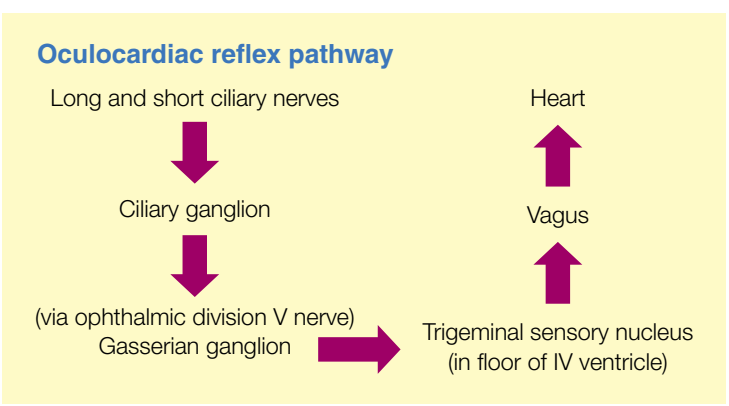
Aqueous volume – although alteration of aqueous volume is the mainstay of glaucoma therapy it is of limited importance during anaesthesia because without direct drainage the volume alters slowly. Acetazolamide reduces aqueous production and reduces IOP.

Vitreous volume is of limited importance during anaesthesia. Osmotic diuretics (e.g. mannitol) can dehydrate the vitreous and reduce its volume.

External pressure – direct pressure on the eye, for example with a mask, must be avoided. Increase in tone of the extraocular muscles increases IOP, thus depolarizing muscle relaxants (e.g. suxamethonium) cause an increase in IOP. The rise produced by suxamethonium is maximal at 2 minutes and lasts for 5 minutes. Pre-treatment with non-depolarizing muscle relaxants to prevent this has been advocated but is of unproven value.

Oculocardiac reflex is potent in children. The afferent and efferent pathways are shown in Figure 1. It can be triggered by increases in IOP, traction on the extraocular muscles, trauma or pain. It usually produces a bradycardia but asystole quickly ensues in children if left untreated. Other arrhythmias such as nodal rhythms and ventricular fibrillation can also occur. Without any preventive treatment the reported incidence varies from 30 to 90%. Pre-treatment with a vagolytic is protective. Oral atropine can be given as part of the premedication, and intravenous atropine or glycopyrrolate can be given peroperatively. Infiltration around the extraocular muscles with local anaesthesia also reduces the reflex. It is important that a pulse monitor with an audible bleep is used peroperatively so that both the anaesthetist and the surgeon can hear if a bradycardia occurs.



1

Acute ocular trauma: the question of how to deal with acute ocular trauma in an unstarved child is often discussed. Many centres avoid the problem by avoiding emergency surgery because there is no evidence that waiting for the child to be starved influences the outcome of surgery. However, 6 hours' starvation in a traumatized child does not mean that the stomach will be empty and consideration must to be given to this. Prokinetics (e.g. metoclopramide) together with H_2-blockers (e.g. ranitidine) to increase stomach pH can be given. The management of the anaesthetic is controversial but the need to avoid suxamethonium if the eye is open is paramount because loss of contents can occur from the rise in IOP. The author's opinion is that induction of anaesthesia should be either intravenous with a fast-acting non-depolarizing muscle relaxant (e.g. rocuronium) or inhalational. Intubation is preferable to protect the airway. The child should then be extubated awake.

Postoperative nausea and vomiting (PONV): ocular procedures in general are emetic and if consideration is not given to this a high proportion of children will have PONV. It is produced as a result of the manipulation of the extraocular muscles, by alterations in the IOP or by volume expansion within the orbit. Any child with persistent vomiting following an intraocular procedure must be checked by the surgeon to exclude raised IOP as the cause. As always, prevention is better than cure and suggested drug treatments are shown in Figure 2.

Associated syndromes: eye abnormalities in children are often manifestations of multisystem disorders. Many of these syndromes have anaesthetic significance and any anaesthetist involved in paediatric ophthalmology should look out for any associated problems. Some of the common syndromes are given in Figure 3.

Anti-emetic drugs for postoperative nausea and vomiting

Drug	Dose	Comments
Ondansetron	0.1–0.15 mg/kg (maximum 8 mg)	Excellent anti-emetic; low side-effect profile
Cyclizine	1 mg/kg (maximum 50 mg)	Effective but sedative
Dexamethasone	200–300 μg/kg (maximum 8 mg)	Very effective, particularly for orbital implants

2

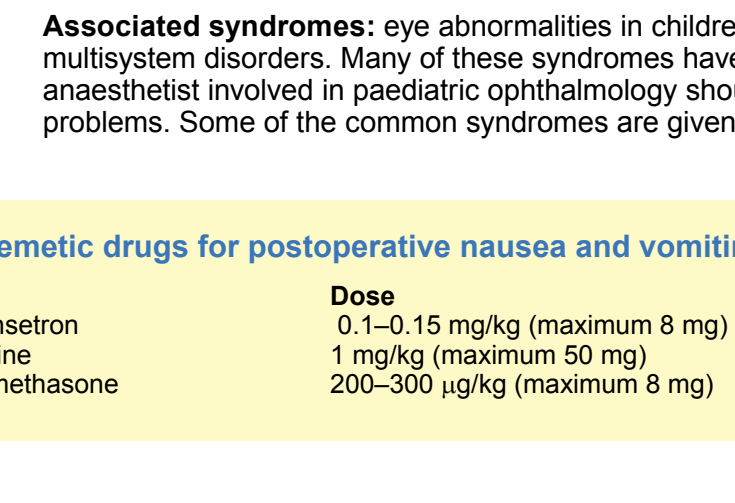
Congenital syndromes

Syndrome	Ocular manifestation	Anaesthetic significance
Down's	Strabismus, cataract	Cardiac problems, hypothyroidism, blood dyscrasias
Goldenhar's	Ptosis	Difficult intubation
Homocystinuria	Lens dislocation	Thromboembolism, hyperinsulinaemia
Marfan's	Lens dislocation, retinal detachment	Heart valve defects, thoracic aneurysms
Sickle haemoglobinopathies	Retinopathy	Sickle crises
Stickler's	Retinal detachment	None
Sturge–Weber	Secondary glaucoma	Epilepsy

3

Malignant hyperthermia is more common in ophthalmic, and in particular strabismus, surgery. Temperature should therefore always be monitored. All anaesthetic departments should ensure that personnel are aware of the recommendations for treatment of malignant hyperthermia as well as the location of the necessary drugs within the department.

Analgesia: most ophthalmic operations are not particularly painful and simple analgesia in the form of paracetamol or other non-steroidal anti-inflammatory drugs (NSAIDs) is all that is required. The main exceptions are strabismus surgery in which the muscle necrosis following suturing can cause marked pain, detachment surgery where an encircling band is used and larger procedures such as tumour resection or eviscerations. Postoperative analgesia should be considered as part of the overall plan of anaesthesia. A multimodal approach using local anaesthesia, paracetamol, NSAIDs and opioids is logical. A suggested regimen is given in Figure 4. Local anaesthesia can take the form of topical local anaesthetic drops or formal local blocks. Sub-Tenon anaesthesia is particularly useful in strabismus and detachment surgery.



4

Specific problems

Measurement of IOP: glaucoma can be defined as a progressive optic neuropathy and if left unchecked eventually results in blindness. The effective management of children with glaucoma includes the accurate measurement of their IOP. In those under 5 years, this usually requires an anaesthetic. All currently available anaesthetic agents, with the exception of ketamine, reduce IOP. The extent of this reduction is unknown and not repro-ducible even in the same individual. This can lead to misleading IOP readings and have a detrimental effect on treatment.

Ketamine is the drug of choice for IOP surveillance. It is a phencyclidine derivative that produces dissociative anaesthesia via its action at the N-methyl-D-aspartate (NMDA) receptors. It produces either no change or a transitory rise in IOP through a combination of its sympathomimetic effects and extraocular muscle contraction. Studies suggest, that this rise is not seen if the child is premedicated with a benzodiazepine. A suggested technique for ketamine anaesthesia is shown in Figure 5.

It is unnecessary to secure the airway and the child should be allowed to breathe spontaneously in air. Supplemental oxygen is occasionally required. Premedication with a benzodiazepine is essential because it causes amnesia (which is useful in repeated anaesthetics in children), 'ketamine sparing' (allowing the dose of ketamine to be reduced) and reduces emergence phenomena. Ketamine causes excessive salivation and should always be used in conjunction with an anticholinergic to reduce the risk of laryngeal spasm. Ketamine is emetic and routine administration of an anti-emetic is required. Children having multiple frequent ketamine anaesthetics can develop an unpredictable resistance to ketamine, necessitating escalating doses. This resistance resolves if ketamine is avoided for a few weeks.

Anaesthetic technique for measuring intraocular pressure

Premedication

- Oral atropine, 30 mg/kg 1 hour preoperatively
- Oral midazolam, 0.5 mg/kg 1 hour preoperatively
- Ametop over convenient vein

Induction

- Intravenous ketamine (50 mg/ml strength) 1–2 mg/kg
- Onset 30 seconds
- Duration 5–10 minutes

  or
- Intramuscular ketamine (100 mg/ml strength) 10 mg/kg
- Onset 2–8 minutes
- Duration 10–20 minutes
- Intravenous access after induction

  or
- Inhalational induction
- Oxygen and sevoflurane up to 8%
- Intravenous access
- Intravenous ketamine as above
- After inhalational induction it is advisable to wait 5 minutes before measuring intraocular pressure to allow sevoflurane washout

Intraocular surgery: the key to successful intraocular surgery is a balanced general anaesthetic with intermittent positive pressure ventilation. Two suitable schemes are shown in Figure 6. The anaesthetic should be planned to try to avoid any of the factors previously described that may increase IOP.

Extraocular surgery is mainly strabismus and lacrimal duct surgery. In general, these are best performed with a straightforward anaesthetic allowing spontaneous breathing. In strabismus surgery, consideration must be given to analgesia, avoidance of the oculocardiac reflex and anti-emesis. A suggested technique is shown in Figure 7.

Anaesthesia for intraocular surgery

Premedication
Midazolam, 0.5 mg/kg orally if required
Ametop to a suitable vein

Induction

Intravenous access	Inhalational – oxygen + sevoflurane
Remifentanil, 1 µg/kg	Intravenous access
Propofol, 2–3 mg/kg	Rocuronium 0.6–0.9 mg/kg

Laryngeal mask airway or tracheal tube

Maintenance

Intermittent positive-pressure ventilation with oxygen + air	Intermittent positive pressure ventilation with nitrous oxide + oxygen + sevoflurane
Remifentanil intravenous infusion 0.3–0.5 µg/kg/minute	

Propofol intravenous infusion 4–8 mg/kg/hour

Analgesia
Diclofenac 1–2 mg/kg p.r.
and/or paracetamol, 20–30 mg/kg p.r.

Reversal

Nil required	Neostigmine, 50 µg/kg + glycopyrrolate, 10 µg/kg

6

Anaesthesia for strabismus surgery

Premedication
- Midazolam, 0.5 mg/kg orally if required
- Atropine, 30 µg/kg orally
- Ametop to a suitable vein

Induction
- Inhalational or intravenous as required
- Laryngeal mask airway

Maintenance
- Spontaneous ventilation with nitrous oxide + oxygen + sevoflurane

Analgesia
- Diclofenac, 1–2 mg/kg p.r.
  And/or
- Paracetamol 20–30 mg/kg p.r.
  And/or
- Codeine phosphate, 1 mg/kg i.m. or p.r.

Anti-emetic
- Ondansetron, 0.15 mg/kg i.v.

Care of the Eye during Anaesthesia

Emert White

Emert White is Consultant Anaesthetist at Warwick Hospital, Warwick, UK. He qualified from Birmingham University and trained in anaesthesia in Nottingham and Southampton. He has a special interest in ocular physiology and anaesthesia.

Perioperative eye injuries and blindness are rare but important complications of anaesthesia. Eye injuries account for 3% of claims against anaesthetists. A better understanding by anaesthetists of orbital anatomy and ocular physiology and the mechanisms of ocular injury may help to reduce injuries.

Arterial supply to the optic nerve and retina

The ophthalmic artery enters the orbit through the optic canal enclosed within the dural sheath of the optic nerve and its first branch within the orbit, the central retinal artery, runs along the inferior aspect of the optic nerve, exiting from the dural sheath of the optic nerve about 10 mm behind the globe. The vascular supply to this posterior part of the optic nerve is from pial branches of the ophthalmic artery and the central retinal artery.

