal tone • Decreases sympathetic drive • Prolongs AV nodal conduction • Positive inotrope	• Slows ventricular rate in AF • Positive inotrope in congestive cardiac failure	• 250–500 μg in 50 ml 5% dextrose over 30 minutes i.v. Repeat once if necessary • Oral loading dose 1–1.5 mg over 24 hours in divided doses • Maintenance 62.5–250 μg/day • Therapeutic plasma range 0.8–2 ng/ml • Reduce dose in renal impairment, old age, low body mass • Antagonized by verapamil • Treat overdose with digoxin-specific antibody fragments	• Nausea, diarrhoea, dizziness, anorexia • Toxicity (nausea, arrhythmias) increased by hypokalaemia, hypomagnesaemia, hypoxia, hypercalcaemia, hypothyroidism • Avoid in heart block, Wolff–Parkinson–White syndrome, hypertrophic obstructive cardiomyopathy, recurrent ventricular arrhythmias
Esmolol • β-blocker • Short half-life (9 minutes) • Cardioselective at low doses • Decreases AV node conduction • Antagonizes circulating catecholamines • Decreases myocardial contractility	• Second-line therapy of SVT after adenosine	• 500 μg/kg i.v. over 1 minute • Follow with infusion of 50–100 μg/kg/minute	• Bradyarrhythmias, heart failure, hypotension • Avoid in impaired LV function, heart block, haemodynamic collapse • Administer with care in asthmatics
Flecainide • Sodium channel blocker • Slows conduction • Negatively inotropic • Metabolized in liver	• AF • SVT with accessory pathway	• 2 mg/kg i.v. over 10 minutes to maximum of 150 mg • Follow with infusion of 1.5 mg/kg/hour for 1 hour, then 0.1–0.25 mg/kg/hour for 24 hours	• Hypotension, bradycardia, blurred vision, paraesthesia • Avoid in heart block, sinoatrial disease, heart failure and pace-makers (pacing threshold may rise)
Lidocaine (lignocaine) • Sodium channel blocker • Shortens action potential • Metabolized in liver	• Haemodynamically stable VT if amiodarone is unavailable	• 1.5–2 mg/kg i.v. as a bolus (effective for 10 minutes only) • Follow with infusion of 4 mg/minute for 1 hour, then 2 mg/minute for 2 hours, then mg/minute • Decrease dose in liver or cardiac failure	• Dizziness, paraesthesia, hypotension, bradycardia, respiratory depression • Toxicity leads to anxiety, metallic taste, confusion and convulsions • Avoid in severe myocardial depression, AV block, porphyria
Verapamil • Calcium channel blocker • Slows AV nodal conduction • Peripheral and coronary vasodilatation • Significantly negatively inotropic	• Established SVT with good LV function	• 5–10 mg i.v. over 2 minutes followed by further 5 mg bolus if needed	• Flushing, hypotension, arrhythmias, headache, gastrointestinal upset, allergic reactions • Avoid in hypotension, broad complex tachycardias, history of heart failure or significantly impaired LV function, heart block, cardiogenic shock, Wolff–Parkinson–White syndrome, porphyria or i.v. in conjunction with β−blockers

Abbreviations: AF, atrial fibrillation; AP, action potential; AV, atrioventricular; LV, left ventricular; SVT, supraventricular tachycardia; VF, ventricular fibrillation; VT, ventricular tachycardia.

2

Vaughan-Williams classification of antiarrhythmic drugs

Class and site of action	Examples	Extra cardiac side-effects
Ia Block fast sodium channels, moderately prolongs conduction and repolarization	Quinidine	Gastrointestinal upset, thrombocytopenia, haemolytic anaemia, hepatic toxicity, lupus-like syndrome, psychosis
	Procainamide	Gastrointestinal upset, lupus-like syndrome, agranulocytosis, psychosis
Ib Block fast sodium channels, minimal effect on conduction and repolarization	Lidocaine (lignocaine)	Confusion, seizures, dizziness, paraesthesia, respiratory depression, reduce dose in hepatic failure
Ic Block fast sodium channels, marked prolongation of conduction	Flecainide	Dizziness, visual disturbances, headache, photosensitivity, ataxia, jaundice, peripheral neuropathy, pulmonary fibrosis
	Propafenone	Blurred vision, dry mouth, gastrointestinal upset, dizziness, headache
II β-blockers (decrease sympathetic stimulation on the cardiac muscle)	Propranolol Sotalol Esmolol	Bronchospasm, lethargy, attenuated hypoglycaemic response, peripheral vasoconstriction, gastrointestinal upset
III Block repolarizing potassium channels	Amiodarone	Vasodilatation, hypotension, photosensitivity, slate-grey skin discoloration, corneal microdeposits, tremor, ataxia, pulmonary fibrosis, liver and thyroid dysfunction, optic neuritis, peripheral neuropathy, gastrointestinal upset, metallic taste, dizziness, paraesthesia, benign intracranial hypertension
	Bretylium	Hypotension, gastrointestinal upset, tissue necrosis with intramuscular injection
	Sotalol	
IV Calcium channel blockers	Verapamil Diltiazem Nifedipine	Hypotension, constipation, gastrointestinal upset, flushing, dizziness, headache, myalgia, paraesthesia, fatigue, ankle oedema, abnormal liver function tests, rash

3

Temporary pacing
The indications for temporary pacing are given in Figure 4.

Indications for temporary pacing

Temporary pacing indicated

- Asystole
- Complete heart block
- Symptomatic bifascicular block (right bundle branch block + left axis deviation (LAD)
- Symptomatic trifascicular block (right bundle branch block + LAD + prolonged PR interval)
- Mobitz type II second-degree heart block
- Symptomatic bradycardia refractive to pharmaceutical therapy

Temporary pacing may be considered

- Mobitz type I second-degree heart block with hypotension not responsive to atropine
- Recurrent sinus pauses not responsive to atropine
- Atrial or ventricular overdrive pacing for recurrent ventricular tachycardia
- Sinus bradycardia with hypotension not responsive to atropine

4

Broad complex tachycardias

The management of broad complex tachycardias is summarized in Figure 5.

Ventricular tachycardia (VT)
It is safe to assume that any broad complex tachycardia is ventricular in origin unless the cardiac history suggests otherwise. Causes of VT include:

- ischaemic heart disease
- ventricular scarring following myocardial infarction or previous cardiac surgery
- right ventricular failure
- electrolyte disturbances in patients with a prolonged QT interval (drugs that prolong the QT interval include antiarrhythmic agents, erythromycin, antihistamines, tricyclic depressants and phenothiazines).

Features in the history and ECG that point to a diagnosis of VT rather than supraventricular tachycardia (SVT) with aberrant conduction include:

- history of ischaemic heart disease
- irregular cannon waves or variable S in V1 (atrioventricular dissociation)
- independent p waves, fusion or capture beats
- positive concordance in all precordial leads
- deep S wave in V6
- RSR pattern in V1
- QRS width greater than 0.14 seconds with right bundle branch block morphology
- QRS width greater than 0.16 seconds with left bundle branch block morphology
- extreme left axis deviation (–90 to 180°).

The patient should be assessed clinically for features of haemodynamic compromise including chest pain, heart failure, low systolic blood pressure (< 90 mm Hg), ventricular rate greater than 150 bpm, and decreased consciousness.

Management of broad complex tachycardias

- If in doubt assume all regular broad complex tachycardias to be ventricular in origin
- The differential diagnosis of a broad complex tachycardia is ventricular tachycardia (VT) or supraventricular tachycardia (SVT) with aberrant conduction. An irregular broad complex tachycardia is likely to be atrial fibrillation with bundle branch block
- Avoid verapamil in any broad complex tachycardia – it may cause haemodynamic collapse
- Intravenous adenosine may be used safely in broad complex tachycardia as a diagnostic aid. VT will be unaffected but an SVT with aberrant conduction will probably be terminated. Transient AV-nodal blockage will reveal the underlying rhythm in atrial flutter or atrial tachycardia
- The drug of choice in VT is amiodarone
- Potassium and magnesium deficiencies should be corrected where possible
- Synchronized DC cardioversion under sedation should be considered if there is any evidence of haemodynamic compromise
- Treatment of torsade de pointes should include magnesium and pacing rather than antiarrhythmogenic drugs

5

Treatment
If haemodynamic compromise is present:

- DC synchronized cardioversion under sedation (100 J, 200 J, 360 J)
- correct any potassium or magnesium deficiencies using potassium chloride, 60 mmol in 60 ml normal saline at a maximum rate of 30 mmol/hour, and magnesium sulphate, 5 ml 50% over 30 minutes
- if patient remains in broad complex tachycardia, administer amiodarone, 150 mg i.v. over 10 minutes
- consider repeated DC synchronized cardioversion
- consider other pharmacological agents (e.g. sotalol, lidocaine (lignocaine), amiodarone); overdrive pacing is a further possibility
- seek cardiological opinion if neccesary.

In the absence of haemodynamic compromise:

- correct potassium and magnesium deficiencies
- administer intravenous amiodarone, 150 mg over 10 minutes, or intravenous lidocaine (lignocaine), 50 mg over 2 minutes, repeated to a maximum of 200 mg
- consider synchronized DC cardioversion under sedation
- consider repeating amiodarone administration
- consider repeated DC cardioversion.

Torsade de pointes
Torsade de pointes is a polymorphic form of VT. It is characterized by beat-to-beat variation and a constantly changing axis. It may be self-limiting but can progress to VF. It may be caused by antiarrhythmic drugs associated with QT prolongation (e.g. Class Ia and Ic drugs, phenothiazines, butyrophenones, tricyclic antidepressants and antihistamines), congenital QT prolongation, electrolyte disturbances (hypokalaemia, hypomagnesaemia, hypocalcaemia), profound bradycardia, myocardial infarction or ischaemia, arsenic poisoning and neurological insults (e.g. subarachnoid haemorrhage, stroke, encephalitis).

Treatment:

- intravenous magnesium (even in patients without suspected magnesium deficiency)
- correct other electrolyte disturbances (e.g. hypokalaemia)
- withdraw precipitating drugs
- consider overdrive pacing at rate of 100 bpm, increasing the rate if needed
- consider use of β-blockers
- DC cardioversion in the event of haemodynamic collapse.

Narrow complex tachycardias

The management of narrow complex tachycardias is summarized in Figure 6.

Management of narrow complex tachycardias

- If the patient is haemodynamically compromised, proceed immediately to synchronized DC cardioversion under sedation
- When considering treatment options in a patient with uncompromised atrial fibrillation, consider whether the arrhythmia has been present for less than 24 hours
- Cardioversion of atrial fibrillation carries a significant risk of thromboembolism
- Intravenous adenosine should be administered rapidly via a large vein in a monitored patient, and followed immediately by a flush of normal saline
- Avoid adenosine in patients with asthma, atrioventricular block or known Wolff–Parkinson–White (WPW) syndrome
- In addition to adenosine, avoid verapamil and digoxin in patients with WPW syndrome. Flecainide or amiodarone may be used in WPW syndrome
- WPW syndrome may give rise to atrial fibrillation or atrioventricular re-entrant tachycardia. Signs of WPW syndrome on a 12-lead ECG in sinus rhythm include delta-waves and a short PR interval. The delta-wave is positive in lead V1 in left-sided accessory pathways, and positive in V6 in right-sided accessory pathways
- Consider the possibility of drug-induced myocardial depression, particularly with polypharmacy
- Consider digoxin toxicity as a cause of atrial tachycardia

6

Irregular narrow complex tachycardia
Atrial fibrillation often occurs in the critically ill patient, particularly in the presence of sepsis, inotropic support, underlying heart disease and in the elderly. Other causes of atrial fibrillation include impaired left ventricular function, hypertension, hypovolaemia, pulmonary embolism, cor pulmonale, thyrotoxicosis, pericarditis, cardiac trauma and toxins (e.g. alcohol). Although many patients tolerate rapid atrial fibrillation with few adverse symptoms, decompensation leading to cardiac failure is common. If the arrhythmia has been present for longer than 48 hours, thrombi may form in the fibrillating atria leading to the complication of systemic embolism. ECG evidence to support a diagnosis of atrial fibrillation includes an irregularly irregular rhythm with absence of p waves.

Choice of therapy depends on haemodynamic compromise and the duration of atrial fibrillation. In most patients, the aim of treatment should be cardioversion, using pharmaceutical or electrical methods. It is important to try to minimize the risk of systemic embolism.

Treatment

- Avoid precipitating factors (e.g. alcohol) and correct electrolyte imbalances. Treat underlying problems such as thyrotoxicosis, cardiac failure and sepsis.
- If there is severe cardiovascular compromise (rate > 150 bpm; systolic blood pressure < 90 mm Hg; critical perfusion or continuing chest pain), immediately give intravenous heparin or subcutaneous low molecular weight heparin, and attempt DC synchronized cardioversion under sedation (100 J, 200 J, 360 J). Amiodarone, 300 mg i.v. over 1 hour, may be given if electrical cardioversion is unsuccessful, repeat if necessary.
- If atrial fibrillation has been present for less than 24 hours in a haemodynamically stable patient, give heparin and attempt cardioversion. Pharmacological cardioversion should be attempted if there is no underlying structural heart disease. Amiodarone, 300 mg i.v. over 1 hour, or flecainide, 100–150 mg i.v. over 30 minutes, are the agents of choice. If pharmacological cardioversion fails or if structural heart disease exists, DC cardioversion with intravenous amiodarone if necessary should be used.
- If atrial fibrillation has been present for over 24 hours and the patient is haemodynamically stable, formal anticoagulation should be commenced and pharmaceutical agents (e.g. digoxin, β-blockers, verapamil or diltiazem) should be used to control the ventricular rate. Four weeks after anticoagulation, DC cardioversion should be attempted in patients without significant mitral valve disease or left atrial impairment. If cardioversion is successful, it is recommended that anticoagulation is continued for a further 4 weeks to avoid thromboembolism. Patients in whom cardioversion is unsuitable and those in whom cardioversion is unsuccessful should be maintained on digoxin and anticoagulation.

Regular narrow complex tachycardias

Sinus tachycardia is the most common rhythm disturbance in critically ill patients. Generally it requires no specific drug therapy, but it is usually one of the first warning signs of systemic illness. Common causes include hypoxaemia, hypercapnia, haemorrhage, thyrotoxicosis, pain, anxiety, infection, pulmonary embolism, cardiac tamponade, pneumothorax and drug or alcohol withdrawal.

SVT: although critically ill patients often develop a sinus tachycardia or atrial fibrillation, regular narrow complex tachyarrhythmias may also occur. These are likely to be caused by atrial flutter, atrial tachycardia, junctional tachycardias (atrioventricular nodal re-entry tachycardia) or the involvement of an accessory pathway (atrioventricular re-entry tachycardia). Management is principally the same, irrespective of the exact type of regular narrow complex tachycardia.

Treatment

- If the patient is haemodynamically compromised, immediate synchronized DC cardioversion under sedation should be considered (100 J, 200 J, 360 J).
- In the absence of cardiovascular compromise, vagal man-oeuvres should be attempted to abolish the arrhythmia or slow the conduction through the AV node in order to reveal atrial flutter. These include the Valsalva manoeuvre, application of cold water to the face and carotid sinus massage (avoid if patient has a carotid bruit).
- If there is no response to vagal manoeuvres, adenosine, initial dose 6 mg given rapidly followed immediately by a flush of 20 ml saline, should be administered via a central vein or large- bore peripheral cannula. The patient should be monitored closely during administration and should be warned to expect transient feelings of chest tightness, nausea and flushing. If the arrhythmia persists, adenosine, three doses of 12 mg, every 2 minutes, may be repeated. Adenosine should be avoided in patients with atrioventricular block and asthma, and care should be taken in patients with chronic obstructive pulmonary disease because it may provoke bronchospasm. Its use is contraindicated in patients with Wolff–Parkinson–White (WPW) syndrome because blockade of the artioventricular node may precipitate rapid atrial fibrillation. The effects of adenosine are potentiated by dipyridamole and antagonised by theophylline.
- If the patient has heart failure, chest pain, heart rate over 200 bpm or hypotension, synchronized DC cardioversion under sedation should be attempted (100 J, 200 J, 360 J). Amiodarone, 150 mg over 10 minutes, may be administered before repeating DC cardioversion if the initial three shocks are unsuccessful.
- If the patient remains cardiovascularly stable, alternative pharmacological therapy should be considered including esmolol, amiodarone, digoxin or verapamil. Verapamil should not be used in the presence of WPW syndrome, previous β-blockade or if signs of impaired LV function exist. Be wary of using multiple pharmacological agents.
- If the arrhythmia continues despite the above measures, a cardiological opinion should be sought regarding the possible indication for atrial overdrive pacing.

Bradyarrhythmias

The definition of a bradyarrhythmia is a heart rate less than 60 bpm. However, it should include patients whose heart rate is proportionally slow for their haemodynamic state. Causes of bradyarrhythmia include :

- acute myocardial infarction
- age-related degenerative disease of the conduction system
- atrioventricular nodal blocking drugs
- hypothyroidism
- hypothermia
- head injury.

Treatment: the management of bradyarrhythmias is summarized in Figure 7.

- Assess the patient for adverse signs including chest pain, heart failure, hypotension or a heart rate less than 40 bpm.
- If adverse signs are present administer atropine, 500 µg i.v. This may be repeated to a maximum total dose of 3 mg.
- If there is no response to atropine, consider an adrenaline (epinephrine) infusion at a rate of 2–10 µg/minute.
- Consider the need for temporary pacing. This may be initially in the form of external pacing leads with mild sedation but should subsequently be via an intravenous temporary pacing wire.
- If adverse signs are absent, it may be appropriate to monitor the patient in a high dependency environment.
- Patients with Mobitz type II atrioventricular block, complete heart block, ventricular pauses greater than 3 seconds, symptomatic bifascicular or trifascicular block or recent asystole may require pacing to avoid the risk of asystole.

Management of bradyarrhythmias

- Treat the patient rather than the ECG. If the patient is not haemodynamically compromised it may be appropriate to observe them in a monitored high dependency setting while removing any precipitating factors
- External pacing may save lives in patients whose bradyarrhythmias do not respond to atropine or adrenaline (epinephrine).

Cardiogenic Shock and Congestive Cardiac Failure

Henry G W Paw

Henry G W Paw is Consultant in Anaesthesia and Intensive Care at York District Hospital, York, UK. He qualified from Newcastle University and trained in Newcastle and Cambridge, UK. He is also a qualified pharmacist.

Cardiac failure occurs when the heart is unable to maintain an adequate cardiac output to meet the demands of the body despite adequate ventricular filling. A diagnosis of cardiac failure alone is inadequate and the cause and any precipitating factors should be determined (Figure 1).

Cardiogenic shock is a severe form of cardiac failure characterized by the triad of hypotension (systolic blood pressure < 90 mm Hg), low cardiac output, and signs of poor tissue perfusion (e.g. oliguria, delayed capillary return, cold extremities, impaired cerebral function). It may be differentiated from other forms of shock by having an elevated pulmonary capillary wedge pressure (PCWP). Even with intensive care, it has a high mortality (> 90%) because pump failure causes impaired coronary perfusion that further reduces cardiac contractility.

Causes of heart failure

Volume overload

Left ventricular failure
- Aortic regurgitation
- Mitral regurgitation
- Ventricular septal defect

Right ventricular failure
- Tricuspid regurgitation
- Atrial septal defect

Pressure overload (obstruction to cardiac output)

Left ventricular failure
- Hypertension
- Aortic stenosis
- Coarctation of aorta
- Cor pulmonale

Right ventricular failure
- Pulmonary hypertension
- Pulmonary embolus
- Mitral stenosis

Myocardial dysfunction
- Ischaemic heart disease
- Hypoxia
- Electrolyte imbalance
- Acidosis
- Septic shock (cytokines e.g. myocardial depressant factor, tumour necrosis factor-α)

Primary myocardial disease
- Cardiomyopathy
- Myocarditis
- Amyloidosis

Mechanical disadvantage
- Large ventricular aneurysm

Prevention of ventricular filling
- Pericardial tamponade
- Constrictive pericarditis
- Restrictive cardiomyopathy
- Diastolic dysfunction

High cardiac output
- Septicaemia
- Thyrotoxicosis
- Arteriovenous fistula
- Systemic-to-pulmonary shunt
- Paget's disease
- Beri beri

Factors aggravating or precipitating cardiac failure
- Arrhythmias
- Anaemia
- Fluid overload
- Corticosteroids, non-steroidal anti-inflammatory drugs
- Hypoxia
- Electrolyte imbalance
- Acidosis
- Infections
- Thyrotoxicosis

1

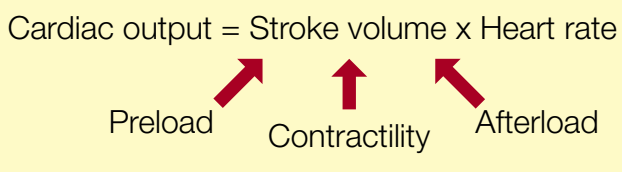
Aetiology

Although there are several causes of heart failure, the most common is ischaemic heart disease. Left heart failure is most often associated with left ventricular myocardial infarction or systemic hypertension. The causes of right heart failure include left heart failure and pulmonary disorders such as chronic obstructive pulmonary disease, pulmonary hypertension and pulmonary embolus. These pulmonary disorders cause an increased pulmonary vascular resistance against which the right ventricle must pump. Myocardial infarction of the right ventricle is uncommon (< 3%). Depressed cardiac function may be precipitated or exacerbated by infection, anaemia, fluid overload or dysrhythmias.

Regulation of cardiac function

Maintenance of an adequate cardiac output depends on stroke volume and heart rate (Figure 2). The essential factors that determine the performance of the heart are venous return (preload), inotropic state or contractility, outflow resistance (afterload) and heart rate.

Determinants of cardiac output

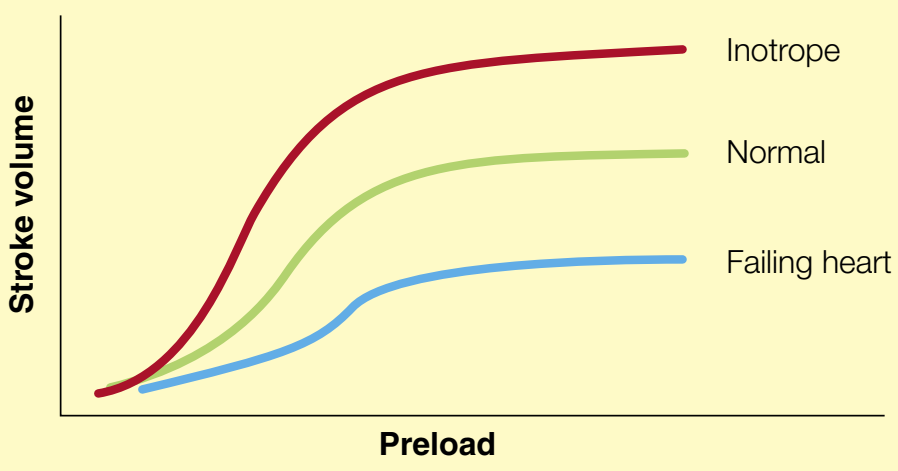


2

Venous return (preload): the increase in ventricular stroke volume (ventricular performance) that occurs with an enlargement of ventricular diastolic volume (preload) is known as the Frank–Starling relationship. In clinical terms, this represents the increase in cardiac output that accompanies an increase in PCWP. In the failing heart, the ventricular function curve is flattened and shifted to the right. Small degrees of myocardial depression are not necessarily associated with a reduction in cardiac output because it is maintained by an increase in venous pressure and tachycardia. However, the ejection fraction is reduced early in cardiac failure. In more severe myocardial dysfunction, cardiac output can be maintained only by a large increase in venous pressure and marked tachycardia. This eventually results in a further reduction in contractility. Despite symptoms caused by increased venous pressure, the cardiac output at rest may be only minimally depressed, but myocardial reserve is so compromised that cardiac output cannot be increased on exertion. In cardiogenic shock, the cardiac output at rest is depressed despite high venous pressures.

Inotropic state or contractility: increased contractility can result from increased sympathetic drive or the administration of inotropic agents. In the critically ill patient, contractility is often reduced, either as a result of pre-existing myocardial disease or the acute disease process itself (e.g. acidosis, hypoxia, sepsis). Changes in myocardial contractility alter the slope and position of the Frank–Starling curve (Figure 3).

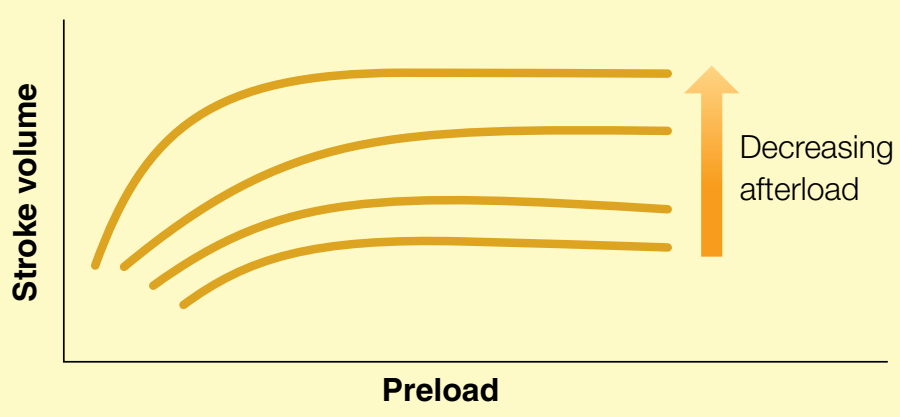
Frank–Starling relationship



3

Outflow resistance (afterload): the afterload is the load or resistance against which the ventricle contracts. For the left ventricle it is determined by the resistance imposed by the aortic valve and the peripheral vasculature (systemic vascular resistance) and influenced by the elasticity of the major blood vessels. Decreasing the afterload can increase stroke volume at any given preload (Figure 4), while also reducing ventricular wall tension and myocardial oxygen consumption. The reduction in wall tension may lead to an increase in coronary blood flow, thereby improving the myocardial oxygen supply:demand ratio. On the other hand, an increase in afterload can cause a fall in stroke volume and an increase in myocardial oxygen consumption.

The effect of changes in afterload on the Frank–Starling curve



4

Heart rate: extreme bradycardia or tachycardia can reduce cardiac output. When the heart rate falls, the increase in stroke volume eventually becomes insufficient to compensate for the bradycardia and cardiac output falls. When a tachycardia occurs the duration of systole is unchanged, whereas diastole, and thus the time available for ventricular filling and coronary blood flow, becomes progressively shorter. In the healthy heart this occurs above 160 beats/minute, but in those with cardiac pathology, stroke volume may fall at much lower rates. Alterations in heart rate are often caused by disturbances of rhythm. For instance, in atrial fibrillation or complete heart block, the absence of atrial contraction reduces stroke volume.

Clinical features

The clinical presentation depends on which ventricle is failing. The division of heart failure into syndromes of left, right and congestive cardiac failure is clinically useful, though it is uncommon for any part of the heart to fail in isolation. The left and right ventricles function in series and left heart failure may lead to right heart failure, the combination being termed congestive cardiac failure. In congestive cardiac failure there is a combination of the signs and symptoms of left and right heart failure.

Left heart failure (Figure 5) causes raised hydrostatic pressure within the pulmonary veins and capillaries. Fluid is forced from the capillaries into the interstitial and alveolar spaces, causing pulmonary oedema. Interstitial or alveolar oedema results in breathlessness and interferes with alveolar–capillary gas exchange, leading to hypoxaemia. Initially, dyspnoea occurs on exercise or lying flat (orthopnoea and paroxysmal nocturnal dyspnoea) but later occurs at rest.

Right heart failure (Figure 6) results in congestion in the systemic venous system, leading to raised jugular venous pressure, hepatomegaly, ascites, and dependent subcutaneous pitting oedema.

In congestive cardiac failure, the features of both pulmonary and systemic venous congestion are present.

Clinical features of left heart failure

Symptoms
- Anxiety
- Dyspnoea
- Tachypnoea
- Orthopnoea
- Paroxysmal nocturnal dyspnoea
- Reduced exercise tolerance

Signs
- Tachycardia
- Pulmonary crepitations
- Wheeze (cardiac asthma)
- Cough productive of pink frothy sputum
- Cyanosis
- Third heart sound (gallop rhythm)
- Displaced apex beat
- Pulsus alternans

5

Clinical features of right heart failure

Symptoms
- Breathlessness
- Fatigue
- Confusion

Signs
- Elevated jugular venous pressure
- Dependent pitting oedema
- Tender and smooth enlargement of liver
- Ascites
- Right ventricular heave

6

Investigations

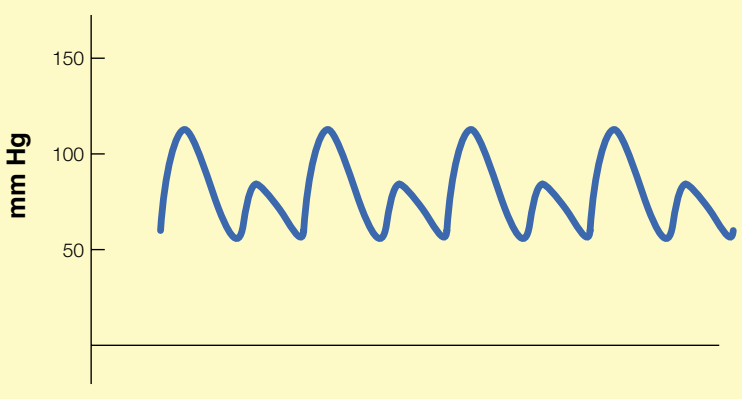
Blood tests: a full blood count should be carried out to identify anaemia. Urea and electrolytes, magnesium and phosphate should be measured. This is especially important in patients taking diuretics and angiotensin-converting enzyme (ACE) inhibitors, which may affect potassium and magnesium handling. Hypophosphataemia can aggravate heart failure. The cardiac enzymes should be assessed. The myocardial-bound isoenzyme fraction of creatine kinase and troponin I or T are specific for myocardial damage. Thyroid function tests should be carried out to identify hypo- and hyperthyroidism.

12-lead ECG is invaluable to detect either full-thickness or subendocardial infarction, left ventricular hypertrophy and dysrhythmias. In myocardial ischaemia, the ECG may be normal between attacks.

Chest radiography: the initial findings include upper lobe blood diversion, perihilar haze and peribronchial cuffing. Later, septal lines (Kerley A and B lines), bat's wing perihilar shadowing and pleural effusions occur. Depending on the cause, the heart size may be normal (acute failure) or enlarged (chronic). Although pulmonary oedema is usually a manifestation of left-sided heart disease, it can be caused by other pathology in critically ill patients (e.g. over-vigorous fluid replacement or pulmonary endothelial damage for example in the acute respiratory distress syndrome (ARDS) or acute lung injury (ALI).

Arterial waveform: in severe heart failure, pulsus alternans, characterized by alternately strong and weak beats in the presence of a regular rhythm may occur (Figure 7). There is absence of bigeminy on the ECG monitor. This is due to the prolonged recovery time of damaged myocardium and indicates a poor prognosis.

Pulsus alternans



7

Central venous pressure (CVP) and PCWP monitoring: measurement of the CVP provides an assessment of right artial pressure and is used as an indirect estimate of right ventricular end diastolic pressure. However, factors such as intravascular volume, intrathoracic pressure and venous tone also affect CVP. Elevated left atrial pressure is a common finding in left heart failure and can be estimated by measuring PCWP using a pulmonary artery catheter. This may be useful in differentiating cardiogenic (high PCWP) from non-cardiogenic pulmonary oedema (e.g. ARDS) and also permits rational use of vasoactive drugs and intravenous fluids. As with CVP monitoring, responses to treatment and trends are more important than absolute values, which are often influenced by intermittent positive-pressure ventilation (IPPV), positive end-expiratory pressure (PEEP), pulmonary disease and myocardial ischaemia.

Echocardiography: transthoracic echocardiography (TTE) and transoesophageal echocardiography (TOE) may provide useful information regarding valvular or other cardiac abnormalities (e.g. ventricular aneurysm, pericardial effusion), regional wall motion and ventricular ejection fraction. An estimation of the ejection fraction in a patient on inotropes, lying in bed doing very little does not provide a true picture of the actual state of the failing heart. However, TTE may not provide adequate views of the aorta and atria and may be unsuitable in patients with COPD or in the obese. TOE is useful in the diagnosis of endocarditis, left atrial pathology (e.g. thrombus), aortic dissection and in patients with mechanical valves.

Oesophageal Doppler monitoring provides flow-based rather than pressure-based monitoring by measuring blood flow in the descending thoracic aorta. It provides good correlation with other estimates of cardiac output and allows assessment of left ventricular filling (preload), contractility and afterload. Changes in waveform provide beat-by-beat visualization of trends and the effects of dynamic challenges to the circulation with fluids, vasodilators or inotropes. It requires repositioning from time to time and is not practical in the non-sedated patient.

Coronary angiography provides a diagnostic tool and allows therapeutic intervention.

Management of acute heart failure

Severe heart failure is a medical emergency, and effective management requires an assessment of the underlying cause, improvement of the haemodynamic status, relief of pulmonary congestion and improvement in tissue oxygenation.

Underlying aetiology
When the diagnosis of heart failure is made, treatment should be directed at the underlying aetiology. For instance, coronary ischaemia should be identified and revascularization considered using percutaneous coronary angioplasty or coronary artery bypass grafting because revascularization may improve ventricular function. Other life-saving treatments include mitral valve surgery for acute mitral regurgitation or closure of a ventricular septal defect caused by myocardial infarct.

Aggravating factors
Regardless of the cause, any aggravating factors should be identified and treated. For example, supraventicular tachyarrhythmias (e.g. atrial fibrillation), should be controlled using appropriate antidysrhythmic drugs.

General measures
The patient will be most comfortable in the sitting position because this encourages blood pooling in dependent parts. Hypoxaemia should be treated initially using high-concentration oxygen (> 60%) by face mask. Unless there are contraindications, subcutaneous low molecular weight heparin (e.g. dalteparin 2500 units) should be administered daily.

Drugs
The drugs used in the treatment of heart failure may be considered in terms of their effects on factors that influence cardiac output (preload, contractility, afterload and heart rate). In severe heart failure, drugs may be best administered intravenously because gut oedema may reduce the absorption of orally administered drugs.

Opioids: morphine, 2 mg i.v. bolus, acts by relieving the distress of dyspnoea and reducing preload by vasodilatation.

Loop diuretics: drugs such as furosemide (frusemide), 40 mg, and bumetanide, 1 mg, act by reducing preload and as potent loop diuretics. Loop diuretics are most effective when the pulmonary oedema is a component of congestive cardiac failure and if the volume of the extracellular fluid compartment is generally increased. When left ventricular failure is acute, pulmonary oedema is a result of fluid shift from the systemic circulation and there is minimal fluid retention. Overzealous use of diuretics in this situation risks hypovolaemia and hypotension.

Nitrates: glyceryl trinitrate and isosorbide dinitrate (infusion rates of up to 12 mg/hour) are useful in the treatment of acute left ventricular failure because they reduce venous return and left ventricular work. Being potent coronary vasodilators they are also useful in myocardial ischaemia. Tolerance rapidly develops with continuous high-dose infusion but reducing the dose for 4 to 8 hours each day usually maintains effectiveness.

Phosphodiesterase inhibitors: enoximone and milrinone are potent inodilators that do not act via adrenergic receptors. Consequently, they may be effective when catecholamines have failed. Their main use is the short-term treatment of severe congestive heart failure, especially in patients with diastolic dysfunction. Phosphodiesterase inhibitors increase cardiac output by 30–70% in patients with heart failure without increasing heart rate significantly because they reduce systemic vascular resistance and pulmonary vascular resistance.

Inotropes: inotropic support with agents such as dopamine and dobutamine (both 5–20 μg/kg/minute) may be required in patients with heart failure or cardiogenic shock. At lower doses (2.5 μg/kg/minute) dopamine may have additional direct renal effects but these have been challenged as being secondary to improvements in cardiac output. Both drugs have inotropic and chronotropic actions via β_1-adrenergic receptors, though at higher doses, dopamine may also stimulate receptors causing increased systemic vascular resistance. Dobutamine reduces preload and afterload, which may reduce blood pressure. Dopamine also depresses prolactin, luteinizing hormone, growth hormone and thyroid function, thereby obtundingthe body's endocrine response to stress. It may alter immuno-logical function, causing humoral and cell-mediated immunosuppression.

Ventilatory support
If hypoxaemia is resistant to high-concentration oxygen delivered by simple face mask, or hypercapnia develops, non-invasive positive-pressure ventilation such as continuous positive airway pressure or bilevel positive airway pressure may be required. These may obviate the need for tracheal intubation and IPPV. Positive-pressure ventilation improves arterial oxygenation, increases functional residual capacity and lung compliance, reduces the work of breathing, and improves V/Q matching. It also improves cardiac function by reducing left ventricular afterload and decreasing myocardial oxygen consumption. In severe pulmonary oedema, with copious pink frothy sputum, repeated bronchial aspirations are required, but removal of PEEP during aspiration should be of limited duration.

Other measures
Venesection still has a role to play in acute pulmonary oedema resistant to other therapies. Continuous veno-venous haemofiltration may be useful in the presence of oliguric renal failure resistant to diuretic. Circulatory assist devices such as intra-aortic balloon pump and left ventricular assist devices can be useful in certain patients with cardiogenic shock resistant to vasoactive therapy. Indications include peri-partum cardiomyopathy, myocarditis or as a bridge to corrective valve surgery, coronary artery bypass surgery or heart transplantation.

Management of chronic heart failure

Once acute heart failure has been stabilized, management is directed at improving prognosis and reducing hospital admissions. Despite the large number of drugs used in the treatment of heart failure, only the ACE inhibitors (e.g. captopril) and β-blockers improve survival. Recently, low-dose spironolactone, 25 mg/day, has also been shown to improve survival in patients with severe congestive cardiac failure (ejection fraction < 35%), when combined with loop diuretics and ACE inhibitors.

Cardiopulmonary Resuscitation

Jerry Nolan

Jerry Nolan is Consultant Anaesthetist and Lead Clinician in Intensive Care at the Royal United Hospital, Bath, UK. He qualified from Bristol University and trained in anaesthesia and intensive care in Bristol, Bath, Plymouth, Southampton and Baltimore, USA. He is Chairman of the Advanced Life Support Course Sub-committee of the Resuscitation Council (UK) and is a member of the Executive Committee of the European Resuscitation Council.

Successful resuscitation from cardiac arrest requires the prompt application of a sequence of interventions known as the 'chain of survival'. The chances of survival are highest for patients in ventricular fibrillation (VF) for whom defibrillation is required as rapidly as possible. After the onset of cardiac arrest, the chances of successful defibrillation decline by about 10% per minute. For this reason, the focus is on rapid defibrillation. The first 'link' in this chain is activation of the emergency services. Out of hospital this implies a telephone call to emergency medical services; inside hospital, the cardiac arrest team should be alerted. The second link, basic life support (BLS) is required unless defibrillation (the third link) can be attempted immediately. The fourth link in the chain, early advanced life support (ALS), maximizes the opportunity for long-term survival.

Resuscitation guidelines

Cardiac arrest teams work more efficiently if all members follow standardized protocols. Following an extensive evaluation exercise, the science supporting the first internationally accepted cardiopulmonary resuscitation (CPR) guidelines was published in August 2000.

Basic life support

The purpose of BLS is to maintain adequate circulation and ventilation until the underlying cause of the cardiorespiratory arrest can be reversed. Failure of the circulation for 3–4 minutes (less if the patient is hypoxaemic initially) will lead to irreversible cerebral damage, and any delay in starting BLS will reduce the chances of a successful outcome.

Classically, BLS implies that no equipment is employed. However, in a health care environment, the professional rescuer will have access to additional personnel and equipment. In particular, adjuncts to airway management are normally available. Nevertheless, the health care professional may have to perform CPR away from a health care environment and therefore should be competent in BLS with no additional equipment.

Mechanism for the production of blood flow during BLS: chest compressions produce forward blood flow by a combination of two mechanisms:
- direct compression of the heart (cardiac pump)
- a generalized increase in intrathoracic pressure (thoracic pump); venous collapse at the thoracic inlet prevents backflow of blood. Even when performed optimally, chest compressions achieve less than 30% of the normal cerebral perfusion.

BLS sequence of actions: brief outlines of the sequence of BLS actions for the lay person are given in Figures 1 and 2.

Basic life support

1 Ensure safety of rescuer and patient

2 Check to see if the patient responds to gentle shaking of the shoulders (shake and shout)

3 If he does not respond:
- Shout for assistance
- Open his airway (head tilt and chin lift manoeuvre). If there is any possibility of a cervical spine injury, avoid head tilt
- Check for breathing for up to 10 seconds

4 If he is breathing:
- Turn him into the recovery position

5 If he is not breathing:
- Send someone for assistance or, if you are on your own, leave the patient and go for assistance yourself
- Give two effective rescue breaths
  Ensure head tilt and chin lift, and pinch the patient's nose
  Blow steadily into his mouth over about 1.5–2 seconds, watching for clear chest rise

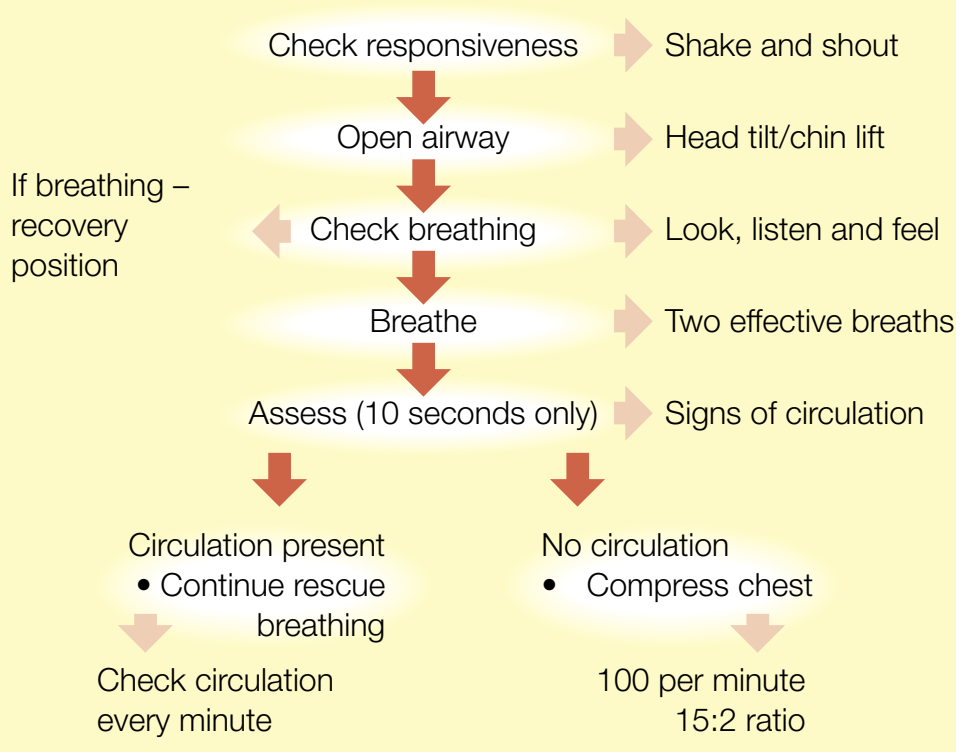
6 Assess the patient for signs of a circulation (taking no more than 10 seconds):
- Look for any movement
- Check the carotid pulse (if adequately trained to do so)

7 If you are confident that you can detect signs of a circulation:
- Continue rescue breathing, until the patient starts breathing on his own
- About every minute recheck for signs of a circulation

8 If there are no signs of a circulation:
- Start chest compressions using the heel of your hand placed over the middle of the lower half of the sternum
- Interlock the fingers of both hands and ensure that pressure is not applied over the patient's ribs
- Compress the sternum by 4–5 cm
- Release the pressure, then repeat at a rate of about 100 times a minute. Compression and release should take an equal amount of time
- Continue compressions and breaths in a ratio of 15:2

1

Basic life support algorithm



2

When to go for assistance: it is vital for rescuers to get assistance as quickly as possible. When more than one rescuer is available, one should start resuscitation while another goes for assistance. Advice on how the lone rescuer should proceed depends on the likelihood of the casualty being in VF.
- In trauma, drowning, or if the patient is a child, the rescuer should perform resuscitation for about 1 minute before going for assistance, because the arrest rhythm is less likely to be VF.
- If the patient is an adult, and the cause of unconsciousness is not trauma or drowning, the rescuer should seek assistance once it has been established that the patient is apnoeic.

No ventilation CPR: the standard method of performing basic CPR is difficult for the lay person to learn and there is evidence that skill retention is poor. During the first few minutes of cardiac arrest, the use of chest compressions alone may be as effective as chest compressions combined with mouth-to-mouth ventilation. In the presence of a patent airway, it likely that chest compressions result in some alveolar ventilation; this may be supplemented by the patient's spontaneous gasps.

BLS in hospital: following cardiac arrest within the hospital, it is likely that more than one health care professional will be available, making it possible to undertake several actions simultaneously. A defibrillator should be close at hand; in the pulseless patient the priority is to bring this to the patient. If the patient has a pulse, urgent medical assessment will be required. In the intervening period, the patient should be monitored, oxygen administered and intravenous access secured.

Airway management and ventilation should be undertaken with the most appropriate equipment immediately at hand. The level of staff training will influence the choice of equipment. A pocket mask, which may be supplemented with an oral airway and oxygen, a laryngeal mask airway and bag–valve apparatus, or a bag–valve–mask device are all suitable.

BLS with defibrillation: traditionally, defibrillation has been viewed as an ALS intervention. However, the increasing availability of simple automated external defibrillators (AEDs) has moved defibrillation into the domain of BLS. Health care personnel and lay people can use AEDs safely and effectively after a short training programme (typically about 4 hours). It is no longer acceptable for nursing staff to have to await the arrival of a cardiac arrest team before attempting defibrillation of a patient in VF, because any delay reduces the chance of survival.

Advanced life support

Treatment algorithm: cardiac arrest rhythms can be divided into two main groups:
- ventricular fibrillation/pulseless ventricular tachycardia (VF/VT)
- other rhythms – asystole, pulseless electrical activity (PEA).

The only difference in the management of these groups is the need for defibrillation in patients who are in VF/VT. Maintenance of BLS, airway management, venous access, the administration of adrenaline (epinephrine) and the identification and correction of contributing factors are common to both groups. The algorithm for the management of cardiac arrest (Figure 3) is used in conjunction with either manual or automated defibrillators.

VF/VT: in adults, the most common rhythm at the onset of cardiac arrest is VF. This may be preceded by a period of pulseless VT. Most long-term survivors of cardiac arrest fall into this group. In order to achieve success, patients must be defibrillated promptly.

BLS should be started if there is any delay in obtaining a defibrillator, but it must not delay defibrillation. If the arrest was monitored, a single precordial thump may be appropriate. If delivered early enough, this may provide enough kinetic energy to convert a fibrillating myocardium to sinus rhythm.

Defibrillation – the initial three shocks are given with energies of 200 J, 200 J and 360 J (or their equivalent – see below). The aim should be to administer all three shocks (if required) in less than 1 minute. After delivery of a shock, there is a delay of a few seconds before an ECG display of diagnostic quality is obtained. Even when a rhythm normally compatible with a cardiac output is obtained, there is often a period of temporary impairment in cardiac contractility, resulting in a pulse that is too weak to palpate. For this reason, if the rhythm following a shock is asystole or PEA, only 1 minute of CPR is given before reassessing the rhythm.

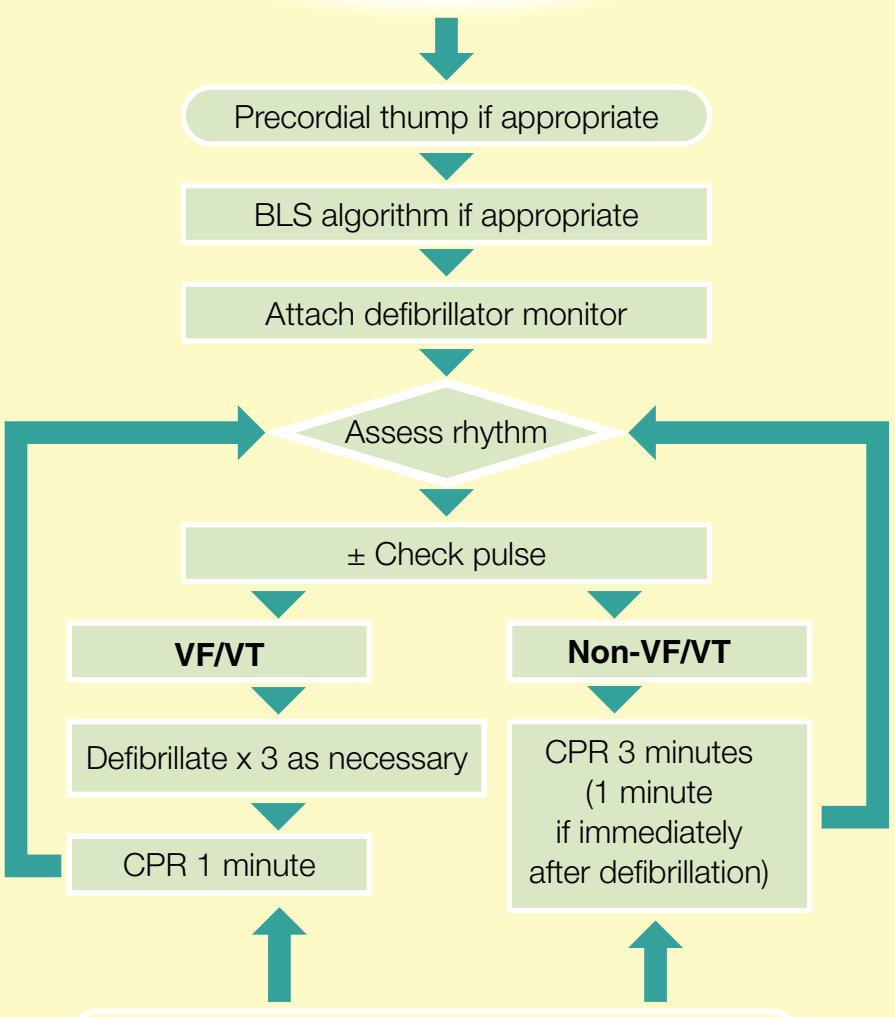
For defibrillators using a conventional damped sinusoidal waveform, the rationale for starting defibrillation at 200 J is that it will cause little myocardial injury and, in most recoverable situations, is adequate to defibrillate the patient successfully. The second shock should also be at 200 J, because the first shock lowers the chest impedance, thereby increasing the current reaching the heart. Third and subsequent shocks are given at 360 J. A number of new defibrillators deliver shocks with biphasic waveforms (polarity is reversed midway through shock delivery). These appear to be more effective than conventional sinusoidal waveform defibrillators; defibrillation is more successful at a lower energy (typically 150 J). Many defibrillators also incorporate impedance compensation (i.e. the shock waveform is adjusted according to the impedance of the patient's chest). The optimal energy level and waveform for biphasic defibrillation remains to be determined.

Airway and ventilation management – if VF persists after three shocks, 1 minute of BLS at a compression:ventilation ratio of 15:2 is undertaken in an attempt to preserve cerebral and myocardial viability. In expert hands, tracheal intubation provides the most secure airway. Attempted intubation by unskilled personnel will delay more important interventions such as chest compressions and further shocks. Furthermore, there is a significant possibility of unrecognized oesophageal intubation. In the absence of a skilled intubator, a laryngeal mask airway or a Combitube are useful alternatives; these devices are less likely to cause gastric inflation and regurgitation than a face mask. The highest possible concentration of oxygen, preferably 100%, should be delivered to the patient's lungs. Once the patient has been intubated, chest compressions should continue throughout ventilation. It takes at least 1 minute for chest compressions to generate the maximal coronary perfusion; this optimal perfusion pressure has to be re-established each time that chest compressions are interrupted.

Drugs – intravenous access should be established as soon as possible. The chosen route will depend on the skills and equipment available. Adrenaline (epinephrine), 1 mg i.v., should be given every 3 minutes. Alternatively, adrenaline, 2–3 mg diluted in 10 ml, can be given via the tracheal tube. Although used universally, the evidence that adrenaline improves outcome following cardiac arrest is weak. There are preliminary data supporting the use of a single dose of vasopressin, 40 units, instead of repeated doses of adrenaline, but long-term outcome data are awaited.

If the patient remains in VF after 1 minute of CPR, three further shocks of 360 J are given. The left-hand loop of the algorithm (Figure 3) is continued with each sequence of three shocks followed by 1 minute of CPR. Potentially reversible causes ('4 Hs and 4 Ts' – see Figure 3) must be excluded, because each can impair the ability to defibrillate VF successfully.

Universal algorithm for the management of cardiac arrest



If VF persists, the use of an antiarrhythmic drug should be considered. Historically, despite the lack of robust data, lidocaine (lignocaine) has been recommended after 12 unsuccessful shocks. Compared with placebo, amiodarone produces an improvement in short-term survival from refractory VF. In the International Guidelines 2000, amiodarone replaces lidocaine as the antiarrhythmic of choice in refractory VF. The use of bicarbonate during cardiac arrest remains controversial. A dose of 50 mmol can be considered if the arterial pH is < 7.1, but there is no good evidence to support this. The generation of carbon dioxide may cause a temporary intracellular acidosis.

Non-VF/VT: the outcome from non-VF/VT is poor unless a reversible cause can be found and treated effectively. With time, VF will degenerate to PEA and asystole.

Asystole – the possibility of a misdiagnosis must be considered; lead disconnection, incorrect gain setting, or equipment failure will give the appearance of asystole despite underlying VF. If there is any doubt, the patient should be treated as for VF. Otherwise, BLS is commenced (or restarted) for 3 minutes, the airway is secured and the patient's lungs are ventilated. Adrenaline, 1 mg, is given every 3 minutes. Although atropine, 3 mg i.v., or 6 mg via the tracheal tube, is traditionally given to block vagal activity, there is no proof that it alters outcome.

Whenever a diagnosis of asystole is made, the ECG should be checked carefully for the presence of P waves or slow ventricular activity. These may respond to cardiac pacing, either external or transvenous. Reversible factors should be identified and treated promptly. The use of high-dose adrenaline is no longer recommended.

PEA is cardiac arrest in the presence of a rhythm normally associated with a cardiac output. The patient's best chance of survival is prompt identification and treatment of any underlying cause (4 Hs and 4 Ts). CPR is started immediately, and a patent airway, ventilation and venous access are secured. Adrenaline, 1 mg i.v., is administered every 3 minutes.

Post-resuscitation care

Patients resuscitated after a short period of cardiac arrest and who have adequate spontaneous ventilation may be managed in a coronary care unit. After more than a few minutes of circulatory arrest, followed by restoration of spontaneous circulation, the patient is likely to require a period of ventilatory and cardiovascular support on an ICU. The duration and level of ventilatory support should be tailored to the requirements of the individual patient.

Outcome

Despite developments in the emergency services, the outcome from prehospital cardiac arrest remains poor, with a survival to hospital discharge rate of about 5%. After cardiac arrest within the hospital, the survival to hospital discharge after VF is as high as 40%. After an initial rhythm of asystole or PEA, this figure is just 6%.

At least two-thirds of in-patients sustaining a cardiac arrest display signs of significant deterioration (e.g. hypoxia, tachypnoea, hypotension) before they arrest. If medical and nursing staff are trained to recognize and treat these physiological abnormalities at an earlier stage, cardiac arrest may be prevented. This strategy is infinitely more sensible than waiting to call a cardiac arrest team after the patient has effectively died.

Chronic Obstructive Pulmonary Disease and Chronic Respiratory Failure

Liz Spencer

Liz Spencer is Consultant in Anaesthesia and Intensive Care Medicine at Gloucester Royal Hospital, UK. She qualified from Southampton University and trained in anaesthesia in Trent and the South West of England. She spent 2 years as a Research Fellow at the Intensive Care Unit at the Bristol Royal Infirmary. Her interests are non-invasive ventilation and multidisciplinary education.

Chronic obstructive pulmonary disease (COPD) describes a spectrum of diseases that are characterized by airflow limitation due to intrinsic airways disease (e.g. chronic bronchitis), bronchospasm (e.g. asthma) and/or parenchyma destruction with associated loss of elastic recoil (e.g. emphysema). Airflow limitation is generally progressive, may be accompanied by airway hyperactivity and may be at least partially reversible. Risk factors for COPD include cigarette smoking and α_1-antitrypsin deficiency (AAT). Most patients with COPD have a combination of the three conditions described below.

Chronic bronchitis is defined as the presence of a chronic cough with sputum production that occurs most days of the week, at least 3 months of the year, for more than two consecutive years in the absence of other specific causes (e.g. asthma, cystic fibrosis, bronchiectasis). Most patients with chronic bronchitis do not have any significant airflow limitation and should not be classified as having COPD. There is mucosal and submucosal oedema and inflammation, with an increase in the number and size of the submucosal mucous glands.

Asthma is an inflammatory disease of the airways that results in reversible airflow limitation. Unlike the minority of asthmatics with poorly reversible airflow limitation, most patients respond well to therapy and therefore do not have COPD.

Emphysema is defined pathologically as a permanent, abnormal air-space enlargement that occurs distal to the terminal bronchiole and includes destruction of alveolar septa.

Diagnosis

COPD is primarily a clinical diagnosis. However, severe emphysema and lung hyperinflation can be diagnosed on a chest radiograph. The lung fields are enlarged and hyperlucent, the diaphragms flattened and the cardiac shadow is narrow. On the lateral film the volume of retrosternal air space is enlarged.

Measurement of the forced expiratory volume in 1 second (FEV_1) and the ratio of FEV_1 to forced vital capacity (FVC) is critical to assess the severity of the disease, to predict prognosis and to follow progression. An FEV_1/FVC ratio of less than 70% is diagnostic of airways obstruction. It falls progressively as the severity of COPD increases.

As patients with COPD deteriorate, respiratory failure (a partial pressure of carbon dioxide in arterial blood ($PaCO_2$) greater than 6.7 kPa or a partial pressure of oxygen in arterial blood (PaO_2) less than 8 kPa breathing air at sea level) often ensues and is frequently chronic and progressive. Hypercapnia is not usually seen until FEV_1 falls below 1 litre. Polycythaemia is seldom seen until PaO_2 is less than 7.2 kPa.

Long-term treatment

As COPD is an irreversible and progressive process, treatment is symptomatic and cannot alter the underlying pathology or improve survival.

Stopping smoking

Smokers with COPD have an accelerated fall in FEV_1. Stopping smoking reduces the rate of decline of FEV_1 at any stage of the disease.

Medications

Bronchodilators provide the mainstay of therapy for most patients. They act by reducing bronchomotor tone and the level of pulmonary hyperinflation. Inhaled agents are as effective as oral agents.

Short-acting β_2-agonists (e.g. salbutamol) have a rapid onset of action and are either used regularly or as required. They activate specific β_2-adrenergic receptors on smooth muscle cell surfaces, which leads to an increase in intracellular cyclic adenosine monophosphate (cAMP) and smooth muscle relaxation. β_2-agonists are available as liquids for nebulization, in aerosol form delivered by pressurized metered-dose inhalers and as dry powders that can be inhaled via special self-actuated devices. Pressurized metered-dose inhalers are the most widely used, but dry powder delivery methods are likely to increase because they do not use chlorofluorocarbon (CFC) propellants.

Anticholinergic agents compete with acetylcholine at postganglionic muscarinic receptors, thereby decreasing cholinergically mediated bronchomotor tone and leading to bronchodilatation. Although muscarinic receptors are more numerous in the larger airways, anticholinergic bronchodilatation occurs at all levels of the bronchial tree. Anticholinergic agents also block vagally mediated reflex arcs that cause bronchoconstriction thereby inhibiting airway reactivity. Anticholinergics have a slower onset of action than β_2-agonists and are best given regularly. Anticholinergics and β_2-agonists may act synergistically.

Theophyllines have been widely used since the early 1900s but their use has diminished owing to their narrow therapeutic range and toxicity. In COPD, theophyllines are only modest bronchodilators with a variable effect on exercise tolerance and symptoms. They are metabolized in the liver but the extent varies between patients because metabolic enzymes are affected by other drugs and disease states (Figure 1).

Theophyllines were thought to produce bronchodilatation by increasing intracellular cAMP, but the precise mechanism is unknown and may involve increased intracellular calcium transport, adenosine antagonism or prostaglandin E_2 inhibition. Theophyllines also appear to increase mucociliary clearance, reduce pulmonary vascular resistance and may improve diaphragm and cardiac muscle contractility. Side-effects include nausea, vomiting, tremor, nystagmus, seizures, gastro-oesophageal reflux and arrhythmias. Plasma theophylline levels should be monitored and maintained in the therapeutic range.

Factors that affect theophylline dose

Need to increase dose

- Cigarettes
- Hyperthyroidism
- Marijuana
- Barbiturates
- Phenytoin
- Rifampicin
- Carbamazepine

Need to decrease dose

- Congestive heart failure
- Liver dysfunction
- Viral/acute illness
- Age > 60 years
- PaO_2 < 6 kPa
- Allopurinol
- Cimetidine
- Ciprofloxacin
- Erythromycin
- Propranolol
- Oral contraceptives
- Verapamil

Corticosteroids: the presence of inflammatory changes in the airways of patients with COPD provides a rationale for the use of corticosteroids. However, the relationship between inflammatory changes, pulmonary function and therapeutic response is not clearly established. Long-term oral corticosteroid therapy may slow the decline of FEV_1 but is not recommended because of the side-effects. On present evidence, inhaled corticosteroids (e.g. beclomethasone, up to 800 µg/day, budesonide, 1600 µg/day, or fluticasone, 2 mg/day) should be given to patients with an objective response to corticosteroids.

Other agents: there is no evidence to support the use of prophylactic antibiotics, other anti-inflammatory drugs (e.g. sodium cromoglycate, nedocromil, antihistamines) pulmonary vasodilators or mucolytics in COPD.

Management of acute exacerbation of COPD

Infections, cardiac failure and pulmonary embolism are the most common factors to precipitate acute respiratory failure in patients with COPD. Signs and symptoms include increasing dyspnoea, increased sputum production (often purulent) and wheeze. Worsening gas exchange is the initial presentation. Stable COPD patients usually have altered ventilation–perfusion (V/Q) matching that worsens when acute respiratory failure develops. For instance, increased airways resistance reduces ventilation in some areas of the lung, thereby increasing low V/Q units; additionally, hyperinflation reduces blood flow in distended alveoli which increases high V/Q units. These alterations are the main reason for the increase in $PaCO_2$ that occurs in COPD despite maintenance of minute ventilation. Worsening of V/Q mismatch is limited by hypoxic pulmonary vasoconstriction but high concentration oxygen may abolish this reflex, causing a deterioration in V/Q mismatch and a further increase in $PaCO_2$.

Presenting history: consider the following:

- previous exercise tolerance (how independent is the patient under normal circumstances and during exacerbation?)
- assess current treatments (use of nebulizers and long-term oxygen therapy)
- time course of current exacerbation
- current symptoms (sputum volume and purulence, dyspnoea, wheeze, chest tightness)
- previous admissions over the last 5 years (any to ICU?)
- smoking history
- social circumstances and quality of life.

Examination: look for the following:

- signs of infection (e.g. pyrexia, purulent sputum)
- signs of airway obstruction (tachypnoea, use of accessory muscles, pursed-lip breathing, audible wheeze)
- peripheral oedema, cyanosis or confusion.

Investigations: the following investigations may be helpful.

- Arterial blood gas analysis and inspired oxygen concentration – hypoxaemia may be severe (less than 4 kPa). The extent of hypercarbia depends on the severity of the condition but $PaCO_2$ levels greater than 10.6 kPa are uncommon. Arterial pH is usually well maintained because bicarbonate is chronically retained. A respiratory acidosis suggests a recent exacerbation and a pH below 7.26 predicts a poor outcome.
- Chest radiograph, preferably a posteroanterior view to check for pneumonia and pneumothorax.
- Full blood count – polycythaemia and leucocytosis occur in severe disease.
- Urea and electrolytes – hypokalaemia is common due to β_2-antagonist, corticosteroids and diuretic therapy.
- ECG – right heart hypertrophy and strain suggest cor pulmonale.
- Initial FEV_1 and peak flow should be assessed.
- Microbial culture of purulent sputum and blood is required.

Treatment

Oxygen therapy – all critically ill patients require 100% oxygen in the emergency situation while the initial assessment is made and therapy commenced. Subsequently many patients with an acute exacerbation of COPD will continue to benefit from high flow oxygen and the aim of oxygen therapy is a PaO_2 of at least 8 kPa. However, when given high inspired oxygen concentrations, a few patients may increase their $PaCO_2$ through complex mechanisms involving altered V/Q mismatch, the Haldane effect and decreased minute ventilation. This acute rise in $PaCO_2$ may cause 'carbonarcosis' with agitation, drowsiness or coma. Monitoring by serial arterial blood gas measurements is essential and when the pH is less than 7.26 the inspired oxygen concentration should be titrated to relieve severe hypoxaemia while maintaining a level of consciousness that retains the patient's ability to cough and cooperate. The level of carbon dioxide is not of prime importance. Once stable, the patient can be monitored using pulse oximetry, but repeat arterial blood gases should be performed at any time if the patient's clinical condition deteriorates.

Some patients with COPD are chronically hypoxaemic and develop counter-regulatory mechanisms such as increased haematocrit and increased oxygen extraction from the tissues. These patients can tolerate acute hypoxaemia better than others.

Bronchodilators – nebulized bronchodilators should be given at least every 4–6 hours. For moderate exacerbations either a β_2-agonist (e.g. salbutamol, 2.5–5 mg) or an anticholinergic (e.g. ipratropium, 0.25–0.5 mg) is appropriate, but for severe exacerbations both should be given because they have a synergistic effect. Although some practitioners power nebulizers using the wall-mounted oxygen supply, the use of compressed air may be preferable in COPD patients with hypercapnia or a respiratory acidosis. Oxygen can be given by nasal prongs at 1–2 litres/minute during nebulization.

Intravenous bronchodilators can be used if the patient fails to respond to nebulizers. There is no place for intravenous β_2-agonists but aminophylline, 0.5 mg/kg/hour, is proven to be of benefit.

Antibiotics – infection often worsens COPD and antibiotics should be administered to any patient with acute-on-chronic respiratory failure (pH < 7.35) and two or more of the following:

- increased breathlessness
- increased sputum volume
- purulent sputum.

Likely pathogens include *Haemophilus influenzae, Streptococcus pneumoniae* and *Moraxella catarrhalis*. Atypical pathogens are seldom a problem though *Chlamydia pneumoniae* may be found. Some infections are viral. For moderate exacerbations, oral antibiotics (amoxicillin (amoxycillin) or tetracycline) should be used but in severe exacerbations, an intravenous broad-spectrum cephalosporin with the addition of a macrolide, if necessary, will be required.

Corticosteroids – it is unclear if systemic corticosteroids alter the course of an acute exacerbation of COPD, but it is common practice to use a 7–14 day course of prednisolone, 0.5 mg/kg/day, or hydrocortisone, 200 mg/day, especially if:

- the patient usually takes corticosteroids
- there has been a previous response to corticosteroids
- the airflow obstruction is resistant to bronchodilators
- this is the first presentation of airways obstruction.

Diuretics should be given if there is peripheral oedema or a raised jugular venous pressure.

Respiratory stimulants – hypercapnia during COPD exacerbations may be due to respiratory muscle fatigue or a blunted ventilatory drive. Doxapram may be used if the respiratory rate is less than 15/minute and acts centrally to increase respiratory drive and respiratory muscle activity. Its effect is significant for only 24–48 hours; the main factor limiting its use is side-effects that can lead to agitation. It should not be used if non-invasive ventilation is being considered.

Anticoagulants – pulmonary emboli are probably more common than previously recognized in severe COPD but full anticoagulation treatment is not currently recommended. Nevertheless, prophylactic subcutaneous heparin must be prescribed for all patients with acute-on-chronic respiratory failure.

Nutrition – many patients with COPD have an increased resting metabolic rate and nearly 50% of those admitted to hospital with acute respiratory failure have some degree of protein calorie malnutrition. Feeds high in carbohydrate should be avoided because they increase carbon dioxide production and oxygen consumption.

Physiotherapy – there are few data to suggest that chest physiotherapy reduces sputum retention in acute exacerbations of COPD and so it cannot be recommended routinely. However, it seems appropriate to provide physiotherapy in those patients who have large volumes of retained sputum in the acute phase.

Managing respiratory failure with mechanical ventilation

Ventilatory support, either as non-invasive ventilation or intermittent positive-pressure ventilation (IPPV) via a tracheal tube, may be necessary for patients who fail to respond to supportive treatment and controlled oxygen therapy. The main goal of mechanical ventilation is the support of gas exchange and fatigued respiratory muscles while the precipitating cause of acute respiratory failure is treated. A trial of non-invasive ventilation should be performed in all patients with respiratory failure and intubation should be reserved for non-responders and those unable to cooperate.

Non-invasive positive-pressure ventilation (NIPPV)

NIPPV avoids the morbidity and mortality associated with IPPV (e.g. sedative drugs, nosocomial chest infections, ventilator dependence) and may reduce intubation rates, mortality, and length of hospital stay. It can be applied intermittently, avoids the need for sedation, and allows the patient to eat, talk and drink. It can also be used outside the ICU, thereby reducing the demand for ICU beds. NIPPV is most beneficial when used early and it has been suggested that all COPD patients with a respiratory acidosis (pH < 7.35) after initial treatment are offered NIPPV.

NIPPV uses two ventilatory techniques – continuous positive airway pressure and inspiratory assist (pressure support) (see page 343). On non-invasive ventilators these pressures are set as expiratory positive airways pressure (EPAP) and inspiratory positive airways pressure (IPAP). The pressure support delivered is IPAP–EPAP.

Patient selection for NIPPV is important. Confused patients and those with a large volume of secretions are less likely to respond well. The prerequisites for success are:

- patient cooperation
- patient can maintain airway and expectorate secretions
- adequate cough reflex
- patient can breathe unaided for several minutes
- functioning gastrointestinal tract
- haemodynamic stability.

Negative non-invasive ventilation

The application of intermittent subatmospheric pressure to the chest wall generates the same gradient of pressure between the peripheral and central veins as a spontaneous breath. Various devices have been used including tank ventilators, cuirasses and jacket ventilators. These techniques are used, mainly to provide long-term support for patients with limited respiratory reserve and nocturnal hypoventilation due to restrictive disorders such as kyphoscoliosis, thoracoplasty, and residual paralysis from poliomyelitis. More recently, non-invasive high-frequency oscillation has been shown to increase carbon dioxide elimination. Consequently the Hayek oscillator has been developed. It consists of a cuirass that surrounds the chest and which maintains subatmospheric pressure with superimposed oscillations.

IPPV

In certain situations NIPPV is unsuccessful and IPPV should be considered (Figure 2). Many medical and ethical issues surround the use of IPPV for COPD patients including the patient's wishes, the likelihood that the patient will survive to leave hospital with a good quality of life and the availability of resources. The provision of IPPV may also cause unnecessary distress to the patient and their relatives. NIPPV can be useful in supporting the patient until the appropriateness of tracheal intubation and mechanical ventilation can be determined. Senior medical staff must be involved in this discussion.

Indications for tracheal intubation and ventilatory support are:

- severe respiratory distress
- failure to cough
- decreasing level of consciousness
- agitated, confused patient.

Determining when to use intermittent positive pressure ventilation (IPPV)

Factors to encourage use of IPPV

- Reversible reason for current decline
- First episode of respiratory failure
- Good quality of life

Factors to discourage use of IPPV

- Previously documented severe chronic obstructive pulmonary disease found to be unresponsive to relevant therapy
- Poor quality of life
- Severe co-morbidity (e.g. congestive heart failure, cancer)

2

Management as the patient recovers

As the patient's condition improves (less dyspnoea, better peak expiratory flow rate (PEFR), improved oxygen saturation in arterial blood) the nebulized bronchodilator can be changed to the patient's usual inhaler. Antibiotics and corticosteroids can usually be stopped after 1 week. PEFR should be recorded twice daily until clinically stable and both FEV_1 and arterial blood gases (on air) should be recorded before hospital discharge. Before discharge the patient's inhaler technique should be assessed and advice given on the treatment regimen and on how to stop smoking.

CNS Infections in Intensive Care

Marcia McDougall
Ian S Grant

Marcia McDougall is Specialist Registrar in Anaesthetics and Intensive Care in Edinburgh. Her areas of interest include nutrition in intensive care and high dependency, and glucose control in intensive care.

Ian S Grant is Consultant Intensivist at the Western General Hospital, Edinburgh. He qualified from Edinburgh University, and trained in general medicine and anaesthesia in Glasgow, before taking up consultant posts in anaesthesia and intensive care in Dundee and Edinburgh. His interests include neurointensive care and long-term ventilation.

Many CNS infections can be treated in a general ward, but prolonged seizures, coma, septic shock or airway compromise are indications for ICU admission for treatment and supportive care. In the UK, severe CNS infections fall into three categories: meningitis, encephalitis and cerebral abscess.

Acute bacterial meningitis

This pyogenic infection of the subarachnoid space and cerebral ventricles is the most common intracranial infection in the UK (incidence 3–5/100,000). The usual causative organisms are:

- *Streptococcus pneumoniae* (40%)
- *Neisseria meningitidis*
- *Haemophilus influenzae*
- *Staphylococcus aureus.*

In post-transplant, alcoholic, diabetic, immunosuppressed or HIV-positive patients, the organism may be atypical (e.g. *Listeria monocytogenes*).

Pathophysiology – bacteria colonize the bloodstream via the nasal or oropharyngeal mucosa, and cross the blood–brain barrier. Direct spread from trauma, sinusitis or mastoiditis, or haematogenous spread from distant infection also occurs. Lipopolysaccharide and teichoic acid produced by Gram-negative and Gram-positive bacteria, respectively, induce meningeal inflammation and cause leucocyte chemoattraction and vascular endothelial damage. This results in cerebral oedema and ischaemia, disruption of the blood–brain barrier and failure of cerebral autoregulation. Blockage of CSF flow may cause hydrocephalus.

Clinical features include:

- a prodromal period of malaise, myalgia, upper respiratory tract symptoms, joint pains and fever
- severe headache
- vomiting
- photophobia
- neck stiffness
- decreased conscious level
- rash: petechial or purpuric (meningococcal infections); maculopapular (staphylococcal or pneumococcal infections)
- cranial nerve lesions
- seizures
- papilloedema
- septic shock (meningococcal and pneumococcal disease).

Signs in the very young and old may be more subtle. The differential diagnosis of acute bacterial meningitis includes viral meningitis, encephalitis, subarachnoid haemorrhage, subdural empyema, brain abscess and legionnaires' disease.

Investigations – the diagnosis is primarily clinical when a rash is present; otherwise it rests on detecting organisms from blood culture or CSF. Lumbar puncture is contraindicated in the presence of focal neurological signs, papilloedema or depressed conscious level unless raised intracranial pressure (ICP) has been excluded by CT scan. Early lumbar puncture (i.e. within 2 hours of antibiotic treatment) may yield diagnostic information from a Gram stain, culture, polymerase chain reaction (PCR) or latex agglutination test. CSF is characteristically turbid, with over 1000 neutrophils/mm^3, low glucose and raised protein levels. Viral meningitis may also cause a neutrophil leucocytosis early in the illness, though it normally leads to a lymphocytosis.

There may be a coagulopathy, peripheral neutrophilia and renal impairment, the latter especially if shock is present.

Management – recommended antibiotics are cefotaxime, 2 g 4–6 hourly i.v., or ceftriaxone, 2 g 12 hourly i.v. Vancomycin, 1 g 12 hourly adjusted according to levels, should be considered in areas with a high prevalence of resistant pneumococci, or if the infection arises after neurosurgery. Different therapy is required in the immunosuppressed, elderly or neonates. Close contacts of patients should receive prophylactic rifampicin, 600 mg 12 hourly for 2 days (10 mg/kg 12 hourly for children). Corticosteroids are beneficial in children with *Haemophilus* meningitis. Early treatment with dexamethasone, 10 mg continued 6 hourly for 4 days, has been shown to improve outcomes in adults with acute bacterial meningitis. If *Listeria* meningitis is considered a possible diagnosis, ampicillin, 1–2 g 6 hourly i.v., should be added.

Intensive care management focuses on supportive care and prevention of secondary brain injury due to ischaemia and hypoxia. Specific guidance includes:

- intubation and ventilation for patients with a Glasgow Coma Score of 8 or less, loss of airway protection or persistent seizures
- avoid factors that increase ICP
- adjust ventilation to maintain a $PaCO_2$ of 4.0–4.5
- nurse the patient in a head-up position
- tape, rather than tie, tracheal tubes
- maintain a normal plasma sodium and euglycaemia
- there should be a low threshold for repeating a CT scan
- if hydrocephalus is present, ventricular drainage may be required
- enteral nutrition should be commenced early
- fever should be treated (active cooling and/or paracetamol)
- treat syndrome of inappropriate secretion of antidiuretic hormone (SIADH) and diabetes insipidus.

Raised ICP should be treated with mannitol, furosemide (frusemide) or hypertonic saline. The cerebral perfusion pressure (mean arterial pressure (MAP) – ICP) should be kept above 70 mm Hg with fluid and vasopressors (e.g. noradrenaline (norepinephrine)). Fluid resuscitation should be guided by arterial blood pressure, central venous pressure and, where appropriate, pulmonary artery pressure monitoring. If cerebral oedema is severe, a thiopental (thiopentone) infusion may decrease cerebral oxygen demands and ICP.

Complications – status epilepticus should be treated with phenytoin, loading dose of 15 mg/kg given over 30–60 minutes, if benzodiazepines fail. If it is persistent, thiopental (thiopentone) or propofol infusion may be required. Continuous full or processed EEG monitoring may be required to detect subclinical status epilepticus or to optimize the thiopental (thiopentone) infusion rate to achieve burst suppression. Neurological deterioration may indicate worsening cerebral oedema or the development of hydrocephalus, subdural empyema or sagittal sinus thrombosis. Long-term complications include cranial nerve palsies, hemiparesis and deafness. Skin loss and digital or limb ischaemia are complications of meningococcal sepsis.

Outcome – mortality is about 25%. It is worse in children and the elderly, in those with a delayed diagnosis, comatose on admission or with raised ICP.

Viral encephalitis

Encephalitis is inflammation of the brain parenchyma, often with meningeal involvement (meningo-encephalitis). It is caused by:

- herpes simplex virus (HSV) I (the most common cause in Europe; annual incidence 1/250,000) 30% of cases are associated with herpes labialis or genitalis
- HSV II (neonates, immunosuppressed patients)
- other viruses (measles, mumps, rubella, varicella zoster, polio, HIV, cytomegalovirus, rabies and Epstein–Barr viruses).

Pathophysiology – virus reaching the brain via the nasal mucosa, or from respiratory or enteral infections causes direct cerebral cytotoxicity by lysis, and excites an inflammatory response leading to cerebral oedema, vascular obstruction, cerebral ischaemia, infarction and atrophy.

Clinical features and diagnosis – in herpes encephalitis, a 7–10-day prodrome of fever, malaise, headache, upper respiratory tract infection, myalgia and personality change leads to focal seizures, confusion, irritability and focal neurological deficits. In severe cases, coma ensues. The differential diagnoses include:

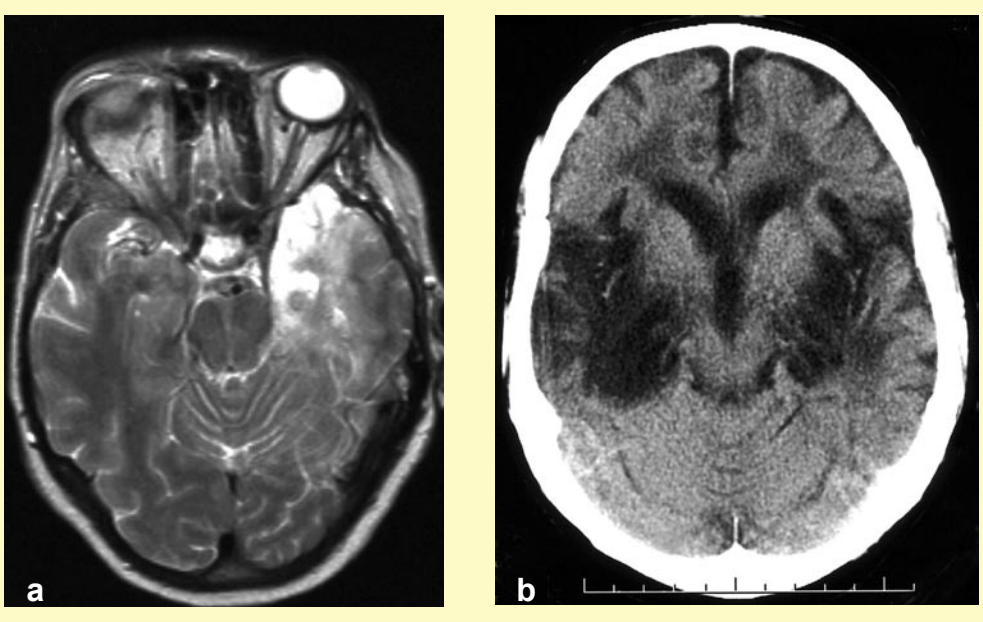
- infectious encephalitides of non-viral origin (e.g. Lyme disease)
- viral meningitis
- acute bacterial meningitis
- sagittal sinus thrombosis
- metabolic and toxic encephalopathies (cocaine and chemotherapeutic agents)
- carcinomatous meningitis
- cerebrovascular accident
- cerebral abscess
- connective tissue disease causing cerebral vasculitis
- cerebral malaria.

In immunosuppressed patients, progressive multifocal leucoencephalopathy, *Toxoplasma*, cryptococcal meningitis, tertiary syphilis, CNS lymphoma, or tuberculous meningitis are alternative diagnoses.

Investigations include:

- a full travel history
- blood culture
- blood for viral and fungal serology; blood films for malaria parasites
- EEG (bilateral periodic lateralized epileptiform discharges are pathognomonic of HSV encephalitis)
- CSF examination, if lumbar puncture is not contraindicated (lymphocytic pleocytosis 50–1500/mm^3, low or normal glucose and a mildly elevated protein)
- CT or MRI if there are focal neurological signs or a decreased conscious level (Figure 1). MRI is more sensitive in detecting the changes of HSV encephalitis
- PCR for HSV and cytomegalovirus (sensitivity > 95%).

Brain biopsy may be required if there is deterioration despite aciclovir, if CT suggests an alternative diagnosis, or in the immunosuppressed. Viruses are detected by immunohistochemical staining of brain tissue.



a Acute herpes encephalitis. T2 axial MRI of the brain showing hyperintensity and swelling of the grey and white matter of the pole of the left temporal lobe (arrowed). **b** Post-herpetic atrophy. CT scan showing marked atrophy and gliosis of both temporal lobes (arrowed) following herpetic infection. Herpes encephalitis is more often bilateral than unilateral. *Scans courtesy of Dr D Collie, Western General Hospital, Edinburgh.*

1

Intensive care management is similar to that for acute bacterial meningitis, although if HSV encephalitis is suspected, aciclovir, 10 mg/kg/over 1 hour i.v. then 8 hourly for 10 days (adjusted in renal failure), should be started. Cytomegalovirus encephalitis is treated with ganciclovir, 5 mg/kg 12 hourly i.v. for 14–21 days. If treatment for retinitis has already been given, add foscarnet, 90 mg/kg 12 hourly. There is no specific treatment for other viral encephalitides; supportive care is indicated.

Complications – worsening cerebral oedema and necrosis may occur, especially in HSV encephalitis. Repeat CT scan may show hydrocephalus or severe oedema; craniotomy with decompressive temporal lobectomy may be life-saving. However, if the swelling is in the dominant hemisphere, residual disability is severe. CSF drainage may relieve hydrocephalus. Bilateral brain swelling with failed response to ICP treatment leads to tentorial herniation and brain death. Such patients are unsuitable as organ donors owing to viraemia.

Outcome in HSV encephalitis is worse in patients over 30 years of age, if treatment with aciclovir is delayed beyond 4 days from onset, and if coma and cerebral oedema are present. Sequelae include amnesia, cognitive deficits, personality change and epilepsy. Secondary brain injury due to hypoxia and infarction may cause physical disability. The mortality is 10–30%, and 60% of survivors who present in coma have neurological sequelae.

Parasitic intracranial infection

Epidemiologically, the most important parasitic infection is cerebral malaria caused by *Plasmodium falciparum.* In the UK, there are up to 2000 cases of malaria every year (usually in the pyrexial traveller or immigrant).

Cerebral malaria: obstruction of cerebral blood vessels by parasitized erythrocytes causes decreased cerebral blood flow, tissue hypoxia and inflammation. The clinical features include:

- coma
- seizures
- hypertonia
- extensor posturing
- hypoglycaemia
- haemolytic anaemia
- coagulopathy
- dysconjugate gaze
- raised ICP
- brainstem herniation.

A mortality of 15–25% can be reduced to 5% with intensive care. Investigations include:

- peripheral blood smears show malarial parasites
- antigen detection with the ParaSight F test
- lumbar puncture may yield parasites in the CSF.

Treatment should be started if clinical suspicion is high, even if tests are negative. Treatment involves quinine, 20 mg/kg over 4 hours i.v. then 10 mg/kg over 4 hours repeated 8 hourly thereafter. Supportive intensive care and ICP management may be required. Exchange transfusion is indicated if parasitaemia reaches 5–10%.

Cerebral abscess and subdural empyema

A localized suppurative infection of the brain parenchyma may arise by direct spread (e.g. sinusitis, mastoiditis, penetrating head trauma, meningitis) or by haematogenous spread (e.g. endocarditis, skin or soft tissue infections, pneumonia, dental abscesses, otitis media). Infecting organisms are often a mixture of aerobic and anaerobic, including streptococci, staphylococci, *Bacteroides*, and less commonly *Klebsiella* and *Pseudomonas*. In the immunocompromised patient, causal organisms may be atypical.

Pathophysiology – a localized area of cerebritis undergoes necrosis and liquefaction. A fibrous capsule with surrounding vasogenic oedema develops. Subdural empyema is the result of spread of infection from sinuses, or following trauma or neurosurgery. Abscess formation may cause rapid deterioration with fever, mass effect, cerebral oedema and tentorial herniation.

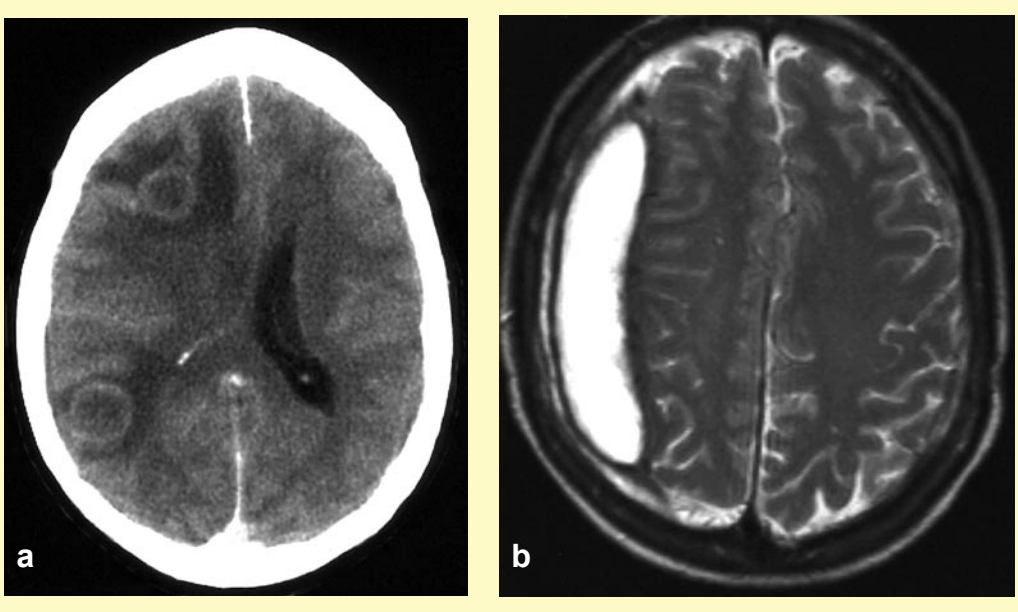
Clinical features and diagnosis – clinical features include:

- headache
- fever (50%)
- focal neurological deficits
- behavioural changes
- decreased conscious level (50%)
- seizures (30%).

Rapid onset and deterioration may indicate rupture into the ventricles. Multiple abscesses carry a higher risk of severe cerebral oedema. Brainstem abscesses may cause cranial nerve palsies, nystagmus, ataxia, swallowing difficulties, abnormal breathing patterns and airway compromise. The differential diagnoses include:

- any cerebral space-occupying lesion
- meningitis
- encephalitis
- cerebrovascular accident
- multiple sclerosis
- cerebral sarcoid.

Investigations – white cell count and ESR are raised. Blood, urine and sputum cultures should be sent for viral, fungal and *Toxoplasma* serology. CT or MRI with contrast should be carried out (MRI is more sensitive for detecting multiple small abscesses and cerebritis; enhancement with contrast favours *Toxoplasma* or cerebral lymphoma, Figure 2). Lumbar puncture is contraindicated in the presence of a space-occupying lesion.



a Cerebral abscesses. Contrast-enhanced CT scan showing multiple thin-walled ring-enhancing lesions (arrowed) in the right cerebral hemisphere with surrounding oedema, and mass-effect with effacement of the right lateral ventricle. Radiologically it may be impossible to distinguish cerebral abscesses from multiple cerebral metastases. **b** Subdural empyema. MRI scan showing a large subdural empyema in the right parietal region (arrowed) causing mass-effect and midline shift, with thickened and inflamed dura mater. Scans courtesy of Dr D Collie, Western General Hospital, Edinburgh.

2

Management – for early, small, multiple, inaccessible, brainstem and some multilocular abscesses, medical treatment with antibiotics is first-line therapy (ceftazidime, 2 g 8 hourly i.v., and metronidazole, 500 mg 8 hourly i.v., the latter to cover anaerobes). Vancomycin, 1 g 12 hourly i.v. adjusted according to levels, is given in the case of post-surgical infection, staphylococcal infection or cephalosporin allergy. Serial CT scans can monitor the size of the abscess to determine the need for drainage. Antibiotics should be continued for 6–8 weeks.

Aspiration is indicated for abscesses over 2.5 cm in diameter, deterioration due to cerebral oedema, diagnostic culture or failure of medical treatment. Abscesses should be drained stereotactically under general anaesthesia. Rapid increase in size with worsening neurological function may necessitate urgent craniotomy and excision. General intensive care management follows the principles of neurointensive care outlined above. Dexamethasone, 10 mg bolus followed by 4 mg 6 hourly, is indicated for worsening cerebral oedema.

Outcome – complications include seizures, hydrocephalus and ventriculitis. Mortality is 15–25%, worse in the elderly and immunosuppressed, those with multiple abscesses and those with rapid deterioration. Brainstem abscesses are associated with a good outcome and resolution of deficits.

Post-surgical infections

Neurosurgical patients in ICU are at risk of infection via ventriculostomy catheters and ICP monitoring devices. Meticulous attention to asepsis during insertion and dressing of such devices must be observed. CSF should be sampled regularly for surveillance culture, or if the temperature or white cell count are raised.

Shunt infections require high dose antibiotics, removal of the shunt and later replacement in a separate location. Common organisms are staphylococci and Gram-negative organisms. Antibiotics may be administered directly into the CSF if the infection proves persistent. Patients with a CSF leak are susceptible to meningitis; there should be a low threshold for CSF examination and antibiotic treatment. ◆

DIC and other Coagulopathies in the ICU

Colin Green

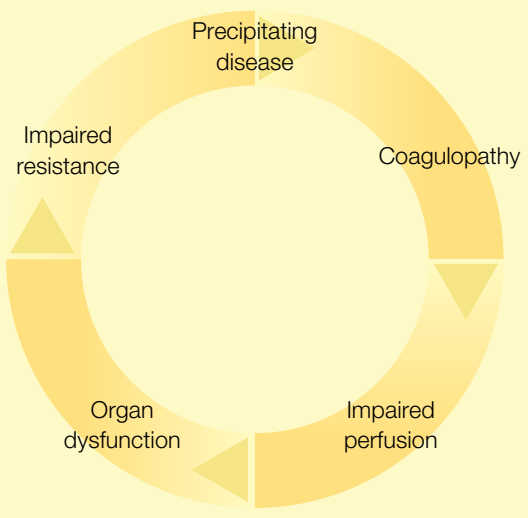
Colin Green is Consultant in Intensive Care and Anaesthesia at Gloucestershire Royal Hospital, Gloucester, UK. He qualified from St Bartholomew's Hospital, London, and trained at the Hammersmith Hospital, St George's Hospital and Great Ormond Street Hospital, London.

Disseminated intravascular coagulation (DIC) and other disorders of the clotting mechanisms are common in the ICU. They are usually the manifestation of a diffuse disease state, which must be treated in conjunction with the clotting defect to break the cycle (Figure 1).

Cessation of bleeding following trauma to blood vessels depends on:
- contraction of the vessel wall
- formation of a platelet plug at the break
- formation of a fibrin clot.

The relative importance of these elements varies with the site and size of the vessels involved.

Consequences of coagulopathy

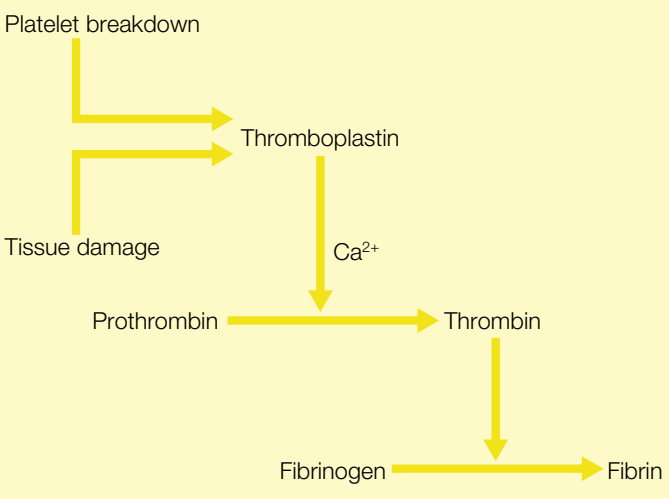


1

Platelet breakdown or tissue damage produces thromboplastin, which, in the presence of calcium ions, results in the formation of thrombin from prothrombin. As a continuation of the clotting cascade, fibrinogen is converted to fibrin, which forms a clot (Figure 2). The coagulation cascade creates a stable fibrin clot. This cascade is an integrated sequence of enzyme reactions, which amplifies a small stimulus into a large response. If this amplification is inappropriate to the clinical requirements, the cycle described in Figure 1 may be set in motion. The sequence begins when factor VII is exposed to tissue factor released at the injured endothelium. A complex forms, which acts on factors IX and X to produce thrombin. Thrombin causes formation of fibrin, which becomes cross-linked, forming a clot. The sequence is nominally divided into intrinsic and extrinsic components (Figure 3). Thrombin also interacts with thrombomodulin, producing a protein conformation that activates protein C. This is an anticoagulant protein involved in the control of the coagulation response to injury. It is a vitamin K-dependent plasma protein, which is synthesized in the liver and circulates as a pro-enzyme. Activated protein C reduces fibrin production and platelet activation, and has a negative feedback effect on thrombin generation. It also prevents activation of factors Va and VIIIa.

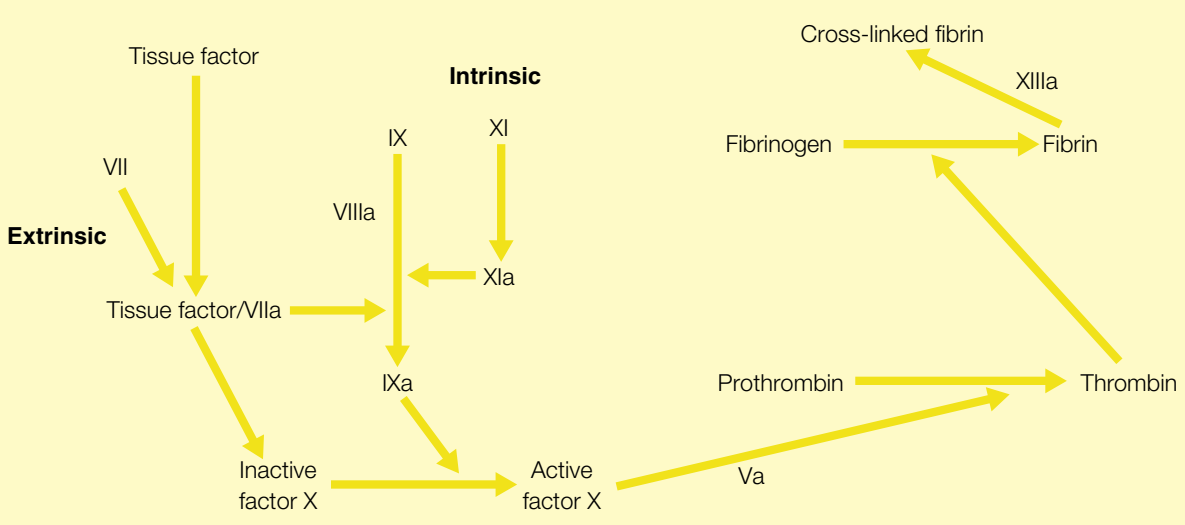
Plasmin is an enzyme that breaks down fibrin and clot, thus re-establishing circulation in small vessels. It is present in the plasma as a precursor (plasminogen). Streptokinase is a therapeutic activator of plasminogen.

Clotting cascade



2

Coagulation cascade



3

DIC

DIC is the most common coagulopathy in the ICU. It is a patho-logical phenomenon involving pan-activation of haemostasis and intravascular formation of fibrin. Sepsis (particularly if caused by Gram-negative organisms) is the most common stimulus but others include:
- trauma (surgery, burns, crush injury, fat embolism)
- obstetric causes (abruptio placentae, amniotic fluid embolus, pre-eclampsia)
- shock (hypovolaemia)
- liver disease (cirrhosis, cholestasis)
- malignancy
- immunological disease (ABO incompatible transfusions).
  Activation may be via:
- the extrinsic pathway by tissue factor released from damaged endothelium or leucocytes
- the intrinsic pathway
- a pathway bypassing normal activation
- direct effects on endothelium or platelets.

Complement activation and cytokine release may amplify the effects. These activities usually produce DIC in its acute or fulminant form, however, it is possible for DIC to appear in a subacute or chronic form. The result is excessive release of thrombin and the deposition of fibrin in the microvasculature. This prothrombic state leads to organ dysfunction and failure. At the same time, excessive plasmin levels lead to clot lysis (fibrinolysis) and the patient presents with haemorrhage, either spontaneously from mucosal surfaces or provoked by intravascular cannulation. Therefore, DIC depends on a balance between thrombosis and fibrinolysis and these opposing elements are represented by the extremes of DIC. The clinical diagnosis of DIC may be inferred by overt haemorrhage or by organ dysfunction, particularly in the presence of one of the common stimuli.

Investigations should include:
- platelet count (decreased)
- prothrombin time (prolonged)
- activated partial thromboplastin time (prolonged)
- fibrin degradation products (elevated); however, this measures only plasmin-cleaved fibrinogen or fibrin (if positive it does not indicate thrombin formation)
- fibrinogen levels (depressed).

The pattern of changes in these tests is often variable. D-dimer assay of plasma samples may be more useful. This is an antigen formed when plasmin breaks down the cross-linked fibrin. It distinguishes between fibrinolysis and fibrinogenolysis. A positive test indicates the presence of thrombin and plasmin.

Treatment is often difficult and controversial. The first step is elimination of the stimulus. Secondary treatment involves replacing deficient clotting factors, though some believe that this exacerbates the situation. Also, it is often argued that plasma protease inhibitors are always present in sufficient concentrations to halt increased coagulation caused by enriched component concentrations. Correction of coagulopathy involves:
- platelet transfusions if there is thrombocytopenia
- fresh frozen plasma to replace clotting factor deficiencies
- cryoprecipitate infusions to maintain fibrinogen levels at 100–150 mg/dl.

Tertiary treatment may involve heparin, but this is potentially dangerous and should be undertaken only after seeking haematological advice. Heparin potentiates antithrombin and therefore inhibits thrombin, factor Xa and other coagulation factors. In the presence of adequate levels of antithrombin, it may inhibit thrombin formation. Heparin is advisable if there are obvious signs of thrombosis or if there is protein C or protein S deficiency. In these circumstances, heparin is usually started as an infusion without a loading dose and its rate of infusion is adjusted according to the level of coagulation component measured (e.g. fibrin degradation products, D-dimer or fibrinogen).

Outcome: DIC is associated with a high mortality rate, mainly due to the underlying cause, rather than to DIC itself. The morbidity associated with DIC is largely related to thrombotic events and the resultant organ dysfunction, although catastrophic haemorrhage is certainly possible.

Other coagulopathies occurring in critical care

Platelet dysfunction

Coagulopathy caused by platelet defects occurs because of a decrease in the absolute number of platelets in circulation or a reduction in their ability to function properly.

Platelet adhesion and aggregation are primary events in normal coagulation. Platelets are first activated by adenosine diphosphate (ADP) (released by damaged endothelial cells), collagen (exposed by endothelial damage) and thrombin. The platelet surface is then modified, binding plasma fibrinogen with extracellular calcium to form an aggregate. The platelets then provide a phospholipid platform, which allows further plasma factor activation. Some inherited conditions affect the absolute number of platelets (e.g. idiopathic autoimmune thrombocytopenia), their adhesion (e.g. Bernard–Soulier syndrome) or their reactivity to collagen or abnormalities in prostaglandin pathways. These are rare and unlikely to be the cause of haemorrhage in most critical care settings. Abnormalities in platelet numbers or activity induced by disease processes or drugs are more common.

Many of the precipitants of DIC result in consumption of large numbers of platelets, rendering the patient thrombocytopenic. This fuels the haemorrhagic element of DIC. Treatment in these cases is aimed at eliminating the cause of DIC and increasing platelet numbers by transfusion.

Iatrogenic platelet dysfunction is common in the ICU. Massive transfusion without platelet transfusion decreases platelet numbers by dilution. Aspirin is the most common drug causing platelet dysfunction. It inhibits cyclo-oxidase and thus inhibits the ability of the platelets to adhere to subendothelial components and aggregate. Long-term aspirin therapy in high doses or self-inflicted overdose thus interferes with clotting.

Heparin is commonly used in extracorporeal circuits (e.g. cardiopulmonary bypass or haemofiltration circuits) to prevent thrombin formation. However, it does not prevent sequestration of platelets. For this reason, low-molecular-weight heparins are commonly used in extracorporeal circuits because they have less effect on platelets. Cardiopulmonary bypass circuits reduce platelet numbers by sequestration and may be a common cause of postoperative haemorrhage in cardiac ICUs. The induced hypothermia which accompanies cardiopulmonary bypass depresses thromboxane A2 synthesis and causes platelet dysfunction.

Platelet dysfunction is also seen in renal failure, due to the effect of urea. The defect lies in the interaction between platelets and the vessel wall.

Liver disease

Liver dysfunction is common in the ICU because of diffuse disease (e.g. septicaemia) or as a primary presentation (e.g. alcoholic cirrhosis, paracetamol overdose). Coagulation factors II, VIII, IX and X are produced by the liver; all except factor IX are involved in the extrinsic system. The synthesis of these factors relies on a vitamin K-dependent carboxylase which causes partial carboxylation and lowered activity. Deficiency is detected by prolongation of the prothrombin time. Vitamin K is poorly absorbed if there is intestinal malabsorption (common in many systemic illnesses), biliary obstruction or an enteric fistula, because bile salts are required for vitamin K absorption. Vitamin K is antagonized by coumarins (e.g. warfarin).

Fresh frozen plasma is used to treat coagulopathy due to liver disease.

Inherited disorders

Other specific, inherited disorders of clotting are uncommon and require haematological advice. ◆

Ethical Issues in Resuscitation and Intensive Care Medicine

Gary Smith

Gary Smith is Consultant in Intensive Care Medicine at Portsmouth Hospitals NHS Trust. He qualified from Southampton University Medical School and trained in anaesthesia and general medicine in Gloucester, Bristol and Southampton, and at Yale University, USA. His interests include the organization of intensive care services, outcome prediction and the training of doctors, nurses and paramedics.

An ethic is a moral principle or a set of principles considered by an individual, group or society to be correct. All areas of healthcare raise moral and ethical dilemmas, but those concerning resuscitation and intensive care medicine (Figure 1) often appear more acute. There are several reasons for this.

- Patients are often unconscious, making it impossible for them to give consent or provide opinions regarding whether treatment should be administered.
- Patient's relatives are more often directly involved in decision-making on behalf of the patient than in other areas of healthcare.
- Intensive care resources are limited and rationing inevitably occurs.
- Ethical issues often involve life and death decisions. Open and honest discussion of difficult ethical matters by patients (where possible), their relatives and healthcare workers usually permits their resolution, however, very rarely, this leads to conflict. This article describes the principles of ethical decision-making and considers some areas that provide dilemmas for intensive care staff. The rights of children and of the unborn child are not considered here.

Examples of ethical issues in resuscitation and intensive care medicine

- Informed consent
- Blood transfusion and Jehovah's Witnesses
- The unconscious patient
- Withholding or withdrawal of treatment
- Research into resuscitation and intensive care medicine
- Decisions not to attempt resuscitation
- Brain death, organ donation and transplantation
- Quality of life
- Cost–benefit
- Patient confidentiality
- Advance statements
- Human immunodeficiency virus infection testing

1

Principles of ethics

It is generally accepted that there are at least four, equally weighted, principles to consider when making ethical decisions.

Respect for autonomy: this is the right of a fully informed individual to choose a certain course of action for him/herself. It encompasses decisions regarding the acceptance or refusal of treatment. The traditional paternalistic approach to healthcare delivery, in which doctors and nurses 'know best' and are the sole decision-makers, is increasingly seen as inappropriate. Consequently, a model of partnership between healthcare professionals and patients is now recommended. In general, provided a patient is competent, and the decision is rational, there is an obligation for healthcare professionals to respect the patient's voluntary decision, even if they disagree (e.g. respecting the decision of a Jehovah's Witness to refuse blood transfusions). Ethically, such an obligation is deemed to be binding, unless it is overridden or outweighed by competing moral obligations. If competent patients make irrational decisions, this may impact on the autonomy of other patients or healthcare workers. However, the courts have ruled that doctors are not obliged to provide treatment contrary to their clinical judgement.

Beneficence is the obligation to do good and is the basis for all medical and nursing care. The end point of beneficence has traditionally been interpreted as 'preserving life'. However, in situations where life is of such poor quality (e.g. because of pain or severe disability) that it is considered less beneficial for the patient than death, the principle of beneficence may include palliation and ensuring a 'good death'.

Non-maleficence is the obligation to avoid doing harm (*primum non nocere*). Conflicts may arise if beneficial medical interventions also cause harm. The potential for the 'double effect' of treatment is well recognized when morphine is administered for palliation, but inadvertently causes respiratory depression or even death.

Justice is the right of a patient to receive an equal share of the distribution of healthcare. Healthcare should not be distributed on the basis of arbitrary criteria (e.g. age, gender, race, sexual orientation) but should be apportioned fairly. Therefore, the principle of justice implies equity (fairness) and equality, and is manifest in arguments over the rationing of healthcare. Discussions about the principle of justice inevitably include the concepts of 'utilitarianism' – bringing about the greatest good to the greatest number of patients – and 'deontology', which relates to the duty of healthcare workers to individual patients.

Dilemmas

Some examples of dilemmas in intensive care and resuscitation are discussed below.

Patient consent

Informed consent is required prior to medical or surgical intervention (e.g. clinical examination, surgical operation, teaching session, entry into a research trial, medical photography) on a competent adult. Although there is generally no legal obligation to obtain written consent, it is regarded as good practice. Nevertheless, verbal or implied consent (i.e. acquiescence to the intervention in full knowledge of what the intervention entails) may suffice. Failure to obtain consent may result in charges of assault; inadequate counselling may result in charges of negligence. Informed consent demands that the patient understands the nature and purpose of the intervention, receives a full explanation of the benefits and risks of the procedure and is provided with a similar description of the alternative measures available. Consequently, the doctor obtaining consent (usually the person undertaking the procedure) must have a thorough knowledge of these matters, otherwise truly 'informed' consent cannot be obtained. For informed consent to be valid, the patient must consent voluntarily and freely.

In intensive care and during resuscitation, it may be impossible to obtain the patient's consent if they are unconscious. Doctors must then act 'in good faith' by providing care that is required to save life or prevent significant clinical deterioration. However, if there is evidence (e.g. a legally binding advanced directive) that a previously competent adult would wish to refuse all or some forms of treatment, this should be respected. In England, Wales and Northern Ireland, no one (not even a relative with enduring power of attorney) may consent legally on behalf of another adult, even though there is an increasing tendency for family members to believe that they have this authority. Consequently, the relatives of an unconscious adult cannot give consent for an operation or any other intervention. It is, however, good practice to discuss the intention to operate with them to establish that they understand the actions about to be taken and the reasoning behind them. This is termed 'informed assent' and is done, in part, to diminish risks of subsequent litigation by relatives who claim that procedures were undertaken without their knowledge. Informed assent has no legal status and has the risk of conflicting with the patient's right to confidentiality.

Consent for human immunodeficiency virus (HIV) infection testing: informed consent must be obtained from any competent patient in whom an HIV test is contemplated. This applies even when the test is being considered because a healthcare worker feels at risk of disease transmission following a needle-stick injury from a potentially HIV-infected patient. If a patient is unconscious, an HIV test may be undertaken without consent, if the test result confers a specific benefit to the patient (e.g. helps to make a diagnosis). If a healthcare worker has a needle-stick injury from an untested, unconscious patient, and the patient is unlikely to regain consciousness within 48 hours, patient testing may be justified but should be discussed with the Trust's Occupational Health Service. If a healthcare worker has a needle-stick injury from a patient who subsequently dies, and there is good reason to suspect that the patient was HIV-positive, it is advised that the dead patient's blood is tested.

Advance statements

Competent persons may state in advance their choices for treatment in the event of becoming incapacitated. This legally binding opinion is known as an advance statement or 'living will'. Such statements may include clear instructions regarding the refusal of certain therapies (advanced directive), may describe the degree of irreversible deterioration beyond which no life-sustaining support should be given and may nominate another person who should be consulted at the time that such decisions must be made. Advanced statements may be written or in the form of a witnessed oral statement.

Withholding and withdrawal of treatment

Modern medicine brings both benefits and dilemmas. In the ICU, the availability of technology does not imply that it is correct for it to be used for all patients. Unfortunately, it may have limited efficacy in some patients and may merely prolong the dying process rather than prolonging life. For instance, physiological stability may be easily obtained using vasoactive drugs and intermittent positive-pressure ventilation, but this does not guarantee hospital survival. In such circumstances, decisions may be made to withhold or limit the extent of treatment offered, or to withdraw that already being provided. Generally, treatment is withdrawn when it has ceased or failed to achieve the benefits for which it was used.

Occasionally, even a treatment that might produce short-term benefit may be withheld or withdrawn if the patient is suffering from a terminal illness. Factors usually taken into account in the decision to withhold or withdraw treatment include the diagnosis, severity of disease, co-existing illnesses, prognosis, response to current treatment, physiological reserve, anticipated quality of life and the patient's wishes, if known.

There is an important distinction between withdrawing or withholding treatment in patients in whom no clinical benefit can be obtained and a deliberate act to end a patient's life (e.g. euthanasia or murder). Withholding or withdrawal of treatment raises several ethical dilemmas, including:

- the wishes of the (often unconscious) patient
- the validity and legality of opinions or decisions made by a surrogate
- the diversion of limited resources from patients with a good chance of survival to those who are unlikely to benefit, if treatment is not withheld or withdrawn
- the definition of futility and who defines it
- the nature of medical treatment (legally, the use of artificial nutrition and hydration constitutes a medical treatment, thus, the principles that cover the withdrawal of any other artificial organ support equally apply to artificial nutrition and hydration)
- withdrawal involves a physical act (e.g. turning off a vasoactive drug) that often brings about the rapid demise of the patient; some healthcare workers find this psychologically unacceptable.

Decisions not to attempt resuscitation

A specific area in which treatment may be withheld is cardiopulmonary resuscitation (CPR). CPR may be attempted whenever cardiac or respiratory function ceases. However, as cardiopulmonary failure is an inevitable part of dying, healthcare workers should identify patients for whom it is a terminal event in their illness and for whom a prior 'do not attempt resuscitation' (DNAR) decision may be appropriate. Guidance on DNAR decisions has been published recently in a combined statement by the British Medical Association, Resuscitation Council (UK) and the Royal College of Nursing. In addition, the Department of Health has mandated that NHS Trusts must have an agreed resuscitation policy that gives respect to patient's wishes. Trusts must also identify a Non-Executive Director to be responsible for overseeing implementation of the policy and its audit.

DNAR decisions cannot be generalized and should always be made on an individual basis, ideally as part of an overall care plan for the patient and in advance of cardiopulmonary arrest. Discussions with the patient, and their family, are potentially distressing and must be handled sensitively; senior, experienced members of the medical team should undertake these. The overall responsibility for DNAR decisions rests with the consultant in charge of the patient's care. Any discussions about whether to attempt CPR should be documented, signed and dated in the patient's record. If the clinical decision is challenged and agreement cannot be reached, legal assistance may help to clarify the appropriate course of action.

Overall survival to hospital discharge following cardiac arrest is about 15%, but may be considerably lower for certain patients (e.g. those with sepsis or cancer). Inappropriate use of CPR makes death undignified and may have ethical implications for others. For instance, repeated attempts that provide only short-term clinical success can be emotionally draining for the patient's family and may mean that resources are diverted from patients with a potentially better outcome. Additionally, failed CPR can lower the morale and enthusiasm of the healthcare team.

The public often has the misconception that a DNAR decision is analogous with a decision not to treat. In fact, a decision not to perform CPR is entirely consistent with the full provision of medical and nursing care up to that point. Consequently, patients and their families should be reassured that all other treatment and care (e.g. analgesia, antibiotics, physiotherapy) may continue to be offered. Finally, decisions about resuscitation must be reviewed regularly and in the light of changes in the patient's condition and wishes.

Research in intensive care patients
Research performed on intensive care patients or those under-going CPR poses several ethical difficulties. For instance, the heterogeneity of patients in ICUs limits the generality of research outcomes. Additionally, the ability to obtain a patient's consent is limited by disease-induced coma or pharmacological sedation. If a patient is unable to give consent to entry into a trial, it is customary to obtain informed assent from the patient's next-of-kin, although deferred consent (consent after patient recovery) is an alternative approach for some studies. Particular problems arise for research into areas of CPR where consent cannot be obtained from the patient and there is insufficient time to obtain informed assent from relatives. Finally, the ethical principles of beneficence and non-maleficence are important here because patients entering into trials do not necessarily benefit from doing so, and may actually be harmed by it. In general, it is advisable to discuss all research into areas of resuscitation or intensive care with the Local or Regional Research Ethics Committees.

Human Rights Act 1998

The Human Rights Act 1998 came into force in October 2000, bringing into UK law many of the rights set out in the European Convention on Human Rights. The Act includes numerous Articles, some of which have implications for healthcare (especially, Articles 2, 3, 5, 6, 8, 9, 10, 12 and 14). For instance, Article 2, which covers the right to life, has implications for withholding or withdrawing treatment. This Article does not mean that healthcare workers must always strive to save life. Rather, it implies that the medical decision-making process must consider the patient's right to life and that the NHS must act 'reasonably' in its decision-making. Withholding or withdrawing treatment does not breach Article 2 if non-treatment is in the patient's best interest (e.g. withdrawing nutrition in a patient with persistent vegetative state). Other Articles of the Act that may have implications for critical care include Article 3 (treatment without consent), Article 8 (the right to be provided with sufficient information to give valid, informed consent) and Article 9 (the right to refuse life-prolonging therapy).

Fever in ICU Patients

Raj Isaac
Bruce L Taylor

Raj Isaac is Clinical Fellow in Critical Care Medicine at the Queen Alexandra Hospital, Portsmouth, UK.

Bruce L Taylor is Consultant in Critical Care Medicine and Anaesthesia at Portsmouth Hospitals NHS Trust, UK. He studied at the Universities of St Andrews and Manchester, and trained in anaesthesia and intensive care in Gloucester, Southampton, Cambridge, Exeter, Bristol, and Brisbane, Australia. He returned to Melbourne, Australia, to train in paediatric intensive care and to complete specialist training in intensive care medicine.

Fever is one of the most common physical signs in critically ill patients. The Society of Critical Care Medicine defines body temperature over 38.3◦C as clinically significant fever. This figure is a conversion of 101◦F to centigrade, and in general a temperature over 38◦C is considered significant.

Fever may indicate infective or non-infective inflammatory processes. Both are common in ICUs and attempts to correlate different processes with temperature ranges and timing have limited clinical value. Prolonged fever is associated with a higher mortality. The causes of fever vary, but ventilator-associated pneumonia, catheter-related sepsis, urinary tract infection and acute myocardial infarction are ubiquitous. Surgical patients have additional potential causes of fever.

Infection is the most common cause of death in critically ill patients, therefore fever should always be taken seriously. Rigorous efforts should be made to identify the sources of sepsis at an early stage. Critically ill patients often have complex underlying illness, therefore it is essential that a detailed history is obtained and that there is access to hospital records. Physical examination should be thorough and include all sites of potential infection. Because of the increasing risk of developing multiple-resistant infection, antibiotic therapy should be based on microbiological cultures; empirical therapy is occasionally necessary. A diagnosis of non-infectious fever should be made only in the appropriate circumstances and in the absence of clinical evidence of sepsis.

Pathophysiology: fever occurs when thermoregulatory mechanisms produce and sustain an elevated body temperature. Exogenous pyrogens (microorganisms, immunological mediators, toxic agents) trigger cytokine release (interleukins 1 and 6 and tumour necrosis factor-α) from monocytes, lymphocytes, macrophages and endothelial cells. These bind with receptors in the preoptic anterior hypothalamus, releasing prostaglandins (PGs), predominantly PGE_2 causing local cyclic-AMP release. This decreases the activity of local warm-sensitive neurons, increasing heat production, activating heat conservation and modifying the thermoregulatory ‘set point’ of the hypothalamus.

Hypermetabolic states (e.g. malignant hyperpyrexia) cause fever by increased heat production.

Fever patterns: a reliable diagnosis cannot be made from the pattern of fever. Most patients have remittent or intermittent fever with or without rigors that usually follow diurnal variation when due to infection.
- Sustained fevers may occur in patients with infectious or non-infectious causes.
- Patients with severe sepsis may be afebrile or hypothermic.
- Septic afebrile patients have a higher mortality.
- The cooling effect of continuous veno-venous haemofiltration may mask ‘latent’ fever.

Aetiology

Non-infectious: in non-infectious fever the temperature is usually less than 38.9◦C. Drug or transfusion reactions may cause higher temperatures (Figure 1). Postoperative patients who develop fever in the first few days may have no infective source.
- General anaesthesia affects anterior hypothalamic thermoregulation (similar patients receiving regional or local anaesthesia remain apyrexial).
- Cytokine release from tissue injury or blood transfusion may be implicated.
- Acute adrenal insufficiency may present as fever.
- Malignant hyperthermia (see later), is usually detected intraoperatively, but its onset may be delayed.