The central retinal artery divides into four major vessels at the optic disc each supplying one quadrant of the retina. The retinal vessels are distributed within the inner two-thirds of the retina, while the choroidal circulation supplies the outer layers of the retina.

Two to three posterior ciliary arteries arise from the ophthalmic artery, each of which divides into one long and 8–10 short posterior ciliary arteries. The short posterior ciliary arteries pierce the sclera and form the choriocapillaris, which supplies the anterior part of the optic nerve, the lamina cribosa and the choroid posterior to the equator.

The choriocapillaris is composed of small lobules supplied by a terminal arteriole. Each lobule has draining venules at the periphery.

The long posterior ciliary arteries travel forward in the suprachoroidal space to the ciliary body where they combine with the anterior ciliary arteries to form the major arterial arcade. Recurrent branches of the long posterior ciliary arteries supply the choroid anterior to the equator and anastomose with the short posterior ciliary arteries.

Watershed zones occur between the:

- choroidal and retinal circulation
- long posterior ciliary arteries
- short posterior ciliary arteries
- long posterior ciliary arteries and the anterior ciliary arteries
- choriocapillaris lobules.

Thus, in the event of ischaemia, the pattern of visual disturbance is variable.

Ocular blood flow and perfusion

Ocular blood flow (OBF) is determined by the pressure difference between mean arterial pressure (Pa) and mean venous pressure (Pv) and the resistance to that flow (R).

$$OBF = \frac{Pa - Pv}{R}$$

Retinal blood flow is about 170 ml/100 g/minute. The choroid receives 65% of the total ocular blood flow, while the retinal circulation receives 2%.

In the upright position, the pressure within the artery entering the eye is 60–70 mm Hg, while the intraocular pressure is 10–15 mm Hg, which under normal conditions provides a perfusion pressure of about 50 mm Hg. The episcleral venous pressure is about 3–7 mm Hg (7–8 mm Hg lower than the intraocular pressure) and increases by 3–4 mm Hg in the supine position. When intraocular pressure increases above 15 mm Hg, the episcleral venous pressure rises in direct proportion to the intraocular pressure thus reducing perfusion pressure. Retinal blood flow is maintained by autoregulation over a wide range of perfusion pressures. Autoregulation does not occur in the choroidal vascular system and increases in intraocular pressure reduce choroidal blood flow.

Ischaemic optic neuropathy

When intraocular pressure increases, retinal blood flow remains constant until the intraocular pressure reaches about 40 mm Hg. At an intraocular pressure of about 60 mm Hg, blood flow to the optic nerve at the disc ceases, but flow is maintained in the choroidal and retinal circulation. In humans there is little correlation between occlusion time and visual outcome, but in other primates irreversible damage occurs if ocular ischaemia exceeds 100 minutes.

Ischaemia of the optic nerve is caused by:

- arterial hypotension (hypotensive anaesthesia, haemorrhage)
- elevated venous or intraocular pressure
- increased resistance to flow (seen in atherosclerosis, diabetes mellitus, hypertension, thromboembolism)
- decreased oxygen delivery (anaemia).

Ischaemia of the optic nerve is classified as anterior or posterior ischaemic optic neuropathy.

- Anterior ischaemic optic neuropathy is characterized by infarction at the watershed zones listed above, a visual field defect, a pale oedematous optic disc and oedema of the optic nerve in the posterior scleral foramen.
- Posterior ischaemic optic neuropathy occurs when the pial branches of the ophthalmic artery become occluded. Blood flow in the posterior part of the optic nerve is significantly less than that in the anterior part. These pial vessels are incapable of autoregulatory control and therefore this part of the optic nerve is more vulnerable to ischaemia in the event of a fall in perfusion pressure or anaemia. Posterior ischaemic optic neuropathy is characterized by a slower onset of visual field defect and mild optic disc oedema.

The incidence of ischaemic optic neuropathy varies between 1/30,000 and 1/60,000 operations. High-risk procedures are spinal surgery, cardiopulmonary bypass and bilateral neck dissection. The primary mechanism of ocular ischaemia following bilateral radical neck dissection is the reduction of the ocular perfusion pressure caused by the increase in venous pressure when the normally adequate venous collateral circulation is sacrificed to ensure adequate tumour clearance.

During spinal surgery, patients may be placed prone with the head in a dependent position thereby elevating venous pressure and reducing perfusion pressure. In the prone position, venous pressure may be further increased by abdominal compression with resultant upward shift of the diaphragm. During spinal surgery, direct pressure on the eye as a result of patient malposition has caused ischaemic optic neuropathy. Stigmata of orbital compression are:

- intraoperative bradyarrhythmias
- hyperaemic conjunctiva
- periorbital numbness
- periorbital abrasions
- periorbital oedema.

Major blood loss resulting in anaemia, intraoperative hypotension and long operative times in combination with the above factors appears to be the cause of ischaemic optic neuropathy following spinal surgery. It is recommended that the haemoglobin level should be maintained above 8 g/dl and the systolic arterial blood pressure at a level greater than 60% of its preoperative recording. Cases of ischaemic optic neuropathy have occurred above these recommended levels.

Ischaemic optic neuropathy should be suspected when a patient complains of painless visual loss (with macular sparing) on emergence from anaesthesia. An urgent referral to an ophthal-mologist for advice on diagnosis and treatment should be sought. The aims of treatment are to reduce optic nerve fibre oedema as it passes through the posterior scleral foramen with cortico-steroids or osmotic diuretics and to optimize oxygen delivery by maintaining normal arterial blood pressure and haemoglobin. Vision seldom improves after ischaemic optic neuropathy.

Anaesthetists need to be aware that reductions in ocular blood flow are multifactorial, which cumulatively can put the eye at risk. Hypotension associated with increases in venous pressure, raised intraocular pressure and poor positioning when prone can jeopardize the eye especially in patients at high risk (e.g. those with hypertension, diabetes, atherosclerosis).

Central retinal artery occlusion

Central retinal artery occlusion is often caused by emboli. It may occur in conjunction with perioperative ischaemic optic neuropathy. It presents with a painless visual defect. Ophthalmic examination shows a pale retina with a cherry-red spot. An urgent ophthalmic opinion is required because treatment often improves the visual defect. Treatment options are:

- vasodilator therapy; inhalation of oxygen/carbon dioxide, calcium channel blockers, nitrates
- removal of obstruction
- increasing perfusion pressure; paracentesis, carbonic anhydrase inhibitor
- thrombolysis
- reducing blood viscosity
- reducing RBC rigidity – pentoxifylline (oxpentifylline)
- corticosteroids.

If the cause of central retinal artery occlusion is embolic, a cardiac or carotid source should be sought.

Aetiology of perioperative corneal abrasions

The most common complication is corneal abrasion. The incidence is 0.03–0.17% depending on the method of reporting. It is most commonly caused by exposure keratopathy, chemical injury or direct trauma.

Anaesthesia reduces the tonic contraction of the orbicularis oculi muscle, which may cause lagophthalmus. If the anaesthetist does not ensure that the eyes are fully closed, exposure keratopathy may occur. Anaesthesia inhibits the protective mechanism afforded by Bell's phenomena, and decreases tear production and tear film stability, which may lead to corneal epithelial drying and lysosomal protection.

Chemical injury can result from cleaning materials on the face mask and inadvertent spillage of antiseptic skin preparations on to the eye. The only antiseptic skin preparation that is not toxic to the cornea is povidone–iodine 10% in aqueous solution. It is the agent of choice when antimicrobial skin preparation of the face is required. Antiseptic solutions with detergent readily penetrate the corneal epithelium causing damage to the underlying iris, ciliary body, lens and blood vessels leading to ischaemia. Chlorhexidine, cetrimide and alcoholic antiseptic solutions cause oedema and de-epithelialization of the cornea. Trauma to the eyes can occur at any time during the perioperative period. During induction of anaesthesia it can be caused by ill-fitting face masks, the laryngoscope, or the anaesthetist's fingers, watchstrap, identification badge or stethoscope. After induction of anaesthesia, trauma to the eyes by surgical drapes, surgical instruments and during patient repositioning have all been reported. In the recovery room, the patient's fingers, pulse oximeter probe, pillow or Hudson mask may injure the eye.

Methods to prevent perioperative corneal injuries include:

- manual closure of the eyelids
- taping the eyelids closed
- using protective goggles
- suture tarsorrhaphy
- bio-occlusive dressings
- contact lenses
- installation of ointment, methylcellulose or viscous gels.

No method is 100% effective and the various protective strategies themselves may be associated with morbidity. Vigilance regarding the perioperative care of the eye is required to reduce these rare but potentially devastating complications.

Eye Signs in Anaesthesia and Intensive Care

Rahul Bajekal

Rahul Bajekal is Specialist Registrar in Anaesthetics at the Hillingdon Hospital, London, UK. He qualified from Pondicherry, India, and trained in anaesthetics in Chandigarh, India. In the UK he trains with the North Thames (West) Deanery.

The eyes are commonly used as clinical monitors in anaesthesia because they are easy for anaesthetists to access, and generally give well-defined responses to interventions. Most eye signs involve motor responses or reflexes related to different parts of the eye (Figure 1).

Eye signs in anaesthesia

Sign	Implications
Local anaesthesia	
• Horner's syndrome	• Cervical sympathetic block
• VI nerve palsy, dilated pupils	• Spinal anaesthesia
Sedation	
• Saccades	• Depth of sedation
General anaesthesia	
• Guedel's signs	• Ether anaesthesia
• Nystagmus	• Ketamine
• Pupillary size	• Opioids
Intensive care	
• Glasgow Coma Score	• Head injury
• Vestibulo-ocular, oculocephalic, corneal, pupillary reflexes	• Brain stem death
• Sustained unreactive pupils	• Poor recovery following cardiopulmonary resuscitation

1

Eye signs in local anaesthesia

The success of a retro- or peribulbar local anaesthetic block of the eye may be gauged from the degree to which it achieves an anaesthetic, immobile globe.

Horner's syndrome: ocular signs as part of Horner's syndrome have been used to monitor cervical sympathetic blockade. Ptosis, miosis and enophthalmos may be indicators of a successful stellate ganglion block. These signs may also herald possible complications, for example if seen with brachial plexus blockade.

Spinal anaesthesia: eye signs have been reported with spinal anaesthesia though not commonly. Abducens nerve (lateral rectus muscle of the eye) palsy has been observed as a complication, sometimes in the absence of a typical post-spinal headache; most cases eventually resolve without intervention. Dilated pupils seen with a high spinal block are associated with other features including cardiovascular and respiratory effects and loss of consciousness. The presence of non-reactive dilated pupils should not delay or interfere with attempts at resuscitation.

Eye signs in sedation
Traditionally, simple eye signs have been used to guide the depth of sedation. Drooping of the eyelid (Verrill's sign) was used by some clinicians while administering diazepam. Loss of eyelid and eyelash reflexes was also used to assess adequacy of sedation. These signs are inconsistent and almost always result in unacceptably deep levels of sedation. Verbal contact with the patient is preferred rather than relying on ocular signs.

Saccades: a recent review has evaluated the role of saccadic eye movements as biophysical monitors of anaesthetic sedation. Saccades have been described as rapid, semi-voluntary, conjugate, gaze-shifting movements designed to centre a target of interest on to the fovea. They may be monitored using electro-oculography or infrared oculometry. Peak saccadic velocity is useful for monitoring benzodiazepine-induced sedation but other parameters and application to other anaesthetic agents is debatable.

Eye signs in general anaesthesia

Guedel's signs: ocular signs used to be taught as part of the clinical assessment of anaesthetic depth. What are commonly known as Guedel's signs or stages of anaesthesia were a continuum of observations extending from analgesia to overdose. Eye signs progressed from loss of the eyelash reflex to successive abolition of the eyelid, conjunctival and corneal reflexes. The positions of the eyeball, eye movements and pupil size were also used to assess the depth of inhalational anaesthesia.

The advent of relaxant and intravenous techniques combined with the increasing popularity of opioids made Guedel's signs obsolete. Pupillary signs were masked by opioids, and other signs were inconsistent with newer inhalational and intravenous agents.

During intravenous induction, anaesthetists commonly test the eyelash reflex. This probably indicates deep sedation though it does not predict general anaesthesia reliably.

Nystagmus is commonly associated with ketamine anaesthesia. Some clinicians have used this with movement and phonation to titrate intermittent boluses of intravenous ketamine. However, isolated eye signs are not useful.

Pupillary size has been used to monitor the depth of anaesthesia and opioid overdosage. Though various studies have used pupillometry to describe the effect of single drugs, applicability to anaesthesia is limited. Opioids generally cause miosis and a decrease in the velocity of the pupillary light reflex. In equianalgesic doses, there is little difference between the various opioids. Mydriasis has been described with pethidine intoxication.