Non-infectious causes of fever

- Acute respiratory distress syndrome (ARDS)
- Adrenal insufficiency
- Alcohol/drug withdrawal
- Aspiration pneumonitis
- Bowel ischaemia
- Deep venous thrombo-phlebitis
- Dissecting aortic aneurysm
- Giant cell arteritis
- Gout and pseudogout
- Haemorrhage into CNS, lung, retroperitoneum, adrenals
- Heat stroke
- Henoch–Schoenlein purpura
- HIV-related non-infective fever
- Hypersensitivity reactions
- Hyperthyroidism
- Myocardial infarction
- Neoplastic fevers
- Pancreatitis
- Pulmonary atelectasis
- Pulmonary/fat embolism
- Post surgical (first 2 days)
- Reaction to blood products
- Reaction to drugs
- Rheumatoid arthritis
- Seizures
- Systemic lupus erythematosus
- Transplant rejection

1

Drug-induced fever (e.g. by antibiotics, anticholinergics, streptokinase) is easily overlooked, little reported and its incidence unknown. High spiking temperatures, chills, leukocytosis and eosinophilia are characteristic. Relative bradycardia is rare.

Fever occurring in a patient receiving blood or blood products may signify a transfusion reaction. Platelet reactions are most common. Fever may be a sign of clinically unsuspected acute myocardial infarction.

The combination of prolonged fever, leukocytosis and pulmonary infiltrates is often inappropriately diagnosed as nosocomial or ventilator-associated pneumonia. Diagnosis may be improved by semiquantitative culture of non-bronchoscopic lavage specimens. Fever may be a feature of the chronic fibroproliferative stages of acute respiratory distress syndrome (ARDS).

Infectious: a temperature over 38.9◦C for more than 2 days usually indicates infection (Figure 2). Critically ill patients are vulnerable to nosocomial infections owing to prolonged hospitalization, antibiotic therapy, invasive devices, co-morbidity and debility. There are particular concerns in surgical patients.
- Delayed resolution of fever despite definitive intervention and antibiotic therapy (e.g. appendix abscess, peritonitis, ascending cholangitis) does not necessarily imply continuing sepsis.
- Fever following trauma may indicate bacterial contamination of wounds, joints or bone; tetanus should also be considered.
- Clostridial myonecrosis or streptococcal cellulitis may cause fever within 72 hours of elective surgery.
- Fever and pain may be presenting symptoms of necrotizing fasciitis in susceptible patients (e.g. the obese, those with diabetes).

Infectious causes of fever in intensive care

Respiratory
- Sinusitis
- Lung abscess
- Empyema
- Pneumonia
- Tracheobronchitis

Invasive devices
- Intravenous/arterial lines (phlebitis, bacteraemia, fungaemia)
- Cardiac valve prosthesis or pacemaker
- Urinary catheter (pyelonephritis, prostatitis, prostatic abscess, urinary infection)

Gastrointestinal
- Antibiotic-associated colitis
- Cholecystitis/cholangitis, acalculous cholecystitis
- Infections due to transfusion (hepatitis B and C, cytomegalovirus)
- Diverticulitis

Surgical
- Wound infection
- Peritonitis
- Deep infection/abscess

Neurological
- Meningitis/encephalitis
- Cerebral/epidural abscess
- Tetanus, poliomyelitis

Cardiovascular
- Endocarditis
- Infected arterial graft
- Viral myocarditis

Skin, soft tissue and bone
- Cellulitis
- Decubitus ulcer
- Necrotizing fasciitis
- Septic arthritis/osteomyelitis

2

Common infective causes

Catheter-related sepsis: about 25% of central venous catheters become colonized; 5% of patients with a central venous catheter develop catheter-related sepsis. The incidence is related to:
- technique of catheter insertion
- length of time *in situ*
- number of ports
- quality of sterile precautions during handling.

Common causal organisms include *Staphylococcus aureus* and coagulase-negative staphylococci, enterococci, Gram-negative bacteria and *Candida* spp. The incidence of catheter-related sepsis can be reduced by strict aseptic precautions during insertion and handling and the use of antimicrobial-bonded catheters.

Ventilator-associated pneumonia is said to occur in 25% of ventilated patients, but is probably overdiagnosed. Focused antibiotic policies guided by non-bronchoscopic lung lavage investigation may improve the outcome of suspected ventilator-assisted pneumonia.

Nosocomial sinusitis is an important, often unrecognized source of infection. It is:
- associated with use of nasogastric/nasotracheal tube (incidence lower with oral tubes)
- diagnosed on clinical or radiological suspicion or transnasal puncture
- treated by removing nasal tubes, sinus drainage and antibiotics. Radiological abnormalities of sinuses do not necessarily imply infection.

Urinary tract infection: urinary tract colonization is common, but clinically significant urinary tract sepsis is rare in patients with normal urine flow. Obstruction or other abnormalities of the urinary tract increase the risk. Urine may yield positive bacterial cultures until the catheter is removed. The use of unnecessary antibiotics risks inducing multiple-resistant bacteria.

Treatment
- Thorough clinical examination is essential.
- The cause (e.g. abscess drainage, potentially infected lines) should be removed or treated.
- Investigations and microbiological surveillance should be performed and repeated as required.
- The diagnosis of non-infectious fever is one of exclusion.

Antipyretics are generally best avoided because fever is an important component of the host response. The response to treatment is more difficult to assess in patients taking antipyretics and temperature enhances the host defences and increases pathogen susceptibility. However, high temperatures are symptomatically unpleasant and other effects (e.g. increased cardiac output, oxygen consumption, carbon dioxide production and energy expenditure) may be deleterious. Antipyretics may be appropriate for some patients, for example those with limited cardio-respiratory reserve or neurological injury. If the body temperature is over 41◦C it is important to prevent further escalation because of the increased risk of cerebral injury.

Cooling methods: the use of sponging, fans and hypothermia blankets is controversial and may be no more effective than antipyretics. Core cooling methods, such as intravenous cooling cannulae, body cavity irrigation or extracorporeal methods are probably more effective. Muscle relaxants may be beneficial to prevent shivering. Large temperature fluctuations, hypermetabolism, increased oxygen consumption and rebound hyperthermia may occur after cooling.

Specific indications for fever reduction: moderate fever may offer physiological advantage, but there is no evidence that very high temperatures (over 40.5◦C) are beneficial. The risk of thermal cerebral injury increases with duration as temperature exceeds 41◦C. Seizures induced by hyperpyrexia and hypoglycaemia multiply this risk and further increase heat production. Fever reduction is therefore indicated in conditions in which hyperpyrexia occurs, including malignant hyperpyrexia, heat stroke, neurolept-malignant syndrome and viral encephalitis. The role of induced hypothermia following traumatic head injury remains unconfirmed, but because persistent pyrexia is associated with a worse outcome, antipyretics and active cooling may be indicated.

Relative indications for fever reduction
Septicaemia/septic shock – in patients with severe sepsis and hyperpyrexia, continuous veno-venous haemofiltration may improve haemodynamic stability and reduce vasopressor requirements although the benefits remain unproven. Whether the effect is secondary to cytokine removal, cooling or both is unknown.

Postcardiac arrest – induced hypothermia may improve outcome and antipyretics or active cooling may be beneficial.

'Febrile' fits in children – cooling to normothermia may reduce the seizure threshold, but antipyretics should be reserved for children with severe discomfort or high fever.

Patients with critical oxygenation – in patients with refractory hypoxaemia, reducing the oxygen demand is logical, though not evidence-based. ◆

Fluid and Electrolyte Balance in Intensive Care Patients

Mark A Hamilton
Andrew R Webb

Mark A hamilton is Anaesthetic Specialist Registrar at University College Hospital, London, UK. He qualified from St George's Hospital, London. He is currently training in anaesthesia and critical care at University College Hospital, London. His research interests include optimization of the surgical patient and exercise physiology.

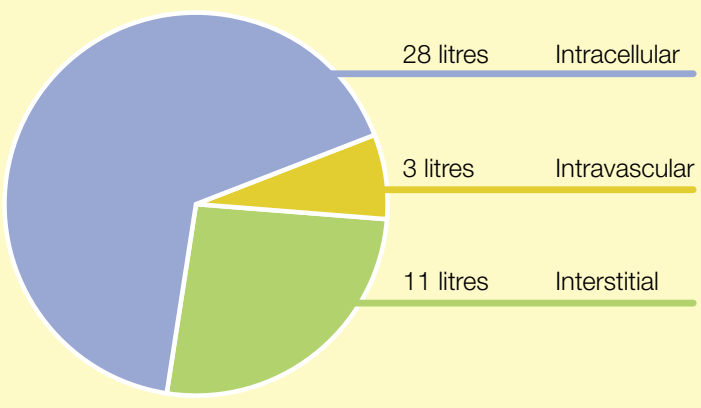
Andrew R Webb is Medical Director at University College Hospital, London. His research interests include fluid management and monitoring of the critically ill.

Fluid and electrolyte balance is one of the basic principles of management of the critically ill patient. Attaining this balance can be achieved only with a good working knowledge of the underlying physiology of body fluid compartments coupled with practical management strategies including accurate record keeping and appropriate interpretation.

Body fluid compartments

In a 70 kg man about 60% of body weight is made up of water (42 litres), for women the value is 55% and declines with age. The total body water is not distributed evenly throughout the body. It is divided into two major components: the intracellular fluid (ICF) and extracellular fluid (ECF), which contain about 28 and 14 litres, respectively. The extracellular space is divided into intravascular and interstitial compartments (see *Anaesthesia and Intensive Care Medicine* **2:2:** 69). The intravascular fluid is the plasma volume, which constitutes about 3 litres, and the interstitium holds the remaining 11 litres (Figure 1). Each compartment contains different concentrations of electrolytes and proteins (Figure 2).

Distribution of body water in the three major body fluid compartments



1

Distribution of electrolytes, water and protein between body fluid compartments

	Intravascular (mmol/litre)	Interstitial (mmol/litre)	Intracellular (mmol/litre)	Typical plasma (mmol/litre)	Daily requirements (mmol/kg/day)
Sodium	140	145	10	135–150	1–1.5
Potassium	3.7	3.8	155	3.5–5.0	1–1.5
Chloride	102	115	3	98–107	1–1.5
Calcium	1.2	1.2	0.01	2.2–2.6	0.07–0.14
Magnesium	0.8	0.8	10	0.7–1.0	0.14–0.17
Phosphate	1.1	1	105	0.8–1.4	0.28–0.56
Bicarbonate	28	30	10	22–30	
Water	3	11	28		2–2.4 litres/day

2

Physical principles

Several physical principles govern the distribution of fluid and electrolytes between body fluid compartments.

Diffusion

Electrolytes move from a region of high concentration to a region of lower concentration in an attempt to achieve equilibrium by diffusion. If diffusion occurs across a membrane then the permeability of that membrane to the electrolyte influences the rate of diffusion. Diffusion is commonly accompanied by bulk flow through biological membranes (when the concentration difference is high) with ordered flow of particles rather than the unordered movement of diffusion alone.

Osmosis

Osmosis is the diffusion of water through a semipermeable membrane from a region of low osmolality to a region of higher osmolality. It leads to the movement of water through all body fluid compartments. The osmotic pressure generated by particles (electrolytes and proteins) is proportional to their number and not their mass.

Active transport

Active transport is an energy requiring process that regulates sodium and potassium exchange at the cell membrane. This gives rise to electrochemical imbalance across the membrane and helps to maintain the resting membrane potential and cell volume.

Colloid osmotic pressure

Any particle (electrolyte or protein) can exert an osmotic pressure, but the free diffusion of electrolytes across the capillary wall negates their osmotic effect. Passage of proteins across the capillary wall is impeded in the normal state. For this reason they exert an osmotic effect within the capillary, commonly referred to as the colloid osmotic pressure or oncotic pressure. The osmotic effect of these proteins is about 50% greater than would be expected for the proteins alone. The reason for this is that most proteins are negatively charged, attracting positively charged ions such as sodium (the Gibbs–Donnan effect). These positively charged ions are osmotically active and therefore increase the effective osmotic pressure.

Starling equation

In health, the movement of fluid across the capillary wall can be described by the Starling equation:

$$J_v = K_{fc}[(P_c - P_i) - \sigma(\pi_p - \pi_i)]$$

where: J_v, solvent flux; K_{fc}, filtration coefficient; P_c, capillary hydrostatic pressure; P_i, interstitial hydrostatic pressure; σ, reflection coefficient; π_p, protein osmotic pressure (oncotic) of plasma; π_i, protein osmotic pressure (oncotic) of interstial fluid.

The reflection coefficient is 0 if the capillary is freely permeable to the protein or colloid in question and 1 if it is impermeable.

In most capillaries the Starling equation is positive, indicating some net movement of fluid to the interstitium. This fluid is normally absorbed by the lymphatic system and returned to the intravascular space. In disease, the permeability of the capillary often increases and more protein and fluid is lost to the interstitium. This decreases the plasma oncotic pressure and, despite an up-regulation of the absorptive capacity of the lymphatic system, interstitial oedema results when interstitial fluid is formed faster than it can be removed by lymphatics. It is for this reason that colloids are given to restore the plasma oncotic pressure and retain fluid within the intravascular space. However, oncotic pressure is dependent on the number of osmotically active particles and not their size or mass. The ideal choice of colloid is therefore a compromise between intravascular retention (dependent on the size of the colloid particles and the rate of their metabolism) and osmotic pressure potential. The lower molecular weight succinylated gelatins are suitable for intravascular expansion if there is a low suspicion of capillary leak. The medium molecular weight hydroxyethyl starches are more suitable for conditions such as sepsis where there is a greater degree of capillary leak.

Crystalloids distribute according to their predominant electrolyte or particle. Fluids such as 5% glucose distribute evenly through all three compartments because the glucose is rapidly metabolized to water. 0.9% saline distributes evenly between the intravascular and interstitial spaces (ECF) because the capillary endothelium is freely permeable to sodium, hence their similar sodium content. There will be some entry of sodium into the cell but this is returned to the interstitial space by the sodium–potassium pump to regulate cell volume and electrochemical balance.

Water and electrolyte balance

The principal electrolytes are sodium, potassium, chloride, calcium, magnesium and phosphate. Many of these electrolytes and minerals are integral constituents of enteral and parenteral feeds and can be adjusted easily for individual patients. However, deficiencies and excesses are common in critical care. It is routine to measure the plasma concentrations of these electrolytes, though they are poorly reflective of total body stores. Excessively high or low values may induce deleterious effects and should be corrected on an as-required basis. All deficiencies or excesses of electrolytes are the result of an imbalance in supply and loss, redistribution and disordered regulation. Where possible, it is important to identify the cause of the abnormality in order to correct the problem. Patients in ICU are subjected to a wide range of noxious stimuli and exhibit an up-regulation in their neuroendocrine response. This results in a tendency to retain water and sodium.

Water

Water and sodium balance are difficult to separate because of their linked regulation mechanisms. The average daily water requirement is 2–2.4 litres/day, generally achieved via parenteral or enteral feeding and drug carriage volume. If these volumes are not achieved they can be supplemented with a crystalloid. The daily fluid loss varies depending on the patient's condition, and it is usual for electrolytes to be lost in proportion to water. However, conditions such as excess sweating, hyperthyroidism, fever, diabetes insipidus and hypercalcaemia cause more water than electrolytes to be lost. 5% glucose may be used to supply intravenous water. In general, there is a further insensible loss of 500 ml/day from the lungs and skin, which must be taken into account in fluid balance calculations.

Sodium

The normal concentration of sodium in plasma is 135–150 mmol/litre. Its principal route of excretion is via the kidney and is mainly regulated by the renin-angiotensin-aldosterone system. The distribution of water and sodium throughout the extravascular space means that they are inextricably linked when considering maintenance and replacement. For the most part, 1–1.5 mmol/kg/day of sodium is required and is usually met from the maintenance fluid or administered feed. Hyper- and hyponatraemia are common and it is important to establish the cause before embarking on treatment. Oedematous patients generally have high body sodium stores but may have relative water deficiency. It should be established if body sodium stores are high, normal or low and whether body water is normal or low. The rate and degree of correction also differs in hyper- and hyponatraemia depending on whether the aetiology is acute or chronic.

Potassium

Potassium is predominantly an intracellular ion, the excretion of which is mainly via the kidney. The normal plasma concentration is 3.5–5.0 mmol/litre. Potassium is exchanged in the kidney for sodium and hydrogen ions and redistributed across cell membranes depending on the acid–base status of the plasma. It is important to maintain potassium because of its effects on membrane stabilization.

Hypokalaemia is a potent stimulus for arrhythmias and promotes muscular weakness. Potassium supplementation is commonly required and should not exceed 40 mmol/hour because the rate of change of potassium is also a potent arrythmogenic stimulus.

Hyperkalaemia can cause life-threatening dysrhythmias and is common in patients with renal impairment. Treatment options include ion exchange resins, glucose and insulin infusions, intravenous bicarbonate, calcium chloride and dialysis.

Magnesium

Magnesium is primarily an intracellular ion and is involved in energy production, utilization and membrane stabilization most often as an enzyme cofactor. It is regulated mainly by the influence of parathyroid hormone (PTH) and aldosterone on the kidney. The normal plasma concentration is 0.7–1.0 mmol/litre. Deficiency is common and a potent source of arrhythmias. It should be corrected with 20–40 mmol infused over 1–2 hours.

Calcium

Calcium is widely distributed with normal plasma concentrations of 2.2–2.6 mmol/litre. PTH and calcitriol regulate its concentration. Only the ionized fraction is active and when it is less than 0.8 mmol/litre may cause tetany, convulsions and a prolonged QT interval. If symptomatic, 5–10 ml of 10% calcium chloride can be administered over 5 minutes.

Phosphate

Phosphate and calcium regulation are linked but calcitriol predominantly regulates phosphate. Severe hypophosphataemia, especially when below 0.3 mmol/litre, can limit ATP formation. Symptoms and signs include muscle weakness, myocardial depression and platelet dysfunction. Supplementation, although empirical, can be achieved with a maximum rate of infusion of 9 mmol over 12 hours.

Fluid management strategies

Maintenance

In general, most maintenance requirements are met from enteral or parenteral feeding and drug carriage fluid. These may be supplemented with a crystalloid. For those who are not fed and/or receiving colloid solutions, a salt containing crystalloid (e.g. lactated Ringer's solution or 0.9% saline) may be required at about 80–100 ml/hour.

Replacement

In general, replacement of fluid should be like for like. Most of the solutions lost from the body contain salt and should be replaced as such. However, it is important to take into account the type of fluid being lost when considering its replacement (e.g. blood, large or small bowel fluid, ascitic fluid, pleural fluid) because they have differing water and electrolyte concentrations. Blood is generally given in a reactionary fashion to maintain haemoglobin at 8–10 g/dl, though a liberal transfusion practice has recently been questioned.

In critical care patients, the correction of hypovolaemia is important to maintain oxygen delivery to the tissues and for removal of waste products.

It is difficult to gain information on the adequacy of resuscitation of the interstitial and intracellular compartments. Many 'soft' endpoints, such as thirst, tissue turgor and fluid balance charts offer at best empirical estimates. The intravascular compartment has in comparison 'harder' end points such as heart rate, central venous pressure, stroke volume, blood pressure and pulmonary artery wedge pressure which, when challenged dynamically, allow an assessment of the adequacy of resuscitation of the circulating volume. Static pressure measurements are a poor guide to the adequacy of intravascular volume replacement. The most efficient way to achieve adequate circulating volume is to use a fluid challenge approach with a colloid. There is controversy as to whether a colloid or crystalloid is most suitable for resuscitation. Colloids are retained in the intravascular space long enough for adequate change in the haemodynamic end points to be assessed and exert a persisting colloid osmotic pressure. Crystalloids do not exhibit this effect, making colloids the logical choice. Fluid may be administered as boluses of 100–200 ml and their effect on haemodynamic end points such as central venous pressure or stroke volume must be observed. Fluid challenges should be repeated until there is no rise in stroke volume or there is a rise in central venous pressure greater than 3 mm Hg. The distribution of the administered fluid is then largely predictable according to its properties and the nature of the underlying illness.

Gastrointestinal Tract Haemorrhage and Ulcer Prophylaxis in ICU

Matthew Williams
Paul J Sadler

Matthew Williams is Specialist Registrar in Anaesthesia at the Queen Alexandra Hospital, Portsmouth, UK. He qualified from Bristol University and is training at the Wessex School of Anaesthesia. His interests include intensive care medicine and medical education.

Paul J Sadler is Consultant in Critical Care and Anaesthesia at the Queen Alexandra Hospital, Portsmouth, UK. He qualified from Sheffield University and trained in anaesthesia and intensive care medicine in Guy's Hospital, Leicester, Nottingham and Birmingham.

Gastrointestinal tract haemorrhage is classified as upper or lower depending on the source of bleeding (about 20% are lower). Acute gastrointestinal bleeding is a common cause of hospital and ICU admission and has a mortality of about 10%. Risk factors that increase the likelihood of death include old age, co-morbidity, coagulopathy and the magnitude of bleeding. Ulcers involving arteries, such as those close to the left gastric artery on the lesser gastric curve, or on the posterior duodenal wall, are particularly problematic. Figure 1 lists the common causes of bleeding.

Common causes of gastrointestinal haemorrhage

Upper gastrointestinal haemorrhage	**Percentage (%)**
Duodenal ulcer	40
Gastric ulcer	17
Acute erosions (gastritis, oesophagitis, duodenitis)	12
Varices	10
Mallory–Weiss tear	5
Cancer	3
Other	13
Lower gastrointestinal haemorrhage	
Colon	74
• Diverticular disease	16
• Angiodysplasia	30
• Carcinoma of the colon	11
Rectal lesion	4
Upper gastrointestinal tract	11
Small bowel	9
• Inflammatory bowel disease	
• Meckel's diverticulum	
• Arteriovenous malformation	

1

Clinical features
Upper gastrointestinal bleeding is characterized by haemat-emesis and the passage of melaena (stools blackened by altered blood). Bleeding ulcers are often painless, especially in the elderly. Signs of massive blood loss are hypovolaemia, pallor, tachycardia, sweating, cyanosis, altered mental sensorium and oliguria. A more occult presentation is possible with pallor, fatigue and the development of anaemia. A history of vomiting before haematemesis suggests a Mallory–Weiss tear.

Lower gastrointestinal bleeding arises from a distal source and is characterized by the passage of fresh blood per rectum (haematochezia). However, bleeding from the small bowel or right colon may manifest as melaena. Abdominal pain suggests ischaemia or inflammatory bowel disease, whereas painless lesions include diverticulosis, angiodysplasia and Meckel's diverticulum. Haemorrhoids (which become swollen in portal hypertension) can be a profound source of bleeding. An occult presentation with anaemia is more likely with lower than with upper gastrointestinal bleeding.

Investigations may include combinations of:
- blood (urgent to include full blood count, coagulation screen, urea and electrolytes, cross-match)
- endoscopy
- angiography
- radiolabelled red cell scan.

Investigations and management are often concurrent, depending on the severity of the case. Blood tests and endoscopy are essential. Barium studies have been superseded by endoscopy. Angiography and radionuclide tests are useful only in lesions that are bleeding briskly at the time. These lesions are usually best managed with surgery, but these techniques may be considered in surgically high-risk patients.

Management

Non-variceal upper gastrointestinal bleeding

Resuscitation – severe hypovolaemia leads to a depressed conscious level and is therefore a potential risk to airway patency, especially when associated with vomiting. The patient should be resuscitated using clear fluids, colloids and blood, guided by regular monitoring of vital signs (including postural blood pressure, conscious level and urine output) and repeat blood investigations. This is best achieved in a high dependency nursing area where invasive monitoring can be instituted; particularly for elderly patients in whom co-morbidity and existing drug therapies make resuscitation more difficult.

Assessment and management – patients who require early intervention (endoscopy or surgery) include those at high risk and those with evidence of significant bleeding (e.g. presence of postural hypotension, cardiovascular instability and blood loss requiring 4 or more units of red cells to be transfused in 12 hours). Rockall devised a scoring system (Figure 2) to stratify the risk of re-bleeding and death following gastrointestinal haemorrhage. This system can help to identify at-risk patients, possibly triggering management decisions at a certain score (e.g. 3, central venous pressure monitoring; 5, surgical referral).

The Rockall score for stratifying risk of re-bleeding and death following upper gastrointestinal haemorrhage

Contributor	**Score**			
	0	**1**	**2**	**3**
Age (years)	< 60	60–80	> 80	
Shock	None	Pulse > 100 Blood pressure > 100	Blood pressure < 100	
Co-morbidity	None		Ischaemic heart disease, congestive heart failure	Renal/liver failure, disseminated malignancy
Diagnosis	None, Mallory–Weiss tear	All others	Upper gastrointestinal tract malignancy	
Endoscopic findings	None		Blood in upper gastro-intestinal tract, adherent clot, visible vessel	

2

Pharmacological intervention includes the early use of proton-pump inhibitors to aid ulcer healing. These can be given intravenously in the first instance. Bleeding due to coagulopathy should be managed with the administration of blood products (as guided by investigations) and antifibrinolytic agents (e.g. tranexamic acid).

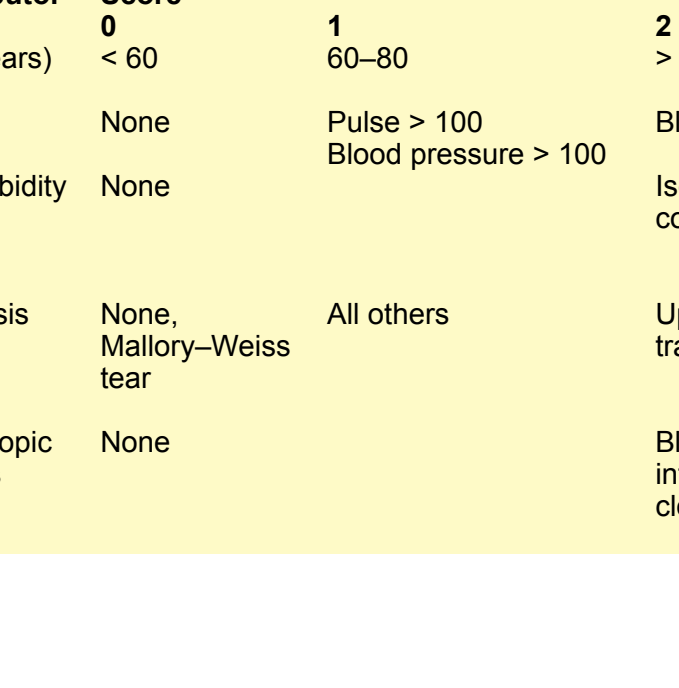
Endoscopic therapy can stop haemorrhage from some sources of upper gastrointestinal bleeding (see below). Endoscopic techniques include adrenaline (epinephrine) injection, electro-coagulation, thermal probes and laser photocoagulation. The initial haemorrhage is usually stopped in over 90% of cases; but 90% of arterial bleeds re-bleed. Endoscopic treatment is more effective than medical treatment alone at reducing the rate of re-bleeding and subsequent transfusion requirements.

Surgery is the definitive treatment for upper gastrointestinal bleeding, but the mortality is 15–20%. Procedures include under-running of bleeding ulcers to secure haemostasis, vagotomy or partial gastrectomy. Results are better when surgery is performed early; therefore, there must be close liaison between senior members of the medical, intensive care and surgical teams.

Variceal bleeding

Acute variceal bleeding is a complication of portal hypertension and has a high mortality. Management includes fluid resuscitation concurrent with medical, endoscopic and/or surgical intervention. Guidelines for management are shown in Figure 3.

Guidelines for management of variceal bleeding



3

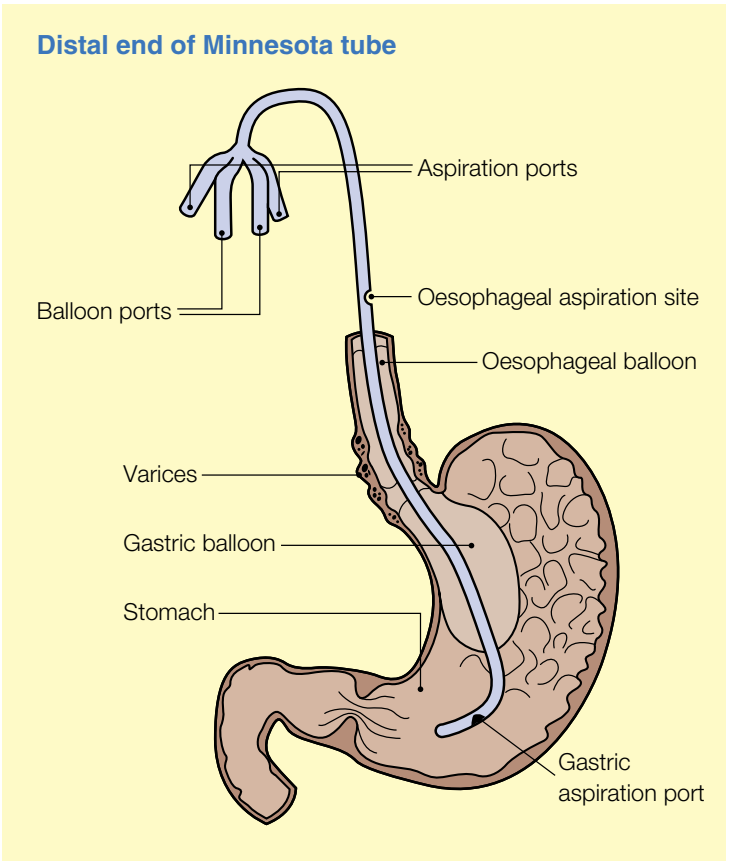
Resuscitation – gastrointestinal haemorrhage with a background of liver disease can precipitate an encephalopathy; therefore attention to airway, breathing and circulation is required. Bleeding can be torrential, but care must be taken not to over-transfuse because rebound portal hypertension risks re-bleeding.

Medical management – the reversal of coagulopathy using blood products is paramount. Antidiuretic hormone (ADH) analogues (vasopressin, terlipressin) are used to lower portal pressure, but can cause cardiac ischaemia and coagulopathy. Somatostatin analogues given as an infusion (e.g. octreotide) are safer but reports of efficacy are varied. Long-term non-selective β-adrenergic receptor blocking agents can decrease portal hypertension and re-bleeding.

Endoscopic therapy – endoscopic injection of a sclerosing agent into varices causes venous thrombosis and tissue fibrosis allowing about 85% of bleeds to be controlled. Complications (ulceration, chest pain, mediastinitis) are common. Gastric lesions are more difficult to inject and control than oesophageal varices. The use of rubber bands to ligate varices is as effective as injection sclerotherapy with fewer complications.

Balloon tamponade – using a balloon to exert direct pressure on the bleeding point can control variceal bleeding. The Sengstaken–Blakemore tube has been replaced by the Minnesota (oesophageal and gastric balloons and aspiration ports) (Figure 4) and Linton (gastric balloon with oesophageal and gastric ports) tubes. Pressure on the gastric veins feeding the varices seems to be more important than direct pressure on the oesophageal varices. Limiting the duration of inflation and pressure is likely to be important in preventing pressure necrosis of the oesophageal mucosa, but definitive advice regarding the precise time to initiate balloon tamponade and the duration of placement is difficult to find. Complications of balloon tamponade include:
- incorrect placement
- aspiration pneumonia
- airway obstruction
- oesophago-gastric rupture
- tissue pressure necrosis.

Tamponade is successful in about 85% of cases, but re-bleeding occurs in about 45% following balloon deflation. Successful tamponade should be followed by re-endoscopy and further intervention as required.



4

Transjugular intrahepatic portosystemic shunt (TIPSS) – using a catheter placed via the jugular vein into the hepatic vein under radiological guidance, a stent can be introduced to create an intrahepatic portosystemic shunt. This reduces portal blood pressure and the risk of bleeding. Complications of TIPSS include intra-abdominal haemorrhage, stent occlusion and hepatic encephalopathy. TIPSS has little impact on long-term survival.

Surgery – the control of bleeding can be achieved by staple transection of the oesophagus or by forming a portocaval shunt. However, long-term survival is not improved.

Lower gastrointestinal bleeding

Lower gastrointestinal bleeds are seldom immediately life-threatening. However, careful resuscitation and monitoring are required.

Endoscopy – electrocoagulation and heater probes can stop bleeding vascular points. Bleeding polyps can be removed.

Angiography – injecting embolizing agents into the vessel identified at angiography can stop vascular bleeding points.

Surgery – surgical removal of bleeding diverticular lesions or vascular abnormalities is indicated when other measures have been unsuccessful. Surgery may also be indicated if the source of bleeding is not identified.

Acute stress ulceration in ICU patients

Patients may present with peptic ulceration caused by pre-existing disease, as part of their critical illness, or secondary to drug therapy (e.g. steroids or non-steroidal anti-inflammatory drugs). In each case, an imbalance between mucosal protection and acid production results. ICU patients are prone to acute stress ulceration, especially those with sepsis, shock, burns, multiple trauma, head injury, spinal injury, respiratory failure, renal failure or hepatic failure.

The incidence of acute stress ulceration has decreased but remains about 20%. Presentation may be occult or overt, with lesions most commonly found in the gastric fundus. Potential sequelae include:

- cardiovascular collapse
- anaemia (requiring blood transfusion)
- increased urea load in the gut
- aspiration of regurgitated or vomited gastric contents.

Prophylaxis and treatment

Significant bleeding should be managed as above. The incidence of stress ulceration is lowered by prophylactic therapy aimed at alkalinizing the gastric contents (gastric pH > 3.5). However, ulceration can occur despite these measures and there is no guarantee of reduced mortality. Alkalinization of the stomach contents may cause overgrowth of gastric bacteria with the potential to lead to nosocomial pneumonia.

Supportive treatment includes optimizing oxygenation and perfusion.

Enteral feeding may reduce ulceration by improving local tissue perfusion and maintaining local protective mechanisms.

Antacids (e.g. magnesium, aluminium) have to be given often to alkalinize the gastric contents effectively. They can lead to ileus or diarrhoea and are seldom used.

H_2-receptor antagonists (e.g. cimetidine, ranitidine, famotidine) act by blocking acid production by the gastric parietal cells. Ranitidine is the most commonly used agent; it can be given intravenously or via a nasogastric tube. The dose should be decreased for patients with renal impairment.

Mucosal strengtheners – sucralfate is a basic aluminium salt of sucrose octasulphate that protects the gastric mucosa against acidity by adhering to the gastric mucosal surface and increasing mucus production. It does not alter gastric acidity and therefore causes no disruption to the normal gastric flora. Problems with its use include constipation, aluminium toxicity and the formation of bezoar when mixed with nasogastric feeds. Bismuth chelate may act in a similar way to sucralfate. It also helps to eradicate *Helicobacter pylori*.

Proton-pump inhibitors (e.g. omeprazole, lanzoprazole) irreversibly inhibit the H^+/K^+-ATPase (proton pump) enzyme to reduce the amount of H^+ transported to the gastric lumen by the parietal cells.

Other drugs – antibiotics may be used to eradicate *H. pylori*. Misoprostol, a prostaglandin E_1 analogue, helps to decrease acid production and improve healing but causes diarrhoea and can only be given orally. ◆

Generalized Convulsive Status Epilepticus

George Thomas
Nicholas Hirsch

George Thomas is Specialist Registrar at the National Hospital for Neurology and Neurosurgery, London. He qualified from Manipal, India, and trained in anaesthetics in Manipal, University College London and the Royal Free Hospital. His interests include neurosurgical anaesthesia and chronic pain.

Nicholas Hirsch is Consultant Anaesthetist at the National Hospital for Neurology and Neurosurgery, London. He is Director of the Neuromedical Intensive Care Unit and has a special interest in respiratory failure due to neurological disease.

Generalized convulsive status epilepticus (GCSE) is the most common form of status epilepticus and affects about 14,000 people annually in the UK. It is a medical emergency and failure to recognize and treat it effectively results in major morbidity and mortality. It is traditionally defined as continuous seizure activity lasting 30 minutes or intermittent seizure activity lasting 30 minutes during which consciousness is not regained.

Clinical features: GCSE is usually diagnosed easily by observation alone and is characterized by unconsciousness, tonic-clonic muscle activity, tongue biting and urinary incontinence. However, as the duration of seizure activity increases, clinical signs of abnormal muscular activity may become subtle (e.g. restricted to minor twitching of the fingers or eyelids). There is seldom doubt about the diagnosis, but other conditions that should be considered include rigors due to sepsis, myoclonic jerking, generalized dystonia and pseudostatus epilepticus.

Aetiology: determining the aetiology of GCSE is of fundamental importance and may be divided into acute and chronic processes (Figure 1). In 50% of cases of GCSE presenting to non-specialized centres, status epilepticus is the first manifestation of epilepsy. The aetiology also affects the prognosis of GCSE.

Aetiological factors of GCSE

Acute processes
- Electrolyte disturbance (e.g. sodium, calcium imbalance)
- CNS infection (e.g. encephalitis, meningitis)
- Cerebral trauma
- Cerebrovascular accident
- Drug toxicity (e.g. alcohol, cocaine)
- Hypoxic cerebral damage
- Generalized sepsis
- Renal failure

Chronic processes
- Pre-existing epilepsy
- Poor anti-epileptic drug compliance
- Alcoholism (especially withdrawal)
- Cerebral space-occupying lesion

1

Pathophysiology: two distinct phases with specific neurophysiological changes occur during the progression of GCSE. In phase I, the increased metabolic requirements of abnormally discharging neurons are adequately met. The increased cerebral activity results in a coupled increase in cerebral blood flow and an increase in autonomic activity. The latter results in tachycardia, hypertension and an increase in blood glucose levels. After about 30 minutes of seizure activity, the compensatory mechanisms that have maintained adequate cerebral perfusion begin to fail. This stage (phase II) is characterized by a failure of cerebral autoregulation, a rise in intracranial pressure, systemic hypotension, hypoglycaemia and a rise in systemic and intracranial lactate levels. When this occurs, cerebral oxygen requirements exceed supply and electromechanical dissociation occurs in which cerebral seizure activity may be accompanied by minimal visible muscular twitching.

The disruption of normal cerebral physiology is further compounded by many of the systemic derangements that are seen during GCSE. These include CNS pathology (cerebral anoxia, haemorrhage, oedema, hippocampal damage, cerebral venous thrombosis), respiratory system pathology (respiratory failure, pneumonia, pulmonary hypertension, pulmonary oedema, pulmonary embolus), cardiovascular system pathology (arrhythmias, hyper/hypotension, myocardial infarction, cardiac arrest), metabolic disorders (electrolyte imbalance, metabolic acidosis, hyperpyrexia, renal and hepatic failure, acute pancreatitis) and other complications (rhabdomyolysis, fractures, sepsis syndromes, disseminated intravascular coagulation).

Management

GCSE requires decisive and rapid treatment. The longer GCSE continues, the greater the likelihood of neuronal damage, systemic complications, unresponsiveness to treatment and the development of chronic epilepsy. The mortality of GCSE is also related to its duration. Management falls into three categories that need to be instituted simultaneously:
- emergency medical management
- identification and investigation of aetiological factors that have precipitated status epilepticus
- drug treatment of the seizures.

Emergency medical management

Monitoring of ECG, blood pressure and pulse oximetry should be started immediately. Generally, patients in GCSE require early tracheal intubation and mechanical ventilation to protect the airway from aspiration of gastric contents and to ensure adequate ventilation and oxygenation while seizures are being controlled. A rapid sequence induction of anaesthesia should be performed using thiopental (thiopentone) or propofol followed by suxamethonium. Before induction, intravenous access is often required to allow fluid resuscitation. The administration of fluids is often all that is needed to restore normotension, but patients who have experienced prolonged status epilepticus may also require inotropic therapy. Blood pressure should be maintained at normal or supranormal levels to ensure an adequate cerebral perfusion pressure. Following intubation, the use of long-acting non-depolarizing neuromuscular blocking drugs is seldom necessary and obscures the clinical manifestations of continuing seizure activity.

Blood should be taken for determination of electrolytes, full blood count, blood glucose, toxicology screen, liver function tests and arterial blood gas analysis. Patients with pre-existing epilepsy should have their anti-epileptic drug levels measured.

A bedside test for glucose should be performed immediately and, if hypoglycaemia is present, 50% glucose, 50 ml, should be given. The theoretical danger of exacerbating cerebral ischaemia by an increased blood glucose level is outweighed by the correction of hypoglycaemia. If there is evidence of alcoholism or malnutrition, intravenous thiamine, 100 mg, should be given before administration of glucose to avoid precipitating Wernicke's encephalopathy.

Metabolic acidosis is common during uncontrolled status epilepticus, but acid–base balance is usually restored with control of seizures and with adequate resuscitation. There is experimental evidence that acidosis in GCSE may be neuroprotective.

High temperatures may occur in status epilepticus due to the increased muscle activity and may exacerbate or prolong seizure activity. Where possible, normal body temperature should be maintained using surface cooling and antipyretic agents.

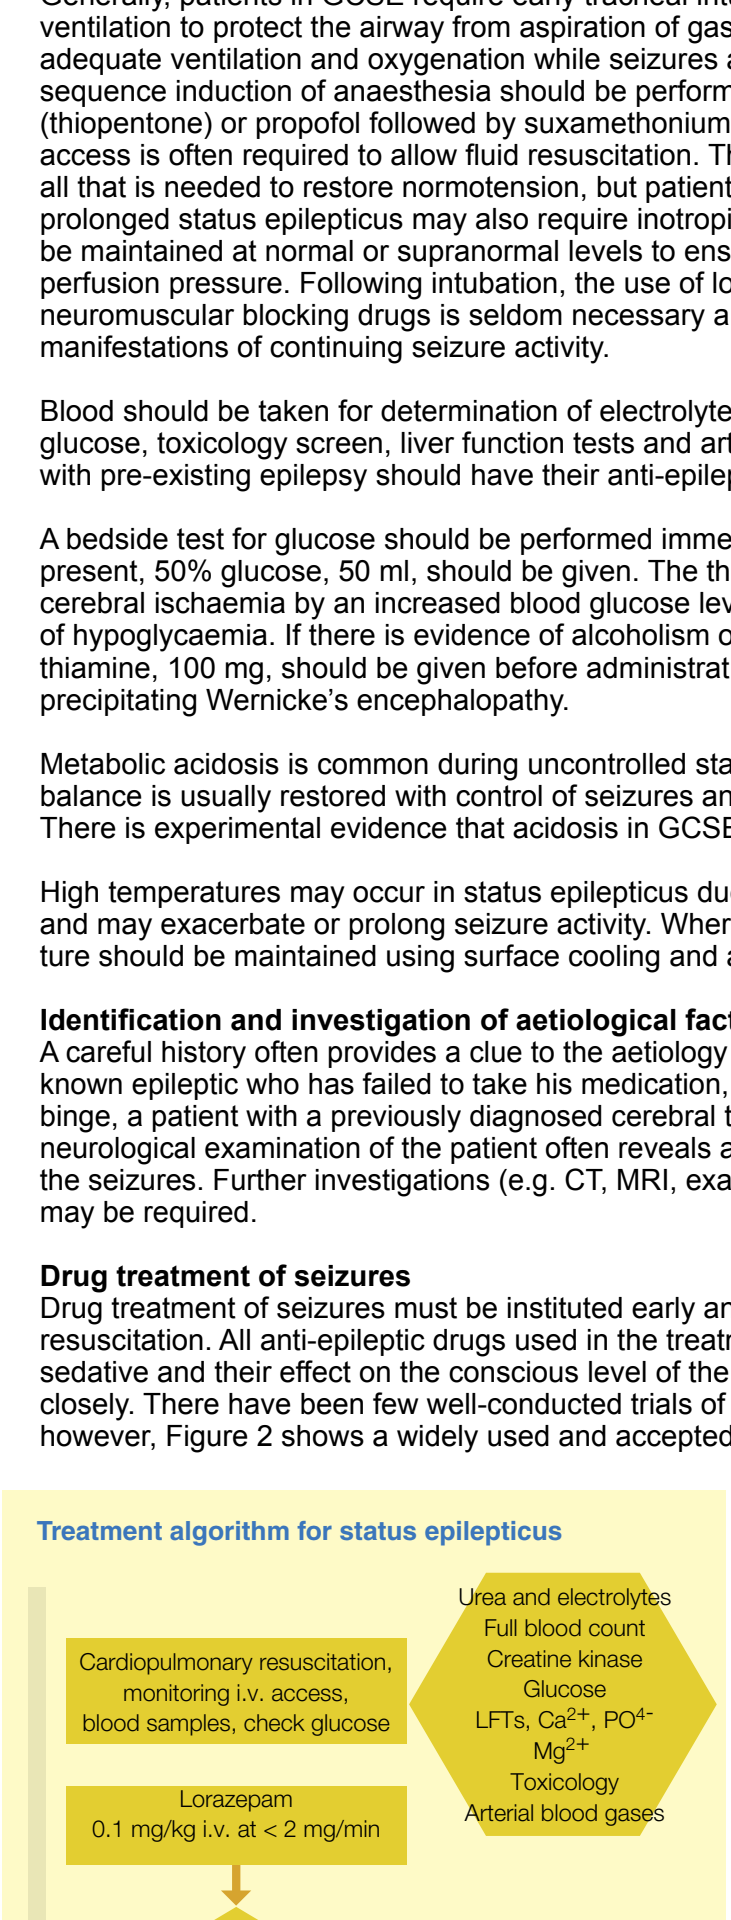
Identification and investigation of aetiological factors

A careful history often provides a clue to the aetiology of the status epilepticus (e.g. a known epileptic who has failed to take his medication, an alcoholic who has been on a binge, a patient with a previously diagnosed cerebral tumour). Similarly, a general and neurological examination of the patient often reveals a systemic or neurological cause of the seizures. Further investigations (e.g. CT, MRI, examination of CSF, blood cultures) may be required.

Drug treatment of seizures

Drug treatment of seizures must be instituted early and should proceed during resuscitation. All anti-epileptic drugs used in the treatment of status epilepticus are sedative and their effect on the conscious level of the patient needs to be monitored closely. There have been few well-conducted trials of the optimum treatment for GCSE, however, Figure 2 shows a widely used and accepted regimen.

Treatment algorithm for status epilepticus



2

Benzodiazepines act by enhancing γ-aminobutyric acid (GABA)-mediated inhibition in the CNS by increasing chloride conductance at the post-synaptic ligand-gated $GABA_A$ receptor. Lorazepam, 0.1 mg/kg i.v., is the benzodiazepine of choice in GCSE. Although it is less lipophilic than diazepam, it terminates seizures as rapidly as the latter. Its main advantage is its long duration of action (over 12 hours) and it is often effective as the sole agent in terminating GCSE. In contrast, diazepam has a short duration of action due to rapid redistribution to body fat stores and is less effective than lorazepam.

Hydantoins (phenytoin and fosphenytoin): if seizures continue following administration of lorazepam, phenytoin, 20 mg/kg i.v., is the drug of choice as a second-line treatment. It acts by blocking neuronal sodium channels and inhibiting repetitive firing of neurons. The range of normal therapeutic plasma levels is 40–80 µg/litre.

Phenytoin should be given only via a large vein, because of its high alkalinity. It should be made up in saline and concurrent administration of other drugs should be avoided because of the risk of precipitation. The maximum rate of infusion is 50 mg/minute, but even lower rates carry the risk of hypotension and arrhythmias. Meticulous monitoring of ECG and blood pressure is mandatory.

Fosphenytoin is a recently introduced water-soluble prodrug of phenytoin and its dose is expressed in 'phenytoin equivalence' (75 mg of fosphenytoin is labelled '50 mg phenytoin equivalent'). Its main advantage over phenytoin is that it can be administered more rapidly. However, serious cardiovascular sequelae may occur and careful monitoring during and after administration is vital.

Phenobarbital (phenobarbitone): if seizures persist despite adequate plasma levels of phenytoin, phenobarbital (phenobarbitone), 10–20 mg/kg i.v., should be given. This barbiturate acts on a receptor site associated with $GABA_A$ chloride channels. Its main side-effects include excessive sedation, respiratory depression and hypotension.

General anaesthesia: refractory status epilepticus that has not responded to hydantoins and/or phenobarbitone requires general anaesthesia using either thiopental (thiopentone) or propofol. This should be carried out in a specialist unit where the anaesthetic agents can be titrated against continuous EEG monitoring. Most authorities aim for a burst suppression pattern on EEG though evidence that outcome is improved is sparse. Optimum levels of phenytoin and phenobarbital (phenobarbitone) should be maintained during this period. Patients are intermittently woken while being monitored for evidence of clinical or electroencephalographic seizures.

Prognosis

Adult GCSE carries an overall mortality of about 25%. Over 85% of those who die do so as a result of the aetiology of the status epilepticus; only about 2% of deaths are due to the GCSE itself. The aetiology also determines outcome; 90% of patients with status epilepticus secondary to drug withdrawal have a good outcome compared with only 30% of patients with status epilepticus due to stroke. Duration of seizures is also an important factor; GCSE lasting over 1 hour has a mortality of 35% while seizures lasting less than 30 minutes have a mortality of 3.7%. ◆

Immune Dysfunction, Immunodeficiency and Immunotherapy

Jonathan B Salmon

Jonathan B Salmon is Consultant Physician at the John Radcliffe Hospital, Oxford, UK. He qualified from Cambridge University and the Middlesex Hospital, London, and trained in general medicine and intensive care in the army and at UCL Hospitals, London.

Critical illness produces multiple defects in immune function with impairment of all components of the immune response. The most common cause of death in patients who have been in the ICU more than 7 days is sepsis. Particular care is required in patients who are immunosuppressed; the emphasis should be on prevention, early detection and aggressive treatment of infection. Although these patients have a worse prognosis than immunocompetent patients, it is not hopeless. However, those who require prolonged intubation and ventilation without return of immune function almost invariably die.

Immune dysfunction due to critical illness

Intravascular catheters and tracheal tubes bypass the normal barriers to infection. Mucosal barrier function may be reduced by ischaemia, trauma or ulceration. Sedation, recumbency, acid suppression and antibiotic use contribute to pooling of secretions, bacterial overgrowth and selection of resistant organisms.

Immune function, particularly cell-mediated immunity and neutrophil function, is depressed following shock or trauma and may persist for days or weeks. Causes include poor nutrition, direct effects of the inflammatory response on immune function, drugs, and metabolic and endocrine effects, particularly uraemia and hyperglycaemia.

Specific immunodeficiencies

Most immunodeficient patients in ICU have acquired rather than congenital disease. The most important clinical groups are neutropenia, T cell deficits (including HIV), and broad-spectrum immunodeficiency related to haematological or other malignancy, chemotherapy and the post-transplant patient. Less important (but significant) are hypogammaglobulinaemias, splenectomy and complement deficiencies. Patients may have more than one immune defect (e.g. lymphoma causing T cell dysfunction and cytotoxic-induced neutropenia).

Neutropenia occurs following decreased production, increased use or decreased survival of neutrophils. It is considered mild if the total neutrophil count is 1–1.8 x 10^9/litre, moderate if 0.5–1.0 and severe below 0.5.

Acquired neutropenia is usually caused by viral infections or drugs but severe bacterial sepsis is an important cause (Figure 1). Automated blood analysers may occasionally read falsely low neutrophil counts and unless neutropenia is an expected part of the patient's illness, a blood film should be checked to confirm the count.

Causes of acquired neutropenia

Infection
- Viruses (influenza)
- Severe sepsis (damage to myeloid precursors and adherence of neutrophils to endothelium)
- Chronic infections (splenic sequestration, brucella, kala-azar, malaria, tuberculosis)

Drugs
Direct toxicity
- Dose related (cytotoxic drugs)
- Idiosyncratic (chloramphenicol, carbimazole, phenothiazines work by enzyme blockade; usually presents within 1–2 weeks and resolves over similar period)

Immunogenic
- Antibody to complex between drug neutrophil surface proteins (phenytoin, chlorpropamide, levamisole, clozepam; reversible within 2 weeks of stopping drug)

Marrow infiltration/obliteration
- Tumour infiltration, radiation damage, myelofibrosis, osteosclerosis

Nutritional defects
- Protein malnutrition, B_{12} or folate deficiency, copper or zinc deficiency

Auto-immune
- Idiopathic or associated with other autoimmune disease
- Neutrophil autoantibodies
- Rheumatoid arthritis, systemic lupus erythematosus, Felty's syndrome

Splenomegaly
- Sequestration (chronic infections (as above), Gaucher's disease, sarcoidosis, lymphoma; usually associated with low haemoglobin and platelet count)

Haemodialysis
- Lung sequestration

Functional disorders
- Chronic granulomatous disease
- Decreased phagocytic function (many systemic diseases e.g. diabetes mellitus, uraemia, malnutrition, alcohol abuse, steroids)

1

Qualitative or quantitative defects in neutrophil function lead to impaired bacterial and fungal killing. Bacterial infections predominate initially. Traditionally, Gram-negative infections have been the most common and remain the most lethal. 50% of neutropenic patients with *Pseudomonas* bacteraemia die within 24 hours unless treated. With increasing use of long-term intravascular cannulae and prophylactic antibiotics, Gram-positive organisms are more common and account for over 50% of isolates in febrile neutropenia. With increasing duration of neutropenia, fungal infections become more common.

Prevention of infection – scrupulous attention to hygiene and isolation in side-rooms with positive pressure and, preferably, high efficiency particulate air (hepa) filtration are important. Cross-infection rates increase as the staff:patient ratio falls, particularly when infectious and immunosuppressed patients are being cared for by the same personnel. As antibiotic resistance increases, these precautions become more vital.

Diagnosis – the symptoms and signs of sepsis may be subtle or absent. Fever may be the sole indicator of infection. However, absence of fever or hypothermia does not rule it out.

Consider why the patient is neutropenic and for how long. What symptoms are there to suggest a source of infection? Was the infection acquired in the community or in hospital? Has the patient had previous infections? Are there any relevant, contributory drugs?

Examination is often unrewarding but should be thorough with particular attention to head and neck, pharynx, ears, optic fundi, chest, abdomen, skin and perineum.

Investigations should include full blood count and film, routine biochemistry (including liver function), cultures of blood, urine, stool if there is diarrhoea and aspirates from vesicles or pustules. Sputum is unreliable; bronchoscopic lavage should be performed if respiratory infection is likely (or blind broncho-alveolar lavage if the patient is intubated). Any suggestion of intracranial pathology should prompt a CT of the brain followed by lumbar puncture. Chest radiographs should be performed routinely. Consider sinus radiographs (but CT is better). CT of chest, abdomen and pelvis may be required if there are no obvious clinical clues.

Treatment – if the neutrophil count is less than 0.5 x 10^9/litre or there is haemodynamic compromise or organ dysfunction, empirical treatment should be started with broad-spectrum antibiotics. If the neutrophil count is more than 0.5 x 10^9/litre and the patient is well, relevant cultures should be performed and the patient observed closely. Antibiotics should be directed primarily at Gram-negative organisms (especially *Pseudomonas*) but the choice of antibiotic should be discussed, at the time, with the microbiology service, unless there is a unit protocol. Treatment for Gram-positive organisms can usually be delayed pending culture results unless the patient is unwell or there is high clinical suspicion. Meropenem or *Tazocin* ± an aminoglycoside often suffices. Metronidazole should be added if there is severe mucositis, necrosing gingivitis, perianal tenderness or abdominal pain.

If fever persists and cultures are negative, re-evaluation is required. The empirical addition of vancomycin or teicoplanin is required to cover Gram-positive infections, many of which are due to cell-wall-deficient organisms, which do not survive conventional culture techniques. With appropriate antimicrobial treatment, the mean time to defervescence is 5 days. Empirical antifungal treatment should be considered in patients who remain febrile after this.

It is common to continue antibiotics until the neutrophil count recovers (often 14 days) but this increases the risk of fungal and resistant bacterial infections. It may be safe and produce fewer complications if antibiotics are stopped 3–5 days after defervescence, provided the patient is monitored closely.

Fungal infections – about 30% of patients who fail to respond to antibiotics have *Candida* or *Aspergillus* infection. Fluconazole has few side-effects and is active against *Candida albicans* and *Cryptococcus* spp. but is ineffective against some other *Candida* species and *Aspergillus*. Amphotericin B has been the mainstay of treatment for these latter organisms but its side-effects include fever, rigors, hypotension and, especially, nephrotoxicity. Lipid-based preparations are less toxic but more expensive. Caspofungin and *Voriconazole*, new antifungals with a broad spectrum of activity and apparently a better safety profile, are promising.

Viruses – herpes simplex, zoster, cytomegalovirus (CMV) and adenovirus infections are common in neutropenia, especially if there is co-existent depression of cell-mediated immunity. Treatment is described below.

Deficiency of cell-mediated immunity: worldwide, the most common cause of T cell deficiency is HIV infection, although in the UK, antiretroviral drugs have reduced its impact. Immunosuppressive treatments (e.g. corticosteroids, ciclosporin (cyclosporin)) are also important causes. Infections are most common with intracellular pathogens (*Mycobacteria* spp., *Listeria*), viral infections, fungi and parasites.

Mycobacteria – *Mycobacterium tuberculosis* usually occurs due to re-activation of old infection. It is common in myelodysplasia, chronic lymphocytic leukaemia and hairy cell leukaemia. Presentation is often atypical, progress rapid and extrapulmonary and disseminated infections are common. Non-tuberculous mycobacteria (especially *Mycobacterium avium-intracellulare* and *kansasii*) are more common in HIV.

Viral infections are common, particularly herpes simplex, zoster, CMV and adenoviruses. Hepatitis B, Epstein–Barr virus and papillomavirus may cause problems. Measles can cause life-threatening infections, especially in children. Herpes simplex and zoster are usually responsive to aciclovir but some simplex isolates are now resistant. Foscarnet is usually effective, but is toxic (renal impairment in 50%). Ganciclovir remains first-line treatment for CMV; some resistance is emerging and foscarnet is an alternative treatment for CMV retinitis in AIDS. Mortality remains high, especially in CMV pneumonitis. Susceptible patients exposed to measles or herpes zoster should receive passive protection with human normal immunoglobulin or varicella-zoster immunoglobulin, respectively. Live-attenuated vaccines should not be used (nor should live-attenuated polio vaccine be given to siblings of susceptible patients because of the risk of intrafamilial transmission).

Fungi – superficial fungal infections are uncommon (except oropharyngeal candidiasis in HIV) but deep-seated or disseminated infections occur due to organisms such as *Histoplasma capsulatum*. Cryptococcal infections are uncommon except in HIV or in patients on high-dose corticosteroids.

Parasitic infections include pneumocystis, toxoplasma and cryptosporidiosis. More rarely, re-activation of malaria, strongyloidiasis or babesiosis may occur.

Pneumocystis pneumonia (PCP) usually presents as progressive respiratory failure with characteristic widespread pulmonary crackles and alveolar shadowing on a chest radiograph. First-line treatment is high-dose co-trimoxazole, 120 mg/kg/day. Steroids are beneficial if pneumonia is severe. Toxoplasmosis often presents as a CNS infection with multiple space-occupying lesions; pyrimethamine/sulphadiazine is usually effective.

Cryptosporidiosis presents as non-resolving diarrhoea. The organism is naturally resistant to most antibiotics and treatment is mainly symptomatic.

The diagnostic approach, initial cultures and imaging are similar to those for neutropenia but the search for infection must be more extensive. As well as routine surveillance cultures, CSF, bone marrow and tests for specific parasites (e.g. strongyloidiasis) should be considered if past exposure is possible.

Other causes of immunodeficiency

Hypogammaglobulinaemia occurs in common variable immunodeficiency (congenital, but mainly presents in the third decade). Functional hypogammaglobulinaemia may occur in multiple myeloma and chronic parasitic infections (e.g. trypanosomiasis). Patients present with recurrent respiratory and gastrointestinal infections.

Complement deficiency leads to recurrent pyogenic infections. Recurrent meningococcal or overwhelming pneumococcal infections may occur. Systemic lupus erythematosus is the most common cause of acquired complement deficiency.

Splenectomy is followed by an annual risk of serious sepsis of 0.5–1%. The risk diminishes over time, but is never eliminated. Functional asplenia (e.g. sickle cell disease) carries similar risks. *Streptococcus pneumoniae* is the most common organism (66% of cases). *Haemophilus influenzae* and *Escherichia coli* are also important, as is malaria, which may be fulminant. Patients should receive long-term antibiotic prophylaxis and immunization against *S. pneumoniae* and *H. influenzae*.

Infections in transplant patients – these patients are at particular risk, not only do they have the underlying disease that made transplantation necessary, those who have had solid organ transplantation have suffered a major surgical insult followed by powerful immune suppression. Bone marrow transplant patients have a particularly intense immunosuppression: before transplantation they undergo ablative treatment leading to absent immune function. However, provided they survive the acute period, the transplanted marrow gradually recovers and much of its immune function is regained.

Organ support in immunodeficiency – management of organ failures in immunosuppressed patients is no different from that in patients with preserved immune function.

Immunotherapy

Attempts to modulate the immune response in critically ill patients have been disappointing. Broad-spectrum immunosuppression with corticosteroids at various doses has produced no convincing benefit (and possible harm at high doses). Specific treatments of individual components of the inflammatory response using monoclonal antibodies have failed to show benefit. The exception is activated protein C, primarily an antithrombotic agent with anti-inflammatory properties which appears to produce an absolute reduction in mortality in severe sepsis.

Other forms of immunotherapy, including intravenous immunoglobulin and, to a lesser extent, plasma exchange have been effective in a limited number of conditions such as Guillain–Barré syndrome and thrombotic thrombocytopenic purpura, respectively. Colony-stimulating factors have been shown to reduce the duration of neutropenia in non-critically ill, haematology patients but have not been shown to produce a clear reduction in mortality. There is no evidence that they are effective in the critically ill. ◆

The Intensive Care Management of Acute Severe Asthma

Kathleen Nolan

Kathleen Nolan is Consultant in Anaesthesia and Intensive Care at Southampton General Hospital, Southampton, UK.

In Western industrial countries, asthma affects about 5% of adults and 10–15% of children. Its prevalence, severity, and mortality are rising, due to a redefinition of diagnostic criteria and increased exposure to allergens and atmospheric pollutants.

Asthma is characterized by partially reversible airway obstruction, airway inflammation and airway hyperresponsiveness.

The diagnosis is often made clinically on a history of episodes of reversible airflow obstruction, often precipitated by factors such as environmental allergens, viral respiratory infections, irritants, drugs or food additives, exercise and cold air.

Pathophysiology

The primary defect in asthma is airflow obstruction with resultant lung hyperinflation and increased work of breathing and oxygen consumption. Eventually, hyperinflation cannot be maintained and there is a reduced total lung capacity, airway closure, alveolar hypoventilation and deteriorating gas exchange.

Bronchial obstruction causes a low ventilation:perfusion (V/Q) ratio, while alveolar overdistension raises the ratio; these lead to hypoxaemia and an increase in dead space.

Pulmonary artery pressure rises owing to hypoxic pulmonary vasoconstriction and the pressure of overdistended alveoli on pulmonary vasculature. High pulmonary artery pressures may impair right ventricular performance and cause leftward displacement of the interventricular septum and impaired left ventricular function. Pulmonary oedema may occur, due to left ventricular dysfunction, or the high negative intrathoracic pressures generated to overcome severe airway obstruction.

Signs and symptoms

The typical signs and symptoms of an acute asthma attack are listed in Figure 1. Risk factors for death include a long history of the disease in young to middle-aged patients, previous life-threatening attacks or hospitalizations, delay in obtaining medical aid, and sudden onset with a rapidly progressive course.

Criteria for admission to ICU include:

- deteriorating peak flow, worsening or persisting hypoxia, or hypercapnia
- exhaustion, feeble respiration, confusion, or drowsiness
- coma or respiratory arrest.

On physical examination, there is hyperinflation, accessory muscle use (in inspiration and expiration) and widespread wheeze. Patients with acute asthma usually have a combination of hypoxaemia, hypocapnia and respiratory alkalosis on arterial blood gas analysis. A normal or increased partial pressure of carbon dioxide in arterial blood ($PaCO_2$) is a danger sign, although observing the trend in $PaCO_2$ is more useful. Monitoring should include continuous ECG and oximetry, frequent estimations of respiratory rate, level of consciousness, blood pressure, temperature and peak expiratory flow rate measurements. Regular examinations of the chest should evaluate air entry, accessory muscle use and evidence of subcutaneous emphysema.

Indicators of a severe asthma attack[1]

Potentially life-threatening features

- Unable to complete sentences in one breath
- Respiratory rate ≥ 25 breaths/minute
- Heart rate ≥ 110 beats/minute
- Peak expiratory flow rate ≤ 50% of predicted normal or if best normal if known
- Peak expiratory flow rate < 200 litre/minute if best normal not known

Immediately life-threatening features

- Peak expiratory flow rate < 33% of predicted normal or best normal if known
- Silent chest, cyanosis, or feeble respiratory effort
- Bradycardia or hypotension
- Exhaustion, confusion, or coma

[1] Statement by the British Thoracic Society, 1997.

Treatment

Initial treatment is directed at the relief of bronchospasm and airway inflammation, using oxygen, β_2-adrenergic agonists, corticosteroids and other agents (Figure 2).

Oxygen – almost all patients have hypoxaemia during acute exacerbations of asthma. Humidified oxygen is administered in high concentrations as determined by pulse oximetry (SpO_2) or arterial blood gas analysis.

β-sympathomimetic agents – the inhaled β_2-adrenergic agonists (salbutamol, terbutaline) have a rapid onset of action and are the first-line treatment for the relief of bronchoconstriction. Salbutamol has more side-effects including hyperglycaemia, hypokalaemia and lactic acidosis. One empirical approach is to start nebulized β_2-agonists as first-line treatment and then to use the intravenous form if the response is poor or the patient is moribund.

Corticosteroids are the most effective treatment for chronic inflammation of asthma. The peak response occurs 6–12 hours after an intravenous dose. Intravenous corticosteroids should be given early and continued until the life-threatening phase is over; oral and inhaled corticosteroids are then appropriate.

Anticholinergic agents block muscarinic receptors, inhibit vagal tone and promote bronchodilatation. They are medium potency bronchodilators and produce substantively less bronchodilatation than sympathomimetics. Nebulized ipratropium is indicated when asthma is severe on presentation, or when β_2-adrenergic agonist therapy fails.

Intravenous aminophylline is regarded as a second-line drug because of its narrow therapeutic range and high incidence of side-effects (cardiac arrhythmias and seizures). Its mechanism of action is unclear, because at therapeutic concentrations phosphodiesterase inhibition is minimal and bronchodilatation is weak There are wide variations in the elimination of aminophylline and plasma concentrations should be checked regularly. The dose is reduced in the elderly and those with hepatic or cardiac disease.

Medical therapy for life-threatening acute asthma[1]

Oxygen

Use the highest concentration available and set a high flow rate

High-dose inhaled β_2-agonists

Salbutamol, 5 mg, or terbutaline, 10 mg, nebulized with oxygen or with a metered dose
inhaler into a large spacer devise (two puffs 10–20 times)

High-dose systemic corticosteroids

Prednisolone, 30–60 mg orally, or hydrocortisone, 200 mg i.v., or both, immediately

If life-threatening features are present

Add ipratropium, 0.5 mg, to the nebulized β_2-agonist

Give aminophylline, 250 mg i.v. over 20 minutes, or salbutamol, 250 µg i.v. over 10 minutes. Continue with infusion. Do not give bolus aminophylline to patients already taking oral theophyllines

[1] Statement by the British Thoracic Society, 1993.

Mechanical ventilation

1–3% of patients admitted to hospital with acute asthma require intermittent positive-pressure ventilation (IPPV). It is indicated in asthmatic patients who exhibit:

- decreasing or decreased level of consciousness
- decreasing PaO_2
- increasing $PaCO_2$
- increasing arterial paradox (fall in systolic blood pressure on inspiration)
- increasing heart rate
- increasing respiratory rate
- decreasing peak expiratory flow rate
- decreasing ability to speak.

Even patients presenting with gross hypercarbia may be managed without IPPV, if medical therapy produces rapid improvement. In contrast, a patient with a low but rising $PaCO_2$ may require IPPV. Other indicators of the severity of an attack will aid decision making (Figure 1).

At the time of intubation, patients with severe asthma are often tachycardic, tachypnoeic, hypoxic, hypercarbic, acidotic, hypovolaemic and hypokalaemic. Unless a difficult intubation is anticipated, rapid sequence induction is appropriate. For potentially difficult intubations, inhalation induction (sevoflurane in oxygen), or an awake blind nasal or fibre-optic intubation with topical anaesthesia may be used. Following intubation, the patient should be given sedatives and, if necessary, muscle relaxants; control mode ventilation is preferable. The chosen ventilatory mode should achieve adequate oxygenation and ventilation at the lowest possible airway pressures, thereby minimizing the risk of barotrauma. This involves the delivery of low tidal volumes (6–8 ml/kg) at a slow rate (< 10 cycles/minute), aiming to keep peak airway pressures below 35 cm H_2O. A prolonged expiratory phase is preferred (I:E 1:2–1:4). Hypercapnia is tolerated ($PaCO_2$ up to 15 kPa) in the belief that it is less harmful than barotrauma. Severe ventilation–perfusion mismatch may be improved using bronchial lavage to remove mucous plugs and, more controversially, positive end expiratory pressure.

Complications of IPPV in asthma are related to barotrauma (e.g. pneumothorax, pneumomediastinum, subcutaneous emphysema) or cardiac depression (e.g. hypotension).

Additional bronchodilators

Inhalation anaesthetics – treatment of ventilated asthmatics with volatile inhalational agents often reduces peak airway pressures and improves arterial blood gases. Halothane (0.5–3.0%) has a low therapeutic ratio in the acidotic, hypovolaemic patient and its prolonged use is associated with bromide toxicity. Isoflurane (0.5–3.0%) is safer and probably as effective. Adequate gas scavenging facilities must be available in the ICU.

Intravenous anaesthetics – ketamine, infusion 10–40 µg/kg/minute, is a potent bronchodilator. It increases catecholamine levels and directly relaxes bronchial smooth muscle, however, it is not licensed for use as a sedative or bronchodilator.

Magnesium sulphate – anecdotal evidence suggests that magnesium sulphate provides useful bronchodilatation, however, this is not confirmed by controlled studies.

Helium-oxygen mixtures – the inclusion of helium, a low density gas, in inhaled gas mixtures lowers airway resistance and decreases respiratory work.

Nitric oxide is a short-acting, endogenous vasodilator and bronchodilator. Its bronchodilatory may be useful.

Weaning: the duration of IPPV in acute severe asthma varies considerably. Complications of mechanical ventilation, such as barotrauma and infection, tend to prolong the duration of ventilation and may be associated with reduced survival. Reversal of bronchospasm is indicated by the absence of wheeze, and a fall in peak inflation pressures, dynamic compliance or the alveolar to arterial oxygen difference.

Mortality in asthma patients undergoing IPPV: reported rates are as high as 38%, but include cases of brain injury from cardiorespiratory arrest prior to ventilatory support. In over 10,000 children with acute asthma, 27 (0.3%) needed IPPV. The single death associated with asthma and IPPV represents 4% of ventilated cases. Death in asthmatics receiving IPPV usually results from barotrauma, hypotension, cardiac arrhythmias or sepsis.

Extracorporeal support

There are several reports of extracorporeal lung assist (ECLA) in severe asthma. With modern ICU management, acute severe asthma has such a low mortality that the additional survival afforded by ECLA is probably marginal.

Outcome

An increase in the mortality rate from asthma has been observed despite improvements in pathophysiological findings and the introduction of new effective therapeutic agents. Patients who have previously required ICU admission and IPPV are at significant risk during subsequent exacerbations of asthma.

Intensive Care Management of Pulmonary Embolism

Brid McGrath
Simon J Fletcher

Brid McGrath is a final year Senior Registrar at the Norfolk and Norwich Hospital, Norwich. She has an interest in intensive care and teaching.

Simon J Fletcher is Consultant in Anaesthesia and Intensive Care at the Norfolk and Norwich Hospital. He qualified from Guy's Hospital, London, and subsequently trained at St Thomas' Hospital, London, University of Mayland, Baltimore, USA, Norwich, and Addenbrooke's Hospital, Cambridge.

Incidence and natural history

Pulmonary embolism is not an isolated disease of the chest but a complication of venous thrombosis. Determining the true incidence of pulmonary emboli is problematic because the presentation is often silent or clinically ambiguous, the diagnosis is difficult, and the intensity of post-mortem examination for pulmonary embolism varies.

The incidence in the USA is estimated to be at least 500,000 per year with a mortality rate of 10%. The incidence is highest in those undergoing emergency surgery following trauma (e.g. hip fractures) and pelvic surgery. Following total hip replacement, 5% of elderly patients develop a pulmonary embolism; nearly half of these cases are fatal. Clinical presentation ranges from the haemodynamically stable patient with pleuritic chest pain to the patient presenting with no cardiac output. The fatality rate is less than 5% in treated patients who are haemodynamically stable at presentation but about 20% in those with persistent hypotension. The mortality from massive pulmonary embolism is high and many patients die before treatment can be initiated. Greater emphasis on prophylaxis is needed if mortality and morbidity are to be reduced in those presenting with cardiorespiratory arrest or severe hypotension.

Pathogenesis

Pulmonary emboli occur as a result of thrombi at a distal site, therefore it is important to consider the whole disease process. Most thrombi form at the site of venous valves in the calf and most of them resolve spontaneously (80%). The other 20% of calf thrombi extend proximally to the ilio-femoral veins. Thrombi that remain confined to the calf pose little risk of embolization, while thrombi in the ilio-femoral systems pose a 50% risk of embolization.

Over 90% of pulmonary emboli originate from the lower extremities. Less common causes of embolization include, axillosubclavian thrombosis, which may occur spontaneously or be related to indwelling central venous catheters. Septic emboli may develop from infected peripheral thrombi; common in intravenous drug abusers.

Pathophysiology

When venous thrombi become dislodged from their site of formation they travel proximally to the heart and lodge in the pulmonary arterial tree. A large embolus will settle at the bifurcation of the pulmonary artery, forming a saddle embolus, which is invariably fatal. The effects of an embolus depend on:

- the extent of pulmonary vascular obstruction
- the pre-existing function of the cardiopulmonary system
- the time over which the obstruction accumulates.

If an embolus obstructs less than 50% of the pulmonary circulation, it may cause no symptoms in a previously fit patient, but cause compromise in a patient with pre-existing cardiopulmonary disease. When more than 50% of the pulmonary circulation is suddenly occluded the patient presents with haemodynamic instability ranging from hypotension to cardiorespiratory arrest.

Obstruction of the pulmonary vascular bed acutely increases right ventricular afterload. The thin-walled right ventricle is designed to work against a low resistance pulmonary circulation and hence functions poorly against a sudden increase in pulmonary vascular resistance. As the right ventricle dilates it pushes the interventricular septum to the left, impeding filling of the left ventricle compounding the fall in cardiac output. The fall in aortic pressure and the rise in right ventricular pressure may cause ischaemia of the right ventricle due to coronary hypoperfusion. The cardinal pulmonary effect is altered gas exchange. The main causes are:

- ventilation–perfusion mismatch – normal parts of the lung become overperfused but have inadequate ventilation to oxygenate the extra blood flow fully
- low mixed venous oxygen saturation caused by decreased cardiac output

accentuates hypoxaemia because there is insufficient time for the desaturated blood to become oxygenated as it passes through the over-perfused part of the lung. Carbon dioxide elimination is nearly always normal because there is a compensatory increase in minute ventilation.

Clinical manifestations

The clinical features of acute life-threatening pulmonary embolism can be explained in terms of the pathophysiological changes. The patient presenting to the ICU team will often have severe cardiorespiratory compromise. Patients will be acutely distressed with dyspnoea and tachypnoea. The physical signs are those of reduced cardiac output, namely, sinus tachycardia, hypotension, cool clammy peripheries, and confusion. There will be both central and peripheral cyanosis and signs of acute right heart strain: a raised central venous pressure, a palpable right ventricular heave, and a gallop rhythm. Finally, patients may present in atrial fibrillation due to a dilated right heart.

The symptoms and signs described above are not specific to pulmonary embolism; they are often the manifestation of any critical illness.

Investigations

Non-imaging diagnostic methods

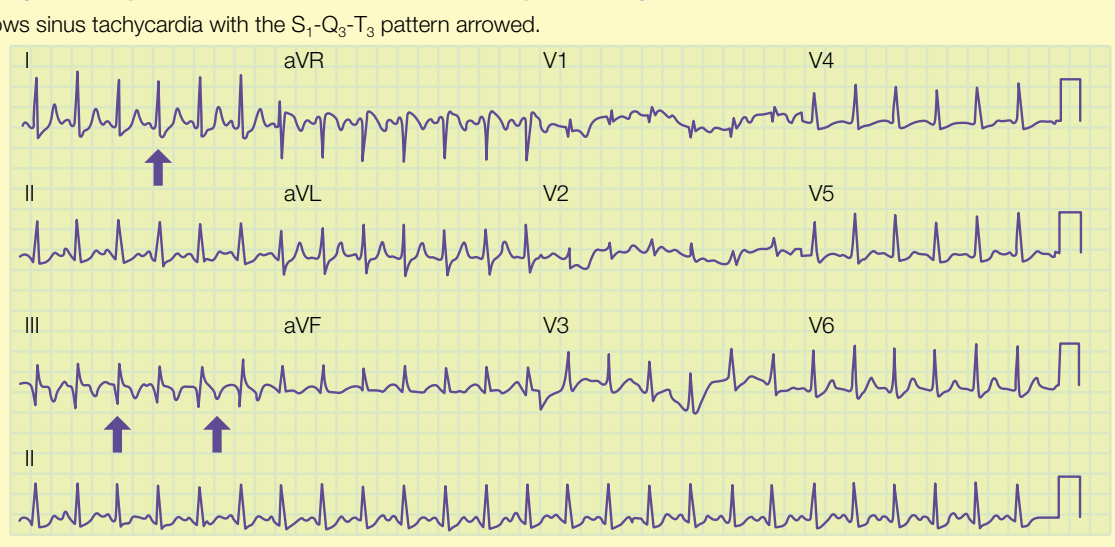
ECG – the ECG is abnormal in over 70% of patients with pulmonary embolism but these changes are nonspecific. Common findings are sinus tachycardia and ST segment abnormalities. In massive pulmonary embolism, evidence of right heart strain may be seen (right axis deviation, T wave inversion in V1–3). The classic S_1-Q_3-T_3 pattern seldom occurs (Figure 1). The ECG is useful in excluding other conditions such as myocardial infarction.

Arterial blood gases – the characteristic changes are a reduced partial pressure of oxygen in arterial blood (PaO_2) and a normal or low partial pressure of carbon dioxide. An abnormal PaO_2 is nonspecific.

Plasma D-dimer enzyme-linked immunosorbent assay (ELISA) relies on the principle that endogenous fibrinolysis is occurring in an effort to break down thrombus to fibrin degradation products (D-dimers). Although elevated levels of D-dimers are sensitive for the presence of pulmonary embolism they are not specific. A variety of clinical conditions encountered in the ICU can result in accelerated fibrinolysis (e.g. recent surgery, myocardial infarction, sepsis).

ECG of a 28-year-old patient who died from a massive pulmonary embolism

The ECG shows sinus tachycardia with the S_1-Q_3-T_3 pattern arrowed.



1

Imaging diagnostic methods

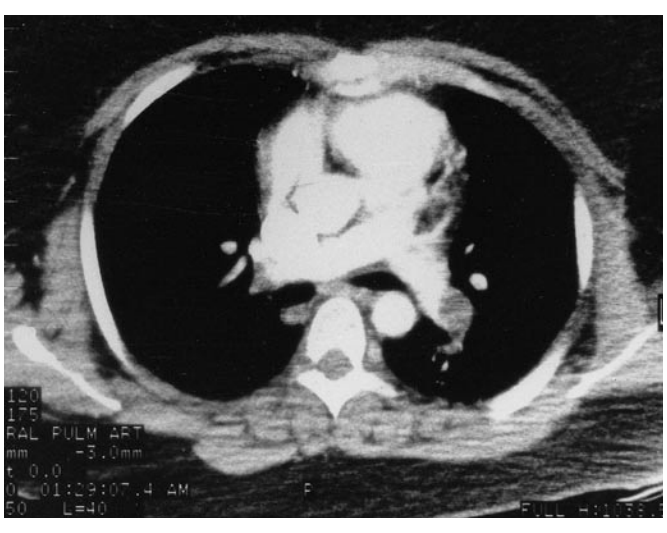
Chest radiography – most patients with a pulmonary embolism have an abnormal chest radiograph. In massive embolism a plump pulmonary artery shadow can be seen in the presence of oligaemia in those parts of the lung affected by emboli. There may be signs of pulmonary infarction; a wedge-shaped area along the pleural surface.

Echocardiography – transthoracic echocardiography can detect right ventricular dilatation and may reveal thrombus floating in the right ventricle or atrium. Transoesophageal echocardiography is particularly useful in the ICU because the patient is often too unstable for transportation. It allows detection of emboli involving the main trunk and the right and left pulmonary arteries.

Pulmonary angiography remains the diagnostic gold standard. It is expensive, invasive, and carries a 0.3% risk of mortality. Angiographic interpretation relies heavily on image quality and the observer's experience. Risks include vasodilatation due to contrast and the possibility of pushing clot in the right heart into the lungs.

Contrast-enhanced spiral CT is emerging as a first-line investigation. The technique is faster, less complex, and less operator dependent than angiography. The procedure has over 90% specificity and sensitivity in diagnosing pulmonary embolism in the main, lobar and segmental pulmonary arteries (Figure 2).

Ventilation–perfusion scanning is the most common imaging method used in the diagnosis of pulmonary embolism, but it cannot be performed in intubated patients.



2 Spiral CT scan of the same patient as in Figure 1. There is a filling defect in the left main pulmonary artery consistent with a large pulmonary embolism.

Management

Diagnostic uncertainty is often accentuated in the critical care setting where the complexity of safe transport often becomes a major determining factor in the diagnostic approach. Subsequently, management decisions are often based on incomplete clinical data.

Resuscitation

Oxygen therapy – oxygen should be administered in high concentration by mask. Patients with a decreased level of consciousness and/or severe respiratory distress require ventilation. Attention should be paid to full monitoring of resuscitation efforts in the form of ECG, invasive blood pressure, and central venous pressure monitoring. Arterial blood gas values can be used to assess the degree of hypoxaemia and indicate the presence of a metabolic acidosis due to hypoperfusion.

Haemodynamic support – the aim of treatment is to restore tissue perfusion to maintain end organ perfusion. It is imperative to maintain right heart filling pressures. The central venous pressure is raised in patients with pulmonary embolism; often as high as 20 mm Hg, this should not prevent fluid administration. A pulmonary artery catheter is not essential but may be useful in monitoring the response of fluid challenges. If hypotension exists after fluid-loading, inotropes should be started (e.g. adrenaline (epinephrine), 0.3–1.5 μg/kg/minute), and the dose titrated to blood pressure.

Definitive treatment

Heparin remains the mainstay of therapy for pulmonary embolism. A loading dose of 10,000 units i.v. or 100–150 units/kg followed by an infusion of 15–25 units/kg/hour is administered as soon as possible. The activated partial thromboplastin time (APTT) ratio should be checked every 6 hours and the infusion adjusted to maintain an APTT ratio of 2–2.5 normal.

Warfarin can be started early because it takes 5 days to achieve its full effect. Heparin should be continued for at least 5 days or until the international normalized ratio (INR) is 2–3. Warfarin without intravenous heparin depresses protein S and C activity at the onset, thus creating a thrombogenic potential.

Thrombolysis – the use of thrombolytic agents in acute pulmonary embolism remains controversial. Trials have failed to show any benefit over conventional treatment. Thrombolytics can increase the rate of thrombolysis in the first 24 hours but there is no convincing evidence that it decreases morbidity or mortality. There is a substantial risk of bleeding including intracranial haemorrhage (0.5–2%).

On this basis, thrombolytic agents should be reserved for those in whom accelerated thrombolysis may be considered lifesaving. Tissue plasminogen activator (tPA), 100 mg as an intravenous infusion over 2 hours is the thrombolytic of choice (less allogenic). It can be administered peripherally or into a pulmonary artery catheter. Heparin infusion is started after thrombolysis to maintain the APTT ratio at 2–2.5.

Pulmonary embolectomy is limited to centres with cardiothoracic surgeons. It has a high mortality rate and should be considered only in particular circumstances, for example in those in whom thrombolysis is contraindicated or who fail to respond.

Other therapies: low molecular weight heparin (LMWH) is licensed for the treatment of pulmonary embolism. It has little use in the compromised patient because subcutaneous LMWH takes 2–4 hours to reach therapeutic effect. Balloon-tipped catheters under fluoroscopy have been used to extract emboli; further investigation is required before their use becomes widespread.

Nitric oxide has been used as an adjunct to critical care management. It is a selective pulmonary vasodilator used to increase oxygenation by improving ventilation–perfusion matching. There are case reports advocating its use because it allows life-threatening hypoxaemia to be improved while instituting definitive therapy.

Intensive Care Myopathy and Neuropathy

Francis J Andrews
Richard D Griffiths

Francis J Andrews is Lecturer in Medicine (Intensive Care) at Liverpool University and Specialist Registrar at Whiston Hospital, Prescot, UK. He qualified from Leeds University and trained in accident and emergency medicine in West Yorkshire. His research interests include muscle wasting and the effect of nutrition on the immune system in critically ill patients.

Richard D Griffiths is Professor of Medicine (Intensive Care), University of Liverpool, and Honorary Consultant Physician Intensive Care, Whiston Hospital, Prescot, UK. He has research interests in muscle, nutrition and the rehabilitation of the post-ICU patient.

The effects of the systemic inflammatory response syndrome (SIRS) on the main organs are widely known, but the effects on peripheral nerve and muscle in the critically ill have only recently begun to be recognized and understood.

Definitions
Recovery from critical illness may be followed by critical illness neuropathy and/or critical illness myopathy. Critical illness neuropathy is an acute axonal neuropathy developing in critically ill patients which remits spontaneously when the critical illness has passed. Critical illness myopathy is an acute myopathy developing during a critical illness. The incidence of myopathy and polyneuropathy varies among studies, but it is estimated that 70–80% of patients with severe sepsis or multiple organ failure develop some form of critical illness neuropathy or myopathy. Various neuropathies and myopathies have been described.

Neuropathies
Critical illness polyneuropathy (CIP) is a common, diffuse, axonal motor and sensory neuropathy, which develops while patients are critically ill in the ICU and, generally, remits spontaneously as the patient recovers from their underlying critical illness. There is a primary axonal degeneration of peripheral motor and sensory fibres, but no evidence of inflammation. Muscle shows scattered atrophic fibres with occasional necrotic fibres.

Acute motor neuropathy is a variant of CIP associated in some cases with the administration of competitive neuromuscular blocking agents (e.g. pancuronium bromide, vecuronium) given for more than 48 hours. There is severe primary axonal degeneration of predominantly motor fibres, demonstrable with nerve conduction studies and electromyography (EMG). Muscle biopsies are non-specific and may show denervation, and atrophic and necrotic changes. Electrophysiological testing may show defects in neuromuscular transmission consistent with a postsynaptic defect.

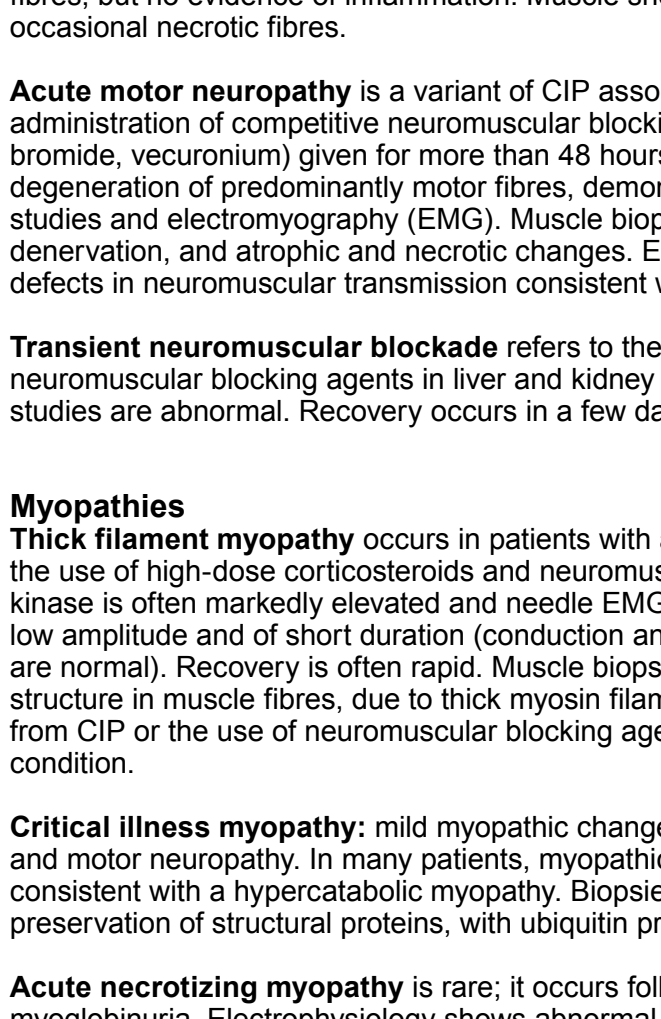
Transient neuromuscular blockade refers to the prolonged effect of competitive neuromuscular blocking agents in liver and kidney failure. Repetitive nerve stimulation studies are abnormal. Recovery occurs in a few days following cessation of the drugs.

Myopathies
Thick filament myopathy occurs in patients with acute asthma and is associated with the use of high-dose corticosteroids and neuromuscular blocking agents. Creatine kinase is often markedly elevated and needle EMG motor unit potentials are polyphasic, low amplitude and of short duration (conduction and repetitive nerve stimulation studies are normal). Recovery is often rapid. Muscle biopsy shows characteristic loss of central structure in muscle fibres, due to thick myosin filament destruction. Muscle denervation from CIP or the use of neuromuscular blocking agents predisposes patients to this condition.

Critical illness myopathy: mild myopathic changes are often seen in patients with CIP and motor neuropathy. In many patients, myopathic changes are more pronounced, consistent with a hypercatabolic myopathy. Biopsies show loss of myosin but relative preservation of structural proteins, with ubiquitin proteolysis.

Acute necrotizing myopathy is rare; it occurs following insults that cause myoglobinuria. Electrophysiology shows abnormal spontaneous activity, highly elevated creatine and myoglobinuria. Muscle biopsy shows widespread necrosis. Recovery is variable.

Pathophysiology
The pathophysiology of critical illness neuropathy and myo-pathy is poorly understood. There is often a marked discrepancy between the results of electrophysiological and histological studies. Early in critical illness, there is often marked atrophy of type I and II muscle fibres, with necrosis being rare; at this stage electrophysiological investigations are normal. Electron microscopy shows early loss of myosin but retention of structural proteins (Figure 1). However, when critical illness neuropathy and myopathy become clinically apparent later during illness, histological examination of peripheral nerves is often normal, despite abnormal EMG and nerve conduction studies as seen in CIP.



Electron micrograph of skeletal muscle taken from **a** normal muscle and **b** a patient with multiple organ failure. Between the Z lines, where the actin is attached there is almost complete loss of the double-ended myosin filaments (arrowed) that form the characteristic central A band.

1

It has been speculated that axonal degeneration is a consequence of the circulating mediators of SIRS, resulting in a common endothelial and vascular pathology that leads to nerve and muscle damage. In this theory, blood vessels supplying peripheral nerves are susceptible to disruption of the microcirculation in critical illness. The resulting increase in vascular permeability and oedema may result in hypoxic neural damage, not manifesting histologically until severe energy deficits occur. In these circumstances, neuromuscular drugs could also have a direct toxic effect on axons. Studies have failed to show any convincing evidence for nutritional deficiencies, medication, Guillain–Barré syndrome, or types of primary illness or injury as primary causes of critical illness myopathy or neuropathy. Severe CIP is asssociated with prolonged ICU stay, hyperglycaemia and hypoalbuminaemia.

History and examination
These patients appear to be recovering from sepsis and multiple organ failure, often following prolonged ventilation, but have difficulty weaning from the ventilator and have limb weakness. Lung or cardiac causes of respiratory insufficiency need to be excluded before considering the diagnosis of neuropathy or myopathy.

Aside from weakness and muscle wasting, neurological signs of neuropathy or myopathy may not always be present. In particular, tendon reflexes may be normal instead of decreased in some patients, and even exaggerated if the patient has a co-existing CNS disorder. A useful sign is that deep painful stimulation of limbs may show weak movements but strong facial grimacing.

Differential diagnosis
It is important to exclude conditions that would have begun before admission to the ICU, such as acute infective, traumatic or neoplastic spinal cord compression, Guillain–Barré syndrome, myasthenia gravis or muscular dystrophy. Usually these conditions are obvious before admission, but deterioration is often so rapid that diagnosis before ICU admission is impossible.

Investigations
Depending on the clinical variables, involvement of the high cervical spinal cord, peripheral nerves, neuromuscular junctions and muscles should be investigated. Patients with weakness following trauma should be investigated for spinal cord trauma before investigations for critical illness neuropathy or myopathy. EMG is the most useful initial investigation. EMG evidence of denervation activity consistent with axonal degeneration is diagnostic of CIP in the absence of other more plausible causes. If performed, nerve conduction studies in CIP show normal speed of impulse conduction but decreased compound motor and sensory nerve action potential amplitudes. Nerve conduction studies may be useful in diagnosing acute motor neuropathy, evidenced by markedly reduced compound motor but normal sensory nerve action potential amplitudes. Repetitive nerve stimulation studies are helpful in establishing the diagnosis of transient neuromuscular blockade. Serum creatine kinase is often elevated in thick filament and necrotizing myopathy but may be normal. Muscle biopsy is the investigation of choice for suspected myopathy and should be performed on all critically ill patients with new onset of weakness and the absence of electrodiagnostic findings suggestive of CIP or transient neuromuscular blockade.

Management
There is no specific therapy for critical illness neuropathy and myopathy. However, it is important to limit or prevent them because of their variable prognosis. The severity of critical illness neuropathy correlates with prolonged sepsis and catabolism, therefore sepsis must be treated aggressively, with attention to adequate nutrition. Evidence also suggests that tight glycaemic control reduces the incidence of CIP. Muscle relaxants and corticosteroids should be used sparingly, especially in acute asthma and in the presence of renal or liver failure. Prolonged physio-therapy and rehabilitation therapy is the mainstay of treatment for established conditions. Careful positioning of the patient is essential to avoid further nerve damage due to pressure areas.

Prognosis
The degree of recovery from critical illness neuropathy and myopathy is related to the severity of the condition. Milder cases of neuropathy are associated with recovery in weeks whereas more severe forms may take months to recover. Some patients with severe neuropathy, especially with evidence of slowing of nerve conduction may not recover. Generally, there is a rapid recovery following thick filament myopathy, but the prognosis may be poorer for some cases of necrotizing myopathy. ◆

Management of the Poisoned Patient

Cliff Reid
Gary Smith

Cliff Reid is Specialist Registrar in Pre-hospital Care for the London Helicopter Emergency Medical Service. He qualified from Southampton University and completed training in emergency medicine at North Hampshire Hospital followed by training in intensive care medicine in Portsmouth. His interests include the interface between emergency medicine and intensive care, and emergency airway management.

Gary Smith is Consultant in Intensive Care Medicine at Portsmouth Hospitals NHS Trust, and Honorary Senior Lecturer in Critical Care in the School of Postgraduate Medicine, University of Portsmouth, UK. He qualified from Southampton University Medical School and trained in anaesthesia and medicine in the South of England and Yale University, USA. His interests include the organization of intensive care services, outcome prediction and the training of doctors, nurses and paramedics

Poisoning is a common cause of hospital attendance, but seldom requires admission to the ICU. In many cases the poison is known and the patient requires only supportive care. Occasionally, the history is unclear or unobtainable; in such cases, the recognition of certain toxicological syndromes or toxidromes (Figure 1) and the selective use of investigations may help. The management of all poisoned patients is summarized in Figure 2.

Recognizable clinical toxidromes

Toxidrome	Features	Causative agents
Anticholinergic	• Agitation, hallucinations, coma • Tachycardia • Large pupils • Dry skin • Urinary retention • Warm, flushed peripheries	• Antihistamines (diphenhydramine) • Anticholinergic plants such as Atropa belladonna (deadly nightshade) • Tricyclic antidepressants • Atropine • Antiparkinsonian agents
Cholinergic	• Lacrimation • Salivation • Bradycardia • Increased respiratory tract secretions • Diaphoresis • Vomiting • Diarrhoea and urinary incontinence • Fasciculations	• Organophosphate carbamate insectides
Opiate	• Respiratory depression • Depressed conscious level • Small pupils	• Heroin and other opiates
Sedative-hypnotic	• Depressed conscious level • Mild respiratory depression • Hypotension in large ingestions	• Benzodiazepines • Some sedative hypnotics
Serotonergic	• Confusion, agitation, restlessness • Myoclonus, hyperreflexia • Diaphoresis • Tremor, rigidity • Hyperthermia	• Serotonergic antidepressants especially in combination (e.g. serotonin reuptake inhibitors, monoamine oxidase inhibitors and tricyclic antidepressants)
Sympathomimetic	• Tachycardia • Hypertension • Hyperthermia • Agitated delirium • Large pupils • Diaphoresis	• Cocaine • Amphetamines, methylenedioxymethamphetamine (MDMA; ecstasy) • Alcohol or sedative hypnotic withdrawal

1

Management sequence for the poisoned patient

Primary survey
A
- Oxygen
- Manual airway opening manoeuvres
- Simple airway adjuncts
- Rapid sequence intubation for airway protection

B
- Assist ventilation as required

C
- Intravenous access 12-lead ECG
- Correct arrhythmias and hypotension
- Monitor urine output

D
- Glasgow Coma Score, pupils, cranial nerves, lateralizing signs (CT scan), blood glucose

E
- Exclude hypothermia
- Fully expose

Monitoring
- Respiratory rate, ECG, non-invasive blood pressure, pulse oximetry

Secondary survey
- Track marks, pressure areas, co-existing injuries, characteristic odour, recognizable toxidrome

History

Investigations
Radiographic
- Chest radiograph for evidence of pulmonary aspiration or non-cardiogenic pulmonary oedema (opiates, salicylates)
- Abdominal radiograph for ingested metals (e.g. iron, lead, zinc)

Laboratory
- Full blood count, urea and electrolytes, arterial blood gases
- Anion gap, plasma osmolality
- Urinalysis: blood, glucose, ketones, urine osmolality
- Advice: Toxbase on-line
- Levels: paracetamol; others as indicated (salicylate, iron, lithium)

Gastric decontamination
- Activated charcoal
- Whole bowel irrigation

Antidote
- Diagnostic – naloxone
- Treatment – N-acetylcysteine

Increased elimination
- Multiple dose activated charcoal
- Haemofiltration or haemodialysis

Supportive

Follow-up/referral

2

Primary survey and resuscitation

Airway and breathing: many drugs taken in overdose cause a variable depression of conscious level that leads to airway obstruction, depressed airway reflexes and reduced ventilatory drive. Patients are at risk of aspiration of gastric contents, hypoxaemia, hypercapnia, and aspiration of vomit. Indications for tracheal intubation include: the inability to maintain a patent airway; a Glasgow Coma Score of 8/15 or less; agitation or combative behaviour that risks harm to the patient; hypoxaemia; and hypoventilation. Careful thought should also be given to the anticipated clinical course of the patient. For example, patients with a fluctuating conscious level, those requiring interhospital transfer and those in whom future deterioration can be predicted should be intubated electively.

A rapid sequence induction technique minimizes the adverse consequences of airway manipulation and intubation, such as pulmonary aspiration, arrhythmias and raised intracranial pressure. The temptation to intubate a comatose patient without providing anaesthesia must be resisted, because this could exacerbate the arrhythmogenic effects of certain poisons. The presence or absence of a gag reflex does not correlate with conscious level or true airway protective ability and should not influence the decision to intubate.

Circulation: some poisons have direct negatively chronotropic or inotropic effects (e.g. β-blockers, calcium antagonists), while others (e.g. tricyclic antidepressants) cause severe tachydysrhythmias that reduce contractility indirectly or precipitate cardiac arrest. CNS depression or drugs with an effect on the peripheral circulation (e.g. α-blockers) may also cause hypotension, whereas sympathomimetics (e.g. amphetamines) may result in tachycardia and severe life-threatening hypertension.

Hypotension will sometimes respond to intravenous crystalloid alone, but a failure to reverse hypotension or oliguria may necessitate central venous or pulmonary artery catheterization to guide volume therapy and vasoactive support.

Arrhythmias should be corrected, though standard advanced life-support guidelines may require modification, because tachyarrhythmias are likely to be refractory to anti-arrhythmic agents or cardioversion. Initial attention must be paid to correcting hypoxaemia, hypercapnia, and electrolyte and acid–base disturbances. For instance, the use of deliberate hyperventilation or intravenous sodium bicarbonate (1–2 mmol/kg body weight) to produce alkalaemia appears to reduce the risk of dysrhythmias, and possibly seizures, in tricyclic antidepressant poisoning.

Disability (neurological assessment): some agents (e.g. insulin, alcohol, hypoglycaemic agents) lower blood glucose and, thus, conscious level; therefore blood glucose measurement should form part of the neurological examination. The presence of lateralizing signs such as hemiparesis may indicate coexisting pathology. Ataxia, nystagmus and seizures may provide clues to toxin ingested.

Exposure and full examination (secondary survey) of the skin may reveal track marks suggesting intravenous drug abuse. Patients who remain unconscious for many hours before being found may develop hypothermia, skin blistering, peripheral neuropathy and rhabdomyolysis.

History

Where possible, the amount and type of poison ingested, as well as the exact time of exposure, should be identified. Co-morbid conditions and the patient's usual medications may influence the progress of the poisoning or the patient's recovery. In patients who have no apparent cause for their condition, consideration should be given to the possibility of body packing or stuffing, in which large quantities of illegal drugs are hidden within body cavities. Such suspicion necessitates rectal and vaginal examination, abdominal radiology and enteroscopy.

Investigations

Blood: routine blood count and urea and electrolyte tests are important to assess the impact of poisoning on electrolyte homeostasis and renal function. An elevated serum creatine phosphokinase may suggest rhabdomyolysis due either to pressure-induced myonecrosis or from a direct toxic effect on myocytes. Arterial blood gas analysis permits assessment of ventilation and identifies acid–base disturbances. Modern blood-gas analysers also provide quantitative evidence of carbon monoxide or abnormal haemoglobin complexes. Other useful investigations include calculation of any anion or osmolar gap. If the anion gap exceeds 16 $\pm$ 4 mmol/litre, it may support the diagnosis of poisoning by salicylates, iron or toxic alcohols. An osmolar gap (the difference in measured and calculated serum osmolality) indicates the presence of unmeasured osmotically active substances (e.g. ethylene glycol).

Urine: the presence of pigment in the urine (haemoglobin or myoglobin), in the absence of RBCs on urine microscopy, suggests myoglobinuria and diagnosis of rhabdomyolysis.

Toxicological investigations: there is seldom an indication for a blanket toxicology screen, because they are expensive, often unavailable during the patient's hospitalization and seldom alter the clinical management. Nevertheless, paracetamol levels should be requested, since the demonstration of toxicity necessitates the administration of *N*-acetylcysteine to prevent hepatocellular injury. Further advice on specific poisons can be obtained:
- on-line at www.spib.axl.co.uk
- by telephone in the UK from the National Poisons Information Service on 0870 600 6266.

Gastrointestinal decontamination

There are several ways to prevent the further uptake of poison present in the gastrointestinal tract, including emesis, lavage and activated charcoal, but few have sound evidence for their use. In particular, the role of gastric lavage is now reserved for patients with life-threatening poisoning presenting to hospital within 1 hour of ingestion.

Specific antidote therapy

Most patients improve with supportive care alone, though some require the administration of specific antagonists or antidotes. The response to the administration of the opiate antagonist naloxone (0.4–0.8 mg i.v. or 0.8 mg i.m. or s.c.) can assist in the diagnosis of opiate overdose. However, the benzodiazepine antagonist, flumazenil, should not be used empirically, because it can induce an acute withdrawal reaction in chronic benzodiazepine users, and may induce seizures if the toxic effects of a tricyclic antidepressant overdose are being masked by concomitant benzodiazepine ingestion.

Enhanced elimination
Activated charcoal, 1 g/kg every 4 hours, may increase elimination of poisons that have an enterohepatic circulation. In addition, the gut wall acts as a semipermeable membrane and assists removal of the drug by an 'intestinal dialysis'.

Forced alkaline or acid diuresis: now seldom used, these methods involve the manipulation of urine pH in order to maintain weak acids (e.g. salicylates, phenobarbitone) or weak bases (e.g. amphetamine, phencyclidine) in their ionized, lipid-insoluble form to limit renal tubular reabsorption. Careful monitoring of acid–base status, electrolytes, and fluid balance is required.

Dialytic techniques: haemodialysis is effective at removing toxins that are poorly protein bound, and have a molecular weight less than 500 Da. Drugs with a high volume of distribution such as tricyclic antidepressants are not cleared effectively. Continuous haemofiltration methods can remove larger molecules than haemodialysis, and continuous methods may be more suitable for drugs with a high volume of distribution (e.g. lithium). In charcoal haemoperfusion, blood is passed via an extracorporeal circuit over a cartridge of activated charcoal. This method is more suitable than haemodialysis for the removal of large or protein-bound molecules. However, it can result in thrombocytopenia, coagulopathy, hypothermia and hypocalcaemia, and in many cases provides no greater clearance of poison than multiple doses of activated charcoal.

Follow-up
Many poisoned patients are young, otherwise fit, adults who often have treatable underlying psychiatric illness. Referral for psychiatric assessment should always be undertaken when they have recovered from acute poisoning.

Nosocomial Bacterial Infections

Aodhán S Breathnach

Aodhán S Breathnach is Consultant Medical Microbiologist in the PHLS Collaborating Centre and Department of Medical Microbiology, St George's Hospital, London, UK.

Nosocomial infections are those acquired in or associated with hospitals. Any infection can, in theory, occur in hospital, but there are many factors in the hospital environment that lead to a particular spectrum of infective problems (Figure 1). Nosocomial infections are common, and may be serious or fatal. Some are unavoidable, but doctors must remember that their duty of care to their patients extends to fundamental matters such as basic hygiene and avoidance of unnecessary antibiotics, which may prevent patients becoming infected.

Typical hospital organisms

	Usual location	Risk factors for acquisition	Typical infections	Comments
Methicillin-resistant *Staphylococcus aureus*	Nasal or cutaneous	Antibiotic use Skin lesions Overcrowding, poor infection control	Skin/wound Orthopaedic Intravenous devices Bacteraemia Endocarditis Respiratory tract Prosthetic devices	Occasional case reports of isolates developing resistance to glycopeptides, which are the agents of choice for invasive infections
Enterococci and vancomycin-resistant enterococci	Gut Hospital environment	Antibiotics – particularly cephalosporins, glycopeptides	Low virulence Typically, vulnerable ICU patients, or renal patients in whom glycopeptide antibiotics are commonly used	Vancomycin-resistant enterococci are more correctly, but rarely, termed 'glycopeptide-resistant enterococci' Heat and disinfectant tolerant, so survive well in hospital environment
Clostridium difficile	Gut Hospital environment	Antibiotics Chemotherapy Lack of hygiene Elderly care wards	Antibiotic-associated diarrhoea/ pseudomembranous colitis	Large outbreaks with fatal cases reported Predisposed by loss of native bowel flora, hence a number of suggested 'alternative'remedies based on the principle of replacing this flora (e.g. live yoghurt, donor faeces)
Multi-resistant Gram-negatives	Gut Hospital environment	Antibiotics Lack of hygiene High-dependency units	Intra-abdominal, respiratory and bloodstream infections in vulnerable patients	Various species (e.g. *Acinetobacter, Klebsiella, Enterobacter, Stenotrophomonas)* Many are indolent opportunists, but some (e.g. *Klebsiella*, *Pseudomonas aeruginosa*) can cause aggressive, virulent infections

NB: Most nosocomial infections are caused by the patient's own flora or by cross-infection with more sensitive organisms not listed above

Background

It is reasonable to expect medical and nursing care to be safe, but hospitals have always been hazardous places – until the 20th century, they were avoided by those who had the option of being treated elsewhere. Paradoxically, with the advent of modern medicine and large urban hospitals in the 19th century, overcrowding, squalor and ignorance increased the danger to patients, and there was a significant risk of death from nosocomial infection following many procedures, from childbirth to amputation.

The current situation is much improved, but hospital-acquired infections still cause considerable illness and some mortality. It has been estimated that, at any one time, 9% of in-patients in the UK have a nosocomial infection; the incidence is highest in surgical wards and ICUs, and lowest in medical units. Apart from the obvious ethical significance of harm resulting from medical or nursing care, nosocomial infections cause a financial burden to hospitals, patients and society. A recent estimate of the cost in the UK was up to £1000 million/year. This figure does not include costs of litigation and compensation; courts increasingly tend to assume that hospital staff are at fault in cases of nosocomial infection.

Predisposing factors for nosocomial bacterial infection

Underlying patient factors (Figure 2) – many patients are intrinsically vulnerable to infection; they are at the extremes of age, are debilitated, or have an underlying illness causing immunodeficiency (e.g. HIV). Neurological illness may lead to aspiration pneumonia; immobility and dehydration may encourage urinary tract infection (UTI). Skin disease and bedsores allow organisms to enter subcutaneous tissue. In addition, and importantly, the normal flora of all patients includes potential pathogens such as *Escherichia coli* in the gut and *Staphylococcus aureus* in the nose.

Predisposing factors in nosocomial infection

Patient factors
- Debility
- Extremes of age
- Impaired gag reflex (e.g. cerebrovascular accident)
- Trauma
- Immunosuppressive illness (e.g. HIV)
- Normal flora – potential pathogens

Medical and surgical interventions
- Surgical incisions
- Intravascular devices
- Urinary catheters
- Prostheses
- Antibiotic use
- Immunosuppression
- Anaesthesia and ventilation

Hospital environment
- Other patients' organisms
- Cross-infection – transient staff carriage
- Environmental organisms
- Lack of hygiene
- Overcrowding
- Understaffing
- Hospital pathogens

Medical and surgical interventions – surgical incisions and intravascular devices provide means of entry for pathogens. Urinary catheterization often causes UTIs. Prosthetic joints and heart valves provide a protected niche for bacterial growth, which usually results in loss of the prosthesis. Immunosuppressive therapy allows even low-virulence organisms to assume a dangerously pathogenic role.

Less obvious ways in which medical therapy can facilitate infection include anaesthesia and ventilation (may lead to nosocomial pneumonia) and antibiotics (alter normal flora, reducing resistance to colonization by hospital organisms). Inadequate disinfection of endoscopes can transmit pathogens such as *Mycobacterium tuberculosis* and *Salmonella*.

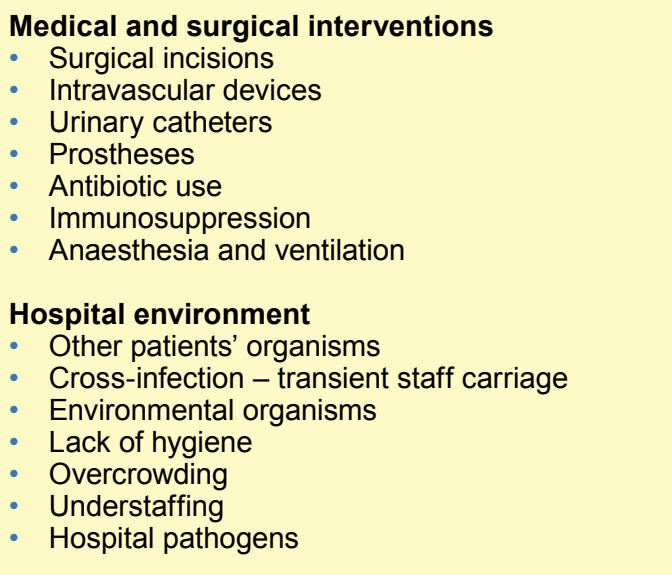
Hospital environment – patients may become infected with new organisms, usually from other patients, or more rarely from staff or the inanimate environment. Transient hand carriage by medical or nursing staff is thought to be the main route of spread, but occasionally other routes are involved, such as the airborne route for respiratory pathogens. Overcrowding, understaffing and lack of hygiene, particularly lack of handwashing, increase the risk of cross-infection.

Antibiotic use in hospital has selected resistant organisms, which readily colonize and infect patients. Many (e.g. coagulase-negative staphylococci, enterococci) are of relatively low virulence, but can cause severe illness in compromised patients; some (e.g. methicillin-resistant *Staph. areus*, MRSA) can be as virulent as their more sensitive counterparts.

Common syndromes and problems of nosocomial bacterial infection

Most nosocomial infections fall into a small number of common categories (Figure 3). Specialist units (e.g. burns, transplant, neurosurgery) see different infections, in addition to the following syndromes. The importance of nosocomial viral and fungal infections should not be overlooked.

Foci of nosocomial bacterial infections



Line-associated infections and bacteraemia: one-third of cases of nosocomial bacteraemia are associated with an intravenous device, 25% are from an unknown source, and the remainder have various sources, including the urinary tract, the gut and ventilator-associated pneumonia. Almost 50% of isolates are staphylococci (MRSA proportion increasing), and these are most likely to be line-associated. The remainder are mostly Gram-negative (*E. coli*, *Klebsiella*, *Enterobacter*, *Proteus* and *Pseudomonas*), with small numbers of enterococci and *Candida* (not bacteria, but generally included in reviews of 'bacteraemia'). Gram-negatives may be line-associated, but are more likely to have a urinary source, or to arise from the gut in patients with intra-abdominal pathology or neutropenia.

Intravenous lines provide both a break in the skin, allowing entry of organisms, and a protected site for bacterial growth shielded from immune defences by a biofilm of platelets, fibrin and bacterial slime. The risk is greater with increasing age of the line, central and multi-lumen lines, and poor insertion technique or line care, leading to infection of the insertion site or hub. Pre-existing skin disease and colonization with pathogens such as MRSA, also increase the risk of infection. The heavy normal flora of the groin means that femoral lines are often infected, despite careful insertion technique.

Presentation and diagnosis – line infections present with septicaemia or obvious infection of the exit site or tunnel, or are silent. Other sequelae (which may manifest only after line removal) include endocarditis and disseminated abscesses (e.g. spinal, ophthalmic). Blood cultures and culture of the line tip, or exit site if clinically infected, are the usual means of diagnosis. There has been interest in diagnostic methods that avoid line removal (e.g. line brushings, quantitative line blood cultures), but these have yet to gain wide acceptance.

Management – line infections (except some caused by coagulase-negative staphylococci) are almost never eradicated by antibiotics without line removal. Infected lines are sometimes left *in situ*, particularly when intravenous access is difficult, but this increases the risk of septicaemic complications.

Nosocomial chest infections: pneumonia is responsible for about 25% of all nosocomial infections, but the precise diagnosis is often uncertain; in severely ill patients, there may be other explanations for fever, hypoxia and pulmonary infiltrates on radiography (e.g. pulmonary oedema, shock lung, segmental collapse). Furthermore, the respiratory tract of hospitalized patients is often colonized with various organisms, and it is difficult to distinguish colonization from genuine pneumonia, even when deep sample collection techniques (e.g. broncholaveolar lavage) are used. The approach must therefore be pragmatic. Microbiology of respiratory samples should guide treatment in those with clinical and radiological evidence of lung sepsis, but the possibility of under-treatment and over-treatment should be acknowledged.

Most studies implicate a variety of Gram-negative organisms as the predominant causative agents, with doubts over the significance of culture results as described above. *Staph. aureus*, particularly MRSA, is the only commonly implicated Gram-positive organism; pneumococci are seldom isolated, but may be under-diagnosed. Thus, empirical treatment guide-lines for nosocomial pneumonia assume Gram-negatives to be the likely cause, and generally recommend agents with Gram-negative activity (e.g. broad-spectrum cephalosporins).

Hospital-acquired tuberculosis and legionnaire's disease are rare, but important because of their severity and because of the possibility of outbreaks. Any smear-positive TB patient who is not adequately isolated may spread the organism to other patients; unrecognized multidrug-resistant TB poses the greatest risk, because these patients are likely to remain infectious for longer. All non-immune contacts are theoretically at risk, but the greatest risk of progression to disease is in HIV-positive and other severely immunosuppressed contacts.

Legionella infection is acquired from the environment; transmission between patients does not occur. The organism normally inhabits water, preferably at 20–40˚C, and is spread to patients via airborne droplets. Sources within hospitals include water-cooled ventilation systems (formerly the cause of large outbreaks), shower heads and tap water. Patients most at risk include the elderly, those with chronic respiratory disease, and the immunosuppressed, particularly recent transplant recipients. The infection presents as severe pneumonia; the organism grows poorly, so diagnosis usually depends on serology or urinary antigen detection.

Surgical site infections: despite asepsis and antibiotic pro-phylaxis, surgical site infections remain common. It is believed that infection usually arises from the patient's own skin flora, inoculated into the wound during surgery; hair follicles and sweat glands cannot be completely sterilized during skin preparation, so no surgical field is completely sterile. Other possible sources include theatre staff (who inevitably shed skin flakes and respiratory droplets during the procedure), perforated gut and contaminated traumatic wounds. These infections usually manifest soon after surgery.

The incidence of infection varies between hospitals and types of surgery. In a recent large English survey, the lowest rates (2–3.5%) were in orthopaedic procedures, and the highest (10–15%) in amputations and abdominal surgery. Severe underlying illness and lengthy operations increase the risk – more than 35% of severely ill patients undergoing prolonged large bowel surgery develop infection. Staphylococci (mostly *Staph. aureus*, 50% of which are MRSA) cause almost 50% of infections; most of the remainder are caused by Gram-negatives, including *E. coli* and *Pseudomonas*.

Most infections are superficial and easily treatable. Deeper infections are rarer, and may be catastrophic, particularly when surgery involves bone, brain, a prosthesis, a vascular graft or a transplant. Group A *Streptococcus* can cause rapidly spreading, often fatal necrotic infections (necrotizing fasciitis).

Urinary tract infections (UTIs): urinary cathers are used routinely in the care of acutely and chronically ill patients, and are responsible for most cases of nosocomial UTI. It is said that bacteriuria develops in 5% of catheterized patients per day; unhygienic insertion technique probably increases the risk, and also increases the risk of cross-infection with other patients' organisms. Greater age, debility and dehydration also increase the risk of UTI. It is important to distinguish asymptomatic bacteriuria from symptomatic infection; the latter occurs in only a minority.

It is reasonable to treat symptomatic infection with anti-biotics, but unless the catheter is removed, the urinary tract will not be sterilized, and may become colonized with antibiotic-resistant organisms. For this reason, it is not recommended to investigate urinary samples from asymptomatic chronically catheterized patients. ◆

Nutrition in Critical Illness

Frankie Dormon

Frankie Dormon is Consultant in Anaesthesia and Intensive Care in Poole, Dorset, UK. She qualified and trained in anaesthesia on the North Thames Circuit and was Consultant in Charge of Intensive Care at Lister Hospital, Stevenage, Hertfordshire, for 10 years. Her main non-clinical interests are teaching PALS, ALERT and CCrISP.

Patient nutrition is an often neglected aspect of the overall management of patients, but 50% of surgical patients suffer protein energy malnutrition. Sepsis, injury and starvation are the main contributors to postoperative morbidity and mortality. Following the initial resuscitation of the critically ill patient, the nutritional status should be assessed and a plan of nutritional management made. It is best to use the enteral route if possible, however adequate calorie intake is often difficult to achieve. The currently available intravenous feeding regimens present a confusing array of mixtures of fat, carbohydrate, amino acids, vitamins and minerals and there are several steps to follow to initiate treatment safely. Many hospitals have a nutrition team, which assists with the management of enteral feed or total parenteral nutrition and helps with monitoring during treatment, but the clinician should have a working knowledge of patient nutrition to initiate a good management plan.

Nutritional requirements

The average 70 kg man requires about 2000 kcal/day. Without food, the body uses glycogen stores and then muscle protein, to provide energy. In the healthy person, the metabolic rate is reduced and stores are conserved. In illness or after surgery, burns or trauma, the following sequence occurs.

- Energy requirements are increased by up to 30%.
- Metabolism is affected by altered levels of catecholamines and cortisol.
- Blood sugar control becomes deranged as patients develop an apparent increased resistance to insulin.
- There are major fluid and electrolyte losses from diarrhoea, vomiting or nasogastric losses, excessive sweating, stoma losses and surgical drains.
- Fluid shifts, caused by leaky membranes or fluid moving into the third space, create difficulties in assessing fluid balance.