Tears have been used as part of scoring systems for adequacy of level of anaesthesia. Used in conjunction with other signs, they may signify light anaesthesia, but alone they are inadequate markers.

Eye signs in intensive care

Various eye signs have been described with concurrent medical conditions. Diseases such as myasthenia may manifest with ptosis; though pure eye signs are inadequate in diagnosis, the constricted pupil may help differentiate a cholinergic from a myasthenic crisis.

The effect of various drugs on the pupils may help to diagnose certain cases of poisoning. The presence of pallor, icterus or oedema of the conjunctiva and periorbital haematomas all aid in diagnosing underlying conditions.

The Glasgow Coma Score (GCS) uses eye signs as one of its three components. Observations range from no eye response to spontaneous eye opening; the score for this parameter ranges from 1 to 4. The GCS is easy to use and standardized. It does not describe pupil size or responses.

Dilated, non-reactive pupils: the presence of a dilated pupil unreactive to light is sometimes used as an indicator of poor prognosis after cardiopulmonary resuscitation (CPR). During the acute phase of CPR, the administration of drugs including anticholinergics may mask underlying pupillary responses. Complete recovery has been seen in patients who were noted to have so-called 'fixed dilated' pupils. The presence of unreactive and dilated pupils in the days following resuscitation suggests a poor prognosis. Current guidelines for CPR do not recommend cessation of resuscitative efforts in the presence of dilated non-reactive pupils.

Brain stem death: eye signs remain a diagnostic test for brain stem death. The neural pathways for ocular reflexes involve the brain stem and their absence, along with other criteria, is used to confirm the absence of brain stem activity. Tests include a fixed pupil, unreactive to light regardless of pupillary diameter along with the absence of corneal, oculocephalic and vestibulo-ocular (to caloric testing) reflexes.

General Anaesthesia for Ophthalmic Surgery

Nicholas C B Pritchard

Nicholas C B Pritchard is Consultant Anaesthetist at Moorfields Eye Hospital, London, UK. He qualified from St Mary's Hospital, London, and trained in anaesthesia in London. His special interests are oculoplastic, paediatric and intravenous anaesthesia.

The use of local anaesthesia for eye surgery is increasing but general anaesthesia will always have a place (Figure 1). Eye conditions are seldom immediately life threatening and it is nearly always possible to wait for the stomach to empty before giving general anaesthesia.

Eye operations are relatively painless procedures; however, patients are often anxious and at the extremes of age. Coexistent disease is common. Most patients are treated on a day-care basis or require an overnight stay only. There are multiple ophthalmic subspecialties. Good cooperation between anaesthetist and surgeon is important and the surgeon requires a 'soft', motionless eye on which to operate. Clinical strategies to ensure immobility are also vital. An analysis of closed insurance claims by the American Society of Anesthesiologists found that 30% of claims for eye injuries associated with anaesthesia were related to patient movement during surgery.

Patient selection for general anaesthesia

Absolute

- Patient preference
- Young children
- Uncooperative patient (e.g. mental retardation)
- Patient unable to keep still (e.g. Parkinson's disease, dystonia, arthritis, nystagmus, tremor, cough, dyspnoea, vertigo)
- Patient unable to lie flat for duration of operation
- Long procedure
- Allergy to local anaesthesia

Relative

- Surgery to the patient's only functioning eye
- Claustrophobia
- Communication problems (e.g. deaf patient, poor language comprehension)
- Bleeding disorder

1

Preparation of patients

Coexistent disease is common in ophthalmic patients and preoperative optimization of medical conditions is required. Investigations can be arranged through the anaesthetic clinic and liaison with appropriate specialists (e.g. cardiologists, neurologists) organized. Eye hospitals are sometimes remote from hospital backup services such as intensive care and CT scanners.

Blood coagulation control: the maximum acceptable inter-national normalized ratio (INR) for a patient taking warfarin depends on the operation (e.g. cataract < 3.5, eyelid procedures < 2). Treatment with non-steroidal anti-inflammatory drugs (NSAIDs) or aspirin should not be stopped for cataract surgery but should be stopped at least 10 days before surgery for eyelid procedures.

Starvation: the patient should be starved of solids for 6 hours before surgery and of clear fluids for 2 hours.

Prophylaxis for deep vein thrombosis: mechanical devices such as compression stockings, calf compressors and ankle elevators are useful. Heparin is usually avoided unless the patient is at high risk, especially for retinal and oculoplastic procedures.

Diabetic control: patients with diabetes should be given local anaesthesia if possible. If they have to be given general anaesthesia, their operation should be scheduled for early on the operating list and their morning hypoglycaemic tablet omitted. It is usually possible for patients to eat and drink soon after surgery, therefore it may be necessary for patients to omit only their morning insulin dose.

Drug treatment should be continued in most patients, especially cardiac drugs, antihypertensives, bronchodilators and cortico-steroids. It should be borne in mind that eyedrops and other ophthalmic drugs have systemic effects (Figure 2).

Systemic effects of ophthalmic drugs

Drug	Effect
β-blockers	Hypotension, bradycardia, bronchoconstriction
Phenylephrine	Hypertension
Acetazolamide	Hypokalaemia
Ecothiopate	Prolonged action of neuromuscular junction blockers broken down by pseudo-cholinesterases

2

Premedication may be required. Give the patient anti-emetics if they have a history of postoperative nausea or vomiting (PONV) or if they are having an emetogenic operation. Antihistamines (H_2-blockers) should be considered if gastric acidity or oesophageal reflux are problems, particularly if a laryngeal mask airway (LMA) is to be used. Anxiolytics may be given if needed, but should be avoided for day case surgery. Antimuscarinics should be given to children having ketamine for glaucoma screening. Topical anaesthetic cream should be used for children and patients with needle phobia.

Marking the side: the surgeon must mark the correct side for surgery before the patient leaves the ward. This is rechecked on arrival in the theatre suite and again in the anaesthetic room before induction. The eye that does not require surgery is taped closed after induction. The surgeon and scrub nurse should check which eye requires surgery for a final time just before cleaning the eye in the theatre.

Induction and maintenance of anaesthesia

Airway control

A mask is required for brief procedures only and avoids airway stimulation. The LMA is the ideal airway for most ocular procedures. Insertion and removal of a tracheal tube causes more cardiovascular stimulation than an LMA. Breath-holding, laryngospasm, bronchospasm and coughing are all less likely using an LMA. However, access to the airway during surgery is not easy without serious disturbance to the surgical field, therefore the LMA must be well positioned and stable before surgery starts. If there is any doubt about the reliability of the LMA position, it is safest to intubate the trachea.

Tracheal intubation is required in:

- the obese
- long procedures
- potential airway soiling – nasal bleeding from lacrimal surgery and mucous membrane graft material harvesting from inside the mouth (lower lip or palate)
- LMA failure
- infants having medium to long operations
- low chest compliance with high airway inflation pressures.

A preformed caudally directed, or an armoured flexible, tracheal tube taped away from the eyes, is ideal.

Intraocular surgery requires intermittent positive-pressure ventilation (IPPV). It allows accurate control of expired carbon dioxide and therefore intraocular blood volume and, to a lesser extent, intraocular pressure. Muscle relaxants are not usually required with the LMA if total intravenous anaesthesia is used. Some patients undergoing total intravenous anaesthesia do not maintain their eyes in the neutral position, they either look up or have a divergent squint. This can happen despite adequate depth of anaesthesia with total intravenous anaesthesia and sometimes a small dose of non-depolarizing muscle relaxant (rocuronium, 10–20 mg, in an adult) is required to correct it and allow surgery. If muscle relaxants must be avoided the surgeon can use a traction suture to return the eye to a neutral position.

Intravenous fluids

Provided there is little if any blood loss there is no need for intra-operative fluids other than maintenance crystalloid solutions. A full bladder causes hypertension and elevates intraocular pressure.

Anaesthetic maintenance drugs

Most standard methods of maintaining anaesthesia are possible. Either of the following work well for almost any combination of ocular operation and patient:

- LMA – remifentanil (Figure 3) + propofol / oxygen / air
- tracheal tube – remifentanil + sevoflurane / oxygen / air ± muscle relaxant for intubation.

The relatively unstimulating nature of most ophthalmic surgery can cause problems during general anaesthesia. Patients often become hypotensive, and sympathomimetics (e.g. ephedrine, methoxamine) should be used to maintain blood pressure and heart rate. On the other hand, awareness and patient movement are hazards if a proper level of anaesthesia is not maintained. In particular, accidental movement of the tracheal tube by the surgeon can cause coughing. The use of a peripheral nerve stimulator can be more of a stimulus than the operation (particularly anterior segment procedures) and can induce movement or coughing.

The benefits of using remifentanil for ocular surgery

- Produces stable, low and controllable blood pressure and heart rate and therefore intraocular pressure
- Rapidly titratable to patient needs
- Avoids need for maintenance muscle relaxants
- Rapid and unique recovery profile with no residual effects
- Dose and duration of infusion have almost no effect on recovery – ideal for long operations
- Low incidence of nausea – particularly with propofol
- Avoids use of nitrous oxide in vitrectomy with gas injection
- Well tolerated in patients with renal and hepatic disease

3

Monitoring

Spirometry is useful to identify changes in the position of an LMA during surgery. Increased peak airway pressure, decreased compliance, reduced tidal volumes and a difference between inspired and expired tidal volume should be sought. Invasive arterial pressure monitoring is useful if profound induced hypotension is required. Central venous pressure monitoring is seldom required. There is an association between malignant hyperpyrexia and oculomuscular abnormalities, however, the usual problem is hypothermia, which may cause shivering postoperatively. Postoperative shivering is most common after long procedures in young fit males having total intravenous anaesthesia. Intravenous pethidine is useful to abolish shivering. It is important to monitor the skin or nasopharyngeal temperature. Warming mattresses, warm air blowing devices and circle breathing systems may be used to maintain body temperature. There is seldom any need to expose the body below the neck, therefore patients can often be kept warm with blankets.

Postoperative management

Pain: NSAIDs and paracetamol/codeine mixtures are usually adequate to control pain. The surgeon can perform a sub-Tenon's local anaesthetic infiltration towards the endof surgery to provide good postoperative analgesia. Severe pain and nausea may result from raised intraocular pressure. This may be caused by a specific surgical complication and the patient should be examined by the operating surgeon rather than be treated for the symptoms. Intraocular pressure can be reduced in the short term by acetazolamide, 500 mg intravenously over 5 minutes, or mannitol, 1 g/kg intravenously over 30 minutes.be treated for the symptoms. Intraocular pressure can be reduced in the short term by acetazolamide, 500 mg intravenously over 5 minutes, or mannitol, 1 g/kg intravenously over 30 minutes.

Extubation is probably best performed deep with spontaneous breathing. It is important that the patient avoids coughing and straining on the tracheal tube.

Posture: after vitrectomy with injection of intraocular gas, the patient will have to posture as soon as they are conscious. A face-down position or with 'one cheek to pillow' is usual. Following oculoplastic surgery, patients are usually nursed in a sitting position.

Specific considerations for surgical subspecialties

Vitreo-retinal
Scleral buckle with or without cryotherapy:pain, PONV, and oculocardiac reflex are often marked, especially in young adults.

Vitrectomy: (the type of gas injected after vitrectomy, to provide retinal tamponade, depends on the required duration of action: Figure 4.) The patient will have to posture postoperatively so that the gas bubble lies over the appropriate area of the retina. Since the introduction of heavy perfluorocarbon liquids in vitreo-retinal surgery, the need for intraoperative posturing (including turning the patient prone) has been eliminated. Patients must not travel by aeroplane nor be exposed to nitrous oxide while the gas bubble is present. Nitrous oxide is 34 times more soluble in blood than nitrogen. Administered nitrous oxide rapidly diffuses into the intraocular gas bubble leading to a large increase in bubble volume and intraocular pressure, which may cause central retinal artery occlusion and blindness. If nitrous oxide is used during the anaesthetic for vitrectomy it must be discontinued at least 15 minutes before gas bubble injection.

Gases used for retinal tamponade

Gases used (all non-expansile)		Time in eye until bubble clears
Air		2–3 days
SF_6	20% (with air)	2–3 weeks
C_3F_8	14% (with air)	55 days (± 15)

Oculoplastics
Oculoplastic operations are often undergone by the elderly, or children with syndromes such as Goldenhar's. Antiplatelet drugs must be stopped for 10 days before these procedures, particularly eyelid surgery.