Assessing nutritional status

The following identify patients at risk of protein energy malnutrition:

- clinical history (e.g. nausea, vomiting, diarrhoea, abdominal distension, previous surgery, weight fluctuations)
- dietary history (types and amounts of food taken, dysphagia)
- physical examination (weight: height, body mass index (BMI), general appearance).

The following tests can be used to establish the severity of protein energy malnutrition and the response to nutritional intervention:

- anthropometric (skin fold thickness)
- biochemical (albumin, transferrin and pre-albumin)
- immunological (lymphocyte count).

However, they are unspecific, and similar abnormalities may be found in other conditions. In particular, albumin can fall rapidly with sepsis.

Enteral feeding

If the patient has any functional bowel, the enteral route should be used if possible. The best nutrition comes from a balanced diet that is chewed, swallowed and digested. Gut motility is influenced by hormones released during mastication. Stomach emptying controls the delivery of food to the jejunum to maximize absorption. The gut mucosa is more likely to retain its normal function if it is bathed in the correct nutrients. The large bowel requires an adequate amount of fibre to ensure regular soft bowel actions. As soon as any of these aspects of feeding are defective, the absorption of nutrients is affected. Factors that reduce the chances of successful enteral feeding are shown in Figure 1. Problems associated with enteral feeding are listed in Figure 2.

Factors that reduce the chances of successful enteral feeding

Inadequate swallow due to:

- Sedation
- Intubation/tracheostomy
- Pharyngeal dysfunction
- Oesophageal disease
- Surgery

Reduced gastric emptying and/or gut motility

- Opioids
- Pain/anxiety
- Postoperative gastric stasis
- Pyloric swelling

Suture lines – perceived risk of anastomotic leak

Paralytic ileus

1

Problems associated with enteral feeding

Problem	Management
• Large gastric aspirates	Use prokinetics (e.g. metoclopramide, erythromycin)
• Diarrhoea	Give fibre feed, examine stool specimen for *Clostridium difficile*, check for faecal impaction and overflow
• Patient can't or won't have a nasogastric tube	Use gastrostomy
• Distended abdomen	Check for constipation, paralytic ileus
• Aspiration/regurgitation of feed causing lung contamination	Monitor gastric residual 4-hourly Limit volume of feed used or use parenteral route
• Failure to deliver target volume	Follow local unit protocol, avoid stopping feed unless absolutely necessary

2

Routes of enteral feeding

Nasogastric feeding is the most commonly used route, but it relies on adequate gastric emptying. Sometimes it is impossible to pass the nasogastric tube or maintain its position. Feed is usually started at about 30 ml/hour via a continuous infusion pump and increased slowly, provided the gastric residue after 4 hours does not exceed 200 ml. Regimens aim for a maximum calorie intake that is dependent on weight and general condition.

Nasojejunal feeding avoids the pylorus and is used in patients with gastric stasis. Nasojejunal tubes are more difficult to pass and often require insertion under direct fibre-optic observation. Feeds are started at about 30 ml/hour. Absorption is assessed by checking for abdominal discomfort and distension.

Percutaneous gastric feeding – using an endoscopic technique, a tube is passed percutaneously into the stomach to avoid the discomfort of a nasogastric tube. These can be used for continuous or bolus feeds. They are commonly used in patients requiring long-term enteral feeding, such as those with cerebral palsy, after head injury and following major maxillo-facial surgery.

Percutaneous jejunal feeding – the percutaneously placed tube passes from the stomach into the jejunum. This route is sometimes used for postoperative feeding if gastric stasis is likely and a nasojejunal tube cannot be passed.

Type of enteral feed

Most enteral feeds are a mixture of fat, carbohydrate, protein, water, electrolytes, minerals and fibre (Figure 3). Standard feeds have about 1 kcal/ml, but more concentrated versions are available with about 1.5 kcal/ml. Energy is delivered as fat and carbohydrate.

Approximate combinations of nutrients in enteral feeds

	Elderly/Frail	Normal	Sepsis
Protein (nitrogen)	8–10 g	10–16 g	16–20 g
Carbohydrate	700 cal	1000 cal	1200 cal
Fat	700 cal	1000 cal	1200 cal
Total calories (non-nitrogen)	1400 cal	2000 cal	2400 cal
Total volume	2.5 litres	2.5 litres	3.0 litres

3

Some specialist feeds (e.g. *Pulmocare*) provide a greater percentage of calories as fat (by providing fewer calories derived from carbohydrate, the amount of carbon dioxide produced is reduced, thereby assisting ventilatory weaning in some patients). Other specialized feeds (e.g. elemental solutions of amino acids or peptides) are available for patients with short-bowel syndrome, malabsorption or severe inflammatory bowel disease. Extra food supplements can also be used to provide extra fat or carbohydrate.

Weaning off enteral feed

Many patients return to general wards on established enteral feed. Weaning back to a normal diet can be best achieved by its introduction during the day and continuing with enteral feed at night, reducing the night feeds as the daytime feed increases. The normal daytime diet can be supplemented by sip feeds comprising sachets of easy-to-digest, milk-based, flavoured feed. Ward nursing staff should be encouraged to keep a clear record of nutritional intake, remembering that nutrition stops for surgery and investigations. Intake is also affected if patients do not like the food offered, are unable to open the packaging or incapable of feeding without assistance. Ward dietitians have an important role in advising on nutritional requirements and can be helpful in finding suitable food supplements to suit an individual patient's needs.

Parenteral feeding

When the bowel is not functioning, unable to be used or all attempts at feeding using this route have failed, parenteral nutrition is indicated. A multidisciplinary nutrition team including doctors, nurses, pharmacists and dietitians can improve the efficacy of total parenteral nutrition (TPN). Insertion of a feeding line is usually undertaken by doctors and cared for by nurses; the dietitian can advise on nutritional requirements and the pharmacist can recommend nutritional preparations and additives. The whole team has a role to play in the continuing care of the feeding line, monitoring of response to therapy and audit of complications.

Patient selection

Common reasons for requiring TPN are:

- post surgery – if bowel function is likely to be disturbed
- short-bowel syndrome
- gastrointestinal fistulae
- prolonged paralytic ileus
- inflammatory bowel disease
- preoperatively – in malnourished patients with ineffective bowel function.

Sepsis, severe burns and pancreatitis were also considered reasons for using the parenteral route, but enteral nutrition is now recognized as more appropriate. In some cases, a combination of parenteral nutrition and enteral feed may be used.

Venous access

Ideally, TPN should be given via a tunnelled subclavian vein central line. The incidence of catheter-associated infection can be reduced by meticulous care during insertion, using a full aseptic technique. A post-insertion, chest radiograph should be taken to exclude a pneumothorax and to check that the catheter tip lies in the inferior vena cava (such positioning reduces the risk of thrombosis). To reduce the risk of catheter-related sepsis, the feeding line should be used for TPN only, and no other drugs or fluids should be given through the catheter nor should the line be used for blood sampling. Some mixtures of TPN are specially formulated to be given peripherally for short-term treatment, but intravenous lines used for such a purpose generally have a short life.

Choice of mixture

TPN solutions should contain a balanced mix of protein, carbohydrate and lipid, together with water, vitamins, electrolytes and minerals. Generally TPN is produced in large bags containing all the requirements for 24 hours. Protein is provided as a balanced solution of essential (40%) and non-essential (60%) amino acids.

Lipid emulsions are used because it is possible to supply a large amount of energy in a small volume (9 kcal/g), which is non-irritant to veins. Glucose (4 kcal/g) is used as the main source of carbohydrate, but requires close control of blood sugar. Feeds with a high proportion of glucose may delay weaning from ventilation in some patients, because they sometimes cause excess carbon dioxide production. Other micronutrients must be added to mixtures to avoid deficiency after a few days. These include vitamins and trace elements, which are usually added to the bags in the pharmacy. Electrolytes can be added if required. Phosphate supplements may be required in considerable amounts in patients with malnutrition.

Monitoring

when the intravenous route is chosen for feeding, it is important that the correct nutrients are given in the correct proportions to avoid serious derangement of electrolytes, blood sugar and fat metabolism. Figure 4 lists the routine investigations that should be undertaken.

Monitoring for patients being given parenteral feeding

Investigation	Frequency	Comment
Blood sugar	4 hourly until stable 6–12 hourly when stable	Patients may require insulin therapy – good glycaemic control is important in critical illness
White cell count	Daily	Rising white count may be first sign of developing sepsis
Electrolytes	Daily	May need additional potassium in daily bag
Urea/creatinine	Daily	Initially to ensure renal function, longer term to guide nitrogen requirements
Calcium/phosphate	Twice weekly	Phosphate can fall dramatically at start of treatment. Hypocalcaemia is common in pancreatitis and sepsis
Plasma lipidaemia	Twice weekly	Liver may not clear lipid infusions
Liver function tests	Twice weekly	Albumin may indicate efficacy of treatment, total parenteral nutrition can cause fatty liver and raised liver enzymes
Plasma transferrin and pre-albumin	Weekly	Assessment of efficacy of treatment
Urinary urea	Alternate weeks	To aid assessment of nitrogen balance
Trace elements (e.g. zinc, copper, iron, selenium)	Alternate weeks	These may become deficient after several weeks' treatment

Recent advances

The constituents of TPN have been modified and simplified over the past few years. The use of a single bag every 24 hours reduces the infection risk by reducing the need to handle the line connections. Several companies have special bags that allow mixing of the constituents immediately before use without the risk of contamination, this increases the shelf-life of the product and enables the pharmacy to supply TPN almost on demand. The vitamins and minerals required are available in single-day vials for addition immediately before use.

Recent research on immunotherapy suggests that the addition of substances such as glutamine, arginine and the omega-3 fatty acids, may enhance the immune response during critical illness. Recent work suggests that blood sugar control in a tight range reduces mortality in critical care patients. ◆

Organ Donation and Maintenance of the Multiple Organ Donor

Suzie J Tanser
Gary B Smith

Suzie J Tanser is Specialist Registrar in Anaesthesia, Royal Navy – Southampton General Hospital. She qualified from St Bartholomew's Hospital, London, then joined the Royal Navy. She trained in anaesthesia and intensive care in Plymouth, Exeter, Portsmouth, Southampton and London and completed advanced training in intensive care in 2001.

Gary B Smith is Consultant in Intensive Care Medicine at Portsmouth Hospital NHS Trust and Honorary Senior Lecturer in Critical Care in the School of Postgraduate Medicine at the University of Portsmouth. After qualifying from the University of Southampton, he trained in anaesthesia and medicine in the South of England and at Yale University, USA. His main interests are multiprofessional education, cardiopulmonary resuscitation and pre-hospital trauma care.

The first reported human-to-human transplant involved corneal grafting and was carried out in Czechoslovakia in 1905. Today, corneas can be stored in an eye bank for up to 30 days, enabling over 2000 transplants to take place in the UK every year. The first successful kidney transplant was performed between two identical twins in the USA in 1954. Improvements in surgery and anti-rejection therapy have led to 75% 5-year functional survival for transplanted kidneys. In 1983, the first combined heart and lung transplant was performed at Harefield Hospital, UK. Today, there are nine UK heart and lung transplant centres and seven UK liver transplant centres. There is a shortage of all human organs for transplantation, partly because of reduced death rates from road-traffic accidents and the loss of public confidence following 'scandals' regarding organ removal. Consequently, it is vital that when suitable organs become available, they are maintained and used appropriately.

Criteria for donation

Living donors (usually first-degree relatives) can donate one kidney, a lung or liver lobe without adverse clinical effect. Corneas, heart valves, bone and skin can be donated up to 24 hours after asystole. The need to maintain structural and functional integrity in other organs dictates that they are usually removed from 'beating heart' donors (i.e. those with brainstem death whose breathing is maintained on a ventilator), though kidneys are occasionally removed in asystole. General criteria for donation are:

- the donor should be 0–75 years (age ranges change regularly)
- diagnosis of brainstem death must have been made according to current criteria
- respiratory support is being maintained (not always necessary for kidney donation)
- no evidence of malignancy (except certain primary brain tumours)
- no evidence of transmittable infection (Figure 1)
- no objection by the Coroner or, in Scotland, the Procurator Fiscal.

If the potential donor fulfils the above criteria, an adequately trained and informed member of staff should approach the family for 'informed assent' to remove organs. The family may decline the offer or stipulate which organs can be removed. Tissues for research may be taken only if this has been agreed by the family or the deceased. Most major religious and cultural groups support transplantation, but some have specific objections. The involvement of a religious leader may be helpful. Once assent has been obtained, the transplant co-ordinator begins the process of organizing the donation process.

Contraindications to organ donation

Infections
- HIV/AIDS
- Hepatitis
- CJD
- Malaria
- Syphilis
- Tuberculosis
- Rabies
- Major systemic sepsis
- CNS disease of unknown aetiology

Malignancies
- Leukaemia
- Lymphoma
- Myeloma
- Any tumour affecting the organ to be transplanted

1

Donation process

Potential contraindications to donation must be identified at an early stage. This often involves detailed, sensitive and explicit questioning of the potential donor's family to exclude the possibility of communicable diseases and to identify possible risk factors (Figures 1 and 2). A full medical and social history should be obtained and a range of supporting laboratory tests undertaken:

- tissue typing
- virology (hepatitis B and C, HIV infection, cytomegalovirus)
- haematology (blood group, cross-match, full blood count, coagulation screen)
- biochemistry (urea and electrolytes, creatinine, liver function tests)
- arterial blood gas analysis
- 12-lead ECG
- chest radiograph
- microbiology (culture and sensitivity results).

Risk factors for communicable disease

People at risk include those:
- who have ever injected themselves with drugs
- who have ever worked as prostitutes
- men who have ever had sex with another man
- who have ever had sex with anyone living in Africa
- who have been treated for haemophilia
- who received human growth hormone before 1985
- who have a family history of CJD
- who have had malaria, rabies or tuberculosis
- who have ever had a neurological disorder of unknown origin
- who have ever had sex with anyone from the above list

2

Organ removal occurs in the referring hospital; the operating theatre co-ordinator should be informed. The transplant co-ordinator organizes the arrival of the retrieval team(s). The donation process may take 12–18 hours, therefore the family may require considerable psychological support.

Physiological changes following brainstem death

Following brainstem death, there is loss of autonomic and endocrine homeostasis. If left untreated, these eventually lead to asystole, usually within 72 hours.

Cardiovascular instability – ischaemia of the brainstem causes an increase in sympathetic outflow to maintain cerebral perfusion. This 'sympathetic storm' may cause arrhythmias, myocardial ischaemia or infarction. Brainstem death results in a loss of sympathetic tone and progressive hypotension. Hypovolaemia due to use of diuretics, mannitol or diabetes insipidus may compound this problem. Arrhythmias due to previous infarction, electrolyte imbalance or hypothermia are common.

Pulmonary effects – the sympathetic storm may cause pulmonary capillary damage; pulmonary oedema occurs in up to half of brainstem-dead patients. Progressive hypoxaemia due to aspiration or infection is also common.

Endocrine failure – there is dysfunction of the hypothalamic–pituitary axis, leading to a fall in circulating cortisol, insulin and free triiodothyronine. This causes electrolyte imbalance, abnormal cellular metabolism, hyperglycaemia and myocardial depression. Diabetes insipidus, due to loss of posterior pituitary function, occurs in about 65% of brainstem-dead patients and results in hypovolaemia and electrolyte abnormalities.

Temperature regulation – the thermoregulatory centre is situated in the hypothalamus; brainstem death causes poikilothermia. Hypothermia results from loss of heat by conduction, convection and radiation, combined with lack of muscular activity, a low metabolic rate and loss of vasomotor tone.

Clinical management of the organ donor

Once brainstem death is diagnosed, the management of the 'donor' is directed to maintaining optimal organ perfusion and oxygenation with a normal fluid, electrolyte and acid–base balance.

Cardiovascular and electrolyte management – particular attention is required if diabetes insipidus occurs, because incorrect replacement of hypotonic urine with salt-containing isotonic solutions causes hypernatraemia. Care should be taken with the choice of site for vascular cannulae. Where possible the arterial cannula is best situated in the left arm and the central venous catheter in the right internal jugular vein. The use of adrenaline (epinephrine) may result in organ ischaemia and preferably is avoided. Dopamine, dobutamine or noradrenaline (norepinephrine) may be used in low doses; suggested goals are:

- mean arterial pressure over 60 mm Hg
- central venous pressure 6–12 mm Hg
- urine output 1–2 ml/kg/hour
- potassium greater than 4.5 mmol/litre.

Respiratory support – the lowest possible fraction of inspired oxygen (FiO_2) should be used. Positive end-expiratory pressure (PEEP) of 5 cm H_2O or over improves oxygenation, prevents airway collapse and limits pulmonary oedema. Carbon dioxide production falls after brainstem death, therefore a reduction in delivered minute volume may be appropriate (best achieved by reducing rate, rather than tidal volume, to prevent airway collapse). Strict asepsis should be maintained when undertaking tracheal toilet, and sputum samples should be sent for microbiological surveillance. Suitable targets are:

- partial pressure of oxygen in arterial blood (PaO_2) over 10 kPa
- $PaCO_2$ 4.5–5.5 kPa
- PEEP 5–7.5 cm H_2O
- FiO_2 less than 40%.

Endocrine replacement improves haemodynamic instability, reduces inotrope requirements and delays asystole. Suggested regimens for adults include:

- antidiuretic hormone (ADH) (vasopressin): bolus 1 unit, infusion 1.5–4 units/hour
- triiodothyronine (T3): bolus 4 μg, infusion 3 μg/hour
- hydrocortisone, 5 mg/kg, or methylprednisolone, 30 mg/kg
- insulin to maintain blood glucose at 4–6 mmol/litre.

Other management issues – the donor's temperature should be maintained using warmed fluids, warmed humidified gases and forced air, and warming blankets. Up to one-third of patients may develop disseminated intravascular coagulation owing to the release of plasminogen activators from dead brain tissue. Coagulopathies may require corrective treatment with blood products; the haematocrit should be maintained at 30%.

Anaesthetic considerations – brainstem-dead patients do not require analgesia or sedation, but may have intact spinal reflexes that cause hypertension or muscular contractions during surgery. Neuromuscular blocking agents and anaesthetic agents or opiates should be used to prevent reflex contractions and perioperative hypertension, respectively. Temperature may fall rapidly following skin incision, predisposing to ventricular fibrillation. Blood loss may be considerable and this should be replaced until circulatory arrest occurs.

Follow-up – the final care of the donor should be identical to that of any other patient who has died. The time of death is recorded as the time of completion of the first set of brainstem death tests. The transplant co-ordinator usually writes to the donor's family within 2 weeks of donation to thank them and inform them of the outcome of the recipient operations. ◆

Organization of and Admission Criteria for High Dependency and Intensive Care Units

Simon Mackenzie

Simon Mackenzie is Consultant in Anaesthesia and Intensive Care at the Royal Infirmary, Edinburgh, UK. His research interests include cardiovascular support, acute liver failure and the use of severity scoring systems in critical illness.

The term 'critical care' is increasingly used to encompass both intensive and high dependency care, but there are important differences between them in terms of organization, patients and treatments.

- Intensive care is 'a service for patients with potentially reversible conditions who can benefit from more detailed observation and invasive treatment than can safely be provided in general wards or high dependency areas'.
- High dependency units (HDUs) provide a level of care intermediate between an ordinary ward and an ICU.

In some hospitals, one area may fulfil both roles: this may be appropriate when separate units would be small and lack flexibility.

Organization

Intensive care
ICUs require a nurse:patient ratio of 1:1, a resident doctor without other duties and consultant cover throughout 24 hours. Few consultants are full-time intensivists, but they should not have other duties while covering the ICU. Most ICUs are 'general', though some support a specific specialty. In the UK, a typical unit contains six beds; this is small in comparison with those in other European countries and the USA. Larger UK units may have greater flexibility to cope with fluctuating demand, but do not necessarily have better outcomes or lower costs. An ICU where care is provided by a team of intensivists, supported by other clinicians when requested, is described as a 'closed' unit. A unit in which patient care is delivered by more than one group of doctors is termed an 'open' unit. In the UK, the latter is more common, though the former may be associated with better outcomes.

High dependency care
For most hospitals, HDUs are a recent development. Many are specialty, usually surgically, based though general units are preferable. HDUs provide greater monitoring and nursing input than is given on general wards, may provide support for single-organ failure (but not ventilation) and can act as a 'step down' area for patients between the ICU and the general ward. The nurse:patient ratio on an HDU is 1:2. There is seldom a resident doctor. Patients are admitted and cared for by their referring team, the members of which will have duties elsewhere. The ICU staff may be involved in aspects of management, but will not be the principal caring team.

Admission criteria

Admission criteria must be practical and ethical. The precise indications for admission depend on the particular unit and the other acute care facilities available. The decision about admission to ICU is a clinical one for the ICU consultant. It is based on the patient's present condition, the treatment possible, the likely response, co-morbidities and the patient's wishes. Scoring systems used for ICU audit (e.g. APACHE, SAPS or MPM, see page 94) cannot be used for individual patient prognostication or admission decisions. Chronological age influences survival after intensive care, but should not be the sole arbiter for ICU admission. Indeed, limited physiological reserve means that elderly patients may require admission to the ICU or HDU in cases where younger patients would not. Similar considerations apply to patients with chronic disease, but patients with irreversible progression of chronic disease should not be admitted.

When to admit
In principle, patients should be referred early and by a consultant. The working arrangements of many hospitals make this difficult to achieve. Many patients are referred late in their illness, after potentially avoidable deterioration, which may include cardiac arrest. To overcome this, some hospitals have developed an emergency team that accepts calls from nursing or medical staff in an attempt to ensure early referral. Typical criteria for referral are given in Figure 1. Late admission may be partly the result of a lack of ICU beds, but staff attitudes are also important. Doctors outside the ICU may fail to appreciate what an ICU can offer or may see ICU referral as an admission of failure. Doctors within the ICU may give the impression that they are too busy to be bothered with patients who are not 'really sick'.

Specific criteria for ICU referral

Airway
- Actual or threatened airway obstruction
- Impaired ability to protect airway

Breathing
- Respiratory rate < 8 or > 30
- Respiratory arrest
- Oxygen saturation < 90% on 50% oxygen
- Worsening respiratory acidosis

Circulation
- Pulse < 40 or > 140
- Systolic blood pressure < 90 mm Hg
- Cardiac arrest
- Metabolic acidosis [H^+] > 62 nmol/litre
- Urine output < 0.5 ml/kg/hour

Neurological
- Repeated or prolonged seizures
- Decreasing conscious level

General
- Patient causing concern to medical, nursing, physiotherapy staff

Note
Much depends on whether there is an identified and easily remediable cause. It is the start of an adverse trend despite treatment that is important

Source: McQuillan *et al. BMJ* 1998; **316**: 1853–8.

1

Who to admit and where
Patients who require tracheal intubation and ventilation should be admitted to an ICU, as should patients who require support for two or more organ systems (Figure 2), even if they do not require ventilation (Figure 3). Patients who require close monitoring rather than organ support can usually be managed in an HDU, as can many with single-organ failure (except those who require ventilation).

Classification of organ system monitoring and support

Advanced respiratory support
- Mechanical ventilatory support (excluding mask continuous positive airway pressure or non-invasive ventilation)
- Possibility of sudden, precipitous deterioration in respiratory function requiring immediate tracheal intubation and mechanical ventilation

Basic respiratory monitoring and support
- Need for more than 40% oxygen via a fixed performance mask
- Possibility of progressive deterioration to the point of needing advanced respiratory support
- Need for physiotherapy to clear secretions at least 2-hourly
- Patients recently extubated after prolonged intubation and ventilation
- Need for mask, continuous positive airway pressure or non-invasive ventilation
- Patients intubated to protect the airway but not requiring ventilation

Circulatory support
- Need for vasoactive drugs to support arterial pressure or cardiac output
- Support for circulatory instability due to hypovolaemia from any cause which is unresponsive to modest volume replacement
- Patients resuscitated after cardiac arrest where intensive or high dependency care is considered clinically appropriate

Neurological monitoring and support
- CNS depression, from whatever cause, sufficient to prejudice the airway and protective reflexes
- Invasive neurological monitoring

Renal support
- Need for acute renal replacement therapy

Notes
- Patients requiring advanced respiratory support should be admitted to ICU
- Patients requiring support of two or more organ systems should be admitted to ICU
- Patients requiring single-organ support may be suitable for high dependency rather than intensive care

2

3 Intensive care treatment of a patient with multiple organ failure.

Respiratory: patients may be referred with hypoxaemia or ventilatory failure. The decision to ventilate a patient may be based on blood gas results, but is usually made on clinical criteria. Patients who are clearly exhausted (e.g. confused, unable to talk, using accessory muscles) and not responding to treatment should be ventilated before respiratory arrest ensues, irrespective of their blood gases. Some patients with hypoxaemia and dyspnoea may respond well to continuous positive airway pressure in the HDU.

Cardiovascular: patients with deteriorating tissue perfusion (e.g. cool peripheries, peripheral cyanosis, reduced skin turgor, slow capillary refill, oliguria, reduced conscious level and metabolic acidosis) should be referred to ICU. Metabolic acidosis is often overlooked when interpreting blood gas or biochemistry results. Patients in shock may have surprisingly normal blood pressure. Although oxygen and fluids are almost invariably required, the underlying cause of shock must be diagnosed and treated. Patients requiring large-volume fluid replacement, central venous pressure monitoring or vasoactive drugs should be admitted to an HDU or ICU.

Neurological: many patients with impaired consciousness caused by head injuries, intracranial haemorrhage, meningitis, encephalitis, drug overdose, hepatic encephalopathy, hypoxia or other causes require admission to the ICU or HDU. Airway obstruction, absent airway reflexes, hypoxaemia, and hypoventilation are all indications for intubation and controlled ventilation. Patients with severe head injuries require ventilation with intracranial pressure monitoring.

Intravenous anaesthetic agents may be used to control recurrent seizures, but they should be administered in an ICU.

Patients with neuromuscular diseases (e.g. Guillain–Barré, myasthenia gravis) may require ventilatory support if airway reflexes are impaired or vital capacity is reduced (< 1000 ml).

High-risk surgery: the perioperative risk of major non-cardiac surgery is high, as is the risk of more modest surgery in patients with significant cardiorespiratory disease. Surgery produces a predictable, but temporary, physiological stress, and such patients can benefit greatly from admission to HDU or ICU postoperatively. Some advocate admission before surgery for 'pre-optimization', aiming for a cardiac index of 4.5 litre/minute/m^2 and oxygen delivery of 600 ml/minute/m^2. Although pre-optimization remains controversial, the value of good perioperative care is established.

Who not to admit

Patients should not be admitted to the ICU if they are too well, if they refuse or if they are too ill to benefit. Admitting patients who are too well wastes resources and exposes the individuals to potential complications.

Patients have the same right to refuse intensive care as they do any other treatment. If they are unable to express a view (e.g. because of coma), discussion with the relatives may be helpful in ascertaining the patient's wishes. Any advance directive should be respected, but, in practice, these are uncommon and may be ambiguous.

Patients should not be admitted if further treatment is futile, whether this is because of co-morbidity or the acute illness. This is often difficult to judge and may be best resolved by a trial of therapy. There is increasing concern that patients may survive but have a poor quality of life. However, doctors should be careful not to make decisions based on their own opinion of another individual's existing or future quality of life.

Oxygen Delivery and Uptake

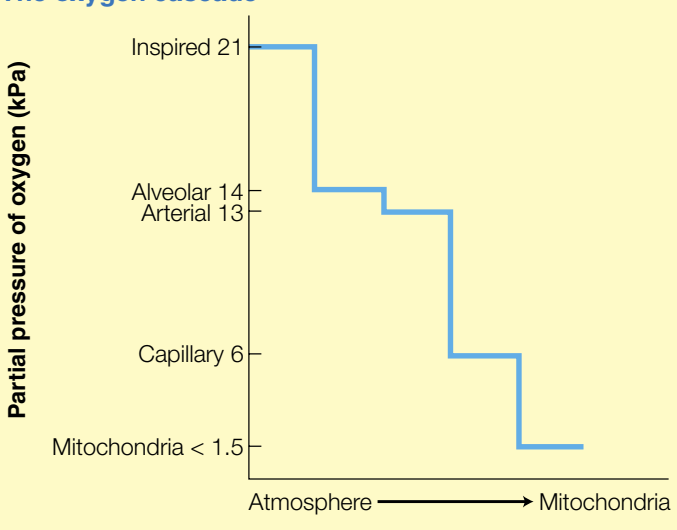
Jeremy M Reid
Ravi Gill

Jeremy M Reid is Specialist Registrar in Anaesthetics at Portsmouth Hospitals NHS Trust. He qualified from Southampton University Medical School. He trained in general medicine and cardiology in Wessex and the South West of England before deciding on a career in anaesthetics. He has an interest in intensive care medicine.

Ravi Gill is Consultant Cardiac Anaesthetist in Southampton, UK. He qualified from Southampton University and trained in anaesthesia at St Thomas' Hospital, London and Southampton, and in critical care in London, Ontario, Canada.

Oxygen is transported from the atmosphere to the tissues where it is used in the mitochondria to produce high-energy phosphate bonds. The declining partial pressure of oxygen as it is transported from the atmosphere to the mitochondria is described by the oxygen cascade (Figure 1).

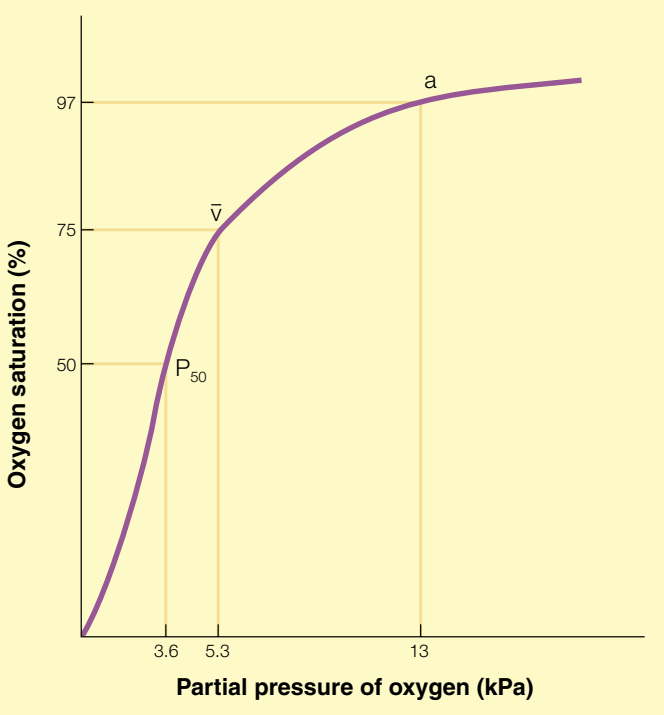
The oxygen cascade



Oxygen carriage in blood

Oxygen in the alveolus diffuses across the pulmonary capillary membranes; in the capillaries it is bound to haemoglobin and dissolved in plasma. The amount of oxygen dissolved in plasma is proportional to its partial pressure (Henry's law) and represents 0.023 ml/100 ml blood/kPa. Oxygen is transported more efficiently when bound to haemoglobin (an iron-porphyrin compound of four polypeptide chains bound to a protein – globin), forming a readily reversible compound known as oxyhaemoglobin. The degree of binding depends on the number of polypeptide chains bound to oxygen. Increased oxygen binding leads to the sigmoid shape of the oxygen dissociation curve (Figure 2). Oxygen loading and unloading differs according to the shape of this curve. Oxygen delivery to the tissues is facilitated by a right shift of P_{50} (the partial pressure of oxygen at which 50% of haemoglobin is saturated) caused by acidosis, raised partial pressure of carbon dioxide in arterial blood ($PaCO_2$), increased temperature and elevated levels of RBC 2,3-diphosphoglycerate.

Oxygen dissociation curve



P_{50}, partial pressure of oxygen at which 50% of haemoglobin is saturated; $\bar{v}$, partial pressure/oxygen saturation of mixed venous blood; a, partial pressure/oxygen saturation of arterial blood.

Oxygen delivery
Oxygen delivery (DO_2) = blood flow x arterial oxygen content of blood (CaO_2)

$$CaO_2 = (Hb \times O_2 \text{ saturation}/100 \times 1.39) + 0.023\ PaO_2$$

where: Hb is haemoglobin concentration in g/dl (theoretically 1 g of pure Hb can combine with 1.39 ml of oxygen); PaO_2, partial pressure of oxygen in arterial blood measured in kPa (0.023 PaO_2 is the amount of dissolved oxygen in 100 ml blood where $PaO_2$is measured in kPa).

A worked example concerning oxygen delivery to the body as a whole is given below.

DO_2 = cardiac output x blood oxygen content
Assume Hb = 15 g/dl
Assume blood to be 100% saturated and the partial pressure of oxygen to be 13 kPa
Assume cardiac output to be 5 litre/minute (i.e. 50 dl/minute)
$DO_2 = 50 \times [(1.39 \times 1 \times 15) + 0.023 \times 13]$ ml/minute
$DO_2 = 50 \times (20.85 + 0.3) = 1056$ ml/minute
Therefore DO_2 is about 1000 ml/minute
Note that the value for dissolved oxygen under normal conditions is so small (0.3 ml/100 ml of blood) that in most clinical situations it may be discounted

Factors affecting oxygen delivery
The oxygen flux equation shows that the factors affecting oxygen delivery to the tissues are:

- cardiac output or regional blood flow
- haemoglobin concentration and abnormal haemoglobin (e.g. carboxyhaemoglobin, methaemoglobin)
- oxygen saturation (related to the partial pressure of oxygen by the dissociation curve).

Manipulating these factors may alter oxygen delivery. For instance, cardiac output may be increased by the use of fluids, inotropes or peripheral vasodilators. Haemoglobin concentration may be increased by the use of RBC transfusion, though transfusion may cause a drop in cardiac output and may not increase overall oxygen delivery. The optimum level of haemoglobin varies depending on the clinical circumstance and remains the subject of great debate. Under normal conditions, blood in the pulmonary capillaries is almost 100% saturated and therefore increasing the concentration of inspired oxygen has little effect on global oxygen delivery. However, if the alveolar/capillary membrane is diseased (e.g. by pneumonia, aspiration) increasing the inspired oxygen concentration may be beneficial. Manipulation of the above factors may be important because the outcome of some high-risk surgical patients has been linked to augmentation of oxygen delivery.

Oxygen uptake

The equation that quantifies single-organ or whole-body oxygen uptake is based on the Fick principle. Using this formula, the saturation of mixed venous blood (SvO_2) reflects the overall degree of oxygen consumption. A worked example, assuming that the saturation of mixed venous blood is 75% and that its partial pressure of oxygen is 5.3 kPa, is provided below.

Oxygen uptake (VO_2) = cardiac output x (arterial O_2 content – mixed venous O_2 content)
$VO_2 = 50 \times \{[(1.39 \times 1 \times 15) + 0.023 \times 13] – [(1.39 \times 0.75 \times 15) + 0.023 \times 5.3]\}$ ml/minute
$VO_2 = 50 \times (21.15 – 15.76) = 269.5$ ml/minute
Therefore global oxygen uptake is about 250 ml/minute

VO_2, calculated using SvO_2, represents the adequacy of whole- body oxygen consumption. SvO_2 is the 'flow-weighted' average of the venous drainage from various tissues. Therefore SvO_2 may be little changed despite severe hypoxia in a tissue receiving little blood flow. SvO_2 also remains relatively normal if cells are unable to utilize the oxygen delivered to them. A clinical example is cyanide poisoning. As cardiac output falls, oxygen is more avidly extracted by tissues and therefore mixed venous oxygen saturation falls.

Relationship between oxygen delivery and uptake

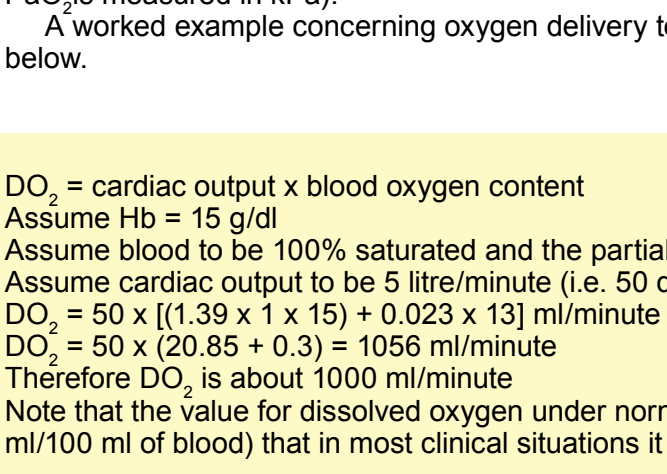
Oxygen delivery is considerably greater than uptake, providing a large margin of safety. To meet metabolic demands, oxygen utilization may need to rise 12-fold. In normal subjects, cardiac output is able to increase only six- or seven-fold, therefore the oxygen extraction ratio (O_2ER) must also be increased if metabolic demands are to be met.

$$O_2ER = VO_2/DO_2$$

VO_2 seldom exceeds DO_2, though it may in a hypermetabolic disease (e.g. sepsis). Usually DO_2 decreases as a result of myocardial failure or haemorrhage and VO_2 is maintained by increasing O_2ER until DO_2crit is reached. DO_2crit is the critical value of oxygen delivery at which oxygen consumption becomes supply dependent (i.e. the point of inflexion in Figure 3). At this point, oxygen extraction is maximal. The amount of oxygen that can be taken up by the tissues is then dependent on the amount of oxygen delivered.

Many studies have examined the relationship between oxygen delivery and uptake. Unfortunately many of them are flawed because they calculate both oxygen delivery and uptake from shared variables with the potential for artefactual results, termed mathematical coupling. Ideally, studies should use independent methods of measuring oxygen uptake and delivery. Further work is needed to clarify the relationship between oxygen delivery and uptake in humans in a clinical setting, before these measurements can be used to guide treatments aimed at improving clinical outcome.

Relationship between oxygen delivery and uptake



As oxygen delivery (DO_2) decreases, oxygen uptake (VO_2) is maintained at the required level by increasing oxygen extraction. VO_2 is independent of delivery over this portion of the curve. When oxygen extraction is maximal (DO_2crit), uptake becomes dependent on supply as demonstrated by the sloping portion of the curve.

The Postoperative Patient in the ICU

Martin Street

Martin Street is Consultant in Intensive Care Medicine at the Royal Sussex County Hospital, Brighton, UK. He qualified from Birmingham University and trained in intensive care in Australia.

The major reasons for admitting patients to an ICU in the postoperative period are the extent of surgery and the presence of significant co-morbidity. This period presents particular physiological challenges, but with the application of resources available in the ICU (Figure 1) patient outcome is improved.

Regardless of the surgical procedure, the clinical management of patients in the ICU has common therapeutic goals.

Resources available in the ICU

- Increased nursing staff levels
- Increased medical staff levels
- Availability of invasive monitoring
- Availability of respiratory support
- Comprehensive understanding of the complex pathophysiology in the postoperative period
- Early warning of complications
- Higher levels of physiotherapy support
- Reduction in perioperative morbidity

Maintenance of tissue perfusion

Multiple organ dysfunction syndrome (MODS) is a leading cause of death in non-cardiac ICUs, with a mortality of more than 50%. Treatment of MODS is largely supportive, therefore its prevention is vital. Current thoughts regarding its generation involve the 'two-hit' theory – an initial insult primes the host response and a second insult leads to a massive release of stress hormones, causing profound cardiovascular and pulmonary changes, and the activation of endothelium complement and clotting pathways. The initial insult can be multifactorial, including infection, trauma, pancreatitis and prolonged shock. Second insults include reperfusion injury, hypoxia and infection. The maintenance of tissue perfusion into the postoperative period is therefore crucial.

It is not clinically possible to measure tissue perfusion at a microvascular level, therefore there is reliance on whole-body estimations of cardiac output, oxygen delivery, mixed venous saturation and blood lactate. In the absence of peripheral vascular disease, estimating the temperature gradient along the limb may give a rough guide to limb perfusion, but more sophisticated estimations may be made by invasive monitoring. Careful monitoring of cardiac filling pressures (central venous or pulmonary capillary wedge pressures) together with cardiac output enables precise titration of fluids and inotropic drugs.

Renal circulation: adequate urine output (> 0.5 ml/kg/hour) has traditionally been seen as a marker for adequate renal vascular perfusion. However, previous administration of loop diuretics may give false reassurance that the patient is adequately hydrated, while coexisting cardiac failure and oliguria may coincide with water overload. The routine use of low-dose dopamine has not been shown to prevent renal failure.

Splanchnic circulation: the introduction of gastric tonometry to assess the pH of the intramucosal cells lining the stomach is believed by some to indicate adequacy of splanchnic perfusion and is used as a basis for fluid resuscitation. Others have found this less reliable as an end-point for cardiovascular management and trial evidence does not support its routine use.

Maintenance of oxygenation

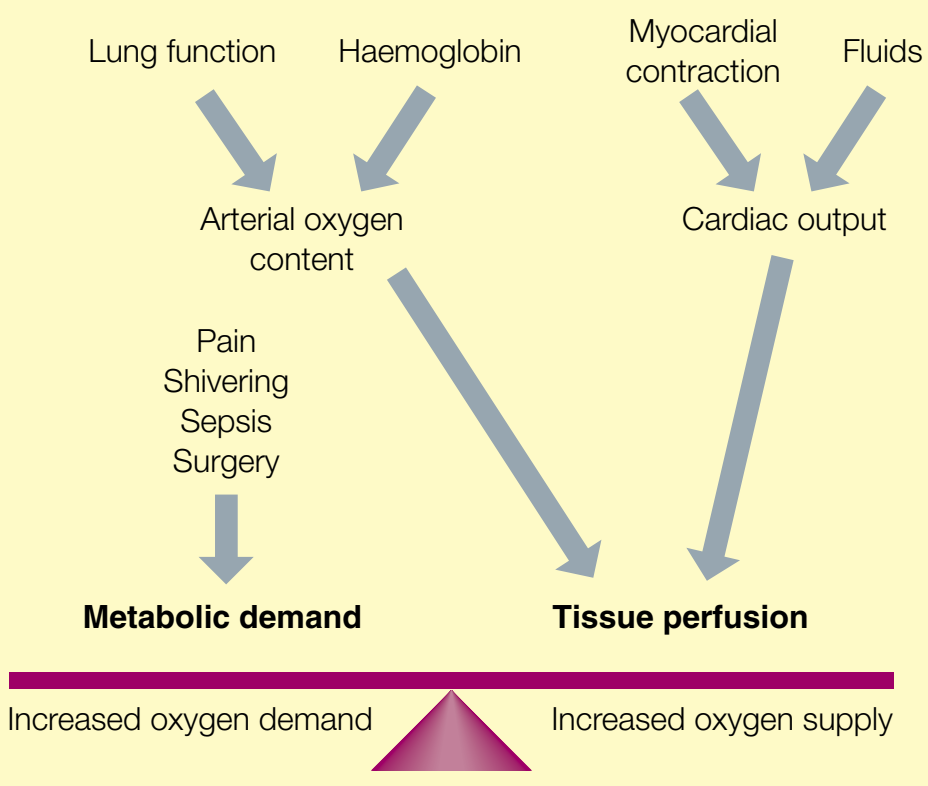
In the immediate postoperative phase, the elimination of nitrous oxide results in falls in arterial saturation. Increased intrapulmonary shunting and ventilation/perfusion mismatch should be treated with supplemental oxygen. Patients whose ventilation is based entirely on hypoxic drive seldom present for elective surgery, but they should be monitored carefully for hypoventilation and rises in arterial carbon dioxide ($Paco_2$).

In clinical practice it is difficult to improve arterial oxygenation significantly because few patients have a haemoglobin saturation below 95% preoperatively. Clinical management should be directed towards halting any decline in pulmonary function. The pain associated with large abdominal incisions has a deleterious effect on respiratory function, causing a reduction in tidal volume and functional residual capacity. The sudden cessation of smoking postoperatively increases secretion production and small airways plugging. This, together with the inhibition of coughing, results in alveolar instability and a tendency to alveolar collapse. Radiographic evidence of basal or plate-like atelectasis often precedes a further reduction in lower lung zone or lobar (usually the left lower lobe) aeration. Respiratory physiotherapy promotes the clearance of secretions and enhances alveolar recruitment in areas of atelectasis.

The combination of poor airway secretion clearance and alveolar instability increases the risk of nosocomial infection. Gram-negative pathogens usually predominate; however, the prolonged use of antibiotics perioperatively risks the selection of more resistant organisms such as *Pseudomonas aeruginosa*.

Postoperative ventilation: elective ventilation is commonly employed following major surgical procedures. This reduces both the metabolic demand associated with the work of breathing and voluntary muscular activity. It allows better matching of oxygen demand to supply until the effects of fluid shifts and blood loss are overcome (Figure 2).

Balance of tissue perfusion and metabolic demand



Analgesia and sedation

Adequate analgesia and sedation maintains patient comfort, ameliorates the metabolic response to surgery and trauma and halts the postoperative decline in lung function. It may be achieved by continuous or patient-controlled opiate infusions. However, local anaesthetic epidural infusions provide better analgesia and improve ability to cough.

Sedation for postoperative ventilation is best achieved with short-acting drugs (e.g. benzodiazepines, propofol) administered by infusion. Their hypotensive side-effects can usually be ameliorated by fluid or inotropic support.

Simple clinical end-points (Figure 3) can be used to guide successful weaning from ventilatory support in the postoperative period.

Clinical management of postoperative ventilation

• Warm peripheries	Achieve by producing adequate cardiac output with the administration of fluids and inotropes to ensure adequate peripheral perfusion
• Wake	Reduce sedation
• Wean	Gradually reduce respiratory support

Maintenance of homeostasis

Haemostasis

Bleeding is a common event in the postoperative phase and results from a variety of causes:

- ligature failure
- relaxation of vessel wall spasm
- hypothermia
- coagulation disorder
- thrombocytopenia.

Patients requiring transfusions exceeding 1 unit/hour over a 4-hour period should be assessed, if necessary by laparotomy, to exclude surgical causes. Haemorrhage may be caused by a combination of 'surgical bleeding' (e.g. slipped surgical ties) and a coagulopathy in the same patient; these may require simultaneous correction.

Haemoglobin

It has been accepted practice to transfuse patients to a haemoglobin of 10 g/dl both pre- and post-surgery. Recent studies have called this arbitrary practice into question and emphasized the disadvantages of supporting a higher haemoglobin in critically ill patients (Figure 4). Further trials are required to elucidate the risk:benefit ratios of these two competing strategies. The use of haemopoietic drugs such as erythropoietin, which offer the benefit of a high haemoglobin without the side-effects of transfusion, may prove useful. However, they are not currently recommended, primarily on cost grounds.

Relative merits of competing transfusion strategies

Advantages of higher haemoglobin

- Improved arterial carriage of oxygen
- Decreased risk of coronary ischaemia
- Margin of safety for further blood loss

Advantages of fewer transfusions and lower haemoglobin

- Improved microcirculatory blood flow and oxygen delivery
- Decreased cardiac work from decreased blood viscosity
- Decreased immunosuppression

Nutrition

In healthy individuals, the intestinal mucosa is an efficient barrier to the entry of bacteria and bacterial products into the portal circulation. Atrophy of the mucosa occurs rapidly after surgery and injury, and is also quantitatively associated with its severity.

Total parenteral nutrition has also been associated with mucosal atrophy and increased bacterial translocation. The introduction of the amino acid glutamine into total parenteral nutrition solutions and the establishment of early enteral nutrition have been shown to inhibit these mucosal changes and to be associated with increased patient survival. The addition of omega-3 fatty acids, arginine and nucleotides to the enteral feed may confer additional benefits.

The placement of enteral feed directly into the jejunum, using percutaneous or endoscopically placed tubes, may be safely instituted in conditions such as pancreatitis that historically have been managed with intravenous feeding.

Pain Relief in Intensive Care

Sue Smith

Sue Smith is Consultant in Anaesthesia and Intensive Care. Her interests include pharmacology, nutrition and steroid metabolism in the critically ill.

For patients in the ICU, many aspects of their illness and treatment may lead to discomfort and pain. However, pain is difficult to assess in ICU patients because of communication difficulties and because the usual clinical signs of pain (sweating, tachycardia, hypertension) may be caused by sepsis, stress or catecholamine administration. Nevertheless, there are opportunities to use analgesic techniques that would be unsuitable for other hospital patients.

Opiate analgesics

Opiates provide the mainstay for analgesia in critically ill patients. Their systemic effects (Figure 1) predominantly result from their actions on μ receptors.

Systemic effects of opiates

Cardiovascular system
- Decrease systemic vascular resistance
- Decrease blood pressure, partly due to histamine release
- Bradycardia in high doses

Respiratory system
- Respiratory depression
- Decreased ventilatory response to hypoxia and hypercapnia
- Antitussive
- 'Wooden chest' syndrome

CNS
- Potent analgesic
- Causes drowsiness
- Relieves anxiety
- Produces euphoria
- Miosis is produced by direct stimulation of the Edinger–Westphal nucleus
- Muscle rigidity

Renal system
- Increased tone in the ureters, bladder detrusor muscle and sphincter
- Urinary retention

Gastrointestinal system
- Nausea, vomiting
- Constipation due to decreased gastrointestinal motility
- Decreased gastric acid, biliary and pancreatic secretions

Metabolic
- Increased secretion of antidiuretic hormone leading to impaired water excretion, hyponatraemia

Other
- Mild diaphoresis and pruritus due to histamine release

Side-effects
- Hallucinations
- Dependence

1

Morphine
Morphine is a phenanthrene derivative. It is both a μ and κ receptor agonist. It can be administered orally, intramuscularly, intravenously (single dose, infusion or via a patient-controlled analgesia device), intrathecally or into the epidural space**.** Age and disease, especially liver and renal failure, alter its pharmacokinetics.

Morphine is well absorbed when administered orally but is susceptible to first-pass metabolism. The bioavailability by this route is only 15–50%. It is 20–40% protein bound and equilibrates slowly with the CSF. There is no correlation between plasma drug levels and the degree of analgesia.

Morphine is metabolized in the liver by conjugation to morphine-3-glucuronide, morphine-6-glucuronide and nor-morphine. The glucuronides are potent analgesics in their own right and have longer elimination half-lives than morphine.

Excretion of morphine occurs predominantly via the urine, but 7–10% appears in the faeces. The clearance of morphine is 1–23 ml/minute/kg and its elimination half-life is 1.7–4.5 hours. The elimination half-lives of the glucuronides vary from 4.5 to over 100 hours with declining renal function.

Morphine metabolites are water soluble, renally excreted and are not removed efficiently by haemodialysis/haemodiafiltration.

Alfentanil
Alfentanil is a highly selective, synthetic, anilinoperidine derivative with μ agonist activity. It produces a bradycardia of vagal origin with hypotension, but cardiac output, systemic vascular resistance and pulmonary capillary wedge pressure are unaffected.

Chest wall rigidity may result from μ receptor stimulation of GABA-ergic interneurons. Alfentanil causes minimal histamine release; bronchospasm is not a feature. The stress response is reduced.

Alfentanil is 10–20 times more potent than morphine, but does not produce hypnosis or sedation. It is 85–92% protein bound and is predominantly metabolized by the hepatic cytochrome P450 enzyme group by N-dealkylation to noralfentanil. The remainder is metabolized using other reactions, including hydroxylation, O-demethylation, and amide hydrolysis followed by acetylation. The major phase II pathway is by glucuronidation. There is evidence for genetic polymorphism in its metabolism and several pathways are saturable. At low doses (< 2 mg/hour in adults), the drug exhibits first-order kinetics, but in liver failure, septic shock or when higher dosing regimens are used, zero-order kinetics operate, thus explaining the long recovery time from termination of the infusion. Its elimination half-life for first-order kinetics is 100 minutes but increases exponentially when saturation occurs. Likewise, the half-life is greatly increased in liver disease and in the elderly. Erythromycin, cimetidine and ranitidine significantly inhibit its metabolism.

Studies suggest that the higher costs of alfentanil (in com-bination with propofol) are outweighed by shorter weaning times, shorter stays in ICU, and a lowered incidence of withdrawal syndromes compared with morphine and midazolam.

Remifentanil
Remifentanil seems to be an ideal analgesic agent for critically ill patients because of its cardiovascular stability and organ- independent pharmacokinetics. It undergoes rapid ester hydrolysis by non-specific esterases to a carboxylic acid derivative, which is much less potent and is excreted by the liver.

Remifentanil is unlicensed, but undergoing trials for ICU use. It does not possess sedative actions and causes significant nausea and vomiting. ‘Board-like’ rigidity, due to GABA-receptor activation in the chest wall can make respiration and ventilation difficult. Consequently, care must be taken in the flushing of intravenous lines in which remifentanil has been administered.

Pethidine
Pethidine is of limited use in critically ill patients because its metabolite (norpethidine) accumulates in renal failure and is excitatory and epileptogenic.

Codeine phosphate
Codeine has a low affinity for opioid receptors. It is less potent than morphine and is traditionally used for analgesia in patients with head injuries, because of the alleged reduced risk of respiratory depression.

If the drug is given intravenously or in overdose, cardio-vascular collapse may occur. Therefore, its use is limited to the treatment of diarrhoea (reduced gastrointestinal motility) and in managing mild-to-moderate pain. The dose should be reduced in patients with renal failure.

Non-opioid analgesics

Paracetamol
Paracetamol is an acetanilide derivative that can be administered orally, enterally or rectally. It is a potent prostaglandin synthesis inhibitor within the CNS; this explains its antipyretic action (inhibition of pyrogen-induced, prostaglandin synthesis by the anterior pituitary). It acts peripherally as an analgesic by blocking bradykinin-sensitive nociceptors. The drug is rapidly absorbed from the stomach, therefore plasma levels can be used as a measure of gastric emptying. Bioavailability is 70–90% owing to first-pass metabolism in the liver. 80% is metabolized to glucuronide and sulphate derivatives, and 10% is metabolized via the cytochrome P450 group to a highly reactive metabolite, which is immediately inactivated by conjugation with glutathione.

Non-steroidal anti-inflammatory drugs (NSAIDs)
NSAIDs are useful for the relief of musculoskeletal pain, as an adjuvant to paracetamol and for reducing opiate dose. However, all NSAIDs, even the highly selective COX-2 inhibitors, have significant side-effects (Figure 2), especially in critically ill patients. NSAIDs exert their anti-inflammatory, analgesic and antipyretic actions by reversibly blocking the conversion of arachidonic acid to PGG_2 – a reaction catalysed by cyclo-oxygenase.

NSAIDs are extensively protein bound and a given dose has a greater effect if hypoproteinaemia exists. NSAIDs increase the anticoagulant effect of concurrently administered warfarin by displacement from plasma proteins.

Side-effects of non-steroidal anti-inflammatory drugs

Cardiovascular system
- Hypertension
- Sodium and water retention
- Peripheral oedema
- Closure of ductus arteriosus

Gastrointestinal system
- Gastritis
- Gastric ulceration and haemorrhage
- Small bowel villous atrophy
- Diarrhoea
- Reversible hepatic dysfunction

Renal system
- Interstitial nephritis
- Renal vasoconstriction
- Cortical blood flow diversion
- Acute renal failure with hypovolaemia and ACE inhibitors

Blood
- Inhibition of platelet aggregation
- Prolongation of the bleeding time
- Decreased killer T cell activity

2

Entonox
The combination of inhaled *Entonox* (50% oxygen; 50% nitrous oxide) may be of benefit during physiotherapy or if regular dressing changes are required (e.g. burns, necrotizing fasciitis).

Antidepressants
Antidepressants have mood-altering properties and permit rapid eye movement (REM) sleep patterns to be established. Tricyclic antidepressants have analgesic properties and also block the reuptake of noradrenaline at the postsynaptic nerve terminals. Noradrenaline is a potent analgesic in the CNS and both pain relief and mood alteration occur within 3–7 days.

The high incidence of anticholinergic side-effects and drug interactions may limit the use of antidepressants.

Epidural blockade

Epidural analgesia is increasing in the ICU because it provides superior pain relief without sedation. The combination of a dilute local anaesthetic solution with a preservative-free opioid produces superior analgesia. The use of epidural analgesia in patients with severe chest injuries has reduced mortality and morbidity by avoiding the need for intubation and ventilation. Epidurals preserve the cough reflex, allow deep breathing, preserve functional residual capacity, facilitate chest physiotherapy and permit early mobilization.

Concerns have been raised about the possible link between epidural anaesthesia and anastomotic breakdown following bowel surgery. One possible cause is that hypotension and reduced cardiac output following the epidural may decrease splanchnic blood flow.

Epidural anaesthesia is useful in reducing the incidence of post-amputation phantom limb pain, especially if the autonomic blockade is established before amputation.

Regional blockade

The ability to leave a catheter in the femoral nerve sheath makes local anaesthetic, femoral nerve blocks useful for relieving pain after femoral fractures or mid-thigh amputations.

Similarly, catheters may be placed in the axillary or brachial plexus sheaths to provide analgesia for fractures and vasodilatation when extensive reconstructive surgery has been undertaken. It may also protect against reflex autonomic dystrophies.

For analgesia to be satisfactory with an intercostal nerve block (e.g. for fractured ribs), it must be repeatedly performed, with the risk of a pneumothorax. This complication is avoided by the placement of an intrapleural catheter and the use of a local anaesthetic infusion.

Stellate ganglion blocks may be used in certain situations, such as quinine overdose, methanol toxicity and inadvertent drug extravasation into the upper limb tissues.

Other therapies

Attention to pressure areas, mobilization, nutrition, mood, prevention of sleep deprivation and communication will relieve the discomfort of immobility. The pleasure of touch and massage may also promote well-being. Transcutaneous electrical nerve stimulation (TENS) machines may also help. Occasionally, other assistance may be required, such as the specialist advice of neurologists, chronic pain specialists or the palliative care team.

The Role of Tracheostomy in ICU

Andrew R Bodenham
Ben N Barry

Andrew R Bodenham is Consultant in Anaesthesia and Intensive Care at Leeds General Infirmary, UK. He trained in London, Cambridge, Brisbane and Leeds. His interests include adult intensive care, the airway, vascular anaesthesia and vascular access.

Ben N Barry is Specialist Registrar in Intensive Care at Leeds General Infirmary, UK. He trained in London, Sheffield and Leeds and has specialized in anaesthesia and intensive care. He has recently finished advanced training in intensive care.

Historically the main indication for tracheostomy has been to bypass an upper airway obstruction, for example that caused by diphtheria. Modern open surgical tracheostomy techniques were standardized in 1909 by Chevalier-Jackson. In the early days of intensive care, including the Scandinavian poliomyelitis epidemics of the 1950s, tracheostomy became the accepted means of airway management for provision of longer-term assisted ventilation (Figure 1). Tracheostomy provides protection against aspiration of pharyngeal secretions and access for suctioning pulmonary secretions. In the following decades, patients requiring intensive care were more commonly managed initially by translaryngeal intubation with tracheostomy only after 2–3 weeks. The recent development of percutaneous tracheostomy techniques has reawakened interest in the place of tracheostomy in the ICU.

1 Adolescent in the early days of the Tetanus Unit at Leeds General Infirmary. Manual ventilation via a red rubber tracheostomy tube with carbon dioxide absorption in a Waters' canister. The patient made a full recovery. Photograph kindly provided by Professor J Norman.

Indications for tracheostomy in the ICU

The most common indication for tracheostomy in ICU patients is prolonged airway care, though there are often coexisting problems that favour early tracheostomy in preference to prolonged translaryngeal intubation (Figure 2). Survivors of prolonged intensive care are often profoundly weak (e.g. from critical illness neuropathy or myopathy) and are therefore unable to clear pulmonary secretions unaided until their condition improves. Acute upper airway obstruction is usually managed initially by translaryngeal intubation but tracheostomy may be used to secure the airway in patients undergoing head and neck surgery, for example for obstructing tumours and after laryngectomy. Patients with laryngeal incompetence, brain injury, cerebrovascular or neuromuscular disease, may require long-term tracheostomy to reduce the risk of aspiration and facilitate removal of pulmonary secretions.

Indications for tracheostomy in ICU

- Prolonged weaning from assisted ventilation
- Acute and chronic neuromuscular conditions
- Poor cardiorespiratory reserve
- Bulbar dysfunction
- Brain injury
- Upper airway obstruction

2

Benefits of tracheostomy

Tracheostomy offers the patient significant advantages over prolonged translaryngeal intubation. The patient is generally more comfortable, allowing a reduction in sedative, analgesic and muscle-relaxant drugs; clearance of airway secretions, general nursing care and enteral nutrition are all facilitated. There is a reduced incidence of accidental extubation and endobronchial intubation. Verbal communication may be possible as the patient awakens and regains laryngeal competence. A fenestrated (speaking) tracheostomy tube may be inserted, or the tube cuff may be deflated to allow phonation. Airway res-istance and anatomical dead space are reduced, reducing the work of breathing and improving the chances of weaning from assisted ventilation. Tracheostomy may allow earlier discharge from the ICU to the high-dependency unit or a general ward.

Timing of tracheostomy

The decision when to convert translaryngeal intubation to tracheostomy remains controversial. An assessment of the risks and benefits for performing a tracheostomy should be carried out daily. Tracheostomy is associated with serious complications (see below). Conversely, the incidence of laryngeal injury and subglottic stenosis increases significantly over time with prolonged translaryngeal intubation.

It is desirable to minimize the risks of both means of airway maintenance. The present consensus is that translaryngeal intubation should be converted to tracheostomy at 7–14 days, unless rapid improvement is likely. If it is apparent earlier that the patient will require prolonged respiratory support (e.g. Guillain–Barré syndrome, cervical cord injury or traumatic brain injury) then earlier tracheostomy may be appropriate. If there is uncertainty about the patient's ability to maintain airway and respiratory function unaided, a trial of extubation is often performed to ascertain the need for prolonged airway instrumentation.

In children and adolescents, the relative risks of tracheostomy are higher than in adults, therefore it is usual not to perform tracheostomy unless it is likely to become a long-term or permanent requirement.

Complications of tracheostomy

The complications of tracheostomy are common to all insertion techniques (Figure 3). The distinction between early and late complications is somewhat artificial because many problems on initial insertion or re-insertion may develop into late complications. The changing indications, less frequent use of open insertion techniques, use of less traumatic tubes and better aftercare should reduce the incidence of complications. However, the overall number of complications is likely to increase as the number of tracheostomies performed in intensive care patients increases.

Complications of tracheostomy

Early

- Haemorrhage
- Obstruction by blood clot or mucous plugs
- Misplacement
- Dislodgement
- Subcutaneous emphysema
- Pneumothorax
- Injury to adjacent structures

Late

- Stomal infection
- Tracheal stenosis
- Tracheo-oesophageal fistula
- Tracheo-innominate artery fistula
- Tracheomalacia
- Obstruction by mucous plugs

3

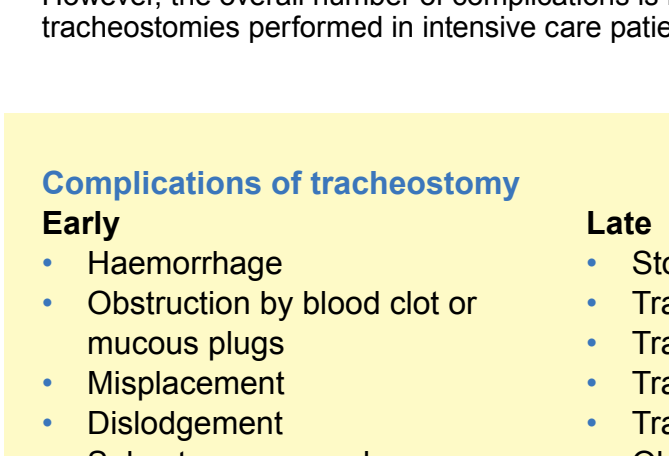
Tracheostomy techniques

Open tracheostomy

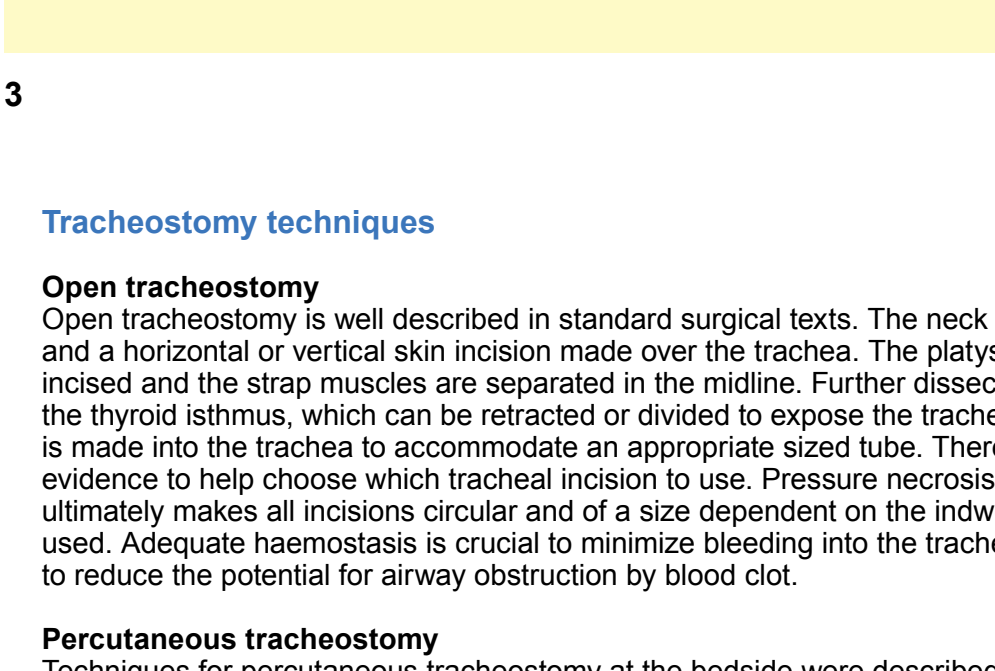
Open tracheostomy is well described in standard surgical texts. The neck is extended and a horizontal or vertical skin incision made over the trachea. The platysma muscle is incised and the strap muscles are separated in the midline. Further dissection exposes the thyroid isthmus, which can be retracted or divided to expose the trachea. An incision is made into the trachea to accommodate an appropriate sized tube. There is little evidence to help choose which tracheal incision to use. Pressure necrosis from the tube ultimately makes all incisions circular and of a size dependent on the indwelling tube used. Adequate haemostasis is crucial to minimize bleeding into the trachea, and thus to reduce the potential for airway obstruction by blood clot.

Percutaneous tracheostomy

Techniques for percutaneous tracheostomy at the bedside were described in the 1960s but medical museums contain much earlier instruments for rapid tracheostomy (Figure 4). New techniques based on the Seldinger needle-guidewire method and better materials have allowed safer percutaneous airway access. Common to all dilatational techniques are: a superficial skin incision, localization of the trachea by needle with free aspiration of air, insertion of a guidewire, formation of a tract with blunt dilators and subsequent insertion of a tracheostomy tube. The technique of dilatation varies between different kits using one or more serial dilators, or specially designed forceps (Figure 5).



4 Tracheostomy set from the 19th century. Note fenestrated silver tube with inner liner. Scalpel and sharp introducing forceps. Kit kindly lent for photography from Thackray Medical Museum, Leeds.



5 Percutaneous tracheostomy kits. **a** Cook Ciaglia serial dilators,12 FG to 36 FG (Portex tube mounted on 24 FG dilator); **b** Cook Blue Rhino single dilator; **c** Portex kit – dilating forceps, cannula over needle, guidewire and dilator; **d** indentations on Portex dilating forceps marking top of groove through which guidewire runs to allow insertion of forceps in closed position.

In ICU, procedures are performed at the bedside with the patient in the conventional position for tracheostomy. Procedures should be performed or supervised by senior staff in daylight hours when surgical and theatre assistance is readily available if required. Anaesthesia should be provided as for a conventional surgical tracheostomy and by a separate anaesthetist. The authors currently use a total intravenous technique with propofol and alfentanil infusions; a muscle relaxant is not essential but makes the procedure easier. The procedure can be performed under local anaesthesia alone, but this is likely to be unpleasant for the patient. The patient is usually already intubated and ventilated prior to the procedure; a laryngeal mask airway provides an alternative means of airway control. The anaesthetist withdraws the tracheal tube under direct laryngoscopy until the cuff is seen to lie within the larynx, avoiding the risk of transfixion of the tube or cuff with the needle and guidewire.

After preparation with sterilizing solution and the application of drapes to maintain a sterile field, the area of incision is infiltrated with local anaesthetic (e.g. 1% lidocaine (lignocaine) with adrenaline (epinephrine) 1:200,000). A superficial 1.5–2 cm horizontal skin incision is made over the space between the second and third or third and fourth tracheal rings. The subcut-aneous and pretracheal fascial layers are opened by blunt dissection with forceps; on occasion, large anterior jugular veins are identified and may require ligation. The trachea is palpated through the incision to improve orientation and confirm anatomy. The thyroid isthmus need not be identified or specifically avoided. The trachea is entered with a cannula over needle, confirmed by the free aspiration of air into a partially fluid-filled syringe. A guidewire is passed into the trachea and the tract dilated to accept an 8 or 9 mm internal diameter tracheostomy tube.

Bronchoscopy using a fibre-optic scope passed through the tracheal tube may be used routinely to guide correct placement of needle, guidewire and tube or may be reserved for teaching or difficult cases only. The presence of a fibre-optic scope may hinder ventilation with consequent risk of hypoxia or elevation in partial pressure of carbon dioxide in arterial blood ($PaCO_2$) and intracranial pressure. It is also easy to cause expensive damage to the bronchoscope by needle puncture.

Open versus percutaneous techniques

Studies have tended to favour percutaneous techniques in ICU patients, but operator experience and aftercare are likely to be as important as individual insertion technique or reported device malfunction. In many units, dilatational techniques have almost completely replaced conventional techniques in adult patients. Percutaneous techniques have the following advantages:

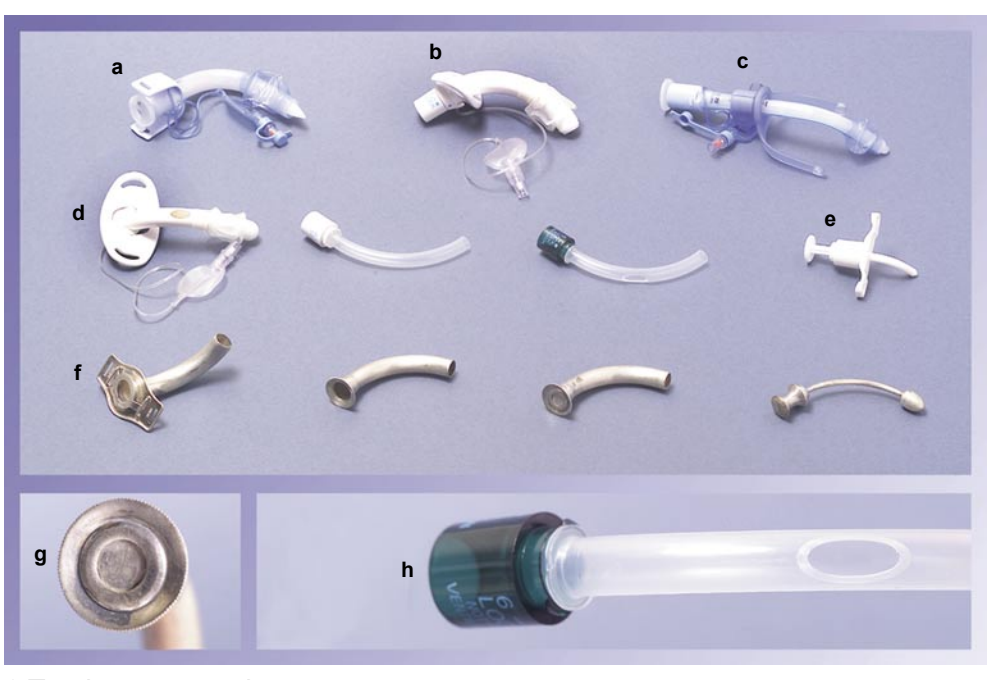
- quicker and easier to perform at the bedside
- less risk of early bleeding
- reduced risk of stomal infection
- better cosmetic result by virtue of the smaller incision.

However, there is a higher risk of tracheal damage and other complications related to insertion.

With experience, percutanous techniques can be successfully performed in more difficult patients including those with abnormal coagulation, chronic lung disease, morbid obesity, previous tracheostomy or thyroidectomy, halo-traction and critical oxygen dependency. Relative contraindications to dilatational techniques include a large goitre, malignant infiltration or other anatomical abnormalities. Worldwide, many centres routinely use open techniques because of the cost of percutaneous devices, lack of experience in such techniques and conservatism in medical practice.

Choice of tracheostomy tube

A large number of different tubes and materials are commercially available (Figure 6) and some manufacturers provide custom-made tubes. In an adult, 7–9 mm internal diameter tubes are typically used. In the patient with an increased distance between skin and trachea (e.g. obesity, tumour, haematoma) a long-shanked adjustable flange tracheostomy tube should be used. Tubes are available with fenestrations to allow speech, removable inner liners for ease in cleaning, plus various other features to aid communication and suction of secretions.



6 Tracheostomy tubes.
a Portex 9.0 mm profile cuff tube; **b** Shiley size 8 low pressure cuff tube; **c** Portex 7.0 mm adjustable flange tube; **d** Shiley size 6 fenestrated tube with plain and fenestrated inner tubes; **e** Shiley 3.0 neonatal tube; **f** silver 34 FG tube with plain and speaking valve inner tubes and trocar; **g** silver tube speaking valve; **h** Shiley fenestrated inner tube.

Role of cricothyroidotomy

The larynx lies superficially at the level of the cricothyroid membrane and so this procedure may be performed rapidly in an emergency to relieve airway obstruction. Kits are available for rapid insertion of 4–6 mm tubes using a modified Seldinger technique or a traditional surgical cut-down may be performed. Cricothyroidotomy in the non-emergency setting is commonly referred to as ‘minitracheostomy’; it has been used for patients with sputum retention and atelectasis not requiring protection against pulmonary aspiration or assisted ventilation. The widespread use of percutaneous tracheostomy has made the use of minitracheostomy for such patients less common.

Aftercare and decannulation

Obstruction is a recurrent problem with all types of tracheostomy tube. Humidification, tracheal suction and physiotherapy are all essential to avoid accumulation of respiratory secretions with crusting and subsequent tube blockage. If left untreated, the patient will suffer respiratory distress, hypoxia and hypercapnoea, proceeding to cardiorespiratory arrest.

The risk may be reduced by adequate frequency of suction and removal of the inner tube for cleaning, or changing the tube, as applicable. In the short term, a spontaneously breathing patient will manage to breathe adequately through a formed stoma. Never be afraid to remove a tracheostomy tube if there is doubt regarding its patency and the adequacy of the airway. The stoma will usually be established by 7 days and there should be little difficulty in replacing the tube: alternatively the patient may be reintubated by the oral route.

In the patient who is recovering following intensive care, there is a general tendency to leave the tracheostomy tube in place for too long. Once the patient is able to cough to clear secretions and protect the airway, consideration should be given to removing the tube, because its presence limits generation of an effective cough and may promote a tracheitis. There is no ideal way to assess when the patient is ready for decannulation, though a multidisciplinary approach, in consultation with physiotherapists and nurses is prudent. The risks associated with a failed decannulation are likely to be minimized if decannulation is carried out during daylight hours because the patient requires a period of close observation and may require tube reinsertion. After successful decannulation, stomas are usually left to granulate and close spontaneously. Recently closed wounds may be re-opened by blunt dissection if needed. A few patients require late surgery to release a tethered wound or excise a persistent sinus.

Secondary Transport of the Critically Ill

Saxon Ridley

Saxon Ridley is Consultant in Anaesthesia and Intensive Care at the Norfolk and Norwich Hospital, UK. He qualified from the Royal London Hospital and trained in London, Whitehaven, Exeter and Glasgow. His research interests include outcome following intensive care and the cost of intensive care.

Transport of patients may be divided into primary and secondary. Primary transport refers to the movement of patients from the scene of an accident or the onset of illness to hospital where their presenting problems can be assessed, stabilized and treated. Secondary transport refers to the movement of the patient after initial assessment and may be to specialized diagnostic or therapeutic facilities within the same hospital (intra-hospital) or another hospital (inter-hospital).

In the UK, the secondary transfer of critically ill patients started under the auspices of the Clinical Shock Study Group in Glasgow. This specialized transfer team has been responsible for most of the inter-hospital transfers in the West of Scotland for almost 30 years. Early publications from this group outlined the physiological changes that could be expected during transfer of critically ill patients and these principles form the basis of the clinical management of such patients. In the UK, just over 10,000 critically ill patients require secondary transfer each year. Despite the logistic advantages and improved patient outcome when transfers are undertaken by specialist teams, there are few such teams and most transfers are undertaken by the staff of the referring hospital who do not regularly perform such tasks.

In the UK, where intensive care facilities are relatively sparse, the concept of ICUs working together as a web to provide a geographical or regional service is being considered to maximize the use of resources. The recent introduction of the National Intensive Care Bed Register and biannual census of ICU beds emphasizes the political interest in this area.

Reasons for transfer

Patients may require transfer to an alternative ICU for several reasons.

Upgrade in care: specialist services may not be available at the base hospital. Examples include regional centres for cardiac and neurosurgery, burns and renal failure management. Occasionally, transfer is required because the referring clinician believes that the patient may benefit from the greater expertise and experience available at a larger centre.

Special investigations such as MRI under general anaesthesia are available only at certain large hospitals.

Inadequate facilities at the referring hospital may require the patient to be transferred to an ICU.

Social: moving a critically ill patient to an ICU nearer home to facilitate family support and minimize disruption to family life may be advantageous.

Principles

The principles underpinning transfer of the critically ill may be broadly divided into organizational and clinical. Attention to both is vital if transfer is to be effective and safe.

Organization
Good communication between the referring and receiving hospitals is essential. Communication is usually on a regional or geographical pattern. Senior medical staff should make all transfer decisions.

Nominated consultant: in each hospital a consultant should be responsible for the transfer of all critically ill patients. The consultant should develop local protocols for a safe and efficient transfer service that can be maintained on a 24-hour basis. The consultant should also be responsible for auditing care during transfer and ensuring that the accompanying staff are adequately trained.

Accompanying personnel: working in the confined space of an ambulance is difficult and should not be delegated to inexperienced staff because clinical signs are not easy to recognize and the work is unsupervised. Training of the accompanying staff is vital to ensure patient safety.

Transfer teams: ideally, movement of critically ill patients should be conducted as a regionally or geographically based service; however, this would require significant additional funds and may not be feasible in the short term. Regional teams are probably best for the semi-elective transfer of patients requiring an upgrade of care or special investigations. For potentially unstable patients requiring urgent surgery, the regional team's response time may be too long and the patient may require a more expeditious transfer.

Clinical principles
The overriding clinical principle is that the intensive care environment should be moved with the critically ill patient, though active intervention is almost impossible *en route*.

Preparation and stabilization: anything that may have to be done *en route* should be carried out before departure. Resuscitation, stabilization and preparation are mandatory before departure from the referring hospital. Monitoring is essential to ensure stability or to detect any adverse physiological changes that may occur during transfer. The systolic arterial blood pressure must be measured with an intra-arterial cannula because vibration and movement artefacts make non-invasive methods unreliable. Manipulation of the cardiac filling pressures may be needed to stabilize the patient before transfer. Patients must be hypervolaemic and if fluids alone are inadequate to render the patient hyperdynamic, then inotropes should be added. Modern portable transfer monitors have at least two pressure channels and so should allow simultaneous measurement of arterial and central venous blood pressure.

Stabilization of the respiratory system usually involves tracheal intubation and mechanical ventilation. The effectiveness of mechanical ventilation should be checked by blood gas analysis before departure and capnography *en route*. A high inspired oxygen fraction is required because of changes in ventilation/perfusion mismatch associated with acceleration and deceleration forces during transfer.

Sedation is vital so that the adrenergic response to transfer is minimized. An uncontrolled adrenergic response confuses the physiological trends associated with transfer.

Speed of transfer: a stable ICU patient should be moved at normal speed in an unhurried fashion. Normalization of physiological parameters before transfer offers some scope for deterioration as a result of the normal forces experienced during travel. Speed is required only for specific, initial life-saving interventions such as extradural haematoma evacuation and aortic aneurysm rupture repair. Relevant case notes, radiographs, a referral letter and investigation reports should be transferred with the patient. A record of the patient's physiological parameters and interventions undertaken *en route* should also be left at the receiving centre.

Personnel

Medical staff: all medical staff involved in transferring critically ill patients should be competent in intensive care medicine and be familiar with the equipment used in the care of these patients. Before taking responsibility for a transfer, staff should receive training and accompany transfers as an observer. Resources are required to achieve this and to ensure safe transfer systems throughout the UK. At least two personnel should accompany a patient during transfer; often the second member of the team is a nurse who should be experienced in the care of the critically ill and specifically in patient transfer.

Insurance cover: adequate insurance to cover the death or disability of staff accompanying patients as a result of road traffic accidents is required. In the UK, such personal accident insurance is one of the benefits of membership of specialist societies such as the Intensive Care Society and the Association of Anaesthetists.

Equipment

The equipment required during a transfer may be divided into four broad categories (Figure 1). The first category is the equipment needed for basic care such as the ICU bed or cot, laundry, sources of warmth and comfort. Life support equipment such as the ventilator and other respiratory support, including oxygen supply may be considered as the second category. The third category includes monitoring devices and the fourth includes equipment required to treat the patient. Two types of treatment equipment are required: that needed for continuing intensive therapy and that required for emergencies arising because of physiological deterioration or equipment failure (e.g. blocked tracheal tube, loss of oxygen, power failure, avulsed intravenous infusion lines).Equipment required for intra-hospital transfer is similar to that needed for inter-hospital transfer; to avoid duplication of equipment and to maximize staff familiarity with one standard apparatus inventory, institutions may elect to use their inter-hospital mobile ICU for intra-hospital transfers.

Categories of equipment for transfer

Basic care
- ICU bed or cot, warmth, comfort

Life support equipment
Airway
- Laryngoscopes, spare batteries and bulbs
- Sterile cuffed tracheal tubes (various sizes)
- Sterile cuffed tracheotomy tubes (various sizes)
- Tracheal tube introducers (metal and gum elastic)
- Airways, oral and nasal (various sizes)
- Suction catheters and suction device
- Catheter mounts
- Disposable humidifiers
- Fixed-performance oxygen masks and piping
- Lubricating jelly
- Artery forceps
- Tape and adhesive dressing
- Magill forceps

Breathing
- Portable ventilators (ideally capable of volume-controlled ventilation, positive end expiratory pressure generation, variable inspired oxygen fraction, lightweight, simple, gas driven, robust and reliable)
- Oxygen cylinder with appropriate pressure-reducing valves for ventilator and fresh gas flow to face mask
- Disposable (or autoclavable) ventilator tubing
- Self-inflating resuscitation bag with anaesthetic masks (various sizes)

Circulation
- Intravenous cannulae (various sizes)
- Cannulae appropriate for intra-arterial pressure monitoring
- Intravenous fluids and administration sets
- Central venous catheters (various lengths and diameters)
- Sutures and dressings
- Infusion pumps with appropriate syringes
- Three-way Luer lock taps and intravenous line extensions

Monitoring equipment
- Central venous and pulmonary occlusion pressures, direct measurement
- Arterial oxygen saturation
- Temperature
- Blood pressure (direct intra-arterial and non-invasive)
- ECG
- End tidal carbon dioxide tension

Treatment
Continuing ICU management
- Drugs and intravenous fluids

Emergency treatment needed during transfer
- Nasogastric tubes (various sizes)
- Scissors and razors
- Syringes and needles
- Sterile, plain and alcohol-soaked swabs
- Gloves and aprons
- Defibrillator

Children
During the development of paediatric intensive care services, the importance of regional retrieval teams was appreciated and now most regional paediatric ICUs support such teams. Adverse events are more common if paediatric retrieval is not carried out expertly. For example, a study in Birmingham, UK, reported that 75% of transfers were complicated by an adverse physiological event, equipment failure, or inadequate documentation of vital signs. In 1995, an American study of 180 paediatric transfers reported adverse physiology changes occurring in 72% and major equipment mishaps in 10%. Major interventions were required in 40% of these transfers. In a subsequent phase, the introduction of a specialist paediatric transfer team resulted in no adverse events. In another study, it was found that only 4% of 51 critically ill children suffered preventable physiological deterioration when accompanied by a specialist transfer team. The patient's severity of illness, as judged by the PRISM (Pediatric Risk of Mortality) score, decreased during transfer, reflecting an improved clinical state as a result of the pre-transfer and intra-transfer resuscitation.

Neurosurgical
Emergency neurosurgical patients requiring further management at the regional neurosurgical centre represent a dilemma. The effects of secondary brain damage, mainly resulting from hypoxia and hypotension, must be minimized. These complications are best treated by experienced staff who are familiar with the problems that occur during transfer. However, the response time of any regional transfer team may limit their effectiveness under such circumstances and staff from the referring hospital must move the patient. This is best managed if protocols and guidelines developed in conjunction with the regional neurosurgical centre are followed (Figure 2).

Guidelines used for transfer of patients requiring further neurosurgical management

Indications for intubation and ventilation before transfer

- Coma (Glasgow Coma Score – GCS ≤ 8)
- Loss of airway reflexes
- Ventilatory insufficiency
  ($Pa_{O_2} \leq 9$ kPa on air or ≤ 13 kPa on O_2)
  ($Pa_{CO_2} \leq 6$ kPa)
- Respiratory arrhythmia
- Spontaneous hyperventilation with $Pa_{CO_2} \leq 3.5$ kPa

Additional indications for intubation

- Deteriorating consciousness (decrease in GCS by ≥ 2)
- Fractured mandible
- Bleeding into the upper airway
- Patient fitting

Aeromedical
Road transfer is satisfactory for most critically ill patients. It has the advantages of low-cost, rapid mobilization, less weather dependency and easier patient monitoring.

Air transfer should be considered for longer journeys (over 50 miles or 2 hours). Its apparent speed must be balanced against organizational delays and intervehicle transfer at either end of the flight. Helicopters are recommended for journeys of 50–150 miles or where access is difficult, but they provide a less comfortable environment than road ambulance or fixed- wing aircraft. Helicopters are expensive and have a poorer safety record than fixed-wing aircraft. Fixed-wing aircraft, preferably pressurized, should be selected for transfer distances over 150 miles.

The problems associated with aeromedical transfers are altitude, temperature control, noise, vibration, visibility and unfamiliar environments. Changes in barometric pressure are hazardous, because a small pneumothorax expands by 20% with an increase in altitude of 6000 ft.

Quality and audit

Transfer forms are vital to record physiological changes and therapy before and during transfer. Regular audit of transfers is necessary to maintain and improve standards. The responsible consultant should review all transfers in and out of the hospital and a similar process should be established at regional and national level. The referring hospital, the receiving hospital, the ambulance service and any external auditing system should retain copies of the transfer documentation.

Sedation and Neuromuscular Paralysis in the ICU

Andrew J Soppitt

Andrew J Soppitt is Specialist Registrar in Intensive Care and Anaesthesia at Southampton General Hospital, UK. He qualified from Birmingham University and trained in general medicine in Birmingham and in anaesthetics in Bath and Southampton, UK.

Patients receiving mechanical ventilation usually require sedation and/or analgesia. The patient's underlying disease state and the indications for mechanical ventilation should be considered before selecting and administering sedative agents. The risk of prolonged sedation after discontinuation of drug therapy can be reduced with careful selection of agents and their dosing regimen. There must be a clear reason for using muscle relaxants, because there are disadvantages to their use.

Sedation

During intensive care, sedation is required to relieve the discomfort and anxiety caused by procedures such as tracheal suction, physiotherapy and manual handling, and to facilitate the tolerance of tracheal tubes and intermittent positive-pressure ventilation (IPPV). It may also be useful in managing other aspects of intensive care, such as insomnia, hallucinations and agitation. However, the use of sedation should not be excessive and, in general, the aim should be to create a cooperative, calm and pain-free patient who will tolerate the necessary interventions of intensive care and permit clinically useful assessments to be undertaken.

Inappropriately deep sedation should be avoided, because it has several potential adverse effects including hypotension, prolonged recovery time, delayed weaning from IPPV, ileus, the development of drug tolerance or a 'chronic' confusional state. Occasionally, deep sedation is appropriate, for example in the management of patients with refractory hypoxaemia or raised intracranial pressure, or in those for whom neuromuscular paralysis is appropriate (see below). It may also be used to reduce oxygen consumption and metabolism.

Although pharmacological methods of managing anxiety and discomfort in the ICU are the mainstay of therapy, other approaches may be useful:

- good communication between ICU staff and the patient
- control of the environment (e.g. noise, temperature, humidity)
- management of thirst, hunger, constipation
- attention to ventilation (hypercapnia increases sedative requirements)
- aromatherapy and massage
- adequate analgesia (may include regional techniques).

Pharmacological methods of sedation

The ideal sedative agent possesses the following qualities:

- an easily controllable level of sedation
- no effect on major organ functions
- a short onset and offset of action
- metabolic pathways independent of hepatic or renal function
- no accumulation
- inactive metabolites
- inexpensive
- no interactions with other ICU drugs.

Drugs used for sedation include opiates, benzodiazepines, propofol, barbiturates, butyrophenones and other antipsychotic agents, central-acting α_2-agonists, and the volatile anaesthetic isoflurane. Newer rapidly titratable drugs are also available including alfentanil and remifentanil (Figure 1).

Sedative drugs may be administered by bolus or by continuous infusion. In general, sedation is best maintained using an infusion technique, with additional boluses 'as required'. Bolus administration alone leads to fluctuating sedation levels. The clearance of most commonly administered drugs relies on metabolism and excretion by the liver or kidney or both; their duration is prolonged in hepatic or renal failure. Drugs metabolized at least in part by other mechanisms include propofol and remifentanil.

Opioids are traditionally given to treat pain, but they possess sedative properties by virtue of their central action on opioid receptors. In the UK, morphine, fentanyl and alfentanil are the most commonly used, though others (e.g. remifentanil) are being considered. The specific features of opiates are listed inFigure 2. The adverse effects of opioids include:

- respiratory depression
- cardiovascular depression (hypotension and bradycardia are common, secondary to a decrease in sympathetic tone)
- depression of intestinal motility
- pruritus.

Benzodiazepines used in the ICU include midazolam, diazepam and lorazepam. They all exhibit anxiolytic, hypnotic, muscle relaxant and anticonvulsant effects, and synergy with opioids. Rapid intravenous injection in an unstable patient may produce airway compromise and cardiovascular depression. Diazepam, and to a lesser extent midazolam, have active metabolites that can accumulate over days of use and extend their duration of action. Lorazepam does not accumulate in lipid stores or have an active metabolite, but its elimination half-life is more than 10 hours. Overdose or accumulation of benzodiazepines can be reversed by flumazenil. This benzodiazepine-receptor antagonist has a shorter half-life than agonist benzodiazepines and may need to be given by infusion.

Propofol (2,6-diisopropylphenol) is a lipid-soluble agent with a rapid onset and short duration of action. Recovery from sedation usually occurs within 10 minutes and is not significantly lengthened by prolonged drug administration. However, some accumulation may occur in obese patients, because the drug is lipid soluble. Propofol is rapidly metabolized by hepatic and extrahepatic mechanisms. When compared with midazolam for ICU sedation, propofol has shorter arousal times, but there is no difference in the quality of sedation. Propofol is a potent vasodilator, and can cause significant hypotension, especially in the hypovolaemic or septic patient. Prolonged infusions lead to increased serum triglyceride and cholesterol concentrations. In fluid-restricted patients, the large volume of infusion may pose problems. Propofol is not licensed for sedation in children because several deaths have been reported following its use in very young children. Patients receiving propofol infusions may develop green or reddish-brown urine.

Ketamine – in subanaesthetic concentrations ketamine has analgesic and sedative properties, but it should not be used as monotherapy because of its excitatory and hallucinogenic side-effects. These can be avoided if ketamine is administered in combination with a benzodiazepine or propofol. Ketamine acts at the N-methyl-D-aspartate (NMDA) receptor. Its catecholamine-releasing properties may have advantages or disadvantages, depending on the circumstances. It is expensive.

Barbiturates are unsuitable for therapeutic sedation, because they are cardiovascular depressants and accumulate following prolonged use. Thiopental (thiopentone) may be useful in managing status epilepticus or raised intracranial pressure.

Etomidate is not used by infusion on the ICU, because an excess mortality has been associated with its use, secondary to adrenal suppression.

Butyrophenones and phenothiazines – haloperidol and other antipsychotic agents (e.g. chlorpromazine) have greater antipsychotic than sedative effects at lower doses, and decrease hallucinations, paranoia and motor activity. They can be used for promoting calmness and clarity in critically ill patients with delerium or delerium tremens. Haloperidol may be the preferred agent, because it exhibits less α-adrenoceptor-blocking tendency, but any of these agents may cause vasodilatation, hypotension, a prolonged QT interval, extrapyramidal symptoms or neuroleptic malignant syndrome.

Clonidine – α_2-adrenoceptor agonists (e.g. clonidine) inhibit catecholamine release, and exert synergistic interactions with opioids and other sedatives. Administration of α_2-adrenoceptor agonists results in functional central sympatheticolysis, which may be useful in withdrawal syndrome from chronic alcohol abuse, during the weaning from long-term mechanical ventilation and in patients with tetanus. Clonidine doses are usually 0.9–1.5 mg/day, but may range up to 15 mg/day. Contraindications include hypovolaemia (risk of refractory hypotension) and severe arrhythmias.

Isoflurane delivered into the ventilator circuit in concentrations of 0.25–0.50% has been used to provide sedation of ICU patients. Problems include vasodilatation and the need for expired vapour scavenging.

Chloral hydrate is used in paediatric intensive care practice as an adjunct to intravenous sedation, particularly during weaning from ventilation. It is metabolized in the liver to the active compound trichloroethanol. The acetate and glucuronide metabolites accumulate in renal dysfunction

Pharmacology and dose of sedative drugs

	Plasma half-life (hours)	Elimination/ metabolism	Recovery time after prolonged sedation	Active metabolites (half-life hours)	Loading dose (mg/kg)	Infusion rate (mg/kg/ hour)
Morphine	2–4	Liver >> kidney	Days	Morphine-6-glucuronide (2–10)	0.05–0.15	0.02–0.1
Fentanyl	1.5–6	Liver	Hours–days	None	0.0001–0.0004	0.001–0.004
Alfentanil	1–2	Liver	Minutes–hours	None	0.004–0.014	0.01–0.1
Remifentanil	0.7–1.2	Blood/tissue Esterases	Unchanged	None	0.0005–0.001	0.0001–0.0005
Midazolam	1.0–12.3[1]	Liver	Hours–days[1]	None	0.025–0.35	0.025–0.2
Diazepam	20–50	Liver	Days	Desmethyldiazepam (30–200) + others	0.1–0.2	0.007–0.15
Lorazepam	10–20	Liver	Days	None	0.02–0.04	0.002–0.05
Propofol	< 1	Liver/extra-hepatic	Minutes–hours	None	0.5–3[2]	0.5–8

[1] May accumulate, especially after 48 hours, in the elderly and in obese patients, exacerbated by liver or renal failure. Initial short half-life results from redistribution into fat, not elimination.

[2] Slow intravenous titration until loss of consciousness occurs, because it may cause significant hypotension, especially if the patient is hypovolaemic or shocked.

1

Specific features of opiates in the ICU

Morphine

- Cheap, 'gold-standard'
- Long-acting, slow to reach steady state
- Renally excreted, metabolite (morphine-6-glucuronide) accumulates in renal failure
- May cause histamine release, risking hypotension

Fentanyl

- Initial rapid redistribution, but lipid stores are soon saturated
- No additional accumulation in renal failure
- Minimal cardiovascular effects

Alfentanil

- Relative lack of lipid solubility and short half-life minimize accumulation, except in severe hepatic failure
- Minimal cardiovascular effects
- Relatively expensive

Remifentanil

- Metabolized by nonspecific blood and tissue esterases, hence short duration of action unaffected by organ dysfunction
- Expensive

Pethidine

- Metabolite (norpethidine) accumulates during infusion and may cause convulsions

2

Monitoring sedation levels

Clinical – several sedation scores have been advocated, but none has undergone rigorous testing or gained widespread clinical acceptance. Ideally, a sedation score for regular use in a busy ICU must be valid and simple. Most objective sedation scores based on a single continuum (e.g. the Ramsay scale; Figure 3) are simple to use, but lack the detail to document the patient's mental state accurately. They do not contain a separate assessment for pain, and fail to distinguish between level of consciousness and abnormal mental states. In October 1999, the Intensive Care Society published national guidelines on sedation, concentrating on the principles of management, applicable to any drug.

Electrophysiological – most sedation scores are useless for patients receiving neuromuscular relaxants in whom an accurate physiological monitor is required. Possibilities include:

- bispectral index, a form of EEG processing
- auditory-evoked potentials
- oesophageal contractility.

The first two techniques appear reliable at discriminating consciousness from unconsciousness in the anaesthetized patient, but their role in the ICU has yet to be established.

Neuromuscular paralysis

The use of muscle relaxants fell from about 90% in the early 1980s to less than 10% in the 1990s. During this period, ICU practice changed from the use of deep to rousable sedation. Indications for muscle relaxants in the ICU include:

- refractory hypoxaemia (may decrease oxygen consumption)
- to allow inverse ratio or prone ventilation
- raised intracranial pressure
- status epilepticus
- tetanus
- during patient transport.

Ramsay scale for clinical endpoints for sedation

Level	Description
1	Anxious, agitated or restless
2	Cooperative, oriented, and tranquil
3	Responds to commands only
4	Asleep, but brisk response to glabellar tap or loud auditory stimuli
5	Asleep, but sluggish response to glabellar tap or loud auditory stimuli
6	No response

3

Neuromuscular blockers – the ultra-short acting depolarizing agent suxamethonium (succinylcholine) is predominantly used to facilitate emergency tracheal intubation. It is unsuitable for prolonged or frequently repeated use in the ICU. Figure 4 shows the features of commonly used non-depolarizing agents.

Monitoring neuromuscular blockade in intensive care is required to avoid overdose. The degree of neuromuscular blockade can be assessed by stopping the infusion, by witholding further doses, or by regular measurement of neuromuscular transmission using a peripheral nerve stimulator (e.g. train-of-four count).

Problems with muscle relaxants

- The patient may receive inadequate sedation.
- Accumulation of the parent compound or active metabolite may occur with the aminosteroidal muscle relaxants, especially during hepatic or renal impairment.
- Prolonged neuromuscular paralysis may occur after discontinuing relaxant therapy, as a result of drug accumulation or, in some cases, a myopathy. Myopathy is more likely in the presence of severe sepsis, or high-dose corticosteroid therapy.
- The protective reflexes may be lost.
- Hypokalaemia, hyperkalaemia, hypophosphataemia and many drugs (e.g. aminoglycoside antibiotics) may enhance paralysis.

Features of common non-depolarizing agents

Vecuronium

- Chemical analogue of the aminosteroid pancuronium
- Intubating dose 0.1 mg/kg, duration 35–45 minutes
- Infusion dose 1–2 μg/kg/minute
- Cardiovascularly stable
- Short duration of action makes it suitable for administration by infusion
- May accumulate when renal function is impaired

Pancuronium

- Long-acting (0.1 mg/kg lasts 90–100 minutes)
- Possesses vagolytic effects
- May accumulate if given by infusion

Rocuronium

- Aminosteroid agent, similar to vecuronium but with a slightly longer duration of action
- After a bolus dose of 0.6–1.2 mg/kg, onset time is almost as rapid as suxamethonium. Satisfactory intubating conditions occur after about 75 seconds (or less with higher dose)

Atracurium

- Benzylisoquinolinium derivative with a duration of action similar to vecuronium; can be given by continuous infusion
- Intubating dose, 0.4–0.5 mg/kg; infusion, 4–12 μg/kg/minute
- Organ-independent metabolism; little tendency to accumulate
- Histamine release common if given too rapidly
- A metabolite (laudanosine) accumulates in profound hepatic failure; it causes convulsions in animals, but not in humans

Cisatracurium

- Potent stereoisomer of atracurium; lower doses required, resulting in less generation of laudanosine
- No histamine release in clinical doses
- May be the agent of choice on the ICU, for its cardiovascular stability, and organ-independent metabolism
- Intubating dose, 0.1 mg/kg; infusion dose, 1–2 μg/kg/minute

Sepsis

Jonathan M Fielden

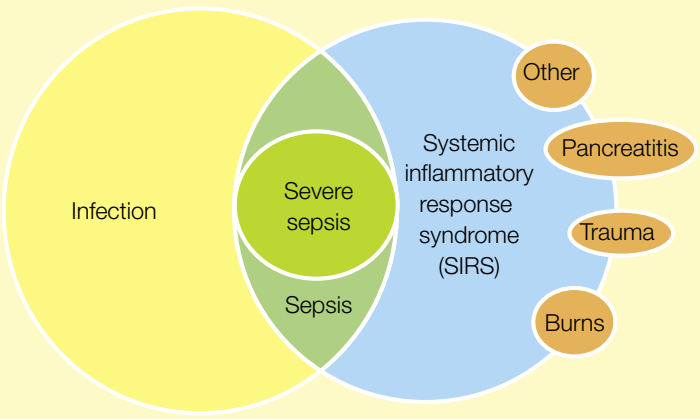
Jonathan M Fielden is Consultant in Anaesthesia and Intensive Care Medicine and Clinical Director of Emergency Services at the Royal Berkshire Hospital, Reading. He qualified from Bristol, training in general medicine and then anaesthesia and intensive care in Bristol, Southampton, Portsmouth, and Sydney, Australia. His research interests include outreach, resuscitation and sepsis.

Sepsis remains a significant challenge to intensive care medicine. It is the cause of 27.7% of UK adult general ICU admissions. These 23,000 cases represent an estimated incidence of 0.5/1000 population; mortality is about 45%. In the USA, sepsis is the thirteenth leading cause of death and is a significant economic burden. Sepsis kills as many people as acute myocardial infarction. Early recognition and removal of the source of infection are key factors in management. Until recently, treatment has been largely supportive but understanding of the sepsis process has allowed the development of novel interventions that are improving survival.

Definition

Sepsis is part of the body's response to infection (Figure 1). Early investigations into treatment for sepsis were hampered by a lack of knowledge about the mechanisms driving sepsis. Bone *et al.* clarified this and produced the agreed consensus definitions (Figure 2). Sepsis is characterized by a systemic inflammatory response (SIRS) to an infective insult and key abnormalities of the homeostasis of coagulation and endothelial function. However, only 60% of cases are likely to be confirmed microbiologically and there is no correlation between severity of sepsis and documented infection. Bone *et al.* also categorized the stages of the body's response to sepsis (Figure 3). Recent research has revealed the key aspects of the pathophysiological derangement and allowed targeted research.

Spectrum of response



1

ACCP/SCCM consensus conference definitions[1]

Systemic inflammatory response syndrome (SIRS)
Response to a wide variety of severe clinical insults manifest by two or more of the following:
- temperature > 38 °C or < 36 °C
- heart rate > 90 beats/minute
- respiratory rate > 20 breaths/minute or partial pressure of carbon dioxide in arterial blood ($PaCO_2$) < 4.2 kPa (32 mm Hg)
- WCC > 12 x 10^9/litre or < 4 x 10^9/litre, or > 10% immature forms

Sepsis
Two SIRS criteria plus (signs of) infection

Severe sepsis/SIRS
Sepsis/SIRS associated with organ dysfunction, hypoperfusion of hypotension

Sepsis-induced hypotension
Systolic blood pressure < 90 mm Hg or reduction > 40 mm Hg from baseline in absence of other causes

Septic shock/SIRS shock
Severe sepsis/SIRS with hypotension despite adequate fluid resuscitation with perfusion abnormalities including those requiring inotropes

Multiple organ dysfunction syndrome (MODS)
Presence of organ dysfunction in an acutely ill patient such that homeostasis cannot be maintained without intervention

[1]ACCP, American College of Chest Physicians; SCCM, Society of Critical Care Medicine.

2

Reaction to sepsis

Infectious insult
Host factors
- Epithelial barrier
- Local defence (e.g. pH)
- Immune status
- Genetic factors

Immunity
- T and B cell response

Infecting agent factors
- Bacteria (link to epithelium, biofilms)
- Gram-negative endotoxaemia
- Gram-positive exotoxins
- Fungi

Preliminary systemic response
Febrile reaction
Cytokines
- Tumour necrosis factor-α
- Interleukin-1
- Interleukin-6
- Interleukin-8
- Interferon-γ

Overwhelming systemic response
Endothelial cell dysfunction
- Shift of phenotype to thrombotic state
- Increased permeability
- Vasodilatation

Organ dysfunction

Compensatory anti-inflammatory reaction
- Interleukin-4
- Interleukin-10
- Transforming growth factor-β

Immunomodulatory failure

3

Mechanism of sepsis-induced multiple organ failure

The SIRS response in sepsis results in systemic vasodilatation, increased cardiac output, falling blood pressure and reduced oxygen extraction from the tissues. The circulatory abnormalities of SIRS and sepsis lead to global tissue hypoxia. The key advancement in understanding the link between sepsis and multiple organ failure was the definition of the disturbance of homeostasis of coagulation and fibrinolysis. The initial insult (infection in sepsis) alters endothelial function with the release of tissue factors. There is also release of a variety of cytokines (the proinflammatory agents: tumour necrosis factor-α (TNF-α), interleukin (IL)-1β and IL-6; the excess anti-inflammatory cytokines IL-4, IL-10, IL1-receptor antagonist and soluble TNF receptor I and II) and upregulation of circulating monocytes. This leads to activation of the extrinsic system of coagulation and formation of thrombin, further amplifying the thrombotic response via the intrinsic coagulation cascade. The subsequent microvascular clotting leads to organ dysfunction and failure. There is also a reduction in some of the natural inhibitors of clotting (e.g. activated protein C) from increased consumption and endothelial injury. The normal homeostatic balance of fibrinolysis in the face of thrombosis is also disrupted in sepsis by increased inhibition from cytokine-induced increases in plasminogen activator inhibitor type 1 and plasmin–antiplasmin complexes.

The combination of increased thrombosis and reduced fibrinolysis creates microthrombi, which lead to multiple organ dysfunction and organ failure. The clinical manifestations are seen as the development of, for example, acute respiratory distress syndrome, disseminated intravascular coagulation or renal failure.

Management of the septic patient

The first step in the treatment of sepsis is recognition of the critically ill patient. The signs are often missed, and delay in referral to ICU and poor management of critically ill patients is all too common. Maintaining a high index of suspicion, monitoring the vital signs for the hallmarks of SIRS and identifying the possible sources of infection are vital. One of the most sensitive markers of deterioration in critically ill patients is an increase in respiratory rate, a sign often poorly recorded unless emphasized with the use of Medical Early Warning Scores or a similar system. Careful history and examination identify possible sources of infection and guide initial therapy.

Initial therapy

Immediate resuscitation based on the 'ABDCE' system is important to stabilize the patient. At this stage, exact diagnosis is unimportant and treating immediate life-threatening problems is the goal. Once the patient is stabilized, possible sites of infection should be examined, including:
- all body surfaces and cavities
- blood
- sputum or bronchoalveolar lavage fluid
- aspirated lesions/collections
- urine
- faeces
- CSF should be cultured if there is suspicion of intracerebral infection (provided raised intracranial pressure can be confidently excluded).

Intra-abdominal signs should prompt early surgical review and operative intervention unless good reason suggests otherwise. Blood should be taken for blood count, urea and electrolytes, calcium, magnesium, liver function tests, coagulation tests (prothrombin time, activated partial thromboplastin time, fibrinogen) and arterial blood gases including assessment of lactate. Some advocate assessment of other biochemical markers of infection (e.g. procalcitonin, C-reactive protein, von Willebrand factor) but this has yet to receive universal acceptance.

Indwelling intravascular catheters should be assessed for signs of phlebitis or infection. If not required, they should be removed and cultures taken from the insertion site and per lumen. Chest radiography and imaging of other sites should be arranged. If invasive monitoring or inotropic support is required, admission to a high dependency unit is indicated. Patients requiring respiratory support or monitoring beyond the capabilities of this unit should be admitted to ICU.

Antibiotic therapy

Initial therapy should be guided by a clinical impression of the probable site of infection, together with guidance from microbiologists on empirical therapy and specific agents, once microbiological sensitivities are known. Early accurate treatment is important and should be guided by local knowledge and agreed guidelines to prevent overuse of broad-spectrum antibiotics and further development of microbiological resistance. As a guide, use the right drug, at the right dose, at the right time, treat the patient and not the figures, and avoid toxicity.

Supportive management

Early management to return physiological parameters towards the normal range for that patient shows promise in improving outcome. Rivers *et al.* have recently shown a reduction in hospital mortality for early (i.e. Emergency Department) goal-directed therapy using a protocol to drive up central venous pressure to 8–12 mm Hg, by maintaining mean arterial pressure (MAP) at 65–90 mm Hg and keeping central venous blood oxygen saturation above 70%, using fluids, inotropes and vasopressors. This contradicts some earlier studies of goal-directed therapy in ICU, but Rivers and his colleagues argue that early intervention prevents the augmentation of the SIRS response driven by tissue hypoxia in the uncorrected septic patient. Furthermore, they were not aiming for supranormal values, which may have been a problem with earlier studies. The principle of early detection and correction of reduced tissue perfusion seems logical.

First-line treatment involves fluid resuscitation, aiming for a MAP of 65–90 mm Hg. Central venous pressure can be used as a guide for 'over filling' but aiming for a specific value, particularly when the patient is ventilated, is difficult. The place of pulmonary artery catheters is under debate and subject to a multicentre trial. Several studies promote their use, particularly before high risk surgery but others doubt the benefit. Initially, the use of the Rivers criteria for central venous pressure, MAP and urine output (> 0.5 ml/kg/hour) are reasonable aims. This can be supplemented by using lactate measurements and measurement of oxygen delivery and use.

There is no evidence that the use of any particular inotrope is best in sepsis. Noradrenaline (norepinephrine) is probably the first vasopressor of choice when aiming to reverse the vasodilatation and reduced systemic vascular resistance often seen in sepsis. When increased inotropy and chronotropy are required, dobutamine is often used. Adrenaline (epinephrine) has the benefit of α and β sympathetic activity and is often advocated if simplicity is required (e.g. initial resuscitation, theatre); there is evidence of detriment from increased hepatic lactate production. There are advocates for other inotropes (e.g. dopexamine) but the use of dopamine is diminishing because of significant evidence against its use.

Many patients require ventilation to maximize oxygenation and minimize the work of breathing. Following work in acute respiratory distress syndrome, most advocate the use of a protective lung ventilation strategy with tidal volumes limited to 6–8 ml/kg, mean airway pressures less than 35 cm H_2O, relatively high positive end-expiratory pressure (PEEP) of 5–15 cm H_2O, and a limitation of fraction of oxygen in inspired air (FiO_2) to a maximum of 0.6.

Early aggressive (high volume 30–50 ml/kg) continuous veno-venous haemofiltration (CVVHF) is advocated in sepsis. It is thought that the removal of inflammatory mediators aids resolution of the SIRS response. Whether short-term or prolonged CVVHF is best is unproven. However, the development of renal failure is common and continued CVVHF is often required. Continuous treatment is more beneficial than intermittent.

As part of aiming to return physiological parameters to normal, aggressive management of blood sugar (4.4–6.1 mmol/litre) levels with insulin is beneficial. In addition, treatment of the relative adrenal insufficiency often found in sepsis with replacement doses of hydrocortisone, 300 mg/24 hours, often reduces inotropic requirements.

Novel therapies

Vasopressin – the profound vasodilatation seen in sepsis can become refractory to catecholamine support. Treatment with vasopressin or vasopressin analogues (e.g. terlipressin) improves MAP and reduces the need for other vasopressors. This matches the research evidence of the basis of vasodilatory shock in sepsis and SIRS. The mechanism is thought to be related to the relative naivety of the vasopressin receptors to stimulus during sepsis, unlike the down-regulated catecholamine receptors.

Methylene blue is known to be an antioxidant. Infusion of methylene blue improves vascular responsiveness to inotropes in the septic patient.

Activated protein C is one of the most recent treatments available in sepsis. It has a physiological role in maintaining the coagulation and fibrinolytic balance as well as in reducing inflammation through inhibiting thrombin-mediated inflammatory activities and leucocyte attachment to the endothelium. It is reduced during sepsis and levels correlate to poor outcome. The PROWESS study showed that activated protein C could significantly reduce (28 day) mortality in sepsis (absolute risk reduction 6.1%), a goal not achieved by any other inflammatory/coagulation mediator study. Although awaiting long-term outcome data, and despite its high cost, this seems to be a significant and cost-effective advance.

Prevention

Close attention to hand washing and skin decontamination with alcohol reduce nosocomial spread. Efforts to limit antibiotic resistance through careful policies and surveillance are important. Simple measures to reduce ventilation-associated pneumonia such as semi-recumbent positioning also have a role, as does careful insertion and management of indwelling intravenous and urinary catheters. Adequate and appropriate nutrition, ideally via the enteral route, should be administered.

Outcome

Sepsis carries a high mortality (45%). Until the recent PROWESS trial, most research showed a mortality of 30–60%. It increases by 15–20% for each additional organ failure, and non-survivors tend to consume significant health resources. There is hope that early normalization of physiology and the appropriate use of agents that reduce the SIRS response (e.g. activated protein C) will reduce mortality. ◆

Severity of Illness Scoring Systems

John Pappachan

John Pappachan is Consultant in Intensive Care Medicine at Southampton University Hospitals Trust, UK. He trained in Newcastle, London and Wessex. His research interests include the epidemiology of intensive care, renal replacement strategies in sepsis, and the genetic predisposition to sepsis.

This contribution describes systems used to predict the hospital outcome of patients admitted to an ICU. An acute physiology score is usually derived using values obtained in the first 24 hours following ICU admission. Hospital outcome is then predicted using a logistic regression equation. Development and validation, a brief description of the most popular systems, their applicability in the UK and the standardized mortality ratio (SMR) are described.

Scoring systems

Data collection on the ICU is necessary to facilitate research, quality assurance and resource management. Severity of illness scoring systems aid the case-mix adjusted collection of such data. However, none is perfect and their use to triage individual patients and to compare the quality of care in different ICUs is severely limited. An appreciation of their limitations and the statistical methods of assessing their goodness of fit are vital if the information that they provide is to be used appropriately.

Potential uses for scoring systems include:

- case-mix adjustment for entry into randomized controlled trials
- audit and comparison of ICU performance
- a mechanism to decide resource allocation.

Scoring systems use a logistic regression equation based, variably, on disease severity, age and diagnosis to derive the probability of hospital death (on a scale of 0 to 1, where 0 = survival and 1 = death). The SMR describes the ratio of expected to observed deaths. Case-mix variation and the need to derive binary (live or die) data from a probability estimate, limit the use of such systems to evaluate ICU performance.

System development and validation

Patient variables and the coefficients used to describe their influence on survival are selected either by clinical consensus or more robust statistical analysis. Typically, systems are developed from information collected on a cohort of patients admitted to a group of ICUs over a given period. The predictive equation is then validated on a subsequent cohort of patients admitted to the same or other units.

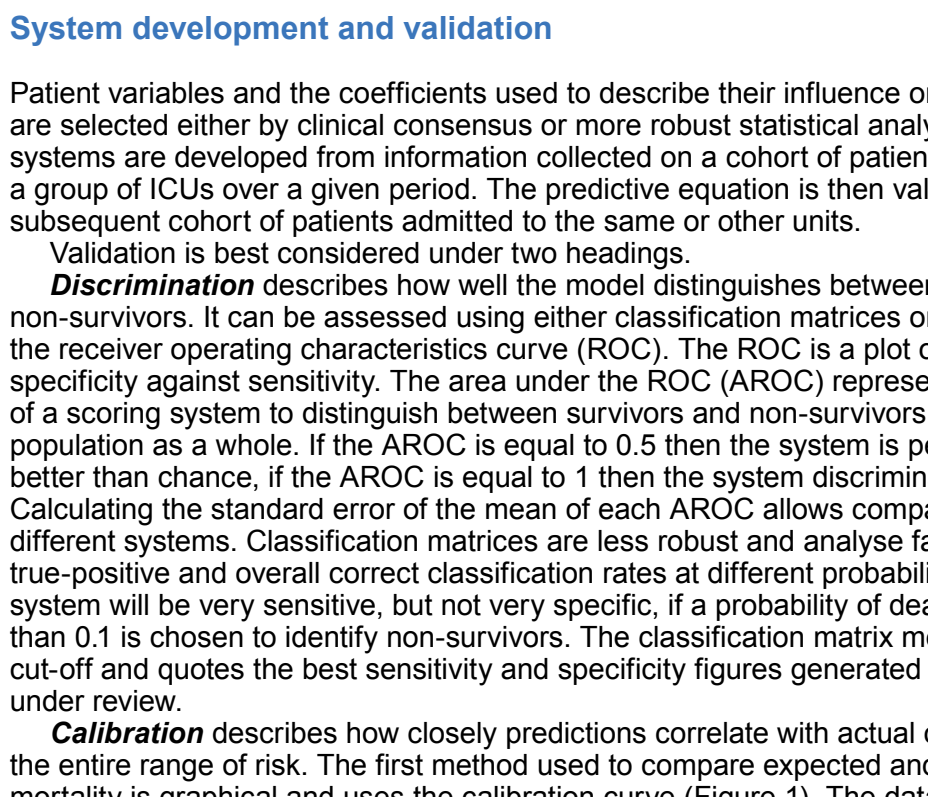
Validation is best considered under two headings.

Discrimination describes how well the model distinguishes between survivors and non-survivors. It can be assessed using either classification matrices or the area under the receiver operating characteristics curve (ROC). The ROC is a plot of derivatives of specificity against sensitivity. The area under the ROC (AROC) represents the ability of a scoring system to distinguish between survivors and non-survivors in the patient population as a whole. If the AROC is equal to 0.5 then the system is performing no better than chance, if the AROC is equal to 1 then the system discriminates perfectly. Calculating the standard error of the mean of each AROC allows comparison between different systems. Classification matrices are less robust and analyse false-negative, true-positive and overall correct classification rates at different probability cut offs. A system will be very sensitive, but not very specific, if a probability of death of greater than 0.1 is chosen to identify non-survivors. The classification matrix method varies the cut-off and quotes the best sensitivity and specificity figures generated by the system under review.

Calibration describes how closely predictions correlate with actual outcome across the entire range of risk. The first method used to compare expected and observed mortality is graphical and uses the calibration curve (Figure 1). The data generated when APACHE III (see below) was applied to ICU patients in the UK demonstrated the trend for observed mortality to increase as the predicted risk of hospital death increases. However, there was a significant overestimation of mortality in the lower-risk bands, which represented most of the sample population. This implies either that the system does not fit the data, or that the ICUs examined were performing poorly.

In an attempt to answer this question, a statistically more robust method of assessing calibration is used. The Hosmer–Lemeshow C and H cumulative χ^2 statistics compare the actual and expected mortality rates across 10 defined bands of mortality risk (H^2) and 10 deciles, which include equal numbers of patients (C^2). A significant result ($p < 0.05$) suggests poor system calibration. The only published assessment of APACHE III in UK patients suggests poor 'goodness of fit'. That for the APACHE II system (see below) in a selected group of ICUs suggests better, but still imperfect, calibration. To date, no system has been both developed and validated in UK patients. Thus it is not possible accurately to assign an observed difference between predicted and observed outcome to poor ICU performance or poor system fit.

Calibration curve describing the relationship between observed and expected mortality using APACHE III in the ICU (UK)



1

APACHE II and other systems

APACHE II used a theoretical approach to the selection and weighting of variables used in its predictive equation. This was based on consensus opinion and the findings of previous studies. Other scoring systems, for example the Mortality Prediction Model (MPM), were developed using a combination of univariate and multivariate logistic regression techniques. Neither approach has been proven to be superior in terms of the resulting goodness of fit of the system to target populations.