Orbital
Blood loss is possible during major orbital surgery, such as three wall orbital decompression procedures for thyrotoxic exophthalmos, and tumour resections. Transfusion of blood is seldom required, but induced hypotension with head-up positioning and maintenance of low to normal arterial carbon dioxide tensions all help to improve the surgical field and reduce bleeding. Retrobulbar or sub-Tenon's local anaesthetic infiltration is useful during enucleation surgery to reduce postoperative pain.

Glaucoma
In patients with glaucoma, reduction of the intraocular pressure is desirable. All anaesthetic agents except ketamine and suxamethonium reduce intraocular pressure. Local anaesthetic injection can further compromise optic nerve function and retinal perfusion by increasing intraocular pressure in patients with advanced glaucoma. Intubation (and extubation) of the trachea, can cause rises in intraocular pressure of up to 50 mm Hg. LMA insertion is much less stimulating and should be used if possible.

Cataract
Cataract operations are short and the surgical stimulus is low, therefore they are usually carried out under local anaesthesia. The use of LMA and total intravenous anaesthesia is good for anterior segment surgery.

Commonly mentioned topics

The oculo-cardiac reflex
Operations associated with the oculo-cardiac reflex include:
• squint
• scleral buckle retinal repair
• orbital implant
• evisceration
• enucleation.

The oculo-cardiac reflex is mediated via the trigeminal afferent with vagal efferent. It manifests as a slowing in the sinus rate, which may become irregular. Sinus arrest with asystole can occur but recovers when the precipitating cause (usually a surgeon pulling on the muscle) is abolished. Other arrhythmias that may be seen include atrioventricular junctional rhythms, wandering pacemakers, extrasystole and bigeminy.

Prophylactic antimuscarinic drugs (glycopyrrolate, 3–5 μg/kg, or atropine, 10 μg/kg) should be given after induction before the operations listed above, particularly if the patient is having total intravenous anaesthesia or other drugs that increase vagal tone. This pretreatment will reduce the chance of bradycardia not abolish it. Further doses may be required.

Local anaesthetic infiltration around the muscles abolishes the afferent pathway. Non-depolarizing muscle relaxants also reduce the incidence of the reflex by reducing extraocular muscle tone. There is a decrease in incidence with increasing age.

The 'open eye'
In an open eye the intraocular pressure is the same as atmospheric pressure. The danger is of expulsion of ocular contents. It is seldom necessary to operate as an emergency. Penetration of the eye by copper fragments may be an exception, but even then a delay for stomach emptying is usually possible. Do not try to empty the stomach with a nasogastric tube. An LMA can be used for open eye surgery, subject to the restrictions mentioned above.
• Avoid ketamine and suxamethonium, which increase intraocular pressure.
• Aim for a smooth, rapid induction. Rocuronium, 1 mg/kg, is suitable for muscle relaxation.
• Some degree of head-up tilt may be maintained during induction.
• Avoid mask pressure directly on the eye.
• Do not rush intubation. Wait for the induction drugs to have full effect.
• Coughing, straining or gagging during premature intubation attempts can lead to loss of ocular contents.

Local Anaesthesia for Ocular Surgery

Caroline Carr

Caroline Carr is Consultant Anaesthetist at Moorfields Eye Hospital, London, UK. She qualified from Oxford University and St Mary's Hospital, London, and trained in anaesthesia in London. Her special interest is in teaching local anaesthetic techniques.

Most surgery of the eye and its surrounding structures can be performed under local anaesthesia. General anaesthesia is reserved for those unable to cooperate (e.g. children), for bilateral surgery, and for extensive or lengthy procedures. Routine cataract surgery is usually performed under local anaesthesia and efforts have been concentrated on finding methods that have few serious complications. Traditionally, the surgeon administered the ocular anaesthesia as operator–anaesthetist. Recognition of occasional serious systemic complications of ophthalmic local anaesthesia, especially in medically compromised patients, led to involvement of the anaesthetist. The Joint Working Party report on Anaesthesia in Ophthalmic Surgery recommended the involvement of the anaesthetist, including performing the local anaesthetic.

Anatomy

With any local anaesthetic technique a detailed knowledge of anatomy is essential; that is beyond the scope of this article but the relevant areas are mentioned below.

The orbit may be visualized as a quadrilateral pyramid lying on its side. The open base forms the orbital rim at the front of the skull and the apex lies at a depth of 40 mm. The optic canal and superior orbital fissure open into the apex and admit the nerves and blood vessels of the orbit. The tip of the 40 mm needles used in traditional retrobulbar blocks could reach those vital structures at the orbital apex.

The globe is roughly spherical, with an average diameter of 24 mm and is suspended in the orbit by connective tissue. It is displaced towards the orbital roof and to the temporal side and projects anteriorly beyond the orbital rim. Needles placed medially and inferiorly in the orbit are less likely to penetrate the globe. The optic nerve pierces the globe medially to the posterior pole. The equator is midway between the two poles.

The extraocular muscles: the four rectus muscles originate at the apex of the orbit and insert into the globe behind the limbus, forming a cone within the orbit. The superior oblique muscle originates at the orbital apex and passes through the trochlear pulley on the medial side of the orbital roof behind the rim before passing back to insert on the globe. Needles should be avoided in this area to prevent trochlear damage. The inferior oblique muscle originates at the front of the orbit, on the medial side of the floor, and passes back and up between the lateral rectus and the globe before inserting. Inferomedial needle placement should be avoided to prevent muscle damage.

Orbital connective tissue: Tenon's capsule is a thin membrane of elastic fibres enveloping the globe from limbus to optic nerve. It adheres closely to the sclera with fine bridging fibres. All structures that attach to or pierce the globe cross the sub-Tenon's space including the long and short ciliary nerves. Local anaesthetic placed in this space provides globe anaesthesia. The globe is supported anteriorly by connective tissue slings passing from Tenon's capsule to the orbital wall. Posteriorly it is supported by a diffuse matrix of connective tissue from the sheaths of the extraocular muscles. All the connective tissue is embedded in fat. The connective tissue system allows local anaesthetic solution placed in the orbit to diffuse throughout the contents to provide anaesthesia of sensory and motor nerves.

The orbital blood vessels: the ophthalmic artery is a branch of the internal carotid and supplies the globe, orbital contents and neighbouring structures of the nose and forehead. It enters the orbit through the optic canal, crosses over the optic nerve to run medially in the orbit as it sends out branches to the contents. Venous plexuses on the medial wall and floor of the orbit drain via the superior and inferior ophthalmic veins through the superior orbital fissure into the cavernous sinus. Needles must be placed with care in the medial side of the orbit to avoid these vessels.

The nerve supply to the orbit: motor innervation is from cranial nerves III, IV, VI and VII (Figure 1). Sensory innervation is via the ophthalmic and maxillary divisions of cranial nerve V (Figure 2). Parasympathetic innervation is through fibres in cranial nerves III and VII. Sympathetic innervation is from the superior cervical ganglion. The optic nerve is cranial nerve II.

Motor innervation of the eye

Muscle	Nerve supply
Inferior oblique	Oculomotor (III)
Superior rectus	Oculomotor (III)
Inferior rectus	Oculomotor (III)
Medial rectus	Oculomotor (III)
Levator palpebrae superioris	Oculomotor (III)
Superior oblique	Trochlear (IV)
Lateral rectus	Abducens (VI)
Orbicularis oculi	Facial (VII) temporal and zygomatic branches

1

Sensory innervation of the eye

Structures	Nerve supply
Sclera, cornea, iris and ciliary body	Short ciliary nerves Long ciliary nerves
Conjunctiva – superior	Supraorbital nerve Supratrochlear nerve Infratrochlear nerve
Conjunctiva – inferior	Infraorbital nerve
Conjunctiva – lateral	Lacrimal nerve
Conjunctiva – limbal	Long ciliary nerve
Periorbital skin	Supraorbital nerve Supratrochlear nerve Infraorbital nerve Lacrimal nerve

2

The eyelids: the orbicularis oculi muscle is a flat elliptical muscle surrounding the orbital margin, which closes the eyelids. The levator palpebrae muscle opens the upper eyelid. It originates at the orbital apex and passes forward between the orbital roof and superior rectus to fan out to insert into the upper eyelid.

Methods of local anaesthesia

Topical
Topical anaesthesia provides good surface anaesthesia of the globe without the complications of a regional block. The patient retains full eye movement. Commonly used for superficial surgery of the conjunctiva and cornea, including removal of sutures and small foreign bodies, topical anaesthesia alone is now often used for cataract surgery. With the newer surgical techniques, akinesia and reduction of intraocular pressure are not of such importance. Patients experience discomfort owing to sensation from the iris and ciliary body but this can be abolished by intracameral preservative-free 1% lidocaine (lignocaine), up to 1 ml.

Infiltration
Local infiltration of the skin with anaesthetic is used for eyelid surgery in adults. For anaesthesia of deeper structures, the supraorbital and infraorbital branches of the trigeminal nerve are blocked where they emerge from the supraorbital notch and infraorbital foramen. 0.5% bupivacaine, 1–2 ml, with adrenaline (epinephrine) 1:200,000 are injected subcutaneously at each site. To avoid subcutaneous haemorrhage:

- aspirin should be stopped 2 weeks preoperatively
- warfarin should be stopped 3 days preoperatively
- avoid injection into deeper tissues
- use adrenaline (epinephrine) 1:200,000 as a vasoconstrictor in the local anaesthetic solution.

Retrobulbar block
The classical technique of retrobulbar block provided good akinesia and anaesthesia and was usually supplemented with a facial nerve block to paralyse orbicularis oculi. The principle of the technique was to deposit a small volume (2–3 ml) of anaesthetic solution in the muscle cone at the apex of the orbit using a 40 mm long needle. Rare, but serious, complications occurred with these blocks, including retrobulbar haemorrhage, globe perforation, damage to the optic nerve or ophthalmic artery and spread of the anaesthetic to the brain stem along the optic nerve dural sheath.

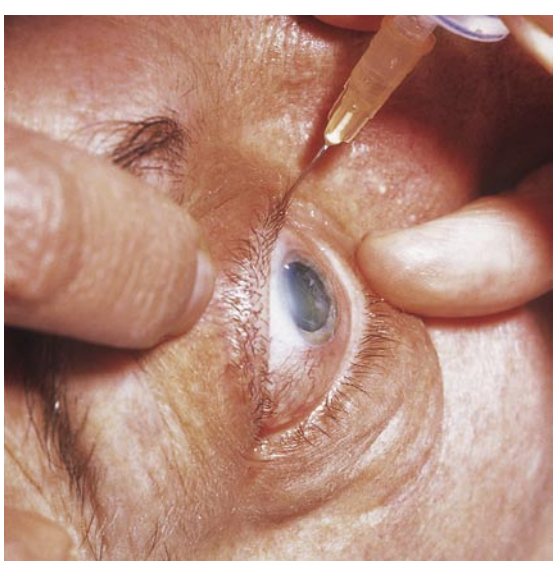
Peribulbar block
Peribulbar anaesthesia was introduced in 1986 to avoid the complications of retrobulbar block. A shorter needle is used and places larger volumes of anaesthetic solution outside the muscle cone with the needle tip no further back than the equator. The anaesthetic spreads throughout the orbit and provides satisfactory operating conditions. The technique usually consists of two injections of local anaesthetic, one inferior and one medial to the globe. These sites are selected to avoid vital structures within the orbit. The volume used is usually enough to block the nerves to orbicularis oculi directly. More recent adaptations of the technique have been to direct the lateral injection up into the muscle cone just behind the globe. This produces a more rapid and reliable onset of block with a smaller volume of anaesthetic solution, and often the medial injection is omitted. This is the 'modern retrobulbar' technique. However there is still a risk of globe perforation.

Technique of peribulbar block (Figures 3 and 4)

- The patient lies supine with his head on a pillow.
- The eyes are in neutral gaze.
- A few drops of topical anaesthetic are applied to the conjunctiva (0.4% oxybuprocaine).
- The inferotemporal injection is given first, using a 25 G 25 mm sharp needle and 5 ml of anaesthetic solution.
- Insert the needle through the conjunctiva, 2 mm away from the globe, midway between the lateral canthus and the lateral limbus.
- Keep the needle tangential to the globe and advance posteriorly and medially to a depth of 15 mm. Keep the needle tip lateral to the sagittal plane of the lateral limbus.
- Following test aspiration, slowly inject 2–5 ml of anaesthetic. Assess orbital tension digitally.
- Withdraw the needle, close the patient's eye and maintain gentle pressure for 2 minutes.
- Give the medial injection using a 25 G 12 mm needle.
- Insert the needle medial to the medial caruncle, with the needle bevel facing medially.
- Advance posteriorly at 90° to the face to the depth of the needle hub.
- Initial resistance may be felt at the medial check ligament.
- Following aspiration, slowly inject 2–5 ml of anaesthetic, assessing orbital tension.
- Withdraw the needle, close the patient's eye and maintain gentle pressure for 5–10 minutes.
- Assess the block and for hypotony for intraocular surgery apply an oculopressor device for 10 minutes.