APACHE II was developed in 1985 from a database of 5815 intensive care admissions to 13 ICUs in the USA. The severity of illness of patients is assessed using the worst values of 12 physiological variables in the first 24 hours following admission to the ICU. These values generate an acute physiology score (APS) by following the weighting system described in Figure 2. Adding the weightings for chronic disease and age to the APS generates the final APACHE II score. The probability of hospital mortality is generated using the logistic regression equation shown in Figure 2. This equation adds the diagnostic category weight.

APACHE III, the direct successor of APACHE II, uses 17 physiological variables, comorbidity and age to produce an acute physiology score. In addition, it uses the diagnostic code and a weighting for source before ICU admission to predict outcome, length of stay, and the likely intensity of nursing required. It presently represents the largest published ICU database and has been promoted for use as a management tool for use in the allocation and evaluation of ICU resources. However, its predictive equation is not in the public domain, its claimed correction for lead-time bias (the effect of treatment before ICU admission) is unproven, and it has been shown to fit a UK database poorly.

There are a variety of simplified, more physiologically based systems available, such as the MPM and the Simplified Acute Physiology Score (SAPS).

The APACHE II weights for physiological variables

Physiological variable	High abnormal range					Low abnormal range			
	+4	+3	+2	+1	0	+1	+2	+3	+4
Temperature – rectal (°C)	≥ 41	39–40.9		38.5–38.9	36–38.4	34–35.9	32–33.9	30–31.9	≤ 29.9
Mean arterial pressure	≥ 160	130–159	110–129		70–109		50–69		≤ 49
Heart rate (ventricular)	≥ 180	140–179	110–139		70–109		55–69	40–54	≤ 39
Respiratory rate (non-ventilated or ventilated)	≥ 50	35–49		25–34	12–24	10–11	6–9		≤ 5
Oxygenation: A-aDO_2 or PaO_2 (mm Hg) A: $F_IO_2 \geq 0.5$ record A-aDO_2	≥ 500	350–499	200–349		< 200				
B: $F_IO_2 \leq 0.5$ record only PaO_2					> 70	61–70		55–60	< 55
Arterial pH	≥ 7.7	7.6–7.69		7.5–7.59	7.33–7.49		7.25–7.32	7.15–7.24	< 7.15
Serum sodium (mmol/litre)	≥ 180	160–179	155–159	150–154	130–149		120–129	111–119	≤ 110
Serum potassium (mmol/litre)	≥ 7	6–6.9		5.5–5.9	3.5–5.4	3–3.4	2.5–2.9		< 2.5
Serum creatinine (mg/100 ml) – double point score for acute renal failure	≥ 3.5	2–3.4	1.5–1.9		0.6–1.4		< 0.6		
Haematocrit (%)	≥ 60		50–59.9	46–49.9	30–45.9		20–29.9		< 20
WBC (total/mm^3; 1000s)	≥ 40		20–39.9	15–19.9	3–14.9		1–2.9		< 1

Glasgow coma score (GCS). Score = 15 minus actual GCS
Total acute physiology score (APS) = sum of the 12 individual variable points.
The APS is summed with age points and chronic health points according to APACHE II definitions.
The probability of hospital death (R) is then calculated from the equation:
ln (R/1 – R) = –3.517+ (APACHE II score x 0.146) + (0.603, only if post-emergency surgery) + (diagnostic category weight).

2

The standardized mortality ratio (SMR)

For a cohort of patients numbering 200 or more, the accepted method of comparing outcome after adjusting for presenting factors that might influence it (e.g. the severity of physiological derangement, age and diagnosis – i.e. case-mix adjustment), is to use the SMR. This represents the ratio of observed deaths in the cohort, to the number of deaths predicted by a scoring system. If the SMR is 1 then the cohort is acting as predicted; if the SMR is significantly greater than 1 this suggests there is excess mortality. If scoring systems were perfect, transferable and able to adjust for case-mix equally well in both development and external datasets, the SMR might reflect ICU performance. These assumptions are not always valid and there are other confounding variables, such as lead-time bias and poor treatment in the ICU leading to a physiological deterioration, that limit the use of the SMR for the audit of ICU performance.

Ventilatory Modes

Matthew Williams
Martin G Tweeddale

Matthew Williams is Specialist Registrar in Anaesthesia at the Queen Alexandra Hospital, Portsmouth, UK. He qualified from Bristol University and is training at the Wessex School of Anaesthesia, based in Southampton, UK. His interests are anaesthesia for major surgery and intensive care medicine.

Martin G Tweeddale is Consultant in Intensive Care Medicine at Queen Alexandra Hospital, Portsmouth, UK. He completed a PhD in pharmacology before qualifying in medicine from Westminster Hospital. He trained in medicine and clinical pharmacology at McGill University Montreal, Canada, moved to critical care medicine and directed ICUs in Newfoundland and Vancouver before being appointed at Portsmouth.

Vesalius first discussed tracheostomy and ventilation as a means of resuscitation in 1555 but it was another 300 years before the first ventilator, an iron lung, was built in Paris by Woillez. Early in the 20th century, positive-pressure ventilation during anaesthesia allowed the development of more complex surgery, but only in the 1950s did the early versions of today's ICU ventilators become available.

Over time, ICU ventilators have become increasingly sophisticated and complicated, so that they now provide intensivists with a variety of modes to use in different clinical situations. However, the terminology used to describe these modes is not standardized. For much of this article, the terminology of the Siemens 300 ventilator is used because of its wide use in the UK.

To avoid confusion, the authors focus on two fundamental characteristics of all the modes available on ICU ventilators:

- the way each breath is delivered (i.e. constant pressure versus constant flow)
- whether the breaths are controlled or supported.

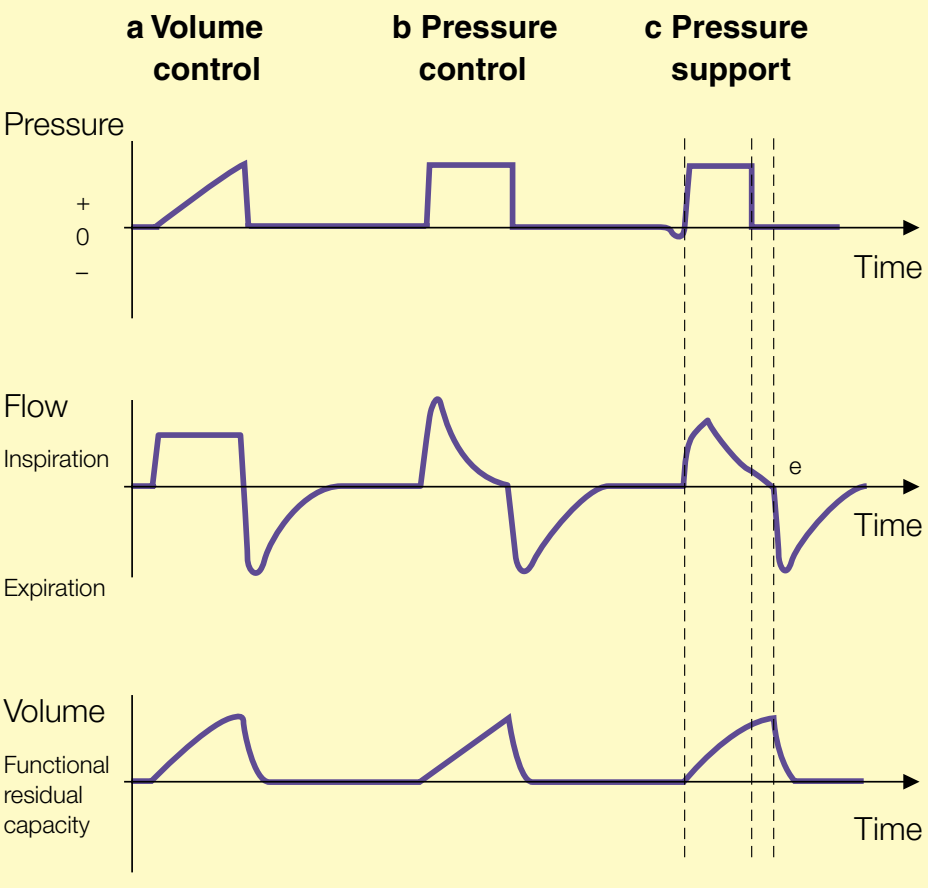
In all modes, exhalation is passive. Indications for and complications of mechanical ventilation are dealt with elsewhere.

Controlled modes

Controlled mechanical ventilation (CMV) is the ultimate 'controlled' mode because it delivers only a pre-selected tidal volume at a set rate. Apart from alarm settings, the only other parameter that can be adjusted is the inspiratory flow rate. This is controlled either directly (which determines the inspiratory:expiratory (I:E) ratio) or indirectly by altering the I:E ratio. In the latter case, any change in inspiratory time (with tidal volume and rate fixed) changes the flow rate. A disadvantage of using I:E ratios to govern inspiratory flow rate (as with the Siemens 300) is that the latter changes whenever rate, tidal volume or inspiratory time are adjusted. The waveforms are as represented for volume control in Figure 1a.

In the CMV mode, exhalation commences once the set tidal volume has been delivered. CMV is suitable only for apnoeic patients (e.g. in the operating theatre or during transport when the patient is paralysed). It should not be used when there is any possibility for spontaneous breathing because synchrony between patient/ventilator is difficult to attain. On some ventilators, 'CMV' is an assist-control (A–C) mode (see below).

Representative single breaths in three commonly used modes



In pressure support, the support ceases in the terminal phases of inspiration – the patient then determines the onset of exhalation (e). This differs from the control modes where the onset of exhalation is time (or volume) cycled.

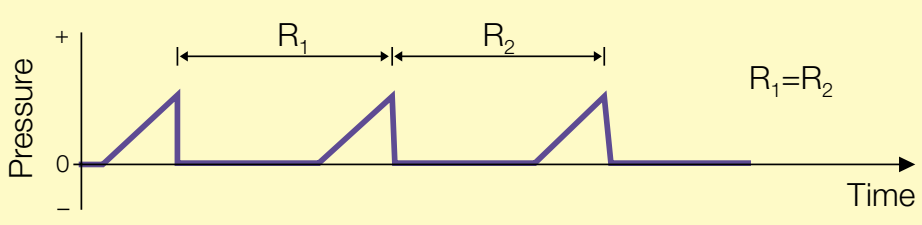
1

Assist-control – volume control sets a baseline rate and tidal volume as in CMV, but allows inspiratory effort by the patient to initiate additional breaths. The patient can therefore set their own respiratory rate, but all patient-triggered breaths (Figure 2) will be of the pre-set volume. This encourages better synchrony between patient and ventilator (and hence reduces the sedation requirements) while markedly reducing the inspiratory work of breathing. The possibility of weaning can be considered once the patient starts to trigger the ventilator. Exhalation occurs as in CMV (Figure 2).

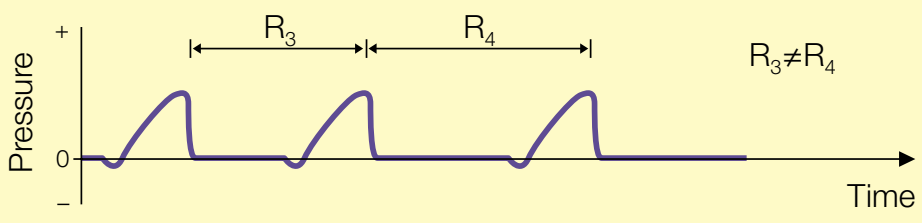
In assist-control, the inspiratory flow rate may be adjusted as in CMV. When patient-triggered breathing occurs, the inspiratory flow should be set to meet, but not exceed, the patient's inspiratory flow demands. This improves synchrony and maximizes the reduction in work of breathing. Many modern ventilators respond to high respiratory drive in patients by delivering a tidal volume above the set value in assist-control.

Pressure versus time waveforms comparing controlled and assist-control ventilation

a Control mode



b Assist mode



The graphs show the negative pressure generated by the patient to trigger assisted breaths at their own rate (thus R–R intervals are not constant). In control mode, the breaths are delivered at a predetermined interval irrespective of patient effort

2

Pressure control (PCV) is also an assist-control mode, but instead of applying a constant inspiratory flow, the ventilator provides a constant inspiratory pressure that is applied for a set inspiratory time – a 'square' wave of pressure (see Figure 1b). Flow is provided solely to maintain the set inspiratory pressure. Therefore, initial flow is high but decreases throughout inspiration. Expiration starts immediately on completion of inspiration (i.e. is time cycled), so close attention to the I:E ratio is essential in this mode.

At longer inspiratory times, the flow and pressure curves are different in PCV from those of volume control or assist-control (see Figure 1). However, at shorter inspiratory times, the flow and pressure curves are similar to assist-control using a decelerating inspiratory flow pattern – a facility that many ventilators provide in the belief that it is more natural.

In PCV, the tidal volume delivered is dependent on the respiratory system impedance as well as inspiratory time, and therefore changes with the changing clinical situation. Tidal or minute volume alarms should therefore be set to give adequate warning of excessive or under ventilation.

The main advantage of PCV is its potential to recruit atelectatic lung units while reducing the risk of barotrauma. When lung compliance is low because of acute respiratory distress syndrome or acute lung injury (ARDS/ALI), there is a broad distribution of time constants between different lung units. In assist-control, such a 'stiff' lung requires high end-inspiratory pressures to inflate units with a longer time constant, but such pressures applied to normally compliant lung units can result in over-inflation and barotrauma. By definition, PCV limits the maximum pressure applied to any part of the lung, and therefore reduces the risk of over-inflation. In PCV, lung recruitment is achieved by applying this constant pressure for a long inspiratory time, even to the extent of reversing I:E ratios. With reversed I:E ratios, as frequency rises, expiratory time progressively shortens and may reach a value that prevents full exhalation during each cycle. This results in the generation of intrinsic positive end-expiratory pressure (PEEP) and consequent hyperinflation. Since intrinsic PEEP may be either helpful or detrimental, its presence should always be sought and its potential consequences noted, particularly if obstructive airways disease co-exists with ARDS/ALI.

Triggering

Control modes use time cycling to determine the respiratory rate, but during assisted ventilation, this time cycling is over-ridden by the patient's inspiratory efforts. Most commonly, a set negative pressure must be generated by the patient in order to trigger the ventilator to deliver a breath. The trigger sensitivity (which uses electronic logic systems to compare the signal with a reference) is normally set at 1–2 cm H_2O below PEEP but this setting can be altered (if it is decreased, the work of breathing is increased and vice versa). Once the ventilator detects that the trigger sensitivity has been exceeded, the demand valve opens and inspiration commences. Too high a setting can lead to auto-cycling especially if water collects in the breathing circuit. Because pressure triggering can lead the patient to inhale for a short time against a closed system (until the demand valve opens), some newer ventilators have established a flow-triggered system. Here, a constantly monitored flow is delivered to the circuit (flow-by) during exhalation, and the ventilator initiates inspiration whenever this bias flow is reduced by the patient's inspiratory effort. As with pressure triggering, the level of inspiratory effort (reduction in bias flow) required by the patient to initiate inspiration can be adjusted. Although it is claimed that flow triggering can reduce the inspiratory work of breathing more than pressure triggering, it is difficult to prove an advantage of one over the other.

Pressure support (PS)

PS is widely used in the ICU, particularly during weaning. It allows excellent matching of the patient's respiratory drive with the ventilator so that less sedation is required. In addition, the cardiovascular consequences of PS may be less than those of controlled modes since the maximal inspiratory support pressures are generally lower and are not maintained throughout inspiration.

PS can be used only in a spontaneously breathing patient because each breath must be triggered by the patient. Each triggered breath is then supported to a pre-set pressure level. Support ceases when the inspiratory flow falls to less than 5–10% of its peak value, at which point the ventilator opens the expiratory port (see Figure 1c). Thus, the patient is never faced with attempting to exhale against a closed system. With PS, the patient can control not only the respiratory rate but also tidal volume and I:E ratio. PS reduces the work of breathing in proportion to the set pressure, which can vary from zero (weaned) to full support (equivalent to PCV). As PS is progressively reduced, the patient takes up an increasing proportion of the inspiratory work until he is breathing spontaneously (although a low level of PS may be required to overcome the resistance of the ventilator circuit and tracheal tube). This makes PS the best available weaning mode in the opinion of many.

In PS, a square pressure waveform is delivered once a breath is triggered. At high support pressures in a patient with increased respiratory drive, the initial flow required to generate this pressure can be very high and therefore uncomfortable to the patient. The rate of rise of inspiratory flow can be adjusted by the 'slope' control to allow a more progressive achievement of the pre-set pressure and therefore better synchrony between patient and ventilator. Apnoea and low minute volume alarms must be available with this mode. Many ventilators now provide an assist-control backup should apnoea arise.

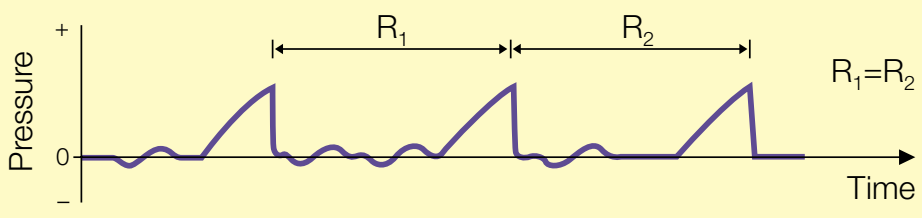
Hybrid modes

Many modern ventilators provide a variety of hybrid modes, a few of which are discussed below.

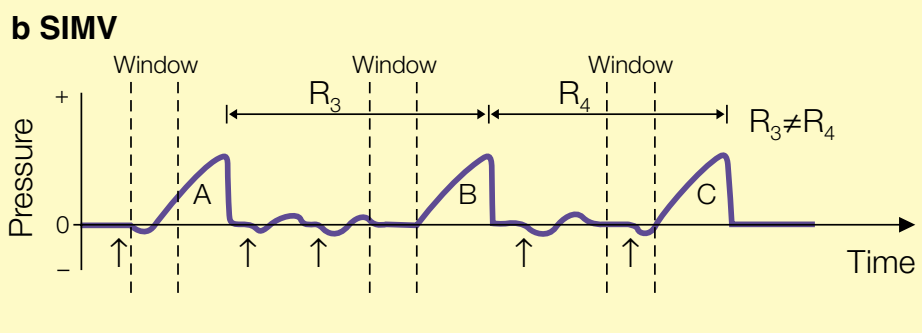
Intermittent mandatory ventilation (IMV) allows the patient to breathe spontaneously between mandatory breaths. The mandatory breaths are delivered at a pre-set time regardless of patient effort (Figure 3a). Thus, the mandatory breath may come at any point in the patient's spontaneous respiratory cycle. This may be difficult for the patient to tolerate and may increase the work of breathing, because the patient is fighting the ventilator. Inspiratory work may also be increased if the spontaneous respiratory efforts are inadequate and hence waste energy without ventilatory benefit.

Spontaneous breaths are possible between mandatory breaths in intermittent mandatory ventilation (IMV) and synchronized IMV (SIMV)

a IMV



b SIMV



IMV breaths are regular (as in controlled ventilation). In SIMV breaths are patient triggered (as in A–C) if the spontaneous inspiratory effort (↑) is detected during the machine-determined windows (breaths A and C); if no inspiratory effort is detected, a mandatory breath is delivered (breath B)

Synchronized intermittent mandatory ventilation (SIMV) was introduced over 20 years ago to avoid the problems of IMV. Modern ventilators invariably have SIMV not IMV, though they sometimes call it IMV. In SIMV, the patient receives a mandatory predetermined rate of either volume- or pressure-controlled breaths. The minute is broken into SIMV periods, determined by the rate set, during which each SIMV breath will be delivered, either triggered by the patient or time (see Figure 3b). On top of this the patient may trigger one or more spontaneous breaths between each SIMV breath; these breaths may be unsupported but, to avoid wasted respiratory effort, are often assisted by a preset level of PS (also possible in IMV). SIMV is therefore similar to assist-control in which the mandatory breaths are patient triggered and is hybrid because it also allows either spontaneous or supported breaths between the mandatory breaths.

SIMV can potentially be a bridge from assist-control to PS in weaning only if the patient's spontaneous breaths are adequate in rate and depth to tolerate a progressive reduction in the SIMV rate. Therefore, the patient must be examined to assess the adequacy of the spontaneous breaths even if arterial blood gases are reassuring.

Volume support (VS) is a pressure support mode in which a minimum tidal and minute volume are set. The ventilator progressively adjusts the inspiratory support pressure to whatever level is necessary (limited by the peak pressure alarm) to ensure that both targets are met or exceeded. In this mode, neither minute nor tidal volume can drop below the pre-set values. Predictably, if tidal volume decreases, the ventilator increases the PS until the volume target is again met. If the respiratory rate drops, tidal volume (i.e. PS) is adjusted to meet the target minute ventilation. If the rate rises, PS is adjusted to meet the target tidal volume, even if set minute volume is thereby exceeded. If both minute and tidal volume targets are exceeded, the PS is reduced until one or other target is again met.

Theoretically, this mode should allow 'automatic' ventilator-controlled weaning. However, the authors' experience suggests that this mode delays weaning, perhaps because it is difficult to define the 'right' settings for each patient and to follow the pattern of ventilator changes. If set too high, support is always provided and the patient cannot be weaned; if too low, the support is withdrawn too soon and weaning fails.

Pressure-regulated volume control (PRVC) attempts to combine PCV and VC. The ventilator adjusts the pressure control level to give a pre-set tidal volume at the lowest possible inspiratory pressure. Effectively, the ventilator tests the patient's compliance with an initial breath at 10 cm H_2O above PEEP. It then varies the delivery pressure incrementally to find the minimum PC value that delivers the required tidal volume. This mode is designed to compensate for the unavoidable variation in tidal volume with PCV as clinical conditions change. Because volume is fixed in PRVC, inflation pressure must be monitored to give warning of changes in patient compliance or resistance.

Adjuncts to oxygenation

PEEP sets an elevated pressure baseline during mechanical ventilation to prevent expiratory airway closure and aid oxygenation by increasing functional residual capacity (FRC) and reducing respiratory workload. Although labelled PEEP, it is applied throughout the ventilatory cycle. PEEP is achieved by a variety of methods that function as Starling resistors to raise the expiratory pressure without significantly increasing expiratory resistance. Excessive PEEP can lead to lung hyperinflation and so impair cardiac output and increase dead space. It may also contribute to barotrauma. PEEP must be optimized for each patient.

Continuous positive airway pressure (CPAP) is an elevation in baseline pressure throughout the respiratory cycle during spontaneous ventilation. It can be applied via a mask or a tracheal tube, and by a ventilator or a freestanding device. The aim is to prevent or reverse airway closure, thus maintaining or increasing functional residual capacity (FRC) and therefore oxygenation. Increasing FRC may place the patient's lungs on a more favourable point on the compliance curve and thus minimize the work of breathing. CPAP is maintained at a pre-set level during inspiration and expiration.

During ventilator CPAP, inspiratory flow is made available in proportion to the patient's inspiratory efforts, but only to maintain the required CPAP level. If the demand valve is slow to respond, or the patient has an excessive respiratory drive, flow delivery may be inadequate initially, leading to a drop in the CPAP level and increased respiratory work. For external circuits, sufficient flow must be provided throughout the respiratory cycle so that patient demands are always met.

Other modes of ventilation

Non-invasive ventilation (NIPPV) is increasingly used with a nasal or full face mask in the management of respiratory failure or acute pulmonary oedema, as an alternative to tracheal intubation and conventional ventilation. Easily portable, NIPPV has the advantages of lessening respiratory work and having fewer cardiovascular effects, but the mask can be difficult to tolerate (pressure sores and necrosis may occur with prolonged use) and gastric distension can arise. NIPPV is well established for patients with ventilatory failure secondary to chest wall deformity or neuromuscular disease; together with CPAP, it has its place in sleep-related disorders.

NIPPV can be delivered by a ventilator with all modes possible, although some are not well tolerated, or more commonly via a stand-alone machine. These machines are pressure generators, behaving similarly to PS on mechanical ventilators, in that a pre-set pressure is delivered to support triggered breaths in addition to having a baseline PEEP. On some models, the machine can be set for the breaths to be time cycled, similar to mechanical ventilation. Humidification can be added to the circuit to prevent the drying of secretions by the gases delivered. To be effective, patient selection and close monitoring are essential.

Others: in this brief overview, it is not possible to describe recently released modes (such as proportional assist or pressure release ventilation) or methods that have been used when conventional ventilation is not succeeding (e.g. high-frequency ventilation or partial liquid ventilation).

Acute Head Injury: Initial Resuscitation and Transfer

Richard Kendall
David K Menon

Richard Kendall is Specialist Registrar in Emergency Medicine at Addenbrooke's Hospital, Cambridge, UK. He qualified from St George's Hospital Medical School, London. His main professional interest is in medical education – both undergraduate and postgraduate.

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India; Leeds General Infirmary, The Royal Free Hospital and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Initial resuscitation

In the UK each year, about 1 million patients present to hospitals with head injury. These injuries range from the relatively trivial to the fatal and some form of classification is necessary. The most useful clinical classification of head injury is by severity. For adults, the Glasgow Coma Scale (GCS) is the best method for initially classifying the severity of head injury (Figure 1):

- mild GCS 14–15
- moderate GCS 9–13
- severe GCS 8 or less.

Initial assessment and resuscitation should follow the guidelines suggested by the ATLS (advanced trauma life support) protocol. The identification of compromised airway, inadequate ventilation or circulatory insufficiency must take precedence over detailed assessment of the neurological state.

Glasgow Coma Scale (GCS)

Eye opening response	
Spontaneously	4
To speech	3
To pain	2
None	1
Best motor response	
Obeys commands	6
Localization to painful stimuli	5
Normal flexion to painful stimuli	4
Spastic flexion to painful stimuli	3
Extension to painful stimuli	2
None	1
Best verbal response	
Oriented	5
Confused	4
Inappropriate words	3
Incomprehensible sounds	2
None	1
Normal adult total score	**15**

1

Airway management: the priority is to secure, maintain and protect a clear airway. Remove secretions and foreign bodies by manual extraction or suction. Provide oxygen by non-rebreathing mask (10–12 litres/minute). Hold the neck immobile in line with the body, apply a rigid or semi-rigid cervical collar and (unless the patient is very restless) secure the head to the trolley with sandbags and tape. This is achieved with two sandbags, one on each side of the head, and two pieces of tape, one across the forehead and one across the chin, to secure the head and the sandbags to the trolley. Cervical spine injury can be difficult to diagnose in the unconscious patient and should be assumed to be present until it can confidently be excluded. A normal lateral radiograph of the cervical spine does not exclude the possibility of important cord injury. Maintain aligned immobilization of the neck when turning the patient during examination and treatment. Criteria for tracheal intubation are listed in Figure 2.

Indications for intubation and ventilation after head injury

Immediately

- Coma (not obeying, not speaking, not eye opening; GCS < 8)
- Loss of protective laryngeal reflexes
- Ventilatory insufficiency (as judged by blood gases):
  hypoxaemia (PaO_2 < 11 kPa on oxygen)
  hypercarbia ($PaCO_2$ > 6 kPa)
- Spontaneous hyperventilation causing $PaCO_2$ < 3.5 kPa
- Respiratory arrhythmia

Before the start of transfer to the neurosurgical unit

- Deteriorating consciousness (GCS has decreased by 2 points or more since admission to A&E, not caused by drugs) even if not in coma
- Bilaterally fractured mandible
- Copious bleeding into mouth (e.g. from skull base fracture)
- Seizures

An intubated patient must also be ventilated:
aim for PaO_2 > 11 kPa, $PaCO_2$ 4.5–5.0 kPa

2

The choice of anaesthetic drugs and neuromuscular blockers used for intubation is an individual decision that is modified by drug availability and clinical circumstance. Intravenous anaesthetic agents are indicated before intubation, even in neurologically obtunded patients, because they attenuate the rises in intracranial pressure associated with intubation. Most of these patients require a rapid sequence intubation with cricoid pressure and in-line cervical immobilization with removal of the collar, tape and sandbags. In such circumstances, the rapid onset of action of suxamethonium outweighs any theoretical risk that it might cause an increase in intracranial pressure. The use of opiates in a patient who is intubated and ventilated is not contraindicated, but large bolus doses of fentanyl or alfentanil may cause reductions in mean arterial pressure (MAP) and reflex rises in intracranial pressure (ICP), even in the ventilated patient. Tracheal tubes should be secured with adhesive tape that does not pass round the neck, or with loosely tied tape (to avoid compressing venous return from the head). It is advisable to pass an orogastric tube to empty the stomach, which commonly dilates after trauma. Nasogastric tubes or nasotracheal intubation are best avoided in patients in whom a basal skull fracture has not been excluded.

Clearing the cervical spine: there is no consensus about how the cervical spine should be cleared of significant injury when it is safe to remove immobilization. Purists claim that the cervical spine can only truly be cleared in a conscious patient, not intoxicated, with normal neurological examination, normal plain radiographs and with no painful distracting injury. This is impossible in a patient with a moderate or severe head injury because they will have a decreased level of consciousness. In such patients, it is acceptable to clear the cervical spine with the aid of plain radiographs and CT. A lateral radiograph of the cervical spine should delineate all seven cervical vertebrae and the cervico-thoracic junction. Anteroposterior radiographs of the cervical spine are difficult to interpret in intubated patients, and when doubt exists a CT is indicated. Radiological assessment of the cervical spine is discussed in *Anaesthesia and Intensive Care Medicine* **3:5:** 163. Plain radiographs and CT delineate bony injury only and may miss significant ligamentous injury. There is increasing interest in using MRI to exclude such injuries.

Breathing: a mechanical ventilator should be used whenever possible, and the adequacy of ventilation assessed clinically and by arterial blood gas analysis. If possible, an indwelling cannula should be inserted when the initial arterial sample for blood gas analysis is obtained, thus allowing serial blood gas measurement and continuous recording of blood pressure. Pulse oximetry is valuable for indirect measurement of how well the patient is being oxygenated, but provides no information about arterial carbon dioxide tension. Avoid excessive hyperventilation, which can depress the myocardium and induce cerebral ischaemia.

Circulation: the circulatory management of patients with significant head injury is given in Figure 3. Hypotension is a late sign of hypovolaemic shock, especially in children and fit young adults. Pulse rate, respiratory rate and capillary refill time are useful ways of assessing the circulation after injury. An isolated head injury is almost never the cause of shock, especially in adults. Maintenance of cerebral perfusion pressures (CPP = MAP–ICP) above 60 mm Hg is the intervention that best improves outcome. The ICP is not measured at this stage, but is certain to be high if the CT scan suggests raised intracranial pressure. Assume the ICP is greater than 20–30 mm Hg, and maintain MAP above 90 mm Hg. Avoid severe hypertension (MAP > 120 mm Hg).

Systemic and cerebral haemodynamic management in acute head injury

Suspect hypovolaemia, even in the absence of hypotension
Tachycardia, arterial respiratory swing, delayed capillary refill, source of bleeding, oliguria

Confirm hypovolaemia
Measure central venous pressure (CVP) if necessary

Find a cause for hypovolaemia (unlikely to be isolated head injury)
Multiple fractures, thoracic or abdominal haemorrhage (consider body CT)

Correct hypovolaemia
Targets: CVP = 8–10 cm H_2O; haematocrit 30% normal clotting, Na^+, K^+
Use 0.9% saline, Hartmann's solution, *Gelofusine, Haemaccel*, blood, fresh frozen plasma
Avoid 5% dextrose, hetastarch and hypotonic solutions

Catheterize bladder and measure urine output
Polyuria is usually the consequence of mannitol, and may require colloid supplements
If polyuria is disproportionate or persistent consider diabetes insipidus

Assume elevated intracranial pressure
Assume intracranial pressure > 20 mm Hg unless proven otherwise in patients with GCS < 12

Maintain mean arterial pressure at 90–100 mm Hg
This will ensure cerebral perfusion pressure ≥ 60 mm Hg; use vasopressors or inotropes if needed

If resistant hypotension consider
Myocardial contusion, tamponade, tension pneumothorax, high spinal cord injury, coning

3

It is advisable to set up two large-bore, peripheral, intravenous infusions and rapidly infuse an electrolyte solution such as normal saline or Hartmann's solution (not dextrose). Under-infusion is a more common error than overinfusion and the loss of more than 15% of blood volume must be corrected by blood transfusion. In patients with obvious hypovolaemia, early direct monitoring of arterial pressure and central venous pressure is helpful for assessing the adequacy of resuscitation. The sources of blood loss should be identified and controlled. Delay in recognizing thoraco-abdominal injuries and major pelvic and limb fractures is common and is associated with a high incidence of hypovolaemic shock and a poor outcome. A patient in persistent clinical shock despite fluid resuscitation must not be transported for CT or to the neurosurgical unit until the source of blood loss has been identified and controlled – in theatre if necessary.

Dysfunction: GCS measurements should be recorded as soon as possible and repeated frequently (at least every 10 minutes during the first hour in hospital). In a drunken patient with head injury, never assume the altered conscious level is simply a result of alcohol. Record any asymmetry of limb movements and compare the pupils repeatedly for size and reaction to light. Any deterioration in conscious level or the development of focal neurological signs must be recorded and acted on; the patient may have become hypoxaemic or shocked, or have an expanding intracranial haematoma. An infusion of mannitol, 0.25–1.0 g/kg, may allow transfer to a neurosurgical unit. Conscious level and limb movements cannot be measured in a patient who is pharmacologically paralysed and ventilated. Repeated assessment of pupil size and reaction is important in such neurologically inaccessible patients.

Exposure (other injuries): remove all the patient's clothing and check for injuries from head to toe, front and back. Some injuries do not need treatment at once but will do later, and all should be documented. Consider the need for abdominal and thoracic CT scans when the head is being scanned (Figures 4 and 5). Patients with major thoracic or abdominal injuries may require urgent exploration in theatre. CT of the torso is best used in patients who are not so unstable as to require exploration, but would benefit from having such injuries excluded before transfer.

Indications for neurosurgical referral and/or urgent CT scan

- GCS < 9 persisting after resuscitation
- Deterioration in level of consciousness or progressive focal neurological deficit
- Skull fracture with any of the following
  - Confusion or deteriorating impairment of consciousness
  - Seizures
  - Neurological symptoms or signs
- Open injury
  - Depressed open fracture of skull vault
  - Base of skull fracture
  - Penetrating injury
- Patient fulfils the criteria for a CT of the head but this cannot be obtained within a reasonable time (2 hours)

4

Indications for CT of the head before referral to neurosurgeons

- Skull fracture and GCS of 15
- Seizures
- Confusion or neurological symptoms or signs persisting after initial assessment and resuscitation
- Unstable systemic state precluding transfer to neurosurgery
- Diagnosis uncertain
- Tense fontanelle or suture diastasis
- Significant head injury requiring general anaesthesia

Indications for referral to neurosurgeons after head CT

- Abnormal CT
- Normal CT but unsatisfactory progress

5

Monitoring: the minimum standards of monitoring for anaesthesia apply equally to a seriously injured patient during resuscitation and transfer. They are continuous monitoring of blood pressure, ECG, oxygen saturation and urine output. Ventilated patients require monitoring of end tidal carbon dioxide concentrations and repeated arterial blood gas measurement.

Antimicrobial prophylaxis: booster doses of tetanus immunization are indicated in most patients. A suitable anti-staphylococcal agent is appropriate for patients with significant open injuries. Specific antimicrobial prophylaxis is ineffective and possibly harmful if there is CSF leak or a skull fracture.

Referral and transfer

Much time may be saved if the information outlined in Figure 6 is available when speaking to the neurosurgeon, and at the time of transfer.

What the neurosurgeon needs to know at referral

Patient's age and previous medical history (if known)
History of injury

- Time of injury
- Cause and mechanism (e.g. height of fall, approximate velocity of impact)

Neurological state

- Talked or not after injury
- Conscious level on arrival at the A&E Department
- Trend in conscious level after arrival (sequential GCS)
- Pupil and limb responses

Cardiorespiratory state

- Blood pressure and pulse rate
- Arterial blood gases, respiratory rate and pattern

Injuries

- Skull fracture
- Extracranial injuries

Imaging findings

- Haematoma, swelling, other

Management

- Airway protection, ventilatory status
- Circulatory status and fluid therapy (? mannitol)
- Treatment of associated injuries (? emergency surgery)
- Monitoring
- Drug doses and times of administration

6

Patients with head injuries are at risk during intra- and inter-hospital transfer. Adequate resuscitation and the optimization of systemic haemodynamics can reduce the risks and allow the maintenance of physiological homeostasis during transfer. Undesirable changes in the patient's homeostasis may be unnoticed or untreated because of inadequate monitoring, lack of equipment and drugs, or inexperienced escorts. Failures of communication can compound the problem and it is important that protocols and admission procedures facilitate a comprehensive handover.

Timing – the decision that a patient has been rendered stable for transfer (Figure 7) requires experience and follows a period of monitoring in the resuscitation room. This can legitimately delay the transfer, and it is helpful to telephone the neurosurgical unit as the journey starts to give the estimated time of arrival. Never start a journey with an unstable patient because of the high risk of complications during the journey.

Checklist before transfer of patient with head injury to a neurosurgical unit

Respiration

- Is the PaO_2 > 11 kPa?
- Is the $PaCO_2$ 4.5–5 kPa?
- Is the airway adequately protected for the journey?

Circulation

- Is the mean arterial pressure > 90 mm Hg?
- Is the pulse rate < 100/minute?
- Is peripheral perfusion adequate?
- Is there reliable and adequate venous access?
- Has enough volume/blood been given to replace losses?
- Is there a suggestion of continuing bleeding?
- Is the patient catheterized (essential if mannitol has been administered)?

Head injury

- What is the GCS score?
- What is the trend in GCS score?
- Is there any focal neurological deficit?
- Is there a skull fracture?

Other injuries

- Has a cervical spine injury been excluded?
- Have broken ribs/pneumothorax been excluded/dealt with (chest drain)?
- Could there be an intrathoracic or abdominal bleed?
- Are there pelvic or long bone fractures?
- Have extracranial injuries been splinted (cervical collar, limb splints)?

Imaging

- If the patient is sufficiently stable, was the need for CT of thorax, abdomen or cervical spine considered at the time of head scan?

7

Escort – the minimum escort for a patient with severe head injury is a doctor and a trained nurse or paramedic. They are professionally responsible for the patient until they hand over at the neurosurgical unit. They must be well informed about the patient before the journey starts, and ideally should have been involved in the patient's care in the resuscitation room. They must know what can go wrong during the journey and must have the skills and equipment to identify and deal with these problems. A doctor competent in airway procedures must escort every intubated and ventilated patient. Patients who are at substantial risk of deterioration during transfer are best intubated before leaving the referring hospital. When the risk of deterioration is less, the presence of an appropriately equipped and skilled doctor during transfer will ensure airway protection should the patient deteriorate during transfer. If in doubt, intubate before transfer.

Monitoring – it is unwise to rely solely on eyes and ears when monitoring a patient in the back of a noisy, dark, moving ambulance. The monitoring started in the resuscitation room should be continued. There must be reliable intravenous access. The ECG should be monitored continuously as should the blood pressure (sphygmomanometry is unreliable in a noisy, moving ambulance). Invasive blood pressure monitoring is ideal; failing this an automated non-invasive blood pressure machine is mandatory, but may be inaccurate in the back of a fast moving ambulance. All lines must be secured, and arterial and central venous lines should be clearly labelled to prevent inadvertent drug injection through them. A pulse oximeter is mandatory. Capnography during transport is ideal, but is often unavailable. An injured patient quickly becomes cold in an ambulance and should be wrapped in blankets (preferably a foil blanket). It is not essential to correct mild hypothermia ($\geq$ 36.0°C) because it may contribute to cerebral protection. The ventilator should have a pressure dial to indicate inflation pressure and a blow-off valve to avoid barotrauma. There should be a system to deliver high-flow oxygen to the patient, and two oxygen cylinders should be carried, both full and checked before use.

Other equipment and drugs – even if the patient has been intubated before transfer it may be necessary to reposition or replace a tube which obstructs or falls out, and the ambulance must carry a range of tracheal tubes and two working laryngoscopes. The oxygen supply can fail, and it is always advisable to carry a self-inflating bag. Intravenous lines inserted before transfer may block or fall out or may have to be supplemented for rapid fluid infusion during transfer. A range of cannulas and fluids should be carried. If blood has been cross-matched before the journey it should travel in the ambulance, not in a separate taxi. The escorts should carry drugs for cardiac resuscitation, non-depolarizing muscle relaxants, short-acting analgesics and sedatives for controlling ventilation, anticonvulsants and mannitol.

Ambulance and trolley – modern ambulances do not always offer a smooth, quiet ride but usually provide reasonable space and lighting. The problems of working in any moving vehicle make it vital to stabilize the patient and set up monitoring before transfer. The ambulance seldom needs to travel at great speed, which can worsen cardiovascular instability; a smooth ride at constant speed is safer. The patient should be placed in the ambulance head first because this allows better tolerance of any sudden deceleration during the journey. Most centres suggest that the head is elevated by about 15° throughout transfer. If life-saving procedures (e.g. tracheal intubation) are required during the journey it is best to stop the ambulance briefly rather than attempt heroics under poor conditions.

Handover – the escorts should give the neurosurgical staff an accurate description of all injuries, the trends in conscious level and neurological signs since injury or admission, and the drugs and intravenous fluids given. They should not leave until this has been done. The neurosurgical team may need further information later and must know whom to contact. All medical and nursing clinical notes, observation charts, drug prescription sheets, radiographs and scans should be left with the neurosurgical team.

Anaesthesia and the Cervical Spine: Surgery and Trauma

Ian Calder

Ian Calder is Consultant Anaesthetist at the National Hospital, Queen Square, and the Royal Free Hospital, London, UK. He qualified from Liverpool University and trained in Liverpool and London. His research interests lie in airway management.

The main considerations in anaesthesia for cervical spine surgery are the risk of neurological deterioration and airway problems.

Risk of neurological deterioration (spinal cord injury)

Patients with disease of the cervical spine or spinal cord run an increased risk of developing spinal cord injury during anaesthesia. The mechanism of the damage is uncertain. MRI shows that the shape of the spinal cord and the anterior and posterior spinal arteries changes with posture. People with healthy spines, kept in abnormal postures for several hours, or exposed to low blood pressure, have developed spinal cord injury. Prolonged cord deformation can result in spinal cord injury and patients with an abnormal spine have developed a spinal cord injury after short periods (less than 1 hour) of anaesthesia. The risk of general anaesthesia may stem from the immobility it induces. A position that would be tolerated only briefly by a conscious patient can be maintained for a dangerously long time under anaesthesia. Anaesthetists should be aware that some patients deteriorate neurologically for no discernible reason following cervical trauma and that absence of radiological evidence of damage does not mean that a spinal cord injury will not occur. Up to 50% of patients with spinal cord injury after traumatic neck injuries have no radiological evidence of trauma. Cervical injury may compromise the homeostatic mechanisms safeguarding the spinal cord.

Instability of the cervical spine is thought to be a risk factor for the development of a spinal cord injury during anaesthesia. Instability is hard to define. White and Panjabi defined it as 'loss of the ability, under normal physiologic loads, to maintain relationships between vertebrae in such a way that there is neither initial nor subsequent damage to the spinal cord or nerve roots, and there is neither development of incapacitating deformity, nor severe pain'. The mechanism of injury may involve several factors, such as deformation of the blood supply of the cord, reductions in spinal cord perfusion pressure and cord compression. 40% of patients with fractures or dislocations of the spine have vertebral artery damage.

Direct laryngoscopy may have caused a spinal cord injury in patients with cervical spine disease but there is no convincing case report in the literature. Direct laryngoscopy causes the same small amount of movement in cadaver spines rendered unstable by surgical preparation as jaw thrust or chin lift. A comparative study of different airway control systems (laryngeal mask airway (LMA), intubating LMA, lightwand, fibrescope, direct laryngoscopy) showed no significant difference between the methods, in terms of movement of an unstable C3 vertebra. Flexible fibre-optic laryngoscopy and intubation is useful in cervical spine disease because direct laryngoscopy is often difficult. The use of the gum-elastic bougie to minimize the amount of glottic exposure is deservedly popular in the UK.

Manual in-line neck stabilization: there is conflicting evidence about whether this practice results in any worthwhile reduction in movement at unstable cervical sites. Enthusiastic application may make direct laryngoscopy difficult. There is an analogy with cricoid pressure application because in both situations the airway difficulty induced could be hazardous for the patient.

Pathology

Spinal cord injury may be associated with spondylosis, herniation of intervertebral discs, spinal stenosis, tumours, syringomyelia, infections, rheumatoid arthritis, ankylosing spondylitis or trauma.

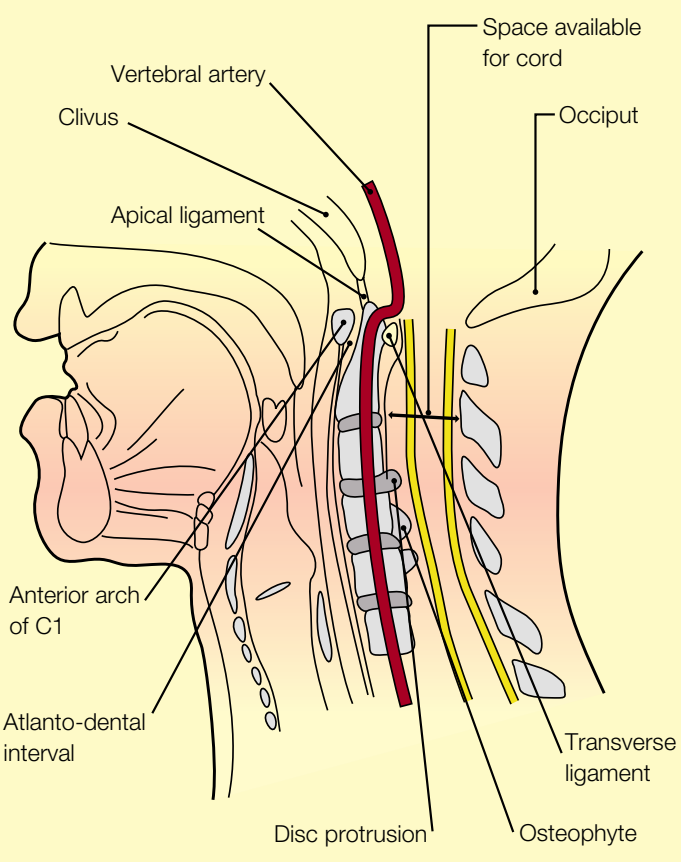
Cervical rheumatoid arthritis: spinal involvement in rheumatoid arthritis is common, with the upper cervical joints being affected most often. There are three main patterns of involvement in the cervical spine:

- atlanto-axial subluxation (Figure 1) (65%)
- 'vertical' subluxation (20%)
- sub-axial subluxation (15%).

1 Radiograph of the neck showing tuberculous abscess eroding C2 and causing atlanto-axial subluxation.

All three types may be present. The amount of atlanto-axial subluxation has been assessed by measuring the distance between the anterior arch of the atlas to the odontoid peg on lateral radiographs (Figure 2), the distance being known as the atlanto-dental interval (ADI). The size of the ADI does not correlate well with neurological symptoms and signs, or cord compression seen at MRI. Whether there is any correlation between the size of the ADI and the risk of spinal cord injury during anaesthesia is unknown. The clinical presentation of cervical rheumatoid disease is seldom acute. An insidious progression of neck pain, occipital headache, stiffness and crepitus occurs. L'Hermitte's phenomenon of an electric shock sensation up and down the spine can occur. Temporomandibular joint and arytenoid joint involvement is common. Rheumatoid cervical disease may be symptomless, therefore the question arises whether patients should have flexion/extension lateral radiographs before anaesthesia for procedures unrelated to the cervical spine. Requesting radiography demonstrates the anaesthetist's concern and appreciation of the possibilities.

Section through the neck



2

Prevention of injury during anaesthesia for cervical surgery

There is an increased risk of spinal cord injury in:

- patients with preoperative myelopathy
- cranio-cervical junction surgery
- multi-level surgery
- insertion of fixation devices.

Great care should be taken with positioning. The position should look comfortable. Hypotension may reduce spinal cord blood flow. Hypertension causes oedema formation in experimental cord injury models. Normotension is recommended. Many practitioners avoid muscle relaxant drugs after intubation, so that irritation of the cord or a nerve root produces limb movement.

Spinal cord monitoring during cervical surgery: there is no evidence that monitoring improves outcome. Sensory evoked potentials are routine in many centres (stimulus applied to median nerve and recorded from the scalp over the sensory cortex). They are reasonably robust to volatile agents, unlike motor evoked potentials, which are easily abolished with volatile agents. Motor monitoring involves stimulation of the motor cortex with an electrical discharge, and is not routinely used in many centres.

High-dose steroids: NASCIS I, II and III (North American Spinal Cord Injury Study) have shown that large doses of methylprednisolone improve outcome after spinal cord injury. The current recommendation is an initial dose of 30 mg/kg, then 5.4 mg/kg over 24 hours if the treatment is begun within 3 hours, or over 48 hours if treatment commences 3–8 hours after injury. However, whether there is any real benefit is still debated.

Airway problems

Direct laryngoscopy is often difficult in patients with disease of the upper three vertebrae. The Mallampati examination is useful in cervical disease; the test can be regarded as a way of testing cranio-cervical extension. Mandibular protrusion is often impaired in high cervical disease as temporomandibular joint disease tends to be associated with cranio-cervical junction pathology. Grade C protrusion is always predictive of difficult laryngoscopy (see *Anaesthesia and Intensive Care Medicine* **3:7:** 246).

Anterior cervical haematoma can cause airway obstruction after surgery. In some cases there may be only a small, or even no, haematoma. The obstruction is caused by swelling of the periglottic tissue, which may make direct laryngoscopy difficult. Both the LMA and gum-elastic bougie have proved life saving. The wound should be opened as soon as possible. An inhalational induction with sevoflurane or halothane is generally regarded as the wisest option. Extubation should be delayed for about 24 hours. ◆

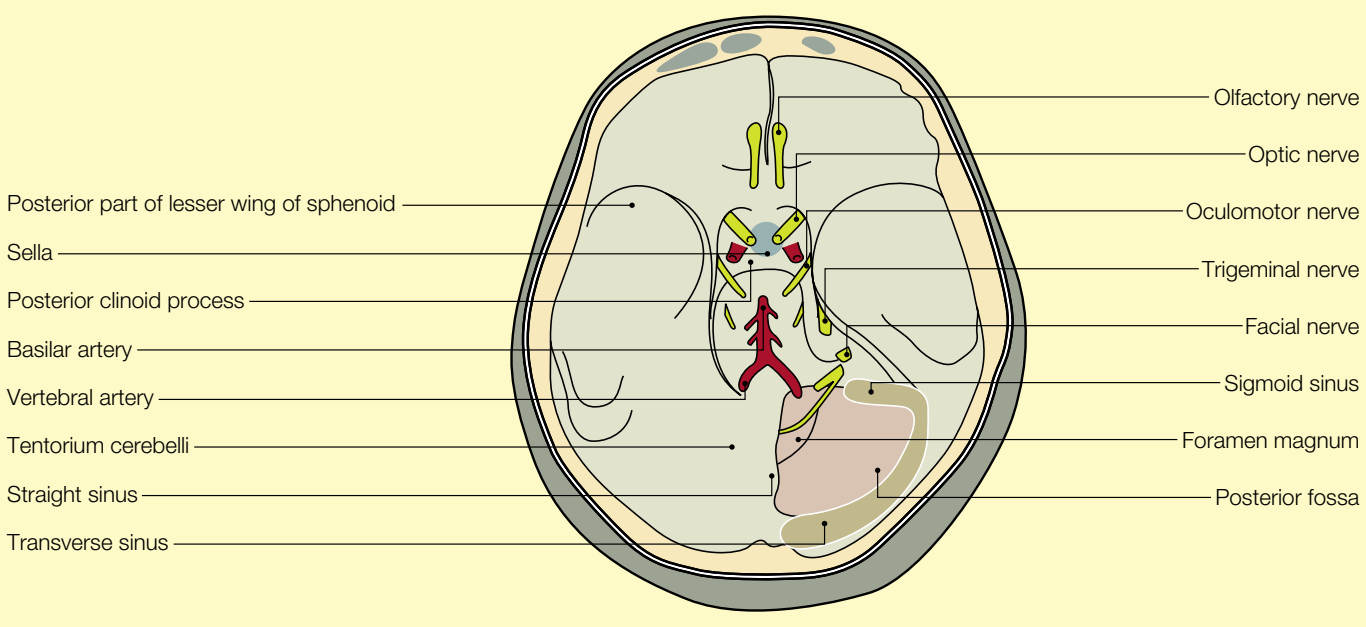
Anaesthesia for Posterior Fossa Surgery

Arun K Gupta

Arun K Gupta is Director of Critical Care and Consultant Anaesthetist at Addenbrooke's Hospital, Cambridge, UK. He qualified from St Mary's Hospital, London, and trained in anaesthesia and intensive care in the East Midlands and East Anglian Regions as well as spending 2 years in Richmond, VA, USA. His research interests are in mechanisms of secondary brain injury, in particular, regulation of brain oxygenation and metabolism.

Anatomy
The posterior cranial fossa is a rigid, deep compartment that is almost circular in outline and contains the cerebellum and brainstem. These structures are covered by a dural sheet (the tentorium cerebelli) which separates them from the cerebrum superiorly (Figure 1). Anteriorly lie the dorsum sellae, the clivus, the posterior part of the sphenoid and the basilar part of the occipital bone. The squamous part of the occipital bone, the transverse sinus and the superior sagittal sinus lie posteriorly and the petrosal and mastoid part of the temporal bone, the internal auditory meatus and the sigmoid sinus lie laterally. The occipital bone, foramen magnum, jugular foramen and hypoglossal canal lie inferiorly. Compared with the supra-tentorial compartment, the posterior fossa is small, and a small increase in its volume can rapidly result in life-threatening brainstem compression.

Relationship of posterior fossa to other intracranial landmarks



1

Pathology
Tumours – primary tumours are the most common indication for posterior fossa surgery and are more common in children than in adults. Up to 70% of all childhood brain tumours originate in the posterior fossa and include medulloblastomas, ependymomas, tumours of the choroid plexus, gliomas and astrocytomas. In contrast, 15–20% of adult brain tumours lie in the posterior fossa. Metastatic tumours, usually from the lung, kidney, breast and skin are the most common posterior fossa lesion in adults. Other primary tumours include meningiomas, acoustic neuromas (Schwannomas arise from the VIIIth cranial nerve, often in the cerebellopontine angle), clival tumours, glomus jugulare tumours, arachnoid and epidermoid cysts. Haemangioblastomas can develop in the cerebellum and often secrete erythropoietin, resulting in polycythaemia.

Vascular lesions – 15% of aneurysms occur in the posterior circulation with half of these appearing at the basilar bifur-cation. Haemorrhage or vasospasm from posterior circulation aneurysms may have a profound effect on brainstem blood flow. Arteriovenous malformations of the posterior fossa often involve the brainstem with a haemorrhage rate of 2–3% per year. Cerebellar haematoma is usually a result of systemic hypertension and cerebellar infarct may cause swelling and obstructive hydrocephalus. Both conditions may represent neurosurgical emergencies. Small vessels impinging on cranial nerves in the posterior fossa can result in symptoms such as trigeminal neuralgia. Surgical decompression has a good success rate.

Craniocervical abnormalities may require posterior fossa decompression. In the young this is usually for congenital abnormalities such as Arnold–Chiari malformation; in the elderly, degenerative changes are more common.

Positioning
Patient positioning for optimal surgical access during posterior fossa surgery may have major implications for the anaesthetist.

Supine position: patients with cerebellopontine angle tumours (e.g. acoustic neuromas) are often operated on in this position. However, access to the posterior fossa often requires substantial lateral rotation of the head, resulting in stretching of the jugular veins and brachial plexus. These problems can be reduced by placing a sandbag under the ipsilateral shoulder. Maximizing exposure through a relatively small craniectomy site may require lateral rotation of the operation table, and the use of 'safety belts' will ensure that patients do not slide off.

The prone position offers good access to midline structures but bleeding can obscure the surgical field. Head-up tilt is used to reduce haemorrhage but this increases the risk of air embolism. The chest and iliac crests should be well supported to ensure free movement of the abdomen during respiration. Obese patients are at particular risk because of restricted diaphragmatic movement and high intrathoracic pressure. Pressure on the iliac vessels should be avoided, reducing the risk of deep venous thrombosis and improving emptying of the epidural venous sinuses. The head is fixed in clamps in preference to a horseshoe to minimize pressure on the face and eyes. Pressure points should be well padded and the tracheal tube kept as secure as possible.

The lateral position is suitable for approaches to lesions not in the midline, particularly the cerebellopontine angle. This position facilitates gravitational retraction of the dependent cerebellum and facilitates CSF and venous drainage. A variation called the 'park bench' position is often used; so-called because of its resemblance to the way a tramp sleeps on a park bench. A pad should be placed under the body in the axilla to minimize weight on the lower arm and shoulder. The pelvis should be fixed with supports in front and behind. The lower leg is flexed at the hip and knee. The upper leg is kept straight and slightly externally rotated to lock the knee with the foot on a firm support, which will prevent the patient sliding down the table if significant head-up tilt is used. A pillow is placed between the legs. The lower arm is flexed across the body and the upper arm is taped along the upper side of the body. The head is fixed in pins. Excessive flexion of the neck can obstruct the internal jugular veins. This can be avoided by ensuring a two or three fingers-breadth gap between chin and sternal notch.

The sitting position provides good surgical access to midline structures, improves surgical orientation and allows good drainage of blood and CSF. Functional residual capacity and vital capacity are improved and access to the airway is facilitated. However, there are increased risks of cord compression, pneumocephalus and venous air embolism. Macroglossia and peripheral nerve injuries are also more common in the sitting position. Hypotensive techniques increase the risks of ischaemic damage. Many authorities now contend that with modern anaesthetic techniques there is no place for the sitting position in neuroanaesthesia. Excessive head-up tilt in other positions, however, exposes the patient to similar risks.

Anaesthetic management
Preoperative assessment
In addition to the routine assessment for patients undergoing general anaesthesia and specific assessment for patients scheduled for craniotomy, information relevant to posterior fossa surgery needs to be obtained during the preoperative visit. Any cranial nerve impairment needs to be documented, with particular reference to the lower cranial nerves, which may affect the gag reflex. Patients with impaired gag reflexes may have a history of aspiration pneumonia. Furthermore, this may impair airway protection postoperatively and extubation at the end of surgery may need to be delayed or elective tracheostomy considered. Patients are often dehydrated with associated biochemical derangements because of reduced oral fluid intake, or vomiting owing to raised intracranial pressure. Preoperative fluid replacement may be required.

Consultation with the surgeon will reveal the required position for surgery, and the patient should be assessed for the proposed position. In some cases, alternative positioning may have to be considered (e.g. obese patients requiring the prone position).

Premedication should include all regular medication, with a short-acting benzodiazepine reserved for those who are neurologically intact and who are particularly anxious.

Intraoperative management
Induction: as with any craniotomy, induction is achieved using an appropriate induction agent, normally an intravenous induction agent in adults, though a smooth inhalational induction with sevoflurane may be appropriate in children. Neuromuscular paralysis and an opioid facilitate tracheal intubation. The hypertensive response to intubation and head-pin insertion can be obtunded by supplementation of appropriate intravenous agents. If hypotension occurs, it should be treated promptly. An armoured tracheal tube should be inserted and secured firmly. A nasogastric tube should also be placed if there is any risk of postoperative bulbar dysfunction or the patient is to be ventilated postoperatively.

Direct arterial pressure monitoring is essential and can be established before induction if clinically indicated, or more commonly after induction. A central venous line is usually required. Access to the internal jugular veins may be difficult, and subclavian cannulation, or antecubital fossa or femoral long lines are useful alternatives. Core temperature and urine output must also be monitored during surgery. Especially in surgery where there is a risk of high venous air embolism, an oesophageal stethoscope and/or precordial Doppler probes are essential additional monitors.

Maintenance: the choice of particular agents is not critical but stable anaesthesia is paramount. The effects of a particular drug on blood pressure and neurophysiological monitoring should be considered. Muscle relaxation is best provided by continuous infusion of short- or medium-acting agents, which helps ventilation and prevents movement in a relatively lightly anaesthetized patient. If motor nerve function is monitored as a guide to resection (e.g. the facial nerve monitoring during acoustic neuroma surgery), muscle relaxation must be discontinued and sufficient depth of anaesthesia must be provided to obtund airway reflexes using other agents.

Neurophysiological monitoring is often used. Facial nerve monitoring is routine with all large acoustic neuroma excisions. Auditory evoked potentials are used as a safeguard during dissection near the brainstem, particularly during acoustic neuroma surgery. When somatosensory and motor evoked potentials are monitored, they can be suppressed during deep anaesthesia. Furthermore, paralysis can occur in the absence of somatosensory evoked potential changes.

Deliberate hypotension should be employed with caution if significant head-up tilt is used. It is also important to remember that surgery near the brainstem can induce further hypotension and bradycardia.

Postoperative management
Patients with good preoperative neurology may be extubated at the end of surgery providing the intraoperative course was uncomplicated. Coughing and straining should be avoided during the emergence period. Extubation at the end of surgery should not occur if significant brainstem or cranial nerve injury has occurred. This may manifest as repeated episodes of intraoperative haemodynamic instability. Pulmonary oedema may be precipitated by large venous air embolism or after surgery to the floor of the fourth ventricle. Respiratory failure can occur suddenly, even when awake.

Complications of posterior fossa surgery
Arrhythmias are often caused by manipulation of the brainstem. Bradycardia can occur when the periventricular grey matter and the reticular formation are stimulated. Most arrhythmias occur during surgery near the pons and the roots of nerves V, IX and X. Surgeons should be made aware of bradycardic episodes, which should stop when the offending surgical stimulation ceases. Anticholinergics should be used only as a last resort after discussion with the surgical team, because abolition of vagally induced bradycardia removes a useful indicator of potential brainstem injury. Severe hypertension can result from stimulation of the trigeminal nerve.

Airway problems: macroglossia and upper airway swelling can occur following prolonged surgery in the prone position. This is due to obstruction of venous and lymphatic drainage. Cranial nerve damage can also cause serious airway problems.

Neurological complications: extreme neck flexion can cause midcervical quadriplegia. Prolonged surgery and hypotension are contributory factors. Surgery near the roots of nerves VII–X may lead to loss of airway reflexes, dysphagia and dysphonia. Peripheral nerve damage can result from faulty positioning. The brachial plexus, ulnar nerve and common peroneal nerve are most vulnerable.

Pneumocephalus: following a craniotomy, an air-filled space between the dura and arachnoid remains after CSF has leaked away during surgery and brain bulk is reduced. In the recovery period, brain bulk increases again as cerebral oedema develops, arterial carbon dioxide concentrations increase and CSF reaccumulates. The trapped air then comes under increasing pressure and tension pneumocephalus can occur, which if left untreated can result in brain herniation and cardiac arrest. Nitrous oxide worsens the situation. Pneumocephalus presents as delayed recovery or deteriorating neurological state and should always be considered if this occurs. Pneumocephalus can be reduced by discontinuing nitrous oxide 15 minutes before surgery finishes and by allowing the arterial carbon dioxide tension to rise towards the end of the operation. Air may remain within the cranium for 2 weeks postoperatively and nitrous oxide should be avoided for this period after posterior fossa surgery.

Venous air embolism: a vein cut during surgery will normally collapse, preventing air being sucked into the circulation. In posterior fossa surgery, cut veins may not collapse: veins in the skull are held open by the surrounding bone; suboccipital veins are held open by cervical fascia; and the large venous sinuses are held open by the dura. Air can thus readily enter the circulation if these veins are opened. The incidence of air embolism in the sitting position is reported at 25–50%. However, recent use of transoesophageal echocardiography has reported an incidence as high as 75%. In most cases, the amount of air entering the circulation is small and may have little clinical importance. When larger volumes of air enter the right heart, cardiac output is reduced leading to systemic hypotension. Air also passes into the pulmonary arterial circulation, leading to a rise in pulmonary vascular resistance and an increase in pulmonary artery pressure. The ECG shows signs of right ventricular strain and right ventricular failure may occur. Physiological dead space increases as air blocks the pulmonary circulation with many alveoli ventilated but not perfused. This in turn leads to a decrease in carbon dioxide excretion and a fall in end-tidal carbon dioxide tension. Central venous pressure rises as a result of obstruction to right ventricular outflow. This increase in central venous pressure, together with arrhythmias and the classical mill-wheel murmur on auscultation are late signs. Occult atrial septal defects or a probe patent foramen ovale may be present in up to 35% of all individuals in autopsy studies. The rise in pulmonary pressures associated with venous air embolism that may predispose to right-to-left shunting in such individuals may result in systemic air embolism. In practice, though some degree of air embolism occurs in up to 75% of patients; clinically significant air embolism remains an uncommon complication.

Detection of air embolism

- Precordial Doppler device – the altered reflection of ultrasonic beams from an air–gas interface means that precordial Doppler probes can detect bubbles of air in the circulation and can indicate air emboli as small as 1 ml (some critics claim that the device is oversensitive). An experienced observer is required. Diathermy machines interfere with probe function.
- Capnography – a continuous capnograph shows a fall in end-tidal carbon dioxide concentration as air enters the pulmonary circulation. It is less sensitive than the Doppler but is much easier to use. However, other causes of a fall in end-tidal carbon dioxide tensions, such as reduced cardiac output can cause confusion.
- End-tidal nitrogen – entry of air into the pulmonary circulation results in a rise in end-tidal nitrogen, which mirrors the decrease in end-tidal carbon dioxide. However, nitrogen increase is more specific than end-tidal carbon dioxide and is not influenced by other cardiovascular changes.
- Pulmonary artery pressure – air embolism increases the pulmonary artery pressure proportionally to the size of the embolism.
- Pulse oximetry detects air embolism that results in significant cardiorespiratory compromise, but is best viewed as an indicator of the magnitude of circulatory disturbance and an index of the progress of treatment.
- Transoesophageal echocardiography is a highly sensitive method of detecting intracardiac air and of diagnosing atrial septal defects.

Prevention of air embolism – volume loading patients to raise their central venous pressure reduces the hydrostatic pressure gradient and reduces the likelihood of air embolism. Similarly, raising end-expiratory pressure may reduce the negative pressure in an open vein in the posterior fossa. However, positive end-expiratory pressure reduces venous return and may cause systemic hypotension.

Anti-gravity suits and medical anti-shock trousers help to reduce venous pooling in the lower limbs. The increase in venous pressure reduces postural hypotension and decreases the negative hydrostatic pressure in the posterior fossa.

Nitrous oxide diffuses into embolic bubbles and increases their size. If there is a significant air embolism, nitrous oxide should be discontinued. A central venous catheter is a useful cardiovascular monitor and is a helpful diagnostic tool if air enters the circulation. It also provides a useful method of attempting to aspirate air from the right atrium.

Management of air embolism

- Flood the operative field with saline and cover the wound with wet swabs to prevent further air entrainment.
- Ventilate with 100% oxygen, discontinue nitrous oxide.
- Raise the venous pressure at the operative site, which can be done by squeezing the veins in the neck.
- Aspirate from the cerebral venous pressure catheter to try to aspirate air from the right atrium.
- If cardiovascular collapse occurs, standard resuscitative measures should be used.

Anaesthesia for Supratentorial Craniotomy

Ravi Shankar
Arun K Gupta

Ravi Shankar is Specialist Registrar in Anaesthesia at the Addenbrooke's Hospital NHS Trust, Cambridge, UK. His subspecialty of interest is neuroanaesthesia.

Arun K Gupta is Director of Critical Care and Consultant Anaesthetist at Addenbrooke's Hospital, Cambridge, UK. He qualified from St Mary's Hospital, London, and trained in anaesthesia and intensive care in the East Midlands and East Anglian Regions as well as spending 2 years in Richmond, VA, USA. His research interests are in mechanisms of secondary brain injury, in particular, regulation of brain oxygenation and metabolism.

Surgery in the supratentorial region is required for a variety of pathologies including vascular malformations and space-occupying lesions. This article describes the general principles of patient management for such surgery and provides specific details about anaesthesia for mass lesions. Vascular malformations are discussed on pages 143–4.

Anatomy
The supratentorial compartment contains the cerebral hemispheres. the floor is formed by the anterior and middle cranial fossae along with the tentorium cerebelli, and the cavity is roofed by the calvarium.

Pathology and pathophysiology
Space-occupying lesions comprise:
- primary tumours (gliomas, meningiomas of the olfactory groove, medial sphenoidal wing and the base of the anterior cranial fossa)
- secondary tumours, vascular lesions (aneurysms and arteriovenous malformations)
- abscesses
- haematomas (spontaneous or traumatic).

Patients with anterior fossa lesions may present with seizures, neurological deficits or signs and symptoms of raised intracranial pressure (headache, nausea, vomiting, hypertension and bradycardia). The neurological deficits may be visual, caused by pressure on the optic nerve and chiasma, alteration or loss of smell due to involvement of the olfactory nerve, compression of the internal carotid artery or middle cerebral artery. Invasion through the superior orbital fissure may lead to proptosis.

Anaesthetic management

Anaesthesia for supratentorial surgery requires an understanding of intracranial physiology to facilitate manipulation of intracranial pressure (ICP), cerebral blood flow (CBF) and cerebral metabolic requirement of oxygen ($CMRO_2$) to optimize perioperative conditions. The aims of anaesthetic management are listed in Figure 1.

Aims of anaesthetic management in supratentorial craniotomy

- Preoperative assessment and optimization of associated medical conditions
- Haemodynamic stability (hypotension can lead to ischaemia in areas of impaired autoregulation; hypertension increases the risk of haemorrhage and vasogenic oedema)
- Maintain cerebral perfusion and prevent increases in intracranial pressure
- Facilitate surgery by providing a slack brain
- Provide cerebral protection if required
- Rapid recovery to enable neurological assessment in the immediate postoperative period

1

Preoperative assessment
A complete history and clinical examination of the patient provides an opportunity to identify associated diseases as well as to obtain specific information regarding the surgery. Underlying cardiac or respiratory disease must be controlled before surgery. Common associated conditions such as chronic untreated hypertension need to be controlled to reduce the risk of perioperative myocardial and cerebral ischaemia owing to the rightward shift in the autoregulatory limits of CBF.

The acute neurological condition must be assessed including the preoperative Glasgow Coma Score (GCS), an examination of radiological images and an evaluation of concurrent disease. Preoperative examination of CT and/or MR images provides information about lesion size, ease of surgical access, positioning of the patient and indirect information regarding likelihood of blood loss. It also allows assessment of pathology that may cause intracranial hypertension or reduced intracranial compliance. It must be remembered, however, that intracranial hypertension may exist in the absence of imaging signs. A substantial risk of venous air embolism or bleeding may be associated with lesions encroaching on the sagittal sinus.

A full drug history is important because some drugs affect anaesthetic management. Steroids, diuretics and anticonvulsants affect plasma biochemistry, glucose tolerance, the risk of upper gastrointestinal bleeding, intravascular volume and drug pharmacokinetics. Anticonvulsants and steroids should be continued.

Premedication (e.g. a short-acting benzodiazepine) is only given if the patient is particularly anxious, provided there is no evidence of raised ICP.

Induction
Induction is performed using an intravenous anaesthetic agent, titrated to minimize the reduction in blood pressure, together with a nondepolarizing muscle relaxant and a short-acting opiate. Normotension should be maintained by anticipating stimuli and preventing haemodynamic responses. The hypertensive response to laryngoscopy and intubation can be obtunded with an additional bolus of intravenous induction agent, a short-acting opioid or β-blocker, or intravenous lidocaine (lignocaine). Insertion of skull pins for cranial fixation provides a potent stimulus and the hypertensive response should be pre-empted by local anaesthetic infiltration, an additional dose of induction agent and/or a supplemental dose of opiate.

When the airway has been secured with an armoured tracheal tube, the tube should be carefully taped and secured on the side contralateral to the operation. The eyes should be taped and padded.

Monitoring
In addition to establishing routine monitoring before induction, invasive arterial blood pressure monitoring may be established before induction if the patient is unstable or at high risk, or after induction in patients who are more stable. After induction, a nasopharyngeal temperature probe and urinary catheter should be inserted. A central venous line is helpful in most patients, and is mandatory if there is a clinical indication (e.g. cardiorespiratory disease, large anticipated blood loss). A pulmonary artery catheter may be required in severe cardiac disease. Other neuromonitoring such as EEG, somatosensory evoked potentials and a jugular bulb catheter can also be established if required.

Intra-operative management
Positioning: access is usually through a frontal, parietal or temporal craniotomy, which allows the patient to remain in the supine position. A neutral position of the head with a reversed Trendelenburg tilt (15° head up) favours venous drainage from the cranium and helps to reduce ICP. Extreme head rotation for parietal and temporal access may impair venous drainage by kinking the internal jugular vein. A shoulder roll placed on the ipsilateral side reduces the impact of this position on venous drainage. The prolonged duration of certain neurosurgical procedures demands close attention to pressure points, nerve compression and thromboembolism prophylaxis. Thromboembolism deterrent stockings or sequential pneumatic calf compression devices may be used to reduce the incidence of deep vein thrombosis.

Maintenance of anaesthesia: the anaesthetic technique largely depends on the ability to control ICP, maintain haemodynamic stability and provide rapid emergence. Total intravenous anaesthesia with propofol infusion has been used successfully in a number of studies. Propofol reduces $CMRO_2$, thereby reducing CBF and cerebral blood volume (CBV) by preserving flow metabolism coupling. This helps to maintain cerebral perfusion and oxygenation to areas of brain that may be at risk of ischaemia. Propofol also preserves carbon dioxide reactivity thus allowing manipulation of CBF and CBV with changes in arterial carbon dioxide levels.

The addition of an opioid contributes to haemodynamic stability and reduces the requirement for anaesthetic agents. Most short-acting opioids are equally effective for haemodynamic stability, but remifentanil allows more rapid emergence compared with fentanyl and alfentanil, probably because its metabolism gives it a short context-specific half-life. All fluorinated volatile inhalational agents increase CBF and CBV by a direct intrinsic effect causing vasodilatation. The magnitude of this increase in vascular diameter depends on the balance between the intrinsic vasodilatory action and the reduction in blood flow secondary to the dose-related decrease in $CMRO_2$. Reactivity to carbon dioxide may be impaired with older anaesthetic agents, though it tends to be better preserved with the newer agents such as isoflurane and sevoflurane. Isoflurane and sevoflurane also have minimal effects on ICP in concentrations less than 1.5 minimum alveolar concentration, and the vasodilatory effects can be attenuated by mild hypocapnia. In contrast, nitrous oxide causes an increase in $CMRO_2$ with a coupled increase in CBF which is unaffected by hypocapnia, which makes its use unfavourable in patients with raised ICP.

Although there is debate about the most appropriate com-bination of agents for craniotomy, Todd and colleagues have shown that propofol/fentanyl, high-dose isoflurane/nitrous oxide and fentanyl/nitrous oxide are equally satisfactory.

An infusion of short- or medium-duration neuromuscular blockers (e.g. atracurium, vecuronium) facilitates ventilation at lower intrathoracic pressure. The lungs are ventilated aiming for a partial pressure of carbon dioxide in arterial blood ($PaCO_2$) of 4.0–4.5 kPa. Many anaesthetists allow body temperature to drift to 35–36°C when neural tissue is at risk of ischaemic injury as part of the procedure, though there is no evidence that this is beneficial. Rewarming should begin as soon as this risk is over, and certainly by the time dural closure begins.

Optimization of surgical conditions: a ‘slack’ brain facilitates surgical access with minimal retraction, which reduces the likelihood of ischaemic damage. The dura should be observed at the time of craniotomy to ensure that it is not tense or bulging out of the craniotomy site. Mannitol, 0.5–1 g/kg, may be infused about 30 minutes before dural opening to reduce brain bulk. It is an osmotic diuretic that was thought to act by drawing water from the brain, but it is now also thought to improve the rheological properties of the blood in the cerebral circulation, increase CBF and reduce CBV and ICP. Limiting plasma osmolality to 320 mosm/litre reduces the risk of rebound oedema. Mannitol may also theoretically worsen oedema by crossing a damaged blood–brain barrier. Furosemide (frusemide), 0.25–1 mg/kg, reduces the ICP to the same extent as mannitol, and lowers cerebral venous pressure, thereby optimizing CSF reabsorption.

Hyperventilation has been used in neuroanaesthesia for many years to reduce ICP. However, evidence from patients with traumatic brain injuries suggests that it may be detrimental by causing cerebral vasoconstriction and a reduction in CBF below a critical threshold. The evidence has lead to guidelines recommending that such patients should not be hyperventilated prophylactically below an arterial carbon dioxide concentration of 35 mm Hg (4.7 kPa) during the first 24 hours after injury. If hyperventilation is required, $PaCO_2$ levels should be monitored and maintained above 4.0 kPa, and the use of jugular oximetry considered, with the aim of maintaining jugular bulb oxygen saturation above 55%. Intraoperative complications specific to such surgery include haemorrhage and acute cerebral oedema. The management of intraoperative cerebral oedema is outlined in Figure 2.

Management of intraoperative cerebral oedema

- Optimize ventilation and blood gases
- Maximize venous drainage
- Deepen anaesthesia – bolus intravenous anaesthetic agent, adjust inhalational agent concentration
- Diuretics – mannitol, 0.5–1.0 g/kg
  ± furosemide (frusemide), 0.25–1.0 mg/kg
- CSF drainage
- Minimize cerebral metabolic requirement of oxygen – bolus lidocaine (lignocaine); thiopental (thiopentone) or propofol infusion
- Consider further doses of diuretic and CSF drainage

2

Fluid management: central venous pressure is used as a guide to maintain normovolaemia. Reduced osmolality of extracellular fluid results in brain oedema. Normal saline is slightly hyperosmolar and Hartmann's solution is slightly hypo-osmolar compared with extracellular fluid. Net transfusion of free water should be avoided and dextrose-containing solutions should not be used. Fluid replacement is required if patients are dehydrated (often the case in those who have an impaired conscious level) or in those who have had a rapid diuresis owing to mannitol. Colloid solutions are appropriate to restore intravascular volume following diuresis, fluid deprivation or moderate blood losses. Patients who have lost more than 1 litre of blood generally require transfusion. It is essential to ensure that haemostasis is monitored intraoperatively and abnormalities are corrected promptly.

Emergence from anaesthesia

During closure of the craniotomy, the anaesthetic may be reduced with the aim that the patient rapidly regains consciousness at the end of the procedure. It is important to normalize mean arterial pressure and $PaCO_2$ before closure to reveal any bleeding points, and to ensure that intraoperative brain swelling does not increase the likelihood of intracranial hypertension when the patient is normocapnic. Obvious brain oedema may prompt a decision to leave the bone flap out, institute ICP monitoring, or opt for a period of postoperative sedation and ventilatory support. The ideal emergence should be free from coughing, straining, hypertension and allow rapid and reliable neurological assessment in the immediate postoperative period. These complications lead to increased venous or arterial bleeding and oedema formation at the operated site. In poorly autoregulating areas, hypertension leads to vascular engorgement and further brain swelling. If the paranasal air sinuses have been breached, coughing after extubation may lead to tension pneumocephalus. Hypertension during emergence may be controlled by bolus doses of labetalol or esmolol. Neuromuscular paralysis should be reversed at the time of dressing application so that coughing and straining are minimized. Lidocaine (lignocaine), 1.5 mg/kg intravenously, is a useful adjunct to reduce coughing towards the end of an anaesthetic. Patients with a preoperative GCS of 13–15 can be extubated when they open their eyes to command and have demonstrated the ability to protect their airway.

Postoperative care

Assessment of pupillary size and its reaction to light should be undertaken soon after the procedure and documented. The neurological state is assessed as soon as possible in the recovery room and any gross abnormality should be brought to the notice of the surgical team. Simple analgesics such as paracetamol or opioids (e.g. codeine phosphate) are traditional and may be adequate, however, many patients require more potent analgesia. In patients who have been extubated, any sudden deterioration in GCS or neurological deficit should be viewed seriously and an urgent CT scan should be considered. ◆

Anaesthesia for Imaging Relevant to the CNS

Jonathan P Coles
David K Menon

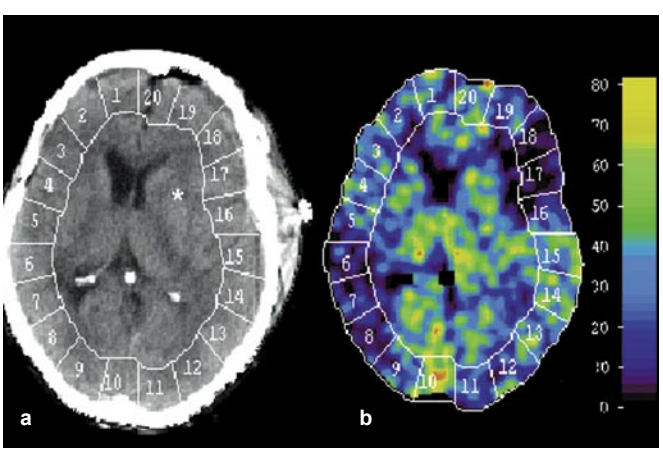
Jonathan P Coles is a Wellcome Research Training Fellow at Addenbrooke's Hospital, Cambridge, UK. He qualified from Leicester University and trained in anaesthesia in Leicester before moving to the Anglian Region and Cambridge.

David K Menon is Professor of Anaesthesia at the University of Cambridge, and Director of the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India, Leeds General Infirmary, The Royal Free Hospital and Addenbrooke's Hospital, and was an MRC Research Fellow at the Hammersmith Hospital.

Neuroradiology is an expanding field and likely to involve an increasing input from the anaesthetist. Many patients need careful anaesthesia and perioperative care during procedures carried out in sites remote from the normal operating theatre or ICU.

Imaging techniques

CT provides wide access to tomographic structural imaging. Rapid imaging following administration of intravenous contrast or inhalation of xenon allows computation of cerebral blood flow and blood volume (Figure 1). Image-guided stereotactic surgery allows access to intracranial lesions without craniotomy. A mechanical frame is attached to the patient's head, a CT scan is performed, and a computer calculates three-dimensional co-ordinates within the brain. In frameless stereotaxy, the initial CT or MRI is stored on computer and fixed points on the skull are mapped on to the image using a sensor wand.



1a CT and **b** xenon CT of a patient following surgery for cerebral artery aneurysm. On the CT there is evidence of oedema within the left hemisphere (∗) with compression of the ipsilateral ventricle and midline shift. The xenon CT shows low regional cerebral blood flow, particularly in regions 17 and 18, suggestive of infarction. Scale: ml/100 g/minute.

γ **cameras** are commonly used for imaging following the injection of γ-emitting labels. Single photon emission CT (SPECT) uses conventional γ-emitting nuclear medicine isotopes with multiple detectors to generate tomographic images that are non-quantitative. Positron emission tomography (PET) uses isotopes such as ^{15}O and ^{18}F, which emit positrons. The annihilation of these positrons can be localized in space by pairs of γ detectors, and provides quantitative images of cerebral physiology.

Interventional neuroradiology (INR): flow-directed microcatheters are introduced into blood vessels via the femoral artery under local or general anaesthesia and manipulated through the carotid or vertebral vessels. A variety of devices and drugs including microcoils, stents, balloons, glues, thrombolytics, sclerosing and chemotherapeutic agents can be introduced for diagnostic angiography, coiling or ablation of cerebral aneurysms and arteriovenous malformations, percutaneous transluminal angioplasty, or intravascular thrombolysis.

MRI and magnetic resonance spectroscopy (MRS): magnetic resonance images are produced using powerful static magnetic fields and intermittent oscillating radiofrequency electromagnetic fields that elicit signals from the nuclei of certain atoms. MRI and MRS allow structural and functional imaging and *in vivo* biochemical analysis. Magnetic field strengths are measured in Tesla (1 T = 10000 Gauss (G)). The magnetic field strength at the surface of the earth is 0.5–1.5 G. Field strengths of 0.05–3.0 T are used in clinical MRI and tend to be based on cryogenic superconducting magnets, which are maintained at –273°C by immersion in liquid helium.

Safety

Biological safety: all the above techniques, excluding MRI, involve exposure to ionizing radiation, which is defined by the estimated dose equivalent in milliSieverts (mSv). In the UK, the range of background radiation is 2–8 mSv/year (chiefly from naturally occurring radioactivity). Radiation safety is based on the 'as low as reasonably achievable' (ALARA) principle. The maximum distance from the X-ray source should be maintained wherever possible. Lead glass shields, lead aprons and thyroid shields should be used (together with radiation exposure badges in selected settings) to assess cumulative radiation burden. The available data generally support the safety of exposure to magnetic fields, but unnecessary exposure to high magnetic fields should be avoided, based on general safety principles.

MRI

Projectile risks from ferromagnetic objects – ferromagnetic objects (e.g. oxygen cylinders, identification badges, paging devices) can become dangerous projectiles and should not be taken into the MR suite unless they are known to be safe.

Implanted devices may be ferromagnetic and move in the magnetic field. Such movement may be disastrous if the implant is large or in a critical location (e.g. intraocular foreign bodies, cerebral aneurysm clips). Patients with an intracranial aneurysm clip should not be imaged using MR, unless the clip has been documented to be non-ferromagnetic, or the patient has already been imaged at the same field strength with no problems. Even non-ferromagnetic implants can result in significant image distortion, or cause local burns because their temperature is increased in the presence of radiofrequency currents. Fatalities have been reported in patients with cardiac pacemakers. The magnetic field causes the reed switch on pacemakers to stick, and revert to fixed rate mode where delivery of a pacing spike on the upstroke of a T wave can result in an R on T phenomenon and trigger ventricular fibrillation. MRI is contraindicated in the presence of pacemakers and other implanted electronic devices, unless it is known with absolute certainty that it will function safely. If there is doubt, the implants should be tested with a powerful hand-held magnet and checked against the manufacturer's specifications. MR units usually have a checklist for patients and staff to exclude the presence of implants.

Monitoring devices – in addition to the above hazards, monitoring devices may dysfunction as a consequence of exposure to magnetic fields. Leads from such devices present a particular hazard because induced currents may result in burns. Simple precautions can help to ensure safety (Figure 2). Devices are described as MR safe when they do not represent a risk to the patient, and MR compatible when they also continue to function in the MR environment without degrading imaging.

Other issues – the most commonly used MR contrast agent (gadopentate dimeglumine – Gd-DTPA, *Magnevist*®), has an ex-cellent safety record. The helium contained in cryogenic magnets can boil off (quench) rapidly when the temperature rises. This dilutes room oxygen and the cold vapour gives frostbite and burns.

Precautions to avoid problems with monitoring devices in magnetic resonance environments

- Check insulation on all monitoring wires and magnetic resonance (MR) cables is intact
- Do not cross cables or form large diameter loops of wire, instead plait leads around each other
- Remove any equipment not in use
- Separate all cables from the skin (using padding)
- Keep monitoring equipment as far away from the examination area as possible
- Use only MR-compatible devices
- Ensure limb extremities do not contact each other

2

Monitoring

Neuroradiology often requires the transport of the patient, and monitoring in an unfamiliar environment. Minimal monitoring standards outside the operating theatre should apply:

- circulatory function including ECG, blood pressure, and auscultation of heart sounds or pulse oximetry
- oxygenation, including oxygen analyser, and pulse oximetry
- ventilation if general anaesthesia is induced, ideally by capnography
- temperature, if changes in body temperature are intended, anticipated or suspected.

Monitoring in MRI suites

Integrated monitoring systems based on technology developed for the MRI environment are widely available, and represent the standard of care (Figure 3). Even MR-compatible devices should be used with special attention to ensure their safe application (see Figure 2). Other monitoring problems include ECG distortion. Changes occur in early T waves and late ST segments that mimic hyperkalaemia or pericarditis and radiofrequency currents produce ECG artefacts (Figure 4). Intracranial pressure can be measured accurately via a ventriculostomy. Several intra-parenchymal sensors are MR safe, but not MR compatible.

ECG with: **a** the subject outside the magnet bore; **b** the subject in the magnet bore (note the ST-T changes); and **c** the ECG trace during operation of the imaging sequence.

4

Anaesthesia and sedation

General issues common to most neuroradiological settings include:

- isolated unfamiliar environment
- hard narrow scanning table that will not tilt rapidly
- potential for disconnection of equipment during movement within the scanner
- rapid heat loss in the air-conditioned environment.

The choice of sedation or anaesthesia for patients undergoing imaging should be discussed by the anaesthetist and neuroradiologist. High-dose sedation may be inappropriate in patients with potential respiratory problems and raised intracranial pressure. General anaesthesia and airway protection is required for prolonged and uncomfortable procedures, extreme cases of anxiety and claustrophobia, failed sedation and for critically ill patients requiring intermittent positive-pressure ventilation. The anaesthetic technique should aim to maintain stable cerebral perfusion pressure and minimize cerebral oedema. Both volatile and intravenous anaesthesia can be used; the choice depends on clinical circumstances.

INR: patient immobility is crucial to ensure success and prevent complications such as rupture or intimal tearing of small vessels. Patient management may need to allow for the following.

- Rapid titration of sedation or anaesthetic depth. Rapid neurological assessment may be required. Problems include patient anxiety, comfort on prolonged immobility, and discomfort following contrast injection.
- Haemodynamic manipulation. To aid therapy, assess vascular reserve and treat ischaemic episodes. This may have adverse effects in unstable patients with neurological disease and should be used with caution.
- Management of complications. These include vessel rupture and haemorrhage, ischaemic episodes (following thromboembolism, vasospasm, hypoperfusion, vessel dissection, stenosis or venous outflow obstruction), neurological complications, radio-contrast reactions and pulmonary embolization of particles.
- Anticoagulation. Heparin is commonly given to achieve an activated clotting time two to three times baseline and prevent thrombosis.

CT: most procedures involve little stimulation and anaesthesia is required only for unstable patients in intensive care and for children. Propofol is commonly used for fast titration of levels of sedation and rapid return of consciousness. Small infants tolerate scanning procedures without sedation if fed, wrapped well and placed prone. Supplemental oxygen can improve the safety margin of sedation in children.

MRI requires an immobile patient to be placed in a noisy, dark, cold and uncomfortable space that is isolated from radiology and anaesthetic staff. Induction and recovery of anaesthesia should ideally take place with dedicated equipment incorporating commercially constructed MR-compatible anaesthetic machines, ventilators and infusion devices. Sedation techniques in children include ketamine, barbiturates, benzodiazepines, high-dose chloral hydrate (50–150 mg/kg) and low-dose propofol infusions.

Applied Cerebrovascular Physiology

David K Menon

Stuart A Booth is Specialist Registrar in Anaesthesia at Addenbrooke's Hospital, Cambridge, UK. After qualifying from Birmingham University, he trained in medicine at the Derbyshire Royal Infirmary and in anaesthesia and intensive care at Bury St Edmunds and Cambridge.

David K Menon is Professor of Anaesthesia at the University of Cambridge and Director of the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India, Leeds General Infirmary, The Royal Free Hospital and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Understanding the principles of the physiology of the brain, and the effects of drugs and pathological processes on it, is of fundamental importance for anaesthetists in the management of patients with brain injury, and for the provision of anaesthesia in neurosurgical patients.

Cerebral metabolism and blood flow

The ability of the brain to maintain membrane ionic gradients and transmit electrical impulses depends on a continuous supply of metabolic substrates. Glucose is the primary energy source of the brain and is actively transported across the blood–brain barrier. The cerebral metabolic rate of glucose utilization is about 5 mg/100 g brain/minute, with 90% taken up in aerobic metabolism. During starvation, however, the brain is able to adapt and use different substances for metabolism (e.g. ketones, lactate, amino acids: see **PHYSIOLOGY**). In normal circumstances, oxygen consumption closely parallels glucose consumption (3.5 ml/100 g brain/minute or 50 ml/minute). In adults, stores of glycogen are exhausted in less than 3 minutes in the face of normal brain activity and there are no significant stores of oxygen. Owing to the high brain oxygen consumption, cessation of cerebral blood flow results in unconsciousness within 10 seconds.

The brain accounts for 20% of basal oxygen consumption and 25% of basal glucose consumption, which under normal circumstances is more than adequately met by the 15% of cardiac output that the brain receives (750 ml/minute in adults). The mean resting cerebral blood flow in young adults is about 50 ml/100 g brain/minute. There are, however, regional differences in blood flow, with mean values for grey and white matter being 80 and 20 ml/100 g brain/minute, respectively. Blood flow also parallels metabolic activity, varying between 10 and 300 ml/100 g brain/minute. Functional impairment results from reductions in cerebral blood flow; the EEG slows at flow rates below 20–25 ml/100 g brain/minute, it is flat at a rate of 15–20 ml/100 g brain/minute, and irreversible brain damage occurs at rates below 10 ml/100 g brain/minute.

The blood–brain barrier

Endothelial cells in cerebral capillaries contain few pinocytic vesicles and are sealed by tight junctions (zona occludens), with no anatomical gap. Consequently, unlike other capillary beds, the endothelial barrier of cerebral capillaries presents a high electrical resistance and is remarkably non-leaky. This property of the cerebral vasculature is termed the blood–brain barrier, and comprises three cellular components (i.e. endothelial cell, astrocyte and pericyte), and one non-cellular structure (endothelial basement membrane). The blood–brain barrier is a function of the cerebral microenvironment rather than an intrinsic property of the vessels themselves. Passage of substances through the blood–brain barrier is directly proportional to lipid solubility and the presence of active transport mechanisms, but indirectly proportional to molecular weight, ionic charge and the degree of plasma protein binding. Thus lipophilic substances, such as carbon dioxide, oxygen and anaesthetic agents, freely enter the brain, whereas ions, proteins and large molecules penetrate the blood–brain barrier poorly. Water moves freely by bulk flow, whereas there is some impedance to small ions such as sodium. Acute changes in plasma electrolyte concentrations (and osmolality) produce changes in the osmotic gradient between plasma and brain interstitial fluid. Although these changes are transient, they result in rapid fluid shifts in the brain, leading to altered neurological function. Thus, marked abnormalities in serum sodium or glucose should be corrected slowly. Disease processes, such as severe hypertension, stroke, infection, tumours, trauma, sustained seizure activity, marked hypercapnia and hypoxia, can cause disruption of the blood–brain barrier. If this occurs, fluid movements across the barrier become dependent on hydrostatic gradients rather than osmotic gradients.

CSF

The main function of CSF is to protect the brain from trauma. It also recirculates interstitial proteins back to plasma (there are no brain lymphatics). The volume of CSF in an adult is about 150 ml (with a turnover of 21 ml/hour) with roughly equal proportions in the cranial and spinal compartments. Most CSF is formed (secretion and ultrafiltration) in the choroid plexus of the cerebral ventricles (mainly lateral). It is iso-osmolar compared with plasma, but has a lower concentration of K^+, Ca^{2+}, HCO_3^-, H^+ (pH 7.33), protein and glucose, and a higher concentration of Na^+, Cl^-, Mg^{2+} and carbon dioxide. CSF flows from the lateral ventricles, through the foramen of Monro, to the third ventricle and then the fourth ventricle (via the aqueduct of Sylvius). It then passes through the foramen of Magendie (medial) and foramina of Luschka (lateral) into the cisterna magna to continue into the subarachnoid spaces around the brain and spinal cord. Reabsorption of CSF occurs at the arachnoid granulations.

Intracranial pressure and volume relationships

In adults, the skull is a rigid structure, which forms an almost completely closed box. It contains four components: brain parenchyma and interstitial fluid (80%), blood which is mainly venous (12%) and CSF (8%). Each fluid component is essentially incompressible, and any increase in the volume of one component if unaccompanied by a compensatory decrease in the volume of another, will result in a rise in intracranial pressure (ICP), as the intracranial volume is fixed (Monro–Kellie doctrine). The normal ICP is less than 15 mm Hg, but varies with arterial pulsations, respiration, coughing and straining (venous pressure). Blood flow to the brain is governed by cerebral venous pressure only when it exceeds ICP; in such situations, cerebral blood flow is dependent on arteriovenous pressure differences. In most instances, however, cerebral blood flow is dependent on the pressure difference between the mean arterial pressure (MAP) measured at the level of the brain and ICP. This is the cerebral perfusion pressure (CPP):

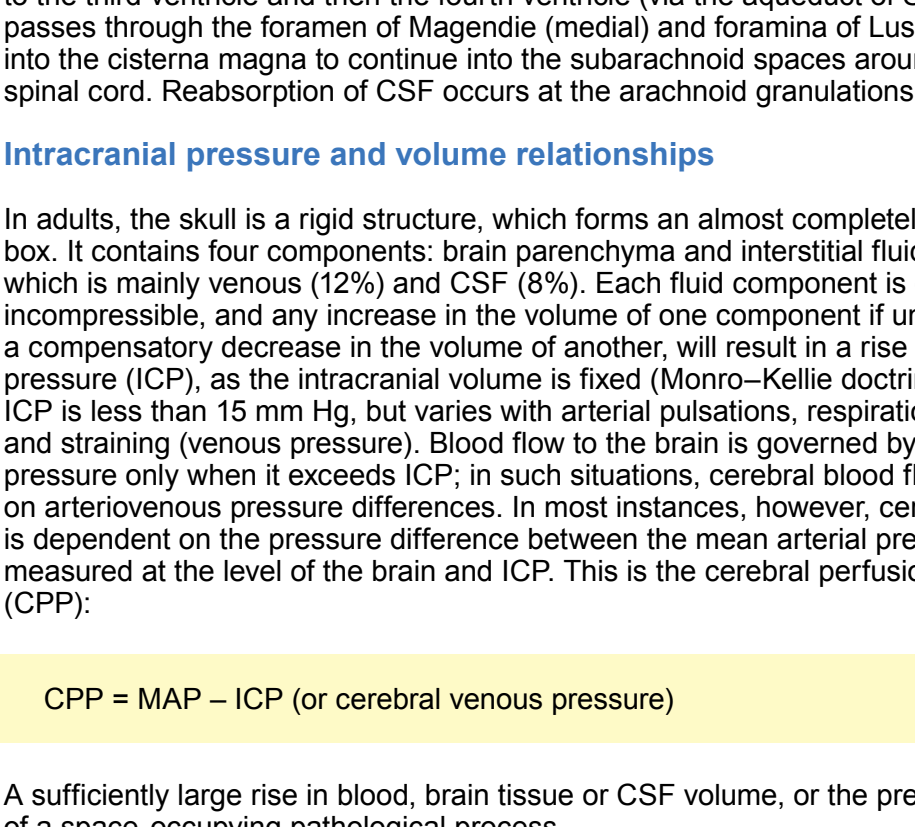
$$CPP = MAP - ICP \text{ (or cerebral venous pressure)}$$

A sufficiently large rise in blood, brain tissue or CSF volume, or the presence of a space-occupying pathological process (e.g. haemorrhage, tumour, abscess), will result in an increase in ICP. However, compensatory mechanisms can initially prevent rises in ICP. These include:

- displacement of CSF from the cranial to spinal compartment
- increased CSF absorption
- decreased CSF production
- decreased cerebral blood volume.

Intracranial compliance is initially high due to these processes. However, as intracranial space occupation continues (by physiological or pathological means), the limits of these mechanisms are exceeded. Intracranial compliance falls and ICP rises dramatically with small increases in intracranial volume, such as 5–10 ml of blood (Figure 1). Therefore, although the cerebral blood volume forms only a small part of the intracranial volume, inappropriate anaesthetic management may cause it to increase as a result of coughing, positive end-expiratory pressure (PEEP), or severe hypertension. Conversely, physiological and pharmacological interventions by the anaesthetist may result in marked reductions in ICP in the presence of intracranial hypertension. Although the absolute magnitude of such a decrease in volume may be small, it may result in a marked fall in ICP.

Intracranial pressure–volume curve



1

Physiological determinants of cerebral blood flow and volume

Regional metabolism

Increases in local neuronal activity are accompanied by increases in regional cerebral metabolic rate. This is termed flow–metabolism coupling. It has now been shown that increases in regional cerebral blood flow during functional activation tend to track glucose utilization, but may be far in excess of an increase in oxygen consumption. This results in regional anaerobic glucose utilization, and a consequent decrease in the local oxygen extraction ratio and increase in local oxyhaemoglobin saturation. The cellular mechanisms underlying these observations have highlighted the role played by astrocytes in the regulation of cerebral metabolism. These data suggest that astrocytes utilize glucose glycolytically and produce lactate, which is transferred to neurons where it serves as a fuel in the citric acid cycle. Astrocytic glucose utilization and lactate production appear to be, in large part, coupled to the astrocytic reuptake of glutamate released at excitatory synapses.

The regulatory changes involved in flow–metabolism coupling have a short latency (about 1 second) and may be mediated by metabolic or neurogenic pathways. The metabolic pathways include the increases in perivascular K^+ or adenosine concentrations that follow neuronal depolarization. Dopamine, acetylcholine, nitric oxide and, possibly, 5-hydroxytryptamine, substance P and neuropeptide Y, released by nerves that supply cerebral vessels, may mediate neurogenic flow–metabolism coupling.

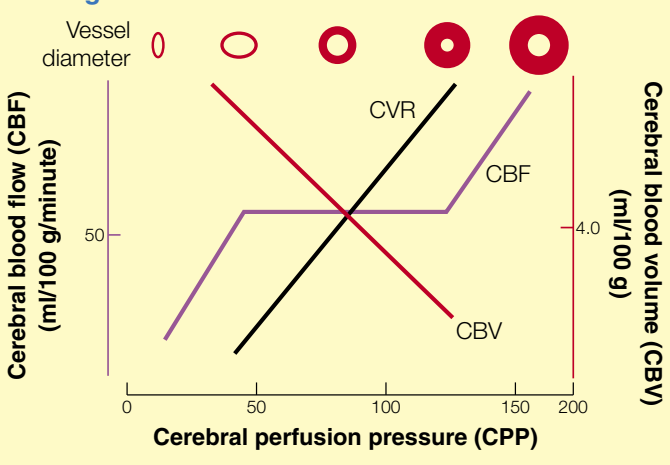
Cerebral perfusion pressure

The ability of the cerebral circulation to maintain cerebral blood flow at a relatively constant level, in the face of changes in cerebral perfusion pressure, by altering cerebrovascular resistance is termed autoregulation (Figure 2). In normal circumstances, as both ICP and cerebral venous pressure are low, systemic arterial perfusion pressure (i.e. mean arterial pressure) becomes the primary determinant of cerebral perfusion pressure. However, in pathological states, ICP becomes a significant factor for cerebral perfusion pressure. Autoregulation has limits above and below which cerebral blood flow is directly related to perfusion pressure. Above the higher limit of autoregulation, increases in mean arterial pressure lead to forced dilatation of cerebral arterioles, disruption of the blood–brain barrier and formation of cerebral oedema with a resultant increase in cerebral blood volume and ICP. Below the lower autoregulatory limit, cerebral blood flow falls linearly with decreasing perfusion pressure.

Unlike flow–metabolism coupling, autoregulatory responses are not immediate; estimates of the latency for compensatory changes in regional cerebrovascular resistance range from 10 to 60 seconds. Changes in cerebrovascular resistance probably arise as a result of myogenic reflexes in the resistance vessels, but these may be modulated by sympathetic nervous system activity or the presence of chronic systemic hypertension. Thus, sympathetic blockade or cervical sympathectomy shifts the autoregulatory curve to the left, while chronic hypertension or sympathetic activation shifts it to the right. These modulatory effects may arise from angiotensin-mediated mechanisms. Primate studies suggest that nitric oxide is unlikely to be important in pressure autoregulation.

In reality, the clear-cut autoregulatory thresholds with varying cerebral perfusion pressure shown in Figure 2 are not observed; the autregulatory 'knees' tend to be more gradual, and there may be wide variations in regional cerebral blood flow for a given value of cerebral perfusion pressure. Symptoms of cerebral ischaemia have been shown to appear when the mean arterial pressure falls below 60% of an individual's lower autoregulatory threshold. However, generalized extrapolation from such individualized research data to the production of 'safe' lower limits of mean arterial pressure for general clinical practice is hazardous for several reasons. These include the wide individual scatter in regional cerebral blood flow autoregulatory efficiency and the coexistence of local fixed vascular obstruction (e.g. carotid atheroma or vascular spasm).

Autoregulation



A change in cerebrovascular resistance (CVR) occurs in response to changes in CPP to maintain CBF. Note that cerebral vasodilatation, and thus a decrease in CVR, maintains CBF with reductions in CPP. This increases CBV which results in critical increases in intracranial pressure in patients with poor compliance (e.g. B in Figure 1)

2

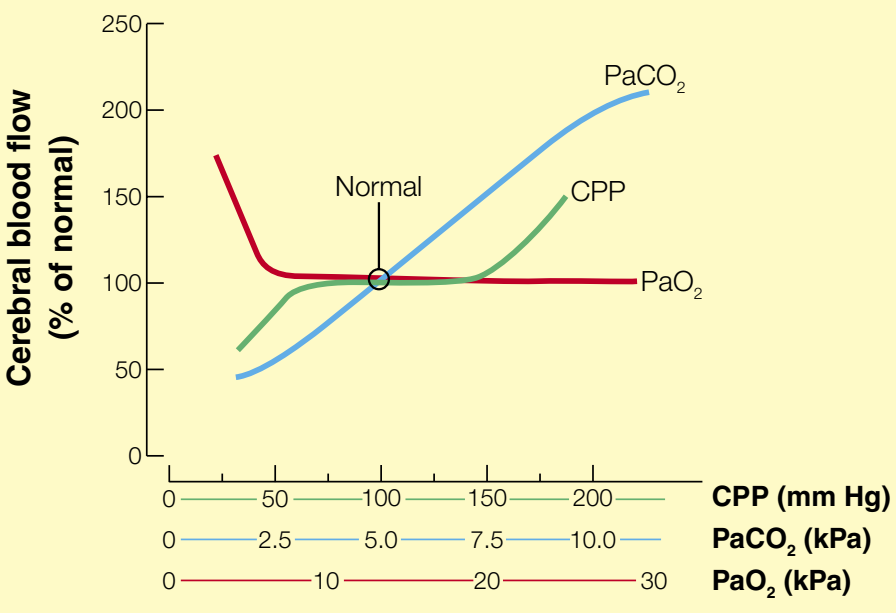
Partial pressure of carbon dioxide in arterial blood ($PaCO_2$)

Cerebral blood flow is proportional to $PaCO_2$, subject to a lower limit, below which vasoconstriction results in tissue hypoxia and reflex vasodilatation, and an upper limit of maximal vasodilatation (Figure 3). On average, in the middle of the physiological range, each kPa change in $PaCO_2$ produces a change of about 15% in cerebral blood volume and 20% in cerebral blood flow. In patients with low intracranial compliance, this decrease in cerebral blood volume can result in dramatic reductions in ICP. However, moderate hypocapnia ($PaCO_2$ of about 3.5 kPa) is no longer recommended to reduce cerebral blood volume in intracranial hypertension because these levels of hypocapnia in head-injured patients can result in dangerously low regional cerebral blood flow levels. Prostaglandins and nitric oxide mediate the vasodilatation produced by carbon dioxide.

Arterial oxygen content

Classical teaching is that cerebral blood flow is unchanged until the partial pressure of oxygen in arterial blood (PaO_2) falls below about 7 kPa, but rises sharply with further reductions (Figure 3). However, recent transcranial Doppler data suggest cerebral thresholds for cerebral vasodilatation as high as 8.5 kPa (about 89–90% oxygen saturation). This nonlinear behaviour is because tissue oxygen delivery governs cerebral blood flow, and arterial oxygen content is related primarily to haemoglobin oxygen carriage (and thus oxygen saturation) rather than PaO_2. The vasodilator responses to hypoxaemia show little adaptation with time, but may be substantially modulated by $PaCO_2$ levels. Nitric oxide does not play a role in the vasodilatory response to hypoxia. Blood haematocrit (and hence viscosity) was also thought to play a role in determining cerebral blood flow. However, it is more likely that changes in cerebral blood flow caused by alterations in haematocrit are the consequence of changes in arterial oxygen content, rather than in blood viscosity.

Effect of pressure changes on cerebral blood flow



The curve for cerebral perfusion pressure (CPP) for patients with chronic systemic arterial hypertension is shifted to the right. $PaCO_2$, partial pressure of carbon dioxide in arterial blood; PaO_2, partial pressure of oxygen in arterial blood.

3

Temperature

Cerebral blood flow changes by about 5–7%/°C. Hypothermia decreases both cerebral metabolic rate and cerebral blood flow so that, at 27°C, metabolic utilization of oxygen is 50% of normal. These reductions in cerebral metabolic rate allow safe circulatory standstill for up to 40 minutes in patients maintained at temperatures of 18°C. In healthy brains at this temperature, autoregulation, flow–metabolism coupling and carbon dioxide reactivity remain intact. An increase in temperature to 42°C leads to an increase in the utilization of oxygen and cerebral blood flow. Temperatures exceeding 42°C appear to cause neuronal damage and reduced oxygen uptake.

Autonomic nervous system

The autonomic nervous system mainly affects the larger cerebral vessels, up to and including the proximal parts of the anterior, middle and posterior cerebral arteries. β_1-adrenergic stimulation results in vasodilatation while α_2-adrenergic stimulation leads to vasoconstriction. The effects of systemically administered α- or β-agonists are less significant. However, significant vasoconstriction can be produced by extremely high concentrations of catecholamines (e.g. in haemorrhage) or centrally acting α_2-agonists (e.g. dexmedetomidine). The autonomic nervous system may be involved in cerebral vasospasm after brain injury (e.g. subarachnoid haemorrhage).

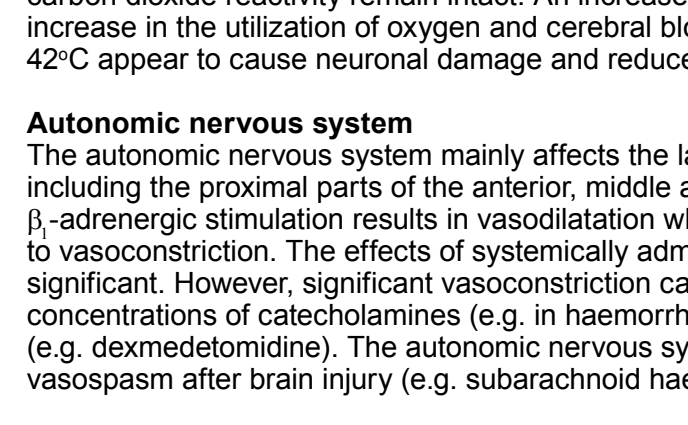
Cerebral venous pressure

Venous obstruction can be caused by supine or head-down positioning, coughing, straining, incomplete muscle relaxation, or tight tracheal tube ties in ventilated patients. While PEEP levels that result in cerebral venous pressures greater than ICP can exacerbate intracranial hypertension, in most instances moderate applications of PEEP will improve arterial oxygenation and potentially result in reductions in ICP. Obstruction of cerebral venous drainage increases ICP by increasing cerebral blood volume and by promoting cerebral oedema formation due to hydrostatic pressure changes. Such oedema can produce microcirculatory disturbances that add to the detrimental effects of intracranial hypertension on cerebral blood flow via cerebral perfusion pressure changes.

Mechanisms in regional cerebral blood flow control

Some of the mechanisms involved in cerebrovascular control are shown in Figure 4, several of which have been referred to earlier. In addition, the level of free Ca^{2+} is important in determining vascular tone, and arachidonate metabolism can produce prostanoids that are either vasodilators (e.g. prostacyclin) or vasoconstrictors (e.g. thromboxane A_2). Endothelin (ET), produced by endothelin-converting enzyme in endothelial cells, balances the vasodilator effects of nitric oxide in a tonic manner by exerting its influences at ET_A receptors in the vascular smooth muscle.

Mechanisms involved in the regulation of regional cerebral blood flow in health and disease



The figure shows a resistance vessel in the brain in the vicinity of a neuron and an astrocyte (A). E, endothelium; M, muscular layer; PGs, prostaglandins; TXA_2, thromboxane A_2; ET, endothelin; ECE, endothelin-converting enzyme; ET_A, ET_A receptor; NO, nitric oxide; CO, carbon monoxide; DA, dopamine

4

Nitric oxide in the regulation of cerebral haemodynamics

Recent interest has focused on the role of nitric oxide (NO) in the control of cerebral haemodynamics. NO is synthesized in the brain from the amino acid L-arginine by the constitutive form of the enzyme NO synthetase. This form of the enzyme is calmodulin dependent and requires Ca^{2+} and tetrahydrobiopterin for its activity. Under basal conditions, endothelial cells synthesize NO, which diffuses into the muscular layer and, via a mechanism mediated by cyclic guanosine monophosphate (cGMP), produces relaxation of vessels. There is strong evidence to suggest that NO exerts a tonic dilatory influence on cerebral vessels. Some of the endothelium-derived relaxant factor (EDRF) activity in cerebral vessels may be due to compounds other than NO. For example, carbon monoxide produced by heme-oxygenase may be responsible for significant cerebral vasodilatation, especially when NO production is reduced.

NO plays an important role in cerebrovascular responses to functional activation, excitatory amino acids, hypercapnia, ischaemia and subarachnoid haemorrhage. Furthermore, NO may also play an important part in mediating the vasodilatation produced by volatile anaesthetic agents, although other mechanisms, including a direct effect on the vessel wall, cannot be excluded.

Neurogenic flow–metabolism coupling

In the last 10 years, focus has been placed on flow–metabolism coupling being effected by a diffusible extracellular mediator. However, there is now accumulating evidence to suggest that dopaminergic neurons may play a major part in such events and, in addition, may control blood–brain barrier permeability.

Measurement of cerebral blood flow and oxygenation

All clinical and many laboratory methods of measuring global or regional cerebral blood flow are indirect and may not produce directly comparable measurements. It is also important to treat results from any one method with caution, and attribute any observed phenomena to physiological effects only when demonstrated by two or more independent techniques. Methods that provide absolute estimates of regional cerebral blood flow use one of two principles: they either measure the distribution of a tracer, or estimate blood flow from the wash-in or washout curve of an indicator. Other techniques do not directly estimate regional cerebral blood flow, but can be used either to measure a related flow variable (such as arterial flow velocity) or to infer changes in flow from changes in metabolic parameters. Some techniques that have been used for the measurement of cerebral blood flow and oxygenation are described briefly in Figure 5.

Techniques for measuring cerebral blood flow and oxygenation

Technique	Global/regional	Features
Kety–Schmidt minute	Global	Invasive (requires jugular bulb and arterial catheters). Time consuming (10–20 data collection). Repeated measures possible. Can be performed in ICU
Intracarotid ^{133}Xe	Regional	Invasive. One hemisphere only. Primarily looks at superficial cortex. Washout or dynamic CT method. Repeated measures possible
Inhaled ^{133}Xe	Regional	Non-invasive. Primarily looks at superficial cortex. Washout or dynamic CT method. Repeated measures possible but not at rapid intervals. Extracranial tissue contamination
SPECT	Regional	Distribution of photon-emitting tracer estimates rCBF. Cheaper than PET, but poorer resolution. Difficult to repeat measurements. Not bedside test
PET	Regional	Distribution of positron-emitting tracer estimates rCBF. Good resolution. Expensive and complex. Repeated measures possible. Not bedside test
Functional MRI	Regional	Intravenous contrast label used or utilizes change in regional oxygenation during functional activation. Excellent resolution. Repeated measures easy with non-contrast method. Not bedside test. Non quantitative in most settings
TCD ultrasound	Regional	Measures flow velocity and therefore CBF indirectly. Measures relative, not absolute CBF. Non-invasive bedside measurement for continuous monitoring. Repeatable but needs same probe angle and vessel diameter to compare values
$SjvO_2$	Regional	Permits continuous monitoring of jugular venous bulb oxygen saturation. Fibre-optic catheter commonly used. Invasive bedside measurement. Indicates balance between oxygen supply and demand
NIROS	Regional	Spectroscopic measurement of regional haemoglobin oxygenation and cytochrome redox state in restricted and poorly defined volume (transcranial cerebral oximetry).Non-invasive bedside measurement for continuous monitoring

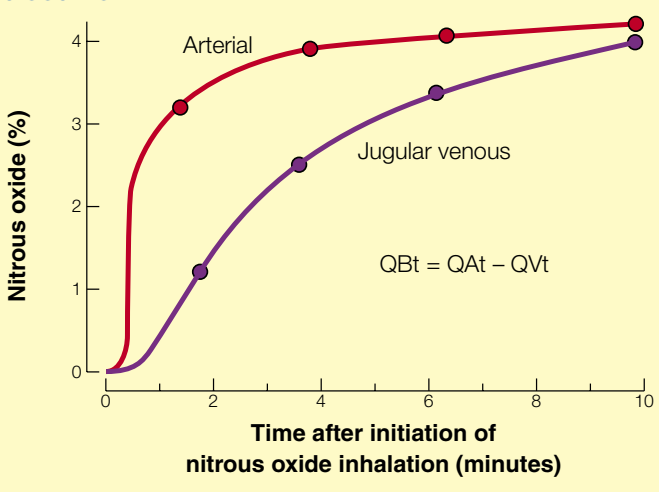
Abbreviations: rCBF, regional cerebral blood flow; SPECT, single photon emission tomography; PET, positron emission tomography; TCD, transcranial Doppler; $SjvO_2$, jugular venous oxygen saturation; NIROS, near infrared optical spectroscopy.

5

The Kety–Schmidt technique

The Kety–Schmidt technique involves the insertion of catheters into a peripheral artery and the jugular bulb. An inert, freely diffusible tracer, such as 10–15% inhaled nitrous oxide, is administered, and paired arterial and jugular venous samples of blood are obtained at rapid intervals for measurement of nitrous oxide levels. The resultant plot of concentration versus time produces an arterial and a venous curve (Figure 6). The jugular venous level of nitrous oxide rises more slowly than the arterial levels because delivered nitrous oxide is taken up by the brain. The rate of equilibration of the two curves measures the rate at which nitrous oxide is delivered to the brain, and thus provides a means of measuring global cerebral blood flow.

Kety–Schmidt method of measuring global cerebral blood flow



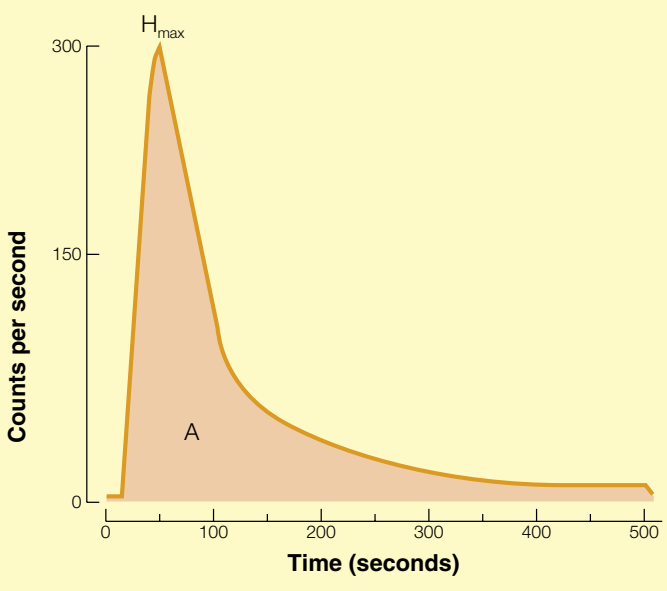
The rate of increase in arterial and jugular venous concentrations of a diffusible tracer gas (e.g. nitrous oxide) are compared. A rapid equilibration implies a high cerebral blood flow (CBF), while a slow equilibration is evidence of a low CBF. QBt, quantity of tracer taken up by brain in unit time; QAt, quantity of tracer delivered to brain by arterial blood in unit time; QVt, quantity of tracer removed by cerebral venous blood in unit time.

6

Xenon-133 washout

An array of collimated scintillation counters positioned over the head can be used to measure the regional decay in radioactivity after the intracarotid or intra-aortic injection of ^{133}Xe. The slope of the washout curve for radioactivity is proportional to regional cerebral blood flow. This washout curve is bi-exponential (Figure 7) and may be resolved into two mono-exponential components, which represent fast and slow washout components. Although these are often referred to as grey matter and white matter components, there is no basis to support such an anatomical distinction because the two curves represent pharmacokinetic compartments, rather than specific neuroanatomical structures. The technique provides two-dimensional information regarding regional cerebral blood flow, but is invasive and primarily evaluates superficial cortical blood flow. Furthermore, intra-carotid injection permits the assessment of only a single cerebral hemisphere at a time. One modification involves the inhalational or intravenous administration of ^{133}Xe; although this makes the technique less invasive, problems arise because of recirculation and contamination by extracranial tissues. The simultaneous presence of activity in both cerebral hemispheres also leads to the 'look-through' phenomenon, where regional cerebral blood flow reductions on one side may be missed because of activity sensed in deeper areas of contralateral brain tissue.

Measurement of cerebral blood flow using intracarotid injection of xenon-133



Blood flow is calculated from the maximal height (H_{max}) and integration of the area under the curve (A).

7

Tomographic regional cerebral blood flow measurement

Tomographic information regarding regional cerebral blood flow may be obtained by quantitative studies of the washout of a radiodense contrast agent, using rapid sequential X-ray CT imaging (dynamic CT scanning). Inhaled stable xenon has been used most often as the contrast agent. Xenon-enhanced CT gained popularity owing to its high spatial resolution and the availability of the equipment. In addition, it can be performed in neurological emergencies because of the short examination time. Recent studies have been performed using standard radioiodinated intravenous contrast agents.

Single photon emission tomography (SPECT) and positron emission tomography (PET) use γ-emitting (e.g. ^{99}Tc) and positron-emitting isotopes (e.g. ^{15}O, ^{18}F, ^{11}C, ^{13}N), respectively, to produce tomographic images of regional cerebral blood flow. PET, in addition to imaging cerebral blood flow, can provide information about cerebral blood volume, oxygen metabolism, and the oxygen extraction fraction. Functional MRI (fMRI) produces tomographic images of regional cerebral blood flow in one of two ways. One technique uses an intravenous contrast agent in the same way as the techniques previously mentioned use other agents. MRI can also produce, without the use of external contrast agents, tomographic images of changes in regional cerebral blood flow. The technique maps the increases in magnetic resonance signal intensity produced by the decreases in regional deoxyhaemoglobin levels that occur during regional activation.

In general, continuous clinical monitoring of the adequacy of cerebral perfusion tends to use techniques other than those outlined above. The parameter most commonly monitored in head-injured patients is cerebral perfusion pressure, though many centres are increasingly using fibre-optic jugular venous oximetry and transcranial Doppler measurement of middle cerebral artery flow velocity. Monitoring of the processed EEG or evoked potentials provides information regarding the consequences of reduced cerebral blood flow, and this technique has been used in the context of cardiopulmonary bypass and carotid endarterectomy. Near-infrared optical spectroscopy and laser Doppler flowmetry are investigational techniques the roles of which have not been clearly defined.

Transcranial Doppler (TCD) ultrasonography

TCD measures the velocity of RBCs flowing through the large vessels at the base of the brain using the Doppler shift principle. Since the diameter of these basal vessels is unaffected by common physiological variables, such as mean arterial pressure and $PaCO_2$, flow velocity in these vessels provides an index of flow. Although many of the intracranial arteries may be studied, the middle cerebral artery is most commonly insonated because it is easy to detect, receives a substantial proportion of the blood flow from the internal carotid artery and allows easy probe fixation. Provided the angle of insonation and the diameter of the vessel insonated remain constant, relative changes in cerebral blood flow velocity correlate closely with changes in cerebral blood flow. Changes in TCD velocities and waveform patterns can be used to detect cerebral ischaemia, hyperaemia and vasospasm. In addition, the characteristics of the TCD waveform may be used to provide a non-invasive estimate of cerebral perfusion pressure.

Jugular venous oximetry

Cerebral oxygenation has conventionally been assessed by jugular bulb oximetry. Traditionally, the superior sagittal sinus is thought to drain primarily into the right internal jugular vein, and it is common practice to place jugular bulb catheters on this side in order to monitor the oxygenation in the supratentorial compartment. More recent data suggest that supratentorial venous drainage is less lateralized, and a case has been made for bilateral jugular bulb catheterization. Normal jugular bulb oxygen saturations tend to be 65–70%. Reductions in the jugular bulb oxygen saturation or increases in arterio-jugular difference in oxygen content of more than 9 ml/dl provide useful markers of inadequate cerebral blood flow and can guide therapy. Values of jugular bulb oxygen saturation below 50% have been shown to be associated with a worse outcome in head injury. Conversely, marked elevations in jugular bulb oxygen saturation may provide evidence of cerebral hyperaemia.

Clinical Neuroprotection

David K Menon
Elisabetta Bandera

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India; Leeds General Infirmary, The Royal Free Hospital and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Elisabetta Bandera is Specialist Registrar at the Istituto di Anestesia e Rianimazione, Ospedali Civili di Brescia, Italy. She qualified from Università degli Studi di Brescia. She trained and worked for 6 months as specialist registrar at the Neurocritical Care Unit at Addenbrooke's Hospital, Cambridge, UK.

Neuroprotection begins with basic resuscitation comprising airway, respiratory and cardiovascular support. Unless normoxia and normotension are maintained, the application of drugs is ineffective. While this article focuses on agents that achieve neuroprotection by reversing one or more of the secondary injury processes, other therapeutic interventions can reduce neuronal injury by optimizing cerebrovascular physiology. Drugs such as mannitol and dexamethasone, can reduce post-traumatic and peritumoral oedema, respectively, and thus augment cerebral perfusion pressure and oxygen delivery. Similarly, haemodynamic augmentation for hypervolaemia and hypertension can enhance cerebral blood flow in the setting of intracranial hypertension or cerebral vasospasm. Agents that antagonize most recognized injury mechanisms have been shown to be neuroprotective in animal models. This contrasts with the clinical setting, where one of the major disappointments in recent years has been the repeated failure of neuroprotective agents.

Neuroprotective interventions
Categories of drugs that have been evaluated in animal models of CNS ischaemia and trauma are outlined below. Specific issues that need to be considered when evaluating the clinical relevance of experimental studies are listed in Figure 1.

Critical issues in assessing preclinical neuroprotective studies

- Species in which studies are performed (effectiveness in more than one species is reassuring; primate models are increasingly seen as relevant)
- Is the model well characterized? (especially problematic in traumatic brain injury)
- Is intervention at a relevant time point? (pre-ischaemic interventions may be irrelevant to clinical stroke therapy)
- Duration of follow-up (increasing evidence supports a need to follow up animals for several days to weeks, because neuronal loss may be delayed)
- Does the study address outcome or only modification of mechanistic changes?
- Have age and gender of the experimental animals been specified and/or controlled? (older animals may show less benefit, there may be gender variations)

Excitatory amino acid antagonists (EAAs): raised levels of glutamate in the extracellular fluid (ECF) have been demonstrated following ischaemia and trauma, and neuroprotective interventions have been targeted at all three glutamate receptor subtypes (*N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA/kainite) and metabotropic) and at various regulatory sites on the NMDA receptor (e.g. the glycine site). The reference compound in this category is dizocilpine (MK-801), a non-competitive antagonist at the NMDA receptor, which had significant CNS side-effects and never reached clinical trials. Newer compounds and regulatory site agents (e.g. glycine and polyamine antagonists) may be better. NMDA receptor antagonists may provide additional neuroprotection when used in combination with antioxidants or thrombolysis, suggesting a possible role for multidrug combinations in neuroprotection.

Experimental data attest to the efficacy of EAAs in animal models. However, a variety of EAAs, including cerestat (a non-competitive NMDA blocker), selfotel (a competitive NMDA blocker) and eliprodil (a polyamine regulatory site antagonist), have proved disappointing in stroke and head injury.

Sodium channel blockers: the neuroprotective potential of drugs such as phenytoin (and its prodrug fosphenytoin), lamotrigine, lubeluzole and riluzole has been shown experimentally. They block sodium channels and attenuate glutamate release. No clinical successes have been reported.

Antioxidants and free radical scavengers: several antioxidants have been effective in animal models, including superoxide dismutase and catalase, the spin-trap phenyl-t-butyl nitrone (PBN), iron chelators (e.g. desferroxamine) and the aminosteroid tirilazad. They all exhibit neuroprotective efficacy in animal models but there have been no successful clinical trials. Initial optimism regarding pegorgotein (PEG conjugated superoxide dismutase) and tirilazad mesylate has been unfounded. One of the few exceptions to the list of failures is the use in acute spinal cord injury of methylprednisolone at high doses (30–35 mg/kg, followed by 5.4 mg/kg/hour for 24 hours) which may provide part of its benefit through antioxidant effects.

Inflammation and corticosteroids: inhibition of tumour necrosis factor α (TNFα), interleukin-1 (IL-1), and IL-8 release or activity improves outcome in focal cerebral ischaemia and trauma models. Inhibition of leukocyte-endothelial interactions is also neuroprotective, and antagonism of adhesion molecules such as ICAM-1, E-selectin and P-selectin reduces neuronal injury.

Despite experimental success with anti-inflammatory therapy, a recently reported trial of anti-ICAM-1 antibody (*Enlimomab*) in acute stroke showed increased morbidity and mortality in treated patients, and recent guidelines covering the intensive care management of patients with head injury have emphasized the lack of objective benefit from corticosteroids. Animal data provide evidence of both harm and benefit from corticosteroid therapy. However, a recent meta-analysis of corticosteroid therapy in head injury concluded that available clinical evidence cannot exclude a benefit from corticosteroid therapy. These conclusions have been widely discussed and have triggered a large (10,000 patients) MRC-sponsored randomized trial of corticosteroid therapy in head injury (the CRASH trial; http://www.crash.lshtm.ac.uk).

Anaesthetic neuroprotection does not depend exclusively on the extent of metabolic suppression and may involve several mechanisms (Figure 2). There is increasing interest in the neuroprotective effects of non-barbiturate anaesthetics. Barbiturates, propofol and isoflurane provide neuroprotection. Ketamine, in addition to its anaesthetic effects, may provide neuroprotection by acting as an NMDA receptor antagonist.

Recent clinical studies of anaesthetic neuroprotection are inconclusive. One study addressing the relative merits of intravenous anaesthetic agents and isoflurane in the clinical setting of temporary clip application during aneurysm surgery showed that pre-treatment with intravenous anaesthetics improved tolerance to ischaemia, but patient numbers were small and it is not clear whether comparable metabolic suppression was achieved. In another study, while barbiturate coma was effective in treating refractory intracranial hypertension following stroke, it produced no improvement in outcome.

Mechanisms by which anaesthetic agents may exert their neuroprotective effects

- Reduction in synaptic transmission
- Reduction in calcium influx
- Ability to block sodium channels
- Membrane stabilization
- Improvement in distribution of regional cerebral blood flow
- Suppression of cortical EEG activity
- Reduction in cerebral oedema
- Free radical scavenging
- Potentiate γ-aminobutyric acid (GABA)-ergic activity
- Alteration of fatty acid metabolism
- Suppression of catecholamine-induced hyperactivity
- Reduction in CSF secretion
- Anaesthesia, de-afferentation and immobilization
- Facilitates uptake of glutamate in synapses

Nitric oxide and the endothelin system: the vasoconstrictor effects of endothelin are normally balanced by vasodilatation produced by endothelial nitric oxide. Overactivity of the endothelin system represents a potential therapeutic target in stroke and subarachnoid haemorrhage. However, neuronal nitric oxide can worsen secondary injury, and nitric oxide synthase inhibition in experimental animals has variable effects, depending on the selectivity of the inhibitor, the model and the systemic haemodynamic perturbations that are produced. Reduced nitric oxide production may be one of the mechanisms by which hypothermia (see below) effects neuroprotection; no clinical studies are available.

Calcium channel blockade: studies continue to show neuro-protection by calcium blockers active at several calcium channel subtypes. Failures in other studies may be explained by the relative importance of the N, Q and P subtypes of voltage-gated calcium channels in neuronal injury, because they may be relatively resistant to block by common calcium-blocking agents. The use of prophylactic nimodipine in aneurysmal sub-arachnoid haemorrhage is one of the few clinically neuroprotective interventions that has been successful, with reductions in morbidity and improvements in outcome.

Hypothermia: several reports document continued experimental success with mild hypothermic neuroprotection. It causes metabolic suppression above 30°C, but other mechanisms are also important. Mild-to-moderate hypothermia (≥ 28°C) can reduce excitatory amino acid release, nitric oxide production, cytokine responses, adhesion molecule expression, neutrophil infiltration, arachidonate release and production of free radicals. The effects of hypothermia result in better preservation of the blood–brain barrier, reduced intracranial hypertension, preservation of cytoskeletal integrity, a lower frequency of spreading depolarization and modulation of gene expression.

Clinical hypothermia – the ischaemic brain tends to be warmer than systemic temperature, and this finding has been confirmed in clinical head injury and stroke. Use of an extracorporeal heat exchanger has been described for rapid cooling following brain trauma, but forced convective cooling seems to be the best means of inducing hypothermia in patients. Pharmacological methods of temperature reduction have non-sustained effects. Selective cooling of the brain during retrograde perfusion in hypothermic circulatory arrest for major cardiovascular surgery may enhance cerebral hypothermia and give added protection while reducing systemic risks.

A series of pilot studies in 1993 suggested significant benefit from induced hypothermia in patients with closed head injury, and formed the basis of an NIH multicentre trial of nearly 400 patients using mild hypothermia (33°C for 48 hours) following head trauma. The initial results were encouraging, but the final results suggest that hypothermia is ineffective in this setting. This is disappointing because many of the expected mechanistic effects of mild hypothermia have been documented in clinical disease. One explanation for this discordance is that hypothermia worsens outcome in patients with head injuries without intracranial hypertension, suggesting that the risk to benefit ratio from hypothermia is maximal in patients with refractory intracranial hypertension in whom the benefits are maximal. A more recent case-controlled pilot study suggests that mild hypothermia (33°C for 12 hours) may improve outcome in patients who experienced cardiac arrest out of hospital.

Miscellaneous and emerging neuroprotective targets
Calpain is a protease implicated in several events in the injury cascade. The potent calpain inhibitor MDL 28,170, rapidly penetrates the brain, prevents cleavage of structural and regulatory proteins and produces significant neuroprotection with therapy initiated up to 6 hours after the onset of ischaemia.

Immunophilins – the immunosuppressant drugs cyclo-sporin A and FK506 bind to specific receptors in the brain and inhibit calcineurin and nitric oxide synthase, modulate neurotransmitter release and cytosolic calcium increases, and mediate nerve growth and regeneration following ischaemia. They are beneficial in ischaemia models.

Caspases are a family of cysteine aspartate proteases (including interleukin converting enzyme (ICE) and CPP32 or caspase 3) involved in apoptotic neuronal death. Their inhibition has been associated with neuroprotection in transient focal ischaemia.

Poly (ADP-ribose) polymerase (PARP) is an abundant nuclear enzyme activated as a DNA repair mechanism by DNA nicks that are typically mediated by oxidant or nitric oxide. PARP transfers ADP monomers from NAD^+ and depletes cellular adenine nucleotide and hence ATP stores when the demand and supply balance of cellular energy is critical. Inhibition or genetic inactivation of the enzyme is neuroprotective.

Matrix metalloproteases are upregulated in a variety of experimental brain injury models, and result in damage to the extracellular matrix with disruption of the blood–brain barrier following ischaemia. Matrix metalloprotease inhibitors can reduce peri-haemorrhagic oedema formation and neuronal injury in ischaemia models.

Adenosine may have neuroprotective effects at A_1 receptors by modulating glutamate-induced rises in cytosolic calcium. Adenosine may also improve microvascular flow, inhibit platelet aggregation, reduce inflammatory responses, and at low concentrations may protect against apoptosis. Adenosine is thought to play a role in ischaemic preconditioning, and exogenous adenosine agonists may potentiate the neuroprotective effects of transient brief ischaemia. The synergistic effects of aspirin and dipyridamole in stroke prevention may be at least partly due to dipyridamole acting as an adenosine reuptake inhibitor.

Neural repair, regeneration and gene therapy – neurotrophins and neural transplantation have been used extensively in neuronal culture preparations, in animal models of ischaemia, Parkinson's and Huntingdon's disease, and these interventions are now being clinically tested for Parkinson's and Huntingdon's disease. Epidermal growth factor, brain-derived neurotrophic factor, nerve growth factor and hepatocyte growth factor all improve neuronal survival or behavioural outcome following experimental ischaemia or trauma. Published clinical trials of neurotrophic therapy have been disappointing, and there are no clinical data addressing the use of these substances in acute neuro-protection. Grafting neural cell lines into ischaemia lesioned brains has improved behavioural outcome, and temporar gene transfer for therapy may be feasible in acute brain injury.

Failure of clinical neuroprotection

For most neuroprotective agents, the translation of experimental success into clinical benefit has been disappointing. Clinical trials that have recently been halted or shown no benefit are listed in Figure 3. Figure 4 lists possible reasons for the failures.

Results from clinical outcome studies of neuroprotective agents

Mechanism of action	Agent	Outcome data
Non-competitive NMDA blocker	Aptiganel	Studies in stroke and acute head injury terminated at interim analysis due to lack of benefit
	Magnesium	No benefit in in-hospital cardiac arrest
Competitive NMDA blocker of benefit	Selfotel	Stroke study halted by steering group due to lack
NMDA polyamine site antagonist	Eliprodil	Stroke study halted by pharmaceutical sponsor
GABA agonist	Chlormethiazole	No benefit in acute stroke within 12 hours in study population Possible benefit in large strokes
Anti-ICAM-1 antibody	Enlimomab	No benefit in acute stroke
Antioxidants	Ebselen	No benefit in stroke on intention-to-treat basis Possible subgroup efficacy
	High-dose tirilazad	Stroke study stopped after 126 patients: no significant benefit
Poorly defined	Lubeluzole	Multinational study showed no benefit in acute stroke within 6 hours
	Piracetam	No benefit with therapy within 12 hours Post hoc analysis suggests benefit with early treatment Possible neuroprotective benefit in cardiopulmonary bypass
	Citicholine	No benefit on intention-to-treat basis Possible subgroup efficacy

GABA, γ-aminobutyric acid; ICAM-1, intercellular adhesion molecule; NMDA, *N*-methyl-D-aspartate.

3

Possible causes of failure of clinical neuroprotection trials

- Experimental demonstration of neuroprotection incomplete (functional end-points?)
- Inappropriate agent: mechanism of action not relevant in humans
- Inappropriate dose of agent (plasma levels suboptimal either globally or in subgroups)
- Poor brain penetration by agent
- Efficacy limited by side-effects that worsen outcome (e.g. hypotension)
- Inappropriate timing: mechanism of action not active at time of administration
- Inappropriate or inadequate duration of therapy
- Study population too sick to benefit
- Study population too heterogeneous: efficacy only in an unidentifiable subgroup[1]
- Study cohort too small to remove effect of confounding factors
- Failure of randomization to distribute confounding factors equally[1]
- Insensitive, inadequate or poorly implemented outcome measures[1]

[1]May benefit from small mechanistic studies in homogeneous, well characterized, clinical subgroups.

4

The future

The success of experimental neuroprotection is undeniable and several publications have explored exciting new therapeutic targets. However, the challenge facing clinical neuroscientists is the failure to translate these successes into positive results from outcome trials. Two approaches have been suggested for overcoming the problems of patient heterogeneity and lack of sensitivity of outcome measures. The first is to accept that these problems are unavoidable and mount larger outcome trials of 10,000–20,000 patients which will address benefits of a magnitude less than the 10% improvement in outcome that most drug trials are designed to detect. The alternative is to mount smaller, more detailed, studies in homogeneous subgroups of patients whose physiology is characterized by modern monitoring and imaging techniques. Repeated application of these techniques during the course of a trial can provide evidence of reversal of pathophysiology and hence mechanistic efficacy. Such surrogate end-points could be used to select drugs or combinations of drugs for larger outcome trials. ◆

Head injuries account for up to half of all trauma-related deaths and often cause severe functional impairment in survivors. The in-patient case fatality rate varies widely between centres with mortality ranging from 15 to over 50%. Good outcome, defined as a Glasgow outcome scale (Figure 1) of 1 or 2, varies from less than 50% to nearly 70%. Few of the interventions used by specialist centres in severe head injury have been subject to prospective, randomized clinical trials. Recommendations for their use are based largely on clinical experience.

Glasgow outcome scale

1 Good recovery
- Resumption of normal life
- Minor neurological or psychological deficits may persist

2 Moderate disability
- Able to travel independently, work in sheltered environment or at reduced level to that before injury
- May have deficits in speech and memory and personality change

3 Severe disability
- Usually dependent in activities of daily living and institutionalized
- May live at home with large amount of support
- Unable to work even in sheltered environment

4 Persistent vegetative state
- Eyes open, sleep–wake cycles
- No speech, communication or response to external stimuli

5 Death

Timing of assessment should be stated.

1

Determinants of outcome: cerebral injury from trauma can be divided into primary and secondary types. Primary injuries result from mechanical disruption of brain tissue occurring at the time of the initial trauma. Secondary insults occur in the period following the initial injury and can be related to outcome (Figure 2). The severity of secondary insults has an additive effect on outcome. Management of head injury in the critical care unit aims to avoid, detect and treat secondary injuries. It is important to emphasize the role of rapid resuscitation and appropriate transfer of such patients to neurological critical care units.

Effects of physiological insults following head injury on mortality and neurological outcome

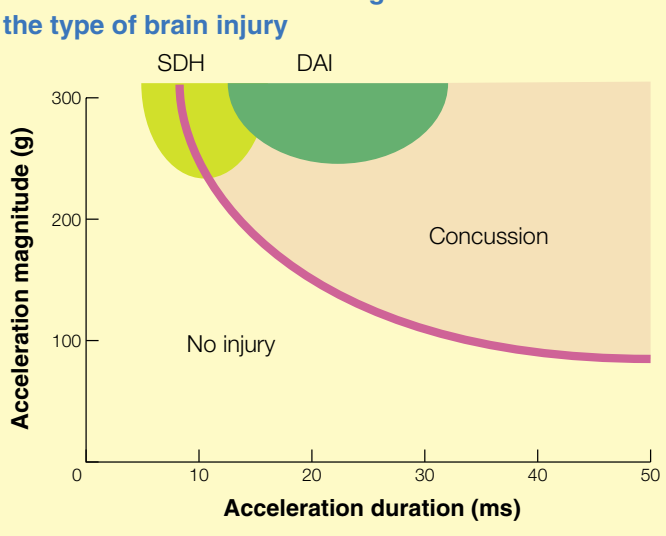
Insult	Mortality	Grades within Glasgow outcome score
Duration of hypotension (systolic blood pressure ≤ 90 mm Hg)	Yes	Yes
Duration of hypoxia (SaO_2 ≤ 90%)	Yes	No
Duration of pyrexia (core temperature > 38°C)	Yes	No
Intracranial hypertension (intracranial pressure > 30 mm Hg)	Yes	No
Cerebral perfusion pressure (< 50 mm Hg)	Yes	No

2

Pathophysiology of acute head injury

Macroscopic and microscopic changes: the severity and type of impact affects the structural changes that occur following head injury (Figure 3). Acceleration and deceleration forces can produce axonal injury, brain contusions and intracranial haematomas. Microscopic injury includes ischaemia, astrocyte swelling with microvascular compromise, disruption of the blood–brain barrier and recruitment of inflammatory cells.

Effect of the duration and magnitude of forces on the type of brain injury



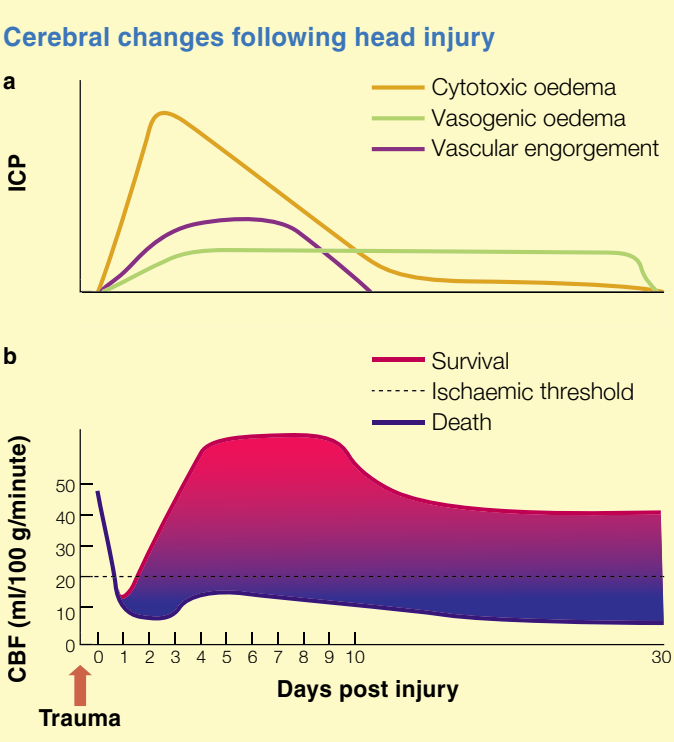
DAI, diffuse axonal injury; SDH, subdural haemorrhage.

3

Cerebral haemodynamics and intracranial pressure: cerebral blood flow (CBF) shows a triphasic response following head injury (Figure 4). In the first 12 hours, global blood flow is reduced, the magnitude being directly related to the severity of the injury. Between 12 and 24 hours, CBF increases and the brain may exhibit supranormal CBF, which is often described as hyperaemia, but may be coupled to hypermetabolism in many patients. CBF begins to fall again several days after injury. In some patients, the fall in CBF may be associated with significant increases in large vessel flow velocity suggesting vasospasm.

Apart from intracranial haematomas, elevation of intracranial pressure (ICP) in the early phase following head injury is usually a result of cytotoxic oedema. From the second day, elevations of CBF and cerebral blood volume make vascular engorgement an important contributor to raised ICP. The blood–brain barrier becomes leaky between days 2–5 post injury and vasogenic oedema then contributes to raised ICP (Figure 4).

Cerebral changes following head injury



Temporal patterns of **a** mechanisms responsible for intracranial pressure (ICP) elevation and **b** cerebral blood flow (CBF) changes following head injury. (Modified from Bullock R, Chesnut R M, Clifton G *et al.* Guidelines for the Management of Severe Head Injury. *J Neurotrauma* 1996; **13:** 643–734)

4

Secondary neuronal injury: several mechanisms have been implicated in secondary neuronal injury including excitatory amino acid release, intracellular calcium overload, free-radical mediated injury and activation of inflammatory processes. Production of pro-inflammatory cytokines with upregulation of adhesion molecules leads to early neutrophil influx and later recruitment of lymphocytes and macrophages. Mononuclear cells may contribute to a prolonged inflammatory response associated with amyloid deposition. Head injury is a risk factor for the deposition of amyloid in the brain and for Alzheimer's disease.

Genetic influences: polymorphism of the apolipoprotein-E (ApoE) genotype directly affects outcome from severe head injury. Possession of the ApoEε4 genotype confers an increased risk of poor outcome. Identification of further genetic markers of outcome may allow targeted neuroprotection strategies.

Management of severe head injury

There is no universally accepted treatment algorithm for patients with severe brain injury but that used at the authors' hospital is given in Figure 5. Widespread variations in practice have led to the recent production of two sets of guidelines from the European Brain Injury Consortium, and a collaboration of the Brain Trauma Foundation, the American Association of Neurological Surgeons and the Congress of Neurological Surgeons. Basic physiology supports the benefits of maintaining CBF and oxygenation. Hypotension (systolic blood pressure < 90 mm Hg) and hypoxia (partial pressure of oxygen in arterial blood (PaO_2) < 60 mm Hg (8 kPa)) worsen outcome.

Cerebrovascular autoregulation may be impaired in patients with severe head injuries. CBF is maintained at a cerebral perfusion pressure (CPP = mean arterial pressure – ICP) above 60–70 mm Hg, a figure higher than in healthy subjects. Although there is controversy over appropriate therapeutic targets, most centres aim for a CPP above 70 mm Hg and an ICP less than 20 mm Hg. A CPP below 50 mm Hg is significantly related to increased mortality. ICP is an independent, albeit weaker, determinant of outcome. Elevations in blood glucose and body temperature may also worsen outcome in acute brain injury.

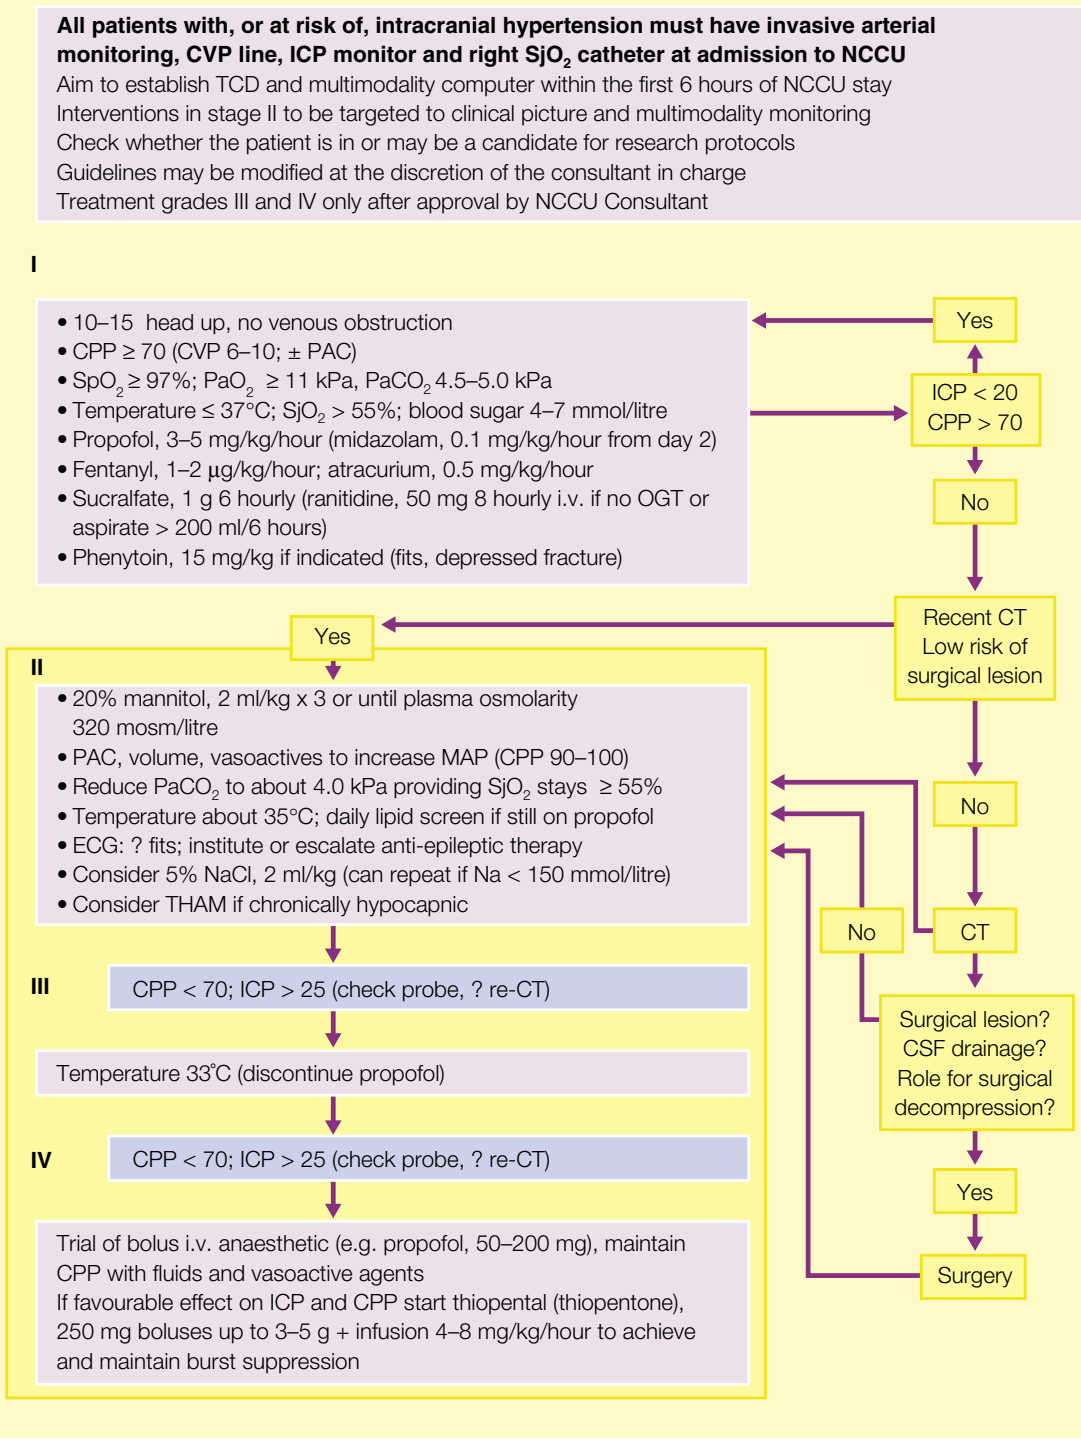
Systemic monitoring: invasive monitoring of arterial blood pressure, continuous pulse oximetry, core temperature monitoring and regular analyses of arterial blood gases and blood glucose are required to optimize physiology. Manipulation of mean arterial pressure may require the placement of central venous or pulmonary artery catheters.

Intracranial pressure monitoring: the need to optimize CPP mandates the need for ICP monitoring. ICP monitoring allows early detection of mass lesions or increasing cerebral oedema in sedated and paralysed patients. The most accurate monitoring method is an intraventricular catheter, but intraparenchymal micromanometers (Codman, USA) or fibre-optic probes (Camino, USA) are increasingly used owing to ease of insertion and lower infection rates. Intraventricular catheters offer the advantage of being able to drain CSF to control ICP. The choice of monitoring technique depends on local preference and expertise.

Other monitoring techniques

Jugular venous oximetry – placement of a catheter high in the jugular bulb allows continuous recording of jugular venous oxygen saturation (SjO_2). SjO_2 varies with the ratio of cerebral oxygen consumption to CBF. Reductions in SjO_2 (< 50%) and increases in SjO_2 (> 75%) may be associated with worse outcomes. The technique averages SjO_2 from the whole brain and may be normal when ischaemia and hyperaemia coexist. SjO_2 monitoring is technically difficult and up to half the episodes of cerebral desaturation may be false-positive results.

Management of intracranial pressure (ICP) and cerebral perfusion pressure (CPP)[1]



[1]Algorithm used in the Neurosciences Critical Care Unit (NCCU), Addenbrooke's Hospital, Cambridge, UK.

Note sequential escalation of therapy and targeting of multiple mechanisms for ICP control.

Abbreviations: CVP, cerebral venous pressure; SjO_2, jugular venous oxygen saturation; PAC, pulmonary artery catheter; SpO_2, oxygen saturation; $PaCO_2$, partial pressure of carbon dioxide in arterial blood; PaO_2, partial pressure of oxygen in arterial blood; OGT, orogastric tube; MAP, mean arterial pressure; TCD, transcranial Doppler; THAM, Tris (hydroxymethyl) amino methane

Transcranial Doppler (TCD) ultrasound can be used to measure blood flow velocity in major cerebral arteries. The most commonly imaged artery is the middle cerebral artery. Reductions in flow velocity are a useful indicator of reduced intracranial perfusion if ICP is raised. Increased flow velocities may result from either hyperaemia or arterial vasospasm. Vaso-spasm can occur in patients suffering traumatic subarachnoid haemorrhage and increases the incidence of poor neurological outcome. Hyperaemia and vasospasm may be distinguished by relating intracranial velocities to those in the carotid artery in the neck.

Newer techniques – near infra-red spectroscopy, direct tissue oximetry, cerebral microdialysis, xenon-enhanced CT scanning and PET imaging are being investigated in acute head injury.

Basic intensive care

Exclusion of surgically treatable lesions

CT scanning should be used routinely for all patients with severe head injury to exclude any surgically treatable mass lesions. CT scans should be repeated for any new episode of unexpected intracranial hypertension.

Ventilatory support

Patients with a Glasgow Coma Score (GCS) less than 8 require intubation for airway protection. Mechanical ventilation ensures that oxygenation is adequate and that the partial pressure of carbon dioxide (pCO_2) is controlled in the low normal range. The use of hyperventilation to reduce cerebral blood volume and hence ICP is controversial. Even moderate hyperventilation may reduce CBF to ischaemic levels and patients without intracranial hypertension are managed at near-normal partial pressures of carbon dioxide in arterial blood ($PaCO_2$ 4.5–5.0 kPa). Controlled hypocapnia can be used to reduce an elevated ICP, but $PaCO_2$ levels are generally maintained above 4.0 kPa, and cerebral oxygenation monitored using jugular bulb oximetry.

Sedation: intravenous anaesthetic agents decrease CBF, cerebral metabolism and ICP. Autoregulation and the cerebrovascular response to carbon dioxide are preserved. Continuous infusions of propofol or midazolam have largely replaced barbiturates because of their better pharmacokinetic profiles. The lipid load resulting from continuous infusion of propofol should be taken into account when calculating daily calorific intake. The routine use of neuromuscular blockers varies between centres, but they may be useful in preventing the rises in ICP associated with coughing or patient–ventilator asynchrony. Long-term use of neuromuscular blockers (especially the corticosteroid-based agents) has been associated with the development of acute neuromyopathy and prolonged neuromuscular blockade.

Fluid management: fluid replacement in the patient with head injuries should be guided by repeated measurement of volume status. Fluid movement across the intact blood–brain barrier is governed by osmolarity rather than oncotic pressure. As such, hypotonic fluids such as dextrose-containing solutions should be avoided. Residual free water after dextrose metabolism can worsen cerebral oedema and elevated plasma glucose levels are associated with worse outcomes.

Osmotherapy: mannitol, 0.25–1 g/kg, may be used to elevate plasma osmolality and reduce brain oedema when ICP is elevated. Volume status must be measured and plasma osmolality should not be allowed to exceed 320 mosm/litre. Hypertonic saline (5–25%) has also been used to treat intracranial hypertension, and may produce ICP reductions without the large volume shifts that are triggered by mannitol-induced diuresis.

Feeding and stress ulcer prophylaxis: enteral feeding should be established early. Patients with head injuries have high nutritional requirements and the aim should be to replace 140% of resting metabolic expenditure by the seventh day following trauma. Parenteral nutrition should be considered for patients who cannot be fed enterally, but it is associated with a higher incidence of hyperglycaemia. Patients in whom enteral feeding has not or cannot be established should receive stress ulcer prophylaxis with sucralfate or H_2-blockers.

Anti-epileptic therapy: the incidence of post-traumatic seizures is highest in patients with a GCS less than 10 and in those in whom an intracranial haematoma, contusion, penetrating injury or depressed skull fracture is present. Seizure prophylaxis with phenytoin or carbamazepine can reduce the incidence of early post-traumatic epilepsy but has little effect on late seizures, neurological outcome or mortality.

Second-line therapy

Induced hypertension: the rationale for maintaining CPP stems from the finding that CBF is commonly reduced following traumatic brain injury, and that cerebral ischaemia is consistently found on post-mortem examination of fatal head injury. Inadequate CPP may result in ischaemia-induced secondary brain injury. Cerebral vasodilatory responses to CPP reductions increase cerebral blood volume and further increase ICP. The optimum target for CPP is unclear and may vary between patients and in the same patient at different times following injury. Most centres agree on the range 60–70 mm Hg for maintaining CPP. If ICP is increased, mean arterial pressure may be elevated using volume expansion, inotropes and vasopressors. The relative efficiency and safety of these interventions has not been studied.

Therapeutic hypothermia is widely used in cardiac and neurological surgery to protect the brain during cardiac standstill, and reduces elevated ICP. In animal studies, mild- to-moderate hypothermia (33–36°C) has been shown to be neuroprotective in cerebral ischaemia, but the clinical benefit remains unproven in patients who do not have refractory intracranial hypertension. Although early studies of moderate hypothermia in head injury suggested benefit, recent publication of the largest study to date has shown a lack of effect. Mortality and poor neurological outcomes were similar in the hypothermia and the normothermia groups, with patients in the hypothermia group having more hospital days with complications.

Barbiturate coma: intravenous barbiturates have been used to reduce ICP in acute head injury for many years. Although their use may improve ICP when other measures have failed, the effects on outcome are unclear. Barbiturates are administered as a continuous infusion; titrated to produce burst suppression on the EEG. This achieves near-maximal suppression of cerebral metabolism and blood flow. Further increasing the dose of barbiturates may increase complications without therapeutic benefit. The most common side-effect is cardiovascular depression and hypotension. Barbiturates should be used only with appropriate cardiovascular support. The prolonged period required for recovery after barbiturates is another drawback to their use.

Decompressive surgery: drainage of CSF via a ventriculostomy is effective in reducing ICP especially (but not exclusively) in patients with hydrocephalus. Two other surgical options are available for the management of resistant intracranial hypertension, craniectomy and lobectomy. Removing part of the skull allows room for the brain to swell. Although ICP usually falls acutely, the pressure may rise over time as swelling continues. Lobectomy of either the non-dominant temporal or frontal lobe also reduces ICP. These techniques have not been subject to a prospective, randomized, controlled study. The decision to perform decompressive surgery lies with the individual neurosurgeon.

Brain volume regulation (Lund therapy) is based on concepts that are contrary to many conventional beliefs regarding the management of intracranial hypertension, and focuses on the prevention and control of cerebral oedema rather than CPP. Transcapillary filtration is controlled by using clonidine and metoprolol to reduce mean arterial pressure. Cerebral blood volume is reduced using a combination of low-dose thiopental (thiopentone) as a sedative, and dihydroergotamine to constrict large veins. Normal colloid oncotic pressure is maintained by infusion of albumin or plasma. Neurological outcome is favourable, but a randomized, controlled trial is awaited.

Investigational neuroprotective agents

Calcium channel blockers – nimodipine has been used successfully for the treatment of vasospasm associated with primary subarachnoid haemorrhage. Trials in traumatic subarachnoid haemorrhage are inconclusive.

Corticosteroids – although the use of early high-dose methylprednisolone is of benefit in traumatic spinal cord injury, the use of corticosteroids in acute head injury is controversial. The use of high-dose, short-duration methylprednisolone therapy is the subject of an ultra-large, randomized, controlled trial, the Corticosteroid Randomization After Significant Head injury (CRASH) trial.

Excitatory amino acid antagonists have a role in experimental head injury and antagonists of their action can afford neuroprotection. However, they have not been effective in outcome trials.

Antioxidants – animal studies suggest that free radicals play a prominent role in head injury and that this may be ameliorated by the use of antioxidants. Two antioxidants (pergorgotein and tirilazad) have been studied in large scale, human trials but have demonstrated no improvement in clinical outcome. ◆

General Principles of Neurosurgical Postoperative Care

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India; Leeds General Infirmary, The Royal Free Hospital and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

The postoperative period can be critical for neurosurgical patients, who may present with intracranial hypertension, altered sensorium and/or depressed airway reflexes. The deterioration in physiological homeostasis produced by anaesthesia and surgery poses additional risks. Failure to detect and correct alterations in systemic and cerebral physiology rapidly can result in irretrievable neurological damage. The main groups of neurosurgical patients requiring intensive or high dependency care following neurosurgery are listed in Figure 1.

Neurosurgical patients requiring postoperative intensive or high dependency care

- Patients with preoperative cardiorespiratory illness
- Long surgery, large blood loss, coagulopathy, incidental hypothermia, unstable haemodynamics
- Patients at risk of, or documented to have, intracranial hypertension
- Patients requiring ventilation to provide stability for venous haemostasis
- Patients requiring or recovering from a period of hypothermia induced for cerebral protection
- Patients requiring postoperative intracranial pressure monitoring
- Requirement for blood pressure manipulation as a part of induced hypertension for cerebral perfusion pressure maintenance or as a part of triple-H therapy
- Induced hypotension for treatment of hyperaemia following carotid surgery or surgery for arteriovenous malformations

1

Monitoring

Clinical assessment is the primary form of monitoring. Other basic monitoring includes blood pressure, ECG monitoring, pulse oximetery and careful recording of fluid balance.

Arterial blood gases and invasive blood pressure

Arterial access is required in all ventilated patients for the measurement of arterial blood gases. Direct arterial pressure measurement is indicated following neurovascular procedures (clipping of ruptured aneurysms, resection of arteriovenous malformations, and the early postoperative period following carotid endarterectomy) in patients with haemodynamic instability, intracranial hypertension, and those requiring vasoactive agents for blood pressure control.

Central venous pressure (CVP) monitoring and pulmonary artery catheterization
CVP monitoring is needed for patients with large volume losses, cardiac disease, vasoactive infusions, and hypotension or oliguria not readily responsive to fluid challenge. CVP monitoring may also be essential in the patient with pathological polyuria due to diabetes insipidus or the condition of 'cerebral salt wasting' that occurs following subarachnoid haemorrhage. However, the CVP is an indirect measure of intravascular volume status, which is influenced by right heart compliance, pulmonary or right heart disease, intrathoracic pressure and posture. Measurement of pulmonary artery wedge pressure provides a more reliable index of intravascular volume status in the critically ill patient, and the use of thermodilution catheters allows the monitoring of cardiac output and systemic vascular resistance. These data are of particular benefit in patients with concurrent severe cardiorespiratory disease or sepsis. Pulmonary artery catheters are also valuable to guide the use of complex vasoactive interventions as a part of cerebral perfusion pressure augmentation in intracranial hypertension or triple-H therapy (see *Anaesthesia and Intensive Care Medicine* **3:4:** 143) for vasospasm following subarachnoid haemorrhage.

Neurological examination

Changes in conscious level or new focal deficits may provide the first evidence of postoperative intracranial bleeding or cerebral oedema. Neurology should be reviewed with particular regard to the operation performed and preoperative neurological status. Regular observations should include the measurement of pupillary size and reaction, limb power and the Glasgow Coma Score (GCS; see *Anaesthesia and Intensive Care Medicine* **3:4:** 132). Although originally designed to quantify the severity of head injury, the GCS allows wider quantification of neurological dysfunction and facilitates the detection of trends in neurological status. One crucial decision is whether to undertake CT in a patient whose GCS is substantially worse than in the preoperative period. While many decisions are clear-cut, a short period of observation may help in others. Gradual improvement in GCS, absence of new focal neurology and the presence of normally reacting pupils and acceptable haemodynamics suggest residual anaesthetic effects. However, clinical signs of intracranial events may be nonspecific, and it is better to err on the side of over-investigation rather than to miss an early intracranial event.

Intracranial pressure (ICP) monitoring

ICP monitoring should be considered in all patients who have intracranial hypertension or are at risk of developing it. It is particularly indicated in patients who remain sedated and cannot be assessed by regular neurological examination. It is essential to relate ICP measurements to mean arterial pressure (MAP), and to monitor cerebral perfusion pressure (CPP; where CPP = MAP–ICP) continuously, because many therapies to treat neurosurgical patients target ICP or CPP. They include a reduction in cerebral oedema by cerebral dehydration, administration of corticosteroids, hyperventilation, blood pressure control, reduction of CPP, surgical decompression, CSF drainage and hypothermia.

Other monitoring modalities

Transcranial Doppler ultrasound, jugular venous saturation monitoring, and EEG and evoked potential monitoring may be useful in individual patients. Their use is discussed in *Anaesthesia and Intensive Care Medicine* **3:4:** 127.

Investigations

Routine postoperative tests including a full blood count, clotting screen, urea and electrolytes are required after most major neurosurgical procedures, along with arterial blood gases if the patient is ventilated or has a low oxygen saturation. A chest radiograph is indicated if the patient is ventilated, a central line has been inserted or gas exchange is abnormal. Imaging of the CNS should be undertaken if there is deterioration in the patient's neurological state or a rise in ICP.

ICU management

Airway and ventilation

Inability to protect or maintain the airway or maintain acceptable blood gases mandates intubation and ventilation. Airway protection should also be considered in patients with a GCS of 8 or less, haemodynamic instability, inadvertent post-operative hypothermia, sepsis or those who require controlled hyperventilation in order to reduce ICP.

While conventional ventilation strategies are generally applicable to neurosurgical patients, some specific issues need attention. It is important to maintain partial pressure of carbon dioxide in arterial blood ($PaCO_2$) within tight limits (the author uses an initial target value of 4.5–5 kPa), because even mild hypercapnia can result in cerebral vasodilatation and a rise in ICP. Conversely, profound hypocapnia may result in dangerous cerebral vasoconstriction and ischaemia. Central ventilatory drive may be compromised by drugs or disease, therefore the use of ventilatory modes that do not assure a near constant minute volume (e.g. pure pressure support ventilation) may be inappropriate. Similarly, while mild arterial desaturation (SaO_2 < 90%) is often well tolerated by non-neurosurgical patients, the resulting hypoxic cerebral vasodilatation can markedly increase ICP in a non-compliant brain.

Haemodynamic management

Intraoperative blood loss can be difficult to estimate, and the pulse rate, blood pressure, urine output and CVP provide a guide to the patient's haemodynamic state. Blood or colloid replacement should be guided by these modalities in conjunction with the haematocrit. Fluid and electrolyte balance must be monitored closely with regular assessment of blood gases, urea and electrolytes. Glucose-containing solutions should be withheld from neurosurgical patients at risk of cerebral oedema or ischaemia, because the residual free water after glucose is metabolized reduces plasma osmolality and accelerates cerebral oedema formation; also, increases in blood sugar can worsen outcome in the ischaemic brain. Prompt normalization of coagulation and platelet levels is essential in patients who have undergone intracranial procedures.

Analgesia, sedation and muscle relaxation

Postoperative pain after brain surgery is an important clinical problem. Pain most often occurs within the first 48 hours after surgery but a significant number of patients endure pain for longer. The subtemporal and suboccipital surgical routes result in the highest incidence of postoperative pain. Appropriate analgesia for spontaneously breathing patients includes codeine phosphate, 30–60 mg up to 6 hourly i.m./p.o./n.g., paracetamol, 1 g 6 hourly p.o./n.g./p.r., and/or diclofenac, up to 150 mg/day (if the patient has no bleeding problem or renal insufficiency). Traditionally, powerful opiates have not been used in patients undergoing cranial surgery, but there is increasing recognition that some of these patients may be in significant pain, and many centres are now beginning to use small doses of intravenous opiates in selected patients with careful monitoring of CNS state. Parenteral opiates, preferably using a patient-controlled analgesia system, are widely used following spinal surgery where changes in the level of sedation are not a critical part of postoperative monitoring. Patients undergoing simple discetomies often do not require strong opiates for postoperative analgesia.

Sedatives are used to decrease anxiety and diminish awareness of noxious stimuli in ventilated patients. Propofol, 1–5 mg/kg/hour, is appropriate for short periods of sedation, while longer periods of ventilation may be facilitated by midazolam. Prolonged or high-dose propofol use presents problems of cost, cardiovascular depression and lipid loading. Low-dose fentanyl, 1–2 μg/kg/hour, is commonly used, but there may be a role for shorter acting opioids (e.g. alfentanil, remifentanil) which facilitate rapid recovery and weaning from ventilatory support.

Neuromuscular blockade is sometimes required to facilitate ventilation and prevent increases in ICP. Prolonged neuromuscular blockade and myoneuropathy are most commonly reported with the long-acting or steroid-based neuromuscular blockers, therefore atracurium is commonly used if paralysis is indicated.

Complications specific to neurosurgical operations

Management of raised ICP

Intracranial hypertension is multifactorial and may result from hydrocephalus, vascular congestion and/or cerebral oedema. A patent airway, adequate oxygenation and mild hyperventilation, along with maintenance of an adequate CPP, provide the foundation of care in such patients. There is no role for fluid restriction in patients with raised ICP, because cerebral hypoperfusion will worsen cerebral ischaemia and cause further increases in ICP by promoting cerebral vasodilatation. Reduction in vasogenic oedema can be achieved using osmotic agents. Both 20% mannitol, 5 ml/kg, and 5% hypertonic saline, 2 ml/kg, are effective, and may improve cerebral perfusion via micro-circulatory and rheological effects. Furosemide (frusemide) can be used as an adjunct.

Corticosteroids are effective in reducing vasogenic oedema associated with mass lesions (e.g. intracerebral tumour or haematoma). The ICP effects of corticosteroids require many hours to become apparent and they are ineffective (and possibly detrimental) in brain trauma and ischaemic stroke.

Hypocapnia causes cerebral vasoconstriction and reduces cerebral blood volume, thereby reducing brain bulk and ICP. Aggressive hyperventilation should be avoided, because there is a danger of severe vasoconstriction with resultant ischaemia. Mild-to-moderate hyperventilation ($PaCO_2$ of about 4.5 kPa) may be relatively safe, but is best used with the safeguard of jugular bulb oximetry, which provides a warning against cerebral ischaemia.

Changes in CVP can have a marked influence on ICP. Flexion or torsion of the neck can obstruct cerebral venous outflow and increase brain bulk and ICP. Application of positive end-expiratory pressure (PEEP) or other ventilatory patterns that increase intrathoracic pressure can theoretically increase ICP, but seldom do so in practice, because CVP dictates ICP only when ICP is less than CVP. There is no reason to withhold PEEP if it is required to optimize gas exchange. Muscle relaxation and sedation can indirectly reduce elevated ICP by decreasing mean intrathoracic pressure and spikes in pressure caused by coughing.

It is generally accepted that reducing brain temperature lowers metabolism, cerebral blood flow, cerebral blood volume and CSF secretion with resultant reductions in ICP. However, there is debate as to whether hypothermia may be neuroprotective in the absence of intracranial hypertension. There is no doubt that elevations in body temperature are injurious to the ischaemic or traumatized brain, and aggressive treatment of pyrexia is essential in neurosurgical patients.

In the event of intractable intracranial hypertension with preserved electrical activity on EEG, the use of high-dose intravenous anaesthetics such as thiopental (thiopentone), titrated to burst suppression, may reduce metabolic needs and result in cerebral vasoconstriction and ICP reduction.

Intracranial hypertension can be reduced by CSF drainage, especially (but not exclusively) in the presence of hydrocephalus. External ventriculostomy allows controlled drainage of CSF and permits catheter flushing in the event of blockage, but it is associated with a significant risk of infection, and microbiological surveillance is mandatory. Surgical removal of intracranial tissue or masses reduces ICP, and can reduce shifts in brain tissue that are associated with herniation and/or focal neurological dysfunction. Intractable intracranial hypertension may respond to decompressive craniectomy.

Intracranial bleeding
Awake patients may suffer reductions in GCS and/or focal neurological deficits related to the site of bleeding. In sedated patients, ICP monitoring may provide an early indication of postoperative intracranial haemorrhage, which should prompt early CT scanning for confirmation.

Seizures
Prolonged seizure activity produces irreversible cerebral damage, independent of any accompanying hypoxia and acidosis, as a result of the excessive metabolic demands and energy depletion in continuously firing neurons. Cerebral oedema and lactic acid accumulation ensue. Intravenous benzodiazepines are commonly used as initial treatment for seizure control, followed by phenytoin (intravenous loading dose 15 mg/kg over 1 hour, with maintenance at 3–4 mg/kg/day) because it does not cause significant depression of the conscious level.

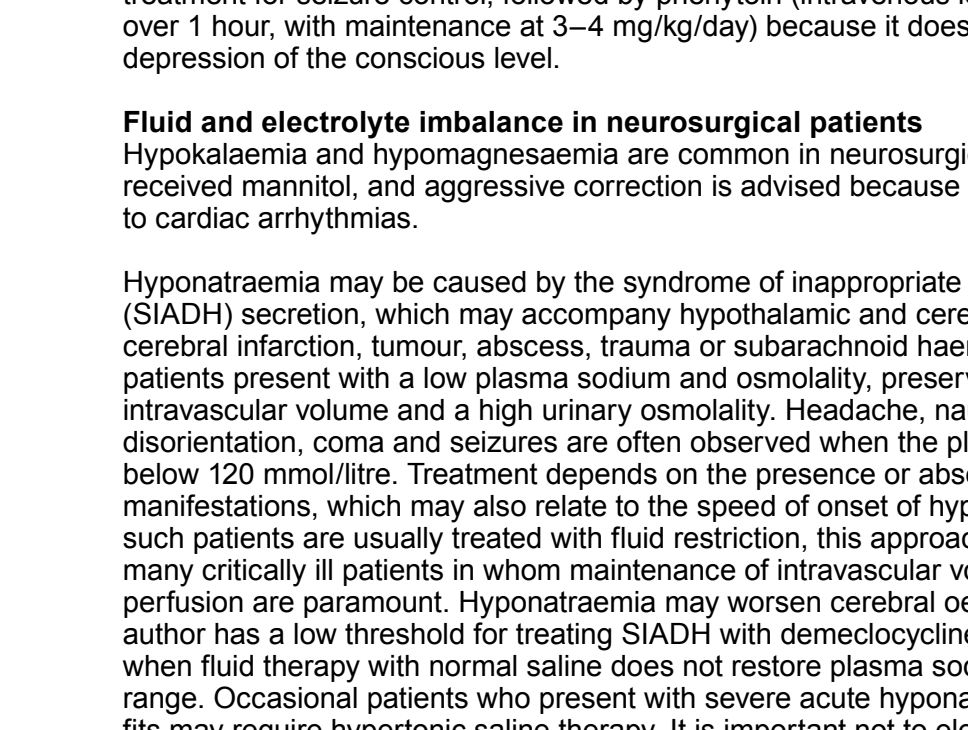
Fluid and electrolyte imbalance in neurosurgical patients
Hypokalaemia and hypomagnesaemia are common in neurosurgical patients who have received mannitol, and aggressive correction is advised because they may predispose to cardiac arrhythmias.

Hyponatraemia may be caused by the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, which may accompany hypothalamic and cerebral lesions, including cerebral infarction, tumour, abscess, trauma or subarachnoid haemorrhage. Such patients present with a low plasma sodium and osmolality, preserved or expanded intravascular volume and a high urinary osmolality. Headache, nausea, confusion, disorientation, coma and seizures are often observed when the plasma sodium falls below 120 mmol/litre. Treatment depends on the presence or absence of clinical manifestations, which may also relate to the speed of onset of hyponatraemia. While such patients are usually treated with fluid restriction, this approach is inappropriate in many critically ill patients in whom maintenance of intravascular volume and cerebral perfusion are paramount. Hyponatraemia may worsen cerebral oedema, therefore the author has a low threshold for treating SIADH with demeclocycline, 300–1200 mg/day, when fluid therapy with normal saline does not restore plasma sodium to the normal range. Occasional patients who present with severe acute hyponatraemia, coma and fits may require hypertonic saline therapy. It is important not to elevate plasma sodium levels too rapidly in patients who have been chronically hyponatraemic, because this may predispose to the development of central pontine myelinolysis. In such patients, plasma sodium should not be raised at a rate greater than 1 mmol/hour or 12 mmol in 24 hours.

Hyponatraemia in other neurosurgical patients, especially following subarachnoid haemorrhage, may be the consequence of ‘cerebral salt wasting’. Such patients present with a low plasma sodium and high urinary sodium output, and are usually fluid depleted. This syndrome may be the consequence of excessive secretion of brain natriuretic peptide, and is treated with aggressive volume expansion with sodium-containing crystalloid or colloid.

Many neurosurgical conditions including trauma, intracranial hypertension, tumours, subarachnoid haemorrhage and brainstem death can lead to diabetes insipidus. The relative lack or absence of antidiuretic hormone in these patients results in the passage of large volumes of dilute urine (up to 0.5–1 litre/hour) with the rapid development of hypovolaemia, plasma hyperosmolality and hypernatraemia. Diagnosis is made by detecting high plasma osmolality coupled with low urinary osmolality. Treatment is with deamino-D-arginine vasopressin (DDAVP, 1–8 μg boluses, repeated as required) and hypotonic fluids. Mild elevations in plasma sodium should be left untreated, because they may help to minimize vasogenic oedema. Also, the aggressive and rapid reduction of plasma sodium and osmolality in patients who have been chronically hypernatraemic may result in cerebral oedema. Diagnosis of changes in plasma osmolality in neurosurgical patients is facilitated by reference to nomograms that relate plasma and urine osmolality (Figure 2).

Nomogram relating plasma and urine osmolality showing diagnostic categories for different abnormalities



Classically, the syndrome of inappropriate antidiuretic hormone (SIADH) results in concentrated urine with high osmolalities and sodium levels (> 25 mmol/litre) despite hyponatraemia, low plasma osmolality and intravascular volume repletion or expansion. Patients with cerebral salt wasting (CSW) also have high urinary sodium levels (25 mmol/litre), but excrete large urine volumes and are volume depleted. Unlike CSW, fluid restriction in SIADH results in reduction in urinary sodium, but the volume depletion produced by this diagnostic intervention is inappropriate in critically ill patients. These differentiating features may be confounded in critically ill patients by variable volume loading and use of diuretics.

Modified from: Moses A M, Blumenthal S A, Streeten D H. Acid–base and Electrolyte Disorders associated with Endocrine Disease: Pituitary and Thyroid. In: Arief A I, Defronzo R A, eds. *Fluid Electrolyte and Acid-Base Disorders.* New York: Churchill Livingstone, 1985; 851–92.

Intrahospital transfers
Tomographic imaging is commonly needed in the postoperative neurosurgical patient, and for some patients this may involve multiple journeys. Such transfers expose the sick brain to the risk of physiological insults, and careful planning, appropriate monitoring, and the presence of an anaesthetist is essential for patients who are ventilated or haemodynamically compromised. Communication with the imaging department is a priority to prevent delays. Monitoring levels should be similar to those used in the ICU, and should include pulse oximetry, ECG, blood pressure (invasive if arterial line *in situ*), ICP monitoring and capnography. Infusions required on the ICU should continue, including appropriate doses of sedation, analgesia and muscle relaxant. Haemodynamic control in a ventilated patient can be difficult during transfer with periods of hyper- or hypotension. Gentle movement, with carefully timed boluses of sedation can help to minimize this problem. Resuscitative drugs should be carried with the patient. During the time spent in the scanner careful attention must be paid to the patient’s physiological state with particular regard to airway, breathing and circulation. Ideally, the scanning room should have its own piped oxygen and compatible mains electricity supply to avoid the hazards of running out of oxygen or battery power. Any intervention to stabilize the patient must take priority over the scanning procedure. ◆

Neuromonitoring

Luzius A Steiner
David K Menon

Luzius A Steiner is Clinical Research Fellow in Anaesthesia and Neurosurgery at Addenbrooke's Hospital, Cambridge, UK. He qualified from the University of Basel, Switzerland, and trained in anaesthetics and intensive care medicine in Switzerland. His current research is on cerebrovascular autoregulation in patients with head injuries.

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India; Leeds General Infirmary, The Royal Free Hospital and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Neuromonitoring has become an important aspect of neuro-anaesthesia and intensive care because it is assumed that the early detection of insults to the brain is possible and can reduce injury. Various monitoring technologies are available, but there is little evidence that their use improves outcome. Although most clinical monitoring is based on sound physiological premises, the absence of such evidence makes the objective choice of best monitoring technique for a particular patient or procedure difficult.

Monitoring cerebral function

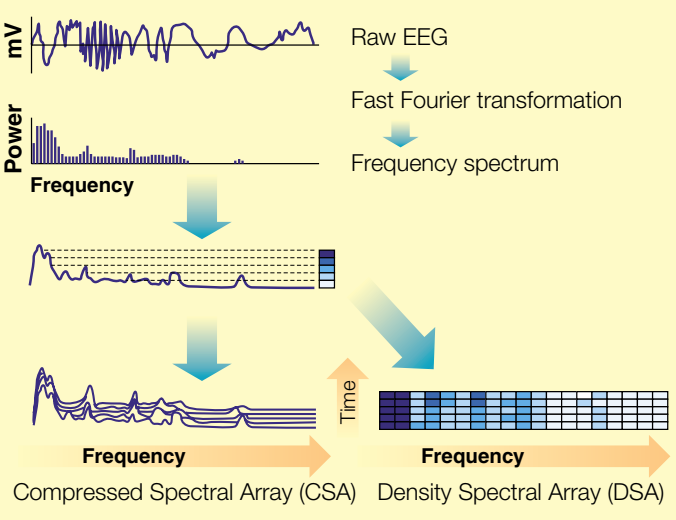
EEG

The EEG signal is predominantly generated by postsynaptic potentials of cortical pyramidal neurons. When neighbouring cells have synchronous changes of these potentials, their current loops are summed in the extracellular fluid, which creates a regional current flow that is large enough to be detected by scalp electrodes (the normal range of EEG amplitude in adults is 10–100 μV). The EEG is therefore predominantly a cortical phenomenon. Magnitude and frequency of the EEG signal are determined by the synchronicity of postsynaptic potentials. Synchronicity is strongly influenced by neuronal circuits connecting the cortex with the thalamus and the brainstem. Higher cortical function is associated typically with desynchronization while anaesthesia and other factors that depress cortical function are associated with increasing synchronicity.

Indications for EEG monitoring in neuroanaesthesia and intensive care include diagnosis and management of seizures, assessment of drug effects (e.g. dose control for EEG burst suppression), making specific diagnoses (e.g. certain types of encephalitis), monitoring for ischaemia during carotid surgery and monitoring depth of anaesthesia.

Processed EEG: a standard EEG consists of an 8–32 channel trace printed on paper at 30 mm/second (or 300 pages/hour) and provides an enormous amount of data, which requires interpretation by a specialist who assesses frequency, amplitude and specific waveform patterns. The standard EEG is not well suited for intraoperative use. Various approaches have been used to summarize such information in a format that can be rapidly understood and allows recognition of trends. The number of tracings is reduced (typically one per hemisphere) and after artefact detection the signal is further processed. The technique most commonly used calculates a spectral array. This calculation results in a set of frequency bins, with the power in each bin representing the magnitude of the signal. Two display methods are popular. The Compressed Spectral Array (CSA) displays a temporal series of frequency versus power histograms in a three-dimensional manner, while the Density Spectral Array (DSA) transforms the power of each frequency bin into a grey-scale intensity and plots this versus time (Figure 1). Both techniques allow display of up to 1 hour of data on a single screen.

Two common methods for transforming EEG data



The CSA and DSA formats can be interpreted easily intraoperatively and allow rapid detection of trends

Bispectral index (BIS): bispectral analysis provides a new approach to computerized EEG analysis. It analyses the frequency and phase angles of the components of a signal and takes into account the interactions of some waves with others. It calculates new summary measures of EEG activity. The BIS, as calculated by a commercially available device (Aspect Medical Systems, Natick, MA, USA), makes use of this approach. Its calculation involves the determination of several ECG descriptors, including information from bispectral analysis. Each of these descriptors performs best in a specific range of anaesthetic effects. The displayed BIS value is the result of a proprietary combination of these descriptors, which has been selected using a database incorporating EEG recordings from thousands of patients undergoing anaesthesia with different anaesthetic regimens and clinical information relating to anaesthetic depth.

The BIS is a dimensionless number ranging from 0 to 100 that gives information on depth of anaesthesia. Using propofol, midazolam or isoflurane, 95% of patients are unconscious at a BIS of 50. However, caution must be used when choosing a single value as a threshold for non-responsiveness or awareness. Many questions remain concerning the effects of various classes of drugs (e.g. anticonvulsants, anxiolytics) or effects of temperature on the BIS. The BIS has not been validated for titrating sedation in the ICU, and its utility in patients with organic CNS disease is unknown.

Evoked potentials

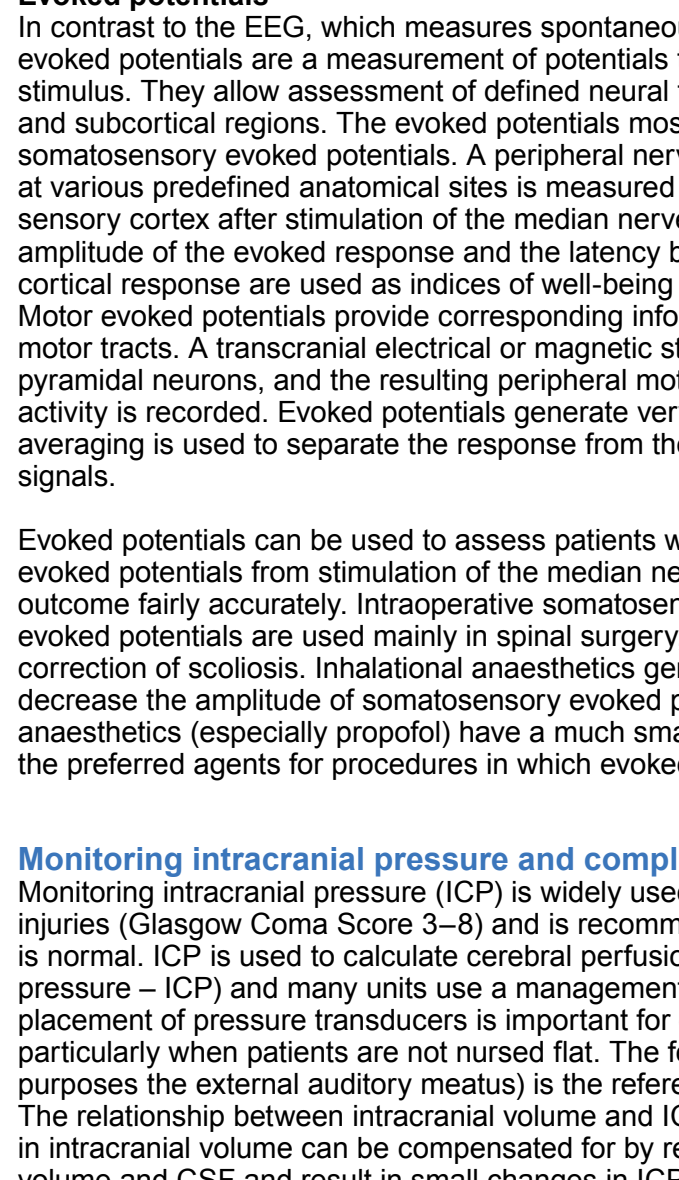
In contrast to the EEG, which measures spontaneous electrical activity of the cortex, evoked potentials are a measurement of potentials that are produced in response to a stimulus. They allow assessment of defined neural tracts including peripheral nerves and subcortical regions. The evoked potentials most often used in anaesthesia are somatosensory evoked potentials. A peripheral nerve is stimulated, and the response at various predefined anatomical sites is measured (e.g. Erb's point, cervical spine, sensory cortex after stimulation of the median nerve at the wrist). Typically, the amplitude of the evoked response and the latency between stimulus application and cortical response are used as indices of well-being of the monitored neural pathways. Motor evoked potentials provide corresponding information regarding the integrity of motor tracts. A transcranial electrical or magnetic stimulus is used to activate cortical pyramidal neurons, and the resulting peripheral motor nerve response or muscle activity is recorded. Evoked potentials generate very small signals (< 10 μV) and signal averaging is used to separate the response from the much stronger EEG and ECG signals.

Evoked potentials can be used to assess patients with head injury. Somatosensory evoked potentials from stimulation of the median nerve can predict unfavourable outcome fairly accurately. Intraoperative somatosensory evoked potentials and motor-evoked potentials are used mainly in spinal surgery, typically during procedures for correction of scoliosis. Inhalational anaesthetics generally increase the latency and decrease the amplitude of somatosensory evoked potentials. Opioids and intravenous anaesthetics (especially propofol) have a much smaller influence on the signals and are the preferred agents for procedures in which evoked potentials are monitored.

Monitoring intracranial pressure and compliance

Monitoring intracranial pressure (ICP) is widely used in patients with severe head injuries (Glasgow Coma Score 3–8) and is recommended even when the CT scan is normal. ICP is used to calculate cerebral perfusion pressure (CPP = mean arterial pressure – ICP) and many units use a management strategy based on CPP. The placement of pressure transducers is important for obtaining a correct value of CPP, particularly when patients are not nursed flat. The foramen of Monroe (or for clinical purposes the external auditory meatus) is the reference point for zeroing transducers. The relationship between intracranial volume and ICP is not linear. Initial increases in intracranial volume can be compensated for by reductions in intracranial blood volume and CSF and result in small changes in ICP, however, with rising ICP these mechanisms are exhausted and small increases in intracerebral volume lead to large rises in ICP (Figure 2a). This is illustrated by the fact that the amplitude of the ICP curve, which is brought about by the small increase in cerebral blood volume that every cardiac contraction causes, is normally in the range of a few mm Hg, but is much larger when the intracranial compliance is reduced. In the presence of reduced intracranial compliance, changes in cerebral blood volume caused by changes in CPP are reflected in ICP (Figure 2b).

Measurement of intracranial pressure (ICP)



a Intracranial pressure–volume relationship. Initially, increases in intracerebral volume can be compensated and small changes in ICP ensue (A), after exhaustion of these mechanisms (B) small changes in volume lead to a massive increase in ICP.
b Relationship between cerebral perfusion pressure (CPP), vasodilatation or vasoconstriction, cerebral blood volume (CBV) and ICP. This sequence of events is only observed when cerebrovascular pressure autoregulation is intact and intracranial compliance is reduced.

The gold standard in ICP monitoring is the direct measurement of intraventricular fluid pressure via a catheter inserted into one of the lateral ventricles. In addition to monitoring pressure, these catheters allow withdrawal of CSF to treat raised ICP, however, the infection rate is up to 10%. The best alternatives to the ventricular catheter are probes that use a miniature strain gauge pressure sensor mounted at the tip of a thin catheter (change of ICP results in a change in resistance) or a fibre-optic catheter (change of ICP results in a change of reflection of the light beam). These catheters are inserted into the brain parenchyma and have a low infection rate. Their main problem is a small drift of the zero line. It is important to realize that an intraparenchymal reading probe reflects a local value and that ICP is not necessarily uniform within the skull; significant pressure gradients may exist in patients with intracranial hypertension (e.g. supratentorial measurements do not necessarily reflect infratentorial pressure). When it is impossible to insert an ICP monitoring device (e.g. because of severe coagulopathy) it is possible to estimate CPP from a transcranial Doppler examination. Pressure measured in the lumbar CSF space is not a reliable estimate of ICP, and such measurements may be dangerous in patients with space-occupying lesions.

A recent development is the Spiegelberg Compliance Monitor. It uses an intraventricular catheter with an air-filled pouch at its tip. By repetitively injecting small volumes of air into this pouch and measuring the pressure response, the cranio-spinal compliance can be calculated. Whether this information improves the management of patients with head injuries is unknown.

Monitoring cerebral blood flow and metabolism

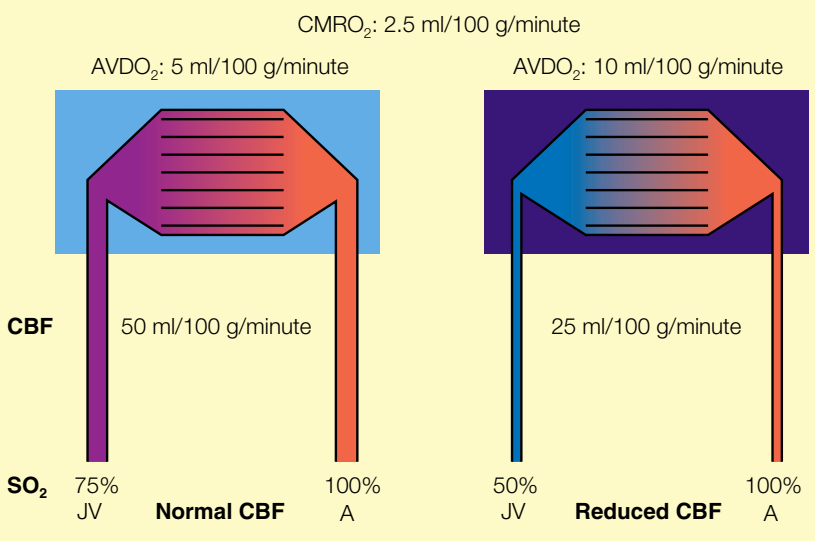
Inadequately low cerebral blood flow (CBF) significantly contributes to the occurrence of (secondary) brain insults. This suggests that monitoring CBF would detect and prevent such insults and thus improve treatment and outcome in neurosurgical patients. There is no ideal method of monitoring CBF; most methods produce non-quantitative measurements of physiological variables, which are assumed to be proportional to CBF. Many methods to measure CBF are available, but in most centres they are not routine procedures in patients with brain injuries. The most common approach is to assess the adequacy of CBF using jugular bulb oximetry.

Jugular bulb oximetry

Jugular bulb oximetry provides information about the adequacy of global CBF in relation to metabolic demands. A catheter is inserted into one of the internal jugular veins and advanced upwards into the jugular bulb where blood draining from the hemispheres can be sampled. All methods that rely on blood sampling from one of the jugular bulbs are prone to the influence of asymmetry of cerebral venous drainage. This may introduce an unquantifiable risk of acquiring misleading data and there is no consensus on which side should be cannulated. Generally, the right internal jugular vein is preferred because it is often the dominant vessel. The position of the catheter should be checked radiologically. A catheter tip at the level of the first or second cervical vertebral body lies above the point at which the jugular vein receives its first extracranial tributary (the common facial vein), and samples intracranial venous drainage. Blood can be sampled intermittently or a fibre-optic catheter can be used to determine jugular venous oxygen saturation (SjO_2) continuously. Intermittent sampling can give erroneous results because a certain amount of extracranial blood can be aspirated, especially if the sample is withdrawn too quickly. The fibre-optic technique needs regular recalibration of the sensor to deliver accurate readings and is susceptible to artefact because of suboptimal catheter position inside the vessel. Normal values for SjO_2 are thought to be 55–85%. Low CBF (ischaemia) raises oxygen extraction, increases the arterio-jugular oxygen content difference and leads to lower values for SjO_2, whereas hyperaemia leads to a decrease in arterio-jugular oxygen content difference and high values for SjO_2 (Figure 3). Some centres use SjO_2 to optimize hyperventilation in patients with head injuries, but it has not been demonstrated convincingly that this approach is superior to CPP oriented management, one reason being the low sensitivity of SjO_2 to detect ischaemia.

Use of jugular bulb oximetry

With a normal cerebral blood flow (CBF) of 50 ml/100 g/minute, an arterial (A) oxygen saturation (SO_2) of 100%, and a cerebral metabolic rate for oxygen ($CMRO_2$) of about 2.5 ml/100 g/minute, the extraction of oxygen by the brain results an arterio-venous difference in oxygen content ($AVDO_2$) of 5 ml/dl and a jugular venous (JV) saturation of 75%. In the face of a reduction in CBF (to 25 ml/100 g/minute as shown on the right), the only mechanism by which $CMRO_2$ can be maintained is by increased oxygen extraction, with an increase in $AVDO_2$ and a decrease in jugular bulb saturation. Jugular bulb saturations are therefore an indicator of the adequacy of CBF, with low values (< 50%) in ischaemia, and high values (> 85%) in hyperaemia



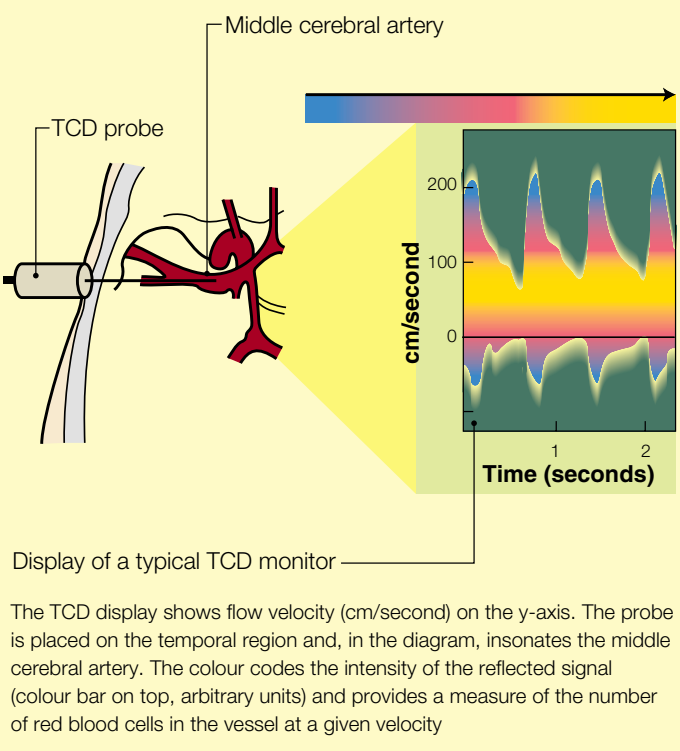
3

Recently, two techniques for quantitative determination of global CBF at the bedside using jugular bulb catheters have been proposed. One uses continuous jugular thermodilution the other a double-indicator (dye and iced water) method providing non-continuous measurements. The usefulness of both methods is currently being evaluated.

Transcranial Doppler (TCD) ultrasonography

TCD ultrasonography makes use of the fact that the temporal bone can be penetrated by ultrasound and uses the Doppler shift principle to measure blood flow velocity in the basal cerebral arteries (Figure 4). It is easy to use and non-invasive. However, the assumed linear relationship between flow velocity and CBF (CBF ~ FV x area of the insonated vessel x angle of insonation) is present only if the diameter of the insonated vessel does not change during the examination. This assumption is fulfilled for most clinical situations because changes in common physiological variables (e.g. blood pressure, partial pressure of carbon dioxide in arterial blood) do not change the diameter of the investigated vessels significantly. The main disadvantage of TCD is that although continuous measurements are possible they are prone to artefact. TCD is a valuable tool for rapid estimation of CBF and can differentiate vasospasm from hyperaemia, which influences the treatment of patients after subarachnoid haemorrhage or head injury. TCD can be used to assess cerebrovascular autoregulation and vasoreactivity to carbon dioxide, which can give prognostic information about patients with head injuries. Mean flow velocity (the time averaged mean of the signal) is mainly used for interpretation. Further pulsatility of the Doppler wave form is often reported and mainly graded by the (Gosling) pulsatility index, which is calculated as the signal amplitude divided by mean flow velocity. The pulsatility index is not a reliable estimator of cerebrovascular resistance and should be interpreted with caution because it is influenced by many uncontrollable variables (Figure 5).

Transcranial Doppler (TCD) ultrasonography



The TCD display shows flow velocity (cm/second) on the y-axis. The probe is placed on the temporal region and, in the diagram, insonates the middle cerebral artery. The colour codes the intensity of the reflected signal (colour bar on top, arbitrary units) and provides a measure of the number of red blood cells in the vessel at a given velocity

4

Interpretation of transcranial Doppler results

Diagnosis	FVm MCA	FVm ICA	MCA:ICA ratio	Pulsatility
Normal	60–70 cm/s	40–50 cm/s	1.76 ± 0.1	0.7 ± 0.1
Hyperaemia	↑	↑	→	↓
Vasospasm	↑	→	↑	↑↓
ICP↑	→	→	→	↑

FVm, mean flow velocity; ICP, intracranial pressure; MCA, middle cerebral artery. Normal values for FVm MCA are reported over a wide range and influenced by age, gender, haematocrit and metabolic factors. ICA, internal carotid artery. An MCA:ICA ratio (or Lindegaard ratio) > 3 in combination with FVm MCA > 120 cm/second indicates MCA spasm. This ratio has not been validated for vasospasm of the anterior or posterior cerebral artery.

5

Near infrared spectroscopy (NIRS)

NIRS measures changes in the chromophore levels of oxygenated and deoxygenated haemoglobin (i.e. 'cerebral haemoglobin saturation'). It is a non-invasive monitor that is placed on the forehead and allows estimation of relative changes in cerebral oxygenation and blood flow. The main limitation of NIRS is the inability to discriminate between extracranial and intracranial blood flow changes. NIRS is the most controversial method for monitoring the brain. This is reflected in the conflicting results correlating NIRS measurements with other modalities to monitor CBF and cerebral oxygenation.

Thermal diffusion and laser Doppler flowmetry

Measuring microcirculatory blood flow to estimate CBF is an alternative to monitoring CBF. The thermal diffusion probe is inserted through a burr hole and placed on a cortical region of interest. The probe consists of two small metal plates, one of which is heated. Blood flow is calculated from the temperature difference between the plates. Recently an intraparenchymal thermal diffusion probe has been evaluated. Its values of CBF are in good agreement with values obtained by stable xenon CT for a volume of about 5 cm^3 around the probe. Laser Doppler flowmetry allows continuous real-time measurements of local microcirculatory blood flow. However, the sample volume is small (1–2 mm^3) and only relative changes in flow can be assessed.

Partial pressure of oxygen (pO_2) in brain tissue

Recently, intraparenchymal catheters that measure tissue pO_2 and in the case of the *Neurotrend*™ monitor pCO_2, pH and temperature have been introduced. Two methods of measurement are available, one uses a miniature Clark-type electrode, the other uses fibre-optic technology. Normal brain tissue pO_2 is in the range 3.5–4.0 kPa. The role of brain tissue pO_2 monitoring has yet to be defined.

Microdialysis

Microdialysis samples extracellular brain fluid. It is based on the transfer of molecules (5–20 kD) over a semipermeable membrane. A thin catheter lined with a dialysis membrane is placed in the brain parenchyma and perfused continuously at a slow rate (0.3–2.0 μl/minute) with a physiological solution. The concentration of glucose, lactate, glutamate, aspartate and other neurotransmitters, drugs and cytokines can be determined in the dialysate. Studies to determine the value of cerebral microdialysis in clinical decision-making are under way.

Multimodality monitoring

Secondary ischaemic insults can be short-lived and may be missed because of limited temporal and spatial resolution as well as the limited sensitivity of monitoring devices. This led to the concept of multimodality monitoring. The combination of several monitors can improve understanding of the continuing pathophysiology and also increases the likelihood of detecting relevant insults (Figure 6). ◆

Multimodality monitoring in a patient with head injury

Values for intracranial pressure (ICP), cerebral perfusion pressure (CPP), jugular bulb oximetry (jugular venous oxygen saturation, SjO_2) and transcranial Doppler (TCD) are integrated. Repetitive waves of raised ICP lead to changes in the recorded parameters, however, insults are not always detected by all modalities. FV, flow velocity (Courtesy of Dr M Czosnyka, Academic Neurosurgery, Addenbrooke's Hospital, Cambridge, UK).

Neuromuscular Disorders: Relevance to Anaesthesia and Intensive Care

Jonathan G Hudsmith
David K Menon

Jonathan G Hudsmith is Specialist Registrar at Addenbrooke's Hospital, Cambridge, UK. He qualified from Southampton University, and trained in anaesthesia in Canterbury and Lewisham. His interests include postgraduate anaesthetic teaching, undergraduate teaching and obstetric anaesthesia.

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India; Leeds General Infirmary, The Royal Free Hospital and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Guillain-Barré syndrome

Guillain-Barré syndrome is an acute inflammatory poly-neuropathy characterized by a progressive neuropathic weakness and areflexia. The incidence is 1–2/100,000 and affects all age groups. Up to 75% of patients have preceding infection, usually of the upper respiratory tract or gastrointestinal tract. Various bacterial and viral organisms have been implicated, including *Campylobacter jejuni* and *Mycoplasma pneumoniae*.

The mechanism of the disease is unclear, but the association with preceding infection suggests an immune mechanism for the demyelination of peripheral nerves. The presence of circulating antibodies against neural gangliosides supports this view. It is possible that the immune response to the infection generates self-reactive antibodies that mediate the inflammatory demyelination.

Diagnosis

Guillain-Barré syndrome is diagnosed by the presence of:

- progressive weakness of more than one limb (due to neuropathy)
- areflexia
- duration of progression of less than 4 weeks.

Laboratory features include an increase in CSF protein (in 90%) a normal white cell count (in 90%), and an electromyograph suggestive of demyelination and axonal damage. Other supportive diagnostic criteria are presented in the clinical features below. Figure 1 lists the differential diagnoses.

Differential diagnosis of Guillain-Barré syndrome

- Acute myasthenia gravis
- Diabetes mellitus
- Poliomyelitis
- Botulism
- Acute intermittent porphyria
- Polymyositis
- Lead poisoning
- Organophosphate poisoning
- Shellfish poisoning
- Transverse myelitis

1

Clinical features

Guillain-Barré syndrome can present with symmetrical weakness, pain and sensory impairment. The weakness commonly ascends from the legs, with 90% of patients affected maximally at 3–4 weeks. Proximal limb weakness is usually the earliest motor sign. Paraesthesia occurs in 50% of patients, and is often in a 'glove and stocking' distribution. Neuropathic pain (which may be severe) commonly occurs in the back, sides and between the scapulae. The Miller-Fisher syndrome is an atypical variant of the condition characterized by a classical triad of areflexia, ataxia and ophthalmoplegia. About one-third of patients have respiratory muscle weakness requiring positive pressure ventilation. Bulbar weakness often occurs in association with respiratory muscle weakness and predisposes to pulmonary aspiration, which necessitates adequate airway protection.

Autonomic dysfunction occurs in 65% of patients. Sinus tachycardia is the most common manifestation and requires treatment only if severe. Vagal stimulation may precipitate dangerous bradyarrhythmias. Other autonomic features include urinary retention, postural hypotension, sweating and ileus.

Management

The management of patients in ICU involves supportive therapy and specific treatments. Vigilant nursing is essential. Careful, regular turning prevents pressure sores. Passive physiotherapy (and use of limb splints) reduces the risk of tendon contractures. Patients often require long-term ventilation. Tracheostomy should be performed early if prolonged ventilation is likely.

Deep vein thrombosis prophylaxis is mandatory, because thromboembolic complications remain a major cause of morbidity and mortality. All patients should receive prophylactic subcutaneous low molecular weight heparin, and wear thromboembolic disease prevention stockings. Adequate nutritional support can be provided via enteral feeding. If ileus is severe and unresponsive to prokinetic agents such as metoclopramide, parenteral nutrition may be required. Autonomic disturbances such as persistent tachycardia and hypertension should be treated appropriately, usually with β-blockers. Temporary or permanent cardiac pacing may occasionally be indicated for severe episodes of bradycardia. Infection, particularly of the respiratory tract is common, and should be treated promptly and effectively.

Pain is common, and can be particularly distressing at night. Despite sometimes being responsive to simple analgesics, stronger pain relief is often indicated. The constipating effects of opioids should be avoided if possible. Neuropathic pain can be relieved by carbamazepine or amitriptyline.

Specific therapy includes two immunomodulatory interventions: plasma exchange and intravenous immunoglobulin. Plasma exchange is most beneficial if given within 2 weeks of diagnosis and instituted before positive pressure ventilation is required. Typically 200–250 ml/kg of the patient's plasma is exchanged with 4.5% human albumin solution. This exchange is repeated up to five times.

Intravenous immunoglobulin (IvIg) is easier to administer than plasma exchange but is expensive. Patients with autonomic dysfunction or cardiovascular disease may tolerate IvIg better, but it also has adverse effects. Anaphylaxis, aseptic meningitis and renal failure have been reported, and the risks of transfusing a blood product are also present. A recent study has suggested that the combination of IvIg and methylprednisolone may be more effective than IvIg alone. However, despite the clear therapeutic benefit of immunotherapies on reducing length of hospital stay and residual disability, there appears to be no reduction in mortality rate compared with that of untreated patients. Typical mortality for patients with Guillain-Barré syndrome is 5%, and 25% are left with a degree of disability 1 year after the onset of symptoms.

Myasthenia gravis

Myasthenia gravis is a rare disease of the neuromuscular junction, with an incidence of 1/20,000. It is an autoimmune disease characterized by fatiguable muscle weakness resulting from failure of neuromuscular transmission. This is a result of production of IgG antibodies to the postsynaptic membrane (anti-acetylcholine receptor antibodies), which reduce receptor density at the neuromuscular junction. It may be congenital or acquired later in life. It is more common in females, and has a peak incidence in the third decade of life. 3–4% of patients with myasthenia gravis have other autoimmune disease (e.g. thyrotoxicosis, pernicious anaemia, rheumatoid arthritis, systemic lupus erythematosus). Myasthenia gravis is characterized by fluctuating weakness of the muscles of the head, face and neck. Classic presentation is with diplopia and ptosis due to weakness of the ocular muscles. Bulbar weakness may present as dysarthria and dysphagia. Moderate proximal muscle weakness may occur, as may respiratory muscle weakness, especially during exacerbations. Weakness increases with exercise and improves with rest.

Diagnosis is from the history and confirmed by a high titre of receptor antibodies on immunoassay. Diagnosis can also be confirmed clinically by a positive 'Tensilon' (an anticholinesterase) test. Edrophonium (Tensilon) is administered and improved muscle function is observed when compared with administration of placebo. Electromyography studies show decreased amplitude following a single twitch, fade on tetanic stimulation and post-tetanic facilitation.

Management: patients may present to the ICU during a myasthenic crisis, often precipitated by infection, or as a consequence of over-treatment with anticholinesterases, causing a cholinergic crisis. Treatment for myasthenia gravis includes anticholinesterases (pyridostigmine), immunosuppression (corticosteroids, azathioprine, cyclosporin (ciclosporin)), removal of antibodies (plasma exchange) or thymectomy. Thymectomy is indicated in patients with a thymoma, younger patients (< 50 years), and women of child-bearing age (in whom immunosuppressants may be inappropriate).

Anaesthetic considerations

Preoperatively, the ability to swallow should be assessed. Respiratory function should be optimal before surgery, and adequacy of ventilation checked with an arterial blood sample. Plasma exchange may be necessary. A chest radiograph may reveal signs of aspiration, a thymoma with upper mediastinal widening or an anterior mass (lateral film). Anticholinesterase therapy should be reduced by 20% preoperatively, and withdrawn on the day of surgery. Patients are better slightly myasthenic than cholinergic.

Patients with myasthenia gravis are relatively resistant to small doses of suxamethonium, and tend to get a dual (phase II) block with high doses. Conversely, they are extremely sensitive to non-depolarizing neuromuscular blocking drugs, and these should be avoided if possible. Drugs such as atracurium should be administered at one-tenth the normal dose. Spontaneous return of neuromuscular function should be allowed, to avoid clinical confusion caused by the administration of anticholinesterase agents. It is also essential not to exacerbate muscle weakness by avoiding hypokalaemia, aminoglycosides, quinine and ciprofloxacin.

Regional anaesthesia should be used if possible to avoid the use of neuromuscular blocking drugs. Additionally, intubation may also be achieved via deep inhalational anaesthesia and local anaesthetic spray to the vocal cords.

During anaesthesia for thymectomy, it is essential to place intravenous access in a lower limb vein, because there is a risk of damage to the superior vena cava during surgery.

Postoperatively, patients may require ventilation. Anticholinesterases should be restarted, but the initial dose required may be less than the preoperative dose.

Lambert–Eaton myasthenic syndrome

Lambert–Eaton myasthenic syndrome is characterized by severe muscle weakness. It occurs in 1% of patients with bronchial carcinoma. It is also associated with thyroid disease and connective tissue disease, and is mediated by decreased release of acetylcholine from the presynaptic membrane. It can be distinguished from myasthenia gravis because:

- it causes proximal rather than bulbar/ocular weakness
- muscle power increases with exercise
- tendon reflexes are diminished
- there is no fade on tetanic stimulation
- tetanic stimulation increases muscle strength
- the Tensilon test is negative
- muscle pains are common.

Treatment is by removal of the bronchial tumour, or admin-istration of 3,4-diaminopyridine. Patients are sensitive to both depolarizing and non-depolarizing neuromuscular blocking drugs.

Myotonic syndromes

Myotonic syndromes are a group of hereditary diseases characterized by delayed muscle relaxation following contraction. Myotonic dystrophy is the most common, with an incidence of 1/25,000. Inheritance is autosomal dominant with anticipation (increasing severity in successive generations). Males and females are equally affected. Patients typically present between 20 and 40 years with a reduced life expectancy. A characteristic facies is present, with frontal balding, an expressionless face, smooth forehead, ptosis, presenile cataracts and a lateral (or inverted) smile. Masseter and sternocleidomastoid muscle wasting occurs, and bulbar weakness can predispose to aspiration and chest infections. Once muscle wasting develops, tone and reflexes are reduced and foot drop is common. Myotonia is secondary to abnormal closure of sodium/chloride channels following depolarization, leading to repetitive discharge and contraction. It is precipitated by:

- cold
- exercise
- shivering
- pregnancy
- hyperkalaemia
- suxamethonium
- neostigmine.

Associations include a low IQ, gonadal atrophy, diabetes mellitus, dysphagia, constipation, delayed gastric emptying, respiratory muscle failure, obstructive sleep apnoea and thyroid adenoma. Cardiac involvement includes conduction defects, valve defects and cardiomyopathy. There is a progressive worsening of cardiac conduction, with an increasing risk of tachyarrhythmia and sudden death.

Anaesthetic considerations
Cardiorespiratory function must be thoroughly investigated preoperatively, because cardiac pacing may be necessary. Invasive cardiac monitoring may be indicated. Monitoring of body temperature and neuromuscular blockade is essential. Patients are sensitive to all depressant drugs, therefore sedative premedication is avoided. There is also increased sensitivity to induction agents, opioids and non-depolarizing neuromuscular blocking drugs. Suxamethonium may produce a generalized myotonic response rendering laryngoscopy, tracheal intubation and ventilation difficult or impossible. This may not be reduced by subsequent administration of non-depolarizing neuromuscular blocking drugs. If neuromuscular blockade is required, atracurium is the agent of choice, with spontaneous reversal (because neostigmine may precipitate myotonia). Myotonic contraction may also occur with surgical diathermy. Regional anaesthesia can be useful, although the myotonic reflex is not blocked.

Admission to intensive care may be required if there is cardiovascular instability, or if the patient is slow to regain consciousness or adequate neuromuscular function. Swallowing and gastric emptying are often impaired, therefore asymptomatic aspiration is common, necessitating a delay in feeding postoperatively.

Myotonia congenita
Myotonia congenita is less prevalent than myotonic dystrophy, with little systemic involvement and a normal life expectancy. There is generalized muscular hypertrophy and stiffness on initiating movement, which is relieved by exercise. There is no muscle weakness, although the myotonia may be severe. Anaesthetic problems are the same as for myotonic dystrophy, although there is an important association with malignant hyperthermia.

Muscular dystrophies
Muscular dystrophies are a hereditary group of conditions of unknown aetiology, characterized by atrophy of some muscle groups and pseudohypertrophy of others. The most common is Duchenne muscular dystrophy (transmitted as an X-linked recessive condition, occurring in 1/3500 live male births). Symmetrical weakness of the proximal and pelvic muscles is evident from 2 years of age, which progressively worsens, with patients becoming wheelchair bound due to contractures and scoliosis. Cardiorespiratory problems and mental retardation are common. Serum creatine kinase is often elevated from birth and can be 30–300 times the normal value. Death usually occurs before 30 years of age as a result of cardiorespiratory failure.

Anaesthetic considerations
Preoperatively, assessment of cardiorespiratory function by exertion is problematic because effort is limited by the muscular disease and most patients are extremely immobile. Echocardiography is essential and often reveals chamber hypertrophy and mitral valve prolapse (25%). If respiratory function is severely compromised (vital capacity < 20 ml/kg), the risk of death is high. During the perioperative period, physiotherapy is essential and antibiotics are often indicated. There is an increased risk of malignant hyperthermia in these patients, and suitable precautions, including the availability of dantrolene, are recommended. Suxamethonium is additionally contraindicated because of the risks of hyperkalaemia and cardiac arrest. Volatile anaesthetic agents and suxamethonium have both been implicated in precipitating rhabdomyolysis and cardiac arrest. Intravenous anaesthetic agents and opioids appear to be safe. Patients are sensitive to non-depolarizing neuromuscular blocking drugs and they should be used incrementally with appropriate monitoring. There is still a risk of delayed recovery associated with skeletal muscle weakness. Regional anaesthesia should be used if possible, avoiding many of the above complications and providing good postoperative analgesia. High dependency postoperative care is essential, with aggressive physiotherapy and clearance of secretions. Despite all the above precautions, cardiac arrest resistant to resuscitation may occur.

Neuromuscular complications of intensive care
Muscle weakness in critically ill patients is not a result of inactivity, as previously thought, but caused by neuromuscular disorders arising during the ICU stay. It usually presents as a failure to wean patients from the ventilator. Three causes are recognized:
- critical illness polyneuropathy
- prolonged neuromuscular blockade
- necrotizing myopathy.

Motor neuron disease
Motor neuron disease is a group of disorders characterized by a progressive degeneration in motor function, while sensory and higher function remain normal. Males are affected more commonly than females. The diagnosis is made clinically and using EMG studies. No treatment is of any proven benefit. Patients typically present with weakness and wasting of muscle groups with fasciculation. The disease affects smooth, striated and cardiac muscle. Death occurs within 3–5 years of diagnosis.

Anaesthetic problems relate to the increased sensitivity to intravenous induction agents and both depolarizing and non-depolarizing neuromuscular blocking agents. Respiratory muscle involvement is commonplace and must be managed appropriately in the perioperative period. If the brainstem is involved, there is a significant risk of aspiration due to bulbar weakness. ◆

Neurovascular Anaesthesia and the Management of Ischaemic Stroke

Jonathan G Hudsmith
David K Menon

Jonathan G Hudsmith is Specialist Registrar at Addenbrooke's Hospital, Cambridge, UK. He qualified from Southampton University, and trained in anaesthesia in Canterbury and Lewisham. His interests include postgraduate anaesthetic teaching, undergraduate teaching and obstetric anaesthesia.

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. He trained at the Jawaharlal Institute, India; Leeds General Infirmary, the Royal Free Hospital and Addenbrooke's Hospital. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Neurovascular anaesthesia covers the preoperative resuscitation and optimization, intraoperative management and postoperative neurointensive care of patients with intracranial vascular lesions. This article deals mainly with subarachnoid haemorrhage (SAH) and arteriovenous malformations (AVM) and briefly describes the management of ischaemic stroke.

Regardless of the cause of intracranial haemorrhage, many pathological mechanisms operate to precipitate cerebral ischaemia. Management of intracranial haemorrhage centres around adequate neuroprotection, via maintenance of adequate cerebral blood flow (CBF) and prevention of secondary cerebral ischaemia.

Subarachnoid haemorrhage (SAH)

Cerebral aneurysms account for 75–80% of SAH, cerebral AVM for 4–5%, and in the remaining 15–20%, no source of haemorrhage can be found.

Cerebral aneurysms

Aneurysms arise from vessels of the circle of Willis, usually at a bifurcation. They occur in 2–5% of the population, and are three times more common in women than in men. 90% of aneurysms involve the anterior circulation and 10% the posterior circulation. 20% of patients have multiple aneurysms. SAH accounts for 10% of cerebrovascular disease and has an annual incidence of 15/100,000. It can occur at any age, with a peak incidence between 55 and 60 years of age. Aneurysm formation is more likely in those with hypertension, some genetic and collagen abnormalities and in those who smoke or are pregnant.

Risk of rupture is 0.05–6%. Rupture is often, but not always, related to hypertensive episodes. One-third of patients die before reaching hospital, one-third have a poor outcome and one-third are functional survivors. The main risks facing patients who reach hospital include recurrent haemorrhage, development of delayed ischaemic neurological deficits (vasospasm) and hydrocephalus. For those who survive the initial haemorrhage, the peak risk of re-bleed occurs in the first 48 hours. On the first day of SAH, there is a 4% risk of re-bleeding, which decreases to 1.5% by the third day. By day 14, the cumulative re-bleeding incidence is 19%. Six months after SAH, 50% of patients have re-bled, and the long-term risk stabilizes at 3% per year.

Presentation of SAH

Headache is the presenting symptom in 85–95% of patients. Classically, it is severe and of sudden onset. Other symptoms include loss of consciousness, photophobia, nausea, vomiting, lethargy and neurological deficits. Signs of meningism are also common. Bleeding increases intracranial pressure (ICP), leading to a reduced cerebral perfusion pressure (CPP). A sudden rise in ICP prevents continuing bleeding from the aneurysm site. If ICP subsequently decreases, CBF recovers, allowing function to improve. Non-survivors show no recovery of CBF.

Grading SAH

The severity of SAH is assessed and graded according to the Hunt and Hess classification (Figure 1), or the World Federation of Neurological Surgeons (WFNS) SAH Scale (Figure 2), which uses the Glasgow Coma Scale (GCS). A higher WFNS grade results in worse outcome as a result of increased initial damage, an increased risk of developing intracranial hypertension, reduced CBF autoregulation (Figure 3) and reduced carbon dioxide vasoreactivity (Figure 4). These physiological abnormalities expose the injured brain to ischaemic insults and reduce its ability to cope with them.

Management

Hunt and Hess classification of intracranial aneurysms

Category	Criteria
0	Unruptured aneurysm
I	Asymptomatic or minimal headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity ± cranial nerve palsy
III	Drowsiness, confusion or mild focal deficit
IV	Stupor, moderate-to-severe hemiparesis, possibly early decerebrate rigidity and vegetative disturbances
V	Deep coma, decerebrate rigidity, moribund appearance

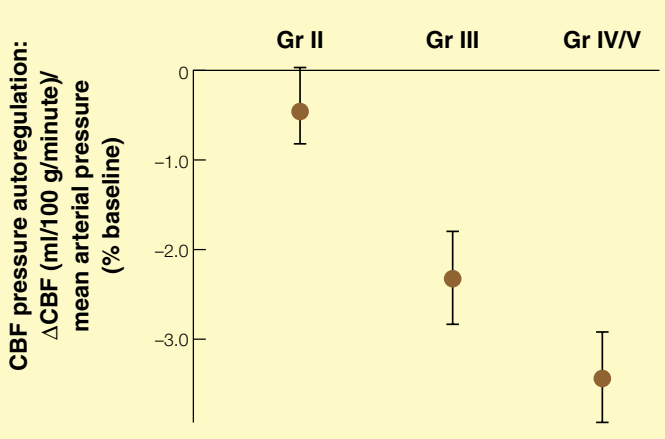
1

World Federation of Neurological Surgeons (WFNS) SAH Scale

WFNS grade	GCS score	Motor deficit
I	15	Absent
II	13–14	Absent
III	13–14	Present
IV	7–12	Present or absent
V	3–6	Present or absent

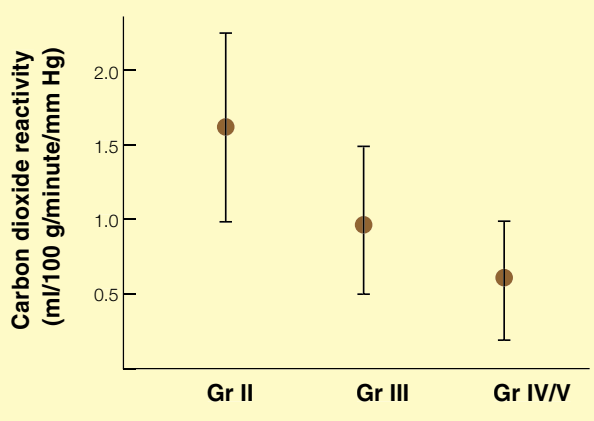
2

Change in cerebral blood flow (CBF) pressure autoregulation with grade of subarachnoid haemorrhage



3

Change in carbon dioxide reactivity with grade of subarachnoid haemorrhage



4

Conservative non-surgical management of SAH is associated with a higher mortality than surgical management (40% versus < 10%). Reasons include reduction in the risk of re-bleeding, removal of the blood clot, irrigation and toilet of the operative site, and improved acute functional outcomes, which improve long-term survival.

Timing of surgery: surgery can be early (1–3 days post SAH) or late (10–14 days post SAH). Early surgery, soon after aneurysm rupture, reduces the risk of re-bleeding (and subsequent morbidity and mortality). Early surgery is technically more difficult because of oedema and inflammation. However, because the risk of vasospasm relates to the presence and extent of cisternal blood, some studies suggest that early removal of clot may reduce the risk of developing a delayed ischaemic deficit. Surgery typically involves ablation of the aneurysm with specialized clips (clipping). In some cases, operative access may make this impossible, and the aneurysm is wrapped in muslin to induce fibrosis (wrapping). While this does not ablate the aneurysm immediately it does secure it over time. Increasingly, interventional neuroradiology is being used as an alternative to surgery, usually by placing thrombogenic coils in the aneurysm (coiling). Early clipping or coiling facilitates the medical and neuroradiological treatment of vasospasm.

Cardiovascular dysfunction: ECG changes following SAH are common, and occur more often in those with severe neurological impairment. The degree of myocardial dysfunction does not correlate with the SAH-induced ECG changes, however, the greatest degree of myocardial dysfunction occurs in patients with worse WFNS grades. Pathological Q waves can develop after an SAH, and can be misinterpreted as evidence of a recent myocardial infarction. Diffuse myocardial ischaemia occurs in 50% of patients, with widespread ST segment and T wave changes. Mechanisms for this cardiovascular dysfunction include catecholamine release triggered by SAH, direct trauma to cerebral autonomic control centres, and a hypothalamic neurogenic mechanism. It is difficult to differentiate between SAH-associated ECG changes and actual myocardial ischaemia. Most patients with ECG changes have acceptable perioperative cardiovascular risk, but further investigation (with echo-cardiography) may be needed in some patients, and delayed surgery may be justified in patients with major left ventricular dysfunction, or in those with new Q waves or bundle branch block, who are at high risk of malignant dysrhythmias.

Blood pressure commonly rises after SAH, and is often a normal compensatory response to maintain CPP, in response to a rising ICP. Hypertension in this setting should only be treated if it is severe. Systolic pressures above 160 mm Hg may increase the risk of re-bleeding and rupture, and antihypertensive treatment may be indicated, preferably using drugs that do not produce cerebral vasodilatation (e.g. labetalol). It is also important to avoid hypotension, and the pressure at which neurological deterioration occurs should be recorded so it can be used to guide blood pressure goals intraoperatively.

Volume status and electrolyte imbalance: hypovolaemia and intravascular volume depletion are common and fluid resuscitation is essential. Volume depletion may be the result of poor intake, autonomic hyperactivity, bed-rest or increased urinary volume loss. Inappropriate diuresis may be the consequence of diuretics, diabetes insipidus or the syndrome of cerebral salt wasting, which result in increased urinary losses of sodium ions and water. Hyponatraemia occurs in up to 40% of patients and, when severe, is associated with an impaired level of consciousness, cerebral oedema and vasospasm. This may be due to cerebral salt wasting, inappropriate secretion of antidiuretic hormone or administration of hypotonic maintenance fluids. Invasive monitoring may be required to guide fluid management. Normoglycaemia should be maintained, to prevent the poor outcome associated with hyperglycaemia after brain injury.

Anaesthetic management

Premedication: the use of sedative premedication is controversial and probably best avoided. Grade III–V patients seldom require premedication, and it is best reserved for particularly anxious grade I–II patients. Antacid prophylaxis is mandatory for those at risk of aspiration.

Monitoring should include ECG, pulse oximetry, end-tidal capnography, urinary output and temperature. Invasive arterial blood pressure measurement should be established before induction, allowing accurate observation of blood pressure as well as allowing sampling for blood gas and haemoglobin measurements. Central venous catheters are inserted after induction, to guide fluid management when using diuretics and mannitol. Pulmonary arterial pressure monitoring should be used if impaired myocardial function is present. Such monitoring is also useful in elderly patients, and those with poor grade SAH, because hypertensive, hypervolaemic and haemodilutional therapy is often used in these patients. More specialized intraoperative monitoring may include jugular bulb oximetry, transcranial Doppler, electroencephalography (EEG), intraparenchymal probes and cerebral function monitors.

Induction of anaesthesia involves titration of the depth of anaesthesia and the blood pressure to match surgical need. The ICP must be controlled and cerebral metabolic demands minimized to prevent cerebral ischaemia and provide good operating conditions. Aneurysmal rupture is related to transmural pressure across the wall of the aneurysm. Abrupt increases in arterial pressure or sudden decreases in ICP may cause a re-bleed. Aggressive hyperventilation and hypocapnia can also predispose to rupture. The incidence of rupture at induction is 1–2%, and is associated with high mortality and postoperative morbidity. Rupture should be suspected when a sustained rise in blood pressure occurs on, or shortly after, induction or intubation. Intubation is ideally preceded by a short trial of laryngoscopy with careful monitoring of blood pressure; a significant hypertensive response should trigger administration of a supplemental dose of induction agent before intubation is attempted. Supplemental doses of induction agent or high dose opiates may also be required to avoid the pressor responses associated with the placement of surgical pins. If an aneurysm re-bleeds at induction, surgery should be deferred to allow detailed assessment of the patient. Management of intraoperative rupture is discussed below.

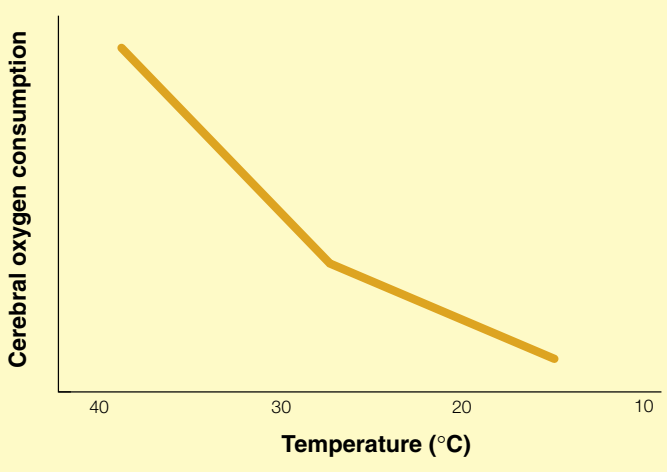
Maintenance: the ideal technique produces a ‘slack’ brain (to minimize retraction pressure), while ensuring maximal cerebral protection by keeping cerebral metabolic requirements to a minimum. No evidence favours one particular technique. Total intravenous anaesthesia, using propofol and an opioid (e.g. remifentanil), is increasingly used for maintenance of anaesthesia during aneurysm surgery. Propofol allows rapid adjustment of anaesthetic depth and has better recovery characteristics than other agents.

Brain relaxation: several methods are used to reduce the brain bulk, CSF volume and cerebral blood volume (CBV), including a 15–30° head-up tilt, mild hypocarbia, mannitol and furosemide (frusemide). A head-up tilt facilitates venous return and reduces ICP. Mild hypocarbia (about 4.5 kPa) can be used, however the potential ischaemic effects of hyperventilation must be balanced against the benefits of reducing CBV. Hyperventilation is a quick method of reducing CBV, but its application is best guided by a monitor of the adequacy of cerebral oxygenation, such as a jugular bulb saturation (SjO_2) monitor. Hyperventilation should be titrated to keep the SjO_2 above 55%.

Mannitol is an osmotic diuretic administered as a 20% solution at a dose of 0.5–1.0 g/kg. Brain bulk is reduced by osmotic dehydration and a transient increase occurs in intravascular volume and CBF. CBV is reduced as a consequence of these changes, and by improved rheology of red blood cells, and CSF production is reduced. These effects result in a decrease in ICP, which peaks at 45–60 minutes. Furosemide (frusemide) is often used in conjunction with mannitol or alone in patients whose cardiovascular system may be compromised by mannitol. Bolus administration of propofol, thiopental (thiopentone) or lidocaine (lignocaine) also reduces CBV by reducing cerebral metabolism and thus CBF.

Hypothermia: most drugs reduce only the active component of cerebral metabolism. However, hypothermia reduces the active and basal components, which increases the time of ischaemia tolerated. Cerebral metabolism is 15% of normal at 20°C (Figure 5). Other mechanisms (e.g. suppression of cytokine, free radical and glutamate release) are thought to contribute to the neuroprotection offered by hypothermia in addition to the reduction in cerebral metabolism. Prophylactic hypothermia during aneurysm clipping is the focus of a multicentre Phase III trial (Intraoperative Hypothermia during Aneurysm Surgery Trial 2; IHAST 2). Deep hypothermia is not without risks. Problems include the accuracy of temperature measurement, optimal temperature used, method of rewarming, delayed awakening, postoperative shivering, coagulation disorders and aggravation of cardiovascular disease.

Relationship between temperature and cerebral oxygen consumption



5

Temporary clipping/induced hypotension: intraoperative rupture of an aneurysm is an emergency. Management should include administration of 100% oxygen and prompt volume replacement, with blood if necessary. Other measures that may be used include the application of temporary vascular clips on the feeding artery, controlled hypotension, anaesthetic neuroprotection (usually with barbiturates) or the prophylactic use of hypothermia in high-risk cases.

Temporary clips applied to the feeding vessel are used to reduce the risks of intraoperative rupture, or the risk of bleeding from a ruptured aneurysm. This results in focal ischaemia in the vessel territory, which may be worsened by systemic hypotension. Brisk haemorrhage from a ruptured aneurysm may obscure the surgical field and make clipping of the aneurysm or application of a temporary clip impossible. Under these circumstances, the induction of systemic hypotension using potent anaesthetic agents, short-acting vasodilators or β-blockers may allow visualization of the surgical field and stop haemorrhage. The minimum mean arterial pressure required to prevent ischaemia is unknown. Temporary clipping is becoming more popular and induced hypotension is practised less. This distinction is crucial, because induced hypertension during temporary clipping may permit improved collateral flow and reduce the risk of infarction. The risk of infarction is high if clipping is prolonged beyond 15 minutes. Bolus doses of intravenous anaesthetic agents or the application of hypothermia may be neuroprotective in this setting, but strong evidence is lacking. While many intravenous agents are used in this setting, what little evidence there is supports the use of barbiturates (typically thiopental (thiopentone), 250–1000 mg), which may be effective even when administered after the application of the temporary clip.

Recovery: a rapid return to consciousness allows early neurological assessment. It is important to normalize mean arterial pressure and the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) before closure, to reveal any bleeding points and ensure that intraoperative brain swelling does not increase the likelihood of intracranial hypertension in a normocapnic patient. Obvious brain swelling may prompt a decision to leave the bone flap out, institute ICP monitoring, and/or opt for a period of postoperative sedation and ventilatory support. Assuming a smooth intraoperative course, grade I–II patients are extubated. Grade III–V patients often require a period of postoperative ventilation, unless their preoperative conscious level permits more rapid recovery. Blood pressure must be closely monitored in recovery. Hypertension is often seen as a response to restore CPP and CBF. Uncontrolled hypertension in the immediate postoperative period can precipitate intracerebral haemorrhage and/or vasogenic oedema. Boluses of short-acting opioids, propofol or lidocaine (lignocaine) can facilitate blood pressure control at extubation. More prolonged hypertension, despite adequate analgesia, needs prompt treatment with nifedipine, labetalol or esmolol.

Failure to recover to an expected GCS level is usually related to anaesthetic factors, though this must not be assumed to be the case. Factors that need to be considered include:

- partial neuromuscular blockade
- residual opioid and sedative drugs
- hypoxia and hypercarbia
- metabolic factors (e.g. hyponatraemia)
- postictal state
- brain swelling
- hydrocephalus
- postoperative haemorrhage
- ischaemia (surgical/vasospasm).

The time-course of recovery or deterioration may suggest surgical causes of poor recovery. Once drug-related effects have been excluded and/or treated, a CT scan is performed to exclude hydrocephalus, cerebral oedema, intracranial haemorrhage, haematoma or a re-bleed. A negative CT may prompt a cerebral angiogram to exclude vascular occlusion or vasospasm.

Management of delayed ischaemic neurological damage

Delayed ischaemic neurological damage classically presents as a focal deficit in the second week after SAH, and has been attributed to reductions in large vessel calibre (vasospasm). However, the presentation and presumed cause may be different. Reductions in large vessel calibre may be observed at presentation and deficits may persist into the fourth week post-bleed. There is also increasing evidence that while large vessel vasospasm may contribute to ischaemic deficit, microcirculatory and autoregulatory abnormalities are also important.

The differential diagnosis includes aneurysmal re-bleed, postoperative haemorrhage, retraction injury (which follows long periods of intraoperative brain retraction), epilepsy with postictal Todd’s paralysis, hydrocephalus and electrolyte abnormalities. The history, radiographs, CT and routine biochemistry help to exclude these diagnoses and an EEG is occasionally required to exclude non-convulsive seizures. A clear history of deficit modulated by blood pressure alterations strongly supports a diagnosis of delayed ischaemic neurological damage.

Confirmation of the diagnosis requires angiography, but strong supportive evidence is provided by transcranial Doppler ultrasound, with perfusion imaging that demonstrates reductions in regional CBF. Patients with significant deficits that constitute a neurological emergency must be treated within hours. Prompt and effective therapy can reverse ischaemia and substantially improve outcome. Management includes the following three therapies.