Any technique using a blindly placed sharp needle may result in serious complications threatening sight, including globe perforation. The more recently described technique of sub-Tenon's block is now commonly used for most surgery on the globe.

3 Peribulbar block – inferolateral injection.

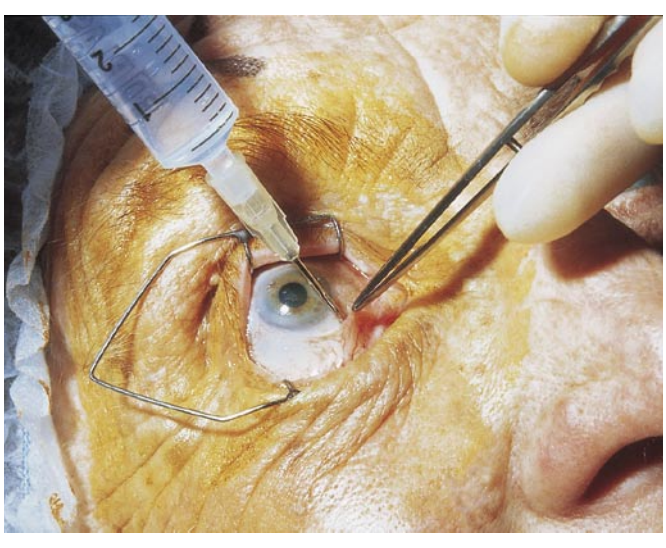


4 Peribulbar block – medial injection.

Sub-Tenon's block
Local anaesthetic is introduced to the sub-Tenon's space through a small incision in the inferior nasal quadrant of the eye. Posterior diffusion of the anaesthetic blocks sensation from the eye by direct action on the ciliary nerves as they pass through the sub-Tenon's space. If a suitable volume of anaesthetic is used, complete akinesia is obtained as it diffuses into the muscle cone from the sub-Tenon's space.

Technique of sub-Tenon's block (Figure 5)
- The patient lies supine with his head on a pillow.
- A few drops of topical anaesthetic are placed on the conjunctiva.
- A few drops of 5% aqueous iodine are placed on the conjunctiva.
- A small speculum is inserted to hold the eyelids apart.
- The patient looks up and laterally.
- The conjunctiva and Tenon's capsule are pinched firmly with non-toothed forceps 5–7 mm from the limbus in the inferonasal quadrant.
- With round-ended spring scissors a small snip is made through both layers.
- The closed scissor tips are passed through the hole and the blades opened while gently withdrawing them to form a short tunnel.
- A blunt curved 19 G 25 mm sub-Tenon's cannula is passed into the sub-Tenon's space and allowed to slide round the globe, over the sclera to a depth of 15–20 mm in the inferonasal quadrant.
- Up to 5 ml of local anaesthetic is injected slowly.
- The cannula is withdrawn and slight pressure maintained over the closed eye for 2 minutes, when complete akinesia and anaesthesia are seen.
- Sub-conjunctival haemorrhage is kept to a minimum by using topical adrenaline (epinephrine) 1:10,000, avoiding cutting conjunctival vessels, avoiding extensive dissection and using gentle direct pressure.

Globe perforation has not been reported with this technique and it is often used as the technique of choice in the long myopic eye. One case of retrobulbar haemorrhage has been reported and the anaesthetist must always be aware of this risk with any needle or cannula technique of ocular block.



5 Sub-Tenon's block.

The local anaesthetic mixture
The characteristics of a block depend on the anaesthetic solution used as well as the technique. 2% lidocaine (lignocaine) is effective within 5 minutes and gives 30–40 minutes of surgical anaesthesia. 0.5% bupivacaine has a slower onset of action but longer duration of surgical anaesthesia (up to 4 hours). The newer local anaesthetic ropivacaine has been used successfully in peribulbar blocks but has little advantage over bupivacaine in the small volumes needed in eye blocks. Mixtures of lidocaine (lignocaine) and bupivacaine are often used to provide rapid onset with delayed offset but are of no practical advantage. Addition of 1:200,000 adrenaline (epinephrine) reduces haemorrhage in skin infiltration techniques but is not used in orbital blocks because the vasoconstriction may compromise retinal blood flow. The enzyme hyaluronidase in concentrations of 5–30 iu/ml enhances spread of anaesthetic and speed of onset.

Patient management

Preoperative assessment is performed as for any anaesthetic. The patient's concomitant medical conditions should be controlled before surgery. Contraindications to ocular local anaesthesia are patient refusal, being unable to lie flat and still for the surgery, and allergy to local anaesthetic. The technique to be used should be explained carefully and supplemented with leaflets and other patients' experiences. Preoperative starvation is unnecessary unless the patient is at high risk. Anticoagulated patients must maintain their international normalized ratio (INR) within therapeutic limits (2–3) for ocular surgery under topical, peribulbar or sub-Tenon's anaesthesia. During surgery the patient should have intravenous access and pulse oximeter, ECG and non-invasive blood pressure monitoring should be available if required. Trained staff should monitor the patient and the anaesthetist should be available for resuscitation or sedation – this is a controversial point because of manpower implications.

Sedation
Most patients readily tolerate ocular surgery under local anaesthesia with careful explanation, gentle handling and a sympathetic approach. Occasionally, an anxious patient may require sedation. An anaesthetist provides this with the appropriate monitoring. Various techniques may be used. A small dose of intravenous midazolam, 0.5–1.5 mg, before the anaesthetic provides amnesia while allowing verbal communication.

Ophthalmology and Anaesthesia

Luke Herbert

Luke Herbert is Vitreo-retinal Fellow at Moorfields Eye Hospital, London, UK

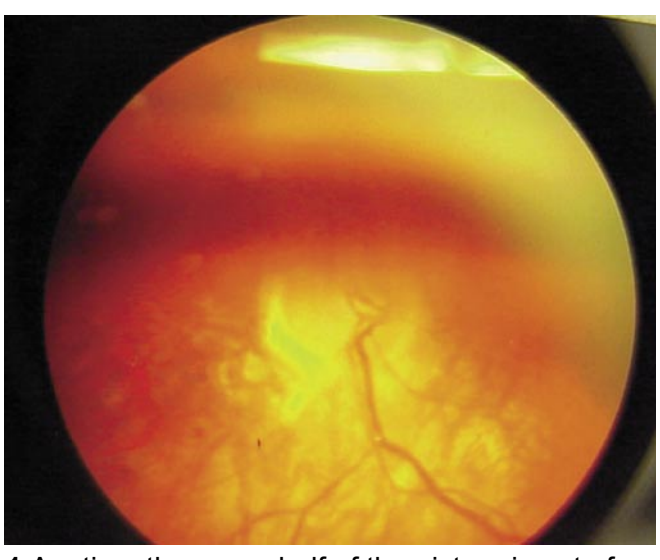
Possible eye problems in theatre

Intraocular gas
As part of the management of retinal detachment and some other retinal conditions, long-acting gas is injected into the vitreous cavity (Figure 1). The surface tension of the gas/fluid interface is used to close holes in the retina. However, the gas bubble has to be positioned correctly and lying on the back is usually contraindicated.

The wrong management of patients with gas-filled eyes can cause blindness. Several different gases can be used, the most persistent of which, C_3F_8, can remain in the eye for 3 months. The gases are poorly soluble and remain in the vitreous cavity, in equilibrium with, mainly, nitrogen. However, if a very soluble gas (e.g. nitrous oxide) is inhaled, there is a massive influx of gas into the eye. This can cause the intraocular pressure to rise rapidly, which can lead to blindness. Patients with gas in the eye must never be given nitrous oxide as part of anaesthesia. A typical situation in which this might occur is when the patient has ophthalmic surgery with long-acting gas injection and after discharge from the eye unit, develops an acute surgical problem such as acute retention of urine. The patient is then anaesthetized with nitrous oxide at a different unit, and wakes up blind.

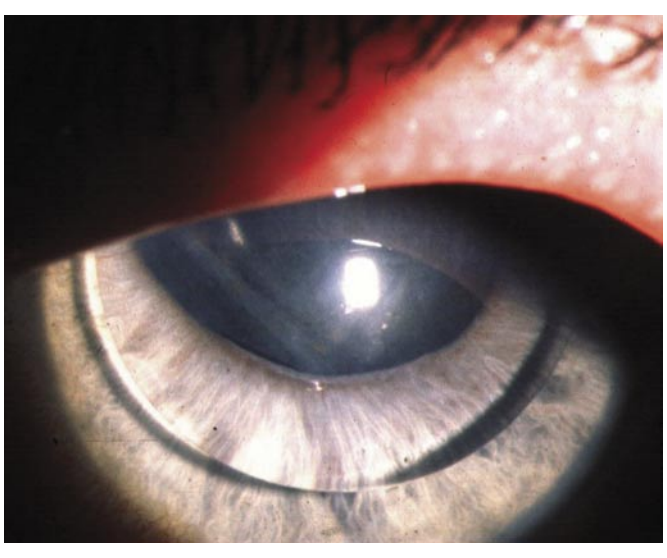
Some surgeons are also concerned about the use of nitrous oxide in the primary surgery. If an eye is filled with gas, which the surgeon expects to be say, 16% C_3F_8 in air, but the patient is anaesthetized with nitrous oxide, a large portion of the volume will be taken up by the volume of the nitrous oxide. When the patient resumes breathing room air the nitrous oxide rapidly leaves the eye, leaving the globe soft and vulnerable to minor trauma, and reducing the amount of gas in the eye thus reducing the duration of gas fill.

The total volume of gases in the eye tends to increase in the early postoperative period as nitrogen diffuses in to the eye but C_3F_8 (which is poorly soluble) diffuses out slowly. This can lead to raised intraocular pressure. It is important not to ignore pain as a symptom of high pressure after surgery.



1 A retina: the upper half of the picture is out of focus because there is a bubble of gas in the eye.

Silicone oil
In some patients, silicone oil is used instead of gas to plug holes in the retina. Silicone oil floats in the eye. If the patient lies flat on their back, oil can float into the anterior chamber of the eye (Figure 2), which can cause severe long- and short-term problems.



2 Oil has come into the anterior part of the eye and forms a round globule in front of the iris and lens.

Odd-looking eyes
A patient waking with a fixed dilated pupil, a divergent squint and a glassy appearance to the eye may have a prosthetic eye. Ask the patient about this before anaesthesia – it is not always easy to recognize a glass or plastic eye. Prosthetic eyes and their sockets are unsterile, and organisms colonizing prosthetic sockets have infected remote surgical sites.

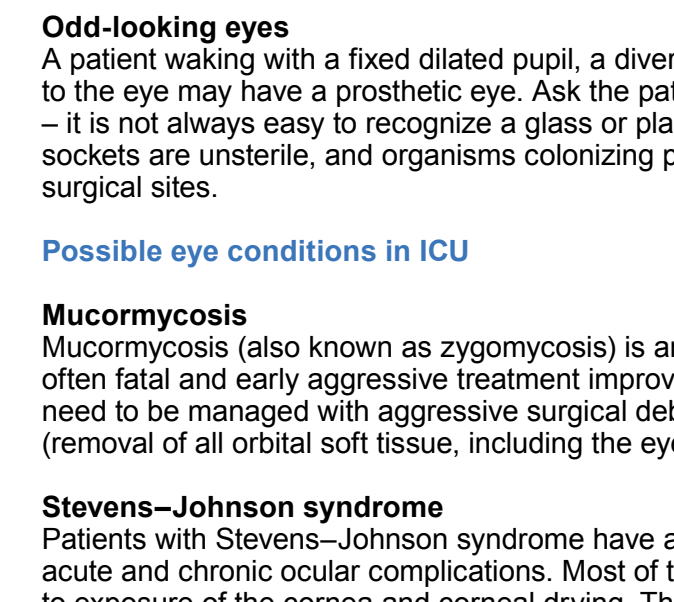
Possible eye conditions in ICU

Mucormycosis
Mucormycosis (also known as zygomycosis) is an uncommon fungal disease. It is often fatal and early aggressive treatment improves outcome. Orbital involvement may need to be managed with aggressive surgical debridement including orbital exenteration (removal of all orbital soft tissue, including the eye).