Prophylactic therapy with calcium channel blockers – nimodipine therapy over the first 3 weeks after aneurysmal SAH has been shown significantly to reduce incidence of vasospasm and improve outcome. Both enteral, and more commonly, intravenous nimodipine may result in significant hypotension requiring haemodynamic support.

Triple H’ therapy includes the induction of controlled **h**ypervolaemia (with monitoring of CVP or PA pressures), **h**aemodilution (to a haematocrit of 30–33%, ostensibly to improve flow characteristics through the narrowed vessel) and **h**ypertension to improve flow through narrowed arteries. Mean arterial pressure tends to be maintained below 110 mm Hg in patients with unclipped aneurysms, but levels of 130–140 mm Hg are occasionally required (and achieved) in some patients with clipped aneurysms.

Interventional neuroradiology – selective intra-arterial vasodilator infusions or angioplasty may be beneficial in resistant vasospasm or in patients who develop cardiovascular complications of triple H therapy.

Arteriovenous malformations (AVMs)

AVMs are congenital abnormalities of the cerebrovascular bed. Most are supratentorial and superficial, the remainder are infratentorial or dural. They usually present at 20–40 years of age. The risk of bleeding is 2% per year and the annual rate of death and disability is 4%. 5–10% are associated with cerebral aneurysms (most of which resolve following AVM resection).

Most patients present with an intracranial haemorrhage. Presenting symptoms include seizures, headache and signs of intracranial hypertension. A steal syndrome manifesting as a progressive neurological deficit may also occur. In contrast to cerebral aneurysms, haemorrhage is unrelated to blood pressure and is usually venous in origin.

Most AVMs are treated by embolization particularly if the surgical risk is high. Surgical risk depends on size, anatomy of feeding arteries and venous drainage, and location and eloquence of adjacent brain areas. Surgical resection tends to be reserved for small, superficial AVMs.

Perioperative management: blood products should be readily available because bleeding from AVMs can be torrential. Increases in jugular venous pressure can be transmitted to the cerebral circulation and further enhance bleeding from the AVM. Care must be taken with head-down positioning, tracheal tube tapes, central lines and the application of positive end-expiratory pressure. Induced hypotension may promote visualization of the surgical field, but at the risk of inducing venous thrombosis or ischaemia in non-autoregulating adjacent brain. Blood pressure management should be discussed with the surgical team.

Postoperative haemorrhage may occur from a residual AVM. In addition, hyperaemia is a major source of postoperative morbidity and mortality, producing oedema or haemorrhage and intracranial hypertension, which may be caused by two factors.

- Normal perfusion pressure breakthrough occurs when the brain bordering the lesion is subjected to ‘steal’ from the low resistance circuit of the AVM and adapts by lowering its autoregulatory thresholds. Resection of the AVM exposes this brain to the normal CPP, which may exceed its upper limit of autoregulation. Hyperaemia, microhaemorrhages and vasogenic oedema may result. Staged removal by excision or embolization may allow the brain to regain autoregulatory mechanisms.
- Occlusive hyperaemia. Venous outflow obstruction may cause haemorrhage if arterial feeders are not occluded completely. Venous obstruction may also result in hypoperfusion, owing to stagnation of CBF.

The risk of seizures following AVM resection is about 50%. Blood pressure control is of paramount importance in the postoperative period. Hypertension must be avoided to prevent hyperaemia. β-blockers can be used to control blood pressure, without delaying emergence. Blood pressure should be maintained in the low to normal range. Postoperative ventilation is indicated for patients who suffer excessive bleeding, or have brain swelling. ICP monitoring may be needed.

Management of ischaemic stroke

The annual incidence of stroke is 1–2/1000 population. 80% are caused by ischaemic cerebral infarction, 10% by SAH and 10% by primary intracerebral haemorrhage.

The publication of the National Institute of Neurological Disorders and Stroke (NINDS) trial of alteplase (rtPa) for acute stroke patients in 1995, and its subsequent approval by the US Food and Drug Administration, has increased interest in acute stroke treatment. If given within 3 hours of onset of stroke, rtPa resulted in a trend towards neurological recovery at 24 hours, and at 3 months 50% of survivors had no or minimal disability compared with 38% in the control group. Mortality at 3 months was the same in both groups, despite the rate of symptomatic brain haemorrhage increasing tenfold. There is controversy about its safety, its wider applicability outside clinical trials and its availability. Furthermore, recent studies from Europe do not confirm the positive results of the NINDS study. At present, only 6–12% of stroke patients are likely to be eligible for thrombolysis. Advancements in investigating acute stroke, particularly MRI, may improve the targeting of thrombolysis to those patients most likely to benefit. Any increasing use of thrombolysis will have major implications on stroke services in the future.

There is increasing interest in using intensive care in patients with ischaemic stroke in specific settings. The first of these is to provide physiological optimization in patients in whom cardiorespiratory dysfunction exposes the ischaemic brain to risks of secondary insults. Specific issues include airway and blood gas maintenance in patients with low GCS levels, and thresholds for intervention to treat hypertension in the early stroke period. In general, it is important to maintain near-normal arterial blood gas levels and to avoid treating mild-to-moderate hypertension in the acute period. Sustained blood pressure elevation above 200/120 mm Hg may provide a reasonable threshold for considering antihypertensive therapy.

A second indication is the care of patients who have undergone thrombolysis and require careful monitoring, either because of comorbidities, or complications of the procedure. Finally, there is increasing interest in the use of ICP and CPP oriented therapies (including decompressive craniectomy) in patients with massive non-dominant hemisphere infarctions. ◆

Pharmacological and Pathological Modulation of Cerebrovascular Physiology

Stuart A Booth
David K Menon

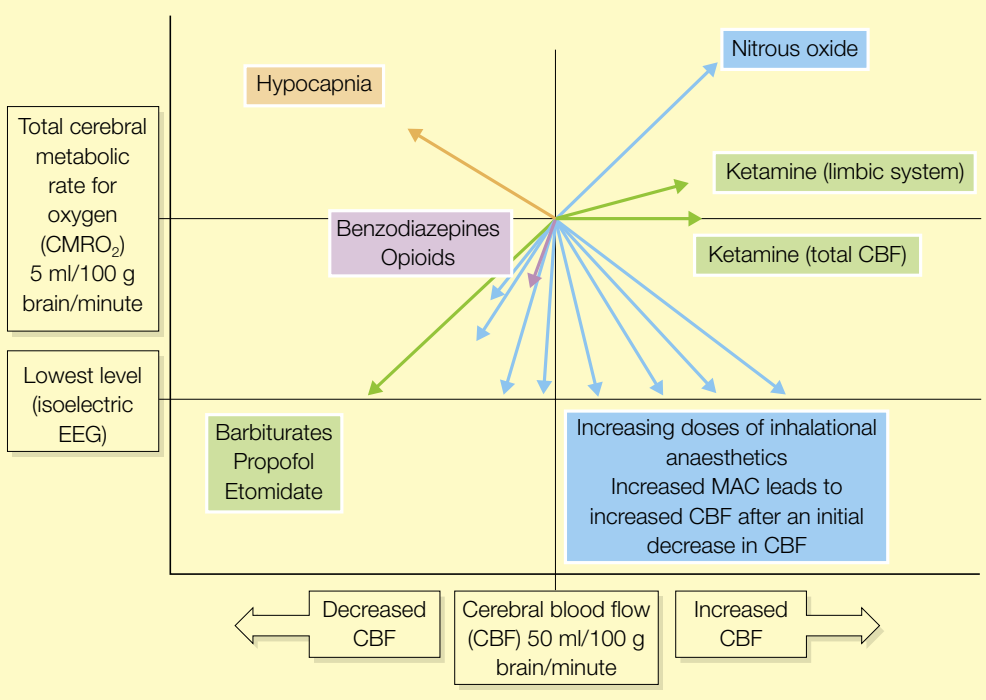
Stuart A Booth is Specialist Registrar in Anaesthesia at Addenbrooke's Hospital, Cambridge, UK. After qualifying from Birmingham University, he trained in medicine at the Derbyshire Royal Infirmary and in anaesthesia and intensive care at Bury St Edmunds and Cambridge.

David K Menon is Professor of Anaesthesia at the University of Cambridge and Director of the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Pharmacological modulation of cerebral physiology

The importance of understanding the effects of drugs used in anaesthetic practice on cerebral physiology cannot be overemphasized. Drugs can exert changes in cerebral blood flow, cerebral metabolic rate and cerebral perfusion pressure, and on cerebral blood volume and intracranial pressure (ICP). These effects may be desirable, for example by reducing intracranial volume and ICP, and thereby improving neurosurgical conditions, or undesirable, for example increasing intracranial volume and ICP, and thereby predisposing to brain herniation in patients with intracranial hypertension (Figure 1).

Effect of drugs used in anaesthetic practice and hypocapnia on cerebral metabolic rate and cerebral blood flow



Hyperventilation and the resulting hypocapnia can lead to vasoconstriction (decreased CBF) and an increase in $CMRO_2$, which is a particularly unfavourable situation. Increasing the inhalational anaesthetic agent concentration (minimum alveolar concentration – MAC) does not decrease CMR below a lower limit. However, it does increase CBF thereby increasing cerebral blood volume and intracranial pressure. This is hazardous for patients with poor intracranial compliance.

1

Fluorinated volatile anaesthetic agents

Fluorinated volatile anaesthetic agents have previously been thought to cause a disturbance in flow–metabolism coupling and attenuate or abolish autoregulation with increasing concentrations, leading to an increase in cerebral blood volume, and thus ICP, despite a reduction in cerebral metabolic rate. However, it is now appreciated that commonly used agents (e.g. isoflurane) preserve flow–metabolism coupling and autoregulation at clinically useful concentrations. There is a dose-dependent decrease in cerebral metabolic rate (to a lower limit), which predisposes to cerebral vasoconstriction as flow–metabolism coupling is preserved. Superimposed on this is the dose-dependent vasodilatory effect of these agents. The effect on cerebral blood volume is a balance between these two antagonistic processes. For example, isoflurane, although a more potent vasodilator of cerebral vessels than halothane, causes more of a reduction in cerebral metabolic rate at equipotent doses. This leads to greater vasoconstriction (secondary to flow–metabolism coupling), which antagonizes the greater dilating effect of isoflurane. Carbon dioxide reactivity of the cerebral circulation is preserved in a normal brain despite the use of these agents, and hypocapnia can further reduce their vasodilatory effect.

The initial popularity of halothane as a neurosurgical anaesthetic agent was reversed by the discovery that it was a potent cerebral vasodilator and could result in clinically significant elevations in ICP in patients with intracranial space-occupying lesions. Enflurane was shown to produce epileptogenic activity, causing an increase in cerebral metabolic rate, cerebral blood flow and thus cerebral blood volume and ICP. As a result, its use in the context of neuroanaesthesia also declined. Halothane reduces cerebral metabolic rate to a lower level than isoflurane. It also has the greatest attenuating effects on autoregulation compared with the other volatile agents. Halothane at 1 MAC (minimum alveolar concentration) almost completely abolishes autoregulation, whereas isoflurane significantly impairs it only above 1 MAC. There is little difference between the two agents in the reduction in global cerebral blood flow at levels of about 1 MAC. Halothane selectively increases cortical blood flow while markedly decreasing subcortical blood flow, whereas isoflurane produces a more generalized reduction in cerebral blood flow. As with all volatile agents, cerebral blood flow increases with increasing concentrations of isoflurane (> 1 MAC) towards the levels in awake patients. Isoflurane has been shown to have a beneficial effect on CSF dynamics by increasing reabsorption.

Initial studies suggested that desflurane and sevoflurane have effects on the cerebral vasculature very similar to isoflurane (e.g. similar reductions in cerebral metabolic rate). However, more recent studies have shown distinct differences between these agents. Desflurane, like isoflurane, can produce EEG burst suppression, but this effect may be attenuated over time. Initial clinical reports suggest that desflurane may cause a clinically significant rise in ICP in patients with supratentorial lesions, despite its proven ability to reduce cerebral metabolic rate. These increases in ICP may be related to cerebral vasodilatation and/or changes in CSF production and reabsorption.

Sevoflurane is non-irritant and has desirable pharmaco-kinetics for neuroanaesthesia. Unlike other volatile agents, sevoflurane up to 1.5 MAC preserves autoregulation. Although reductions in cerebral metabolic rate are similar with both agents, the vasodilatory effect of sevoflurane is about one-third of that seen with isoflurane.

Nitrous oxide

In equi-MAC doses, nitrous oxide is a more powerful vasodilator than any of the fluorinated volatile anaesthetic agents. It also leads to an increase in cerebral metabolic rate, which results in increases in cerebral blood flow and volume, producing a particularly unfavourable pharmacodynamic profile in patients with raised ICP (Figure 1). Furthermore, the vasodilatation produced by nitrous oxide is not decreased by hypocapnia. The effects of nitrous oxide in neuroanaesthesia need to be considered in relation to the effects of the other anaesthetic agents used. Sevoflurane (like all the volatile agents) reduces cerebral blood flow compared with the awake state, but the addition of nitrous oxide can increase cerebral blood flow to a level greater than that in the awake state. Conversely, when propofol is used to maintain anaesthesia, the addition of nitrous oxide has no effect on cerebral blood flow or cerebral metabolic rate, which is an effect that is also seen when barbiturates are used in combination with nitrous oxide.

Intravenous anaesthetics

Intravenous anaesthetic agents, with the exception of ketamine, all reduce global cerebral metabolic rate to a minimum of about 50% of baseline (which corresponds to an isoelectric EEG), coupled with similar reductions in cerebral blood flow (Figure 1). As flow–metabolism coupling is unaffected, these agents have an indirect vasoconstrictive effect, thereby reducing cerebral blood volume and ICP. Autoregulation and carbon dioxide responsiveness are unaffected.

Propofol has a favourable pharmacokinetic profile for neuroanaesthesia and is the only agent that can provide a realistic alternative to volatile agents for maintenance of anaesthesia. As a result, it is being used increasingly in neuroanaesthesia and critical care. However, it is a potent cardiodepressant and systemic vasodilator, and can cause significant reductions in mean arterial pressure. Consequently, it is important to be aware of its potential for causing a fall in cerebral perfusion pressure.

Experimental studies have indicated that intravenous anaesthetic agents may have a neuroprotective role in patients with intracranial disease. Both thiopental (thiopentone) and propofol have significant anticonvulsant activity, reduce intracellular calcium influx, scavenge free radicals and inhibit N-methyl-D-aspartate (NMDA) responses *in vitro*. However, direct evidence of clinical benefit from these agents is scanty.

Ketamine dilates cerebral vessels and increases global cerebral blood flow and ICP. Total cerebral metabolic rate is unchanged, but regional increases occur particularly in limbic structures. Seizure activity is also a concern and CSF absorption is impaired. These changes may be partially attenuated by hypocapnia, propofol, benzodiazepines and halothane. Recently, there has been renewed interest in the use of ketamine, an NMDA antagonist, for its neuroprotective properties. The results of further studies are awaited.

Opioids

If ventilation is not controlled, increases in cerebral blood flow, volume and ICP, secondary to respiratory depression and hypercapnia, can occur after opioid use. During controlled ventilation, however, the administration of small-to-moderate doses of opioids does not adversely affect cerebral blood flow and cerebral metabolic rate. Autoregulation and carbon dioxide reactivity are also maintained. Nevertheless, high doses of fentanyl and sufentanil have been shown to depress cerebral metabolic rate and cerebral blood flow. Chest wall rigidity, causing a rise in central venous pressure, may also occur. Bolus administration of fentanyl, sufentanil or alfentanil may be associated with increases in ICP in patients with intracranial hypertension. This is probably due to autoregulatory vasodilatation of cerebral vessels that follows an initial decrease in cerebral blood flow (due to reductions in mean arterial pressure and thus cerebral perfusion pressure), which leads to an increase in cerebral blood volume. These effects are unlikely to be clinically significant if detrimental haemodynamic and blood gas changes can be avoided. Remifentanil, like alfentanil, has similar minimal effects on cerebral haemodynamics when given as an infusion.

Muscle relaxants

Most nondepolarizing neuromuscular blockers have little effect on cerebral blood flow or cerebral metabolic rate, although atracurium, mivacurium and D-tubocurarine may increase cerebral blood volume and ICP secondary to histamine release and vasodilatation. Succinylcholine can produce increases in ICP, probably secondary to increases in cerebral blood flow mediated via muscle spindle activation. However, these effects are transient and mild and can be blocked by prior precurarization if necessary; they provide no basis for avoiding succinylcholine in patients with raised ICP when its rapid onset of action is desirable for clinical reasons.

Other drugs

Benzodiazepines tend to produce small decreases in cerebral metabolic rate and cerebral blood flow, but there is a ceiling on this effect whereby increasing doses produce no further reductions in these variables. Droperidol has no effect on cerebral metabolic rate and minimally reduces cerebral blood flow. α_2-agonists, such as clonidine, dexmedetomidine and xylazine, reduce cerebral blood flow if there is no significant reduction in mean arterial pressure. Vasodilators, such as nitrates and sodium nitroprusside, increase cerebral blood flow and volume in the absence of hypotension, so predisposing to raised ICP. Vasopressors increase cerebral perfusion pressure, cerebral blood flow and volume when autoregulation is impaired (with disease processes or outside the autoregulatory pressure limits). However, increases in CPP in the presence of intact autoregulation result in reductions in CBV and hence ICP. Mannitol is an osmotically active diuretic that does not normally cross the blood–brain barrier. It decreases ICP in two ways. First, it has an almost immediate effect by improving microcirculatory flow and oxygen delivery; reflex vasoconstriction reduces cerebral blood volume. Secondly, it causes a reduction in brain water thereby reducing intracranial volume.

Pathological modulation of cerebral physiology

Ischaemia

Graded reductions in cerebral blood flow are associated with specific electrophysiological and metabolic consequences (Figure 2). Ischaemia is thus a continuum between normal cellular function and cell death; cell death, however, is not merely a function of the severity of ischaemia, but is also dependent on its duration and several other circumstances that modify its effects. Thus, the effects of ischaemia may be ameliorated by the cerebral metabolic depression produced by hypothermia or drugs, exacerbated by increased metabolic demand associated with excitatory neurotransmitter release, or compounded by other mechanisms of secondary neuronal injury (such as cellular calcium overload or reperfusion injury).

Electrophysiological and metabolic consequences of graded reductions in cerebral blood flow

Cerebral blood flow (ml/100 g brain/minute)	Electrophysiological/metabolic consequence
> 50	Normal neuronal function
?	Immediate early gene activation
?	Cessation of protein synthesis
?	Cellular acidosis
20–23	Reduction in electrical activity
12–18	Cessation of electrical activity
8–10	ATP rundown, loss of ionic homeostasis
< 8	Cell death (also depends on other modifiers, such as duration and metabolic rate)

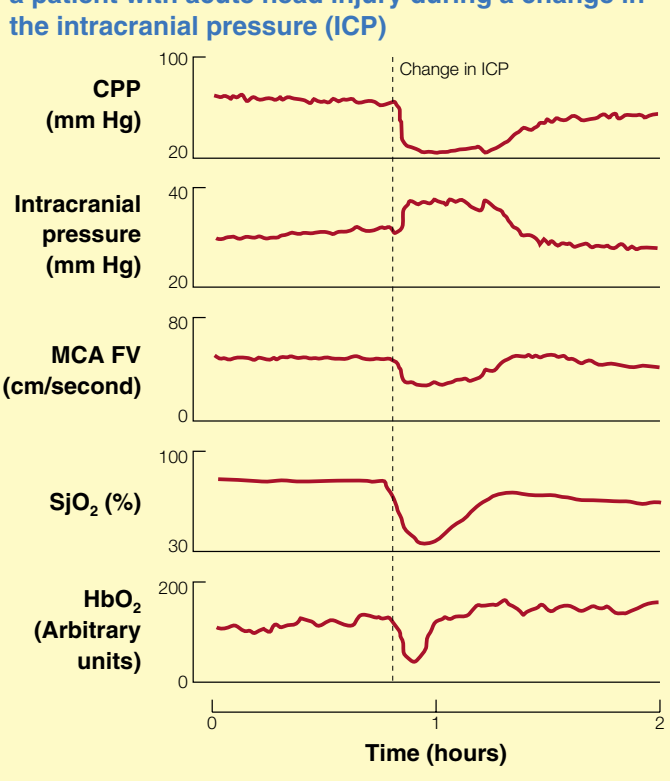
2

Head injury

Severe head injury is accompanied by both direct and indirect effects on cerebral blood flow and metabolism. Cerebral blood flow may be high or normal but is more usually low soon after the ictus. Studies have shown that 30% of patients have significant cerebral ischaemia within 6–8 hours of a head injury. Global hypoperfusion in these studies was associated with 100% mortality at 48 hours, and regional ischaemia with significant deficits. Patterns of cerebral blood flow also vary in relation to the time after injury. Initial reductions are replaced, especially in patients who achieve good outcomes, by a period of relative increase in cerebral blood flow. Towards the end of the first week after injury, this may be replaced by reductions in cerebral blood flow resulting from vasospasm associated with traumatic subarachnoid haemorrhage. Changes in cerebral blood flow are non-uniform in the injured brain. Blood flow tends to be reduced in the immediate vicinity of intracranial contusions, and so cerebral ischaemia associated with hyperventilation may be extremely regional and not reflected in global monitors of cerebrovascular adequacy.

Elevations in ICP result in reductions in cerebral perfusion pressure and cerebral ischaemia, which lead to secondary neuronal injury (Figure 3). There is strong evidence that maintenance of a perfusion pressure above 60 mm Hg improves outcome in patients with head injury and raised ICP. Traditionally, patients with intracranial hypertension have been nursed head-up in an effort to reduce ICP. It is important to realize, however, that such manoeuvres will also reduce the effective mean arterial pressure at the level of the head, and run the risk of reducing cerebral perfusion pressure. A 30° head-up elevation may provide the optimal balance by reducing ICP without decreasing cerebral perfusion pressure.

Continuous record of multimodality monitoring in a patient with acute head injury during a change in the intracranial pressure (ICP)



Note the fall in cerebral perfusion pressure (CPP) and reduction in the middle cerebral artery flow velocity (MCA FV) measured using transcranial Doppler, suggesting reduced MCA flow. The ischaemia associated with the reduction in CPP produces jugular venous desaturation (SjO_2) and a fall in oxyhaemoglobin signal (HbO_2) measured by near infrared optical spectroscopy (NIROS).

3

Hypertensive encephalopathy

Current concepts of the causation of hypertensive encephalopathy are based on the forced vasodilatation hypothesis. Severe acute or sustained elevations in mean arterial pressure overcome autoregulatory vasoconstriction in the resistance vessels and result in forced vasodilatation. These vasodilated vessels, exposed to high intraluminal pressures, leak fluid and protein and result in cerebral oedema, which is multifocal and later diffuse. In the absence of actual encephalopathy, it is important to recognize that untreated hypertension results in a shift of the autoregulatory curve to the right, with elevation of cut-off points for loss of autoregulation.

Subarachnoid haemorrhage

Cerebral autoregulation and carbon dioxide responsiveness are grossly distorted after subarachnoid haemorrhage, more so in patients with worse clinical grades. Such patients may be unable to compensate for reductions in mean arterial pressure produced by anaesthetic agents and develop clinically significant deficits. Significant vasospasm after subarachnoid haemorrhage occurs in up to 30–40% of patients, typically several days after the initial bleed, and may be due to one or more mechanisms. Nitric oxide may be taken up by haemoglobin in the extravasated blood or be converted to peroxynitrite (a highly reactive free radical species) by superoxide radicals produced during ischaemia and reperfusion. Alternatively, spasm may be secondary to lipid peroxidation of the vessel wall by various oxidant species, including superoxide and peroxynitrite. Other authors have proposed a role for endothelin. Vasospasm tends to be worst in patients with the largest amounts of subarachnoid blood, suggesting that the blood contributes to the phenomenon. Vaso-spasm is associated with parallel reductions in regional cerebral blood flow and cerebral metabolic rate in the regions affected.

The clinical impact of late vasospasm has been substantially modified by the routine use of calcium channel antagonists, such as nimodipine, and by the routine use of hypertensive hypervolaemic haemodilution (triple H therapy). Triple H therapy involves the use of colloid administration (with venesection if needed) to increase filling pressures and reduce haematocrit to 30–35%. If moderate hypertension is not achieved with volume loading, vasopressors and inotropes are used to maintain mean blood pressures as high as 120–140 mm Hg. The hypertensive element of this therapy protects non-autoregulating portions of the cerebral vasculature from hypoperfusion, while the haemodilution improves flow and oxygen delivery through vessels, the calibre of which is reduced by spasm. Such interventions produce clinically useful improvements in cerebral blood flow in regions of ischaemia.

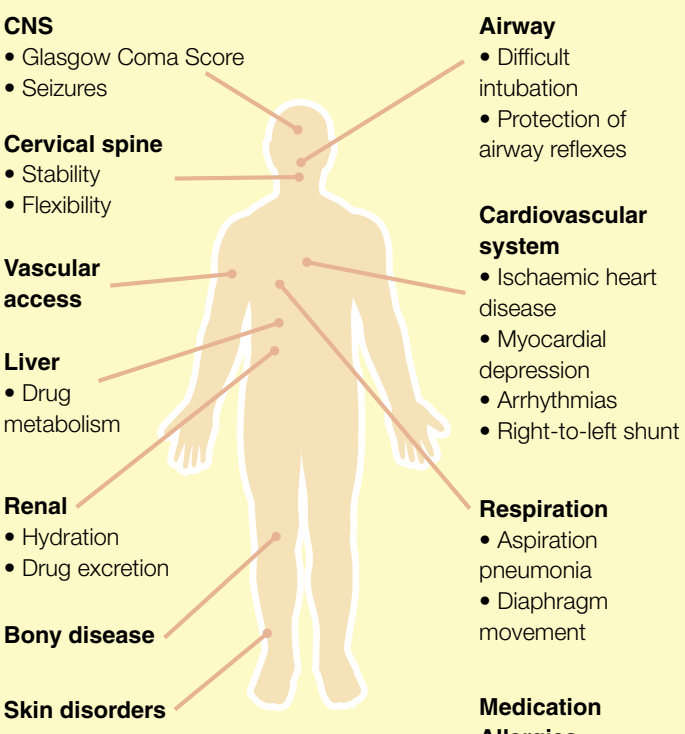
Preoperative Assessment of the Patient with Neurological Disease

Catherine Duffy

Catherine Duffy is Consultant Neuroanaesthetist at Addenbrooke's Hospital, Cambridge, UK. She graduated from the University of Queensland, Australia. She trained in anaesthesia in Queensland and did a fellowship in neuroanaesthesia in Toronto, Canada.

The role of the anaesthetist in neurosurgery is to provide the safest possible operating conditions for the surgeon and the patient. To achieve this, a comprehensive knowledge of CNS physiology and the effects of drugs on the brain are required. The anaesthetist must assess the patient's presenting neurological condition and any underlying medical disease that may affect neurosurgery (Figure 1). The urgency of surgery tends to be determined by the patient's presenting neurology. The Glasgow Coma Score (GCS) (Figure 2) provides a useful and easily communicated means of rapidly assessing neurological status.

Preoperative checklist



1

Glasgow Coma Score

Eye opening	
• spontaneous	4
• to speech	3
• to pain	2
• none	1
Best verbal response	
• orientated	5
• confused	4
• inappropriate words	3
• incomprehensible sounds	2
• none	1
Best motor response	
• obeys commands	6
• localizes pain	5
• withdraws to pain	4
• abnormal flexion to pain	3
• extension to pain	2
• none	1
Total	3–15

2

Airway and ventilation: patients with a GCS less than 9 are at risk of developing hypoxia and hypercarbia, which exacerbate intracranial hypertension. To control intracranial pressure and protect the airway, tracheal intubation and ventilation should be instituted at the earliest opportunity in neurologically obtunded patients.

Fluid and electrolyte balance should be optimized before surgery. To maintain adequate cerebral perfusion, it is important to correct dehydration, which occurs as a result of reduced intake or use of diuretics (including mannitol) in the preoperative period. An attempt should be made to correct electrolyte abnormalities that may occur as a result of syndrome of in-appropriate antidiuretic hormone secretion (SIADH) or diabetes insipidus. Corticosteroids are used preoperatively to control tumour-related cerebral oedema. They cause hyperglycaemia, which has to be controlled, often using an insulin sliding scale regimen. This may have to be continued intraoperatively because hyperglycaemia worsens neurological outcome in the event of an ischaemic injury.

Cardiovascular disease: patients with ischaemic heart disease should be assessed and optimized before neurosurgery. Chronic hypertension causes rightward shift of the cerebral blood flow autoregulation curve such that hypotensive episodes are more likely to cause cerebral hypoperfusion. It is therefore important that blood pressure is well controlled preoperatively.

Preoperative investigations: the anaesthetist should ensure that appropriate preoperative investigations have been performed and the results are available. In particular, it is vital that clotting abnormalities are assessed and corrected before surgery. Depending on the anticipated blood loss, blood should be grouped and saved or cross-matched.

Concurrent medication: the patient's usual medications, including corticosteroids, anticonvulsants, antihypertensives, antacids and antibiotics should be continued throughout the perioperative period. Sedative premedication is best avoided in neurologically compromised patients. In anxious patients with a GCS of 15, oral benzodiazepines are useful. In patients with a history of postoperative nausea and in those undergoing posterior fossa surgery, which predisposes to nausea and vomiting, an oral anti-emetic should be included in the premedication. In patients undergoing spinal surgery, and in whom there is no contraindication, a non-steroidal anti-inflammatory drug (NSAID) premedication is effective in reducing postoperative analgesic requirements. An antisialagogue may be used in patients in whom awake fibre-optic bronchoscopic intubation is planned.

Planning perioperative care: for major neurosurgical procedures, appropriate provision should be made for intensive care or high-dependency nursing in the postoperative period. Some factors specific to the site and nature of neurosurgery warrant special consideration; this article is restricted to the neurological diseases encountered by the neurosurgical anaesthetist.

Craniotomy for supratentorial masses

Masses in the supratentorial compartment fall into three groups.

Tumours – primary lesions range from benign meningiomas to highly malignant glioblastomas. Secondary tumours are the most common intracranial neoplasm; 50% of secondaries originate in the lung. The patient should have been investigated for primary disease and a thorough assessment of the primary site should be made.

Haematomas – traumatic acute extradural and subdural haematomas are often associated with other injuries, which must be prioritized. Major chest or abdominal injuries cause cerebral hypoperfusion as a result of hypotension and necessitate urgent surgery to stop blood loss. In trauma patients, the cervical spine should be treated as unstable until radiographs or CT scans prove otherwise. To achieve optimal neurological results, acute haematomas must be evacuated within 4–6 hours of onset.

Abscesses – patients with an abscess may be immuno-compromised and are often systemically unwell due to infection. Surgery should not be delayed. Antibiotics must be continued perioperatively.

CT scans should be reviewed by the anaesthetist for evidence of raised intracranial pressure, looking in particular for oedema, hydrocephalus and midline shift. Proximity to venous sinuses should be noted, because of the high risk of severe intraoperative haemorrhage. Preoperative angiography provides useful information about the vascularity of tumours. Occasionally, large vascular meningiomas can be embolized in the neuroradiology suite before surgery. This can limit intra-operative blood loss but successful embolization requires that surgical removal take place within 48 hours because the process of necrosis can trigger marked cerebral oedema.

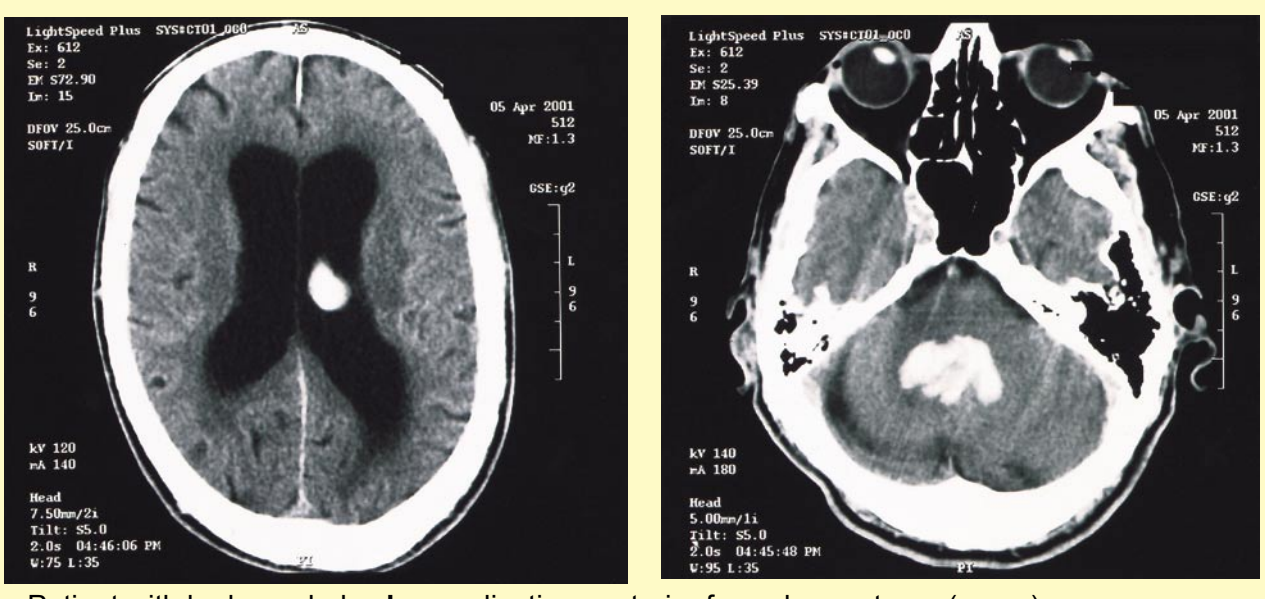
Posterior fossa surgery

The posterior fossa is a small rigid compartment that contains vital structures and through which there is a narrow outflow of CSF. Patients with posterior fossa lesions can present as life-threatening emergencies. Expansion of a posterior fossa lesion can cause acute intracranial hypertension due to hydrocephalus which must be drained urgently (Figure 3).

As with the supratentorial compartment, posterior fossa tumours, haematomas and abscesses may require surgical removal. Posterior fossa surgery is also undertaken to decompress cranial nerves and to correct craniocervical abnormalities.

To allow surgical access, the patient may have to be placed in the prone, lateral, 'park bench' or sitting position. Preoperatively, the patient's suitability for the proposed surgical position must be assessed. For example, obese patients are not suited to lying prone for a prolonged period. Because of its significant risk of morbidity and mortality, the sitting position is reserved for patients in whom it provides the only means of accessing the surgical lesion. Patients with cervical spine disease are unsuitable for this position because neck flexion stretches the spinal cord causing hypoperfusion and potential quadriplegia. The sitting position is contraindicated in patients with known right-to-left shunts because of the risk of paradoxical air embolism following entrainment of venous air. Exclusion of a right-to-left heart defect on preoperative echocardiography does not rule out the risk of paradoxical air embolism. Transpulmonary passage of air can probably still occur in the absence of a right-to-left shunt.

Large posterior fossa masses compress the brainstem resulting in lower cranial nerve palsies. Patients should be examined for impaired gag reflex and evidence of chronic aspiration. If it is anticipated that the patient will be unable to maintain airway protection after surgery, appropriate support in intensive care should be arranged at the time of preoperative evaluation.



a Patient with hydrocephalus **b** complicating posterior fossa haematoma (arrow).

3

Neurovascular surgery

Cerebral aneurysms
Cerebral aneurysms are present in 2–5% of the population. Rupture occurs at a rate of 0.05–6% per year and is related to hypertensive episodes. In the event of a subarachnoid haemorrhage, one-third of patients do not reach hospital, one-third have a poor outcome and one-third are functional survivors. Outcome correlates with neurological condition at presentation which is graded according to Hunt and Hess (Figure 4) or World Federation of Neurological Surgeons (Figure 5) scales. Early surgery (within 48 hours of subarachnoid haemorrhage) reduces the risk of rebleeding but does not change the incidence of vasospasm, which typically occurs 4–9 days after the haemorrhage. Nimodipine improves outcome following subarachnoid haemorrhage and should be started on admission and continued throughout the perioperative period.

Of major concern to the anaesthetist is the cardiac dysfunction that is often associated with patients with a poor grade. This manifests as arrhythmias and depression of ventricular wall function secondary to diffuse myocardial ischaemia. The underlying mechanism is thought to be massive catecholamine release triggered by subarachnoid haemorrhage. These patients are usually in an ICU or high-dependency environment in the preoperative phase. Cardiac function should be assessed and optimized before surgery.

Hunt and Hess classification of patients with intracranial aneurysms

Category	Criteria
0	Unruptured aneurysm
I	Asymptomatic or minimal headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, no neurological deficit other than cranial nerve palsy
III	Drowsiness, confusion or mild focal deficit
IV	Stupor, moderate to severe hemiparesis, possibly early decerebrate rigidity and vegetative disturbances
V	Deep coma, decerebrate rigidity, moribund appearance

4

World Federation of Neurological Surgeons (WFNS) Subarachnoid Haemorrhage Scale

WFNS Grade	Glasgow Coma Score	Motor deficit
I	15	Absent
II	14–13	Absent
III	14–13	Present
IV	12–7	Present or absent
V	6–3	Present or absent

5

Carotid artery surgery
Multi-centre trials in Europe and North America have shown carotid endarterectomy to be worthwhile in symptomatic high-grade (> 70%) carotid artery stenosis. The place of surgery in low-grade and intermediate stenosis is not established. Patients with vascular disease are often elderly and have coexisting medical conditions that must be optimized before surgery.

55% of patients presenting for carotid artery surgery have evidence of ischaemic heart disease. The risk of postoperative myocardial infarction is ten times greater in these patients than in those without coronary artery disease. Given that myocardial infarction accounts for 40–60% of postoperative mortality, it is essential that ischaemic heart disease is optimized preoperatively using medical therapy.

70% of patients with carotid endarterectomy have a history of hypertension. Poorly controlled blood pressure increases myocardial oxygen demands, thereby increasing the risk of myocardial ischaemia. Postoperative hypertension is associated with hyperperfusion syndrome in which an area of brain that has lost the ability to autoregulate owing to chronic underperfusion is suddenly reperfused following endarterectomy. Hyperperfusion can lead to cerebral oedema and intracerebral haemorrhage. To minimize the risk of surgery, blood pressure must be controlled.

Smoking is a risk factor for vascular disease and many patients presenting for carotid endarterectomy have chronic obstructive pulmonary disease. Some improvement in lung function may be achieved with preoperative bronchodilator and corticosteroid therapy. To benefit from surgery, patients should stop smoking permanently.

20% of carotid endarterectomy patients have diabetes mellitus, which is associated with renal impairment, ischaemic heart disease and autonomic neuropathy. Diabetic patients should be assessed for evidence of end-organ disease. A sliding scale may be needed to achieve tight control of blood glucose in the perioperative period.

The patient's preoperative neurological condition should be carefully documented. Progressive neurological deficits are associated with an increased risk of postoperative deficit.

Spinal surgery

Spinal injuries
In patients with spinal injuries, care must be taken to minimize the risk of secondary spinal cord damage. Hypoxia, hypercarbia and hypovolaemia should be treated aggressively and a neutral position should be maintained whenever the patient is moved.

The anaesthetist is often involved in the airway management of patients with cervical spine injuries. To minimize the risk of neurological injury in a patient with an unstable cervical spine, patients should be intubated using manual in-line traction and stabilization. The neck is immobilized using a hard collar or sand bags, while an assistant applies gentle traction to the mastoid processes. Fibre-optic intubation may provide the best alternative for securing the airway in some patients.

If the patient deteriorates neurologically, early surgery may be required to stabilize the spine. The anaesthetist needs to be aware of the systemic effects of spinal injury and make a thorough preoperative assessment.

Within the first 3–5 days of injury, these patients present a picture of spinal shock. Patients with high spinal injuries are bradycardic due to the loss of T1–4 sympathetic cardiac innervation. In subsequent months, they develop autonomic hyperreflexia and, in the chronic phase, postural hypotension.

Patients with spinal injuries at or above C5 need ventilatory support and are at risk of chest infections. Below C6, there may be some respiratory impairment due to paralysis of intercostal muscles. Provision for appropriate postoperative respiratory support should be made at the time of preoperative assessment. Patients with chronic spinal damage may have renal failure with electrolyte abnormalities secondary to long-term bladder dysfunction.

Chronic spinal disease
Of particular concern to the anaesthetist is the patient with ankylosis of the cervical spine in whom intubation can be difficult, especially when temporomandibular joint movement is restricted, as in rheumatoid cervical joint disease, or when dentition is abnormal. When difficulty is anticipated, preparation should be made for awake fibre-optic intubation. This must be discussed in advance with the patient. The anaesthetist should ensure the anaesthetic room is equipped for providing topical airway anaesthesia and fibre-optic intubation. Sedation and an antisialagogue can be administered intravenously on arrival in the anaesthetic room.

Patients with connective tissue disorders must be assessed for cardiac, respiratory, renal and haematological manifestations of their disease. These patients are often taking long-term corticosteroid or other immunosuppressive therapy. The side-effects of such medication must be considered and care paid to the sterility of technical procedures.

Pituitary surgery

Pituitary lesions present as a mass effect or as endocrine changes. 30% of tumours are hormonally inactive and present with headaches or visual field defects due to compression of the optic chiasm. The remainder present with a range of symptoms due to hyper- or hypo-secretion of one or more hormones. Expansion of one cell-type adenoma can compress surrounding normal areas resulting in undersecretion of other cell types. Large pituitary lesions compress the hypothalamo-pituitary stalk, reducing the effect of hypothalamic neuroregulatory hormones. Because of the complex nature of pituitary lesions, these patients are assessed by the endocrinology team in conjuction with the neurosurgeon.

The usual surgical approach is trans-sphenoidal; the nasal mucosa is vasoconstricted using intranasal cocaine post-induction. The anaesthetist should ensure that the patient does not have any conditions (e.g. ischaemic heart disease) that contraindicate the use of cocaine. Patients should be warned that they will have nasal packs at the end of the procedure and will have to breathe orally. A transcranial approach is preferred for tumours that have spread extensively beyond the pituitary fossa but it is associated with a higher rate of morbidity.

Patients undergoing pituitary surgery receive perioperative corticosteroid therapy. An appropriate dosage regimen is usually prescribed by the endocrinology team. Posterior pituitary damage is rare when the trans-sphenoidal approach is used so vasopressin replacement therapy is seldom required.

Acromegaly
Enlargement of soft tissues and cartilage makes patients with acromegaly difficult to intubate. A history of hoarseness and stridor should alert the anaesthetist to airway problems. Indirect laryngoscopy may be helpful in the preoperative work-up. If difficulty is anticipated, plans should be made for awake fibre-optic intubation.

A history of sleep apnoea should be sought. This is usually peripheral in origin owing to airway changes but there may also be a central component as a result of elevated levels of growth hormone. 30% of patients with acromegaly have hypertension. Occasionally they may have cardiomyopathy, in which case a preoperative echocardiogram to assess left ventricular function is useful. Appropriate intraoperative invasive monitoring should be planned in advance. 25% of patients develop diabetes, which should be controlled preoperatively.

Cushing's disease
The classic features of Cushing's disease (central obesity with a short thick neck) can make patients with this disease difficult to intubate. There may be an associated history of sleep apnoea. If there is a history of gastro-oesophageal reflux or peptic ulcer disease, preoperative antacid therapy should be prescribed and plans made for rapid sequence induction. 85% of patients with Cushing's disease have hypertension, which can be refractory to treatment. Left ventricular hypertrophy and congestive cardiac failure are not uncommon. Appropriate cardiac investigations should be available preoperatively. 60% of patients with Cushing's disease have diabetes mellitus. Due to osteoporosis and a tendency to bruising, care should be taken when transferring and positioning these patients. Vascular access may be trouble-some due to fragile skin and loss of connective tissue.

Secondary Neuronal Injury Mechanisms

Dan W Wheeler
David K Menon

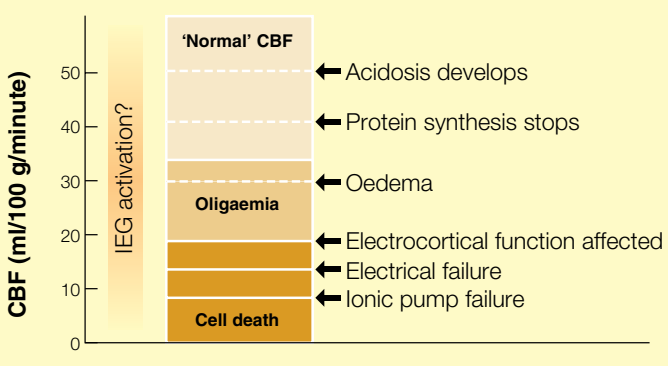
Dan W Wheeler is Clinical Lecturer in Anaesthesia at the University of Cambridge, UK. He qualified from Oxford University. His research interests include modelling human gas exchange and delivering genes to neurons.

David K Menon is Professor of Anaesthesia at the University of Cambridge and Consultant in the Neurosciences Critical Care Unit at Addenbrooke's Hospital, Cambridge. His research interests include mechanisms of secondary neuronal injury, metabolic imaging of acute brain injury and imaging anaesthetic action in the brain.

Cerebral injury is common and results in substantial morbidity and mortality. Neuronal systems are fragile owing to structural and functional complexity, the post-mitotic status of neurons and their specialized metabolic requirements.

Primary neuronal injury occurs when there is trauma causing physical disruption of neurons, or when the oxygen supply is deficient owing to inadequate oxygenation of blood or perfusion of brain tissue. It is common to cite cerebral blood flow thresholds at which several physiological or pathophysiological processes occur, but little is known about what triggers these important biological processes (e.g. immediate early gene expression)(Figure 1).

'Ischaemic thresholds' for pathophysiological events in acute brain injury



Some of the figures are clinically relevant (e.g. cerebral blood flow (CBF) of about 10 ml/100 g/minute for irreversible neuronal injury), but others are speculative, and few data are available for CBF thresholds for key neurobiological processes in ischaemia such as immediate early gene (IEG) expression

1

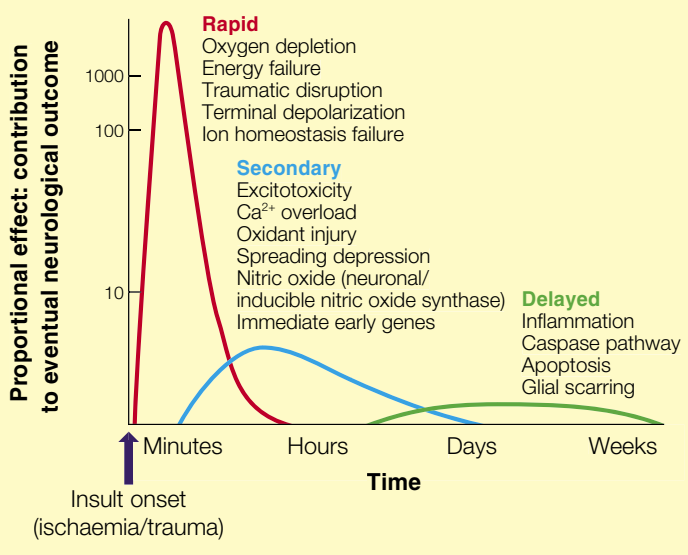
Secondary neuronal injury is caused by damaged and dying neurons releasing factors that have a detrimental effect on other cells, especially neighbouring cells in the CNS. Increasing knowledge of secondary injury mechanisms may provide further useful treatments. The mechanisms may be directly cytotoxic or may compound the imbalance between oxygen supply and demand by:

- further reducing cerebral perfusion through pathological vasoconstriction (vasospasm), autoregulatory dysfunction or microcirculatory occlusion
- increasing neuronal oxygen requirements by inducing ionic shifts, inducing epileptiform activity or precipitating slow waves of depolarization (spreading depression)
- compromising systemic cardiorespiratory physiology.

Reducing secondary injury – simple measures are important. Rapid correction of cerebral hypoperfusion and hypoxia reduce secondary injury. A fuller understanding of the molecular mechanisms of secondary neuronal injury may allow neurons to be protected from secondary injury by other means. However, current application of such knowledge is limited, and clinical trials of drugs inhibiting some secondary injury mechanisms have proved disappointing.

Most knowledge about secondary neuronal injury mechanisms comes from experiments in cell cultures or animal models, some of which produce contradictory results. The importance and timing of many of these mechanisms remains speculative in humans (Figure 2) and direct observation of human pathophysiology may be required to understand clinical disease.

Time course and outcome relevance of pathophysiological processes in cerebral ischaemia



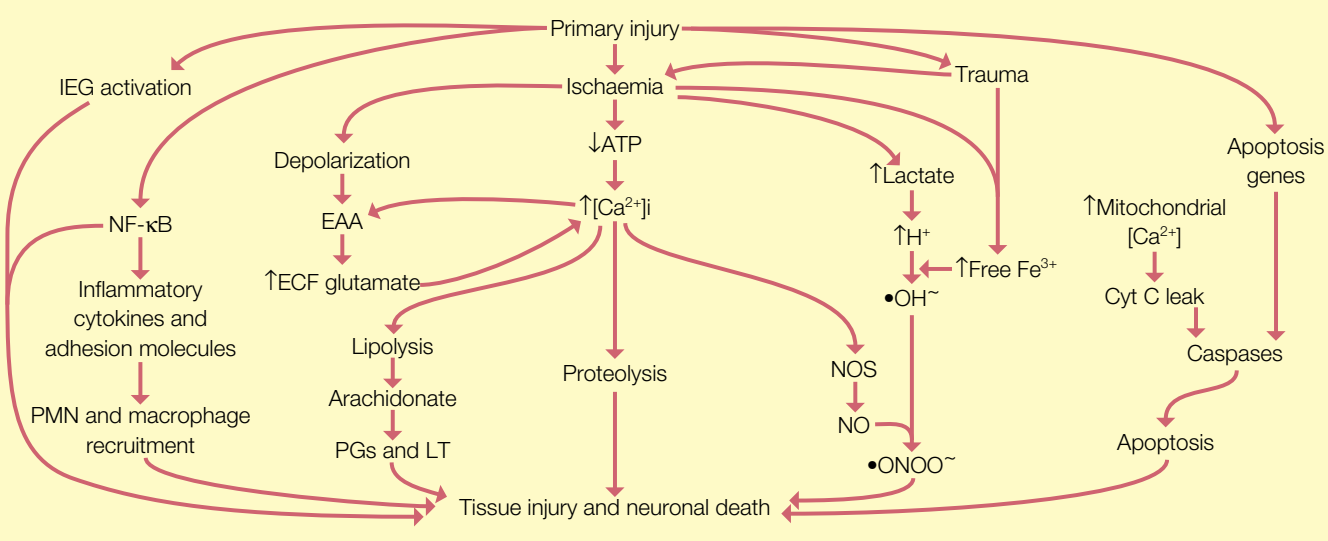
2

Neuronal death is complex. Cells may die by necrosis when cell membrane pumps fail and cells burst, or death may be triggered by an active process ('programmed suicide') called apoptosis. Necrosis and apoptosis can both occur in the same cell, and dying or struggling cells can switch between them as their environment and metabolic demands change. Cellular damage eventually leads to an inflammatory response, which may contribute to late CNS damage. This article concentrates on what kills neurons rather than the means by which they die.

Pathways that damage neurons

Figure 3 shows the main pathways that damage and kill neurons. They are interlinked and can form positive feedback systems.

Processes in secondary neuronal injury



ATP, adenosine triphosphate; $[Ca^{2+}]i$, cytosolic calcium concentration; cyt C, cytochrome C; EAA, excitatory amino acid; ECF, extracellular fluid; IEG, immediate early gene; LT, leukotrienes; NF-κB, nuclear factor NF-κB; NO, nitric oxide; NOS, nitric oxide synthase; ONOO, peroxynitrite; PMN, polymorphonuclear leukocytes; PGs, prostaglandins

3

Glutamate-mediated neurotoxicity and calcium homeostasis

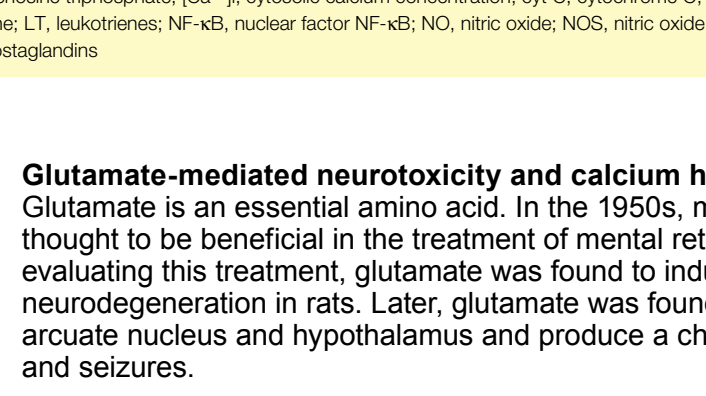
Glutamate is an essential amino acid. In the 1950s, monosodium glutamate was thought to be beneficial in the treatment of mental retardation and seizures. While evaluating this treatment, glutamate was found to induce rather than alleviate retinal neurodegeneration in rats. Later, glutamate was found to be toxic to neurons in the arcuate nucleus and hypothalamus and produce a characteristic syndrome of vomiting and seizures.

Other excitatory amino acids (EAAs) and neurotransmitters (e.g. aspartate) were found to have similar effects and introduced the concept of 'excitotoxicity'. When a neuron is injured or is depleted of energy stores, its cell membrane depolarizes and large amounts of glutamate are released. More glutamate leaks out of damaged cell membranes. Glutamate reuptake systems also fail, and extracellular glutamate levels rise precipitously. Neighbouring cells are depolarized by the excessive glutamate and release more glutamate causing positive feedback, resulting in a vicious spiral of increasing extracellular glutamate concentration. Glutamate damages neurons by depolarizing their membranes, allowing a huge influx of sodium and calcium. The swollen neuron can survive if it has sufficient ATP to power its Na^+/K^+-ATPase pumps and handle the osmotic load, but exhibits cytotoxic oedema following metabolic failure, with eventual loss of viability. Human intracerebral glutamate levels are markedly elevated in brain injury, but there is doubt as to whether synaptic levels are truly toxic. In experimental models, inhibition of glutamate-induced depolarization and cytosolic Ca^{2+} overload improves neuronal survival.

Receptors: the fact that glutamate can damage discrete areas of brain and leave others untouched implied the effect was receptor-mediated. Two classes of glutamate receptor have been identified: ionotropic and metabotropic.

- Ionotropic receptors are coupled directly to ion channels and their activation causes sodium and calcium influx. Depending on their subunit assembly and specific agonist sensitivity, ionotropic receptors are either classified as *N*-methyl-D-aspartate (NMDA) receptors, or α-amino-3-hydroxy-5-methyl-4-isoxazole propionate/kainic acid binding (AMPA/kainite) receptors.
- There are eight subtypes of metabotropic receptor expressed on specific neuron subpopulations and coupled to different secondary messenger systems. Their effects range from excitatory to anti-excitatory. There are several regulatory sites on the NMDA receptor complex that modulate calcium influx when the receptor is activated (Figure 4). Regulatory sites that increase calcium influx (e.g. the glycine site) provide additional targets for neuroprotective interventions.

NMDA (N-methyl-D-aspartate) receptor



The NMDA receptor is an ionotropic glutamate receptor directly coupled to an ion channel that allows Na^+ and Ca^{2+} to enter the cell and K^+ to leave it. NMDA, glutamate and glycine are potent agonists. Other modulatory sites include the polyamine and redox regulatory site. Mg^{2+} is an antagonist, blocking the centre of the ion channel

4

Calcium influx acts as an important effector of glutamate neurotoxicity. The arrival of extracellular calcium triggers the release of intracellular calcium stores from the endoplasmic reticulum. The cytosolic calcium concentration rises to such an extent that protein kinase C, nitric oxide synthase (NOS) and a cascade of phospholipases, endonucleases and proteases are activated, which destroy the cell and its contents. The process has been described as an 'osmotic explosion'. It is possible to block calcium channels and spare the cell. The main calcium channels responsible for extracellular influx are the N, P and Q channels. There are no selective pharmacological blockers for these channels, but nimodipine improves outcome in spontaneous and traumatic subarachnoid haemorrhage. Whether this is due to prevention of catastrophic calcium influx into struggling neurons or its effect on vasospasm is unknown.

Increases in cytosolic calcium concentrations are partly buffered by mitochondrial calcium uptake. However, mitochondrial calcium overload can change the permeability of the inner mitochondrial membrane to macromolecules (a change in the properties of the mitochondrial permeability transition pore). The subsequent leak of cytochrome C is one trigger for apoptosis via the caspase pathway (see below). Drugs such as cyclosporin and tacrolimus can inhibit this process, and may be useful neuroprotective agents.

Glutamate, nitric oxide synthase and free radicals
When NMDA receptors are activated, nitric oxide (NO) is generated in the presence of calcium. NO is mildly cytotoxic. It is synthesized from L-arginine by the three isoforms of nitric oxide synthase (NOS). NO and $\bullet O_2^-$ react to form peroxynitrite ($\bullet ONOO^-$). With a relatively long half-life of about 1 second, this highly reactive free radical can diffuse over several cell diameters and breaks down into the damaging hydroxide radical ($\bullet OH^-$).

It would be reasonable to expect that high glutamate levels would cause secondary neuronal injury via these pathways too. The corollary of this is that inhibiting NOS might limit injury. Surprisingly, NOS inhibition has been found to reduce, to not affect, or even to increase secondary neuronal injury. These contradictory results may result from the specific isoform of NOS inhibited, the time at which NOS inhibition occurs, and the levels of NO present in injured tissue. Soon after injury, endothelial NOS (eNOS) produces NO, which dilates cerebral blood vessels and inhibits platelet aggregation, processes that result in improved blood flow and oxygen delivery. Low levels of NO may also modulate the redox regulatory site at the NMDA receptor to prevent calcium influx. Later, neuronal NOS (nNOS) and inducible NOS (iNOS) in inflammatory cells become the dominant source of NO production. The high levels of NO produced by these routes in the brain parenchyma overwhelm the beneficial effects of eNOS and NO becomes predominantly neurotoxic.

Cells generate free radicals as byproducts of normal and aberrant activity. In health, free radicals are scavenged and inactivated by a number of enzymes (superoxide dismutase, catalase, glutathione peroxidase) and chelators (ferritin, transferrin, vitamin E, uric acid). If oxygen and ATP are scarce, these energy-requiring safety mechanisms are compromised. An excess of free radicals breaks DNA strands, modifies DNA bases, alters protein structure and function and damages lipid bilayers. Free radical production and protection by free radical antagonists is well established in experimental CNS injury.

Immediate early genes and transcription factors
Acute insults to the brain trigger the expression of immediate early genes (IEGs) via a highly complex alteration in the balance of secondary messenger enzyme activity. IEGs most commonly expressed in CNS injury include c-*jun*, c-*fos*, *jun-B* and *jun-D*. The gene products are transcription factors, which activate another cascade of proteins via activator protein-1 (AP-1). AP-1 alters the expression of genes involved in the cell cycle, cell survival and regeneration. Several key genes also have a role in preventing (*bcl-2, bcl$_x$*) or producing (*bad, bax*) apoptosis.

Nuclear factor-κB (NF-κB) is another transcription factor independent of the AP-1 family. It can transduce a signal directly from the cell membrane to the nucleus without the need for enzyme cascades, implying a rapid response time. NF-κB release results in upregulation of a variety of proinflammatory mediators including cytokines and adhesion molecules, and may injure neurons through non-inflammatory mechanisms. Paradoxically, NF-κB expression may be neuroprotective in some settings.

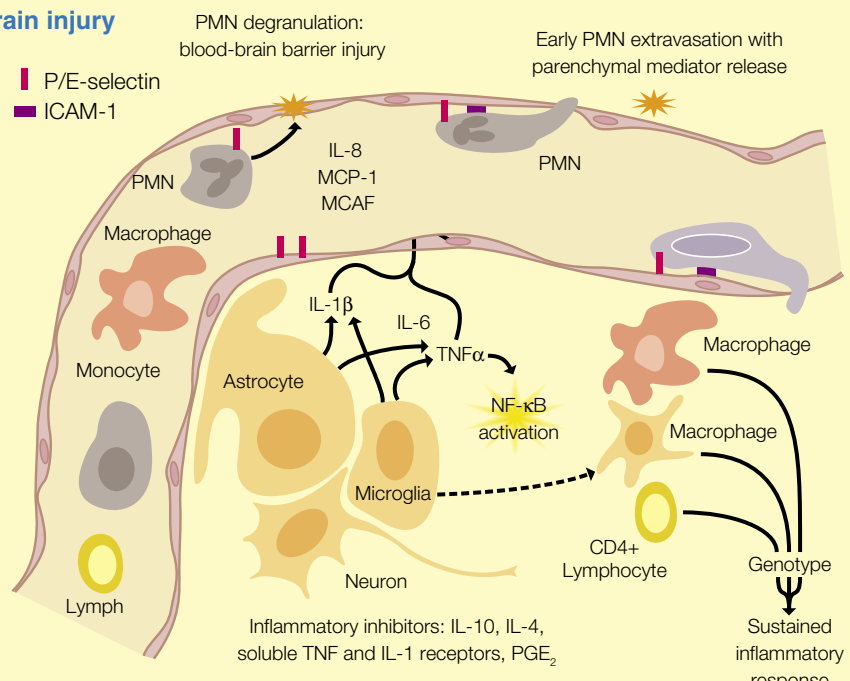
Proteases: caspases and calpains
Caspases (*c*ysteinyl *a*spartate-*sp*ecific prote*ases*) are a family of proteases fundamental to apoptosis. Their role was first elucidated in the nematode *Caenorhabditis elegans*. Three genes (*ced* genes) were found to regulate cell death as the worm developed, two causing cell death and one preventing it. Humans probably have 14 such genes, divided into the ICE (interleukin-1β converting enzyme) and CED-3 subfamilies. *In vivo* studies have shown that caspases are important in effecting neuronal apoptosis after cerebral injury.

Calpains are calcium-activated proteases belonging to a papain family of cysteine proteases. They are the enzymes that break down the cell's cytoskeleton, digest signal transduction enzymes and second messenger systems, and digest cell membrane receptors. They are the end-point of apoptosis, destroying its machinery and packaging it so that it can be phagocytosed. They may also be important in neuronal differentiation and long-term potentiation. As the end-point of apoptosis, they may be useful targets for future interventions.

The inflammatory response
The blood–brain barrier isolates the CNS from systemic inflammatory processes in health, but an inflammatory response is observed following acute CNS insults. The temporal pattern of inflammatory cell recruitment is modified in the CNS, but cytokine production, chemokine release, inflammatory adhesion molecule upregulation, and neutrophil recruitment are all observed in cerebral ischaemia and trauma (Figure 5). Neutrophils can be found at injury sites within hours, and remain for 24–48 hours. Macrophages arrive later, either recruited from the circulating monocyte population, or derived from the resident CNS macrophage population called microglia. Microglia behave differently from peripheral macrophages. In their resting state they have few of the features of macrophages and express few of the same genes. When activated they become phagocytic and secrete the inflammatory factors TNFα and TGFβ. The population of microglia in the CNS is small so the debris of a dead neuron is removed more slowly than in the peripheral nervous system. When the debris is cleared, astrocytes grow where the neuron once was, in response to IL-6 and TGFβ. This astrocytic scar forms a barrier to re-innervation.

Inflammatory responses following acute brain injury

The cytokines TNFα and IL-1β are secreted early by astrocytes and microglial cells, with later production of IL-6. Subsequently, both endothelial and parenchymal cells produce chemokines, including IL-8, monocyte chemoattractant protein-1 (MCP-1) and monocyte chemotactic and activating factor (MCAF), which attracts monocytes and macrophages. Leukocytes attracted by these chemokines undergo margination and extravasation subsequent to interaction with adhesion molecules such as P- and E-selectin and intercellular adhesion molecule-1 (ICAM-1), the endothelial expression of which is upregulated by cytokines and oxidants. The initial cellular response is mainly polymorphonuclear (PMN), and although this persists in man, later cellular responses predominantly consist of invading macrophages and CD4+ T lymphocytes. These cells, along with microglia-derived tissue macrophages, may be responsible for a sustained inflammatory response, the magnitude of which may show genetic polymorphism. TNFα also produces activation of the nuclear factor NF-κB, which has wide-ranging effects. Note that several anti-inflammatory mediators are also upregulated by injury and limit the intensity of the process



Intervening to prevent scar tissue formation and possibly to encourage re-innervation is attractive. However, the molecular relationship between neurons, microglia and astrocytes is poorly understood and likely to be highly complex. Many trophic factors are yet to be identified, but transplanting primary neurons and stem cells into injured areas is a mode of delivery that is generating much interest. ◆

Anaesthesia for Operative Obstetrics

Andrew McLeod
Roshan Fernando

Andrew McLeod is Specialist Registrar in Anaesthetics at the Middlesex/UCL/Royal Free School of Anaesthesia, London. He began his training and interest in obstetric anaesthesia at St Thomas' Hospital, London.

Roshan Fernando is Consultant Anaesthetist at the Royal Free Hospital, London, where he also heads the Obstetric Anaesthesia Services. His research interests include balance function after combined spinal-epidural analgesia in labour and platelet function during pregnancy.

Anaesthesia for obstetric operations must accommodate the physiological changes of pregnancy, and preserve maternal and fetal well-being. Delivery may be required rapidly when the fetus is at risk. Emergency procedures often occur outside working hours and in remote facilities. Obstetric surgery is associated with comparatively high mortality, and increasing medico-legal involvement.

Caesarean section

Elective lower segment caesarean section is performed for cephalopelvic disproportion, malpresentation, multiple pregnancies, placental insufficiency, and at maternal request following previous caesarean section. Emergency caesarean section is required when fetal or maternal well-being is acutely threatened.

Assessment: patients at high risk of operative delivery should be made known to the anaesthetic team and assessed. Women presenting for caesarean section are often well informed, and many have experienced it before. It is important to establish the woman's preference for anaesthesia and elicit information about any:

- obstetric history and previous caesarean sections
- previous anaesthetics used (or family history of suxamethonium apnoea or malignant hyperthermia)
- problems in this pregnancy (e.g. hypertension, diabetes, coagulation disorders)
- medications and allergies (e.g. latex, skin preparations, antibiotics).

Regional anaesthesia should be encouraged, and anxieties allayed, though potential complications must be discussed honestly. The presence of painful labour contractions may limit the extent of any discussion, but not its legal validity. An assessment of intubation difficulty must always be made and recorded. A simple bedside test such as Mallampati's classification is useful, but lacks a high positive predictive value. Difficult intubation (see page 218) should always be anticipated. Early insertion of an epidural catheter (for analgesia) is highly desirable when operative delivery is likely, particularly if general anaesthesia involves an added risk (e.g. known difficult intubation).

Emergency caesarean section: fetal distress is diagnosed from continuous fetal heart rate monitoring and fetal blood gas analysis, but remains an unreliable predictor of condition at birth. A briefer 'decision-to-incision' and 'incision-to-delivery' interval is associated with better initial fetal outcomes. Infants delivered by emergency caesarean section under general anaesthesia have been shown to have lower Apgar and other neurobehavioural scores compared with those under regional techniques. Both anaesthetist and obstetrician should decide which anaesthetic to use depending on the speed and safety required. All methods aim to prevent fetal acidosis by:

- ensuring adequate maternal oxygenation
- avoiding hypotension
- minimizing aortocaval compression
- preventing excessive maternal hypocapnia.

The left lateral position minimizes aortocaval compression (and improves uterine perfusion). Supplementary oxygen for the mother also improves fetal oxygenation. Maternal blood pressure should be maintained with non-glucose-containing crystalloid solutions and intravenous ephedrine. Discontinuing oxytocin infusions, and administering tocolytic agents (e.g. magnesium or β-agonists) reduces uterine activity and can improve acidosis. Fetal monitoring should be continued, because lasting improvement may allow time to convert to regional anaesthesia.

Regional anaesthesia

Regional techniques avoid many of the life-threatening complications of general anaesthesia. An increasing use of regional anaesthesia, has paralleled a fall in anaesthetic-related maternal mortality, though the absolute number of general anaesthetics has fallen only marginally. Apart from safety, regional anaesthesia has four other advantages.

- Fetal exposure to depressant drugs is minimized.
- Maternal participation at delivery is made possible, and the mother can bond with, and care for, her baby sooner.
- Blood loss is reduced.
- Postoperative analgesia is improved using spinal or epidural opioids.

Regional anaesthesia should be performed in a fully equipped operating theatre or anaesthetic room. Adequate resuscitation facilities must be available, together with the necessary drugs and equipment in case conversion to general anaesthesia is required. Reliable, large-bore (14 G or 16 G) venous access must be established before any regional procedure, and pulse oximetry and ECG monitoring established with frequent measurements of arterial blood pressure. Fluid pre-load of 1000–1500 ml of crystalloid solution is normally given. Correct aseptic technique includes wearing a gown, mask and gloves. Skin preparation with chlorhexidine in alcohol solution is effective, provided it is allowed to dry. Skin and deeper tissues are infiltrated with local anaesthetic (e.g. 2% lidocaine (lignocaine)) at the intended site.

Spinal anaesthesia is the quickest and simplest technique. It produces a superior quality of anaesthetic block, and requires anaesthetic doses that cause minimal toxicity to mother or fetus. However, there is no opportunity to provide intraoperative supplementation via the same route in the event of inadequate anaesthesia, or prolonged surgery.

Spinal injection can be performed in the lateral position, but in the obese patient the sitting position helps to identify the midline, and assists the mother to flex her back. The L3/4 or L4/5 interspaces are chosen to avoid direct trauma to the spinal cord. A 25 G or preferably 27 G pencil-point (Whitacre or Sprotte) needle causes a low rate of post-dural puncture headache (PDPH). These small-gauge needles often require an introducer needle. Commonly used regimens are listed in Figure 1.

Commonly used regimens for regional anaesthesia

Caesarean section

Spinal

- Bupivacaine (hyperbaric – usually 0.5% bupivacaine in 8% glucose), 10–12 mg, ± fentanyl, 25 μg, or diamorphine, 200–300 μg

Epidural

- Test dose: 0.5% bupivacaine, 3 ml (± adrenaline (epinephrine), 5 μg/ml)
- Loading dose: 0.5% bupivacaine, 20 ml (± adrenaline (epinephrine), 5 μg/ml) + fentanyl, 50–100 μg, or diamorphine, 2–5 mg (in saline, 10 ml)
- 0.5% levobupivacaine, 20 ml, + opioid
- 0.75% ropivacaine, 20 ml, + opioid

Extension of *in situ* epidural

- 2% lidocaine (lignocaine), 15–20 ml, + adrenaline (epinephrine), 5 μg/ml, ± opioid
- 0.5% bupivacaine, 15–20 ml, (± adrenaline (epinephrine), 5 μg/ml) ± opioid
- 50:50 mixture 0.5% bupivacaine and 2% lidocaine (lignocaine), 15–20 ml, (± adrenaline (epinephrine), 5 μg/ml, ± 8.4% sodium bicarbonate, 2 ml) ± opioid
- 0.5% levobupivacaine, 15–20 ml, ± opioid
- 0.75% ropivacaine, 15–20 ml, ± opioid

Operative vaginal delivery (forceps, ventouse)

***In situ* epidural catheter**

- 0.25–0.5% bupivacaine, 10–15 ml, + fentanyl, 25–50 μg

Spinal or combined spinal-epidural

- 0.5% bupivacaine (hyperbaric), 1.5–2 ml, ± fentanyl, 25 μg

1

Epidural anaesthesia: insertion of an epidural catheter is technically more difficult than spinal injection, and more time is required to produce an effective block. However, the block can be established incrementally if needed, and supplemented during surgery. Preparation, precautions and position are the same as for spinal anaesthesia. The two approaches to the epidural space are the midline and the paramedian; the former is most commonly used.

For the midline approach, the epidural needle is inserted into the interspinous ligament, normally below the L2/3 interspace, and the epidural inner stylet withdrawn. The epidural space is identified by loss of resistance to injection of saline. The saline technique reduces the incidence of dural puncture with the epidural needle. The epidural catheter is passed through the needle, which is itself removed, leaving only the epidural catheter *in situ*. The epidural catheter is then withdrawn leaving 4–5 cm in the epidural space, and finally taped to the skin and a bacterial filter attached to the distal end. A test dose of local anaesthetic should be administered to exclude subarachnoid or intravascular placement (Figure 1). If dural puncture has occurred, the catheter can be resited in an adjacent space, but the response to the test dose must be monitored carefully. Alternatively, the catheter can be advanced into the subarachnoid space, and used as a spinal catheter.

***In situ* epidural catheter:** an epidural catheter, that has been used for labour analgesia and is functioning correctly, can be used to extend the existing block for emergency caesarean section. No optimum solution has been found to do this rapidly and effectively, but choices are shown in Figure 1.

Combined spinal-epidural anaesthesia combines the speed of onset and quality of spinal anaesthesia, with the flexibility of an epidural catheter, though it is technically more difficult to perform. Concerns have been raised that 'drug flux' may occur from the epidural space once a hole has been made in the dura. This has been reported, but the risk is thought to be significant only if large-gauge spinal needles are used, and high local anaesthetic concentrations are subsequently injected epidurally.

This combined technique is most commonly performed as a 'needle through needle' technique, in which a long spinal needle such as a 119 mm, 27 G Whitacre spinal needle is advanced (once the epidural needle has been correctly located in the epidural space) through the dura mater into the subarachnoid space. The spinal injection provides rapid anaesthesia for surgery and the epidural catheter is used for intra-operative supplementation or for postoperative analgesia.

Infiltration and field block: direct infiltration of the anterior abdominal wall with local anaesthetic, layer by layer, can make surgery possible. Alternatively, intercostal and iliohypogastric blocks and/or rectus sheath block combined with direct infiltration of the incision line have been used. Visceral reflexes can also be obtunded to some degree by injection of local anaesthetic around the uterovesico fold and paracervical area. Up to 100 ml of 0.5% lidocaine (lignocaine) with 1:200,000 adrenaline (epinephrine) may be used. Most obstetricians have limited experience with this technique.

Intraoperative care of the patient: the patient should be placed in the full lateral position while the block develops, and supplementary oxygen given. Complaints of nausea normally indicate hypotension and require prompt treatment with ephedrine. Ethyl chloride spray or needle-prick testing will establish the extent of sensory blockade, which should reach an upper level of the T4 dermatome (See *Anaesthesia and Intensive Care Medicine* **1:1**: 42). Surgery should not proceed until this sensory level is achieved. Patients should be warned that some discomfort may be encountered at delivery, or if the uterus is brought out during closure. Continued reassurance is important. Oxytocin, 10 i.u., is routinely given after delivery and at the end of surgery, rectal analgesics (e.g. diclofenac sodium, 100 mg) can be administered.

Problems

Hypotension (defined as a 20% or greater fall in systolic blood pressure) is more common during spinal than epidural anaesthesia, and also in non-labouring women. Sympathetic blockade causes reduced venous tone, pooling of blood in the lower body, and decreased systemic vascular resistance. Hypotension adversely affects uterine perfusion and fetal acidosis, and precipitates maternal nausea and vomiting. It requires prompt treatment, including the adoption of the lateral position, intravenous fluids and vasoconstrictors. Ephedrine is the vasoconstrictor of choice, owing to its sparing effect on uterine vasculature.

Nausea and vomiting are common. They may potentially lead to the aspiration of gastric contents. Hypotension is the most common precipitant, though prior opioid administration contributes.

Inadequate block results from failure of technique, or allowing insufficient time for the block to develop. It is more common with epidural than with spinal anaesthesia, due partly to inadequate spread within the epidural space, and also catheter migration into paravertebral spaces. Poor block is the most common reason for conversion to general anaesthesia, and also a potential source of litigation.

Dural puncture has a theoretical frequency of 0.3% or 1/200 (to which units should aspire), but is often more common. The symptoms of PDPH can be severe and disabling in post-partum patients, and are also associated with significant sequelae (see page 222). Symptoms should be actively sought at follow-up, and established headaches treated actively with epidural blood patching. Many units treat milder headaches with conservative treatment including bed rest, oral analgesics, intramuscular ACTH, subcutaneous sumatriptan and oral or intravenous caffeine.

Total spinal blockade occurs when an epidural dose of local anaesthetic is inadvertently given intrathecally, causing complete motor and sensory blockade, profound hypotension, loss of consciousness and airway reflexes.

Side-effects of local anaesthetic drugs manifest as toxicity when upper safe limits are exceeded, or accidental intravenous injection occurs. Spinal or epidural opioids can cause pruritus and respiratory depression. Delayed respiratory depression with opioids is uncommon in obstetric patients and less likely to occur with more lipid-soluble compounds (e.g. fentanyl, diamorphine). Intrathecal or epidural diamorphine is probably the most common opioid used in the UK to provide postoperative analgesia after caesarean section under regional block.

Neurological complications are four times more likely to be caused by the fetus passing through the pelvis, or by iatrogenic injury. In contrast, complications from regional anaesthetic techniques occur in about 1/13,000 deliveries.

Paraplegia and cauda equina syndrome result from spinal cord compression by epidural haematoma, or abscess. Haematoma is extremely rare, but classically presents with sharp irradiating back pain and sensorimotor deficit. Early symptoms of epidural abscess include headache and backache, which may be most severe at the epidural site. Later signs of bladder and bowel disturbance may occur with or without signs in the lower limbs. Once symptoms have developed, urgent surgical decompression is required within 8 hours, to prevent permanent neurological damage.

Nerve injury can be caused by epidural or spinal needles. Direct contact with a nerve root for example, may produce transient paraesthesia, while nerve root trauma usually causes severe lancinating pain radiating to the dermatome it supplies. Patients may be left with areas of paraesthesia, hypoanalgesia or weakness, which take variable lengths of time to resolve. Adequate follow-up and reassurance are important, ideally involving a neurologist experienced in this area.

Meningitis is a rare but recognized complication of regional anaesthesia. Bacterial meningitis is usually caused by species of *Streptococcus* or *Staphylococcus*, resulting from direct haematological spread or poor aseptic technique on insertion. Aseptic meningitis may be caused by viral infection, equipment contamination, or in association with certain drugs.

Contraindications may be absolute or relative (Figure 2). The need for extremely urgent delivery may allow insufficient time for regional methods to be performed. Spinal deformities (e.g. scoliosis) make regional anaesthesia technically more difficult and less reliable. Neurological diseases (e.g. multiple sclerosis) are not a contraindication to epidural anaesthesia, though data on intrathecal injections are lacking.

Coagulopathy can place patients at risk of epidural haematoma, though most women are prothrombotic in late pregnancy. Adequate haemostasis depends on platelet numbers and function. Most UK centres agree that a count of over 100 x 10^9/litre is safe for performing neuraxial blockade, and the range 80–100 x 10^9/litre remains acceptable if coagulation tests are normal. Counts below 50 x 10^9/litre represent an absolute contraindication. Pre-eclamptic patients may present with falling platelet counts, or impaired coagulation, and recent values are essential. Prophylactic administration of heparin, particularly low molecular weight heparin (LMWH), is increasingly common. For unfractionated heparin, present guidelines state that neuraxial blocks can be performed 4 hours after the last dose, and the catheter removed 4 hours following a subsequent one. For LMWH, 12 hours should elapse. Recent consensus is that aspirin and other antiplatelet drugs when used alone are not a contraindication to regional block. In less clear-cut cases, point of care monitors such as the thromboelastogram may have a role, and advice from a haematologist should be sought.

Anticipation of significant haemorrhage – placenta praevia occurs where the placenta implants ahead of the presenting fetal part (in about 1/200 pregnancies). It remains a principal cause of massive obstetric haemorrhage, but is now better detected and managed by caesarean section. The exact grading depends on the extent to which the placenta covers the lower segment and os, but this does not dictate the choice of anaesthesia. There is no consensus, though modern practice is increasingly using regional techniques, except where urgent delivery is essential, or significant maternal hypovolaemia has occurred. In all cases, potential haemorrhage must be anticipated. It results from incision of the placenta (particularly when anterior), uterine atony, or the occurrence of placenta accreta. Reliable, large-bore venous access must be established before surgery, cross-matched blood should be available, and measures to promote uterine contraction may be needed.

Systemic sepsis – maternal pyrexia is common in labour, but does not generally indicate sepsis. Prolonged rupture of membranes (defined as over 24 hours) is the most important cause, and may be associated with chorioamnionitis in which 8% of women will be bacteraemic. Regional techniques may incur the risk of meningitis or epidural abscess, though a causal relationship is unproven, and the incidence of these complications remains low, even in febrile patients. Most authorities conclude that epidural catheters can be safely sited in patients with chorioamnionitis once antibiotic treatment has commenced, but should be avoided if there are signs of untreated sepsis.

Contraindications to the use of regional anaesthesia

Absolute
- Maternal refusal
- Coagulopathy
- Local sepsis
- Severe uncorrected hypovolaemia
- Known allergy to local anaesthetic agent

Relative
- Urgent delivery
- Spinal deformities
- Anticipation of significant haemorrhage
- Systemic sepsis

2

General anaesthesia
Large-bore venous access must be established (minimum calibre 16 G). The patient should be prepared on the operating table, in a left tilted position or with a left uterine wedge. Pulse oximetry, automated blood pressure cuff, and ECG are the minimum levels of monitoring required. Capnometry is also considered essential to confirm tracheal intubation, and satisfactory ventilation. A source of suction, gum elastic bougies, and smaller sized tracheal tubes (e.g. 5–7 mm internal diameter) must be available, together with short-handled laryngoscopes and alternative designs of blade (e.g. the McCoy laryngoscope). Equipment to assist with oxygenation in the event of failed intubation should be immediately accessible, and includes simple oral airways, laryngeal mask airways, and a cricothyroid puncture set.

The surgical team routinely prepare and drape the skin before induction, to minimize subsequent delay. Preoxygenation of the lungs is achieved by 3 minutes' breathing (or four vital capacity breaths) 100% oxygen through a close-fitting mask. Anaesthesia is induced intravenously as a rapid sequence with thiopental (thiopentone), 6–7 mg/kg, and suxamethonium, 1.5 mg/kg. Cricoid pressure is applied by an assistant. Tracheal intubation must be confirmed by observing the chest for equal expansion, auscultating the chest at both axillae and over the stomach, and by the presence of a regular capnograph waveform. Preparations for a potential failed intubation (see page 218) must be made beforehand, and a drill followed.

Anaesthesia should be ensured by administering adequate concentrations of a volatile agent (e.g. 1% isoflurane with oxygen:nitrous oxide 50:50), and a non-depolarizing muscle relaxant (e.g. atracurium). After delivery and clamping of the umbilical cord, the nitrous oxide concentration can be increased, and opioid analgesia given (e.g. morphine, 10 mg i.v.), together with prophylactic antibiotics. Oxytocin, 10 i.u., is routinely given once the fetus has been delivered, and may be followed by an infusion (e.g. 20–40 units over 2–4 hours). At the end of surgery, rectal analgesics (e.g. diclofenac sodium, 100 mg) can be administered, and patients recovered in the left lateral position and extubated when awake.

Problems

Failure of oxygenation is the most serious and life-threatening complication of general anaesthesia. Functional residual capacity is reduced in pregnancy, causing rapid desaturation in the apnoeic patient. Hypoxia results from an inability to manage a difficult airway, though this has usually followed unsuccessful tracheal intubation. Failed intubation in obstetric patients (see page 218) is eight times more common than in the general surgical population. Full dentition and enlarged breasts make insertion of the laryngoscope more difficult, while obesity and upper airway oedema impede direct laryngoscopy, and make the airway more difficult to manage. Additionally, cricoid pressure applied in the wedged position can displace the glottis laterally, and intubation attempted before suxamethonium is maximally effective will be more likely to fail.

Aspiration of gastric contents continues to cause maternal morbidity and mortality. Lower oesophageal sphincter tone is reduced in pregnancy and gastric emptying is delayed during labour, the delay being exacerbated by opioid administration. All women must receive antacid prophylaxis before caesarean section. Ranitidine, 150 mg, given orally at 12 and 3 hours before surgery effectively reduces acid secretion, and metoclopramide, 10 mg, on the morning of surgery contributes to reduced gastric volume, and increased lower oesophageal sphincter pressure. For emergency surgery, ranitidine, 50 mg, can be given intravenously. A non-particulate antacid (e.g. sodium citrate 0.3 M, 30 ml) should also be given within 20 minutes of surgery.

Hypertensive response to intubation may be exaggerated in patients with pre-eclampsia or pre-existing hypertension. It may be obtunded by β-blockade, or short-acting opioid drugs and, if hypertension poses an increased risk (e.g. cerebrovascular disease), intra-arterial blood pressure monitoring should be instituted.

Maternal awareness represents a terrifying ordeal with potentially long-lasting psychological consequences. In the past this has resulted from small induction doses of thiopental (thiopentone) causing inadequate anaesthetic drug concentrations before intubation, and from deliberate avoidance of volatile agents caused by concerns of uterine relaxation (leading to past awareness rates of 12–26%). Pregnant women may have higher anaesthetic requirements owing to increased cardiac output, and high catecholamine levels secondary to pain and anxiety.

Fetal depression is increased with a longer ‘induction-to-delivery’ interval.

Postoperative care
patients should ideally be cared for in a designated recovery area. Blood pressure, pulse rate, respiratory rate and arterial oxygen saturation must be monitored for at least 1 hour before return to the post-natal ward.

Postoperative analgesia after regional techniques (see page 214) can be provided with intrathecal opioids (e.g. diamorphine, 200–300 µg) administered together with the local anaesthetic at the time of spinal injection, or by subsequent top-ups of epidural opioid (e.g. diamorphine, 2.5 mg) via an epidural catheter. Respiratory depression, especially with less lipid-soluble opioids, is a serious complication, and if adequate observations cannot be made, these techniques should be used with caution. Lipid-soluble opioids (e.g. diamorphine) are seldom associated with delayed respiratory depression in the obstetric population and are routinely used in many UK units. Paracetamol and regular non-steroidal suppositories are highly effective (e.g. diclofenac sodium, 150 mg/day, in divided doses for 3–5 days).

Monitoring for complications of regional anaesthesia (as listed above) must include observation for signs of spinal cord compression or neurological deficit, and also headache and backache.

Thromboprophylaxis – in recent years, thromboembolism has been the leading cause of death in pregnancy, occurring frequently after caesarean section. Important risk factors are age over 35 years, obesity, grand multiparity, immobility, pre-eclampsia and emergency caesarean section. Women at moderate or high risk must receive thromboprophylaxis, for example unfractionated heparin starting at the time of surgery and continued until discharge from hospital.

Pregnancy-related illnesses

A number of maternal medical conditions can complicate pregnancy, but pre-eclampsia and cardiac diseases have particularly important implications for anaesthesia.

Pre-eclampsia complicates 5–10% of pregnancies, presenting as a syndrome of hypertension, proteinuria and/or oedema usually after 20 weeks’ gestation. The only definitive treatment is delivery for which caesarean section is commonly required. Regional anaesthesia is strongly indicated except where coagulopathy is present. In mild disease, most women have normal platelet counts and coagulation, though 20% may show evidence of a consumptive thrombocytopenia and platelet function abnormalities especially in severe pre-eclampsia. In the HELLP (Haemolysis, Elevated Liver enzymes, Low Platelets) syndrome variant, thrombocytopenia can be severe with counts of less than 50 x 10^9/litre. If a recent platelet count is above 100 x 10^9/litre, coagulation is unlikely to be abnormal. Below this level, a coagulation screen must be performed. Spinal and epidural techniques for caesarean section in patients with pre-eclampsia are equally acceptable, and the incidence of hypotension is equivalent. Fluid pre-loading in women with severe pre-eclampsia should be restricted to no more than 500 ml of crystalloid or colloid solution, and hypotension corrected with ephedrine.

With general anaesthesia, the hypertensive response to intubation must be obtunded, to reduce cerebral haemorrhage risk. Intravenous alfentanil, 10–20 µg/kg, or labetalol, 10–20 mg, can be used. Upper airway oedema is common, making intubation and airway management difficult. Smaller sized tracheal tubes may be required, and postoperative ventilation should be considered in cases of potential obstruction. Pre-eclamptic patients are increasingly receiving magnesium therapy, which potentiates non-depolarizing muscle relaxants, and reduced doses should be used.

Cardiac disease is causing increasing maternal mortality, as more women with congenital defects survive to reproductive age. Patients require care in specialist units, with individual assessment and planning, but some general points can be made. Elective caesarean section is commonly favoured. Epidural block may be considered if a slow incremental top-up technique with intra-arterial blood pressure monitoring is used. Sudden cardiovascular changes are reduced, and conditions such as aortic or mitral regurgitation may benefit from reduced systemic vascular resistance.

General anaesthesia may be unavoidable if anticoagulation is required, and in other individual instances. Cardiac considerations should dictate the choice of anaesthesia and, because intra-operative opioids improve haemodynamic stability, they will often be the agents of choice. However, fetal respiratory depression can occur, requiring ventilatory assistance or administration of naloxone.

Oxytoxic drugs can increase pulmonary vascular resistance, promote fluid retention and lead to cardiac decompensation. Many units avoid them at delivery but because this risks post-partum haemorrhage, it is preferable to administer dilute oxytocin over 30 minutes or administer it cautiously in incrementally diluted solutions.

Anaesthesia for other procedures

Cervical cerclage

Cervical incompetence can cause recurrent mid-trimester abortions. In most cases, the cervix can be re-enforced by cerclage, and this is typically performed at 12–18 weeks' gestation as a prophylactic procedure. It may also be attempted in an emergency for actively bulging membranes and, in this situation, reduction of intrauterine and intra-abdominal pressure is important. General anaesthesia has been advocated, because volatile agents can decrease intrauterine pressure and facilitate reduction of the membranes, but coughing and straining must be avoided. In contrast, a regional technique reduces these risks, but positioning, movement and vomiting may increase the possibility of membrane rupture. There is little definite evidence to support either approach. The procedure is performed transvaginally and, if a regional technique is chosen, blockade to T8/10 level is required for which epidural and spinal anaesthesia are both suitable.

Manual removal of retained placenta

The placenta must be manually removed if normal separation does not occur or fragments remain within the uterus. Post-partum haemorrhage may occur in both instances, and patients must be adequately resuscitated first. The choice of anaesthetic technique depends on the degree of haemorrhage and the presence of an *in situ* epidural catheter. Manual removal requires anaesthetic block to a sensory level of T6. If an epidural catheter is in place, incremental boluses of 0.5% bupivacaine or 2% lidocaine (lignocaine) with adrenaline (epinephrine) 1:200,000 up to a total volume of 20 ml may be used to provide anaesthesia. Alternatively, a spinal technique as outlined above can be used, using bupivacaine, 10 mg.

General anaesthesia is required if regional methods are contraindicated or at maternal request. Conduct is the same as for caesarean section, though opioids can be used at induction because fetal depression is not a consideration. Intraoperative uterine relaxation can be provided with transiently high concentrations of volatile agent. Alternatively, nitroglycerine, 50–500 µg i.v., has been used to relax the uterus. Haemorrhage and uterine inversion are potential complications.

Operative vaginal delivery

Additional analgesia or anaesthesia is often needed for ventouse or forceps delivery. The choice of technique is influenced by the presence of an existing epidural catheter, the degree of pain that the mother is likely to experience (e.g. forceps delivery compared with ventouse), the urgency of delivery and the likelihood of success; failed vaginal delivery usually necessitates immediate caesarean section. The following options can be considered.

- An existing epidural catheter can be used to augment the block (Figure 1).
- An epidural, spinal or combination catheter can also be inserted.
- The obstetrician can perform a pudendal nerve block to provide analgesia for a low forceps or ventouse delivery, or infiltrate local anaesthetic into the perineum before episiotomy. *Entonox* (oxygen: nitrous oxide) can be given to supplement the block.

Anaesthetic Management of Labour (Induction and Augmentation)

Andrew H Shennan

Andrew H Shennan is Senior Lecturer in the Maternal and Fetal Research Unit at St Thomas' Hospital, London. He qualified from St Mary's Hospital, London. He trained in London, Newcastle and South Africa in obstetrics and gynaecology.

Labour management aims to ensure a safe delivery for both mother and baby. This is achieved through close monitoring of labour progress, together with assessment of maternal and fetal well-being. When problems arise, the options are to instigate more intensive surveillance, introduce therapeutic measures to correct pathology, or to deliver the baby. This article defines labour and its different stages and describes the methods for detecting problems and how to deal with them.

Diagnosis of labour

The correct diagnosis of labour is essential and can be difficult. Incorrect diagnosis leads to high rates of intervention. Labour is characterized by regular uterine contractions, dilatation of the cervix and descent of the presenting part. The key to diagnosing labour is observing a change in cervical state on consecutive vaginal examinations.

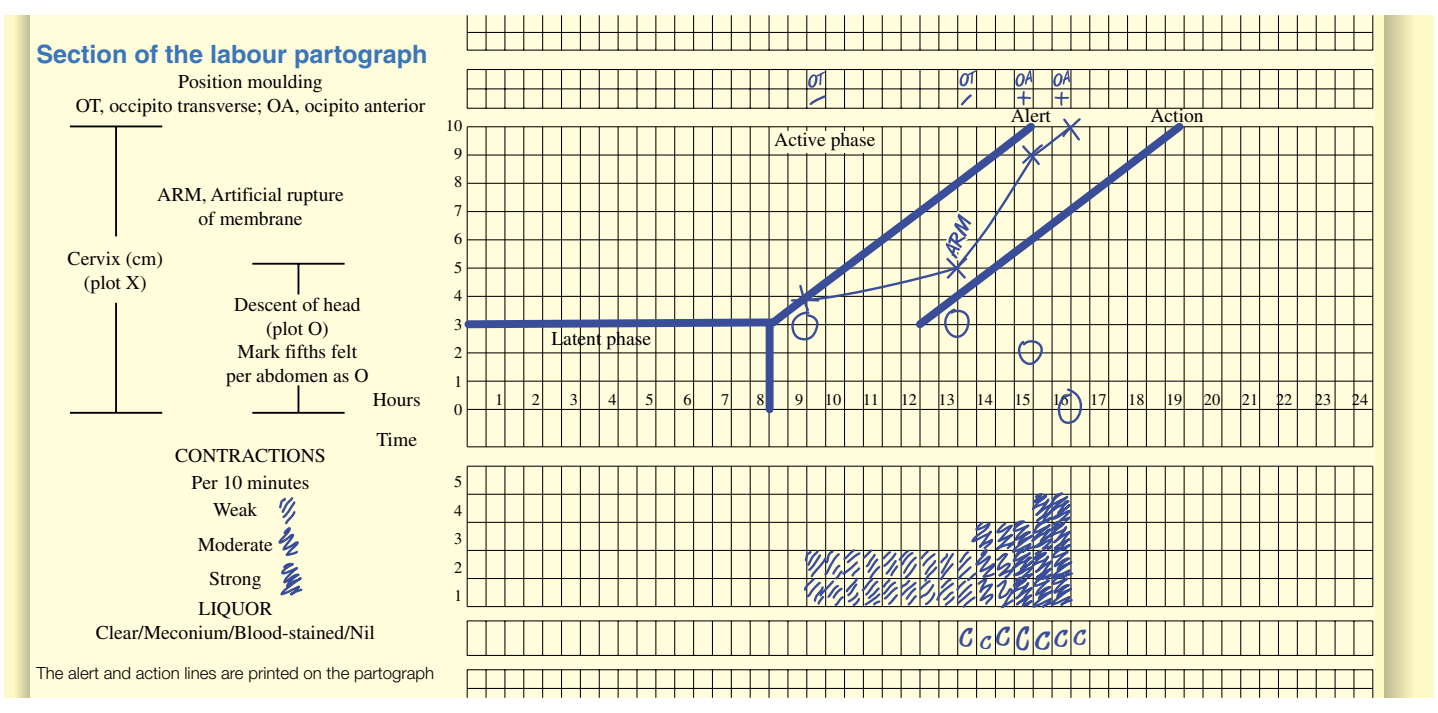
Partogram

The partogram is a graphical record of the progress of labour (Figure 1). The cervical dilatation is plotted against time, along with the descent of the presenting part (usually cephalic). Adequate and progressive descent of the fetal head is a good sign of labour progress. Descent should always be sought in addition to cervical dilatation, because the latter can occur in an obstructed labour. Abdominal assessment of descent is necessary because vaginal assessment can falsely suggest progress when there is increasing swelling on the head (caput). Lines are often drawn to indicate when progress (as judged by cervical dilatation) is slow; this indicates the need for action.

The strength and frequency of the contractions are noted, but they are not reliable signs of an adequate labour.

The state of the liquor is documented. Staining with meconium or blood indicates possible fetal compromise and warrants close fetal monitoring. No liquor with ruptured membranes may be a sign of fetal compromise.

Maternal temperature, pulse and blood pressure are recorded regularly. The fetal heart rate is also noted, primarily to identify a rise in baseline. Tachycardia may indicate fetal distress or infection, and the need for continuous monitoring by cardiotocogram.



1

Assessing risk

The onset of labour: a spontaneous onset of labour is associated with the best chance of a normal delivery. Induction of labour is achieved by ripening the cervix (if necessary) usually with vaginal prostaglandins (PGE2), repeated as necessary. This is followed by an artifical rupture of the membranes when possible, which releases endogenous prostaglandins. Stimulation with oxytocin is used if labour does not become established, usually within a couple of hours. The indication for induction and the induction itself significantly increase the need for intervention in labour, including operative deliveries.

Parity: compared with a multiparous woman, a woman in her first labour (primiparous) is much more likely to require intervention, the progress of labour is slower, and oxytocin is needed more often. Caesarean section and operative vaginal delivery rates are higher in primiparous women (about tenfold). The same partogram is used for all women. A delayed labour in a multiparous woman is more likely to be a result of a serious cause, and is therefore more urgent.

Maternal and fetal disease: risk in labour is dependent on maternal and fetal well-being. A growth-restricted fetus, or a poorly functioning placenta (e.g. in pre-eclampsia) increases the risk of fetal distress. These types of labour are often induced, confounding the problems. Pregnancies of more than 42 weeks' gestation are prone to increased rates of fetal distress and intervention.

Regional analgesia: women having difficult labours often request epidural analgesia. A significant proportion of these women do not achieve a spontaneous vaginal delivery because a regional block increases the need for oxytocin stimulation and assisted vaginal delivery. However, it is unlikely to increase the need for caesarean section.

Support in labour: emotional and physical support in labour has been shown to improve outcome. Having a birthing partner or one-to-one midwifery care is probably the best way to avoid problems.

Stages of labour

Intervention in labour is aimed at preventing a long labour associated with fetal distress and infection.

First stage

The first stage occurs from the onset of cervical change to 10 cm dilatation. The first stage of labour can be divided into latent and accelerative phases (Figure 1). The latent phase can last up to 8 hours, without the need for intervention. A prolonged latent phase should be managed by artificial rupture of the membranes, followed by an oxytocin infusion if progress remains slow. At about 3 cm, the rate of cervical change increases. In about 75% of women in labour in their first pregnancy, the cervix will dilate at least 1 cm/hour during this later accelerative phase. Rates less than this may be abnormal, and indicate a dysfunctional labour or secondary arrest. A dysfunctional labour is usually caused by inadequate uterine activity and is common in primiparous women. It can be corrected using an oxytocin infusion. However, secondary arrest must be excluded. This can result from malposition (e.g. occipitoposterior position) or malpresentation (e.g. brow, which usually requires delivery by caesarean section). Whatever the cause of delay (as assessed on cervical dilatation and head descent), the degree and severity of obstruction can be assessed by the caput and moulding on the head, and the adequacy of the pelvis, during vaginal examination. This determines whether oxytocin can be used to augment the labour and if there is a need for caesarean section. Inefficient uterine action is uncommon in a multiparous women, and oxytocin must be used cautiously even when there are no other signs of obstruction, or the uterus may rupture. True cephalic–pelvic disproportion, a possible cause of secondary arrest (i.e. normal presentation with adequate uterine activity and delay) is rare. Women with a previous caesarean section also have the risk of scar rupture and should be assessed closely, but over 70% achieve vaginal delivery.

Vaginal examinations are performed every 4 hours in normal labour, but can be performed more often if delay develops (usually 2 hourly). If an intravenous infusion of oxytocin is used, it is titrated to contraction frequency so that there are no more than five contractions in 10 minutes. Increased frequency above this may not allow the uterus to relax and increases the risk of fetal distress. Women with prolonged labour should be adequately hydrated, and often require intravenous fluid. The fetus should be continuously monitored with an electronic fetal heart rate monitor. Slow progress between 7 and 10 cm has been associated with higher rates of instrumental vaginal delivery.

Second stage

The second stage occurs from full dilatation (10 cm) to delivery of the baby. A prolonged second stage may increase the risk of fetal distress and pelvic floor damage. The diagnosis depends on the time of the vaginal examination and, in practice, it is the length of pushing that equates best to risk and should be limited. If women do not have the desire to push, and the head still has room to descend, then a delay before pushing is often advised. This is often necessary with an epidural, when oxytocin is also more commonly used. It is unusual to wait for more than 2 hours before commencing pushing, but if delivery has not occurred after 1 hour of pushing, the need for assistance should be considered urgently. Maternal exhaustion usually requires intervention at this time. A ventouse is generally safer, particularly from the maternal viewpoint, and can be performed without an episiotomy in some cases. Forceps are more often used in difficult cases. Rotational forceps, although not widely used, can be employed when the presenting part is malpositioned, but their use requires more skill.

Third stage

The third stage occurs from delivery of the baby to delivery of the placenta. *Syntometrine* (a combination of oxytocin, 5 IU, and ergometrine, 0.5 mg) is given intramuscularly with the delivery of the anterior shoulder. This reduces the incidence of post-partum haemorrhage. Ergometrine can cause nausea and sickness. The placenta is delivered by cord traction, once the uterus has contracted and the placenta separated.

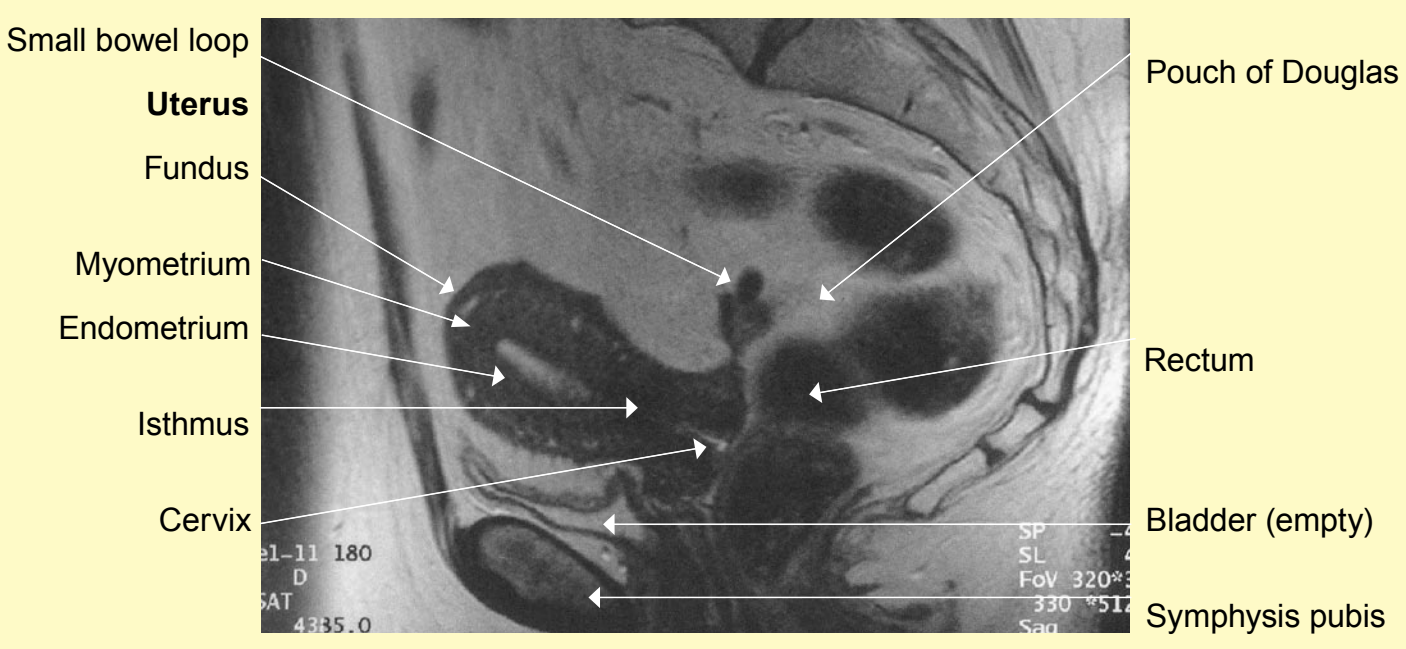
Anatomy of the Uterus

Hazel Adams

Hazel Adams is Consultant Anaesthetist at the Princess Royal and Hurstwood Park Neurological Hospitals, Haywards Heath, UK. Her interests include obstetric and neurosurgical anaesthesia.

The uterus is a muscular tube, widest at the top and flattened anteroposteriorly (Figure 1). It lies between the bladder and the rectum and is separated from them by a layer of peritoneum. The uterine tubes are embedded in its upper lateral edges and extend laterally to the ovaries. The fundus is the domed area above the insertion of the tubes. The body is mainly smooth muscle (the myometrium) arranged in three ill-defined layers. The outer fibres tend towards longitudinal and the inner layers are more circular, acting like sphincters around the blood vessels. The lowest 3 cm of the uterus is the cervix and the part of the body adjacent to the cervix is the isthmus. During pregnancy, the isthmus forms the lower uterine segment, which is where the uterine incision is usually made during a caesarean section.



1 MRI of the female pelvis

The cervix protrudes into the anterior wall of the vagina. The ureters pass forwards to the bladder in the parametrium (the connective tissue surrounding the cervix). The ureters are closely related to the uterine arteries.

The vagina is a fibromuscular tube at 60° to the horizontal. The space between the cervix and vagina is the fornix. Anteriorly the vagina is in contact with the base of the bladder. The urethra is adherent to the anterior wall of the vagina.

The ovaries are attached to the posterior border of the broad ligament by a double fold of peritoneum. The obturator nerve (anterior primary rami of L2, 3, 4) and vessels lie laterally. Pain from the ovary may be referred to the inner thigh. During pregnancy the ovaries are pulled upwards.

Peritoneum: the uterus is enclosed by peritoneum, a double fold of which extends laterally to the walls of the pelvis as the broad ligament. Posteriorly, the peritoneum extends beyond the cervix to the wall of the vagina. It forms the recto-uterine pouch of Douglas, which contains small and large bowel. Anteriorly, the peritoneum is reflected on to the bladder at the level of the isthmus. During a lower segment caesarean section it must be divided in order to avoid damaging the bladder.
Blood supply

The uterus is supplied by the uterine arteries, which usually branch from the internal iliac artery. They pass medially across the pelvic floor in the broad ligament to reach the cervix and give branches to the cervix and vagina. There are anastomoses between both uterine arteries and the ovarian arteries, which increase during pregnancy.

Venous drainage is through the several pelvic plexuses to the internal iliac veins. These plexuses are the cause of the severe haemorrhage associated with a fractured pelvis. There are no valves in the pelvic veins. Raised intra-abdominal pressure may cause back flow through the sacral veins into the venous plexuses within the vertebral column. From there, blood drains into the superior vena cava via the posterior intercostal and the azygos veins.

The ovaries – the ovarian arteries are branches of the aorta below the renal arteries. They are retroperitoneal and enter the broad ligament each giving off a tubal branch.

Nerve supply

The sympathetic supply
Fibres from cell bodies at T11–L2 pass to plexuses continuing downwards in front of the aorta. They form the superior hypogastric plexus at the level of L5 along with fibres from L3 and L4. This plexus divides into right and left hypogastric nerves, which run into the pelvis to form the inferior hypogastric plexus. Each inferior hypogastric plexus lies lateral to the rectum on the side walls of the pelvis. They receive contributions from the sacral sympathetic ganglia.

The uterus is supplied by the superior and inferior hypogastric plexuses. The cell bodies of the sympathetic motor supply to the uterus are mainly at T11 or T12.

The ovaries are supplied by the aortic and coeliac plexuses.

The parasympathetic supply comes from S2, 3, 4. Sacral nerves join the inferior hypogastric plexuses. They continue to the lexuses surrounding the cervix where they synapse.

Function of the autonomic supply: the sympathetic supply is vasoconstrictor and facilitates muscular contraction, especially of fibres near the cervix.

Uterine muscle is mainly responsive to hormonal changes. Some authorities describe motor nerves from T6 and T7 accompanying the sympathetic nerves to the uterus. There is little evidence of parasympathetic innervation of muscle.

The sensory supply
Stretch, contraction, infection and possibly ischaemia all cause pain (Figures 2 and 3). Pain from the body of the uterus is transmitted by sympathetic sensory fibres that enter the sympathetic chain at L5 and ascend. They enter the cord between T10 and L1 and pain can be referred to the corresponding dermatomes. Early labour pain is often felt in the T11–12 dermatomes. As the pain becomes more severe it spreads to T10 and L1. Other fibres travel with the aortic, superior and inferior hypogastric plexuses (i.e. there are alternative pathways entering the spinal cord at different levels).

Pain pathways of relevance to the obstetric anaesthetist

- Sympathetic afferents T10–L1
- Parasympathetic afferents S2, 3, 4
- The rectal, perineal and pudendal branches of the sacral plexus (S2, 3, 4) transmit the pain of perineal stretching
- The ilioinguinal nerve (L1) supplies the root of the clitoris, the labia, the mons pubis and the upper and medial part of the groin
- The genitofemoral nerve (mainly L2) supplies the labia majora
- The posterior femoral cutaneous nerve (S1, 2, 3) supplies the posterolateral labia majora
- A pudendal nerve block will not anaesthetize the whole vulva

2

Important points for the obstetric anaesthetist

- The inferior hypogastric plexus receives fibres from the superior hypogastric plexus, which receives fibres from the coeliac plexus supplied by the splanchnic nerves from T5–T12
- Nerve fibres may enter the spinal cord higher than expected
- Synapses may occur several segments higher
- The peritoneum is supplied segmentally by the spinal nerves that innervate the overlying muscles. Without a block to T4, traction on the peritoneum can cause pain
- The diaphragm is supplied predominantly by C4 (via the phrenic nerve). About one-third of the fibres in the phrenic nerve are sensory and pain is referred to the shoulder tip. The periphery of the diaphragm has a sensory supply from the lower intercostal nerves
- A block from T4–S4 is required for a caesarean section even though the principal nerve supply to the uterus is from T10–T12. Even then sensation from the diaphragm is not completely blocked

3

Pain from the cervix is classically considered to be carried by the pelvic splanchnic nerves (S2, 3, 4). It may be referred to the area supplied by the sacral plexus extending from the lower back to the buttocks, thighs and the mid-calf.

Pain from the isthmus may also be carried via the same pathways as pain from the body of the uterus and be referred to the T12 and L1 dermatomes.

Somatic pain is also perceived during labour. Aδ and C fibres supply the uterus and cervix and accompany the sympathetic nerves. These nociceptive fibres enter the roots between T10 and L1 and synapse at the interneurons in the dorsal horn.

The ovaries: sympathetic vasoconstrictor fibres, with their cell bodies at T10 and T11, reach the ovaries from the aortic plexus. Sensory fibres travel with the sympathetic nerves. Pain from the ovary may be referred to the peri-umbilical area (as well as the inner thigh, see above).

The vagina: sympathetic fibres from the inferior hypogastric plexus and the paracervical plexus supply the blood vessels and smooth muscle. Sensory fibres travel via the pudendal nerve (anterior divisions of S2, 3, 4) to supply the lower vagina. ◆

Antenatal Assessment of the Pregnant Mother

Anne May

Anne May is Consultant Anaesthetist with a special interest in obstetric anaesthesia at the Leicester Royal Infirmary. She is actively involved in research and teaching obstetric anaesthesia and is President of the Obstetric Anaesthetists' Association. She has been running an obstetric anaesthetic assessment clinic since 1991.

Preoperative assessment is a well-recognized part of the anaesthetist's clinical practice and many hospitals have preoperative assessment clinics run by anaesthetists or nursing staff. It is often assumed that pregnancy is a normal physiological condition without risk, but an anaesthetist will be involved with the care of over 50% of women at some time during their delivery. In the UK, the caesarean section rate is over 20% in many units and there are parts of the world where the rates are much higher. In the UK, epidural analgesia rates vary from 5% to 80%.

The need for anaesthetic assessment of the pregnant mother has been highlighted by successive reports on the Confidential Enquiries into Maternal Deaths (CEMD) 1981–84, 1985–87, 1988–90, 1991–93 and 1994–96. Antenatal anaesthetic assessment of pregnant women with cardiac disease was recommended in the 1985–87 CEMD report.

Though maternal mortality has fallen in the last 50 years, as reported in the triennial reports into maternal death, pregnancy still carries a significant risk, which is greatest for women with coexisting medical diseases. An increasing number of women who become pregnant have significant concomitant disease. Some years ago, many of these women would not have contemplated pregnancy, but advances in management and treatment of many diseases mean that such woman can now expect normal fertility. A good example is the excellent control that many women with insulin-dependent diabetes achieve. However, it is important to remember that the underlying condition is still present and may be influenced by the physiological changes of pregnancy and delivery.

Other women who may benefit from antenatal assessment by an anaesthetist include those who may present an anaesthetic problem and those who need to have their anxieties and fears about analgesia and anaesthesia allayed. It could be argued that all women should be seen by an anaesthetist in the antenatal period because they are all potentially in need of obstetric anaesthetic intervention. If a woman has had an antenatal consultation with an anaesthetist, the problems of assessment and consent are less than when the woman presents in a distressed state for anaesthetic intervention. Explanation and assessment are easier in the antenatal period when the woman is calm and pain free.

Women with coexisting medical problems

It is important for the practitioner to consider the effects of the physiological changes at each stage of pregnancy on the disease. The stress of labour and delivery (including pain), and the potential effects of any anaesthetic intervention should also be taken into account.

Cardiac disease

In the Western world, there has been a change in the pattern of cardiac disease, which is illustrated in the most recent CEMD. It is now less common to see women with rheumatic heart disease, while the number with congenital heart disease and ischaemic heart disease has increased. A number of physiological changes of pregnancy affect the cardiovascular system.

- Cardiac output increases to a maximum of 40% at 20–28 weeks' gestation.
- Stroke volume increases and heart rate increases by 10–20 beats/minute.
- Blood pressure decreases in the first and second trimesters and increases in the third trimester.
- Systemic and pulmonary vascular resistance decrease by 25–30%.
- Plasma oncotic pressure decreases by 10–15%, therefore the patient will be prone to pulmonary oedema.
- In labour, the cardiac output increases by 25–50%; mainly mediated through the sympathetic nervous system.
- Autotransfusion of blood from the placenta occurs.

Supine hypotension may cause a reduction in cardiac output of up to 20%. This occurs when the weight of the gravid uterus reduces blood flow through the large vessels (inferior vena cava and aorta) in the supine position.

All pregnant women with cardiac disease should have a full history and examination taken early in pregnancy. Where appropriate, ECG, echocardiography and chest radiography assessments should be undertaken. The team caring for the woman in pregnancy should plan her management in detail and liaise with the cardiologist. It is useful to classify the severity of the cardiac disease using the New York Heart Association (NYHA) classification (Figure 1).

Women with NYHA class 1 or 2 heart disease usually present little problem in pregnancy or labour. Those with more severe cardiac disease may not tolerate the physiological changes of pregnancy, especially as they approach 20–28 weeks' gestation, and will need to be managed by a multidisciplinary team. Caesarean section is required only for obstetric reasons.

In women with severe cardiac disease, epidural analgesia removes the stress response to the pain of labour. Modern low-dose epidural techniques cause little sympathetic block and therefore are safe for most women with cardiac disease. Epidurals are beneficial to women with left heart failure. However, in women with heart disease in whom a drop in systemic vascular resistance would be deleterious, epidural analgesia is not advised. Patients with hypertrophic cardiomyopathy and primary pulmonary hypertension are particularly at risk. Epidural analgesia may be considered in some cases of aortic stenosis where the gradient across the valve is not too great. It is essential to remember the autotransfusion that occurs in the third stage of labour as well as the effect of oxytocin.

Women with cardiac disease need careful monitoring and management throughout labour and the puerperium. Antibiotic cover is important as the CEMD has shown a continuing problem with endocarditis. Clear management plans should be written and agreed by all members of the multidisciplinary team in the antenatal period.

New York Heart Association (NYHA) Classification

NYHA 1
Known cardiac disease with no limitation of physical activity and no objective evidence of cardiovascular disease

NYHA 2
Slight limitation of normal physical activity and objective evidence of minimal disease

NYHA 3
Marked limitation of physical activity and objective evidence of moderate disease

NYHA 4
Severe limitation of activity including symptoms at rest and objective evidence of severe disease

Respiratory disease

The most common respiratory problems seen in pregnant women are asthma and cystic fibrosis. The lung disease may be primarily obstructive or restrictive.

- Obstructive conditions (e.g. asthma, bronchiectasis, cystic fibrosis) may improve after treatment with bronchodilators.
- Restrictive conditions include granulomatous (sarcoid) and fibrotic (postradiation fibrosis, fibrosing alveolitis) disease; they are characterized by fibrotic changes in the lungs, and may be progressive or stable.

Respiratory disease may be exacerbated by the increased respiratory demands of pregnancy. If the disease is severe, pre-pregnancy counselling is advisable. A number of important physiological changes need to be considered.

- Oxygen consumption increases by 20% and metabolic rate by 15%.
- The resting minute ventilation increases by 40–50% with the tidal volume increasing and the respiratory rate remaining unchanged.
- The functional residual capacity (FRC) is decreased in the third trimester, though the vital capacity remains unchanged.
- Forced expiratory volume in 1 second, peak expiratory flow rate and the partial pressure of oxygen in arterial blood remain unchanged while the partial pressure of carbon dioxide in arterial blood decreases to 4.0 kPa.
- Arterial pH is 7.44.

The respiratory centre is reset early in pregnancy as a result of progesterone enhanced by oestrogen, which increases the sensitivity of the chemoreceptors to carbon dioxide. Patients with respiratory disease, in particular those with asthma, are aware of the hyperventilation early in pregnancy and may need reassurance. Towards the end of pregnancy, the enlarging uterus displaces the diaphragm and reduces FRC. FRC remains greater than closing pressure in the upright posture though in the recumbent posture it falls. In the second trimester, airway closure falls within the normal tidal ventilation in a significant number of women.

The effects of these physiological changes may severely compromise the woman with respiratory disease. Pulmonary function tests carried out in the first trimester give a baseline value and these should be repeated in the third trimester or earlier if clinically indicated. Regular peak flow monitoring is a useful assessment in those with obstructive lung disease and may be used as a guide to therapy. Many women avoid taking medication when pregnant and it is important that they are encouraged to continue their maintenance medication.

Women who have treated malignancies may have restrictive lung function and cardiac damage, and require echocardiographic examination of the heart.

In general, women with significant respiratory disease should be encouraged to have a stress-free labour and delivery, minimizing pain and hyperventilation. Epidural analgesia is an integral part of the pain management of these women. If an operative delivery is required, regional anaesthesia is the anaesthetic of choice because general anaesthesia is poorly tolerated.

Haematological disease

In many parts of the world, including the UK, antenatal screening for anaemia, thalassaemia and sickle cell disease is routine. Women with haematological disease may have:

- reduced oxygen carrying capacity (e.g. sickle cell trait)
- increased risk of clotting (e.g. thrombophilia)
- increased risk of bleeding (e.g. idiopathic thrombocytopenia, von Willebrand's disease).

Antenatal assessment is best undertaken by a multidisciplinary team including a haematologist, ideally at a combined clinic. Detailed plans for the management of labour and delivery should include the risks and benefits of regional analgesia and anaesthesia. If regional analgesia is contraindicated, the woman should be told what options are available to her for pain relief including the use of patient-controlled opiate analgesia.