Stevens–Johnson syndrome
Patients with Stevens–Johnson syndrome have acute conjunctivitis that can lead to acute and chronic ocular complications. Most of the acute complications are related to exposure of the cornea and corneal drying. These can be prevented with physical barriers such as simple eye ointment, used copiously every 3–4 hours, or frequent use of lubricating drops (e.g. hypromellose 0.3% or normal saline, given every 30–60 minutes). Drops given so frequently are best used unpreserved to prevent local toxicity caused by preservatives. These drops may not be available in general hospitals in which case normal saline for intravenous use can be used. The solution should be kept cool, and discarded every day.

Chronic complications include scarring of the conjunctival surface. Previously, lysis of nascent scars was encouraged in the acute phase, breaking down conjunctival adhesions with a glass rod, but there is little evidence that this is of benefit. Many ophthalmologists prescribe corticosteroid drops in the acute phase, but there is little evidence of long-term benefit. Occasionally, the noninfected conjunctivitis can become secondarily infected with a sudden increase in the purulence of the secretions; this requires urgent ophthalmic attention.

Fungal endophthalmitis
Systemic fungal infections, typically with *Candida albicans* and occasionally *Aspergillus* spp. can metastasize to the choroid and vitreous cavity causing a fungal endophthalmitis (Figure 3). Patients with long-term intravenous line placement are at particular risk of fungal endophthalmitis. They present with pain, decreased vision and floaters. Many patients with systemic fungal infections do not develop endophthalmitis, and many patients with endophthalmitis show no other signs of infection, especially those who are transiently immunocompromised. *Candida* infections may resolve with systemic treatment alone, usually with oral fluconazole. In patients with advanced involvement of the vitreous, vitrectomy should be carried out to debulk the fungal load and remove the vitreous, which acts as a substrate for further fungal growth. An extended course of treatment is required. With appropriate management, most patients with *Candida* endophthalmitis will maintain some vision. The prognosis is not as good in *Aspergillus* endophthalmitis.



3 Fungal endophthalmitis; the fluffy white lesions are balls of fungus growing within the vitreous cavity.

Ophthalmic complications related to ICU care

Conjunctival oedema (chemosis)
Patients with low plasma oncotic pressure who lie on their back tend to accumulate fluid around the face. This can lead to profound swelling of the looser facial tissues, particularly around the eyes. The conjunctiva is bound to the underlying sclera by a weak meshwork of fibres. This potential space easily fills with tissue fluid causing the conjunctiva to balloon out. This is called chemosis and can be very striking, even preventing the eyelids from closing properly. Treatment is by raising the head of the bed. If the eyelids cannot close, the cornea should be protected with copious amounts of simple eye ointment to prevent drying and corneal exposure.

Corneal exposure
The cornea depends on tears, and the redistribution of tears and resurfacing of the tear film by blinking is essential. The production of tears is reduced when the patient is asleep or unconscious. When asleep, the eyelids can remain partly open, but in most people the Bell's phenomenon in which the eyes roll superiorly helps to protect the cornea from drying. In the anaesthetized, paralysed patient the cornea is vulnerable to drying, because tear production is low, the eyelids can open and the eyes remain in the primary position.

The corneal epithelium and even the conjunctival epithelium cannot survive dry for long. The cornea soon develops small dry spots of dead or dying epithelial cells, known as exposure keratitis. With continued dryness or other insults, these areas lose their epithelium to become corneal erosions, also called abrasions (Figure 4). Once the epithelium is lost the cornea is vulnerable to infection (the conjunctival sac is never sterile) and frank corneal ulcers can develop. This can be a problem in the high-dependency setting where the author has seen febrile, unconscious patients with fans thoughtfully placed to remove the last drops of moisture from the eye. The cornea should be protected with ointment and taping.

This chronically exposed eye has developed a corneal ulcer (**a**). The edges of the corneal ulcer are stained bright yellow (**b**) with fluorescein dye.

4

Corneal abrasion
The anaesthetist has to help protect the patient's cornea from drying and trauma otherwise a corneal abrasion may develop. Abrasions are exquisitely painful; the eye is usually red and the vision may be slightly blurred. However, they heal rapidly, and the pain should reduce within the first day of treatment.

Taping the eye: one way to protect the cornea is to tape the eyelid shut. Taping vertically across the eyelid is unhelpful, because the eyelid can open under the tape and the cornea can rub on the tape (Figure 5). The correct way to tape is from corner to corner (Figure 6).

Venturi masks, if they are badly placed**,** can cause corneal abrasions and corneal infection in debilitated patients. It is common on chronic wards to see the Venturi mask pushed off so that an edge rubs on the eye (Figure 7).

5 The wrong way to tape an eyelid shut.

6 The right way to tape an eyelid shut.

7 Venturi mask pushed off allowing an edge to rub the eye (this picture was posed, but this does happen).

Acute angle closure glaucoma
Anticholinergic agents allow the pupil to dilate and in susceptible patients this can lead to acute angle closure glaucoma. This is more common in older patients who have not had cataract surgery. The signs are of a mid-dilated pupil that does not react (direct or consensual) to light, a slightly dull sheen to the cornea and, in conscious patients, severe pain that can cause confusion and vomiting. Acute glaucoma is not related to chronic glaucoma. If a patient is already receiving treatment for glaucoma it is unlikely that they will suffer an attack because susceptible patients identified in an eye clinic usually have immediate prophylactic laser treatment or surgery.

Systemic problems caused by ophthalmic treatment

Eye drops
Most patients do not regard eye drops as medication and it is common for patients taking two or three eye drops to deny that they take any medication. Almost all eye drops have some systemic side-effects, and the most important are described below.

β-blockers: some topical β-blockers are relatively cardio-selective. All topical β-blockers precipitate asthma attacks in susceptible patients. All β-blockers reduce exercise tolerance and can precipitate heart failure. Most β-blockers are well know, the exception is *Cosopt*, which contains timolol 0.5% maleate.

α-agonists: adrenaline (epinephrine) used to be used as an antiglaucoma medication. It can precipitate angina and hypertensive episodes. Adrenaline (epinephrine) and its pro-drug, dipivefrine, are less fashionable now, but the new selective α_2-adrenoceptor agonists, brimonidine and apraclonidine, can act as systemic hypotensive agents in the same way as clonidine.

Pilocarpine is less commonly used now, but it used to be the mainstay of glaucoma therapy. It constricts the pupils, making assessment of pupillary function impossible. Pilocarpine worsens asthma in some individuals and is best not used in patients with severe reversible airway obstruction.

Latanoprost is a prostaglandin analogue used in glaucoma treatment. It can precipitate an attack in poorly controlled or brittle asthma.

Atropine is the prototype agent for the mydriatics, including homatropine, cyclopentolate and tropicamide. It is the agent most likely to cause problems in the ICU because of its long duration of action in the eye. Atropine is used for painful blind eyes, to ease ciliary spasm, to reduce pain in the postoperative period and to facilitate examination by keeping the pupil dilated. This fixed dilated pupil can be most disconcerting in an acute ICU setting because the dilating effects can take a week to wear off, particularly in darker eyes.

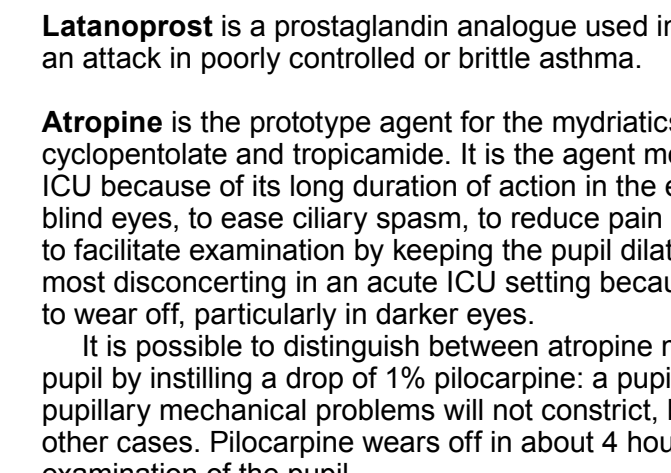
It is possible to distinguish between atropine mydriasis and a pathologically dilated pupil by instilling a drop of 1% pilocarpine: a pupil affected by atropine or by local pupillary mechanical problems will not constrict, but the pupil will constrict in all other cases. Pilocarpine wears off in about 4 hours, so it should not prevent further examination of the pupil.

Systemic medication
Corticosteroids: ophthalmologists do not use systemic corticosteroids often, but when they do, they tend to use high doses, particularly in temporal arteritis. Prednisolone, 80–100 mg/day, is prescribed, even in elderly patients, with all the usual corticosteroid side-effects.

Acetazolamide: some ophthalmologists routinely give the carbonic anhydrase inhibitor acetazolamide at the end of intraocular procedures as prophylaxis against intraocular pressure spikes. It is also used in some patients with chronic glaucoma refractory to treatment. The use of acetazolamide, even for a few days, causes hypokalaemia and a metabolic acidosis.

Posture
Long gone are the days when patients were immobilized for 2 weeks after cataract surgery. However, patients who have had retinal detachment surgery with gas injection or who have had macular hole surgery are often asked to posture for 50 minutes every hour.

These positions are often awkward (Figure 8) and this, combined with prolonged immobility after surgery, increases the risk of deep vein thrombosis. Ophthalmologists are very bad at considering the systemic effects of their surgery, and a little encouragement from anaesthetists might be useful.



8 Ophthalmologists can ask their patients to adopt this posture for up to 2 weeks

Anaesthesia for Joint Replacement Surgery

Rachael Craven
Robin Cooper

Rachael Craven is Specialist Registrar in Anaesthesia in Bristol. She is currently working at the Royal Prince Alfred Hospital, Sydney, Australia.

Robin Cooper is Consultant Anaesthetist at the Gloucester Royal Hospital, UK. He qualified from St George's Hospital Medical School, London, and trained in the South West Region Anaesthetic Rotation. His specialist interest is in paediatric anaesthesia.

Joint replacement surgery is a common and effective procedure for the relief of disability due to severe joint pain and loss of function. The most common joints replaced are the hip, knee and shoulder, but with advances in technology and surgical techniques the range of joints that may be replaced is increasing. Most patients for joint replacement surgery have degenerative joint disease, commonly osteoarthritis. Other conditions necessitating joint replacement surgery include:

- rheumatoid arthritis
- osteoporosis and fracture
- metastatic lesions and pathological fractures
- avascular necrosis of the femoral head.

Most patients are elderly, and commonly have associated problems such as hypertension, ischaemic heart disease, chronic obstructive pulmonary disease (COPD) or renal disease. Younger people presenting for joint replacement surgery often suffer from rheumatoid arthritis, severe osteoporosis or obesity. Presentation for revision of previous replacement surgery is increasingly common.

Preoperative assessment

Problems in multiple systems are common because most patients are elderly. The problems of disease processes associated with orthopaedic conditions should also be considered; the most common is rheumatoid arthritis (Figure 1).

Problems associated with rheumatoid arthritis

Skeletal
- Instability of odontoid peg and atlanto-axial subluxation
- Restricted mouth opening due to temporomandibular joint involvement

Respiratory
- Rheumatoid lung nodules
- Pleural effusions
- Pulmonary fibrosis

Drugs
- Corticosteroids, non-steroidal anti-inflammatory drugs, gold and methotrexate may have significant systemic effects

Other
- Anaemia of chronic disease, pericarditis and amyloid deposits causing renal dysfunction

1

Assessment of co-morbidities

Cardiopulmonary reserve is most commonly estimated by assessment of exercise tolerance. However, this may be impossible or inaccurate because joint disease may limit exercise. In these circumstances the following may be used:

- lung function tests, arterial blood gases and oxygen saturation in air
- resting ECG for silent ischaemia or previous myocardial infarction
- echocardiography for left ventricular function, wall movement and valvular abnormality.

These tests are of limited relevance because they provide information only about the function of rested, rather than stressed, cardiopulmonary systems. Dobutamine stress tests provide information about cardiac function under stress but they are not readily available and have associated risks.

Renal function may be impaired owing to age, hypertension or chronic use of non-steroidal anti-inflammatory drugs (NSAIDs).

Musculoskeletal – other joint involvement is common. The range of limb and neck movements should be noted. Obesity may be a cause or consequence of degenerative joint disease. Assessment for positioning on the table and for regional blockade should be made. In patients with metastatic disease, the bone scan should be checked to ensure there are no spinal deposits that may interfere with regional anaesthesia.

Hip and knee replacement

Preoperative preparation

- Preoperative assessment should be carried out as above.
- Optimization of co-morbidities is required.
- Cross-matched blood must be available.
- Deep vein thrombosis (DVT) prophylaxis is required. If a regional technique is planned, ensure appropriate timing of low-molecular-weight heparin.
- Antibiotic prophylaxis (usually cephalosporin or aminoglycoside) is required.
- Invasive monitoring is seldom indicated unless there is significant cardiac disease or large blood loss is anticipated.
- Large bore intravenous access is required (sited in the non-dependent arm for laterally positioned patients).

Anaesthetic technique

Regional anaesthesia is probably the technique of choice because it:

- reduces blood loss, leading to a decreased need for bank blood and associated transfusion risks
- decreases bleeding at the operative site, improves cement bonding and decreases surgical time
- decreases the incidence of DVT and pulmonary embolus in hip and knee arthroplasty.

The reduction in blood loss seen with spinal anaesthesia, compared with general anaesthesia, is thought to be due to a combination of perioperative hypotension and a comparatively lower haematocrit level. There is a perception that regional anaesthesia reduces the incidence of postoperative confusion and cognitive dysfunction compared with general anaesthesia, but studies have failed to demonstrate this.

The decision to use neuraxial opiates usually depends on the presence of a resident anaesthetist, owing to the potential risk of delayed respiratory depression postoperatively.

Sedation is often desirable because of the duration of the operation, intraoperative noise and patient request. Patients positioned laterally for hip replacement may become restless and uncomfortable because of pain arising from the dependent shoulder. Intermittent midazolam, titrated in 1 mg increments, may be used but often causes intraoperative disorientation and confusion, resulting in patient movement. Increasingly popular is a target-controlled infusion of propofol, 0.5–2 μg/ml, which gives smoother, more titratable sedation. Oxygen should be administered throughout the operative period.

As sedation deepens, airway obstruction or snoring may occur. This is seldom a problem in the lateral position, but some supine patients may require a nasopharyngeal airway.

General anaesthesia: if general anaesthesia is indicated, bleeding may be reduced by modest hypotension in carefully selected patients, using volatile agents. Unless there is a risk of aspiration, spontaneous ventilation with a laryngeal mask airway is usually appropriate.

For hip arthroplasty, analgesia may be supplemented by the use of a 3-in-1 (femoral/obturator/lateral cutaneous of thigh) block. Some anaesthetists favour a lumbar plexus block because this also blocks the sciatic nerve, which has a component supplying the hip. For knee replacement a 3-in-1 block combined with a sciatic nerve block can be effective.

Intraoperative problems

Patient position: in the lateral position, there is a risk of excessive lateral neck flexion and pressure on the dependent limbs.

Hypothermia: orthopaedic theatres are often colder than other theatres, with a higher velocity airflow leading to more rapid patient cooling. Hypothermia may cause poor wound healing, infection, coagulopathy and cardiovascular dysfunction. Some surgeons are opposed to hot air warming devices because of the theoretical risk of increased wound infection, and a discussion of the balance of risks may be indicated. Fluid warmers, blankets and patient hats should be used routinely.

Blood loss: average blood loss in total hip replacement ranges from 300 to 1500 ml and may double in the first 24 hours post-operatively. During knee replacement surgery with an intra-operative tourniquet, most blood loss occurs in the recovery area. Careful fluid balance is essential because compensation for hypovolaemia is poor in the elderly. Provided normovolaemia has been maintained a haemocue can be used to guide blood transfusion requirements.

Cement reactions: prostheses may be cemented in place. At the time of cementing, a drop in blood pressure and oxygen sat-uration is often seen. This was originally thought to be caused by a directly toxic effect of the methyl methacrylate monomer component of the cement, but it is now known to be caused by a shower of microemboli of blood, fat or platelets forced into the circulation by high intramedullary pressure during cement packing and prosthesis insertion. Subsequent embolization to the lungs produces a raised pulmonary vascular resistance and reduction in left ventricular return, resulting in hypotension. The microemboli are toxic to the lung parenchyma causing haemorrhage, alveolar collapse and hypoxia. This may be severe enough to cause cardiovascular collapse, cardiac arrest and death. Reactions are more common and more severe in bilateral joint replacements and also in under-resuscitated patients; therefore it is vital to ensure that the patient is not hypovolaemic before cementing. Fractional inspired oxygen concentration may have to be increased. Cement reactions tend to be less common in knee replacement.

Thromboembolism is common after joint replacement. DVTs are more common following knee replacements than hip replacements. Following knee replacement, most DVTs are distal calf thromboses with a low risk of pulmonary embolus. In hip replacement surgery, extremes of movement at the hip and kinking of vessels lead to endothelial damage and blood stagnation. These thromboses tend to be of proximal veins with a higher risk of pulmonary embolus.

The use of a regional technique, low-molecular-weight heparin, graduated compression stockings or pneumatic compression boots decreases the risk of DVT. Intraoperative low-dose intravenous heparin reduces the incidence of DVT without increased bleeding but is not commonly used. A combination of the above techniques provides the best protection and the anaesthetist should ensure that the local thromboprophylaxis protocol has been followed.

Tourniquet: in some patients with cardiac disease the increase in systemic vascular resistance when the tourniquet is inflated has precipitated left ventricular failure. However, more of a problem occurs on releasing the tourniquet, when the acidic byproducts of metabolism are washed out of the limb causing hypotension secondary to vasodilatation and the effects of acidosis on cardiac contractility. In knee replacement surgery, as the duration of the operation increases, tourniquet pain can become a problem. Additional analgesia or epidural top-up may be required.

Postoperative management

Analgesia

Epidural analgesia is excellent, particularly in reducing quadriceps muscle spasm following knee replacements. However, there is an increased risk of urinary retention and the resulting catheterization may cause a bacteraemia, increasing the risk of prosthesis infection.

Patient-controlled analgesia is the choice in many institutions. Intramuscular opiates may also be considered.

Regular paracetamol, 1 g/6 hours, should be given orally or rectally.

NSAIDs should be used with caution especially in the elderly owing to the increased risk of renal impairment.

Midazolam infusions or baclofen are sometimes required to ease quadriceps muscle spasm.

Fluid balance: stringent fluid balance monitoring is mandatory because blood loss may double in the first 24 hours. Nausea may reduce the patient's oral intake.

Oxygen: perioperative ischaemia is common and generally silent. Oxygen should be given for the first 72 hours postoperatively.

Shoulder replacement

Monitoring and intravenous access
Standard full patient monitoring is required. Large bore intravenous access is made on the non-operative side. Non-invasive blood pressure monitoring is instituted either on the non-operative side with a non-return valve on the intravenous line, or on the lower leg.

Anaesthetic technique
The most common technique is general anaesthesia using an armoured tracheal tube and positive-pressure ventilation. Selected patients may be managed satisfactorily using a spontaneous ventilation technique through an armoured laryngeal mask. Access to the patient's head intra-operatively is extremely restricted. The interscalene approach to brachial plexus blockade provides excellent intraoperative and postoperative analgesia and improves the operative conditions with decreased blood loss and good muscle relaxation. It commonly gives a unilateral phrenic nerve palsy, but this seldom causes alveolar hypoventilation even in spontaneously ventilating patients.

Patient position
The patient is placed in a sitting position, with a bolster behind the shoulder blades to improve surgical access (Figure 2). Care should be taken to ensure there is no excess strain on the lumbar spine. The torso should be securely strapped. Many tables are specially adapted with a built-in extension for the head ring, the height and angle of which may be adjusted.

2 The sitting position.

The head must be securely fastened because there will be considerable pull and movement at the shoulder. Access to the airway intra-operatively is difficult owing to the sitting position and the presence of surgical drapes; the tracheal tube must therefore be securely taped in place. The eyes should be taped and well padded.

Intraoperative problems
Elderly patients often have poor cardiovascular compensatory mechanisms while under general anaesthesia. At the start of the operation, while positioning the patient, a large drop in blood pressure may accompany the change from supine to sitting and vasopressors and a temporary return to a flatter position may be required. Patients are at risk of air embolism from open veins at the operative site.

Postoperative management
Shoulder replacements are extremely painful and, if possible, interscalene block should be used, supplemented with patient-controlled opiate analgesia. Regular paracetamol and NSAIDs (in those in whom they are not contraindicated) should also be prescribed.

Revision arthroplasty
As the number of active elderly people increases, more patients are returning for revision of earlier replacements. As well as the problems of hip or knee replacement, revision arthroplasties have added complications associated with prolonged surgery and high blood loss.

Preoperative preparation
Discuss the anticipated blood loss with the surgeon; this depends on the type of previous prosthesis and the number of components being revised. Pre-donation of autologous blood with acute normovolaemic haemodilution and the use of a cell saver should be considered. Platelets (often not immediately available) and clotting factors may be required.

Monitoring and intravenous access
Invasive blood pressure and central venous pressure monitoring should be considered in view of the long duration of surgery and the likelihood of significant blood loss. A urinary catheter should be inserted with the facility for hourly urine output measurements.

Anaesthetic technique
The technique of choice is probably general anaesthesia, combined with insertion of a lumbar epidural catheter and positive-pressure ventilation. An epidural reduces intraoperative blood loss and improves operating conditions as well as reducing the risk of DVT. Spinal anaesthesia is generally unsuitable because the length of the operation outlasts its effects.

Intraoperative problems
Temperature: it can be difficult to prevent perioperative hypothermia. These operations are long and considerable volumes of intravenous fluid are transfused. Fluid warmers, hot air blowers, humidification systems and patient hats are important because intraoperative hypothermia can contribute significantly to coagulopathy and perioperative blood loss.

Blood loss is often considerable. Pre-donation of 1 unit of blood in the anaesthetic room, using acute normovolaemic haemodilution, is useful if the patient has an adequate starting haemoglobin. Intraoperative use of a cell saver can reduce the need for bank blood and reduce the associated transfusion risks, but once cement is in use, cell salvage must stop. The use of a cell saver is contraindicated in patients in whom joint replacement is for metastatic disease or infection. Platelets and fresh frozen plasma are often required. Transfusion of pre-donated blood should wait until surgical haemostasis is obtained. Fluid balance should be guided by surgical blood loss, central venous pressure trends (where available), pulse, blood pressure and urine output, with the aim of maintaining normovolaemia. The haemoglobin concentration should be assessed often, either from blood gases or by using a haemocue device.

Postoperative management
Should be in a high dependency unit. Oxygen should be prescribed for at least 72 hours. Analgesia should be provided by epidural infusion with regular enteral paracetamol. Close control of fluid balance is aided by the use of central venous pressure monitoring and hourly urine output measurement. Coagulopathies should be treated, but the threshold to transfuse red cells depends, in part, on the presence of co-morbid medical conditions, especially ischaemic heart disease. ◆

Anaesthesia for Spinal Surgery

Ian Crabb

Ian Crabb is Consultant in Anaesthesia and Intensive Care at Gloucestershire Royal Hospital, UK. He qualified from London University and trained in anaesthesia in London and Australia. His interests include major trauma management and cardiovascular monitoring in intensive care.

Clinical features of spinal disorders

Intervertebral disc lesions

Prolapsed discs: lumbar backache is one of the most common causes of chronic debility in Western society. Acute lumbar disc prolapse or chronic degeneration with disc-space narrowing at L4/5 or L5/S1 are the most common pathologies. In acute prolapse, the disc may bulge beneath the posterior longitudinal ligament in the mid line (central disc) or posterolaterally with consequent distortion of the spinal canal or nerve-root compression. Local oedema may exacerbate the problem. Symptoms result from distortion of the posterior longitudinal ligament (chronic pain), pressure on the nerve-root sheath (sciatica) and compression of the nerve itself (muscle weakness, numbness and paraesthesia). Cauda equina compression may cause urinary retention, but is relatively uncommon. Management may include rest, analgesia and physiotherapy, but the prolapsed disc can be treated effectively only by bed rest, disc reduction (including epidural injection or chemonucleolysis) or surgical discectomy.

Cervical disc prolapse may be precipitated by sudden unexpected flexion or rotational movements. In most cases, there is probably a pre-existing disc abnormality. The most common levels for prolapse are C5/6 and C6/7, and symptoms are similar to those of lumbar disc prolapse. Treatment of the prolapse may be effected by rest, reduction using bed rest and traction, or surgical removal, if the symptoms are severe.

Spondylosis: lumbar disc degeneration may occur following recurrent disc prolapse or for other reasons. This results in flattening of the disc, facet-joint displacement, and a degree of instability with limited and painful movement (spondylosis). Conservative treatment for lumbar spondylosis is appropriate in less severe cases. However, if the pain cannot be controlled, spinal fusion is indicated.

Spondylosis is the most common disorder of the cervical spine. In addition to disc flattening, bony spurs may grow at the margins of the vertebral bodies, impinging on nerve roots and producing symptoms. Physiotherapy is the mainstay of treatment, but in severe or refractory cases anterior spinal fusion may be the definitive option.