Musculoskeletal disease

Musculoskeletal diseases seen in pregnant women range from physical disability resulting from nonspecific back problems to those who are severely disabled and wheelchair bound. Assessment includes respiratory and cardiac function for those with severe disease (e.g. severe kyphoscoliosis).

The effect of each stage of the pregnancy on the disease needs to be assessed and this must include the possibility of vaginal delivery. The musculoskeletal abnormality should be assessed by an obstetric anaesthetist to balance the risks and benefits of a regional block; it is helpful if previous records of surgery and radiographs are available. Antenatal consultation is important so that informed consent is obtained for any anaesthetic intervention.

Endocrine disease

The most common endocrine diseases that present in the childbearing population are diabetes and thyrotoxicosis. These women are best managed in a combined clinic, where the obstetrician and endocrinologist manage the pregnancy and plan for delivery. For most of these women a stress-free delivery is advised and epidural analgesia is an integral part of management.

Neurological disease

Antenatal assessment is advisable for women with, or with a history of, neurological disease. Patients with a history of trauma, tumours, infection or cerebrovascular accidents need to be assessed to determine whether there is any residual problem that will be affected by the pregnancy or labour. Consultation with the obstetric anaesthetist is advisable because many of these women are frightened by the thought of a needle in their back or any sensation of numbness. They may have had a bad experience with a lumbar puncture or paralysis, for example in acute post-infective neuropathy. Careful explanation and reassurance about regional analgesia and anaesthesia is important.

Women with established neurological disease include those with spina bifida, myasthenia gravis, epilepsy, or multiple sclerosis. In all these conditions, the assessment should take account of the effect of the pregnancy and labour on the disease. Many women who cope with crutches will need a wheelchair in the later stages of pregnancy. Women with spina bifida may have other risk factors (e.g. associated kyphoscoliosis, tethered spinal cord). Early consultation allows time for full investigations including MRI, and to obtain records of previous investigations and surgery.

Traditionally, regional analgesia and anaesthesia have been avoided in patients with neurological conditions because of the fear of making the condition worse or being blamed if worsening should occur. Although randomized controlled trials are unavailable, there is increasing clinical experience of regional blocks being safely and successfully carried out in these women. Antenatal consultation with an obstetric anaesthetist is important so that the risks and benefits may be explained and a plan made for analgesia and anaesthesia during delivery.

Women with potential anaesthetic problems

General anaesthesia is associated with maternal mortality, although the incidence of death as a direct cause of general anaesthesia has fallen in recent years as demonstrated by successive CEMD reports. The increased risks of general anaesthesia in pregnancy are mainly a result of the physiological changes of pregnancy, in particular the cardiovascular and respiratory changes. These changes are compounded by the physiological changes of pain, the work of the contracting uterus, and the oxygen demands and stress response of labour. Weight gain, oedema, large breasts and swollen mucosa all increase the difficulty in visualizing the larynx at laryngoscopy. The physiological and anatomical changes of pregnancy make airway management and hypoxia more of a problem than in the nonpregnant state. Failed intubation associated with acid aspiration (Mendelson's syndrome) is still a major anxiety for anaesthetists in obstetrics. Failure to intubate the trachea occurs in about 1/300 pregnant women and is ten times more common than in nonpregnant women.

Women who have a potential anaesthetic problem include those with:

- coexisting disease
- obesity
- difficult intubation (known or potential)
- previous anaesthetic problems
- genetic conditions associated with general anaesthetic problems.

Obese women

Obese women have several potential anaesthetic problems. These range from difficulty in finding intravenous access and placing regional blocks to major difficulties in intubation and ventilation if general anaesthesia is required.

Difficult intubation

In women who have had a previous difficult or impossible intubation, the difficulty must be clearly stated in the medical record and clear guidelines for the labour and delivery set out. These women need to be told that regional anaesthesia is the anaesthetic of choice and this may indicate epidural analgesia in labour. If regional anaesthesia is not an option then these women may have to be delivered by caesarean section as an elective procedure using fibre-optic intubation techniques. Antenatal planning is essential for these women.

Genetic diseases

Genetic diseases associated with potential anaesthetic problems are malignant hyperpyrexia and suxamethonium sensitivity. Women with malignant hyperpyrexia are usually aware of the hazards of general anaesthesia and the safety of regional analgesia and anaesthesia for them. It is essential that a clear plan for their delivery is made in the medical record so that all carers are aware of the problem. Women who are suxamethonium sensitive usually have a reasonable knowledge of the problem of prolonged apnoea, though they may not be aware that suxa-methonium is a standard drug used in emergency anaesthesia in obstetrics. They should be encouraged to have regional anaesthesia but told that there are alternative drugs if they need a general anaesthetic. Antenatal assessment is important for these women.

Women with adverse drug reactions

Many women have drug allergies. The antenatal period allows time for records to be found and the advice of an immunologist and pharmacist to be sought where appropriate. Some women need reassurance because their reaction was a side-effect of a drug rather than an allergic reaction. The anaesthetist should ensure that there is clear documentation of true allergies that may be life threatening and that guidelines for suitable pain relief in labour are drawn up taking account of relevant drug allergies and sensitivities.

Women with specific anxieties about their delivery

Elective caesarean section

Women scheduled to have an elective caesarean section are usually admitted on the day of surgery and this makes it difficult to discuss the risks and benefits of regional anaesthesia with them. Many units have introduced leaflets to explain the basics of their anaesthetic. This is helpful, but there are still some women for whom this information is inadequate and who need an antenatal consultation with the anaesthetist. Ideally, this should be available to all women who are to be delivered by planned caesarean section.

Planned pain relief in labour

Information on pain relief in labour is available to all women but some may have particular anxieties and benefit from detailed discussion on epidurals. Women for whom an epidural has been suggested as a planned part of their labour management (e.g. for twins, breech or hypertensive disease of pregnancy) may also benefit from a more detailed discussion.

Previous anaesthetic or analgesic problems

Previous anaesthetic or analgesic problems include a previous bad obstetric experience or, for example:

- dural puncture
- difficult or failed epidural
- pain at caesarean section
- epidural did not extend for caesarean section
- bad experience of general anaesthesia
- bad opiate experience.

These women benefit from antenatal assessment so that plans for their labour and delivery can be made and recorded in their notes.

Assessing the Fetus

Kate Langford
Andrew H Shennan

Kate Langford is a Subspecialty Trainee in Maternal-Fetal Medicine at Guy's and St Thomas' Hospital, London. She qualified from Cambridge University and King's College Hospital, London. Her research interests include monitoring of fetal health and in utero programming of patterns of adult disease.

Andrew H Shennan is Senior Lecturer in the Maternal and Fetal Research Unit at St Thomas' Hospital, London. He qualified from St Mary's Hospital, London. He trained in London, Newcastle and South Africa in obstetrics and gynaecology. His main research interests are in the diagnosis and prevention of pre-eclampsia, intra-partum regional analgesia, and the prevention of prematurity. He specializes in running clinical trials.

The two key assumptions underlying fetal assessment are that:
- fetal compromise is progressive and can be detected at an early stage before permanent damage has occurred to the fetus
- an effective intervention can prevent or ameliorate fetal damage.

Despite widespread use of fetal assessment techniques, these underlying assumptions are not always met. Fetal compromise has various aetiologies that progress at different rates. It is the underlying aetiology that determines whether the assessment of fetal well-being is successful in detecting a stage before permanent fetal damage occurs. The only intervention that can 'rescue' the fetus from an adverse intrauterine environment is delivery, which may result in death or disability from prematurity. In order to minimize the number of fetuses exposed to the risks of iatrogenic prematurity, a judgement must be made as to when fetal compromise becomes permanent damage. Delivery should be undertaken just before this point. Unfortunately, current assessment techniques do not predict this point accurately, and so some fetuses will be delivered more prematurely than necessary and others delivered after they are irreversibly damaged.

Ante-partum assessment

There is no single agreed method of assessing fetal well-being in the ante-partum period and in practice a variety of different parameters are used to provide an overall impression of fetal health. Individual units have different approaches to fetal assessment depending on the technology and expertise available. At its most simple, fetal well-being is assessed throughout pregnancy by health professionals asking the mother at each visit whether the baby is moving well. Ultrasound scanning is commonly used in fetal assessment with parameters such as fetal growth, amniotic fluid volume, placental maturity, and fetal and placental blood flow being measured.

Whatever the method used, effective assessment of fetal well-being depends on the background risk in the pregnancy. All methods of monitoring may give false-positive or false-negative results, the impact of which may be reduced by bearing in mind the likelihood of fetal compromise in the pregnancy being assessed. For example, a decline in movements may indicate a compromised fetus, but in most cases it will not. Decreased movements are most likely to represent compromise in a pregnancy at high risk of fetal problems, such as one complicated by fetal growth restriction, and so should be taken most seriously in this context.

Electronic fetal heart rate (FHR) monitoring to produce a cardiotocograph (CTG) is widely available, but research does not support its use in the ante-partum period. CTGs have never been shown to improve fetal outcome and their use is associated with a trend towards an increase in perinatal deaths (odds ratio 2.85, 95% confidence interval 0.99 to 7.12).

Intra-partum assessment

Fetal heart rate monitoring

The aim of intra-partum FHR monitoring is to identify those fetuses who become hypoxic and acidotic during labour so that delivery can be expedited before permanent damage or death ensues. It was hoped that this would reduced the incidence of cerebral palsy, but it has not done so. This partly reflects the limitations of the method, but is also explained by increasing evidence that most cases of cerebral palsy follow an insult in the antenatal period and therefore will not be prevented by changes to the management of labour.

Intra-partum FHR monitoring may be undertaken by intermittent auscultation using a Pinard stethoscope or hand-held Doppler monitor, or by continuous electronic fetal monitoring to produce a CTG. This article focuses on the CTG, but this does not mean that it is superior to intermittent auscultation for most women. Trials comparing intermittent auscultation with continuous electronic fetal monitoring consistently show no reduction in perinatal death with electronic fetal monitoring. Electronic fetal monitoring is associated with a reduction in perinatal morbidity because it reduces the incidence of early neonatal seizures, however, this is not associated with any reduction in longer-term morbidity (e.g. cerebral palsy). An important drawback of electronic fetal monitoring is that it increases the number of instrumental vaginal deliveries and caesarean sections performed. This increases maternal morbidity and mortality for no improvement in long-term neonatal outcome.

Interpretation of the CTG: the CTG consists of parallel tracings of uterine activity and FHR. The physiological basis for monitoring FHR to detect developing acidosis is that FHR is under the control of the autonomic nervous system. As a fetus becomes hypoxic, and eventually acidotic, the autonomic nervous system is affected before the CNS develops permanent injury. Changes in the FHR may therefore be seen before permanent damage has occurred. The following elements are considered when interpreting the CTG:
- background risk to the pregnancy
- presence and frequency of contractions
- baseline rate (normal range 110–150 beats/minute at term)
- baseline variability (normal range 10–25 beats/minute)
- presence or absence of accelerations in the FHR
- presence or absence of decelerations in the FHR.

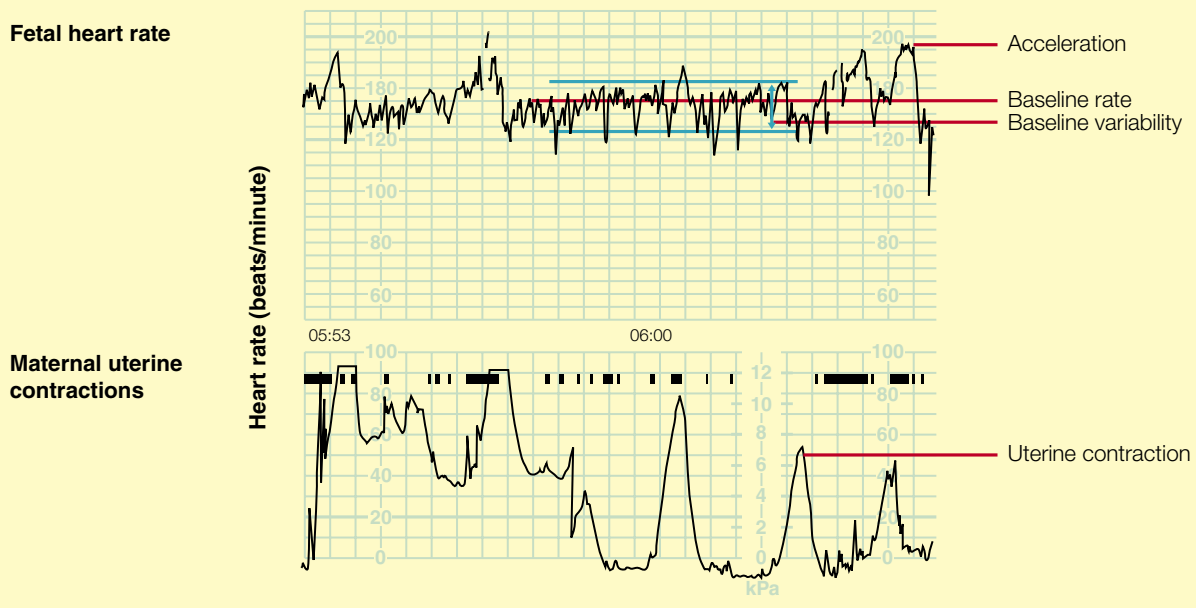
Figure 1 shows a normal CTG from a low-risk pregnancy illustrating the signs of fetal health. The baseline rate is 135 beats/minute and the baseline variability is 15–20 beats/minute. Accelerations in the FHR are present and there are no decelerations. Such a CTG is described as 'reactive' or 'reassuring' as it is a reliable indication that the fetus is not acidotic.

CTG changes that may indicate developing acidosis include:
- a rising baseline rate
- decrease in baseline variability
- lack of accelerations
- presence of decelerations.

Decelerations are classified as early, variable or late depending on their relationship to the timing of contractions and are of differing significance. Late decelerations start after the contractions begin, reach their nadir after the contraction peaks and recover after the contraction has finished. This type of deceleration is most strongly associated with fetal acidosis.

A CTG indicating possible acidosis may be described as 'abnormal' or 'non-reassuring'. There is a high false-positive rate for diagnosing acidosis from the CTG (over 50%) and the term 'fetal distress' should be avoided because it is emotive and a less accurate description of the information conveyed by the CTG than 'non-reassuring'.

A normal cardiotocograph from a low-risk pregnancy



1

Fetal scalp blood sampling

The CTG should be regarded as a screening tool for fetal acidosis and a suspicious CTG requires further investigation or delivery if this is impossible. Once the cervix has dilated beyond 3 cm it is usually possible to obtain a sample of blood from the fetal scalp, which can be analysed for pH and base deficit. In the UK, a scalp pH less than 7.2 is an indication for delivery, though this is arbitrary. There is no significant increase in risk of neurological deficit in the neonate until the pH falls below 7.0 and the base deficit is above 16 mmol/litre, which indicates a metabolic acidaemia. The use of fetal scalp blood sampling has not been shown to improve fetal outcome but rather to reduce the rate of operative delivery and thus maternal morbidity by allowing identification of the numerous cases where the CTG is non-reassuring but the fetus is not acidotic.

Umbilical cord gases

After birth, blood can be taken from the arteries and vein of the umbilical cord and analysed for pH, base deficit and partial pressure of carbon dioxide, providing an indication of whether the fetus was acidotic *in utero* and, if so, whether this was respiratory or metabolic in origin. This is unnecessary if the neonate is vigorous and obviously healthy at birth but may provide useful information if the neonate shows signs of compromise. Good recovery from a respiratory acidosis is the rule but the risk of neurological deficit is raised in significant metabolic acidosis as described above.

Ethical Issues in Obstetric Analgesia

Cleave W Gass

Cleave W Gass is Consultant Obstetric Anaesthetist at St George's Hospital, London. After completing undergraduate medical education at the University of Cape Town, South Africa, he trained in anaesthetics at the St George's School of Anaesthesia,

There has been a shift away from the paternalistic attitude that 'doctor knows best' to a more patient-focused view, respecting the patients' autonomy to make choices about the treatments they receive. This requires doctors to explain the various treatment options to patients as well as the risks involved, so that patients may make an informed choice. In obstetrics particularly, documents such as *Changing Childbirth* have stated that women should be encouraged to express their views and expectations regarding labour and treatments they would prefer in labour, and these should be met in most cases.

The obstetric anaesthetist is likely to be faced with numerous ethical dilemmas, revolving around the ability of a woman to give truly informed consent in labour, which is a period of intense discomfort and anxiety for some women. Additionally, women may have received opiates (e.g. pethidine) before having to make a choice, which could limit their ability to give truly informed consent to anaesthetic interventions in labour. A further ethical complication is the presence of the fetus, especially if there is conflict between the woman's wishes and the optimal outcome for her child. There are also ethical concerns about research on pregnant women. Nationally, anaesthetists may be involved in resource allocation and setting standards of care for women in labour, as well as being required to participate in the National Enquiries into Maternal Death, which may involve issues of confidentiality.

Consent issues in labour

Undertaking a procedure without consent constitutes battery under English law. It is difficult to obtain informed consent for epidural analgesia from the labouring parturient. Ideally, information about proposed anaesthetic interventions in labour should be given before labour begins, but this is not common practice in the UK. A recent study showed that recall of the risks of epidural analgesia was better in women who had attended antenatal education classes than in those who received the information in labour, though the overall recall of information was poor.

Birth plans

Difficulties may arise if a woman has made a birth plan before labour refusing epidural anaesthesia, particularly if there are disagreements between previously expressed wishes and currently expressed desires. Scott maintains that it would be unethical not to provide epidural anaesthesia in these circumstances. However, she cites a case in which an anaesthetist was threatened with physical violence by a woman's partner should an epidural be performed contrary to her prior expressed wishes. Some commentators have compared birth plans with advance directives made by patients in other circumstances (e.g. not to undergo cardiopulmonary resuscitation in certain circumstances). Legally, this situation has not been tested in the UK in pregnancy. In the USA, pregnant women are specifically excluded from the effectiveness of any such declarations while they are pregnant. Therefore, while a birth plan may be taken into account when deciding on epidural anaesthesia, a woman has the right to deviate from this plan at any stage of her labour and the prudent anaesthetist should obtain as valid a consent as applicable in the particular circumstances at that time.

Human Rights Act 1998

The introduction of the Human Rights Act may result in the definitions of informed consent and negligence being challenged. Obstetric anaesthetists should be familiar with the provisions of the Act. Informed consent will probably change to the model used in the USA in which patients are informed of every risk, no matter how minuscule.

Forced obstetric intervention

The way English Courts have regarded enforced caesarean section cases has developed from the highly paternalistic view taken in *Rochdale Healthcare (NHS) Trust v C* in which the judge held that a woman who was in labour was incompetent to make a decision if she was prepared to accept death rather than undergo a caesarean section. It is now recognized that a woman carrying a fetus is entitled to the same respect as any other woman and that 'refusal of medical treatment can be for any reason, rational or irrational, or for no reason at all.'

Under English law, a fetus has no legal status and this concept has been re-affirmed many times in various cases. There is no justification therefore in acting on behalf of the unborn child in these decisions. It is important that anaesthetists recognize that stringent conditions must be satisfied in order that an enforced caesarean section be undertaken, and that if they provide anaesthesia to a competent woman who is refusing an obstetric intervention, they may be accused of battery. An excellent summary of the law and ethics of enforced caesarean sections in the UK can be obtained from the Royal College of Obstetricians and Gynaecologists' website at *www.rcog.org.uk/guidelines/ethics/ethics.htm.*

Research on pregnant women

Anaesthetists involved in research on pregnant women must ensure that there are no unnecessary risks to the woman or the fetus. Some commentators have suggested that the standards for obtaining ethical committee approval for research involving pregnant women should be more stringent. A full explanation of the research aims should be provided and informed consent obtained from the women involved. Failure to do so may leave the anaesthetist open to charges of trespass and battery.

Analgesia for pregnant women

Resource allocation: anaesthetists should ensure that all women have equal access to the provision of safe analgesia and anaesthesia during labour. In the UK, the Obstetric Anaesthetists' Association and other national bodies have responsibility to ensure that training and anaesthetic service in labour wards are of a uniformly high standard. Some anaesthetists may be involved in resource allocation for their hospital or at a national level. Most healthcare service resource allocation is still provided by the medical profession, which is considered to have a largely male perspective in its approach to women's health issues. Resources should be distributed fairly, in a non-discriminatory manner.

Confidentiality must be maintained at all times. Anaesthetists may be required to submit data to various bodies, such as the National Enquiries into Maternal Death. The duty of confidentiality must be maintained after death and the anaesthetist should ensure that no aspects of the case could identify the woman or the hospital involved.

Analgesia for abortion: anaesthetists may be asked to provide analgesic services for women undergoing third-trimester abortions. Scott argues that it would be 'morally wrong to accept a post knowing that one could not possibly undertake all the duties implied in the job description.' The present author does not think that doctors should be compelled to provide services that go against their own beliefs. Senior anaesthetists involved in the provision of labour ward analgesia services should ensure that no anaesthetist is forced into a situation in which their own moral code may be violated. Alternative anaesthetists should be sought at an early stage to ensure that women receive analgesia without compromising any individual's beliefs. ◆

Failed Intubation in Obstetrics

Samyuktha K Backe
Gordon R Lyons

Samyuktha K Backe is Senior Registrar training in the Northern Ireland Deanery and is currently on a year's sabbatical as a Research Fellow in Obstetric Anaesthesia at St James' University Hospital, Leeds. She qualified from Madras University, India, and trained in anaesthesia in the UK.

Gordon R Lyons is Consultant Obstetric Anaesthetist at St James' University Hospital, Leeds, UK. He qualified from the University of Leeds. His research interests are clinical obstetric anaesthesia,epidural local anaesthetics and thromboelastography in the obstetric setting.

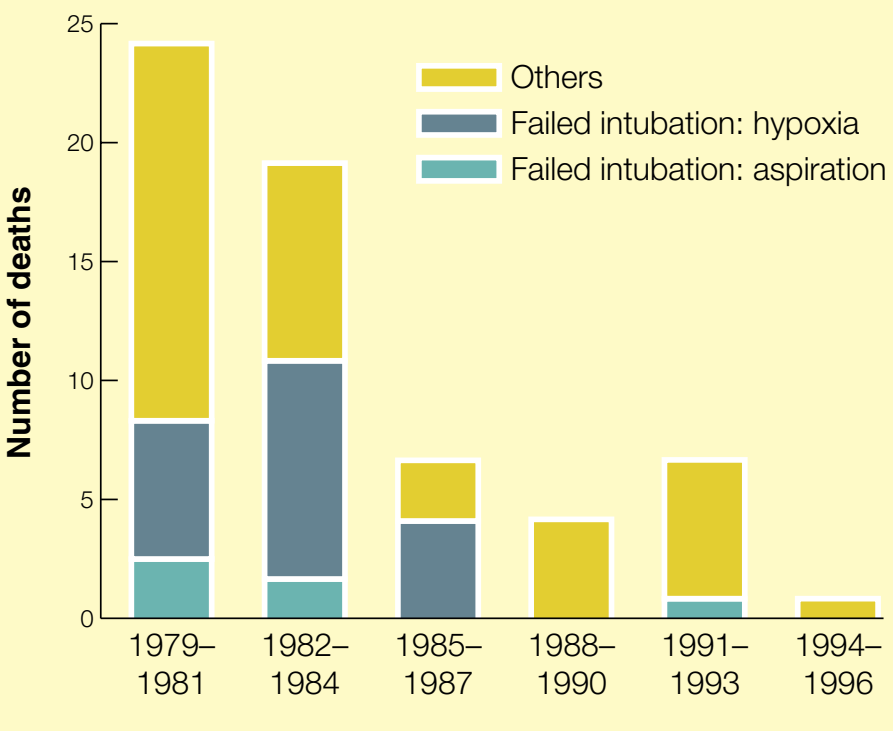
In the UK, between 1979 and 1987, failed intubation was a common cause of direct anaesthetic maternal deaths (Figure 1). In the past 20 years, anaesthetic practice has seen a rise in the use of regional anaesthesia, an increased number of caesarean sections, the routine use of pulse oximetry and capnography and the appointment of anaesthetists with a commitment to obstetrics. Parallel to these changes, anaesthetic maternal mortality has declined sharply.

In practice, the relative impact of the changes on the decrease in maternal deaths is speculative. An audit in the authors' teaching hospital from 1981 to 1999 showed that caesarean deliveries increased from about 400 to 900 per year. Over the same period, the number of general anaesthetics fell from 300 to 20 per year. In the UK, a survey of 31 obstetric units showed a doubling of emergency caesarean section rate since 1982, but the absolute number of general anaesthetics remained about the same. Increasingly, a general anaesthetic is chosen only for women at high risk and only if urgent anaesthesia is required. This suggests that the decrease in maternal deaths related to general anaesthesia is probably due to improved standards of practice rather than simply the increased use of regional techniques.

The incidence of failed intubation in obstetrics is about 1/130–300, which is eight times the rate reported for the general patient population. The obstetric population differs from the surgical population in that it includes young women, mostly with a full set of teeth. Pregnancy is accompanied by changes in physiology that can promote difficulties with intubation, increase the risk of aspiration and accelerate desaturation. Oedema of the larynx due to capillary engorgement and increased total body water in pregnancy is compounded by the venous distension of the head and neck that accompanies the strenuous effort of labour. Pethidine delays gastric emptying and mothers who have had opioids in labour are more likely to present with a full stomach in theatre. Many of these factors coincide, resulting in an urgent general anaesthetic occurring out of hours when organizational weaknesses will be exposed. A full list of contributory factors is given in Figure 2.

The way in which these factors come together can be seen in an imaginary scenario in which an anaesthetic trainee with 18 months' experience is asked to do an emergency caesarean section at night at short notice. The mother is distressed and communication is difficult because she speaks little English. To circumvent problems with communication the trainee elects to give a general anaesthetic. The theatre technician is unfamiliar to the anaesthetist and with the set-up in the obstetric theatre. Overconcern for fetal transmission of the drug leads to the administration of an inadequate dose of thiopental (thiopentone). Cricoid pressure is applied with enthusiasm resulting in a Cormack grade 4 view on laryngoscopy. Multiple attempts at intubation with intermittent pauses to oxygenate follow until more senior help arrives. Further attempts at laryngoscopy coincide with the lightening of anaesthesia and return of muscle tone and regurgitation occurs.

Direct deaths due to anaesthesia in the UK[1]



[1]Data compiled from six confidential inquiries showing a steady decline in maternal anaesthetic mortality. Most deaths are associated with general anaesthesia

1

Factors leading to failed intubation in pregnancy

Causes of increased difficulties of intubation
- Full dentition
- Large breasts due to engorgement and increased body fat
- Increased total body water causing pharyngeal and laryngeal oedema especially in women with pre-eclampsia
- Engorgement of capillary mucosa
- Left lateral tilt, or presence of badly placed wedge
- Poorly applied cricoid pressure

Causes of increased risk of aspiration
- Reduced oesophageal barrier pressure promoting reflux of oesophageal contents
- Opioid administration in labour leading to delayed gastric emptying

Factors leading to accelerated desaturation
- Reduced functional residual capacity which is compounded in the supine position
- Increased maternal oxygen consumption

Organizational issues
- Greater use of general anaesthesia out of hours and for sicker patients
- 24-hour service dependent on less experienced non-consultant staff

2

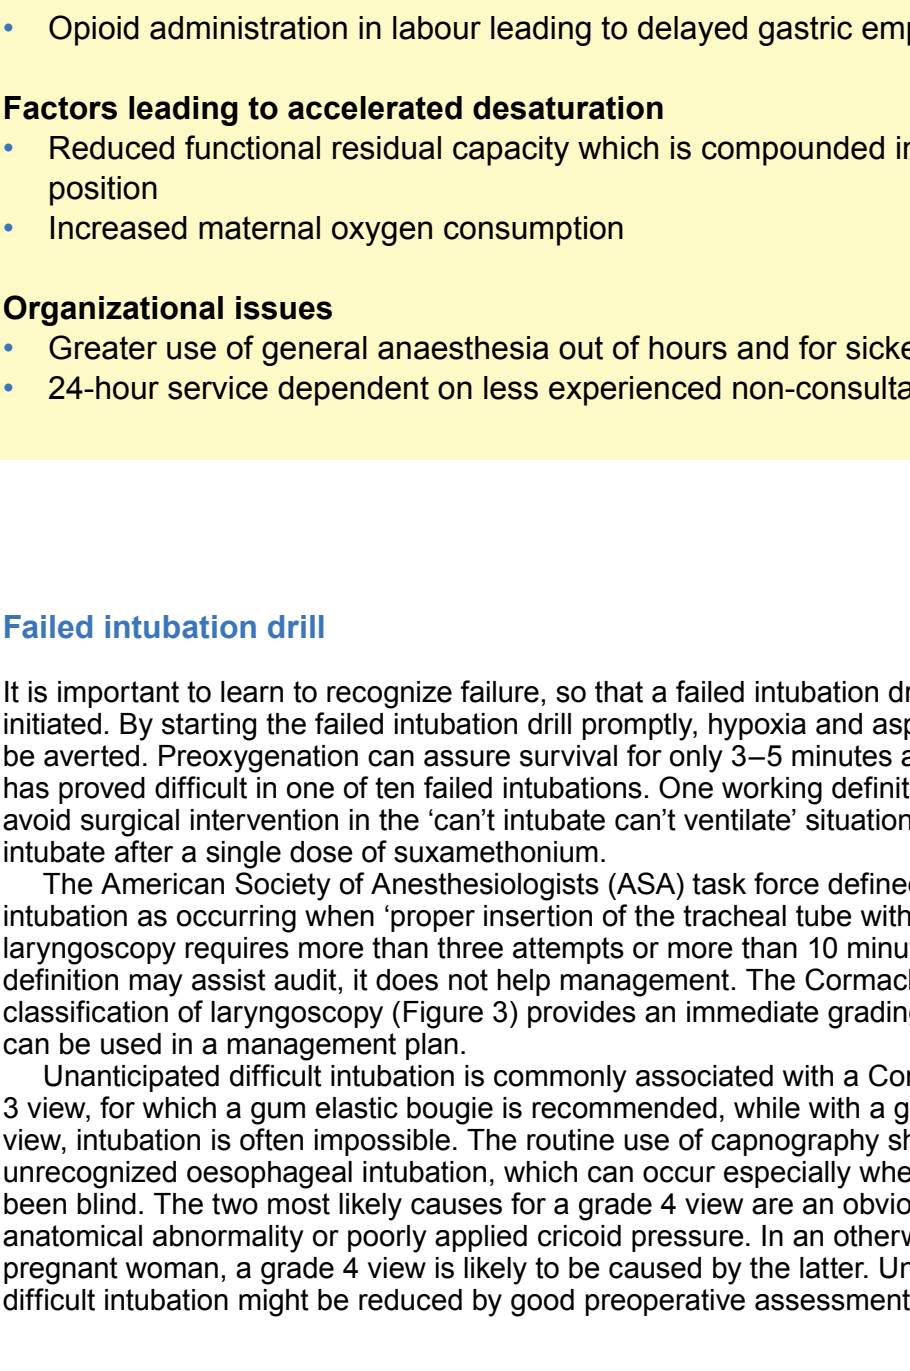
Failed intubation drill

It is important to learn to recognize failure, so that a failed intubation drill can be initiated. By starting the failed intubation drill promptly, hypoxia and aspiration may be averted. Preoxygenation can assure survival for only 3–5 minutes and ventilation has proved difficult in one of ten failed intubations. One working definition, intended to avoid surgical intervention in the 'can't intubate can't ventilate' situation is the inability to intubate after a single dose of suxamethonium.

The American Society of Anesthesiologists (ASA) task force defined difficult tracheal intubation as occurring when 'proper insertion of the tracheal tube with conventional laryngoscopy requires more than three attempts or more than 10 minutes'. While this definition may assist audit, it does not help management. The Cormack and Lehane classification of laryngoscopy (Figure 3) provides an immediate grading of difficulty that can be used in a management plan.

Unanticipated difficult intubation is commonly associated with a Cormack grade 3 view, for which a gum elastic bougie is recommended, while with a grade 4 view, intubation is often impossible. The routine use of capnography should prevent unrecognized oesophageal intubation, which can occur especially when intubation has been blind. The two most likely causes for a grade 4 view are an obvious gross anatomical abnormality or poorly applied cricoid pressure. In an otherwise healthy pregnant woman, a grade 4 view is likely to be caused by the latter. Unanticipated difficult intubation might be reduced by good preoperative assessment.

Difficult intubation algorithm based on view at laryngoscopy (adapted from Cormack and Lehane)



3

Airway assessment

Tests to assess the airway must be easy, rapid, accurate and performable at the bedside. As no test is 100% accurate, higher sensitivity and specificity can be achieved by combining several.

The three most commonly used predictors for difficult intubation are:
- inability to view the posterior pharyngeal wall when mouth is opened wide and tongue protruded
- a thyromental distance less than 7 cm when head is fully extended
- inability to protrude the jaw such that the lower incisors lie in front of the upper incisors.

Frerk predicted difficulty in 14 out of 244 patients in a non-pregnant population using the first two tests. At intubation, 11 proved difficult, of which 9 had been predicted, giving a sensitivity of 81% and specificity of 98%.

Mallampati's original three-tier grading of oropharyngeal view was modified to four by Samsoon and Young with grade 4 representing the most difficult. A significant correlation exists between the Mallampati score and the Cormack and Lehane laryngoscopy view. In 99% of the cases, grade 1 and grade 3–4 laryngoscopic views were associated with class 1 and class 4 airways, respectively. Inter-observer variability can be high, due to phonation, arching of the tongue, and performing the test in the supine position. Wilson's five factors take into consideration the patient's body weight, inter-incisor gap, buck teeth, neck movement and receding mandible. Similar to Mallampati's modified score, it showed a 50% chance of predicting difficult intubation but the inter-observer variability was lower. Other potential risk factors such as short neck and, missing, protruding or single maxillary incisors, have been reported to be significantly associated with difficult intubation.

An assessment that summates anatomical characteristics is more likely to predict problems accurately. If one test is abnormal it cautions the anaesthetist but if two or more are abnormal then appropriate preparation should be made and an awake intubation considered. The high false-positive values of these tests mean that the anaesthetist is often faced with an anticlimax. This is a benign consequence and should not deter clinicians from airway evaluation.

There is no preoperative test with 100% accuracy and the anaesthetist must be prepared for unanticipated difficult intubation. A range of intubation aids should be available. Particularly useful are a short-handled laryngoscope, McCoy laryngoscope and tracheal bougie.

Technique

Tunstall described the first failed intubation drill in 1976. He proposed that if delivery was not urgent, then general anaesthesia should be abandoned, the woman placed in the head-down, left lateral position, and allowed to wake up before proceeding to a regional technique. Urgent delivery proceeded only after stomach emptying with general anaesthesia, using trilene and face mask. Personal experience has taught us that stomach emptying in this situation is not easy and trilene has been replaced by more acceptable and more rapid agents. There are as many expert opinions in management as there are anaesthetists and many modifications of the drill now exist.

A general principle of any drill is that the time of greatest risk is not the time to perform previously unattempted practical procedures. The drill should consist of manoeuvres that are daily events for clinical anaesthetists. Management principles should be based on common sense with the aim of maintaining maternal oxygenation and survival.

Cricoid pressure: general anaesthesia should not be initiated without an anaesthetic assistant who is trained to apply cricoid pressure. Before induction, cricoid pressure is started and is increased firmly to a maximum of 30 Newtons or 3 kg force, which should be sufficient to prevent regurgitation even from a gastric pressure of 40 mm Hg. Forces greater than 40 Newtons, which can be easily misjudged even in trained hands, can lead to airway obstruction, a poor view at laryngoscopy, and difficulty in passing the tracheal tube. Before abandoning intubation it is worth releasing cricoid pressure momentarily to assess if visualization of the airway improves.

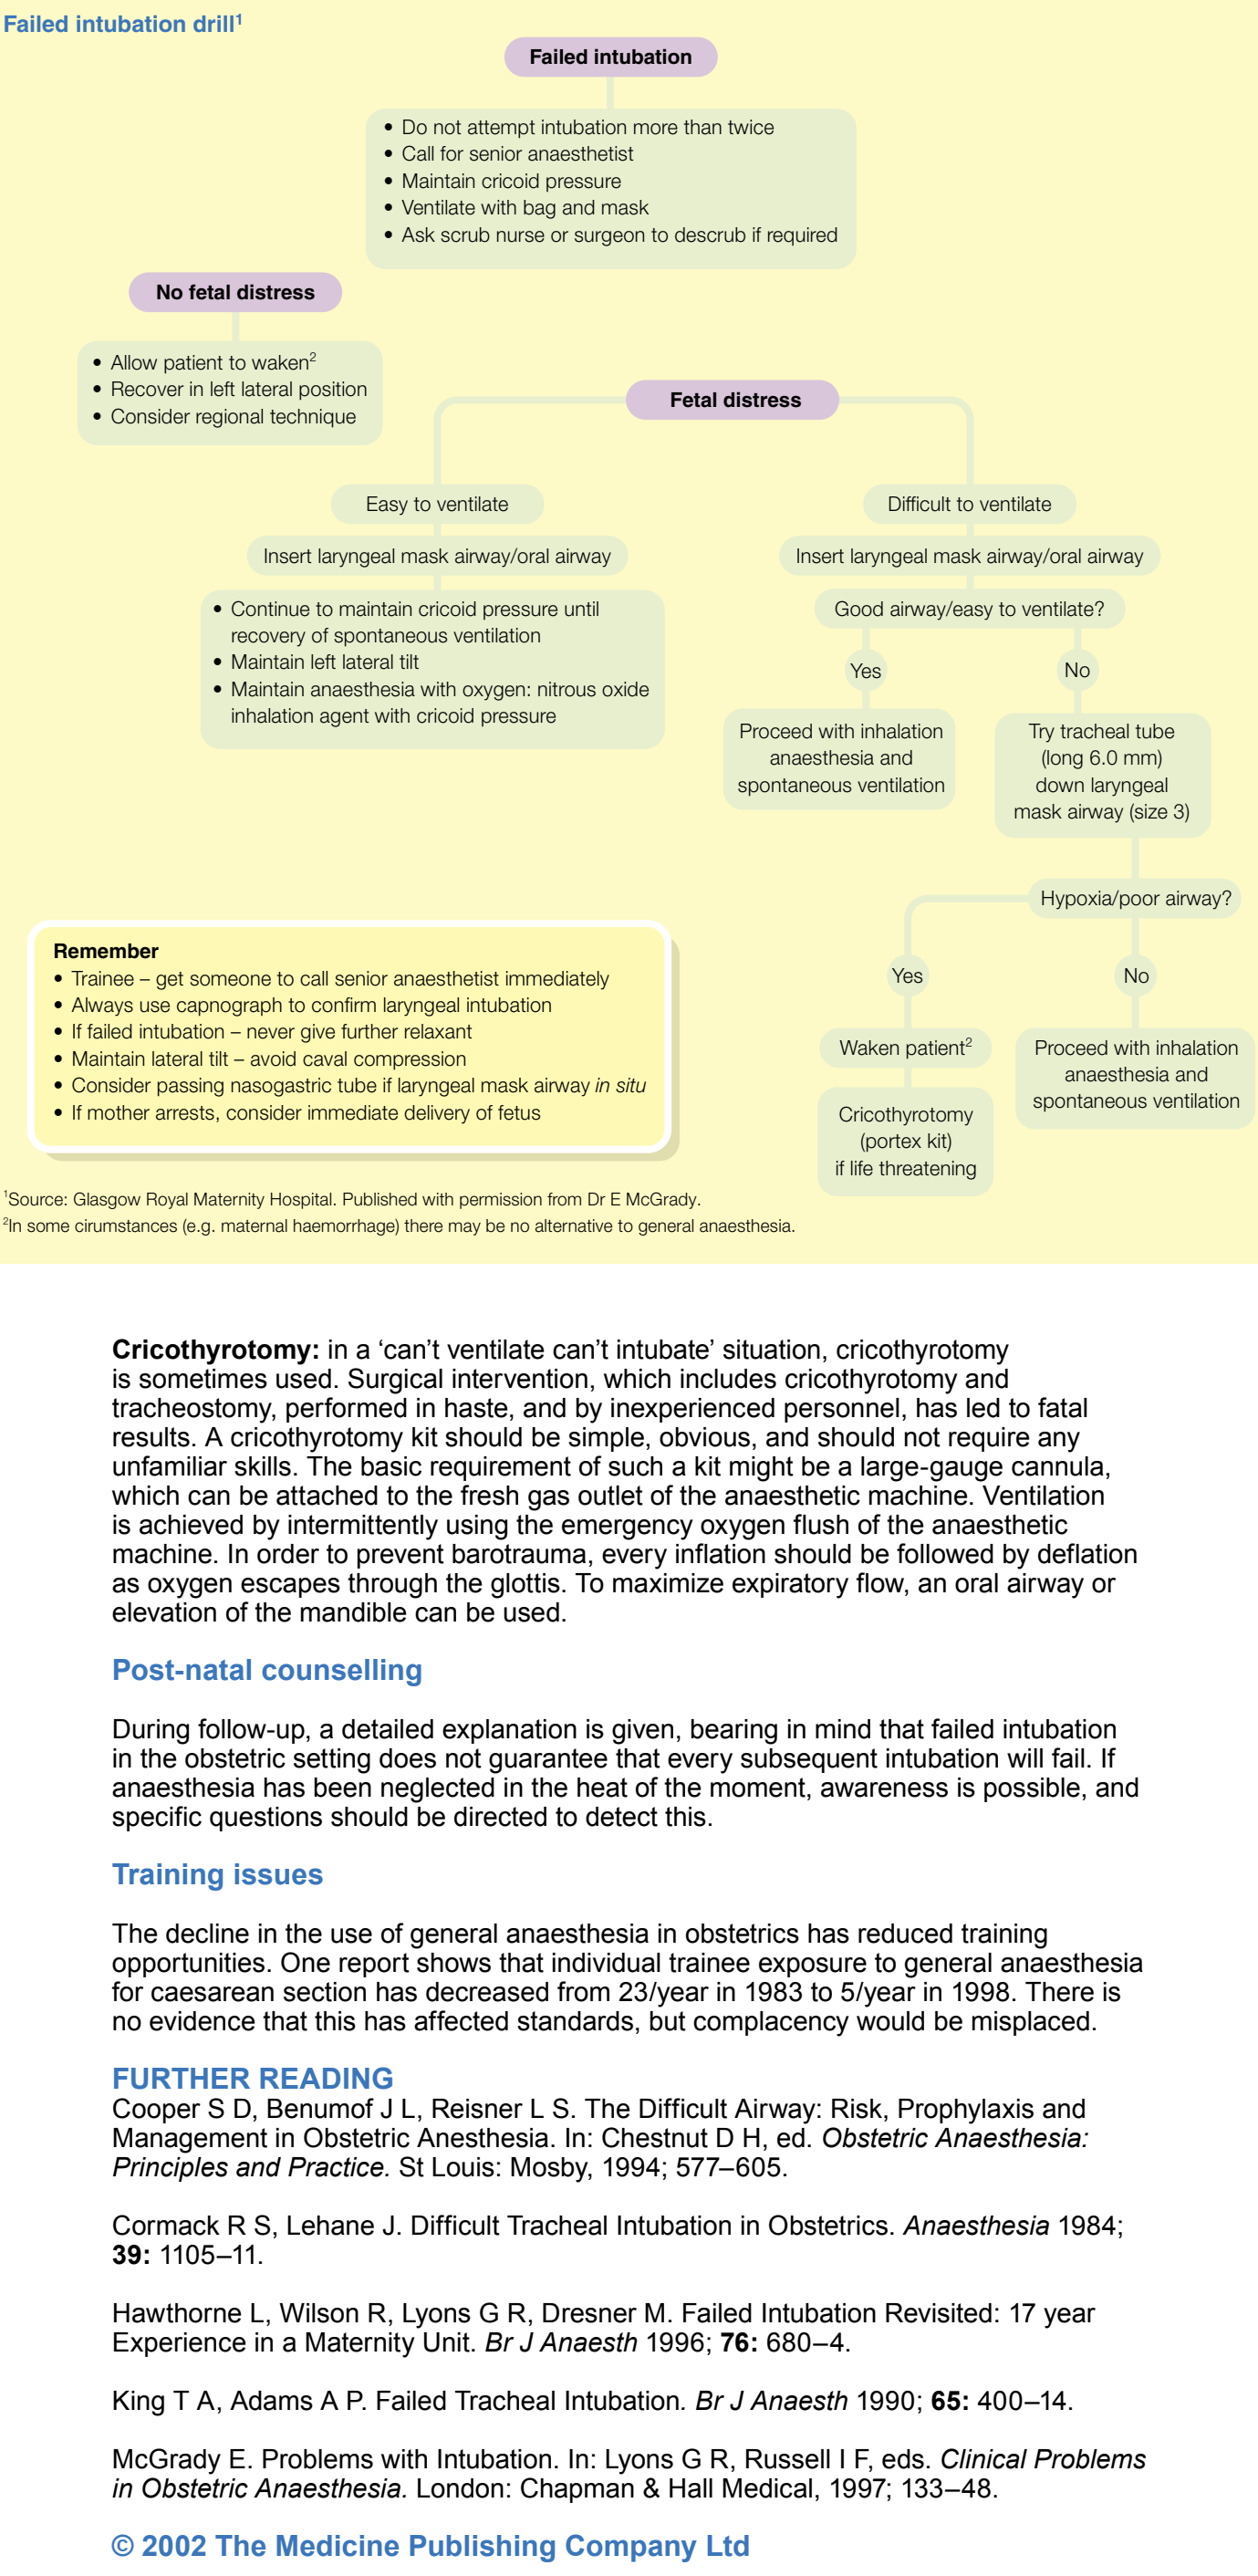
Left lateral position: the original drill advocated the left lateral position. When combined with the head-down position, the mouth is lower than the larynx and pharyngeal pooling will spill out of the mouth before aspiration can occur. If it does occur it is most likely that only one lung will be affected. Cricoid pressure is therefore unnecessary. Also the tongue falls forward resulting in a better airway. However, there are arguments against using the left lateral position.

- Hand ventilation of the patient is more difficult because the counter pressure at the occiput is lost.
- Cricoid pressure cannot be given adequately.
- Surgery or cricothyrotomy is impossible in this position.
- Moving a heavy patient can be difficult.

A balanced practice would be to use the left lateral position if the airway is controlled and a decision has been made to abandon general anaesthesia.

Laryngeal mask airway (LMA): though easy and atraumatic to insert, a LMA does not protect against aspiration, and continuous cricoid pressure interferes with insertion and placement. Without cricoid pressure, the LMA has been used routinely for elective and emergency caesarean section in 224 women with a success rate of 99%. There are reports of successful use of the LMA for failed intubation in caesarean section. On balance, it seems that the LMA should have a place in the drill. Much of the debate is based on arguments that are largely untested and founded either on opinion or anecdote. The only outcome study of failed intubation in relation to caesarean section used cricoid pressure and turned women on their side and head down, in the main without the LMA. All women made a complete recovery. It seems that the measures discussed above are unlikely to make a noticeable change to outcome, and use of any drill is more important than the constituent parts. One example of a failed intubation drill is shown in Figure 4.

Failed intubation drill[1]



[1]Source: Glasgow Royal Maternity Hospital. Published with permission from Dr E McGrady.

[2]In some cirumstances (e.g. maternal haemorrhage) there may be no alternative to general anaesthesia.

4

Cricothyrotomy: in a 'can't ventilate can't intubate' situation, cricothyrotomy is sometimes used. Surgical intervention, which includes cricothyrotomy and tracheostomy, performed in haste, and by inexperienced personnel, has led to fatal results. A cricothyrotomy kit should be simple, obvious, and should not require any unfamiliar skills. The basic requirement of such a kit might be a large-gauge cannula, which can be attached to the fresh gas outlet of the anaesthetic machine. Ventilation is achieved by intermittently using the emergency oxygen flush of the anaesthetic machine. In order to prevent barotrauma, every inflation should be followed by deflation as oxygen escapes through the glottis. To maximize expiratory flow, an oral airway or elevation of the mandible can be used.

Post-natal counselling

During follow-up, a detailed explanation is given, bearing in mind that failed intubation in the obstetric setting does not guarantee that every subsequent intubation will fail. If anaesthesia has been neglected in the heat of the moment, awareness is possible, and specific questions should be directed to detect this.

Training issues

The decline in the use of general anaesthesia in obstetrics has reduced training opportunities. One report shows that individual trainee exposure to general anaesthesia for caesarean section has decreased from 23/year in 1983 to 5/year in 1998. There is no evidence that this has affected standards, but complacency would be misplaced.

Maternal Analgesia, Anaesthesia and the Fetus

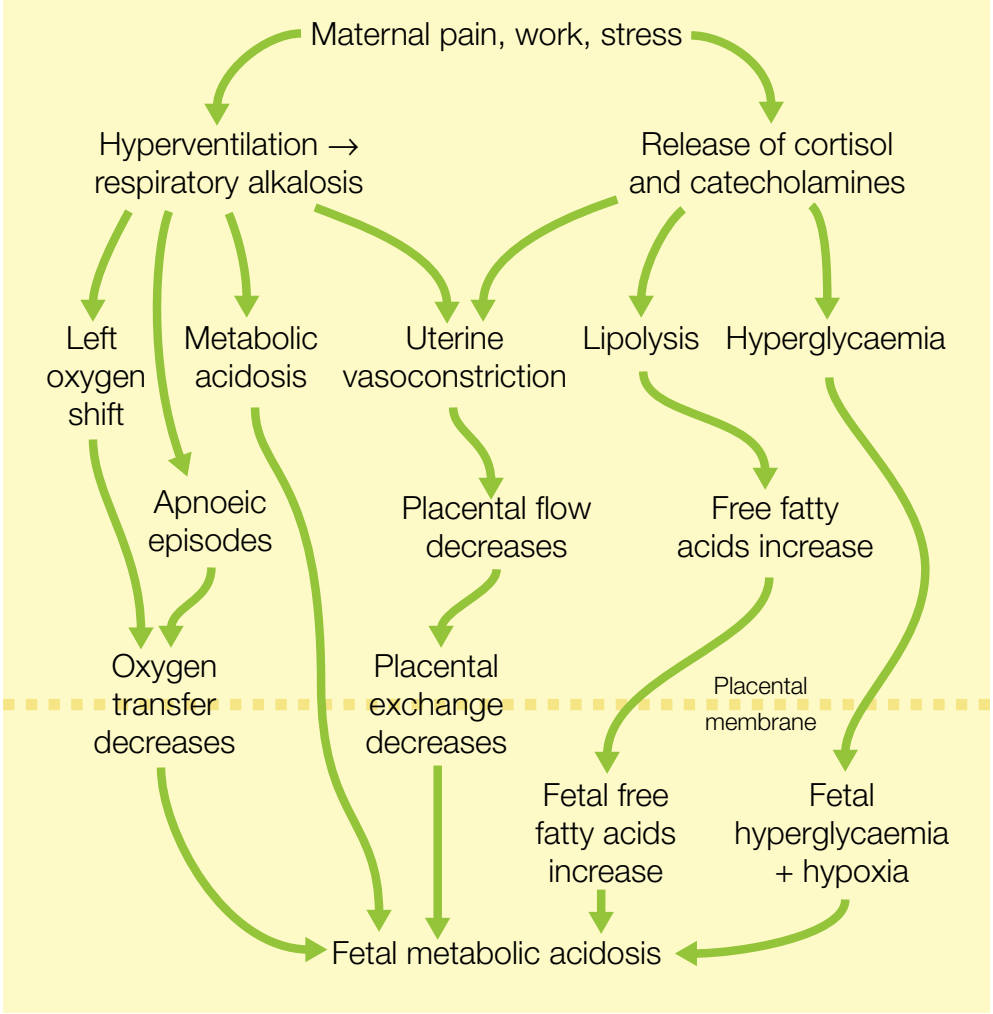
Felicity Reynolds

Felicity Reynolds is Emeritus Professor of Obstetric Anaesthesia at St Thomas' Hospital, London. She has published four books and over 200 articles on obstetric analgesia, placental drug transfer and related topics. She was awarded the FRCOG in 1995. Since retirement she has continued with writing, editing and clinical research.

Although natural labour is painful, such pain has little value and is potentially detrimental to the fetus. Some mechanisms for this detriment are outlined in Figure 1. Reducing labour pain is therefore of potential benefit to the baby.

Drugs given to a parturient may have a direct effect on the baby after crossing the placenta, and an indirect effect via changes in maternal physiology and biochemistry. Systemic analgesia depends on an effective concentration of drug in the maternal blood. Since any compound that crosses the blood–brain barrier also crosses the placenta, such an approach is likely, given time, to affect the fetus as well as the parturient. Regional analgesia does not depend for its effect on the presence of analgesic drug in the maternal circulation, therefore a direct drug effect on the baby is less likely. However, regional analgesia may produce changes in maternal physiology or biochemistry that can affect the baby indirectly. It is seldom appreciated that regional analgesia, properly handled, is not only more effective than systemic analgesia, but also safer for the baby.

Potential adverse effects of maternal labour pain on the fetus



1

Placental drug transfer

Drugs used for anaesthesia and analgesia cross the placenta by passive diffusion. In this respect the placenta behaves like other lipid membranes, allowing lipophilic particles up to a molecular weight of 600–1000 (encompassing most drugs but not plasma proteins) and polar substances up to 60–100 to cross readily. Therefore, drugs used to provide systemic and regional analgesia cross the placenta readily in the unbound and non-ionized state, while hydrophilic substances such as neuromuscular blocking drugs, diffuse slowly and are unlikely to attain effective concentration in the fetus.

The transplacental distribution of lipophilic substances, whose unbound and non-ionized moiety equilibrates readily across the placental membrane, is influenced by the trans-placental gradient for pH and binding protein (Figure 2). As fetal plasma pH is lower than maternal, free base tends to concentrate on the fetal side due to ion trapping, the reverse being true for weak acids. This increases the exposure of the acidotic fetus to basic drugs such as opioid analgesics and local anaesthetics.

Acidic drugs are bound mainly to albumin, which shows little transplacental gradient. While a few basic drugs are also bound to albumin, the principal binding protein is α_1-acid glycoprotein, the concentration of which is variable, but always much lower in fetal than in maternal plasma. Figure 3 shows the physicochemical properties and characteristic equilibrium fetal:maternal ratios of some basic drugs, with antipyrine, which is neither ionized nor protein-bound, for comparison. For drugs mainly bound to α_1-acid glycoprotein, equilibrium fetal:maternal ratio is inversely related to binding. Figure 2 illustrates how such a ratio may be predicted. Although diffusion is no bar to the transfer of lipophilic drugs, the fetal compartment is deep, and equilibration takes longer in fetal than in maternal tissues. Fetal exposure is therefore dependent on blood flow on either side of the placenta (so-called flow-dependent transfer), equilibrium ratios and duration of maternal exposure.

Although the immediate effect of the drug is related to the concentration of the free moiety, a large albumin-bound component represents a storehouse for the newborn. Albumin binding, moreover, tends to decline in the first postnatal days, thereby exacerbating the many adverse effects of a drug such as diazepam.

Placental transfer of hydrophilic substances is slower, permeability-dependent and inversely related to molecular size. Thus, if given in normal doses during general anaesthesia for caesarean section, neuromuscular blocking drugs do not achieve effective concentrations in fetal plasma. Even if polar compounds are given to a mother over a long period, they never reach high concentration in fetal plasma because they are rapidly excreted by the kidney and accumulate instead in amniotic fluid.

Calculation showing how pH and binding protein gradient affect the fetal:maternal total drug concentration ratio illustrated using data for bupivacaine

Bupivacine pK_a 8.1

Mother	Fetus
Protein binding 95%	Protein binding 80%
pH 7.4	pH 7.25
pK_a – pH = + 0.7	pK_a – pH = + 0.85
Base [1] ⟷	Base [1]
↑↓	↑↓
Cation [5]	Cation [7]
Total free = [6]	Total free = [8]
(bound = 19 x free)	(bound = 4 x free)
Therefore: bound = 114	Therefore: bound = 32
Total = 120	Total = 40

Ratio of umbilical venous to maternal venous concentration (UV/MV) = 0.3

Only free base is assumed to diffuse readily. The Henderson–Hasselbalch equation is used to calculate the relative concentrations of cation and base on the two sides of the placenta

2

Physicochemical and pharmacokinetic characteristics of some basic drugs

	Molecular weight	pK_a[1]	Partition coefficient[2]	Adult protein binding (%)	Fetal:maternal ratio
Antipyrine	188	1.5	1.7	0	1.0
Pethidine	251	8.5	20	60[4]	→1→[3]
Lidocaine (lignocaine)	234	7.9	39	75[4]	0.55
Alfentanil	416	6.5	70	91[4]	0.3
Bupivacaine	288	8.1	250	94[4]	0.3
Diazepam	285	3.4	310	95[5]	2.0
Fentanyl	336	8.4	550	88[5]	1

[1]The higher the pK_a the stronger the base.
[2]Approximate oleyl alcohol/buffer partition coefficient.
[3]The fetal:maternal plasma ratio for pethidine rises with time to exceed unity in 3 hours or more.
[4]Principally bound to α_1-acid glycoprotein.
[5]Diazepam is bound principally to albumin and fentanyl to a mixture of plasma proteins.

3

Systemic opioid analgesia

Most studies of the fetal and neonatal effects of maternal systemic opioid analgesia relate to pethidine, which is the most widely used agent. It may cause loss of short-term variability in the fetal heart trace, and reduced muscular activity, aortic blood flow and oxygen saturation, largely via a direct effect. Pethidine exacerbates the episodes of maternal haemoglobin desaturation that normally occur during labour, which may contribute indirectly to its detrimental fetal effects.

Large doses of pethidine are associated with low Apgar scores, while minor degrees of neonatal depression from smaller doses may be undetected by this method of assessment. Nevertheless, even small doses depress neonatal respiration. Neurobehavioural scores are usually reduced while all neonatal effects are reversed by giving naloxone to the baby. Detrimental effects may last for 72 hours or more after delivery and are attributed principally to accumulation of norpethidine. Fetal:maternal ratios of pethidine rise with time after intra-muscular administration (Figure 3), and maximal fetal exposure occurs if pethidine is given to the mother 3–4 hours before delivery, while effects are barely discernible if it is given only within 1 hour of birth.

There are few important differences between pethidine and other opioid analgesics, though it has been claimed that meptazinol produces less neonatal depression. Morphine and diamorphine may not be as dangerous for the baby as was once supposed. Fentanyl, and more recently remifentanil, have been used systemically in labour with less neonatal detriment than is seen with pethidine.

It is probably logical to administer naloxone to every baby whose mother has received opioid analgesics during labour.

Nitrous oxide

Nitrous oxide is not only a slightly less ineffective analgesic in labour than pethidine, it is also less cumulative and less harmful to the baby, who can excrete it via the lungs once born. Nevertheless, in an attempt to obtain maximum analgesia from it, a parturient's natural tendency to hyperventilate during contractions may be encouraged, resulting in hypoventilation and consequent desaturation between contractions, thus potentially exacerbating the detrimental fetal effects outlined in Figure 1. When nitrous oxide is combined with 50% oxygen as *Entonox*, the oxygen may partly offset this effect, though if supplementary oxygen is needed to treat a distressed fetus, administration should be continuous rather than intermittent. Prolonged administration of nitrous oxide is associated with inhibition of the enzyme methionine synthase, a theoretical risk for the fetus.

Despite these theoretical disadvantages, maternal analgesia using 50:50 nitrous oxide and oxygen during labour has not been shown to produce any obvious neonatal detriment.

Adjuncts to nitrous oxide analgesia: to improve analgesia during labour, subanaesthetic concentrations of various volatile inhalational agents (trichloroethylene, methoxyflurane, enflurane and currently isoflurane) have been tried, alone or in conjunction with nitrous oxide. There is some gain in analgesic efficacy, with little obvious neonatal detriment, though higher concentrations have caused neonatal sedation.

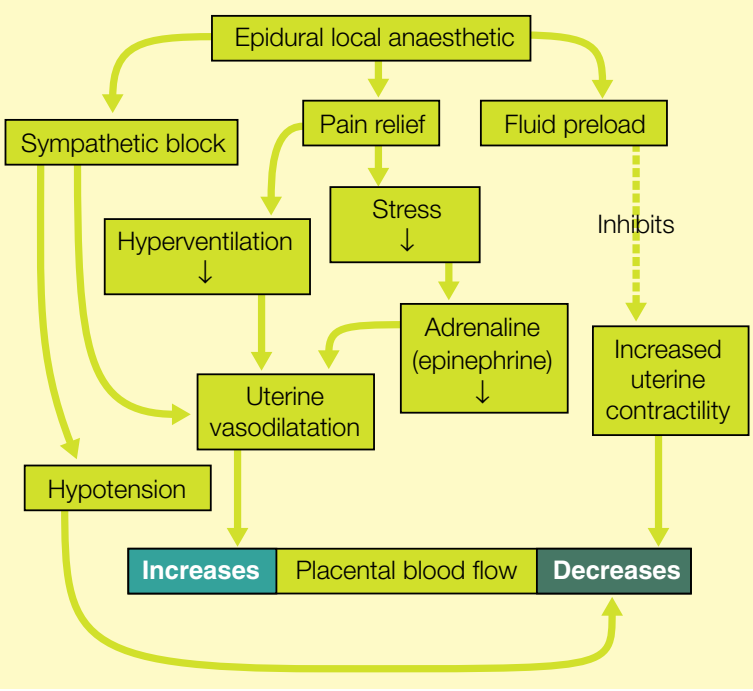
Regional analgesia

Direct effects
Adverse direct drug effects on a baby are likely to be observed only if maternal systemic effects reach a detectable threshold. Thus, when lidocaine (lignocaine) was used to provide continuous epidural analgesia, toxic effects were observed in both mother and baby. The longer action of correctly sited bupivacaine denotes slow absorption and thus favours a local over a systemic effect; the latter is usually observed only after accidental intravenous administration. Although opioids are well recognized to produce direct fetal and neonatal depression when used systemically, their potential to do so when used for regional analgesia is more debatable.

Indirect effects

Following regional analgesia, indirect effects are more likely to be clinically important. Regional blockade, as the only reliable form of labour analgesia, can block the detrimental fetal effects of pain shown in Figure 1. It does, however, have circulatory effects that may be beneficial or otherwise and are summarized in Figure 4. Provided maternal aortocaval compression and hypotension are avoided, the occurrence of a significant increase in maternal placental flow following epidural local anaesthetic is well documented, and is particularly consistent in the presence of pre-eclampsia. With correct management of the mother, adverse fetal effects are unlikely. Although regional analgesia may prolong labour, there is no evidence that this is harmful to the fetus.

Mechanisms by which central neural blockade with local anaesthetic may affect placental blood flow



4

Fetal heart rate

The value of continuous fetal heart rate monitoring in labour is often questioned, but cardiotocography is usually considered mandatory for mothers receiving regional analgesia. As a consequence, numerous fetal heart changes have been observed after the institution of epidural and intrathecal analgesia. Recently, loss of short-term variability, decelerations and major bradycardias have been reported following opioids, particularly given intrathecally. In randomized studies, however, such changes are no more common than after epidural bupivacaine, while meta-analysis of controlled trials shows that fetal heart abnormalities are no more common after epidural than after systemic opioid analgesia.

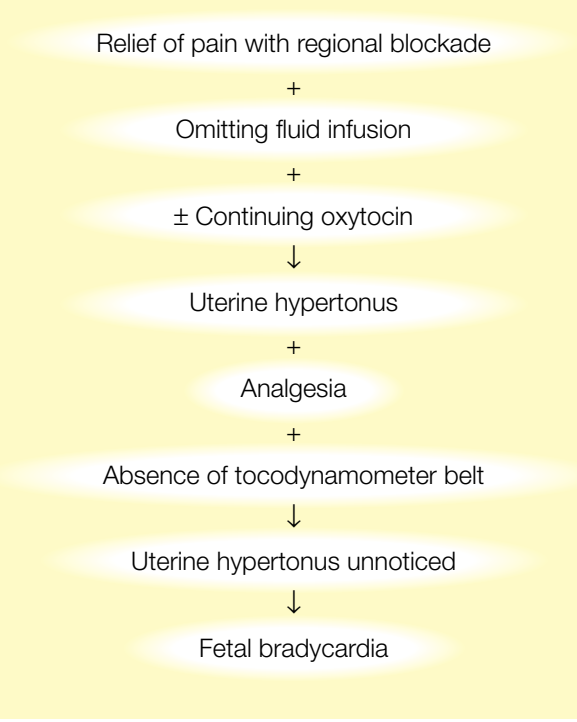
Fetal bradycardia has been associated with the rapid onset of analgesia, and various mechanisms have been considered to explain this, even though a causal relationship has not been established. Maternal placental flow ceases during a uterine contraction. At least some of the bradycardias in question are associated with uterine hypertonus, which is thought to result from a decline in the circulating adrenaline (epinephrine) concentration, itself a myometrial inhibitor (Figure 4). Direct fetal effects from the opioids (unlikely with intrathecal doses), plus maternal hypotension and hypoventilation are possible factors, though unlikely to be unnoticed.

Several points should be borne in mind.

- If local anaesthetic is omitted in the loading dose, and intrathecal opioid given alone, then there will be no sympathetic blockade to cause uterine vasodilatation (Figure 4).
- Fluid infusion before inducing regional analgesia has become less fashionable. A fluid preload has been shown to inhibit uterine contractions and to reduce the incidence of fetal heart decelerations. Uterine hypertonus is, therefore, theoretically more likely to occur in the absence of preload.
- Although a good midwife will continue to monitor the fetal heart, the external tocodynamometer belt is commonly removed before siting an epidural needle. Unless the belt is replaced quickly after the procedure, with the onset of analgesia uterine contractions will be undetected.
- There are occasions when the obstetrician is keen to continue the administration of oxytocin without a break. This should be resisted during epidural insertion in order to avoid the adverse situation outlined in Figure 5.

Whether such cardiotocographic changes are associated with adverse neonatal outcome is unsure, but at times decelerations have been so prolonged as to prompt caesarean section. Provided the changes are brief and do not reflect poor placental perfusion resulting from uterine hypertonus, maternal hypotension or aortocaval compression, their presence is probably irrelevant to fetal outcome.

Administration of oxytocin



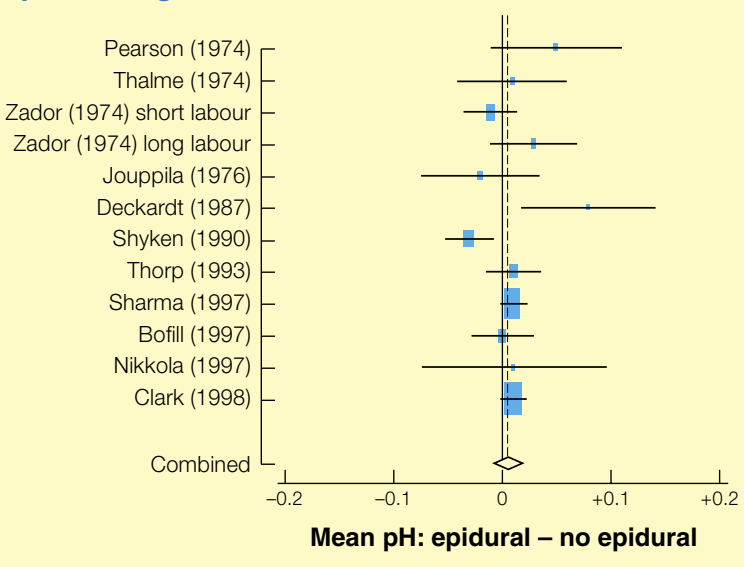
5

Fetal and neonatal acid–base status

Cord blood gas and acid–base balance reflect *in utero* status but give little indication of a newborn's ability to sustain adequate respiration and circulation. Umbilical vein values reflect placental exchange, while umbilical artery values indicate the status of fetal tissue more accurately, though the two are closely related.

Normal labour, associated as it is with maternal pain, stress and tension, may cause progressive maternal respiratory alkalosis and metabolic acidosis (Figure 1). These changes tend to be mirrored in the fetus, while any reduction in placental exchange may increase the transplacental gradient for oxygen, [H^+] and fixed acids. This gradient is also increased during the second stage, particularly with expulsive efforts. Alleviating pain, therefore, has a variable effect on fetal pH, but base excess is more consistently improved. This is confirmed by meta-analysis of trials comparing epidural with systemic opioid analgesia (Figure 6), which also suggest a protective effect of epidural analgesia in long labour.

Meta-analysis of urinary artery pH and base excess in controlled trials of epidural versus systemic opioid analgesia



Mean pH: epidural – no epidural

Uterine artery pH in 12 trials. There was no significant difference between the results of randomized and non-randomized trials, or between the two treatments.

Base excess: epidural – no epidural

Uterine artery base excess data from seven trials. There is a significant difference between the two treatment groups, favouring epidural analgesia.

Both meta-analyses conducted and figures constructed by Paul T Seed of the Department of Public Health Sciences, Guy's, King's and St Thomas' School of Medicine, King's College, London. Reproduced, with permission of the publishers, from: Reynolds F, Porter J. Neonatal Effects of Regional Analgesia. In: Reynolds F, ed. *Regional Analgesia in Obstetrics: A Millennium Update.* London: Springer, 2000: 237–52.

6

Apgar score

Apgar score is strongly influenced by the intrauterine environment and can be used only during the first 10 minutes of life, which is a highly stimulating time for the newborn, so subtle degrees of neonatal depression may be undetected. Nevertheless, meta-analysis of controlled trials showed that there were significantly fewer low Apgar scores at both 1 and 5 minutes with epidural than with systemic opioid analgesia.

Neurobehavioural assessments

Over the years, various tests have been developed to assess the newborn further into the postnatal period. The most popular with anaesthetists – the neurological and adaptive capacity score (NACS) – may not be the most sensitive or reliable. Studies have shown epidural local anaesthetic to be associated with neurobehavioural scores that are variously lower, similar or higher than systemic or no analgesia, while meta-analysis of randomized trials revealed no significant difference in NACS scores between epidural bupivacaine and systemic opioid analgesia, though slightly favouring babies in the epidural group.

Similarly variable results are seen when plain bupivacaine is compared with low-dose combinations of local anaesthetic and opioid. Dose-related effects have been demonstrated for epidural sufentanil and alfentanil, but not for fentanyl, though its use has been occasionally associated with slightly reduced NACS.

Neonatal respiration

Epidural analgesia using bupivacaine, unlike systemic pethidine, is not associated with any depression of neonatal respiration, but the question arises whether neuraxial opioids might reintroduce this danger. Painstaking studies of neonatal respiration have not revealed any obvious detriment from epidural fentanyl infusion, although unnecessarily large doses of neuraxial opioid by bolus or infusion should probably prompt neonatal naloxone administration.

Maternal anaesthesia

It is generally agreed that regional anaesthesia is not only safer than general anaesthesia for the mother but also preferable for the sake of the baby. This is largely true, although with carefully conducted anaesthesia there may be little to choose between them.

General anaesthesia

All general anaesthetic drugs, whether used for induction or maintenance, will accumulate in fetal tissues for about 20–40 minutes, thus if surgery is delayed or prolonged, the baby may be born sedated. This is of little importance, however, compared with asphyxia. It is therefore more important for the baby that the mother receiving general anaesthesia should be induced in a calm stress-free environment, with adequate doses of all agents. Awareness represents a further major stress – potentially far more damaging to the fetus than a little fully reversible anaesthesia.

Propofol is unsuitable for induction of anaesthesia before operative delivery. Too small a dose risks maternal awareness with all its attendant dangers, too big a dose depresses the fetus more than thiopental (thiopentone), and an intermediate dose risks both maternal awareness and neonatal depression.

Regional anaesthesia
Regional anaesthesia has been associated with higher Apgar scores and less neonatal acidosis than general anaesthesia after both elective and emergency caesarean section, but nowadays the difference may be slight. Interestingly, in most comparative studies, neonatal acidosis is more severe with spinal than with epidural anaesthesia. For epidural use, bupivacaine is likely to be safer for the baby than lidocaine (lignocaine), but details of anaesthetic technique may be of less importance to neonatal welfare than other factors.

Other factors in neonatal well-being
Other factors to be considered in neonatal well-being are:
- aortocaval compression – to avoid this a wedge may be better able to produce something approaching the prescribed 15° left tilt than tilting the table (most tables only reach 10° tilt)
- maternal circulatory status – prolonged maternal hypotension may result in fetal acidosis
- maternal oxygen and carbon dioxide tension
- maternal stress
- slow surgery – particularly uterine incision to delivery interval
- fetal status before starting the procedure.

Catherine Nelson-Piercy

Hassan A Shehata is Consultant and Senior Lecturer in Obstetric Medicine at Epsom and St Helier Hospital, Surrey. He qualified from Khartoum University, Sudan, and trained in general obstetrics and gynaecology in the South West Thames Region based mainly at St George's Hospital, London. He trained in obstetric medicine at St Thomas' Hospital. His research interest is in haematological problems in pregnancy and he is currently involved in a study of carbohydrate metabolism in pregnant women with obstetric cholestasis.

Catherine Nelson-Piercy is Consultant Obstetric Physician at Guy's and St Thomas' Hospitals and Whipps Cross Hospital, London. She qualified from Cambridge University and St Bartholomew's Hospital, London, and trained in obstetric medicine at Queen Charlotte's and University College Hospitals, London. Her research interests include obstetric cholestasis, thromboembolism and hyperemesis.

In the most recent Report on Confidential Enquiries into Maternal Deaths in the UK covering 1994−1996, the leading causes of direct maternal deaths are thromboembolic disease (46 patients), hypertension (20), early pregnancy loss (14), haemorrhage (12), amniotic fluid embolism (17), genital tract sepsis (14) and death from anaesthesia (1). This pattern shows little change from the previous triennium. Heart disease (28) is a major cause of indirect death. Other causes of indirect death include epilepsy (19) and asthma (3).

Thromboembolic disease

In the UK, thromboembolic disease remains the leading cause of maternal mortality, accounting for 36% of direct deaths. The rate was 2.1 deaths per 100,000 maternities in 1994−1996 and is increasing. Thromboembolic disease may occur at any gestation, and healthcare professionals should have a low threshold for investigating leg or chest symptoms in pregnant women.

A thromboembolic event occurs in 1/1500 pregnancies. Antenatal deep vein thrombosis (DVT) occurs in 0.06−0.09% of pregnancies, being twice as common in women over 35 years. In the puerperium DVT is also related to maternal age and mode of delivery. Pulmonary emboli are more common in the puerperium, especially following caesarean section.

Physiological changes of the coagulation system in pregnancy: the risk of thromboembolic disease is increased six-fold in pregnancy. There is an increase in coagulation factors I (fibrinogen), V, VII, VIII, IX, X, XII, von Willebrand factor antigen and ristocetin cofactor activity and a decrease in some endogenous anticoagulants (antithrombin, protein S and activated protein C ratio) which is most marked near term and following delivery. Fibrinolysis is impaired during pregnancy.

Peripheral vasodilatation occurs in normal pregnancy, resulting in a marked fall in velocity of blood flow. This fall is most marked in women undergoing caesarean section. It also occurs to a greater extent in the left femoral vein compared with the right. This is secondary to compression of the left iliac vein by the right iliac artery and the ovarian artery, which cross the vein only on the left side, leading to the predominance of left-sided (85%) DVTs in pregnancy.

Management

Ante-partum: every pregnant woman's risk of thromboembolic disease should be assessed at booking, by establishing whether she has a personal or family history. In addition, every pregnant woman who enters a high-risk situation should have her risk re-evaluated. Prophylactic treatment for thromboembolic disease should be offered to women at high risk. Women who have experienced a thrombosis during pregnancy should be closely followed up, preferably by a doctor with an interest in the management of thrombosis in pregnancy.

Previous thromboembolic event −women who have had a single previous thromboembolic event, have no family history and a negative thrombophilia screen should take aspirin, 75 mg/day, throughout pregnancy and low molecular weight heparin (LMWH) at a thromboprophylactic dose (e.g. dalteparin sodium, 5000 U/day subcutaneously) from the onset of labour until 6 weeks post-partum. Women who have had more than one thromboembolic event or who have had a single event but have a positive family history or thrombophilia screen should take prophylactic LMWH from early pregnancy until 6 weeks after delivery.

Positive thrombophilia screen − increasingly, women discover they have a thrombophilia when a family member is screened. The risk of thrombosis in the presence of thrombophilia is lower in those with a family rather than a personal history of thromboembolic disease. It may be appropriate to give low dose aspirin antenatally. Thromboprophylaxis should be determined on an individual basis, but these women require LMWH if they undergo caesarean section.

High-risk obstetric guidelines − in 1995, the Royal College of Obstetricians and Gynaecologists issued guidelines relating to thromboprophylaxis in pregnancy, including treatment following caesarean section (Figure 1). Each unit should have a locally agreed policy, based on these guidelines, which is strictly adhered to. Many hospitals give thromboprophylaxis to most, if not all, women undergoing caesarean section.

Acute episodes− it is essential to confirm or exclude a diagnosis of thrombosis with objective testing. Data from non-pregnant individuals suggest that 16% of patients with untreated DVT develop pulmonary embolus, and 13% of these die, though anticoagulation reduces the risk. Thus, a positive diagnosis of thrombosis requires immediate management, but because the treatment is not without risk, it is vital that the diagnosis is confirmed.

Chest radiography seldom diagnoses pulmonary embolism but may reveal other causes of dyspnoea or chest pain. It should not be withheld solely because of the pregnancy, and can be performed with the knowledge that the amount of radiation is negligible (Figure 2).

Arterial blood gas analysis should be performed in the sitting or left lateral position because in the supine position, inferior vena caval compression by the gravid uterus and functional reduction in pulmonary residual capacity and closing volume may give a false impression of hypoxia. In uncomplicated pregnancy, the partial pressure of oxygen is unchanged or increased, compared with the non-pregnant situation, but falls by about 2 kPa (17 mm Hg) when lying supine. The partial pressure of carbon dioxide in normal pregnancy falls from 5 kPa (35−40 mm Hg) to 4 kPa (30 mm Hg).

ECG lacks specificity, but shows a sinus tachycardia if pulmonary embolism is present. D dimers may be elevated in pregnancy as a result of the prothrombotic changes that occur and are therefore unreliable. There should be a low threshold for performing Doppler ultrasound of the femoral veins or lung ventilation and perfusion scanning (Figure 2).

If a DVT or pulmonary embolus is diagnosed (or strongly suspected), anticoagulation with heparin should be commenced. Warfarin should not be used in the first-line management of thromboembolic disease in pregnant women: it is teratogenic in the first trimester, increases the risk of miscarriage and stillbirth, anticoagulates the fetus and increases the risk of spontaneous haemorrhage (especially intracerebral) *in utero*. Both, heparin and warfarin are safe during lactation.

When an intravenous infusion of unfractionated heparin is used for acute treatment, chronic-phase treatment is commenced after 5−7 days. This is given traditionally as unfractionated heparin 10,000 U b.d. subcutaneously, because the standard non-pregnant dose of 5000 b.d. is insufficient. LMWH is effective and safe in pregnancy, and it is used for treatment and prophylaxis. If used for treatment, it is continued in therapeutic doses to complete 6−12 weeks of therapy depending on individual circumstances and local policy. It is then replaced by a once daily prophylactic dose of LMWH (e.g. enoxaparin, 40 mg, dalteparin sodium, 5000 U, tinzaparin, 50 U/kg) which is continued until 6 weeks postnatally. For pulmonary embolism or extensive iliofemoral DVT, intravenous unfractionated heparin may be used as first-line treatment in the acute phase until there is enough evidence for the efficacy of LMWH in pregnancy in these circumstances.

Thromboprophylaxis at caesarean section

Definition	Management
Low risk	
• Elective caesarean section • Uncomplicated pregnancy • No other risk factors	Early mobilization Good hydration
Moderate risk	
• Emergency caesarean section in labour • Age (> 35 years) • Obese (> 80 kg) • Gross varicose veins • Current infection • Pre-eclampsia • Immobilization before caesarean section for more than 4 days • Major current illness (e.g. heart or lung disease, inflammatory bowel disease, nephrotic syndrome, diabetes)	Prophylactic stockings for thromboembolic disease or subcutaneous heparin
High risk	
• Three or more moderate risk factors • Extended abdominal or pelvic surgery (e.g. caesarean hysterectomy) • Personal or family history of thromboembolic disease • Positive thrombophilia • Paralysis of lower limbs	Prophylactic stockings for thromboembolic disease plus subcutaneous heparin (commencing during caesarean section and continuing for 5 days)

Estimated radiation to the fetus and increased risk of childhood cancer following common diagnostic procedures[1]

Investigation	Estimated radiation to the fetus (mGy)	Probability of fatal cancer to age 15 years
Conventional radiograph		
• Chest	0.01	< 1/1,000,000
• Pelvis	1.1	1/300,000
• Skull	0.01	< 1/1,000,000
• Spine	1.7	1/20,000
CT		
• Chest (including spiral CT)	0.06	1/560,000
• Pelvimetry	0.2	1/170,000
Nuclear medicine		
• Lung perfusion (technetium 99m)	0.2	1/170,000
• Lung ventilation (technetium 99m)	0.3	1/110,000

[1]The baseline UK national risk for cancer in the first 15 years of life is about 1/650, of which 50% is fatal.

Intra-partum: it is important to have a clear delivery plan including every possible emergency situation. The plan should be clearly documented in the patient's notes and agreed by the woman, obstetrician, anaesthetist and haematologist/obstetric physician.

Most obstetric anaesthetists are willing to perform a regional blockade 12 hours following the last LMWH dose. It is important to remember that removal of the epidural catheter has a higher incidence of LMWH-related complications than insertion and this should be delayed until at least 12 hours post LMWH dose. For women with antithrombin deficiency, depending on the titre in the weeks leading up to delivery, an antithrombin infusion may be required before and/or during labour.

Thrombolysis − in non-pregnant patients, there is no clear evidence that thrombolysis improves the clinical outcome of thromboembolic disease, and most physicians reserve its use for critically ill patients. Experience of thrombolytic treatment in pregnancy is even more limited. There is a significant risk of bleeding and it is recommended for use only in life-threatening circumstances.

Post-partum: for women who had thromboembolic disease during pregnancy, a thrombophilia screen should be performed after discontinuation of anticoagulation treatment at least 6 weeks postnatally to assess the risk of recurrence, and to plan management during future pregnancies. Warfarin does not pass into breast milk, therefore women injecting heparin may wish to change to warfarin after delivery, once the risk of post-partum haemorrhage has passed (up to day 5). However, they will have to attend regularly for measurement of their prothrombin time. Contraception should also be discussed. The oestrogen-containing combined oral contraceptive pill is contraindicated in women who have had a thrombosis, but other forms of contraception (hormonal and non-hormonal) are permissible.

Cardiac disease

In the UK, cardiac disease is the second most common cause of maternal death. The physiological haemodynamic adaptation to pregnancy and delivery may place the woman with cardiac disease at serious risk. In the most recent Report on Confidential Enquiries into Maternal Deaths, 29% of the indirect deaths were a result of cardiac disease, of which 26% were congenital, 21% ischaemic and 53% acquired. The incidence of congenital heart disease in pregnancy is increasing, reflecting advances in corrective surgery for severe defects. It is important to consider the woman's risk of ventricular failure (particularly when the right ventricle is acting as the systemic pumping chamber) and any residual pulmonary hypertension. Paradoxical embolism through a right-to-left shunt may cause cerebrovascular accidents in uncorrected Fallot's tetralogy and atrial septal defects. The incidence of rheumatic fever has declined, but rheumatic heart disease, most commonly mitral stenosis, may present for the first time in pregnancy, especially in immigrants.

Whatever the underlying cardiac problem, the ability to tolerate pregnancy and delivery is related to the presence of cyanosis and pulmonary hypertension, the haemodynamic significance of any lesion and the functional state (Figure 3). Cyanosis alone may not be as important in predicting poor outcome as the association of cyanosis with Eisenmenger's syndrome, poor functional class, or both. Poor pregnancy outcome is more likely if the woman is in a poor functional status (NYHA class III or IV) regardless of the specific lesion. Conversely, those in functional classes I or II are likely to do well in pregnancy. Each case must be assessed individually, but women with certain conditions must always be treated as high risk. These include pulmonary hypertension and Eisenmenger's syndrome, severe aortic or mitral stenosis, Marfan's syndrome or cyanotic congenital heart disease.

New York Heart Association (NYHA) functional classification

- Grade I — No breathlessness
- Grade II — Breathlessness on severe exertion
- Grade III — Breathlessness on mild exertion
- Grade IV — Breathlessness at rest

3

Cardiac disease

In the UK, cardiac disease is the second most common cause of maternal death. The physiological haemodynamic adaptation to pregnancy and delivery may place the woman with cardiac disease at serious risk. In the most recent Report on Confidential Enquiries into Maternal Deaths, 29% of the indirect deaths were a result of cardiac disease, of which 26% were congenital, 21% ischaemic and 53% acquired. The incidence of congenital heart disease in pregnancy is increasing, reflecting advances in corrective surgery for severe defects. It is important to consider the woman's risk of ventricular failure (particularly when the right ventricle is acting as the systemic pumping chamber) and any residual pulmonary hypertension. Paradoxical embolism through a right-to-left shunt may cause cerebrovascular accidents in uncorrected Fallot's tetralogy and atrial septal defects. The incidence of rheumatic fever has declined, but rheumatic heart disease, most commonly mitral stenosis, may present for the first time in pregnancy, especially in immigrants.

Whatever the underlying cardiac problem, the ability to tolerate pregnancy and delivery is related to the presence of cyanosis and pulmonary hypertension, the haemodynamic significance of any lesion and the functional state (Figure 3). Cyanosis alone may not be as important in predicting poor outcome as the association of cyanosis with Eisenmenger's syndrome, poor functional class, or both. Poor pregnancy outcome is more likely if the woman is in a poor functional status (NYHA class III or IV) regardless of the specific lesion. Conversely, those in functional classes I or II are likely to do well in pregnancy. Each case must be assessed individually, but women with certain conditions must always be treated as high risk. These include pulmonary hypertension and Eisenmenger's syndrome, severe aortic or mitral stenosis, Marfan's syndrome or cyanotic congenital heart disease.

Management
Ante-partum: women with cardiac disease should be assessed before pregnancy. Counselling regarding possible fetal and maternal risks and, in some women, the need to avoid pregnancy, may be appropriate. Detailed assessment by an obstetrician, cardiologist and obstetric anaesthetist with an agreed plan for delivery is crucial. Women with congenital heart disease should be referred for a detailed fetal cardiac ultrasound scan because the risk of a congenital heart defect (2–5%) is more than double that of the general population. Some women require elective admission for bed rest to maximize oxygen saturation. Maternal cyanosis and hypoxaemia may adversely affect the fetus increasing the risks of intrauterine growth restriction, miscarriage and spontaneous and iatrogenic prematurity. Serial assessment of fetal growth and well-being is appropriate. If antidysrhythmics are required there is most experience in pregnancy with digoxin and β-blockers. Verapamil, adenosine and DC cardioversion are safe, and flecainide is safe in the second and third trimesters.

Intra-partum: antibiotic prophylaxis to cover delivery is advocated for women with structural heart defects. The exceptions are those with a repaired patent ductus arteriosus, those with an isolated ostium secundum atrial septal defect, and those with mitral valve prolapse without regurgitation. Prophylaxis is mandatory for women with artificial heart valves and those who have had endocarditis.

Women should be nursed in the left or right lateral position. The supine and lithotomy positions should be avoided to minimize the risk of pulmonary oedema. If the mother has to be kept on her back, the pelvis should be rotated so that the uterus drops forward, and cardiac output as well as uteroplacental blood flow are optimized. Continuous ECG and oxygen saturation monitoring, and for certain patients, more invasive monitoring with central venous and arterial cannulation, is required. Full resuscitation facilities must be available.

Epidural anaesthesia and analgesia using incremental doses and with judicious pre-loading are well tolerated in most conditions. Nevertheless, extreme caution is needed in cases of limited stroke volume and left ventricular outflow tract obstruction (e.g. aortic stenosis, hypertrophic cardiomyopathy). If a pudendal block is required lidocaine (lignocaine) without adrenaline (epinephrine) should be used. Oxytocin without ergometrine is recommended for management of the third stage. If there are concerns regarding the need to avoid vasodilatation, this can be administered by small increments of a dilute solution. Women should sit up as soon as possible after delivery. Close and regular observation is required for at least 24 hours after delivery, and transfer to a high-dependency or intensive care ward may be appropriate.

Post-partum: if the mother is well, breast-feeding is not contraindicated. Contraception should be discussed together with the safety of future pregnancies.

Pulmonary hypertension
Pulmonary hypertension may be the result of lung disease (e.g. cystic fibrosis), primary pulmonary hypertension, pulmonary veno-occlusive disease, or Eisenmenger's syndrome. The fall in systemic vascular resistance in pregnancy combined with the fixed pulmonary vascular resistance (which usually falls in pregnancy) means that there is an increase in right-to-left shunting and these women cannot increase pulmonary blood flow to match the increased cardiac output.

Maternal mortality is 30−50% in Eisenmenger's syndrome, and pregnancy is contraindicated. If a woman with significant pulmonary hypertension becomes pregnant, termination should be offered. If this is declined, prophylactic heparin should be given and bed rest and oxygen therapy instituted if hypoxia develops. Any systemic hypotension or vasodilatation (such as intra-partum or post-partum haemorrhage or related to anaesthesia) may lead to shunt reversal or increased right-to-left shunting, and should be avoided by immediate volume replacement. Opinion varies as to whether these patients should be delivered by elective caesarean section and whether regional anaesthesia is safe. They should be managed in an ICU by anaesthetists, cardiologists and obstetricians with expertise in the care of complicated heart disease. Any drug given to reduce pulmonary artery pressure (other than inhaled nitric oxide) will also reduce systemic pressures and the temptation to manipulate pulmonary artery pressure with vasodilators should be resisted. For this reason, monitoring with arterial and central venous lines with attention to adequate filling is recommended in preference to Swan–Ganz catheterization. Most women with Eisenmenger's syndrome who die as a result of their pregnancy, do so after delivery.

Aortic stenosis
Aortic stenosis is unlikely to cause problems unless the gradient is severe (over 100 mm Hg in the non-pregnant state). The risks are angina, hypertension, heart failure and sudden death. Symptoms (e.g. angina, dyspnoea, syncope) as well as hypertension may be controlled with β-blockers, provided left ventricular function is good. The development of resting tachycardia may indicate a failing left ventricle, unable to maintain the increased stroke volume of pregnancy. Balloon valvotomy may allow relief of severe stenosis and continuation of the pregnancy in severe cases. During delivery, the main complications are pulmonary oedema secondary to left ventricular failure and low cardiac output from decreased venous return. Venocaval compression and hypovolaemia must therefore be avoided.

Mitral stenosis
The increased blood volume, heart rate, and cardiac output accompanying normal pregnancy increase left atrial pressure and may cause pulmonary congestion and pulmonary oedema. Tachycardia is particularly dangerous in mitral stenosis, because diastolic filling of the left ventricle (which is slowed in mitral stenosis) is further decreased, and there is a consequent fall in stroke volume and a rise in left atrial pressure, precipitating pulmonary oedema. Even if a woman is asymptomatic at the beginning of pregnancy, she may deteriorate rapidly and develop exertional dyspnoea, orthopnoea and paroxysmal nocturnal dyspnoea due to pulmonary oedema later in gestation. This may be precipitated by a rise in the resting heart rate as a result of a failure to increase stroke volume adequately. If tachycardia develops, β-blockers should be given to slow the heart rate and allow time for left atrial emptying. If atrial fibrillation occurs, this should be converted to sinus rhythm with digitalization, or DC cardioversion. The risk of pulmonary oedema is greatest immediately after delivery, owing to the increase in wedge pressure accompanying the rise in blood volume. For this reason, cautious reduction in pre-load is desirable before delivery. Generally, fluid restriction and the fluid losses accompanying labour are adequate to produce a wedge of 14 mm Hg or less. If the pre-load is decreased too much, cardiac output will fall. Decreases in systemic vascular resistance lead to tachycardia and should be avoided. Epidural anaesthesia is desirable for vaginal and abdominal delivery. Pulmonary oedema should be treated promptly if it occurs.

Marfan's syndrome
The cardiovascular features of Marfan's syndrome include mitral valve prolapse, mitral regurgitation, aortic root dilation and aortic incompetence. Marfan's syndrome is inherited as an autosomal dominant condition and those with cardiac lesions tend to have offspring with cardiac abnormalities. Women should be advised that pregnancy carries a significant risk if the aortic root diameter is greater than 4−4.5 cm, or if there has been a steady increase in the aortic root dimension over preceding visits. Pregnancy increases the risk of aortic dissection and aortic rupture, particularly in those with pre-existing aortic dilatation. This risk is related to the family history, and is increased if relatives with the syndrome have suffered aortic rupture. There is a significant risk even in the absence of preconceptual cardiovascular abnormality and though aortic root dilatation may be a predictor of risk, dissection may occur without significant dilatation or hypertension.

Regular echocardiography assessments should be performed throughout pregnancy. β-blockers have been shown to reduce the rate of aortic dilatation and the risk of complications. They should be continued or started in pregnant patients with aortic dilatation or hypertension. For women with stable aortic measurements less than 4 cm, a vaginal delivery under epidural anaesthesia is recommended, unless there are obstetric indications for caesarean section. Epidural anaesthesia helps to limit the rise in systolic and diastolic blood pressure occurring with the pain and anxiety accompanying uterine contraction. Elective caesarean section with regional anaesthesia is recommended for those with aortic root dimensions greater than 4 cm or with increases in aortic root diameter during pregnancy, in order to avoid the rise in cardiac output associated with labour.

Peri-partum cardiomyopathy
Peri-partum cardiomyopathy is a rare condition specific to pregnancy that usually presents peri-partum or in the first month after delivery. There is a dilated cardiomyopathy and congestive cardiac failure with markedly reduced left ventricular function. There is a significant risk of pulmonary, cerebral and systemic embolization. Peri-partum cardiomyopathy is more common in multiple pregnancy, pregnancy complicated by hypertension, and in multiparous and older women. Management includes anticoagulants and conventional treatment for heart failure including bed rest, diuretics, digoxin, after-load reduction and inotropes. Elective delivery should be undertaken if the condition presents antenatally. Thromboprophylaxis should be continued intra-partum and post-partum. Angiotensin-converting inhibitors may be used to treat cardiac failure after delivery. About 50% of patients make a spontaneous and full recovery. Women should be counselled regarding the high risk of recurrence in future pregnancies especially if cardiac size does not return to normal.

Ischaemic heart disease
The incidence of myocardial infarction in pregnancy is increasing as older women who smoke are becoming pregnant. The risk is highest in the third trimester and overall maternal mortality is about 20%. Myocardial infarction in pregnancy has been successfully managed with thrombolysis, balloon angioplasty and coronary artery bypass grafting. Low-dose aspirin, 75−150 mg/day, is safe in pregnancy and should be continued or commenced for primary and secondary prophylaxis or in the acute management of myocardial infarction. Anti-anginal medication including nitrates and heparin may also be used safely.

Asthma

The prevalence of asthma in women of childbearing age is increasing. Asthma is the most common pre-existing medical disorder encountered in pregnancy. Management during pregnancy should include reassurance regarding the safety of medications used to control asthma. The biggest danger to the mother and fetus comes from poorly controlled or undertreated disease.

Changes in respiratory function during pregnancy: normal pregnancy is associated with a 20% increase in oxygen consumption and a 15% increase in the maternal metabolic rate. This extra demand is achieved by a 40−50% increase in resting minute ventilation, resulting mainly from a rise in tidal volume rather than respiratory rate. This hyperventilation causes the partial pressure of oxygen in the arteries to increase and that of carbon dioxide to fall, with a compensatory fall in serum bicarbonate to 18−22 mmol/litre. A mild respiratory alkalosis is normal in pregnancy (arterial pH 7.44). Up to 75% of women experience a subjective feeling of breathlessness at some time during pregnancy, possibly because of an increased awareness of physiological hyperventilation. This is most common in the third trimester and may lead to diagnostic confusion. In late pregnancy, the diaphragmatic elevation caused by the enlarging uterus leads to a decrease in functional residual capacity (FRC), but diaphragm excursion is unaffected and therefore vital capacity is unchanged. There is no change in peak expiratory flow rate or forced expiratory volume in 1 second in pregnancy. However, the fall in FRC may exacerbate hypoxaemia because of premature airway closure when acute asthma complicates pregnancy.

The effect of pregnancy on asthma in an individual woman is unpredictable. Women with mild disease are unlikely to experience problems, whereas those with severe asthma are at greater risk of deterioration, particularly late in pregnancy. Physiological changes during pregnancy that may improve asthma include progesterone-mediated bronchodilation and increased serum free cortisol. Those that may explain deterioration include increased stress and increased gastro-oesophageal reflux. Many asthmatics experience worsening of their symptoms during pregnancy because they stop or reduce medication, due to unfounded fears (either their own or their medical advisers') about its safety.

The effect of asthma on pregnancy in most women is negligible. However, severe, poorly controlled asthma may have an adverse effect on fetal outcome as a result of chronic or intermittent maternal hypoxaemia. Some studies have suggested an increase in the risk of premature labour and low birth weight, though two prospective case-control studies have not confirmed these findings. Similarly, higher rates of pregnancy-induced hypertension or pre-eclampsia, and caesarean section have been reported, but this may be a consequence of increased surveillance of asthmatic pregnancies, rather than a result of maternal asthma. Corticosteroid use may act as a confounder. The magnitude of any adverse effect on perinatal outcome is small and related to the degree of control of the asthma.

Management

Management of asthma in pregnancy does not differ from management outside pregnancy. The priority should be effective control of the disease process, with the aim being total freedom from symptoms both day and night. The medications used to treat asthma are safe in pregnancy. Great attention must be given to reassuring women about the safety of the drugs used to treat asthma in pregnancy and during lactation. Asthma should be treated as aggressively in pregnant women as in non-pregnant women. Pregnancy, because of the increased contact with healthcare professionals, provides an ideal opportunity to optimize asthma management. The drug treatment of asthma requires a short-acting symptom reliever and a long-term daily medication to address the underlying inflammation. All the drugs commonly used to treat asthma, including short- and long-acting β_2-agonists, inhaled corticosteroids, and methyl xanthines are safe in pregnancy. Fluticasone may be used for those requiring high doses of inhaled corticosteroids.

Acute severe asthma is dangerous and should be vigorously managed in hospital. Treatment is no different from the emergency management of acute severe asthma outside pregnancy. Oxygen, nebulized β_2-agonists, nebulized ipratropium, oral or intravenous corticosteroids, and in severe cases intravenous aminophylline or intravenous β_2-agonists should be used as indicated. Provided abdominal shielding is used, a chest radiograph results in minimal exposure of the fetus to ionizing radiation, and if clinically indicated this investigation must never be withheld because the patient is pregnant.

Labour and delivery: acute attacks of asthma during labour and delivery are rare, and women should be reassured. Women may continue to use their regular inhalers throughout labour. Those taking oral corticosteroids (prednisolone, over 7.5 mg/day for more than 2 weeks) at the onset of labour or delivery should receive parenteral corticosteroids (hydrocortisone, 100 mg 6−8 hourly) during labour, and until they are able to restart their oral medication. Prostaglandin E_2 used to induce labour, to ripen the cervix, or for early termination of pregnancy is a bronchodilator and is safe. Prostaglandin F_{20}, indicated for severe post-partum haemorrhage should be used with caution because it may cause bronchospasm.

Asthmatic women may safely use all forms of pain relief in labour, including epidural analgesia and *Entonox*. In the unlikely event of an acute asthma attack, opiates should be avoided. If anaesthesia is required, women should be encouraged to have epidural rather than general anaesthesia because of the increased risk of chest infection and associated atelectasis. Ergometrine has been reported to cause bronchospasm, particularly in association with general anaesthesia, but this does not seem to be a practical problem when it is combined with oxytocin to prevent post-partum haemorrhage. Non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used for pain relief following caesarean section. Women with asthma should be asked about any known aspirin or NSAID sensitivity before the use of these drugs.

Epilepsy

Epilepsy is the most common chronic neurological disorder to complicate pregnancy, affecting about 0.5% of pregnancies. Epilepsy is classified according to the clinical type of seizure, of which the most common are grand mal (tonic-clonic seizure), petit mal (absence seizure), and temporal lobe seizures (complex partial seizure). The term petit mal should be reserved for typical absences occurring almost exclusively in children and associated with 3 Hz spike and wave discharge on the EEG. Absence attacks occur in adulthood as a feature of partial seizures.

Most cases of epilepsy are idiopathic. Secondary epilepsy may be encountered in pregnancy in patients who have previously undergone surgery to the cerebral hemispheres or who have intracranial mass lesions. This should always be considered if the first fit occurs in pregnancy. Epilepsy may be a feature of antiphospholipid syndrome. Other causes of seizures in pregnancy include eclampsia, cerebral vein thrombosis, thrombotic thrombocytopenic purpura, cerebral infarction, drug and alcohol withdrawal and hypoglycaemia (complicating insulin-treated diabetes). Most women with epilepsy in pregnancy have already been diagnosed, but when a first fit occurs in pregnancy, having excluded pre-eclampsia, imaging with CT or MRI of the brain is appropriate.

Effect of pregnancy on epilepsy: in general, pregnancy does not affect the frequency of seizures. About 25% of women report improvement, and 10−30% experience an increased seizure frequency in pregnancy. Poorly controlled epileptics, especially those who fit more than once a month, are more likely to deteriorate in pregnancy. There is no relation to the seizure type or the course of epilepsy during previous pregnancies. Reasons for deterioration in seizure control during pregnancy are shown in Figure 4. There is no difference in the change of seizure frequency between trimesters, though the risk of seizures is greatest peri-partum (see below).

Ante-partum: folic acid should be continued throughout pregnancy because there is a small risk of folate deficiency anaemia. There is no need to change the anticonvulsant used in pregnancy if the woman is well controlled. Prenatal screening for congenital abnormalities with maternal serum screening or nuchal translucency and detailed ultrasound at 18−20 weeks should be offered. A repeat scan at 22 weeks is advisable if cardiac defects are suspected.

The altered pharmacokinetics (Figure 4) in pregnancy mean that drug levels are likely to change, and for most drugs, concentration of the free drug falls. This is because of the increased plasma volume and the enhanced renal and hepatic drug clearance. These effects are partially offset by decreased protein binding. In practice it is useful to have a baseline blood level early in pregnancy to confirm compliance, and to guide any necessary increases. If a woman is fit free there is no need to measure serial drug levels or adjust the dose. In women who have regular seizures, and who are dependent on critical drug levels, it is worth monitoring drug levels (preferably of the free drug) because they are likely to fall, and increasing doses of anticonvulsants should be guided by serum concentrations. The dose of anticonvulsant should be altered only on clinical grounds. Vitamin K, 10−20 mg orally, should be prescribed from 36 weeks' gestation because, in women taking hepatic enzyme-inducing drugs, vitamin K-dependent clotting factors in the fetus may be reduced, thus increasing the risk of haemorrhagic disease of the newborn.

Intra-partum: the risk of seizures increases around the time of delivery. 1−2% of women with epilepsy will have a seizure during labour, and 1−2% will fit in the first 24 hours post-partum. Caesarean section is required only for obstetric indications or if there are recurrent generalized seizures in labour.

Reasons for increase in seizures in pregnancy

- Poor drug compliance
- Nausea and vomiting
- Increased blood volume
- Changes in protein binding
- Increased drug clearance
- Lack of sleep
- Reduction of absorption of anticonvulsant drugs from the gastrointestinal tract during labour
- Hyperventilation during labour

Post-partum: epileptic patients require particular care in the immediate puerperium because of the increased risk of seizures. They should be supervised in the bath. Mothers with major seizures require advice regarding precautions such as bathing infants with somebody else around and changing nappies on the floor. The neonate should also receive vitamin K. All women with epilepsy should be encouraged to breast-feed.

Amniotic fluid embolism

Amniotic fluid embolism is rare but it is associated with a mortality rate of about 80%. Despite a low incidence of 1/80,000 deliveries, amniotic fluid embolism was responsible for 17 confirmed and suspected cases of maternal death in the 1994−1996 UK triennial report. The anaphylactic-like reaction occurs as a result of passage of amniotic fluid and particulate debris into the maternal circulation. Associated maternal factors include multiparity, caesarean section, uterine stimulation, uterine manipulation and increased age. Fetal factors include large baby, polyhydramnios, intrauterine death, placental abruption and rupture of membranes. All but one case in the triennial report had one or more of these complications.

There is a national register for suspected amniotic fluid embolism set up in the UK and the USA. The criteria for entry are detailed in Figure 5.

Management: death usually occurs as a result of cardio-respiratory collapse or disseminated intravascular coagulation. The treatment of amniotic fluid embolism remains supportive and includes adequate oxygenation and ventilation, maintenance of cardiac output and correction of coagulopathy. Current studies are focused on the possible role of leukotrienes, histamine, bradykinin, cytokines, prostaglandins and thromboxane.

Entry criteria for the amniotic fluid embolism register

- Acute hypotension or cardiac arrest
- Acute hypoxia (dyspnoea, cyanosis or respiratory arrest)
- Coagulopathy, disseminated intravascular coagulation or unexplained haemorrhage
- Onset during labour, caesarean section, uterine evacuation or within 30 minutes post-partum
- Absence of any other potential explanation of above symptoms and signs

Medico-legal Aspects of Obstetric Anaesthesia

David G Bogod

David G Bogod is Consultant Anaesthetist with a special interest in obstetrics at City Hospital, Nottingham, UK. He has an extensive medico-legal practice and is a member of the Doctor's Group advising the Association for Victims of Medical Accidents. He is currently reading for a masters degree in health law.

This article is based on British law, but the principles can be extrapolated to most legislatures based on the British or North American legal systems.

The concept of negligence

In order for a patient to bring a successful case of negligence against a practitioner, she must be able to demonstrate that, on the balance of probabilities:

- there was a breach of duty of care
- damage arose as a direct result of that breach.

How good does the care provided by the anaesthetist have to be for him not to be in breach of duty? It is reassuring to know that the necessary standard is not particularly high. The anaesthetist does not have to achieve the level of care that is represented by the brightest and best in his specialty, but only to act 'in accordance with the practice accepted as proper by a reasonable body of medical men skilled in that particular art' (Bolam v Friern Hospital Management Committee (1957) 2 ALLER 118). This standard, known widely as the Bolam principle, implies that, as long as there is support for the individual's practice among his peers, then he has fulfilled his duty of care to the patient, even if another body of opinion would disagree. The Bolam principle has been clarified (some would say diluted) recently by a case in which the judge ruled that the final decision on whether a standard of care was acceptable was the Court's prerogative, and that the expert medical evidence was to be considered only as a guide (Bolitho v City and Hackney Health Authority (1993) 4 Med LR 117 (CA)).

The patient who has not suffered damage does not have a claim in negligence against her doctor, however poorly he may have performed in caring for her. Indeed, to be successful in proving negligence, the claimant must demonstrate not only that damage occurred, but that it was directly caused by the failure of duty of care.

Common features relating to negligence claims

Consent

Patients in the UK do not have to be given a full explanation of all the risks involved in a procedure, but it is important to provide them with enough facts to enable them to make an informed decision. There are no rules about how common an adverse event has to be before it should be mentioned to a patient, and the widely quoted cut-off point of 1% has no basis in UK law. The practitioner should bear in mind not only the probability but also the severity of an adverse event in deciding whether to mention it, and his explanation should relate to his own practice rather than that of the institution or the country as a whole. If in doubt, it is better to inform the patient.

Having told the patient of the risks, benefits and alternatives to what you intend to do, it is good practice to record a brief summary of the explanation.

Taking consent for obstetric analgesia may be difficult if the patient is in severe pain and under the influence of powerful drugs such as nitrous oxide and pethidine. A brief explanation may be the best that can be done in the circumstances, but the reasons for this should be recorded. Consent to continue a procedure should be sought regularly if it is proving difficult or if the patient is distressed.

Record-keeping

Poor record-keeping often makes negligence suits impossible to defend. A contemporaneous record of the level of block and the modality used to test it is essential if a defence is to be successful against a patient who claims to have felt pain during caesarean section. The key points of good record-keeping are detailed in Figure 1. A summary of good practice points is shown in Figure 2.

Good record-keeping

- Note details of risks and benefits explained when taking consent
- Record evidence of the success and extent of regional blockade
- Record reasons for deviating from standard or accepted practice
- Write legibly in black ink
- Always put the date and time
- Sign notes and print your name if your signature is illegible
- Put your specialty and status
- Avoid writing too close to the edges of the paper – words are often missed in photocopying
- It is acceptable to make notes when a crisis is over or to add corrections later, but they must be dated and timed and the previous notes must not be made illegible
- Ensure that all records are properly bound in the patient's folder – this particularly applies to operating or labour analgesia records, which are often loose

1

Avoiding negligence litigation

- Keep good records
- Note details of consent, including the risks and benefits discussed with the patient
- Be honest with the patient at all times
- Prepare good local guidelines and stick to them
- Establish an early referral system for potential problems
- Maintain close communication with other staff involved in the care of your patients
- Do not get overly focused on the technical aspects – maintain perspective
- Do not be reluctant to seek help or a second opinion
- If things go wrong, apologize – do not avoid the patient
- Be nice – nice doctors are less likely to be sued

2

Negligence claims relating to regional obstetric analgesia or anaesthesia

Pain during caesarean section

Pain felt during caesarean section under epidural or spinal anaesthesia is probably the most common successful medico-legal claim made against anaesthetists in the UK. One reason why these claims are difficult to defend is the subjective nature of pain. This, allied to the delay in getting these cases to court, makes it almost impossible for the defence to counter the claimant's description of what she felt at the time.

Pain-free caesarean section cannot be guaranteed, however effective the block. Consequently, the patient who feels pain during the operation is not necessarily the victim of negligence. However, for the anaesthetist to have a good defence, he must be able to demonstrate that he took reasonable steps to minimize the chance of pain and then to treat it when it occurred. These steps are summarized below.

- As part of the consent process, warn the patient about the risk of pain and the possibility of conversion to general anaesthesia. Make a record of the risks explained to the patient in case of later dispute.
- Use a technique that is recognized as acceptable.
- Test the extent of block and demonstrate its effectiveness. A block to touch to T5 has been shown to minimize the risk of pain, and this represents best practice, but the minimum acceptable standard is probably a bilateral block to pinprick to T6. A survey carried out in 1996 showed that only 4% of practitioners regard a T8 block as adequate for caesarean section.
- Treat pain when it occurs by use of epidural top-ups, intravenous or inhalational analgesia, or induction of general anaesthesia. Incidents of pain should be recorded, as should the efficacy of treatment. General anaesthesia should not be withheld without good reason if the patient is not coping with the procedure.
- Provide follow-up and support to the patient who feels pain.

Neurological damage after regional blockade

Neurological symptoms in the lower limbs can arise during childbirth whether or not a neuraxial block has been used. However, the woman who develops a persistent area of numbness or weakness after epidural analgesia is likely to link the two events. The key feature linking neurological damage to the regional technique is whether the patient experienced paraesthesia during the procedure. Persistent paraesthesia should always be a sign to withdraw and reorientate the needle. Failure to do so in a patient who subsequently develops lower limb neurological signs strongly indicates failure of duty of care and causation.

It is not medico-legally incumbent on the anaesthetist to warn the patient of the risk of nerve damage before embarking on the epidural (although it may be good practice). The rare incidence of this complication means that only 20% of anaesthetists would mention it when explaining the risks of epidural analgesia. Practitioners should avoid the temptation to focus on the minutiae of the technical procedure, and to lose the wider perspective. If an epidural is proving difficult and the patient is becoming restless, it is better to call a temporary halt to the proceedings. Consider whether the epidural is needed and whether it would be useful to ask a colleague for help.

Post-dural puncture headache (PDPH)

PDPH is a recognized complication of epidural analgesia and is not necessarily indicative of negligence. Some PDPH claims succeed, however, and this usually relates to delay in treatment, specifically in performing an epidural blood patch. Conservative measures are seldom successful, therefore a blood patch should be offered early and carried out by a senior member of staff. Meticulous follow-up is mandatory, and it should be remembered that PDPH can recur after the patient has returned home. Patients should be told to contact the hospital if they have a recurrence of symptoms, the GP should be informed and it is good practice to arrange a formal follow-up appointment after discharge. ◆

Obstetric Emergencies

Diana Brighouse

Diana Brighouse is Consultant Anaesthetist to the Southampton University Hospitals. She qualified from Southampton University and trained in anaesthesia in Oxford and London. She has developed a particular interest in the care of women with medical and anaesthetic problems in pregnancy.

Amniotic fluid embolism and obstetric haemorrhage are significant causes of maternal death. In the report on Confidential Enquiries into Maternal Deaths in the UK (CEMD) 1994–1996 amniotic fluid embolism is the third cause of direct death after thromboembolism and hypertensive disorders of pregnancy; obstetric haemorrhage is the fourth. Of the 12 deaths resulting from haemorrhage, three were caused by placenta praevia, four by placental abruption and five by post-partum haemorrhage.

Placental abruption

Definition and diagnosis

Placental abruption is the premature separation of the placenta after the twentieth week of gestation. Its incidence is about 2%. It is associated with a high rate (up to 50%) of fetal mortality. The risk factors for placental abruption are:

- smoking
- external cephalic version
- polyhydramnios (following membrane rupture)
- previous abruption
- increasing multiparity
- multiple pregnancy
- blunt trauma
- cocaine ingestion.

Placental abruption is followed by concealed (20–35% cases) or revealed haemorrhage. A grading system has been proposed ranging from grade 0 in which retroplacental clot is found at placental examination after delivery in an asymptomatic woman, to grade 3 in which there is maternal shock, abdominal pain, uterine tetany and a dead fetus. Revealed haemorrhage is not invariable. A coagulopathy is present in 30% of women with grade 3 abruption.

It is important to realize that although this is the typical presentation of placental abruption there may be neither pain nor revealed bleeding. The 1994–1996 CEMD describes a woman presenting in the third trimester ‘feeling unwell’ and ‘pale and clammy’. There was no complaint of pain, and no cardiovascular compromise. The woman died 2 hours after admission to the Accident and Emergency Department, and at emergency caesarean section was found to have 2 litres of blood in the uterus. A high index of suspicion is required for any pregnant woman who is inexplicably unwell, especially if her symptoms are accompanied by any abnormal signs. The incidence of coagulopathy increases as time elapses following abruption, and in the presence of a dead fetus. The complications of placental abruption are:

- maternal hypovolaemia
- fetal distress
- intrauterine fetal death
- disseminated intravascular coagulation (DIC)
- post-partum haemorrhage from uterine atony
- acute renal failure.

Management

Venous access should be secured promptly, and an intravenous infusion of crystalloid begun. In the presence of major haemorrhage it may be necessary to administer group O rhesus negative blood, though group-specific blood is preferable and should be available within 15 minutes. Surgery should not be delayed until blood is available, because the condition of mother and fetus is increasingly jeopardized by a prolonged decision to delivery time.

If the mother is in the third trimester of pregnancy onset of labour usually follows the abruption. If the fetus is not compromised, vaginal delivery is possible. Vaginal delivery is also indicated in severe cases of abruption in which the fetus has died. If labour does not start spontaneously it is usually induced with prostaglandin pessaries.

If abruption occurs during the second trimester of pregnancy, or if there is fetal distress, delivery by caesarean section is necessary.

Anaesthesia and analgesia

Anaesthesia for operative delivery depends on the clinical presentation. Immediate delivery is indicated in the presence of severe fetal distress, or if the mother is hypovolaemic. Resuscitation with intravenous fluids and blood transfusion can be performed at the same time as preparation for operative delivery is made. In this situation, general anaesthesia is indicated. Oral sodium citrate is given before induction of anaesthesia, and many anaesthetists also administer intravenous ranitidine or omeprazole. The uterus is displaced off the vena cava and aorta either by tilting the operating table or by placing a wedge under the patient’s right hip.

The anaesthetist must be alert to the possibility of consumptive coagulopathy in any patient who appears to be bleeding abnormally. If DIC occurs it should be treated with appropriate blood products and the advice of a haematologist should be sought. The patient is at increased risk of postoperative haemorrhage due to failure of the uterus to contract.

In less urgent situations the mother’s condition can be stabilized, and results of haematological investigations awaited. In the absence of a platelet count below 80,000 or an abnormal coagulation screen, regional anaesthesia can be used. Spinal, combined spinal-epidural or epidural anaesthesia are all suitable; the final choice is made according to the anaesthetist’s preferred technique, though the flexibility of the combined spinal-epidural compared with single-shot spinal anaesthesia has led some anaesthetists to recommend it as the technique of choice.

If analgesia is required for labour the mother should be advised to accept epidural analgesia providing that there are no contraindications. Her chances of requiring emergency caesarean section in labour are high, and a functioning labour epidural can readily be extended for operative delivery.

Placenta praevia

Placenta praevia accounted for 25% deaths from obstetric haemorrhage in the 1994–1996 CEMD report. Placenta praevia is the persisting implantation of the placenta in the lower uterine segment. The placenta may partially or completely cover the cervical os and may be positioned anteriorly or posteriorly. Placenta praevia is graded I to IV.

- Grade I, the placenta encroaches on the lower uterine segment.
- Grade II reaches the internal os.
- Grade III asymmetrically covers the internal cervical os.
- Grade IV symmetrically covers the cervical os.

The main risk factors for placenta praevia are the presence of a uterine scar, increasing maternal age and increasing parity. Previous caesarean delivery is a major risk factor, with the risk rising from less than 0.3% in women with no previous caesarean delivery to over 10% in women who have had four previous caesarean sections.

There is a particularly high risk of placenta accreta – placental invasion of the myometrium – in women who have had previous caesarean deliveries. 24% of women with placenta praevia and one previous caesarean section are likely to have placenta accreta, and as many as 67% of women with placenta praevia and at least four previous caesarean deliveries. These women should be investigated with ultrasound scanning during the third trimester of pregnancy to ensure that the placenta is not adherent to the uterine scar. In severe cases of placenta accreta the placenta may invade through the myometrium and into the bladder, bowel or major blood vessels (placenta percreta).

A rare cause of bleeding is vasa praevia, in which an insertion of the umbilical cord encroaches on the cervical os.

Diagnosis

Placenta praevia classically presents as painless vaginal bleeding occurring at any time during the third trimester. It may not present before the onset of labour, when the onset of uterine contractions together with effacement of the cervix precipitates bleeding from the abnormally implanted placenta. Placenta praevia is differentiated from bleeding caused by abruption by the absence of pain, and the diagnosis is confirmed by ultrasound investigation. Placenta accreta, if not diagnosed preoperatively by ultrasound, may present as uncontrollable haemorrhage at caesarean section.

Vasa praevia is invariably accompanied by fetal distress because the blood loss occurs entirely from the fetus.

In the absence of fetal distress, the management of placenta praevia occurring before 37 weeks’ gestation is initially conservative. The diagnosis is confirmed by ultrasound scanning and blood is taken for cross-matching. Intravenous access is secured and the woman is admitted to the antenatal ward. Traditionally she then remains in hospital until delivery, with cross-matched blood being kept continually available. Recently, however, obstetricians have been prepared to allow women with lesser degrees of placenta praevia, especially those who have had only one bleed, to go home and attend the maternity unit regularly as outpatients. Placenta praevia may cause major antenatal haemorrhage, and the mother may present in hypovolaemic shock. If the mother is rhesus negative she should receive anti-D prophylaxis following a vaginal bleed.

Anaesthesia and analgesia

If the mother is bleeding heavily or is hypovolaemic she is almost certain to require operative delivery. This should not be delayed by waiting for cross-matched blood. Volume resuscitation should occur simultaneously with preparations for induction of general anaesthesia. Antacid prophylaxis is given as usual, and anaesthesia is induced with the mother in the wedged supine position to minimize aortocaval compression. The presence of a second anaesthetist is desirable to assist with resuscitation. Early insertion of central venous and arterial cannulas has been recommended in the hypovolaemic woman.

If there is a high suspicion of placenta accreta preoperatively it is mandatory for a senior anaesthetist to administer general anaesthesia, and for there to be a second anaesthetist present to assist. Two large-bore intravenous cannulas should be inserted before induction of anaesthesia, and cross-matched blood should be available immediately. There is a significant risk of proceeding to caesarean hysterectomy in cases of placenta accreta, and the mother should be warned of this (and appropriate consent obtained) preoperatively. Use of direct right atrial and intra-arterial pressure monitoring help to guide volume replacement. If the mother is scheduled for elective caesarean section and is haemodynamically stable many anaesthetists would consider using regional rather than general anaesthesia. It is important to investigate the mother for accurate ultrasound location of the placenta before initiating regional anaesthesia.

In hospitals with the facilities to perform radiological embolization of the uterine or iliac arteries, the possibility of performing a caesarean section in the Department of Radiology should be considered. The appropriate pelvic vessels can be cannulated prior to performing the caesarean section and embolization can be performed in the event of major haemorrhage.

If regional anaesthesia is chosen, epidural, combined spinal-epidural or single-shot spinal techniques can be used. There may be advantages in choosing an epidural or combined spinal-epidural technique that can be extended if surgery proves difficult. Some anaesthetists favour epidural rather than spinal anaesthesia on the assumption that it offers greater cardiovascular stability. Whichever technique is chosen it is advisable to secure intravenous access with two large-gauge cannulas before initiating anaesthesia. Use of direct intra-arterial monitoring may be helpful if this facility is readily available. Cross-matched blood should be available immediately.

A trial of vaginal delivery may be considered for women with minor degrees of placenta praevia. These women should be offered epidural analgesia and it is prudent to anticipate greater blood loss than usual at delivery.

In the absence of access to accurate ultrasonography the anaesthetist may be asked to assist with examination in theatre of a mother with suspected placenta praevia. In this situation, the woman is placed in the lithotomy position and a speculum vaginal examination is carried out. Two large-gauge intravenous cannulas should be inserted before the woman is examined, and if major placenta praevia is confirmed the mother is moved into the wedged supine position and rapid-sequence induction of general anaesthesia is performed.

An alternative technique is to induce regional anaesthesia before vaginal examination and then to proceed to caesarean section under regional anaesthesia. The disadvantages of this technique are that major haemorrhage may occur during surgery and induction of labour and vaginal delivery may be attempted. These considerations should be taken into account when deciding on a suitable anaesthetic approach. In the UK, most obstetric units have access to high-quality ultrasonography and most UK anaesthetists are unlikely to be faced with this dilemma.

Obstetric haemorrhage

The uterus receives 10–15% maternal cardiac output by term. Major haemorrhage can occur with frightening rapidity. The causes of obstetric haemorrhage are shown in Figure 1. Worldwide, obstetric haemorrhage remains a major cause of maternal death. The 1994–1996 CEMD report considered that the care given to eight out of the twelve mothers who died following obstetric haemorrhage was substandard. Failure to diagnose placenta praevia occurred in two cases. In the other six cases, the haemorrhage was recognized but was treated inadequately.

Causes of obstetric haemorrhage

Ante-partum
- Placental abruption
- Placenta praevia

Intra-partum
- Placental abruption
- Placenta praevia
- Uterine rupture

Post-partum
- Uterine atony
- Cervical, vaginal or perineal trauma
- Uterine inversion
- Retained products of conception

1

Ante-partum haemorrhage
Placental abruption and placenta praevia should be treated as discussed above.

Intra-partum haemorrhage
Placental abruption and placenta praevia may both present during labour. Management follows the guidelines outlined above.

Uterine rupture is a rare cause of intra-partum haemorrhage but is accompanied by high fetal mortality and potential maternal mortality. Uterine rupture is almost always associated with labour following previous caesarean section. The causes of uterine rupture are:
- previous caesarean section (especially if classical uterine incision)
- external cephalic version
- previous uterine rupture
- prostaglandins for mid-trimester termination of pregnancy
- obstructed labour (in the developing world).

Scar dehiscence may occur gradually and relatively painlessly, causing progressive fetal distress, and may not be diagnosed until caesarean section is performed. At the other extreme there may be rapid uterine rupture associated with fetal death, severe abdominal pain, maternal shock and cardiovascular collapse. Suspicion of uterine rupture should be raised when breakthrough pain occurs in women who have epidural analgesia for labour, when there is pain that persists between contractions or when there is a loss of beat-to-beat variability on the cardiotocograph.

Post-partum haemorrhage
Blood loss of more than 500 ml following vaginal delivery is classified as post-partum haemorrhage; massive obstetric haemorrhage is blood loss of at least 1500 ml. Primary post-partum haemorrhage occurs within 24 hours of delivery; secondary haemorrhage occurs between 24 hours and 6 weeks after delivery.

Uterine atony: failure of the uterus to contract after delivery of the placenta causes haemorrhage. Causes of uterine atony include:
- prolonged labour
- precipitate labour
- multiple pregnancy
- grand multiparity
- intrauterine infection
- β-sympathomimetic drugs
- magnesium
- volatile anaesthetic agents
- retained products of conception.

Genital tract trauma: blood loss from unrecognized genital tract trauma can be extensive and examination under general anaesthesia is often necessary once initial resuscitation is under way.

DIC may complicate major obstetric haemorrhage of any aetiology, and may also complicate amniotic fluid embolism. The common factor in DIC, regardless of cause, appears to be the release of tissue thromboplastin into the circulation, resulting in platelet aggregation, coagulation and fibrinolysis.

The platelet aggregation together with fibrin production leads to formation of microthrombi in small vessels which stimulate the release of plasminogen activator. Fibrinolysis releases fibrin degradation products into the circulation, which inhibit platelet aggregation and aggravate the bleeding tendency by causing thrombocytopenia. DIC is often diagnosed clinically, and the diagnosis is confirmed by the presence of thrombocytopenia, hypofibrinogenaemia plus elevated fibrin degradation products or D-dimer. Thrombin time is prolonged and antithrombin III activity is reduced.

Management
The principles of management of obstetric haemorrhage are the same regardless of cause (Figure 2). Previous CEMD reports have given clear guidelines for the management of obstetric haemorrhage. The extent of haemorrhage is often underestimated. Delay in treating obstetric haemorrhage aggressively may be fatal.

Management of obstetric haemorrhage

General principles

- Resuscitate the mother
- Give oxygen, intravenous fluids
- Deliver fetus and placenta
- Ensure uterus is empty
- Achieve uterine contraction
- Examine under general anaesthesia if bleeding continues
- Ligate uterine/internal iliac arteries
- Embolize uterine/internal iliac arteries
- Consider hysterectomy

Clinical management

- Call for help
  - obstetrician and anaesthetist
  - extra midwife
  - porters
- Alert haematologist, consultant obstetrician and anaesthetist
- Insert at least two large intravenous cannulas
- Consider CVP line
- Send blood for cross-match (minimum 6 units) and clotting screen
- Give oxygen
- Resuscitate with colloid/group O negative/type-specific blood until cross-matched blood available
- Use blood warmer and pressure infusion device
- Monitor blood pressure, ECG, urine output, blood gases, temperature
- Continue fluid resuscitation following haematological advice
- Consider examination in theatre
- Consider early transfer to ICU

2

Uterine rupture: treatment of uterine rupture is delivery of the fetus by caesarean section, followed by uterine repair or hysterectomy. General anaesthesia should be used for speed and because the mother is likely to be haemodynamically compromised. Women with a history of uterine rupture are usually delivered at 36 weeks' gestation by elective caesarean section.

Uterine atony: initial management should follow the guidelines outlined above. Intravenous access should be secured with two large cannulas and fluid resuscitation should be started. Any drugs likely to be contributing to uterine atony should be discontinued, and oxytocic drugs should be given. If a bolus of syntocinon is given this should not exceed 10 iu, and many anaesthetists would advise a maximum of 5 iu as a bolus, followed by an infusion of 50 iu in 500 ml saline, given over 2–4 hours.

Manual stimulation of uterine contraction may be successful. If haemorrhage continues a bolus of ergometrine is given (Figure 3). Ergometrine causes an increase in systemic arterial and intracranial pressure and provokes vomiting. It should be diluted to 10 ml and administered slowly. Its use is contraindicated in hypertensive women and those with intracranial pathology. If bleeding continues, prostaglandins may be administered; in the UK prostaglandin $F_{2\alpha}$ (*Carboprost, Hemabate*) is used in a dose of 0.25 mg i.m. or directly into the myometrium. There is a relatively high incidence of anaphylactoid reaction to systemic prostaglandins.

Drug treatment of uterine atony

- Stop tocolytics (salbutamol, magnesium)
- Stop volatile anaesthetic agents
- Give syntocinon, 5–10 iu i.v. bolus followed by infusion
- Give ergometrine, 0.25 mg i.v. slow bolus repeated once
- Give *Carboprost,* 0.25 mg i.m. or into myometrium; repeat if necessary at 15 minute intervals; maximum dose 2 mg

3

If bleeding continues the patient should be taken to theatre for exploration of the uterus under general anaesthesia. It is possible that undiagnosed retained products of conception are preventing uterine contraction.

Genital tract trauma: if post-partum blood loss continues despite the above measures it may be necessary to tie off the uterine or internal iliac arteries. If this fails, hysterectomy should be considered. A second anaesthetist should be present during these procedures because coagulopathy has often developed by this stage. Appropriate blood products including fresh frozen plasma, platelets and cryoprecipitate should be given following the advice of a haematologist. The patient should be transferred to the ICU postoperatively.

A small number of obstetric units have access to radiological embolization of the uterine and internal iliac arteries, and this is an alternative to surgical ligation. Although general anaesthesia is usually indicated for obstetric hysterectomy, there have been reported series of obstetric hysterectomies performed under epidural anaesthesia with no difference in complication rates. Regional anaesthesia can be considered only in the well- resuscitated and haemodynamically stable mother, in whom there is no evidence of coagulopathy.

DIC: primary treatment is removal of the triggering event, together with intravascular volume replacement. Replacement of blood products should be guided by a haematologist, and should include transfusion of blood, fresh frozen plasma and cryoprecipitate or fibrinogen. Platelet transfusion is usually indicated if the platelet count falls below 50 x 10^9/litre. The use of heparin, antithrombin III and aprotinin have all been reported in the treatment of DIC but their efficacy has not been evaluated.

Women who refuse blood transfusion: some women refuse blood transfusion either on religious grounds (Jehovah's Witnesses) or because of fear of contracting blood-borne diseases such as HIV. It is important to identify these women during the ante-natal period and to counsel them about the risks of refusing blood transfusion. Delivery should be arranged in a large obstetric unit that has facilities for the management of major obstetric haemorrhage. Management of these women is described in Figure 4.

Management of obstetric haemorrhage in women who refuse blood transfusion

- Ante-natal identification and counselling
- Maximize iron stores antenatally
- Deliver in large obstetric unit
- Secure intravenous access early
- Treat haemorrhage early and aggressively with crystalloid/ colloid
- Consider cell-saving techniques
- Administer oxygen
- Provide opportunity for the woman to change her mind (partner does not have right to consent or withhold consent)
- Consider hysterectomy early
- Consider hyperbaric oxygen if available
- Consider erythropoietin and parenteral iron
- Transfer to ICU
- Arrange counselling for staff if patient dies

4

Inversion of the uterus

Uterine inversion occurs in about 1/2000 deliveries, and is defined as complete or incomplete depending on whether the fundus of the uterus has passed through the cervix. Acute uterine inversion occurs within 24 hours of delivery; subacute and chronic uterine inversion may also occur. Risk factors for uterine inversion include primiparous labour, augmentation of labour with oxytocics, macrosomic fetus, and implantation of the placenta at the uterine fundus. Acute uterine inversion presents with pain, haemorrhage and shock disproportional to blood loss.

Management

Current obstetric opinion favours leaving the placenta undelivered until the uterus has been replaced. The mother should receive fluid resuscitation and an initial attempt at manual replacement is made under regional anaesthesia once the mother is haemodynamically stable. If immediate attempts at replacement are unsuccessful the mother may be given intravenous magnesium, 2 g by slow bolus injection, or a β-sympathomimetic (e.g. salbutamol) to facilitate uterine replacement. The use of volatile anaesthetic agents such as halothane is no longer advocated because of the risk of prolonged uterine atony and further haemorrhage.

If the mother remains haemodynamically unstable despite fluid resuscitation she should receive a general anaesthetic to facilitate uterine replacement.

Hydrostatic pressure is used to replace the uterus if this cannot be done manually, and if this technique fails, laparotomy and abdominal replacement of the uterus is required.

Amniotic fluid embolism

The incidence of amniotic fluid embolism is unknown; in the 1994–1996 CEMD report the UK mortality rate was 7.7/1 million maternities. In Australia between 1973 and 1990, the mortality was 65/1 million maternities. There is under-reporting of non-fatal cases, partly because of diagnostic confusion. The pathophysiology of amniotic fluid embolism is uncertain. Current theories favour the involvement of leukotrienes as a trigger in an anaphylactoid cascade that precipitates a systemic inflammatory response. Most of the traditionally cited risk factors have not been substantiated. An American review found no correlation with duration of labour, use of oxytocics, presence of intact membranes or hypertonic uterine activity. There may be an association with increasing maternal age.

Diagnosis

In the USA, diagnostic criteria for amniotic fluid embolism have been established (Figure 5). Shivering, sweating, dyspnoea or cyanosis may precede cardiovascular collapse. The woman may have convulsions, leading to misdiagnosis of eclampsia. DIC may be apparent soon after initial presentation. Diagnosis is supported by the finding of fetal material in the pulmonary arterial tree.

US criteria for diagnosis of amniotic fluid embolism

- Acute hypotension or cardiac arrest
- Acute hypoxia
- Coagulopathy or unexplained haemorrhage
- Onset of symptoms during dilatation and curettage, labour, caesarean section or within 30 minutes of delivery
- No other explanation for signs and symptoms

5

Management

The management of amniotic fluid embolism is entirely supportive and includes:

- tracheal intubation and ventilation with high inspired oxygen
- fluid resuscitation
- symptomatic treatment of coagulopathy
- aggressive management of haemorrhage
- delivery of fetus and placenta
- supportive use of inotropes.

Maternal resuscitation

Causes of collapse in the pregnant or recently delivered woman include:

- hypovolaemia
- embolism (pulmonary or amniotic)
- cardiac disease
- drug administration
  - anaphylaxis
  - high-spinal/epidural
  - drug abuse (cocaine, temazepam, opioids)
  - drug toxicity (magnesium, opioids, local anaesthetics)
- eclampsia
- intracranial event
- sepsis.

Initial resuscitation attempts must include displacement of the gravid uterus off the major vessels. A purpose-made resuscitation wedge can be used (this needs to be made of a non-compressible material, and to be of adequate length), or a second person can kneel on the floor and use their knees as a wedge. Early tracheal intubation reduces the chances of aspiration of gastric contents.

Use of adrenaline (epinephrine) and cardiac defibrillation should follow standard resuscitation guidelines for the non-pregnant patient. Sodium bicarbonate can precipitate fetal intracerebral bleeding, and reduce cerebral perfusion in the mother, and therefore should be given only in response to proof (from arterial blood gas analysis) of severe metabolic acidosis.

Cardiopulmonary resuscitation of the pregnant mother is unlikely to succeed while the mother remains undelivered, because aortocaval compression prevents an adequate cardiac output being obtained with cardiac massage. The standard ABC of resuscitation should be supplemented with D for delivery in women of more than 24 weeks' gestation. Vaginal delivery with vacuum extractor or forceps, or peri-mortem caesarean section should be performed if resuscitation has not been successful within 5 minutes of cardiac arrest.

North American guidelines suggest that if resuscitation has not been successful within 15 minutes open-chest cardiac massage should be considered. Use of cardiopulmonary bypass has been shown to be life saving in certain clinical situations but this is an option only in hospitals where the obstetric and cardiac units are in close proximity.

Local anaesthetic toxicity

Bupivacaine has a narrower safety margin between therapeutic and cardiotoxic dose than lidocaine (lignocaine). It also has a narrower margin between the dose that is neurotoxic and that which is cardiotoxic. Bupivacaine cardiotoxicity produces asystolic cardiac arrest, or ventricular fibrillation that is refractory to defibrillation. The drugs of choice for treatment of bupivacaine toxicity are atropine, maximum 2 mg, and isoprenaline. Cardiac pacing may be useful. If cardiac function is restored and is complicated by ventricular dysrhythmias these should be treated with bretylium and adrenaline (epinephrine). ◆

Pain Relief in Labour: Alternative Techniques (Gaseous and Parenteral)

Mark Scrutton

Mark Scrutton is Consultant Anaesthetist at St Michael's Hospital and Bristol Royal Infirmary, UK. He qualified from St Thomas' Hospital, London, and trained in anaesthesia in the South Thames Region. His teaching and research interests are in obstetric anaesthesia and the management of the high-risk obstetric patient.

Inhalational agents (Figure 1)

Agents of historical interest
Ether was the first inhalational agent described for analgesia in labour. Although effective, ether was irritant to the airways, slow in onset, and caused nausea and vomiting. Chloroform, introduced at the end of 1847 and famously administered to Queen Victoria by John Snow for the birth of Prince Leopold on 7 April 1853, was less irritant and quicker in onset. However, the dose administered was hard to control and loss of consciousness often occurred. Furthermore, chloroform reduced uterine contractility and readily crossed the placenta causing neonatal depression. Trichloroethylene (*Trilene*) and methoxyflurane have been used for analgesia in labour without any great benefit.

Inhalational agents used for pain relief in labour

Agent	Amount inspired for analgesia in labour (%)
Ether	Unmeasured
Chloroform	0.2–0.9/unmeasured
Trichloroethylene	0.35–0.5
Methoxyflurane	0.35
Nitrous oxide	50
Enflurane	0.25–1.25
Isoflurane	0.2–0.75
Desflurane	1–4.5
Sevoflurane	Not reported

Nitrous oxide
Entonox, a 50:50 mixture of nitrous oxide and oxygen, is the most widely used form of inhalational analgesia in modern obstetric practice. It has a rapid onset in sub-anaesthetic doses and is eliminated between contractions, so that there is minimal accumulation in mother or fetus. Despite promising early reports of analgesic efficacy, *Entonox* has produced poor results in placebo-controlled trials. However, *Entonox* compares favourably with other forms of non-regional analgesia, such as transcutaneous electrical nerve stimulation and pethidine.

To optimize analgesia, *Entonox* inhalation must begin at the start of the contraction in order to try to attain analgesic levels as the contraction peaks. As soon as the contraction starts to wane, inhalation should stop to minimize hangover between contractions. Supplementary, continuous, low-flow *Entonox* via nasal prongs between contractions may improve efficacy.

Side-effects include dizziness, loss of control, nausea and vomiting, but resolve rapidly once *Entonox* is withdrawn. During contractions, hyperventilation may cause hypocapnia that can decrease oxygen transfer across the placenta by causing vasoconstriction and increasing the affinity of maternal haemoglobin for oxygen. Between contractions, hypocapnia combined with the residual sedative effects of *Entonox* may increase the incidence of maternal hypoventilation and consequent arterial oxygen desaturation.

Entonox has no documented effect on the progress or outcome of labour. Comparison of Apgar scores and more complex neonatal outcome measures show no detrimental effects on the baby. The high inspired concentration of oxygen in *Entonox* may be of benefit, particularly when there is fetal distress.

Other agents
The newer volatile agents, desflurane and sevoflurane, offer rapid onset and elimination. Desflurane provides similar analgesia to *Entonox* but with an increased incidence of amnesia. However, the cost of desflurane, the complex vaporizer required for its delivery and its lack of significant therapeutic advantage makes widespread use unlikely. Sevoflurane has not been investigated in obstetric practice, but may become an alternative or adjunct to *Entonox*.

Parenteral analgesics (Figure 2)

History
Opioids have been used for analgesia in labour for hundreds of years, often as an incidental component of a complex potion. In 'twilight sleep', first described in 1902, a single dose of morphine was followed by intermittent doses of hyoscine. Side-effects were severe, analgesia was poor and the technique was abandoned at the end of the 1930s.

Parenteral drugs used for pain relief in labour

Drug	Dose
• Pethidine	50–100 mg i.m. 3–4 hourly; 25–50 mg i.v. 3–4 hourly; 10–25 mg i.v. PCA (lock-out 10 minutes)[1]
• Morphine	5–10 mg i.m. 3–4 hourly
• Diamorphine	2.5–5 mg i.m. 3–4 hourly
• Meptazinol	100–150 mg i.m. 2–4 hourly
• Pentazocine	40 mg i.m. 2–4 hourly
• Nalbuphine	10–20 mg i.m. 2–4 hourly
• Fentanyl	25–100 μg/hour i.v.; 12.5–25 μg i.v. PCA (lock-out 5 minutes)[1]
• Remifentanil	0.5–0.75 μg/kg i.v. PCA (lock-out 3 minutes)[1]
• Tramadol	50–100 mg i.m. 3–4 hourly

[1] PCA, patient-controlled analgesia.

Pethidine
Pethidine was introduced in the 1930s and has since become the most commonly used and widely investigated systemic opioid in labour. Widespread availability and ease of administration has resulted in the continued use of systemic pethidine in labour, despite overwhelming evidence that it is ineffective and has detrimental effects on both mother and baby.

Pethidine is usually given as an intramuscular injection, although intravenous boluses and infusions have been used in an attempt to improve the quality of analgesia. Better analgesia has been reported with intravenous boluses and infusions, but the side-effect profile remains unchanged. Improved efficacy has also been reported with patient-controlled analgesia (PCA), though pethidine consumption may be increased and neonatal depression more common.

A number of attempts have been made to improve the efficacy of pethidine by administering it in combination with other drugs. In general, such combinations have only increased sedation, amnesia and dysphoria, while having little impact on analgesia. When compared with epidural analgesia in randomized trials, pethidine invariably produces clinically inferior analgesia.

Effects on the mother: pethidine causes sedation and dysphoria. Pain relief during contractions is minimal, although some women report feeling less distressed. Respiratory alkalosis caused by hyperventilation associated with pain continues to occur during contractions. This causes a reduction in uterine blood flow and impairs placental gas exchange. Hypocapnia and sedation between contractions exacerbates maternal hypoventilation and hypoxia. Pethidine causes nausea, vomiting and delays gastric emptying.

Effect on the progress of labour: conflicting reports have suggested that pethidine might either slow or accelerate the progress of labour. Slowing of labour may be caused by an effect on maternal oxytocin and acceleration of labour by a number of mechanisms including: increasing the contractility of the body of the uterus; decreasing the contractility of the cervix; and stimulating the production of enzymes responsible for degrading cervical collagen and elastin. None of these changes has been shown to correlate with the duration of the active phase of labour and there continue to be no randomized, controlled trials to suggest that opioids in general, or pethidine in particular, have any effect on the progress of labour.

Effects on the baby: pethidine is a highly lipophilic molecule that is able to diffuse rapidly across the placenta. It is bound principally (30–60%) to α_1-acid glycoprotein. At term, levels of this protein tend to be higher in the maternal than in the fetal circulation and, in theory, favour distribution of pethidine into the maternal compartment. pH gradients across the placenta may be of greater importance. In the compromised fetus, acidosis may cause ion trapping, resulting in increased fetal pethidine levels and concomitant side-effects.

The neonatal side-effects of pethidine are compounded by production of its active metabolite norpethidine by both mother and fetus. Norpethidine is a considerably less potent analgesic than pethidine, but causes more respiratory depression and has pro-convulsant properties. The half-lives of pethidine and norpethidine in the mother are approximately 4 hours and 20 hours, respectively, but in the neonate are 13 hours and 62 hours, respectively. These prolonged half-lives probably explain why some of the behavioural changes observed in exposed neonates persist for several days after delivery.

Intrauterine effects *of pet*hidine include changes in fetal heart rate pattern (reduce**d variability), fetal br**eathing movements and muscular activity, fetal EEG activity and fetal scalp oxygen tension. Though these changes may not represent fetal distress per se, they may result in unnecessary obstetric intervention.

Early neonatal effects of pethidine include respiratory depression that is worst after a dose delivery interval of about 3 hours, and particularly after repeated maternal doses. This results in decreased Apgar scores, depressed oxygen saturations and increased arterial carbon dioxide tensions. Babies are sleepy, less able to develop suckling skills and take longer to establish breastfeeding. In large doses, pethidine can cause impaired thermoregulation in the newborn.

The effects of pethidine on the baby can be rapidly reversed immediately after delivery by administering n***aloxone,*** **a**n opioid antagonist, 60–100 μg/kg intramuscularly. At this dose, naloxone appears to have a clini***cal effect f***or up to 48 hours and reverses the neurobehavioural effects of pethidine without any apparent harm.

Other opioids
Morphine given via any systemic route confers no advantage and causes similar side-effects to pethidine.

Diamorphine is used enthusiastically in a small nu<u>m</u>**b*er of unit***s, but there is little information comparing it with other opioids. Increased lipid solubility suggests that it might reach the sites of action more quickly than morphine, but it is unlikely to offer any great improvement.

Meptazinol is a mixed opioid ***agonist/ant***agonist that enjoys popularity in a small number of units in which it is believed to be superior to pethidine. Though analgesia may be slightly improved, side-effects are similar apart from vomiting, which is more common.

Pentazocine is a mixed opioid agonist/antagonist that was deliberately synthes***ized to mi***nimize potential for abuse (large doses causing dysphoric side-effects). It causes sedation and is irritant on intramuscular or subcutaneous injection. There is no evidence that it provides superior analgesia to pethidi***ne.***

Nalbuphine is a mixed opioid agonist/antagonist similar to pentazocine. Sedation is common and it can cause dysphoria, though less so than pentazocine. There is little evidence that nalbuphine is more effective than pethidine.

Fentanyl is a highly lipid-soluble phenylpiperidine derivative that acts primarily on μ receptors. It is approximate***ly 80–100 ti***mes more potent than morphine. Information about systemic fentanyl in labour consists of unblinded studies and case reports. It is unlikely that fentanyl will provide significantly better analgesia by the systemic route.

Remifentanil is an ultra short-acting opioid analgesic agent. It produces rapid onset and offset of profound analgesia, but equally profound sedation and muscle rigidity. It was hoped that remifentanil might be suitable for intravenous PCA in labour. Unfortunately, although fast in onset, its peak effect does not occur until about 80 seconds after injection, when ***the inte***nsity of contraction pain is declining. Reports suggest that the dose required to provide effective analgesia during contractions can result in a high incidence of sedation, hypoventilation and hypoxia between contractions.

Tramadol is a weak μ agonist reported to have few of the detrimental side-effects associated with other opioids. Evidence concerning maternal and fetal side-effects is conflicting and tramadol has no clear advantages over pethidine.

Non-steroidal anti-inflammatory drugs (NSAIDs)

Compared with pethidine, ketorolac is less effective, but causes fewer maternal and neonatal side-effects. It is unlikely that NSAIDs will gain popularity for analgesia in labour because of the perceived risk of adverse effects on the fetal circulation, in particular, vasoconstriction and premature closure of the ductus arteriosus.

Pain Relief in Labour: Regional, Epidural and Patient-Controlled Epidural Analgesia

Robin Russell

Robin Russell is Consultant Anaesthetist at the John Radcliffe Hospital, Oxford, UK. He qualified from Guy's Hospital, London, and trained in anaesthetics at Guy's and St Thomas' Hospital,London, UK.

Although many methods have been used to relieve the pain of labour, regional blockade is the most effective. In the last national UK survey of pain relief in labour conducted in 1990 by the National Birthday Trust, about 20% of women received epidural analgesia. This figure has recently increased to 24% with a range of 5–40% between units.

Indications for regional analgesia

Maternal

Maternal request – because labour causes many women severe pain, an increasing number of maternity units now provide a 24-hour on-demand epidural service.

Coexisting disease – effective pain relief reduces maternal stress and the associated neuroendocrine response which, in certain conditions such as pre-eclampsia, may benefit both mother and baby.

Potential problems with general anaesthesia – compared with regional anaesthesia, emergency general anaesthesia carries a greater risk for both mother and baby. Regional analgesia can be readily extended to provide anaesthesia for operative delivery, therefore regional block is recommended for women at risk of intervention in whom intubation is expected to be difficult or those with known anaesthetic problems. Regional analgesia is also advisable for obese women because they are at increased risk of requiring operative delivery. Although the procedure may be technically challenging, the hazards of emergency general anaesthesia are avoided.

Fetal

Impaired utero-placental flow – fetal well-being may be improved with epidural analgesia because vasodilatation on both maternal and fetal sides of the placenta improves blood flow. This is of benefit in pre-eclampsia, in the growth-restricted fetus and in those with poor cardiotography (CTG) traces or Doppler studies.

Multiple pregnancy – the risk of malpresentation, especially of a second twin, is increased in multiple pregnancy making intervention more likely. Epidural analgesia reduces the need for emergency general anaesthesia should operative delivery be necessary.

Breech presentation – although many breech babies are now delivered by caesarean section, regional analgesia allows a controlled vaginal delivery with a calm cooperative mother and, if emergency caesarean section becomes necessary, the block may be extended.

Intrauterine death – provided coagulation is normal, regional analgesia may be suitable for pain relief.

Labour

Induction or augmentation of labour results in more severe pain. In prolonged labour, epidural analgesia allows the mother to rest while minimizing fetal acidosis. Operative delivery is more likely and the use of regional analgesia reduces the need for emergency general anaesthesia.

Previous caesarean section – epidural analgesia may be beneficial, although it used to be contraindicated because of fear that the pain of scar dehiscence would be masked. Pain is not an invariable feature of scar rupture and CTG abnormalities are a more reliable indicator of rupture. Scar dehiscence or rupture should, however, be considered in women with a working epidural who develop pain.

Operative or instrumental delivery – any woman in whom intervention is thought likely should be advised to have an epidural so that general anaesthesia may be avoided.

Manual removal of the placenta – in the absence of hypovolaemia, regional block negates the need for emergency general anaesthesia.

Repair of third-degree tear – effective pain relief is needed and local infiltration may be inadequate.

Contraindications to regional anaesthesia

Maternal refusal – informed consent must be obtained and, though this may be difficult in advanced labour, every effort must be made to explain the procedure.

Lack of trained staff – despite the potential benefits of regional analgesia, suitably trained staff must be available to monitor the mother for the duration of the block.

Risk of spinal haematoma – vascular trauma during needle insertion or catheter manipulation in the presence of abnormal coagulation may lead to an expanding haematoma, with the risk of ischaemic damage to neural tissue.

Local or systemic infection – epidural abscess or meningitis may occur in the presence of local or systemic infection. Prophylactic antibiotics may help to reduce the risk.

Coexisting disease – in certain cardiovascular conditions, such as pulmonary hypertension, severe valvular stenosis and bi-directional shunts, regional blocks may produce haemodynamic instability.

Uncorrected hypovolaemia – sympathetic blockade in the presence of hypovolaemia results in a dramatic reduction in cardiac output.

Allergy – true allergy to local anaesthetics is rare. Alternative drugs (see below) may be used where true allergy exists.

Pharmacology

Local anaesthetics

Local anaesthetics have a nonselective action that blocks all nerve fibres. Bupivacaine is the most popular agent in obstetric analgesia having replaced the shorter-acting lidocaine (lignocaine). Unlike its predecessor, it causes less motor block, does not demonstrate tachyphylaxis and produces lower systemic levels in both mother and baby. There have, however, been concerns regarding its safety, especially following accidental intravenous injection when cardiac arrhythmias are more likely to occur in doses close to those producing convulsions.

Bupivacaine is a racemic compound composed of two stereoisomers, of which the levo form is less toxic. Although the danger of cardiotoxicity may be minimized by safe practice (catheter aspiration and slow injection while maintaining eye and verbal contact with the mother), a search for a safer local anaesthetic has led to the development of new agents.

Ropivacaine is a single levo isomer which, in addition to reduced toxicity, may produce less motor block than bupivacaine. This may be because it has only 60% of the potency of bupivacaine. Levobupivacaine, the levo isomer of bupivacaine, unlike ropivacaine, has a similar potency to racemic bupivacaine.

Opioids

Unlike local anaesthetics, opioids produce only selective block of nociceptive pathways. Opioid receptors are found in the substantia gelatinosa of the spinal cord. Epidural or intrathecal injection allows ready access to these receptors at a much higher concentration than that which results from systemic administration. Side-effects such as nausea, vomiting, pruritus, urinary retention and respiratory depression are dose dependent. The lipophilic opioids are preferable because the more polar agents (e.g. morphine) have a slow onset of action and greater potential for side-effects.

Fentanyl is the most widely used agent in the UK. On its own, it does not produce reliable analgesia throughout labour and therefore it is usually combined with low-dose bupivacaine. Sufentanil may be effective without additional local anaesthetic when given intrathecally, but it is not available in the UK.

Alfentanil has been used effectively in epidural infusions, though large doses (30 μg/kg/hour) have been associated with neonatal hypotonia.

Diamorphine has a much longer duration of action and, when given with a loading dose, reduces the subsequent need for bupivacaine.

Pethidine has some local anaesthetic effect, but its duration of action is short.

Other drugs

Adrenaline (epinephrine) and clonidine both augment other analgesics through their α_2-action. Adrenaline (epinephrine) also has an α_1-action producing vasoconstriction, which intensifies the action of bupivacaine, while prolonging that of lidocaine (lignocaine). The anticholinesterase neostigmine produces analgesia, but nausea and vomiting limit its clinical usefulness. Other agents currently under investigation include adenosine, ketamine and midazolam.

Effects and complications of regional analgesia

Accidental dural puncture should occur in less than 1% of cases. An epidural needle may breach both the dura and arachnoid leading to free flow of CSF or, alternatively, the dura alone may be punctured and a catheter placed in the subdural space. A subdural block is typically slow in onset, extends much higher than would be expected with an epidural, but spares the sacral roots. It is often patchy with minimal motor block. Where both dura and arachnoid are torn, epidural insertion may be attempted at another level or alternatively the catheter passed directly into the CSF producing spinal analgesia. With the latter, analgesia is not delayed, there is no risk of repeat dural puncture and, provided appropriate doses are used, there is less risk of a dangerously high block. Furthermore, the block may be safely and quickly extended for operative delivery. As the dose for epidural analgesia is ten times greater than that for spinal use, unrecognized spinal injection of an epidural dose of local anaesthetic results in a rapidly ascending block with hypotension and, ultimately, apnoea and unconsciousness – total spinal anaesthesia. If this occurs, the mother must be intubated, ventilated and circulatory support provided until the block wears off. Urgent delivery of the baby may be required.

Local anaesthetics

Effects on the mother

Sensory block – block of lower thoracic, upper lumbar and sacral nerve roots provides pain relief in labour.

Motor block – increasing motor block, which is dependent on cumulative dose, reduces maternal satisfaction.

Autonomic block – block of preganglionic autonomic B fibres produces vasodilatation, which may lead to venous pooling with a fall in maternal cardiac output. This is exacerbated by the supine position (supine hypotensive syndrome), which must be avoided in women receiving regional block.

Proprioception – increasing doses of local anaesthetics progressively impair dorsal column function making ambulation unsafe.

Stress response – increased cortisol and catecholamine levels resulting from painful labour are reduced. Impaired uterine contractility from β-receptor stimulation and reduced placental blood flow from α-receptor stimulation are prevented.

Temperature regulation – epidural analgesia is associated with a rise in maternal temperature. Both the mechanism and significance of this rise are uncertain, though no adverse effect on either mother or baby has been demonstrated. Similarly, the cause of shivering that is often observed after large epidural top-ups is not fully understood.

Bladder function – difficulty passing urine is not uncommon in labour, though it is more common in those receiving regional blocks.

Toxicity – systemic toxicity (see above) may follow accidental intravenous injection or, rarely, the administration of large epidural doses for caesarean section.

Effects on the baby

Direct effects – lipophilic drugs readily cross the placenta, but adverse effects are unlikely and observed only if the amount in the maternal systemic circulation reaches toxic levels.

Indirect effects – hypotension resulting from autonomic blockade (see above) may reduce placental blood flow and produce fetal acidosis. Hypotension should be treated immediately with intravenous fluids and vasoconstrictors.

Effects on the progress of labour: there remains a widespread belief that regional analgesia has an adverse effect on the progress of labour and mode of delivery. Retrospective analysis reveals increased duration of labour with more operative and instrumental deliveries. However, such methodology is flawed, because women do not choose analgesia at random, but depending on the nature of labour. Consequently, those experiencing prolonged labour, that is more likely to end in intervention, are more liable to request regional analgesia. Moreover, if intervention appears probable, such as in fetal distress, women are advised to have an epidural so that emergency general anaesthesia is avoided.

Randomized studies, in which regional analgesia is compared with systemic analgesia, have produced conflicting results. Some studies have shown an increase in intervention, while others have not. As these studies are not blind, observer bias cannot be eliminated. Impact studies, in which the effects of introducing a service or increasing the number of women receiving regional analgesia are observed, may be more helpful. Several authors have reported little or no change in delivery outcome despite large increases in the epidural rate. The use of historic controls may be criticized as change in practice is not accounted for, however, it may be that this change is necessary to prevent increased intervention.

Delay in siting an epidural before an arbitrary cervical dilatation has been reached is not to be encouraged because no randomized data to suggest a benefit are available. Excessive intravenous fluid loading is also unnecessary and may transiently impair uterine contractility.

Different regional techniques (see below) appear to offer little benefit in terms of labour outcome. However, reducing the local anaesthetic dose leads to more spontaneous deliveries. Appropriate management of the second stage is vital and delay in pushing, providing there is no evidence of fetal distress and analgesia is maintained, allows descent of the presenting part. Pushing should be continued so long as there is continued descent and intervention should occur only when definitively indicated. The judicious use of oxytocin reduces the number of instrumental deliveries in nulliparous women.

Opioids

Effects on the mother

Pain relief – see above.

Pruritus is common, but is seldom troublesome other than with morphine.

Nausea and vomiting are common in labour. The increased incidence with opioids is dose dependent.

Respiratory depression is unlikely if appropriate doses of lipophilic agents are used. The potential for respiratory depression is much greater with epidural morphine.

Hypoxia – minor degrees of maternal desaturation have been observed when opioids are added to epidural solutions, though no adverse effects on mother or baby have been demonstrated.

Bladder function – urinary retention may occur as a result of blocking pelvic parasympathetic outflow.

Gastrointestinal – systemic effects, such as delayed gastric emptying are seen with large or repeated doses.

Reactivation of herpes simplex virus has been reported following epidural morphine.

Effects on the baby: although adverse changes in fetal heart rate have been observed after intrathecal opioids, the significance of these findings has yet to be established. If used appropriately, epidural opioids are unlikely to have clinically important effects on the baby.

Other drugs

Concerns have been raised about the effects of epidural adrenaline (epinephrine) on uteroplacental flow. Most studies have suggested that, in healthy women, its use does not compromise intervillous blood flow, although it may be best avoided in pre-eclampsia, when vessels are more sensitive to catecholamines. The addition of adrenaline (epinephrine) increases motor block. Clonidine in doses much above 100 µg produces maternal sedation and hypotension, both of which are undesirable. Clonidine does not appear to have any adverse effect on the baby.

Techniques

Before siting a regional block, informed consent must be obtained. Wide-bore intravenous access is established, though the practice of routinely pre-loading a fixed volume to prevent hypotension has been questioned. The procedure is performed at the second or third lumbar interspace for epidural analgesia (the lower space is safer for combined spinal-epidural) using a meticulous aseptic technique. Multi-hole catheters provide more reliable analgesia and are best inserted 4–5 cm into the epidural space.

The advantages and disadvantages of different regional techniques are listed in Figure 1.

Advantages and disadvantages of regional analgesic techniques

Advantages	Disadvantages
Intermittent top-up	
• Simple	• Fluctuations in analgesia
• Familiar	• Increased risk of side-effects after bolus
Epidural infusion	
• Continuous	• ? Increased motor block
• Increased safety	• Equipment
• Decreased midwifery workload	• Decreased feedback
Patient-controlled epidural analgesia	
• Autonomy	• Equipment
• Satisfaction	• Decreased anaesthetic input
• Decreased bupivacaine dosage	
Combined spinal-epidural analgesia	
• Rapidity	• Failure
• Ambulation	• Opioid side-effects
• Improved sacral block	• ? Increased neurological problems
• Increased satisfaction	

1

Test dose

To detect intrathecal or intravenous catheter placement, a test dose is given. No more than 15 mg of bupivacaine is injected and the mother is observed for evidence of hypotension, and motor and sensory block (see loading dose below). After 5 minutes, further doses may be given, though it is wise to limit each to less than 15 mg. Intravascular catheter placement is more difficult to detect as small doses of local anaesthetic have little systemic effect. The addition of adrenaline (epinephrine) lacks sensitivity and specificity in labouring women. For increased safety, a multi-hole catheter should be used, and gently aspirated before each injection. Each dose should be injected slowly while maintaining eye and verbal contact with the mother to look for symptoms of local anaesthetic toxicity.

Loading dose

The use of low-dose bupivacaine (< 0.125%) with fentanyl, using volumes of 15–20 ml (i.e. bupivacaine, 10–20 mg) in divided doses where appropriate, to ensure adequate spread, is becoming increasingly popular. A test dose of a more concentrated solution is unnecessary in this situation. Reducing the local anaesthetic dose minimizes motor block thereby increasing maternal mobility. Maternal blood pressure and fetal heart rate should be monitored closely after the loading dose.

Intermittent top-ups

Top-ups are given by either a midwife or anaesthetist as soon as painful sensations return as each dose takes several minutes to become effective. However, levels of analgesia invariably fluctuate and, after each top-up, hypotension is possible. Maternal blood pressure should be checked after each top-up. Top-ups should not be withheld early in the second stage of labour because maternal distress is increased without improving the chance of spontaneous delivery.

Epidural infusions

Epidural infusions decrease the need for top-ups, and reduce variations in pain relief as well as the risk of hypotension. Infusions may also be preferable to top-ups, because intrathecal or intravenous catheter placement should produce gradually increasing symptoms allowing more time for recognition and treatment. The workload for midwifery staff is also reduced.

Although infusions may increase motor block and immobility compared with top-ups of a similar concentration, infusions of more dilute local anaesthetics may be used to maintain analgesia with ambulation still possible. This technique, however, requires infusion pumps and delivery tubing, both of which may be expensive. Feedback on the spread of sensory block is lost during an infusion and a careful check on block height must be maintained.

Bupivacaine, in concentrations of 0.1% or less, is the preferred agent combined with an opioid, usually fentanyl. An initial rate of 10–12 ml/hour may be changed depending on block height, which should be kept at T10. Block height should be checked hourly, and maternal pulse and blood pressure noted every 30 minutes. Mothers should pass urine every 4 hours, otherwise a catheter may be required. In the second stage, block height and perineal sensation should be assessed. If the block is above T10 and perineal sensation absent, the infusion rate should be decreased. If the block is at or below T10, decreasing the rate leads to the return of abdominal pain and is of little benefit. If the mother reports pain, it may be advisable to give a top-up and stop the infusion.

Patient-controlled epidural analgesia (PCEA)

PCEA uses small intermittent self-administered boluses. Compared with continuous infusions of similar concentration, bupivacaine utilization is reduced, as is the need for supplementation. Autonomy allows women greater control and leads to high levels of satisfaction. PCEA does, however, require sophisticated pumps and concerns have been raised regarding the level of anaesthetic input after the initial loading dose.

Solutions containing bupivacaine 0.125% or less with fentanyl, 2–3 µg/ml, are preferable. The local anaesthetic dose is usually bupivacaine, 2.5–5 mg, with fentanyl, 10–12.5 µg, in a bolus of 3–5 ml. Lock-out time is set to 10–15 minutes with an hourly maximum dose of bupivacaine, 15 mg, and fentanyl, 30 µg. Background infusion offers little advantage and is not recommended. Mothers should be monitored as with epidural infusions.

Combined spinal-epidural analgesia (CSEA)

A needle-through-needle technique is most commonly used for CSEA, though the use of separate needles in either the same or different interspaces has been described. Onset of analgesia is more rapid and the quality of sacral analgesia better than with epidural block. Motor block is usually minimal if small intrathecal doses of bupivacaine and fentanyl are used, and most women may ambulate safely following the first dose.

The failure rate of CSEA is up to 10% when administered by those inexperienced in the technique. Intrathecal administration of opioids increases side-effects, especially pruritus, nausea and vomiting. Concerns about threading the epidural catheter through the dural hole are overstated and the incidence of dural puncture headache does not appear to be significantly increased. The possible increase in neurological problems is perhaps of greater concern. Although several cases of meningitis have been described following CSEA, it is uncertain whether the technique increases this risk. The possibility of conus damage is increased if the procedure is performed above the third lumbar interspace.

Intrathecal loading is usually with bupivacaine, 2.5 mg, and fentanyl, up to 25 µg, although in North America sufentanil, 10 µg, is often preferred. Initial analgesia usually lasts for at least 1 hour, after which the epidural catheter must be tested and its position confirmed.

CSEA is used routinely in some units, but many prefer to reserve its use for advanced labour, multiparous women in whom delivery is imminent and for resiting an unsatisfactory block in a distressed woman.

Postnatal complications

Post-dural puncture headache: see **OBSTETRICS**

Neurological symptoms are often attributed to the use of regional analgesia, but are more likely to be due to labour itself. The estimated incidence of prolonged neurological problems is 1/10,000–15,000 after epidural analgesia and 1/5000–10,000 after spinal block.

Chronic backache has been linked to the use of epidural analgesia in labour in several retrospective surveys. However, no prospective study has demonstrated such an association.

Urinary dysfunction may occur postnatally if the bladder becomes over-distended during labour. Long-term bladder dysfunction has not been directly linked with the use of regional analgesia in labour.

Physiology of Pregnancy

Joanna C Girling

Joanna C Girling is Consultant Obstetrician and Gynaecologist with a special interest in Obstetric Medicine at West Middlesex University Hospital, London, UK. She qualified from Cambridge University and St Mary's Hospital, London. She trained in Cambridge and London and was taught obstetric medicine under the aegis of Professor Michael de Swiet at Queen Charlotte's Hospital, London.

Pregnancy initiates many alterations to body systems, some of them extreme. Many of these changes are initiated within the first few weeks of pregnancy and return to baseline values 6 weeks after pregnancy. Knowledge of these adaptations is essential for understanding the physiology of normal pregnancy and the pathophysiology of conditions arising in pregnant women. In addition, some pregnancy-induced changes result in considerable adjustments to the reference ranges for many laboratory criteria; a failure to appreciate these alterations could cause diagnostic error or therapeutic mistakes.

Cardiovascular system

The details of the physiological changes of the cardiovascular system in normal pregnancy are debated, in part because of the difficulties of performing reliable and safe measurements. Longitudinal studies of echocardiography with Doppler measurement of blood flow at the pulmonary, mitral and aortic valves and in the ascending aorta using the women as their own nonpregnant controls give the most accurate assessment of cardiovascular changes.

The placenta creates a low resistance circulation, vasodilatation occurs peripherally and circulating volume increases. Increased heart rate, myocardial contractility and preload, and reduced afterload all influence cardiac performance in pregnancy, by expanding cardiac output.

Heart rate: early in the first trimester, the heart rate increases from about 75 beats/minute to almost 90 beats/minute. Palpitations and premature atrial and ventricular beats are common and usually benign. Stroke volume increases significantly, from 65 to 85 ml in the first trimester, reaching a peak at 20 weeks' gestation, which is maintained until term. Cardiac output changes over a similar time from 5 to 7 litres/minute. This is also maintained until term, and does not decrease in the third trimester; early studies that suggested a fall at the end of pregnancy were inaccurate because they were confounded by use of the supine position, and by changes in pulmonary vasculature and aortic dilatation which older techniques could not account for. This increase in cardiac output is distributed to the uterus (400 ml/minute extra), kidneys (300 ml/minute), skin (300–500 ml/minute) and other sites such as breasts, gastrointestinal tract, and cardiac and respiratory muscles.

Peripheral vascular resistance falls by almost 50% in early pregnancy even before the low resistance placental circulation has a significant effect. The underlying aetiology is uncertain, but oestrogen, prostaglandins, nitric oxide, relaxin and calcitonin gene-related peptide have all been implicated. The reduced peripheral vascular resistance, combined with the obstructive effect of the gravid uterus, contributes to the development of varicose veins and haemorrhoids in pregnancy. It also accounts for the susceptibility of pregnant women to supine hypotension; a left lateral tilt should always be used when lying a pregnant woman on an operating table.

Increases in left atrial and left ventricular end diastolic volume (preload) occur in the second and third trimesters, reflecting the increase in venous return. This combination of increased venous return and reduced peripheral vascular resistance is achieved by a marked increase in blood volume, which reaches a peak of 50% by the third trimester, and a relatively smaller increase in RBC count (20–40%) such that there is a reduction in blood viscosity (this may be one mechanism offsetting the prothrombotic effects of pregnancy; see later). The subsequent physiological dilutional anaemia of pregnancy does not require treatment providing haemoglobin remains above 10.0–10.5 g/dl.

Cardiovascular examination in pregnancy

The cardiovascular changes of pregnancy that are most clinically apparent are listed below.

- Enlargement of the heart by 10–15% and rotation to the left in the frontal plane.
- Mild sinus tachycardia.
- Apex beat displaced to the left.
- Loud third heart sound caused by rapid ventricular filling.
- More pronounced splitting of the second heart sound, especially towards term.
- Ejection systolic murmur in more than 90% of women, caused by flow across the pulmonary or aortic valves.
- Mammary soufflé (a continuous murmur in the left or right second intercostal space, which is uncommon and can be modified by pressure with the chest piece of the stethoscope).
- ECG often reveals a Q wave and inverted T wave in lead III, which should not, for example, be misconstrued as suggesting pulmonary embolus.

Blood pressure measurement: diastolic, and to a lesser extent, systolic blood pressure fall during normal pregnancy. Blood pressure depends on the cardiac output and peripheral resistance. In pregnancy, the increase in cardiac output is less than the decrease in peripheral resistance, therefore overall blood pressure falls. The nadir is reached at 12–16 weeks' gestation; systolic blood pressure falls by 0–9 mm Hg and diastolic pressure by 12–17 mm Hg. In the late second and third trimesters, blood pressure increases towards levels found in the nonpregnant woman (Figure 1).

Although a blood pressure reading of 140/90 mm Hg is often considered to be part of the diagnostic criteria for pre-eclampsia, it is important that the measurement is interpreted in relation to gestation. At term, 20% of women have at least one measurement of 140/90 mm Hg or more; at 30 weeks' gestation this occurs in only 1% of pregnant women, and therefore is much more likely to reflect significant pathology.

Problems in measuring blood pressure in pregnancy include:

- compression of the inferior vena cava by the gravid uterus (pregnant women should not be supine when blood pressure is measured)
- white-coat hypertension
- observer error
- equipment inaccuracies
- uncertainty about which Korotkoff sound to use (evidence is now accumulating that Korotkoff sound 5 (K5) is more reproducible in pregnancy than sound 4 (K4); many now use K5 rather than K4, except in unusual cases when K5 falls to zero).

Automated devices – automated blood pressure devices significantly under-read diastolic pressure in a variable and unpredictable manner, by up to 25 mm Hg, particularly in women with pre-eclampsia. When an automated device is used in pregnancy, measurements should be checked against those obtained from a mercury sphygmomanometer or an aneroid device.

Changes in blood pressure with advancing gestation

1

Obstetric haemorrhage

Obstetric haemorrhage (antenatal or postnatal) can be catastrophic and require aggressive management from a multidisciplinary team. The increased circulating volume of pregnancy provides some initial protection from the effects of haemorrhage. In general, pregnant women have a healthy reactive vasculature, and are able to compensate for blood loss by mounting a tachycardia; blood pressure falls late in the course of obstetric haemorrhage and is an ominous sign (Figure 2).

Blood loss and shock in pregnancy

Blood loss (ml)	Circulating volume lost (%)	Systolic blood pressure (mm Hg)	Symptoms/signs	Shock
500–1000	10–15	Normal	Palpitations, dizziness, tachycardia	Compensated
1000–1500	15–25	Slight fall	Weakness, sweating, vomiting	Mild
1500–2000	25–30	80	Restlessness, pallor, oliguria	Moderate
2000–3000	30–50	50–70	Collapse, air hunger, anuria	Severe

2

Peripheral oedema

Peripheral oedema of the legs and hands occurs in most normal pregnancies as a result of physiological changes:

- obstruction of venous return by the gravid uterus
- peripheral vasodilatation
- increased plasma volume
- decreased colloid osmotic pressure (due to haemodilution rather than altered protein production)
- increased vascular permeability.

The presence of peripheral oedema is seldom helpful in the assessment of pre-eclampsia, and it has been removed from most definitions of the condition.

Physiological changes in coagulation and thromboembolic risk

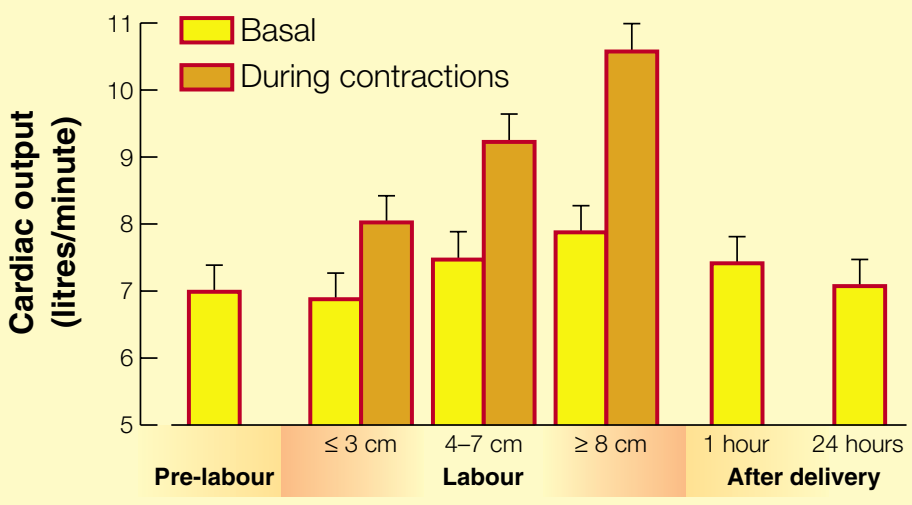
Physiological increases in coagulation factors I (fibrinogen), VII, VIII, IX, XII and a decrease in some endogenous anticoagulants (antithrombin, protein S, activated protein C resistance) occur during pregnancy, and are intended to reduce the risk of haemorrhage, especially at delivery. However, associated with the physiological vasodilatation of pregnancy, they contribute to a six-fold increase in risk of thromboembolism during pregnancy. Trauma to the pelvic veins at delivery, sometimes in association with dehydration or immobility, accounts for the additional thromboembolic risk in the puerperium. In the UK, thromboembolic disease is the leading cause of maternal mortality. Prevention entails assessment of thromboembolic risk in every pregnant woman, and in particular at delivery. Caesarean section is a major risk factor for thrombosis, and the Royal College of Obstetricians and Gynaecologists has issued guidelines for thromboprophylaxis.

The diagnosis of acute thromboembolism should be considered in a pregnant woman with relevant leg or chest symptoms, and care taken in the correct interpretation of investigations. D-dimer measurement is unhelpful because it is elevated in normal pregnancy. Duplex Doppler assessment of the femoral veins is used to diagnose deep vein thrombosis. The amount of radiation involved in ventilation perfusion scanning is negligible in the face of the risks to maternal and fetal well-being of an incorrectly diagnosed pulmonary embolus.

Cardiovascular changes in labour

During labour additional physiological changes occur. Cardiac output increases by a further 15–20%, in part because of 'autotransfusion' from the contracting uterus (Figure 3). At delivery, a further 500 ml or more of blood may be autotransfused as the placenta is delivered; in a small group of women with volume-dependent cardiac disease (e.g. pulmonary or mitral valve stenosis), the postnatal period may therefore be particularly dangerous. Sympathetic nervous system stimulation through maternal pain or anxiety results in a further increase in heart rate and possibly an increase in blood pressure. Regional anaesthetic techniques can play an important role in assisting blood pressure control during labour, both by providing analgesia and as a direct result of sympathetic blockade.

Changes in cardiac output during labour



Changes in cardiac output in 15 women during labour measured using cross-sectional and Doppler echocardiography in the left lateral position. Figures are mean (± SE).

3

Respiratory system

In nonpregnant women, oxygen consumption is 250 ml/minute at rest. During pregnancy, this increases by 15–20% to about 300 ml/minute. The increase is mainly to maintain the additional metabolic requirements of pregnancy; the uteroplacental circulation and the additional 'work' of the maternal circulation. However, ventilation increases by 40%, such that the partial pressure of oxygen is unchanged (i.e. more oxygen is consumed but more is acquired), remaining at about 13 kPa (100 mm Hg). The partial pressure of carbon dioxide is considerably reduced by this increase in ventilation, falling from 5 kPa (35–40 mm Hg), to about 4 kPa (30 mm Hg); thus in, for example, the assessment of severe asthma, an apparently normal partial pressure of carbon dioxide may represent carbon dioxide retention. Arterial blood gas assessment should never be performed in the supine position during pregnancy because inferior vena caval compression by the gravid uterus and functional reduction in pulmonary residual capacity and closing volume may give a false impression of hypoxia; the partial pressure of oxygen falls by 2 kPa to about 11 kPa (83 mm Hg).

This increase in ventilation is achieved by increasing the tidal volume (the volume of air moved during a normal inspiration or expiration) from 500 to 700 ml. The 'driving force' is progesterone, which stimulates the respiratory centre directly and increases sensitivity to carbon dioxide. This is achieved at the expense of the inspiratory and expiratory reserve volumes, but the vital capacity (the volume that can be inhaled from forced expiration) is unchanged. The expanding uterus decreases the residual volume (the volume of air remaining in the lungs at the end of forced expiration) and, therefore, the total lung capacity, thereby reducing the 'dilution' effect of inspired air and further improving ventilation in the alveoli (Figure 4).

There is no change in the respiratory rate, peak expiratory flow rate or the forced expiratory volume in 1 second. Transfer factor falls early in pregnancy, which may account for the deterioration of some cases of severe fibrotic lung disease during pregnancy. However, many pregnant women have a subjective sensation of shortness of breath. It may be related to the extra work resulting from the increased ventilation of pregnancy or to a change in the shape of the thorax as the ribs become more horizontal and therefore at a potential mechanical disadvantage.

Changes in lung volumes during pregnancy

Renal tract

During pregnancy, the kidneys increase in length by 1 cm, and the renal calyces, renal pelvis and ureter dilate. This is more marked on the right than the left side, because of the uterine tendency to dextrorotation, but is mostly under the smooth muscle relaxing effect of factors such as progesterone.

Renal blood flow increases in pregnancy. One consequence of this is a 50% increase in glomerular filtration by the end of the first trimester. The filtered load therefore increases, which is paralleled by increments in tubular reabsorption. The increase in glomerular filtration rate (GFR) is reflected in clinical practice by a rise in creatinine clearance; this also occurs in transplanted kidneys and often in diseased kidneys. As a consequence, serum creatinine begins to fall early in the first trimester, reaching a nadir in the second trimester and then increasing slightly towards term. Therefore, in pregnancy, a serum creatinine level greater than 85 µmol/litre is usually the result of renal impairment; care must be taken to interpret renal function blood results correctly in pregnancy.

Glycosuria is common in pregnancy and does not warrant further investigation unless persistent and severe. It is usually a consequence of the increased GFR; the increased amount of glucose passing into the urine may saturate the active transport system of the proximal tubule which 'retrieves' glucose. This is particularly likely if there has been a significant carbohydrate load.

Uric acid is freely filtered by the glomerulus and actively reabsorbed by the proximal tubule, the net consequence in pregnancy being a 25% fall in the circulating levels. As pregnancy progresses, tubular function changes, net excretion by the tubules falls, and consequently plasma levels increase towards their nonpregnant values in the third trimester. In general, the urate concentration rises in parallel with the number of weeks of pregnancy (< 300 µmol/litre at 30 weeks, < 350 µmol/litre at 35 weeks). In pre-eclampsia, urate levels are increased compared with normal pregnancy. This often occurs early in the course of the disease, and is the result of impaired tubular function. Later in pre-eclampsia, glomerular function may be altered, resulting in an increase in creatinine; interpretation of the result in relation to normal values for pregnancy is critical.

Proteinuria: in normal circumstances, there is virtually no protein in urine. During normal pregnancy there is an increment in proteinuria, the upper limit of normal being 300 mg/ 24 hours. This may reflect the increased GFR, changes in the glomerular basement membrane or altered tubular function. In pre-eclampsia, proteinuria may be marked, with values commonly reaching more than 3 g/24 hours. This is due to (temporary) glomerular damage by pre-eclampsia and usually occurs after an increase in uric acid.

Gastrointestinal tract

The causes of the extensive physiological changes in the gastrointestinal tract in pregnancy are debated. Hormonal effects, including smooth muscle relaxation, and pressure effects from the gravid uterus are likely to be important.

Changes in oestrogen and progesterone result in a fall in pressure at the lower oesophageal sphincter. This combined with slowing of peristaltic waves in the lower oesophagus makes it 'easier' for stomach contents to reflux into the oesophagus. Early in pregnancy, there is also a small increase in intragastric pressure and 80% of pregnant women experience heartburn. The pH of gastric contents and the production of gastric acid are unchanged in pregnancy. The contractile response to exogenous stimuli is impaired, for example protein-rich foods stimulate less production of gastrin, resulting in decreased gastric emptying. This is marked during labour and is exacerbated by the use of parenteral opioids. This is one of the reasons why general anaesthesia should be avoided during labour.

Hormonal relaxation of large bowel smooth muscle contributes to the reduced frequency of defecation in pregnancy.

Physiological effects of human chorionic gonadotrophin

Hyperemesis gravidarum is a potentially serious complication of the first half of pregnancy. Vomiting can be of sufficient severity to cause dehydration, weight loss or both, and the woman is likely to be dependent on anti-emetics and intravenous fluids; thiamine supplementation is essential to prevent Wernicke's encephalopathy. In at least 25% of such pregnancies, abnormal liver or thyroid function may occur, and these are markers of disease severity; biochemical abnormalities resolve as hyperemesis gravidarum abates. The aetiology of the liver abnormality is likely to be a direct toxic effect of the dehydration and starvation. The thyroid abnormality is a result of human chorionic gonadotrophin (hCG). The α subunit of hCG is identical to the α subunit of thyroid stimulating hormone (TSH), and as a consequence hCG has weak TSH-like activity. In some women with hyperemesis gravidarum, hCG subtypes with increased TSH-like activity are produced. This results in a biochemical picture of thyrotoxicosis, which resolves when hCG returns to normal. It does not require treatment with antithyroid agents.

Liver

During pregnancy, the absolute blood flow to the liver is unchanged. Oestrogen influences the metabolism of a number of hormone-binding proteins produced by the liver; for example, the half-life of thyroxine binding globulin (TBG) is extended from 15 minutes to 3 days. This results in increased circulating concentrations of TBG, and therefore of total thyroxine (T4) and tri-iodothyronine (T3). Free T4 and T3 concentrations are essentially unchanged in iodine-replete areas, until the third trimester when they both fall. Pregnancy-specific reference ranges must be applied, and only free T4, free T3 and TSH should be used. Other markers of liver function fall during pregnancy, probably because of the haemodilutional effects of pregnancy (albumin, transaminases, γ-glutamyltransferase and bilirubin fall by about 20%). However, alkaline phosphatase increases; the upper limit of normal for pregnancy is three times greater than the nonpregnant reference range. This is because of placental production of a heat-stable isomer. In cases of clinical uncertainty, heating the blood to 60°C for 10 minutes results in destruction of the heat-labile liver isomer, and reanalysis of the sample allows the source of the excess to be determined. Spider naevi and palmar erythema are common physiological changes in the skin during pregnancy, probably as a result of high oestrogen concentrations. They do not imply liver disease.

Pruritus may occur in normal pregnancy and is probably benign. It must be distinguished from the itching of obstetric cholestasis by the finding of liver function tests outside the normal range for pregnancy, because this condition has a 2% risk of stillbirth.

Post-dural Puncture Headache in Obstetrics

S M Yentis
M Rucklidge

S M Yentis is Consultant Anaesthetist at the Chelsea and Westminster Hospital and Honorary Senior Lecturer at Imperial College School of Medicine, London, UK. He qualified from University College Hospital, London, and trained in and around North West London. His interests include routine and high-risk obstetric analgesia and anaesthesia.

M Rucklidge is Specialist Registrar at the Imperial College School of Medicine, London, UK. He qualified from St Mary's Medical School, London. His interests are the difficult airway and obstetric anaesthesia.

Post-dural puncture headache (PDPH) is a well-known complication of spinal or epidural anaesthesia and diagnostic lumbar puncture. First described by August Bier in 1898, it represents the most common potentially serious complication of obstetric regional analgesia and anaesthesia. The reported incidence of accidental dural puncture during epidural analgesia is 0.19–4.2% in the UK, and 4–6% in the USA.

Aetiology

The precise aetiology of PDPH is unknown, though it probably involves leakage of CSF through the dural hole. This reduces the physical buffering provided by CSF within the skull. In the upright position, the intracranial structures 'settle', exerting traction on pain-sensitive fibres attached to venous sinuses, dura and other structures. This explanation fits with the observation that the bigger the dural hole, the greater the incidence and severity of PDPH. There is evidence of intracranial vasodilatation associated with PDPH, raising the possibility of similarities between PDPH and migraine, in which cerebral vascular reactivity is also implicated.

Contributory factors

Several factors may increase the risk of PDPH following accidental dural puncture (Figure 1). Many investigators have shown that the incidence of PDPH decreases with increasing age. Previous studies have demonstrated increased susceptibility to PDPH in females though recent investigations have found no relationship; the general belief that gender affects PDPH may relate to the inclusion of young parturients in the older studies.

Leakage of CSF through a dural tear is influenced by the size of the spinal needle and the design of the needle tip. In obstetrics, the incidence of PDPH ranges from under 1% with 27 G pencil-point needles to 14% with 20 G cutting needles. Sharp-point spinal needles (e.g. Quincke) cut dural tissues and allow dural tears to persist. Non-cutting atraumatic needles (e.g. Whitacre, Sprotte) are believed to spread dural fibres and allow rebound closure after their withdrawal (see *Anaesthesia and Intensive Care Medicine* **2:3:** 106 Figure 5). The incidence of PDPH following accidental dural puncture with a 16 G epidural needle is 70–85%. Insertion of the epidural needle with the bevel orientated parallel to the longitudinal dural fibres is associated with reduced incidence of PDPH should accidental puncture occur, compared with insertion with the bevel perpendicular to the dural fibres. Dural fibres are thought to close round a longitudinal hole more efficiently than round a transverse hole.

The effect of pushing in the second stage of labour on PDPH is contentious. It was previously common that any woman suffering accidental dural puncture was given an instrumental delivery to avoid pushing, but this practice became unpopular in the 1990s because any neonatal injury arising from the delivery could be traced to the accidental dural puncture. However, a recent retrospective study found that the incidence of PDPH and requirement for epidural blood patch were higher in women who actively pushed in the second stage following a well-documented single accidental dural puncture, compared with parturients who underwent caesarean section without pushing.

Predisposing factors for post-dural puncture headache

Patients' characteristics
- Younger age
- ?Female sex
- Pregnancy

Characteristics of dural hole
- Large size
- Made with cutting, as opposed to pencil-point, needle
- Bevel of needle oriented transverse to dural fibres

Subsequent management of patients
- ?Allowing mothers to push in second stage of labour

1

Presentation and diagnosis

Typically, PDPH presents 1–3 days after accidental dural puncture. It may be severe and is usually occipital or frontal. Neck pain may be a primary feature or secondary to muscle spasm. The headache may be accompanied by dizziness, vomiting and visual or auditory symptoms. Characteristically, the headache is absent or markedly reduced when supine and worse when upright. Following a slow CSF leak (e.g. after spinal anaesthesia with a pencil-point 27 G needle) headache may develop 15–30 minutes after adopting the upright position.

There are many causes of headache post-partum (Figure 2), therefore it is important to confirm the diagnosis. A history of definite accidental dural puncture and a clear postural component to the headache make the diagnosis almost certain, with two caveats. First, it is possible for more than one aetiology to coexist, which may confuse the clinical picture. Second, post-partum presentation of an incidental brain tumour is a rare but well-recognized event, so the fundi should always be examined. In difficult cases, a useful manoeuvre, described by Gutshe in 1990, is to ask the mother to sit up, wait until the headache returns and compress her right upper abdominal quadrant (remembering this may be painful after caesarean section), asking her to comment on the headache's severity. A PDPH will ease, presumably as a result of epidural venous congestion secondary to hepatic compression.

It may be possible to diagnose a dural tear using imaging techniques (e.g. MRI) and estimations of CSF volume, but this is not widely available. The diagnosis in most cases remains clinical.

Causes of headache in the early post-partum period

- Post-dural puncture headache
- Non-specific headache
- Migraine
- Pre-eclampsia
- Meningitis
- Cerebral tumour
- Subarachnoid haemorrhage
- Subdural haematoma
- Cerebral vein thrombosis

2

Management

Left untreated, most headaches resolve over 5–7 days, though PDPH lasting for several months or even years has been reported. Rarely, serious neurological sequelae may follow PDPH, including subdural haematoma and seizures. Deaths from subdural haematoma or coning have been described following accidental dural puncture, diagnostic lumbar puncture and spinal anaesthesia in patients without raised intracranial pressure or other risk factors. Subdural haematoma is presumed to be caused by shearing forces on delicate subdural vessels resulting from intracranial hypotension in the upright position. It is thus considered important to treat PDPH in order to prevent these serious late sequelae, though it is unknown whether symptomatic treatment of PDPH reduces their incidence.

Few treatments of PDPH have been shown to be effective in randomized clinical trials, though several have been described anecdotally (Figure 3).

Treatment for post-dural puncture headache[1]

Supportive
- Avoidance of dehydration
- Emotional support

Drugs
- Simple analgesics
- Caffeine
- Sumatriptan
- Adrenocorticotrophic hormone
- Ergotamine

Interventional procedures
- Epidural blood patch

[1]Most treatments are supported only by weak, if any, evidence.

3

Supportive management
Traditional supportive management of PDPH includes bed rest and hydration. Bed rest may temporarily alleviate symptoms but does not prevent the onset of PDPH and there is no evidence that hydration (rather than avoidance of dehydration) helps. It is important to offer emotional support because the headache may be incapacitating and prevent the mother from caring for her baby.

Drug treatment
Paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used as first-line treatment; while paracetamol may help, NSAIDs are often ineffective (personal observation). Paracetamol–opioid combinations have not been shown to be more effective than paracetamol alone.

Caffeine has been found to provide relief, albeit sometimes transient, in randomized controlled trials. It may also reduce the incidence of moderate or severe headache if given prophylactically following spinal anaesthesia. Its mechanism of action is uncertain but may be related to its ability to increase cerebral vascular resistance and decrease cerebral blood flow and volume. A suitable oral dose is 150–300 mg every 6–8 hours. Side-effects include nausea, convulsions and neonatal irritability.

5-HT, a cerebral vasoconstrictor, is important in the pathophysiology of migraine. Sumatriptan, a 5-HT_{1D} receptor agonist, is effective against migraine, and anecdotal reports (but not randomized controlled trials) suggest that 6 mg subcutaneously, repeated if necessary, may be useful in PDPH. Side-effects include pain at the injection site and transient chest tightness; 5-HT_{1} agonists are contraindicated in ischaemic heart disease.

Use of adrenocorticotrophic hormone (ACTH), 1.5 μg/kg i.v., or its synthetic analogue tetracosactide (tetracosactrin), 1 mg i.m., repeated 24 hours later if necessary, has been described but without validated trials. A mechanism of action has not been proposed.

Another drug that has been used is ergotamine. A combination of caffeine, 100 mg, and ergotamine tartrate, 1 mg, has been successful anecdotally but a definitive report has not been published. In addition, ergotamine is contraindicated in pregnancy and breast-feeding.

Epidural blood patch

Epidural blood patch is generally considered the definitive treatment for PDPH and its effectiveness is well established. Blood is taken aseptically from the patient's arm and slowly injected into the epidural space. First reported by Gormley in 1960 using 2–3 ml blood, more recent evidence suggests larger volumes are more effective; 15–20 ml is usually used as a target though injection may be limited by back pain or discomfort. Success rates of over 90% have been quoted, with complete and instantaneous resolution of symptoms. However, recent reports suggest success rates of 61–75% though over 90% of patients may experience initial relief. There is some evidence that 2 hours or more spent lying flat following epidural blood patch may increase the chance of success. A second blood patch may occasionally be required.

Contraindications to an epidural blood patch are related to placement of the epidural needle (patient's refusal, coagulopathy or infection at the puncture site) or to injection of autologous blood, primarily the potential for epidural injection of infected blood. Pyrexia may reflect concurrent bacteraemia and, despite limited data, many authorities advocate delaying epidural blood patch until the patient becomes afebrile.

Anecdotal evidence suggests that epidural injections of solutions other than blood may be effective in treating established PDPH. Dextran 40, 20–30 ml, has been used with encouraging results, albeit in uncontrolled trials. Fibrin glue, a preparation of pooled human plasma used to treat CSF leak in neurosurgery, has been injected into the epidural space and reported to be effective. Saline has been used to provide temporary relief and as a diagnostic measure before epidural blood patch in difficult cases.

Prevention

Approaches to minimizing PDPH include reducing the incidence of accidental dural puncture and reducing its severity should it occur. The first strategy involves adequate training and supervision, because accidental dural puncture rates are higher in units with a large number of relatively inexperienced trainees. The minimum number of procedures required for trainees to achieve competence is unclear but attempts to define this have been made. Other possibly preventative factors (although evidence is weak) include the use of saline instead of air for loss of resistance and the paramedian approach to the epidural space. There are no published prospective, randomized controlled trials of adequate size comparing air and saline for loss of resistance. There are, however, numerous case reports of complications associated with the use of air, including pneumocephalus, spinal cord and nerve root compression and venous air embolus.

Several methods for reducing the severity of PDPH after accidental dural puncture have been proposed. Subarachnoid insertion of the epidural catheter after recognized accidental dural puncture is an alternative to traditional management (removing the needle and resiting the epidural at an adjacent interspace). The catheter is then used to provide analgesia during labour. A potential benefit of this approach is suggested largely by retrospective studies. The catheter may 'plug' the dural tear during labour and reduce the efflux of CSF; increased formation of fibrin around the catheter has been described experimentally and this may also contribute if the catheter is left *in situ* for 24 hours. Accidental intrathecal injection of epidural doses of drugs must be avoided by labelling the catheter and informing all relevant staff.

There is consistent evidence that prophylactic epidural saline decreases the incidence and severity of headache after accidental dural puncture. Epidural saline is administered either by bolus, 60 ml at 0 and 24 hours, or by continuous infusion, 500–1000 ml over 24 hours. The saline is thought to tamponade the intrathecal space and prevent efflux of CSF.

Prophylactic blood patch (i.e. via the epidural catheter before its removal) has been used in an attempt to reduce the incidence and severity of PDPH, but this is controversial, with poor success rates described by some authors. A possible reason for its failure is the property of local anaesthetics to inhibit coagulation of blood.

Finally, use of neuraxial opioids has been suggested as reducing PDPH after accidental dural puncture but the evidence is weak. A putative mechanism is unknown.

Postoperative Pain Management in Obstetrics

Michael Kinsella

Michael Kinsella is Consultant Obstetric Anaesthetist at St Michael's Hospital, Bristol, UK. He trained at St George's Hospital, London, and obtained postgraduate training at Kingston, Queen Charlotte's and Hammersmith Hospitals. His interests are the haemodynamic effects of pregnancy, obstetric anaesthesia and analgesia.

This article concentrates on pain management after caesarean section, because this operation makes up the bulk of obstetric anaesthetic cases. However, issues unique to pregnancy arise in the first trimester and continue into the post-partum period. In the UK, many drugs are not licensed for use in pregnant women. The licence for a particular indication, or in a certain group of patients, is gained when the manufacturer provides positive evidence of safety. Most pregnant women are healthy, therefore there is little financial reward for pharmaceutical companies in seeking a licence for drugs in this group of patients (with the exception of local anaesthetic drugs). Sometimes there is no drug for a given indication that has a licence for use in pregnancy. When presented with such a situation, it is sensible to use an 'old' drug wherever possible because there will be a body of evidence to support its use if problems arise.

During organogenesis, early in the first trimester of pregnancy, there is the possibility that a drug may cause teratogenesis (the production of a structural malformation in the fetus). No established analgesic or anti-emetic drugs that are used perioperatively are known to have this effect. A recent paper has suggested that use of non-steroidal anti-inflammatory drugs (NSAIDs) during early pregnancy is associated with an increased risk of miscarriage.

Later in pregnancy, there is the possibility that analgesic drugs given to the mother perioperatively have pharmacological effects on the fetus. There is a theoretical possibility that long-term use of NSAIDs might cause closure of the ductus arteriosus *in utero*, though this has not been found to be a problem when high-dose NSAIDs have been used in the short term for the treatment of preterm labour. Long-term use of NSAIDs is also associated with oligohydramnios.

It can be assumed that all drugs are transferred into breast milk, though many in trace concentrations only. The amounts that a breast-fed neonate ingests would not have pharmacological effects. However, many anaesthetists stopped using aspirin for routine post-caesarean section analgesia after the Committee on Safety of Medicines stated that it should not be used in children because of a suspected link with Reye's syndrome.

Caesarean section

In non-obstetric practice it is common to use multimodal analgesia at the time of operation, often given before skin incision to gain the benefit of a possible 'pre-emptive' effect. This is not used for caesarean section to avoid transplacental exposure of the fetus to different drugs, especially potentially sedative analgesics.

Guidelines for the use of analgesia in patients undergoing caesarean section are given in Figure 1.

Analgesia guidelines for caesarean section

General anaesthesia
- Peroperative: morphine at least 20 mg (or morphine and other opioid)
- Postoperative: morphine 1 mg (1 ml) dose given by patient-controlled analgesia, 5 minute lockout

Regional anaesthesia
- Spinal: elective diamorphine, 0.3 mg; very urgent case fentanyl, 25 μg
- Epidural top-up for caesarean during labour: ± fentanyl, up to 100 μg
- Postoperative: intramuscular morphine (up to) 1 hourly as needed – first dose not before 2 hours after spinal or epidural opioid

All cases
- Diclofenac 100 mg suppository at end of operation (contraindicated in cases of haemorrhage or pre-eclampsia)
- Regular paracetamol and diclofenac for first 3 days

Source: St Michael's Hospital, Bristol, UK.

General anaesthesia
In general, strong opioid drugs are not given systemically before delivery by caesarean section because of their depressant effect on the neonate. The use of remifentanil to provide analgesia until delivery, with no neonatal effects, has recently been described. This approach is potentially of major importance in a few cases in which cardiovascular stability is crucial, but its role in routine practice remains to be defined.

Large doses of fentanyl or morphine (e.g. at least 20 mg) given after delivery are tolerated and indeed are required. After the patient wakes, increments of morphine or diamorphine are given intravenously until she has been made comfortable (moderate pain or less), and then patient-controlled analgesia (PCA) is started.

Maternal deaths have occurred after general anaesthesia for caesarean section when hypotensive or shocked patients had several doses of intramuscular or subcutaneous morphine close together. There was a suggestion that excessive blood levels of morphine were produced when muscle blood flow started to return to normal. It is important to be aware of this possibility when the intramuscular route is used, especially as recovery facilities in obstetric units may be of an inferior standard to those in general operating theatres.

Ilio-inguinal blocks have been tried but do not confer much advantage.

Regional anaesthesia
When a regional anaesthetic is used for caesarean section, the analgesic options become more flexible and more effective. The local anaesthetic block provides pre-emptive analgesia. Opioids may be given before delivery, because the doses are lower than those required for systemic analgesia. The ratio of the dose used neuraxially (i.e. epidural or spinal (intrathecal)) compared with the systemic dose depends on two factors. Spinal doses are smaller than epidural doses, and drugs that are less lipid-soluble are used in smaller doses than those with greater solubility. The dose of spinal morphine, which has the lowest lipid solubility of clinically used opioids, is about one-hundredth of the systemic dose.

When there is an option of using either the spinal or epidural route, the spinal option may be preferable because equipotent analgesia is possibly associated with fewer minor side-effects. The serious complication of delayed respiratory depression may also be less likely with the spinal route. The epidural space may act as a 'depot' for delayed absorption, whereas a lipophilic opioid placed into the CSF is rapidly cleared into tissues. These include neural tissues, and thus lipophilic drugs given spinally also have a rapid onset of action.

Worldwide, morphine is the most commonly used spinal opioid. Doses of 0.1–0.15 mg produce prolonged analgesia. It has a good safety record in obstetric practice. However, because of slow absorption from the CSF, the drug is unlikely to have an effect during or immediately after the operation. Thus fentanyl, 10–25 μg, is often combined with morphine for its intraoperative effect.

A simpler answer is to use diamorphine. This has a rapid onset that supplements intraoperative anaesthesia and anal-gesia. It gives postoperative analgesia of comparable duration to morphine but with less central side-effects of itch and drowsiness. The author currently uses diamorphine, 0.3 mg, as the best compromise between analgesia and side-effects, but further studies may alter this. The maternal position in which the spinal block is inserted may influence the duration of analgesia. There is evidence that when insertion is in the sitting position, doses larger than 0.3 mg are needed to produce a comparable effect to 0.3 mg administered while the woman is in the lateral position.

Analgesic considerations are similar when comparing an epidural or combined spinal-epidural, though an epidural opioid is more likely to be required before delivery to supplement the anaesthesia produced by an epidural block on its own. When anaesthesia is provided with local anaesthetic only in the spinal during combined spinal-epidural anaesthesia, it is common to give a dose of opioid through the epidural catheter after delivery of the fetus. Morphine is usually given as a single dose only, whereas diamorphine may be repeated on several occasions.

In a small number of sick mothers, such as those with severe pre-eclampsia, an optimum postoperative analgesic technique may promote cardiovascular stability and therefore aid overall management. The author favours continuous infusion of a low concentration mix of opioid and local anaesthetic, which provides analgesia and possibly a reduction of plasma catecholamines, while avoiding the fluctuations of effect seen with bolus doses. However, this technique is labour intensive and many units would be unable to provide this for routine post-natal cases.

There are a number of units in which all women who have had neuraxial opioids perioperatively are managed in a high dependency unit. Readers should check their own local policies.

Other analgesics
The use of non-opioid analgesics is similar after general and regional anaesthesia. NSAIDs are effective and should be used in most cases, but are contraindicated in pre-eclampsia and if there are concerns about recent or impending haemorrhage and hypovolaemia. It is preferable that oral analgesics (NSAIDs and paracetamol) are prescribed on a regular basis rather than just given when requested.

Other operations

The author adapts the approach given above for other surgical procedures. Postoperative pain may not be a feature of some procedures (retained placenta or insertion of cervical cerclage), but can be severe after repair of episiotomies or large perineal tears. The author uses spinal fentanyl or diamorphine in the latter cases when spinal anaesthesia is used for surgery.

Pain management after vaginal delivery may also be greatly improved by applying a systematic approach to analgesia similar to that used for postoperative patients.

Pre-eclampsia and the HELLP Syndrome

Paul Howell

Paul Howell is Consultant Anaesthetist at St Bartholomew's and Homerton Hospitals, London. He specializes in obstetric anaesthesia and analgesia. He is a co-opted committee member of the Obstetric Anaesthetists' Association and responsible for their regular postgraduate courses.

Pre-eclampsia is a multisystem disorder of endothelial dysfunction, characterized by widespread vasoconstriction and increased capillary permeability. About 10% of pregnant women develop pre-eclampsia, generally leading to reduced placental perfusion. Pre-eclampsia has a variable clinical presentation (Figure 1) and there are no internationally agreed diagnostic criteria. It is traditionally denoted by hypertension, proteinuria and oedema. However, many cases present with one or more of the complications of pre-eclampsia (Figure 2) before hypertension or proteinuria are apparent. Therefore, it is important to consider pre-eclampsia in patients with any of these conditions even if hypertension or proteinuria has not been noted – in some patients these are late (or absent) manifestations of the pre-eclamptic syndrome. It is important not to overlook the presence of upper abdominal pain and vomiting in women in the third trimester, because these are symptoms of hepatic involvement and fulminant disease, and hepatic rupture is an infrequent but dramatic cause of death in pre-eclampsia.

Recognition of pre-eclampsia

- Pregnancy-induced hypertension
- Proteinuria
- Generalized oedema
- Excessive weight gain (> 1.0 kg/week)
- Ascites
- Upper abdominal pain
- Vomiting
- Decreased platelets
  - Increased packed cell volume
  - Increased haemoglobin
  - Increased plasma urate/uric acid
  - Increased plasma von Willebrand factor
  - Increased plasma cellular fibronectin
- Decreased plasma antithrombin III
- Fetal compromise
  - Intrauterine growth factor
  - Intrauterine hypoxaemia

Adapted from: Redman C W G, Roberts J M. Management of Pre-eclampsia. Lancet 1993; 341: 1451–4.

1

Complications of pre-eclampsia

- Cerebral haemorrhage
- Cerebral oedema
- Subcapsular hepatic haematoma/rupture
- HELLP syndrome

2

The relationship between essential (chronic) hypertension, pregnancy-induced hypertension and the pre-eclampsia–eclampsia syndrome are unclear, and often muddled. Oedema is usually omitted from the diagnostic criteria, because it is common in normal pregnancy and difficult to quantify. However, clinical experience suggests that obviously worsening oedema in a patient with pre-eclampsia is a significant clinical marker of leaky capillaries and fulminant disease. Obstetricians often use the plasma urate level as a marker of the progress of the condition. Rule of thumb for singleton pregnancy: plasma urate > 0.xx mmol/litre denotes advancing pre-eclampsia (where xx is the gestation in weeks).

Management of the woman with pre-eclampsia and associated conditions is based on expedited delivery of the placenta (and the baby), and the provision of end-organ protection and support for the mother. Contrary to expectation, pre-eclampsia does not always improve after delivery of the placenta. When pre-eclampsia develops in the preterm mother it is important to balance extra days of fetal maturity against the risks of advancing pre-eclampsia to mother and baby. In general, the more preterm the mother when pre-eclampsia is diagnosed, the more fulminant the condition is likely to be, and the greater the need for expedited delivery.

Mortality
Since 1950, pre-eclampsia has been one of the two most common direct causes of pregnancy-related death in the UK, being second to pulmonary embolism in the 1994–1996 data. Similar findings pertain in other parts of the developed world. For many years most deaths from pre-eclampsia were caused by cerebral haemorrhage, but since the mid-1980s pulmonary oedema (a poorly differentiated mix of iatrogenic fluid overload and adult respiratory distress syndrome) has become the main cause of death.

Pre-eclampsia protocol
To minimize mortality and morbidity a multi-disciplinary approach is essential with open communication between obstetric, midwifery and anaesthetic teams. Establishing a joint labour ward pre-eclampsia protocol may be useful in guiding anaesthetic and obstetric management, particularly for staff in smaller units less experienced with pre-eclampsia, and at points where conservative management may require more invasive action. Suggested guidelines to be included in the pre-eclampsia protocol are shown in Figure 3. The protocol written by Robson *et al.* (see Further Reading) has been used as the basis for local guidelines in many units in the UK. Early referral of severe cases to Regional Advisory Centres has been advocated though transfer of unstable critically ill patients should not be undertaken lightly.

Pre-eclampsia protocol

Guidelines are required for the following

- Control of blood pressure
- Fluid management
- Anti-convulsant prophylaxis
- Acute management of eclampsia
- Pain relief in labour (including management of epidural analgesia)
- Anaesthesia for caesarean section
- Management of oliguria
- Indications for invasive monitoring

3

Haemodynamics
Women with pre-eclampsia have an elevated systemic vascular resistance and a reduced blood volume. Most women with pre-eclampsia have a normal or high cardiac output with a hyperdynamic left ventricle, but a few have a low cardiac output owing to a range of causes.

Pulmonary oedema is a particular hazard owing to the combined effects of low plasma oncotic pressure and increased permeability of pulmonary alveolar capillaries. Other predisposing factors include impaired ventricular function, elevated pulmonary artery occlusion pressure (PAOP) and the poor correlation between central venous pressure (CVP) and PAOP that is seen in some patients, which may encourage iatrogenic fluid overload.

The CVP is usually low in early pre-eclampsia. When it is low, the CVP largely reflects left atrial filling pressures. However, when it rises (above 6 cm H_2O) it often underestimates the left atrial filling pressures, and pulmonary oedema becomes more likely. A high-normal CVP in pre-eclampsia is a warning sign of fluid overload or myocardial dysfunction, and provides an indication for the insertion of a pulmonary artery catheter.

Management includes the combination of controlled vasodilatation (e.g. with hydralazine) with limited colloid intravenous loading, a technique that improves cardiac function and reduces vascular resistance better than using either alone.

Hypertension
In the UK, the three drugs commonly used for the acute control of hypertension in pre-eclampsia are hydralazine, labetolol and nifedipine. Nifedipine should be used by the oral route only, not sublingually owing to the risk of dramatic and uncontrolled hypotension with consequent fetal and maternal compromise, particularly when used as a second-line drug. There is little evidence that any agent or combination is to be preferred, providing adequate reduction in blood pressure is achieved in a controlled manner. In patients with an aggressive form of pre-eclampsia, refractory hypertension may respond only to nitric oxide donors (i.e. nitroglycerine, nitroprusside); these patients require invasive monitoring in an ICU.

Coagulopathy
Pregnancy and early pre-eclampsia are pro-coagulant states, but a few women with pre-eclampsia develop coagulation disorders that put them at increased risk of spinal haematoma formation following epidural puncture. However, the relationship between platelet count, platelet activity and the risk of epidural haematoma following epidural puncture is unknown. There is no evidence of increased epidural bleeding caused by the use of low-dose aspirin in pregnancy. Thrombocytopenia is common in pre-eclampsia, but bleeding time is probably not a useful test. Other coagulation defects seldom occur in pre-eclampsia in the absence of thrombocytopenia, therefore platelet count alone has been proposed as a screening test. Elevations of the partial thromboplastin time (PTTK) in the presence of a normal platelet count are more likely to suggest other conditions (e.g. lupus anticoagulant).

Trends may be more significant than absolute numbers. The thromboelastogram and a new platelet function analyser (PFA 100) are being evaluated, though neither has been validated in pre-eclampsia. The findings have been inconsistent, though data from the thromboelastogram suggest that platelet function is largely retained with platelet counts above 75 x 10^9/litre. For many women with pre-eclampsia the benefits of epidural analgesia outweigh the small (but potentially serious) risk of epidural haematoma formation.

HELLP syndrome
The HELLP syndrome (Figure 4) is marked by **H**aemolysis (often presumed rather than detected), **E**levated **L**iver enzymes and **L**ow **P**latelets. Subcapsular hepatic haematoma formation may be a particular problem. As with pre-eclampsia, not all elements of the syndrome may be apparent simultaneously, and there are no universal diagnostic criteria. Although usually considered a complication of pre-eclampsia, it has been questioned whether HELLP is a distinct entity. Patients with HELLP syndrome show a marked increase in maternal morbidity (including pulmonary oedema, disseminated intravascular coagulation, abruption and renal failure) and risk of death. There is also a significant increase in perinatal morbidity and mortality.

Diagnostic features of HELLP syndrome

Haemolysis
- Red cell fragmentation on blood film
- Plasma bilirubin > 1.2 mg/dl

Elevated liver enzymes
- Aspartate aminotransferase > 70 U/litre
- Lactate dehydrogenase > 600 U/litre

Low platelets
- Platelets < 100 x 10^9/litre

Adapted from: Sibai B M. The HELLP Syndrome (Hemolysis, Elevated Liver Enzymes, and Low Platelets): Much Ado About Nothing? *Am J Obstet Gynecol* 1990; **162:** 311–16.

4

Management remains delivery of the placenta and aggressive supportive therapy. Corticosteroid therapy may reduce the degree of thrombocytopenia, though expert opinion is divided.

Labour analgesia
The benefits of well-controlled epidural analgesia in labour are well recognized, producing excellent analgesia, a marked reduction in maternal plasma catecholamine levels, a useful fall in blood pressure, and optimizing feto-placental perfusion. Early studies from Finland showed that epidural anaesthesia improves the blood flow to the fetus in pre-eclampsia, and more recent Doppler studies suggest that epidurals produce useful vasodilatation on both the maternal and fetal side of the placenta, optimizing feto-placental blood flow. Therefore, the early use of epidural analgesia is recommended. Most epidural studies in pre-eclampsia have used strong epidural solutions and studies of weak local anaesthetic and opioid mixtures are needed.

The block should be established gently to minimize hypotension (e.g. a solution of 0.1% bupivacaine plus fentanyl, 2 μg/ml) and limited colloid preloading is recommended (though it is unclear whether preloading is desirable or necessary). The addition of adrenaline (epinephrine) to the local anaesthetic solution remains controversial, it has little clinical advantage, particularly when epidural opioids are used, and has several potential disadvantages in the pre-eclamptic woman who may be exquisitely sensitive to exogenous catecholamines. Adrenaline (epinephrine) should therefore be avoided in epidural solutions in pre-eclampsia. Ephedrine remains the vasoconstrictor of choice.

Anaesthesia for caesarean section
Women with pre-eclampsia are at increased risk for caesarean section. Careful assessment of the relative risks of general and regional anaesthesia must be made. Regional anaesthesia is usually considered safer, though patients must be assessed on an individual basis, and their coagulation status considered. Some authors consider fulminant pre-eclampsia or eclampsia (and the risk of an eclamptic seizure occurring during surgery) a contraindication to regional block. However, most obstetric anaesthetists would still choose a regional technique (if there are no signs of coagulopathy), believing that even women who have had an eclamptic convulsion may benefit from a regional technique, provided they are alert enough to protect their own airway, and are receiving magnesium sulphate.

Epidural anaesthesia is the preferred technique for caesarean section, and is associated with much lower maternal plasma catecholamine and blood pressure levels compared with general anaesthesia. If a working epidural is already present (i.e. for labour analgesia) this should be extended for surgery.

Spinal anaesthesia is controversial; because of the potential risks of pulmonary oedema, profound cardiovascular instability and fall in cardiac output, and the consequent recourse to intravenous fluids and vasoconstrictors, it is not generally recommended in pre-eclampsia. However, several recent studies suggest that most women with pre-eclampsia who received spinal anaesthesia do not develop catastrophic hypotension (Figure 5), and there is a growing suspicion that women with pre-eclampsia may behave contrary to expectation following spinal anaesthesia. There are insufficient published data to support the general use of spinal anaesthesia in pre-eclampsia, though in individual patients with unstable or fulminant disease, and a difficult, oedematous airway, it may be a safer technique than emergency general anaesthesia. Scrupulous attention to detail is probably a key factor in success. Sequential combined spinal-epidural (low-dose spinal, then epidural top-ups) may prove useful in experienced hands.

Published studies of the use of spinal anaesthesia in pre-eclamptic women

Author	Date	Country	Anaesthetic technique			Study design	Comments
			Spinal	Epidural	General		
Clark (Abstract only)	2000	UK	20			Prospective randomized	Pre-eclampsia patients required less ephedrine than normal controls
Wood	1999	USA	103	35		Case note review	? Selection bias, unequal group size
Sharwood-Smith	1999	UK	11	10		Prospective randomized	Study stopped prematurely owing to poor quality epidural
Ahmed	1999	India	17	16		Case note review	Some in labour
Van Bogaert	1998	S Africa	24			Case note review	
Rout	1998	S Africa	49	49		Case note review	Some in labour
Karinen	1996	Finland	12			Prospective observational	Mixed severity (6/12 severe pre-eclampsia) 2/12 became hypotensive, 2/12 had increased UA PI
Wallace	1995	USA	27	27	26	Prospective randomized	Some in labour, severity unknown. Combined spinal-epidural supplementation in some
Assali	1950	USA	15			Prospective observational	Full supine position procaine 0.2% or 1.0% spinals

The added risks associated with general anaesthesia include airway difficulties resulting from oedema (often aggravated by tracheal intubation), and the pressor response to laryngoscopy and extubation. If general anaesthesia is chosen, care should be taken to obtund the pressor response to laryngoscopy. Several techniques have been described to abolish this, including β-blockers, opioids and/or intravenous lidocaine (lignocaine), but none is completely reliable. A bolus of magnesium sulphate may be the most effective technique. Extubation may be hazardous because the trauma of intubation is likely to aggravate laryngeal and airway oedema. Attention should be paid to the degree of airway oedema at intubation, and if it is significant, consideration should be given to the possible benefit of keeping the tracheal tube in place postoperatively and transferring the patient, intubated and ventilated, to the ICU for stabilization. Residual neuromuscular blockade is another problem in patients receiving magnesium sulphate, because they are sensitive to the effects of non-depolarizing muscle relaxants, and behave similarly to myasthenics. Very small doses should be used with peripheral nerve stimulator monitoring.

Whatever anaesthetic technique is used for caesarean section, adequate recovery facilities are mandatory, and these patients require high dependency nursing for at least 24 hours.

Oliguria
Most workers agree that, despite the presence of oedema, pre-eclampsia is characterized by a vasoconstricted, hypovolaemic circulation. Moderate fluid preloading before vasodilator therapy minimizes hypotension and improves cardiac output, and is usual practice. Oliguria (often considered as < 0.5 ml/kg/hour) is common but generally responds to moderate fluid load and delivery. Renal function should be checked by regular urinary electrolyte or osmolality analysis.

Moderate oliguria in the presence of normal plasma urea and creatinine (remembering that the values in pregnancy are usually lower than in the non-pregnant state) and high urinary osmolality suggest appropriate renal function: conservative management is appropriate. Other causes of oliguria include pre-renal or parenchymal renal failure and glomerular endotheliosis. However, while renal failure in the absence of obstetric haemorrhage is rare in pre-eclampsia, excessive fluid administration may easily precipitate life-threatening pulmonary oedema, aggravated by the underlying pulmonary capillary leak and low albumin levels. Oliguria generally resolves when the pre-eclamptic process improves, therefore the author considers that these patients are best run ‘on the dry side’ and that over-aggressive fluid loading in an attempt to increase urine output should be avoided.

Resistant oliguria occasionally requires the use of furosemide (frusemide), dopamine and CVP or pulmonary artery catheter monitoring, but these should not be used routinely. An agreed pre-eclampsia protocol may be useful to guide fluid administration and the management of oliguria.

Central haemodynamic monitoring
Most patients with pre-eclampsia do not require invasive monitoring, and the indications for CVP or pulmonary artery catheter insertion are controversial. For some years, the use of the pulmonary artery catheter has been strongly advocated in North America and whether the recent challenges to the use of the pulmonary artery catheter will alter this remains to be seen.

Arterial line insertion should be associated with few complications, but the risks of insertion of CVP and pulmonary artery catheter lines in a woman who is probably hypovolaemic and with an actual or incipient coagulopathy should not be underestimated. Some authors recommend avoiding the neck and using peripheral sites for the CVP line. Other problems include the misinterpretation of data obtained from these lines, and inappropriate management decisions based on the data (particularly with respect to fluid management).

In pre-eclampsia, the CVP may underestimate the left atrial pressure once it has risen to high-normal values (6 cm H_2O or above), but it may be useful for dynamic fluid challenges. In the presence of a high CVP or pulmonary oedema, a pulmonary artery catheter is indicated.

Eclampsia
In the UK, eclampsia occurs in about 1/2000 pregnancies. The onset of eclamptic convulsions may be unexpected, may occur before other markers of pre-eclampsia are apparent, and, particularly in the developing world, is associated with increased maternal and neonatal mortality. Airway reflexes may be lost, and pulmonary aspiration and hypoxia may ensue rapidly. Intravenous diazepam may be used for terminating seizures, but an intravenous bolus of magnesium sulphate, 4 g over 5–10 minutes, is recommended.

Magnesium sulphate is the drug of choice in eclampsia, because it is more effective than diazepam or phenytoin in preventing further fits and minimizing maternal morbidity. All eclamptic women should receive magnesium sulphate, though the best dosing regimen remains controversial (4 or 6 g initial bolus, followed by infusion at a rate of 1–2 g/hour). All labour ward staff should be trained in the basic ABC of resuscitation, and must appreciate the importance of turning the convulsing or unconscious patient rapidly on to her side into the recovery position.

The role of anticonvulsant prophylaxis in pre-eclampsia is controversial. For anticonvulsant prophylaxis, phenytoin is ineffective, and older sedative treatments with chlormethiazole and diazepam, which risk respiratory depression and pulmonary aspiration, have largely been eradicated in the UK. Opinion on the use of magnesium sulphate in pre-eclampsia is divided, but a rational argument suggests that if it works in eclampsia by reversing cerebral vasospasm, a condition known to occur in pre-eclampsia, then it seems appropriate to use it in patients with severe pre-eclampsia before they develop eclamptic convulsions. The use of magnesium sulphate in pre-eclampsia and eclampsia has increased markedly in the UK over the past decade.

Pre-eclamptic women are at high risk and should receive regular antacid prophylaxis during labour or delivery (e.g. oral ranitidine, 150 mg 6 hourly) to minimize the risks of pulmonary aspiration during an eclamptic convulsion or at general anaesthesia. ◆

Regional Anaesthesia, Anticoagulation and Antithrombosis

Michael Paech

Michael Paech is Staff Specialist in Anaesthesia in a tertiary women's hospital and a large general teaching hospital in Australia. He is an Examiner for the Australian and New Zealand College of Anaesthetists and the Associate Editor of the journal *Anaesthesia and Intensive Care.* His research interests include obstetric anaesthesia and analgesia, regional anaesthesia, acute pain management and day case anaesthesia.

Physiological changes during pregnancy induce a hypercoagulable state presumably as a means of minimizing blood loss during childbirth. Venous stasis, increased procoagulant activity (elevated levels of factors II, VII, VIII, X and XI and fibrinogen) and reduced anticoagulant activity (increased plasminogen activator inhibitors and reduced protein C) contribute to an approximate incidence of thromboembolism of 1/1000. Obstetric haemorrhage causes maternal mortality in all countries, but in Australia (1991–1993) and the UK (1994–1996), pulmonary embolism was the leading cause of direct maternal death. In the UK, the rate of fatal pulmonary embolism (deaths/million maternities) appears to be rising, from 14.6–15.1 (1985–1993) to 21.8 (1994–1996).

Anticoagulation and antithrombosis

Anticoagulation is commonly instituted during pregnancy. Awareness of thromboembolic risk and concern were heightened by the findings and recommendations of the recent Confidential Enquiries into Maternal Deaths in the UK. Additionally, more patients at risk are now diagnosed and the incidence of operative delivery (a risk factor) remains high. Some units routinely use prophylaxis for thromboembolism following caesarean section, while others base policies on risk-stratification (increased risk with advanced maternal age, high parity, obesity and pre-eclampsia). Prophylaxis against thromboembolism is also initiated for many other parturients (Figure 1). It is now appreciated that hereditary thrombophilias are not uncommon; for example deficiencies of antithrombin, protein C or protein S; activated protein C resistance; or the factor V Leiden mutation. The latter has a 4% prevalence and is detected in 20% of those presenting with a thromboembolic event during pregnancy. The antiphospholipid syndromes and systemic lupus erythematosus are important thrombotic disorders. Many women with serious cardiac disease now achieve reproductive status and continuous anticoagulation may be warranted (Figure 1).

Peri-partum thromboembolism and some other situations demand urgent anticoagulation (Figure 1). This is usually initiated with intravenous unfractionated heparin or a therapeutic dose of low molecular weight heparin (LMWH) subcutaneously for 5–10 days, followed by maintenance with therapeutic LMWH for 3 months. Thereafter, either prophylactic or therapeutic anticoagulation is continued throughout pregnancy and 6 weeks into the puerperium. Despite a relative contraindication because of placental abruption and post-partum haemorrhage, antifibrinolytic drugs (e.g. streptokinase, tissue plasminogen activator) are occasionally used for massive pulmonary embolism.

Warfarin and the vitamin K antagonists are also usually avoided during pregnancy and reserved for anticoagulation after delivery. During organogenesis, fetal embryopathy and cerebral haemorrhage may occur and warfarin given in the second and third trimester may cause fetal CNS abnormalities, haemorrhage and stillbirth.

Antithrombotic and potent antiplatelet drug therapy is rare, though low-dose aspirin therapy is used for prophylaxis against severe pre-eclampsia in certain subgroups and for medical management after myocardial infarction and cerebrovascular disease.

Indications for anticoagulation during pregnancy

Prophylactic therapy
- Postoperative
- History of thromboembolism
- Low-risk thrombophilic disorder
- Antiphospholipid syndromes
- Systemic lupus erythematosus
- Cyanotic heart disease, some corrected congenital disorders, cardiomyopathy, atrial fibrillation, severe mitral stenosis
- Critical illness

Therapeutic therapy
- Mechanical cardiac valve
- Acute thromboembolism
- High-risk thrombophilic disorder
- Arterial thrombosis

Heparin
Heparin is the anticoagulant of choice during pregnancy.

Unfractionated heparin has a long history of safe use, but evidence supporting specific regimens in obstetric patients is lacking. Heparin does not cross the placenta, owing to its high molecular weight (mean 15–40 kDa). Maternal effects (other than bleeding or under-coagulation) include thrombocytopenia (early, mild, transient platelet aggregation or severe IgG antiplatelet antibody-induced). Although thrombocytopenia is uncommon (3% after therapeutic and 0.3% after prophylactic dosing in non-pregnancy after 14 days), the platelet count should be checked after 5–14 days. Following prolonged heparinization, subclinical maternal osteopenia occurs in 20% of women, though fractures are rare. Only the pentasaccharide fraction of unfractionated heparin activates antithrombin III (with subsequent inactivation of factors IIa, Xa and IXa), therefore variability in heparin effect is wide. The pharmacokinetics of unfractionated heparin are altered in pregnancy by placental heparinase, increased plasma volume, renal clearance and heparin-binding proteins. Consequently, requirements increase 1.5–2.5 times after early pregnancy, though they may fall at term with placental ageing. Many obstetric units currently use standard (non-pregnant) prophylactic doses that are inadequate. For example, therapeutic doses of 20,000 units t.d.s. subcutaneously or prophylactic doses of 7,500–10,000 units b.d. subcutaneously, often fail to achieve appropriate levels.

Low molecular weight heparins (LMWH) of 4–5 kDa are alternatives that also do not cross the placenta (Figure 2). In non-pregnant women, LMWH is as effective as, or more effective than unfractionated heparin for acute thromboembolism. Therefore, despite a lack of good evidence, LMWH is currently considered the agent of choice in pregnant women at high risk for thromboembolism. Higher doses (e.g. enoxaparin, 40 mg rather than 20 mg daily) may be required during pregnancy and the puerperium, probably because of increased renal clearance.

Advantages of low molecular weight heparin compared with unfractionated heparin

- Longer half-life
- More predictable and non-dose-dependent bioavailability
- Monitoring (anti-Xa activity) not usually required
- Heparin-induced thrombocytopenia rare
- Heparin-induced osteopenia less common

Regional anaesthesia and analgesia

The increasing use of regional techniques for caesarean section and labour analgesia has meant that many obstetric patients taking anticoagulants present as candidates for central neuraxial block. This poses a dilemma for the obstetric anaesthetist, who, in each case, must balance the relative advantages of central neuraxial block (reduced mortality, reduced thromboembolism or cardiac morbidity, benefits in pre-eclampsia) against the risks (e.g. intraspinal haematoma). The use of regional techniques in anticoagulated patients has been extensively reviewed (see Further Reading), though points pertinent to obstetric anaesthesia were not addressed. It is essential that all pregnant women taking anticoagulants are seen before delivery and a multidisciplinary management plan prepared. Spinal rather than epidural techniques, and intravenous or inhalational labour analgesia may be prudent. General anaesthesia for operative delivery will need to be considered, despite its association with a higher risk of postoperative thromboembolism in high-risk non-obstetric settings.

Intraspinal haematoma is rare (only seven reports in obstetric patients), suggesting that traditional guidelines have been successful in minimizing its incidence. Both the timing of needle insertion and catheter removal are relevant to haematoma formation. Central neuraxial block is generally contraindicated if an antifibrinolytic has been administered within 7–10 days, but is only relatively contraindicated following warfarin which acts for 4–6 days until vitamin K dependent factors II and X are replenished. Retrospective and prospective series report no haematoma formation after central neuraxial block among hundreds of non-pregnant patients on subtherapeutic doses of warfarin. In contrast, warfarin has been implicated in a large proportion of haematomas after lumbar puncture and in several case reports after epidural techniques. Reversal of warfarin using vitamin K (which takes several hours to work) or fresh frozen plasma is seldom used except for the management of uncontrolled obstetric haemorrhage or before urgent surgery. Ideally, aspirin should be stopped at least 3 days before a central neuraxial block. However, in the absence of other risk factors, aspirin does not exclude regional techniques.

The short duration of unfractionated heparin generally assists the organization of obstetric anaesthesia when labour ensues or operative delivery is required. Prophylactic subcutaneous unfractionated heparin peaks at 3 hours and may elevate the APTT (therapeutic doses may do so for up to 24 hours) so testing is advisable. Two large reviews of intraspinal haematoma (see Further Reading) suggest prophylactic unfractionated heparin is seldom implicated and clinical experience is reassuring. A regional technique or removal of an epidural catheter is generally considered safe 4–6 hours after conventional prophylactic doses (5,000 units b.d.), though even this may be conservative practice. In contrast to experience with unfractionated heparin, unfavourable experience with central neuraxial block in the presence of LMWH (though not in obstetric patients) has generated concern in the USA. LMWH has weak fibrinolytic activity and it seems appropriate to apply current general recommendations to obstetrics (Figure 3). Local policies need to be developed, because the window of opportunity for central neuraxial block, when anti-Xa activity is at its lowest, is brief.

Recommendations for low molecular weight heparins (LMWH) and central neuraxial block

- Avoid central neuraxial block for at least 24 hours if therapeutically anticoagulated with LMWH
- Avoid central neuraxial block for at least 12 hours after prophylactic LMWH
- Discuss the timing of prophylactic LMWH preoperatively, or before induction of labour, with the obstetrician
- In patients not at high risk, or if needle insertion is traumatic, begin prophylactic LMWH at least 12 (preferably 24) hours postoperatively
- Remove the epidural catheter when activity is lowest (at least 12 hours after the last dose)
- To avoid clot disruption, do not administer LMWH until 2–4 hours after central neuraxial block or catheter removal
- Avoid concurrent non-steroidal anti-inflammatory drugs, antiplatelet drugs (e.g. aspirin, dextran) and anticoagulants

Social Problems in Pregnancy

Mary Hepburn

Mary Hepburn is Senior Lecturer in Women's Reproductive Health, Glasgow University Department of Obstetrics/Gynaecology and Social Policy/Social Work, and Honorary Consultant Obstetrician and Gynaecologist, Princess Royal Maternity Hospital, Glasgow. She trained as a general practitioner and then as an obstetrician/gynaecologist. She established and is consultant in charge of the Glasgow Women's Reproductive Health Service, a service for women with social problems. Her interests focus on the effects of socioeconomic deprivation and associated problems on all aspects of women's reproductive health (including pregnancy outcome) and on service design and delivery for women with special needs.

Social factors directly and indirectly affect the health of pregnant women and their unborn babies and should be addressed in obstetric management. Drug use is not the foremost route of blood-borne virus infection in the UK, but because both have a social dimension that can affect pregnancy and both illustrate management of social problems in pregnancy they are jointly discussed here.

Problem drug use

There has been a marked increase in drug use among women of childbearing age and consequently during pregnancy. Problem drug use with significant medical and social consequences is closely associated with socioeconomic deprivation, which is associated with poor health and ineffective service use and both are exacerbated by problem drug use. Therefore, pregnant drug-using women have potentially high-risk pregnancies but may receive less maternity care. The design, delivery and content of obstetric care are all important in the management of drug use and associated problems in pregnancy.

In the UK, the most commonly used drugs are opiates/opioids (including heroin, methadone and dihydrocodeine), amphetamines and benzodiazepines. The use of cocaine is also significant. Drugs can affect pregnancy directly and indirectly by their effect on maternal lifestyle and general health. Injecting use carries additional risks.

Opiates/opioids: heroin is a short-acting opiate and withdrawal carries a risk of preterm labour and reduced intrauterine growth. Therapy with longer acting methadone reduces the risk of preterm labour. Opiate/opioid detoxification during pregnancy is dangerous in theory, but not in practice, and can be undertaken at any stage of pregnancy, at any speed, but only if likely to be successful. Management usually involves a combination of detoxification/reduction and maintenance therapy with the aim of achieving the lowest drug dose compatible with reasonable stability. Unlike detoxification, reversal of opiate/opioid effects with naloxone can precipitate severe fetal distress antenatally and postnatally and should be used cautiously and only if necessary. All opiates and opioids can cause withdrawal symptoms in the neonate.

Benzodiazepines: apart from a reported association with cleft palate, benzodiazepine use does not directly affect pregnancy. The most important consequence of benzodiazepine use is social instability, which has implications for delivery of care and parenting. There is no evidence of benefit from benzodiazepine sub-stitution therapy in pregnancy but sudden withdrawal can cause maternal convulsions. Short-term substitution (up to 7 days) to cover withdrawal is recommended. Benzodiazepine use also causes neonatal withdrawal symptoms.

Amphetamines: chaotic injecting use carries risks for maternal health and can be socially destabilizing. However, amphetamines *per se* seldom affect pregnancy outcome, do not cause withdrawals in the neonate and there is no evidence of benefit from substitute prescribing in pregnancy.

Cocaine use is increasing in the UK, but use of crack cocaine is less prevalent than in the USA. In pregnancy, the vasoconstrictor action of cocaine has been reported to cause underdevelopment of organs including limbs and gut as well as reduced brain growth, increased rates of placental abruption, preterm rupture of membranes and fetal death. However, there is evidence of a publication bias in favour of studies with adverse outcomes, which seem to be largely restricted to heavy, chaotic, injecting use. Cocaine does not cause withdrawal symptoms in the neonate and substitution is neither feasible nor beneficial.

Neonatal withdrawal symptoms

Neonatal withdrawal symptoms (neonatal abstinence syndrome) occur with maternal use of opiate/opioids and benzodiazepines. Their severity is largely dose related but the many other relevant co-factors (e.g. intra-partum hypoxia, infection or other illness in the baby) make it impossible to predict outcome for an individual baby. A combination of opiates/opioid and benzodiazepine use is particularly problematic. Breast-feeding reduces the severity of neonatal withdrawals and is especially beneficial in this vulnerable group of babies. While the mother's drug use should be reasonably stable, successful establishment of breast-feeding is in itself sufficient proof of stability. Babies should be gradually weaned because sudden discontinuation of breast-feeding could precipitate withdrawals in the baby.

Obstetric management

Use of opiates/opioids or benzodiazepines can reduce fetal heart rate variability and make it difficult to interpret antenatal or intra-partum cardiotocographs. Reversal of maternal opiate/opioid intoxication or neonatal sedation with naloxone can be dangerous.

Methadone medication should be continued in labour if due. Opiate analgesia can also be given and while, in theory, larger doses may be required this is often not the case in practice. Epidural analgesia is often appropriate but venous access can be difficult, which can also cause problems if immediate delivery by caesarean section is required.

Associated medical problems

Injecting drugs causes vascular damage and infection can lead to endocarditis and valvular damage necessitating use of prophylactic antibiotics during labour and other procedures likely to cause bacteraemia (Figure 1). Blood-borne virus infection is also a risk.

Poor diet and poor oral hygiene make dental caries common. These are often associated with bacteraemia and should be dealt with during pregnancy under antibiotic cover.

Injecting into veins or arteries carries the risk of thrombo-embolic disease and women with current or past episodes of thrombosis with or without embolism require therapeutic or prophylactic anticoagulation.

Blood-borne virus infection

Women should be offered antenatal screening because they are pregnant and not because they are perceived as likely to be infected. Testing should be offered in their interests, not for infection control and should always be offered without pressure to accept.

HIV infection

Known HIV-positive women should be offered interventions to reduce the risk of vertical transmission. Antiretroviral therapy, if already started, is usually continued throughout pregnancy but is otherwise offered during the third trimester. The aim is to reduce maternal viral load, ideally to an undetectable level. Treatment of the baby for the first month of life is also advocated. Elective caesarean section reduces vertical transmission but may not carry significant additional benefit for women with undetectable viral load. If aiming for vaginal delivery, early rupture of the membranes and use of fetal scalp electrodes should be avoided if possible. Breast-feeding increases the risk of vertical transmission and should be avoided.

Hepatitis B infection

Perinatal transmission of hepatitis B can be prevented by immun-ization of the baby at birth. Babies of Ag positive mothers require active and passive immunization while babies of Ag negative mothers require active immunization. Both groups can safely breast-feed. Hepatitis B immunization is recommended for all injecting drug users and for women infected with hepatitis C. A complete course can be safely administered during pregnancy using an accelerated regimen.

Hepatitis C infection

There is no effective immunization against hepatitis C nor any intervention that significantly reduces perinatal transmission. However, maternal screening allows infected mothers to access specialist care and identifies babies who require follow-up. The available evidence suggests breast-feeding does not increase the risk of vertical transmission of hepatitis C.

Outcome of pregnancy among drug-using women

Neonatal abstinence syndrome can be a major management problem but there is no reliable evidence to suggest that it causes permanent damage. However, low birthweight, which may be associated with preterm delivery or fetal compromise has long-term health implications. There is also an increased risk of sudden infant death syndrome (SIDS). Both low birthweight and SIDS are multifactorial in origin and socioeconomic deprivation and associated problems (including smoking) are other aetiological factors.

Design and delivery of care

Management of maternal drug use should be provided within multidisciplinary maternity care. Although unsuitable for midwifery-only care these women can receive much of their care from midwives in the community. The multiple social problems associated with drug use can tax parenting skills especially if the baby is sick. Consequently, drug-using women often require considerable support with childcare. Careful antenatal and post-partum assessment is essential with early introduction of support services.

Effective multidisciplinary collaboration is essential to provide integrated care that addresses the medical and social problems. This provides the best chance of delivery of a healthy baby that can go home with and be adequately cared for by its mother.

Anaesthesia for Eye Surgery in Paediatrics

Jonathan Lord

Jonathan Lord is Consultant Anaesthetist at Moorfields Eye Hospital, London, UK. His specialist interest is paediatric ophthalmic anaesthesia.

Children present for ophthalmic surgery from the neonatal period onwards. Neonates and infants generally present for cataract extraction and treatment for congenital glaucoma whereas older children more often have strabismus, lacrimal, vitreo-retinal or ocular plastic surgery. Many children present for repeated procedures and skilled anaesthesia contributes to a successful result. The problems of anaesthesia are essentially the same as those of paediatric anaesthesia in any field, however, there are some areas that require particular attention.

General considerations

Airway: although not strictly a 'shared airway', most ophthalmic operations involve draping the head and thus abolish or at least reduce access to the airway.

Intraocular pressure (IOP): normal IOP is 10–22 mm Hg. The factors that affect IOP are essentially the same as those that affect intracranial pressure. The control of IOP is an important part of the anaesthetic management of intraocular surgery. Any sudden increase in IOP with an open eye leads to loss of ocular contents and/or an expulsive haemorrhage. The likely outcome of such an event is loss of vision. The main factors involved in the regulation of IOP are the choroidal, aqueous and vitreous volumes together with external pressure.

Choroidal volume can be affected by venous pressure, arterial pressure and arterial partial pressure of carbon dioxide.

- Venous drainage from the eye is valveless and therefore any changes in venous pressure produce an immediate change in ocular pressure by altering the volume of blood within the choroid. Raised venous pressure also impedes aqueous drainage via the canal of Schlemm and causes a secondary rise in IOP. Coughing, straining and retching all increase venous pressure. A 15° head-up tilt reduces IOP.
- Mean arterial pressure has little effect on IOP but sudden increases in mean arterial pressure produce a rapid and unpredictable rise in IOP.
- Alterations in arterial partial pressure of carbon dioxide have a linear effect on IOP. A reduction causes a fall in choroidal volume and thus in IOP and vice versa.