Spondylolisthesis

If intervertebral facet joints become affected by osteoarthritic changes, dysplasia or fractures, one vertebral body may slip forwards on the other (spondylolisthesis). The most common levels for this to occur are L4/5 and L5/S1. Stabilization is achieved by spinal fusion and may be necessary for symptomatic relief.

Spinal stenosis

The spinal canal may be congenitally small or narrowed by the presence of a spondylolisthesis. Further narrowing consequent on disc degeneration and osteoarthrosis may produce neurological symptoms, which may be unilateral (root canal stenosis). Spinal decompression is indicated if symptoms are severe.

Rheumatoid disease

Rheumatoid arthritis affects about 1% of the world's population. The disease causes destruction of synovial joints, tendons and bursae, and 75% of sufferers have extra-articular symptoms. The spine is commonly affected, most often the upper cervical region. Erosion of the odontoid peg or cruciate ligament may result in atlanto-axial subluxation, with the risk of cord compression. 'Vertical subluxation' may result from erosion of the lateral masses of the axis, causing the odontoid peg to approach or enter the foramen magnum. Of relevance to the anaesthetist is that the disease may involve the temporomandibular and arytenoid joints.

Assessment of atlanto-axial subluxation may be made by measuring the distance between the anterior arch of the atlas and the odontoid peg on lateral cervical spine radiographs. However, neither this 'anterior atlanto-dental interval' nor the posterior equivalent correlates well with the severity of neurological symptoms. Stabilization procedures or surgical decompression may be undertaken to relieve neurological symptoms, but they are hazardous, with equivocal benefit.

Spinal curvature

Scoliosis is a lateral curvature of the spine, often with a rotational element. The deformity usually arises in late childhood and may be postural or structural. Postural scoliosis arises as a compensatory mechanism for problems outside the spine, such as a shortened leg or abnormal pelvic tilt. Structural scoliosis is a fixed deformity and is always accompanied by bony abnormalities. Adolescent idiopathic scoliosis is the most common form, presenting in the 10–15 year age group. Operative treatment for scoliosis is indicated for curvatures over 40°, the surgery being potentially complex and challenging.

Kyphosis: 'structural kyphosis' is a fixed, excessive dorsal curvature of the thoracic spine. It may occur in osteoporosis and ankylosing spondylitis. In Scheuermann's disease (adolescent kyphosis), the vertebral bodies become wedge-shaped as they grow. If the curvature exceeds 60°, surgery, which carries a high risk of neurological damage, may be indicated.

Infection

Tubercle bacilli or staphylococci may cause abscess formation within vertebral bodies. Tubercle infection may spread to adjacent vertebrae with caseation and cold abscess formation, resulting in vertebral collapse with a high risk of spinal cord damage. Antibiotic therapy is the mainstay of treatment for both infections. However, abscess drainage or spinal fusion for progressive deformity may be necessary.

Surgical procedures

Lumbar laminotomy and laminectomy: laminotomy (partial removal of vertebral lamina) or laminectomy (complete removal) are performed to decompress the spinal cord and/or nerve roots via a posterior approach with the patient lying prone. Should a discectomy also be necessary, the dura is retracted to one side and the disc removed piecemeal. During these procedures there is a risk of damage to both the dura and retroperitoneal structures (e.g. major vessels). The extent of the procedure depends on the underlying problem and may vary from simple laminotomy for single nerve-root compression to decompression over several segments for spinal canal narrowing. In such cases, a stabilization or fusion procedure (e.g. plate and screws) may also be required.

Microdiscectomy can be performed to decompress nerve roots affected by simple pathology; bone is not usually removed. The patient is placed prone or kneeling and the appropriate spinal level is identified using radiographic control. A small incision is made over the appropriate interspace and an operating microscope is used to retract the nerve-root to allow disc material to be excised.

Thoracic laminectomy and costotransversectomy: thoracic laminectomy involves midline removal of the vertebral lamina to decompress the thoracic spinal canal. Costotransversectomy (removal of transverse process and rib-head) is performed for nerve root compression. Both procedures require the patient to be prone and involve the use of an operating microscope.

Cervical laminotomy, foramenectomy and laminectomy are used to decompress the spinal cord or nerve roots in the cervical region. As with the lumbar and thoracic regions, the nature and extent of the surgery depends on the underlying pathology. The patient may be positioned prone or sitting.

Anterior cervical discectomy is a common neurosurgical procedure performed for disc herniation or degeneration with neurological symptoms. It is often augmented by vertebral fusion with a bone graft.

Other cervical procedures

Vertebral corpectomy is essentially an enlarged version of an anterior discectomy and is performed as an anterior decompression procedure. If access is required above the level of C3, a transoral approach may be used, which may involve a mandibular split and division of the tongue.

Cervical or craniocervical fusion is indicated for spinal instability. The fusion usually involves several adjacent vertebrae and may include fusing the occiput to the upper cervical spine. A posterior approach is used with the patient lying prone.

Spinal reconstruction procedures: significant kyphoscoliotic deformities may benefit from reconstructive surgery and, regardless of the underlying condition responsible for the deformity, the surgical approach to the anterior spine is similar. Surgery to the upper thoracic spine is achieved via a modified and extended anterior cervical exposure, often involving resection of a clavicle, part of the manubrium and first rib. Mid-thoracic spinal surgery is more easily performed via a thoracotomy with rib resection. One-lung ventilation may be required. Once the vertebrae or discs are removed, the spinal cord is at risk of damage, the degree of risk depending on the extent of the vertebral disease and the extent of reconstruction required.

A transdiaphragmatic approach involving detachment of the diaphragm is required for lower thoracic procedures. The lumbosacral spine is approached via a flank incision and retroperitoneal dissection. Often the 11th or 12th ribs are resected, risking damage to the great vessels, ureters, sympathetic chain and presacral plexus. A posterior fusion is also often undertaken with the above procedures.

Anaesthetic considerations

Thoracolumbar procedures (excluding corrective surgery)

Preoperative: surgical procedures on the lumbar spine for disc problems are common. Any preoperative neurological deficit should be recorded in the patient's notes, especially if a regional technique is considered. Generally, these patients are otherwise healthy and no special investigations are normally required.

Intraoperative: it is possible to perform simple lumbar pro-cedures under local or regional (spinal or epidural) anaesthesia. However, this is seldom done in practice because of medico-legal concerns that any new postoperative neurological deficit may be blamed on the anaesthetic technique. A general anaesthetic technique involving intubation and mechanical ventilation is more usual. For all posterior spinal procedures the patient is placed prone or in the knee–elbow position. It is therefore advisable to use an armoured tracheal tube to minimize the risk of kinking and to ensure that the tube is well secured before and after turning the patient. Potential problems with the prone position are summarized in Figure 1. Thoracoscopy is being increasingly used for procedures on isolated regions of the thoracic spine. This requires a double-lumen tracheal tube and for the ipsilateral lung to be deflated.

Problems with the prone position

Potential problem	Comments
Eyes	
• Corneal abrasion	Ensure eyes taped shut
• Optic neuropathy	Increased intraocular pressure leads to decreased perfusion pressure Reduce risk by avoiding compression to the eyes, hypotension, low haematocrit
• Retinal artery occlusion	Avoid pressure on the eyes
Head and neck	
• Venous and lymphatic obstruction	Careful positioning to minimize venous obstruction
• Skull fixation	Insertion of pins into skull can result in a hypertensive response that is difficult to control
Abdominal compression	
• Impaired ventilation	Avoid abdominal compression as far as possible
• Decreased cardiac output	Bean-bag mattress or pillows are better than supportive frames or knee–chest position
Damage to major vessels	
• Aorta or inferior vena cava	Accidental damage following perforation of anterior longitudinal ligament Produces major bleeding into wound, and presents with acute reduction in blood pressure and electromechanical dissociation arrest High mortality
• Iliac vessels	Less acute presentation. High index of suspicion to avoid delayed diagnosis

Any standard maintenance regimen is acceptable. However, blood pressure control is important, balancing the need to ensure spinal cord perfusion with the requirement to produce a bloodless surgical field. Sodium nitroprusside and esmolol infusions have been widely used for this purpose, though remifentanil is becoming popular. Blood loss is usually minimal from simple procedures, though if extensive laminectomies and fusions are performed, cross-matched blood should be available.

Standard monitoring is appropriate for simpler procedures. However, invasive blood pressure monitoring, a central venous pressure line and a urinary catheter should be considered if deliberate hypotension is used or if the procedure is likely to be prolonged and involve large fluid shifts.

Postoperative: most spinal surgery is painful and good postoperative analgesia is important. Local anaesthetic and opioid drugs can be instilled into the epidural space before closing. More usually, however, a regimen including patient-controlled analgesia (PCA) combined with regular oral/rectal analgesics is successful. Postoperative complications include persistent hypotension, haemorrhage, urinary retention, nerve root damage and cauda equina syndrome (urinary/faecal incontinence, perineal sensory loss and lower-limb motor weakness).

Cervical procedures

Preoperative: cervical spine fractures may cause acute spinal cord trauma and result in acute ventilatory failure requiring emergency tracheal intubation. Cervical spine stabilization during intubation is essential. The acute injury may additionally produce dysfunction of the sympathetic nervous system, resulting in hypotension and bradycardia. Simple treatment with fluids and atropine usually suffices, though vasopressors (e.g. ephedrine) may be necessary.

Neurological signs and symptoms may be present. Nerve root compression produces pain in the neck and arm, often associated with weakness and sensory loss. Acute cord lesions above T1 produce paraplegia and if the lesion is above C5 the patient will be quadriplegic.

Careful airway assessment is vital in all patients requiring cervical spine surgery. Difficult intubation may be anticipated if there is reduced movement, swelling or deformity. Up to 40% of patients requiring cervical spine surgery for rheumatoid disease fall into this group. The patient may need to be prepared for an awake fibre-optic intubation and appropriate equipment and skilled staff made available. In certain circumstances (e.g. surgery involving maxillotomy or mandibulotomy), an elective tracheostomy may be necessary for postoperative airway management.

Intraoperative: general anaesthesia with tracheal intubation and ventilation is required; standard maintenance techniques are appropriate. For anterior cervical procedures, the patient is placed supine with the neck extended and supported. For posterior approaches, the patient is usually prone. However, the seated position is preferred by some surgeons, because surgical access may be easier and blood loss reduced. This position is associated with a high incidence of air embolism (25–45%). If a patent foramen ovale is present (20% of the population), paradoxical embolism may occur, resulting in air entering the cerebral or coronary circulations. Standard monitoring may be used for straightforward cases, but arterial and central venous pressure catheters are useful for more prolonged procedures. Additionally, spinal cord monitoring may be required (see below).

Extubation may be problematical and is best performed with the patient awake and able to support their own airway. If the risk of reintubation is high, a tracheal tube exchange catheter (e.g. Cook catheter) may be useful. The catheter can be introduced into the tracheal tube and left *in situ* when the patient is extubated. Should urgent reintubation be necessary, the new tracheal tube can be rapidly railroaded over the exchange catheter. However, prolonged sedation and ventilation should be avoided because this may mask postoperative neurological deterioration.

Postoperative: possible complications include airway obstruction post extubation, which is potentially life-threatening if the patient has had a spinal fusion and is encased in a stabilization device. Airway compromise may result from haematoma formation or neurological deficit. Pneumothorax is an occasional cause of postoperative respiratory distress.

Spinal reconstruction and fusion

Preoperative: spinal reconstruction is indicated for correction of kyphoscoliotic deformities and for stabilization following trauma, infection (e.g. tuberculosis) or metastatic carcinoma. Patients presenting for this type of major surgery require careful preoperative assessment, because complex and chronic problems are common (Figure 2). Preoperative management should include lung function tests (e.g. forced vital capacity, peak expiratory flow rate), arterial blood gas analysis and review by a cardiologist if cardiac abnormalities are suspected.

Preoperative considerations for patients undergoing major reconstructive spinal surgery

Problem	Comment
Respiratory	
• Reduction in total lung capacity and vital capacity	Reduction worse with increasing deformity. If vital capacity < 40% predicted postoperative ventilation likely. NB A further decrease in vital capacity of up to 40% may occur postoperatively; recovery may take up to 2 months
• Increasing V/Q mismatch	Hypoxaemia more likely
Cardiovascular	
• Increase in pulmonary vascular resistance	Independent of severity of scoliosis
• Increasing incidence of congenital heart disease and mitral valve regurgitation	High index of suspicion
Neurological	
• Variable preoperative deficit	Careful preoperative documentation
Musculoskeletal	
• Muscular dystrophy relaxants	Abnormal response to muscle
• Respiratory impairment required	Postoperative ventilation may be
Nutrition	
• Malnourishment	Likely in patients with metastatic carcinoma

2

Intraoperative: intubation with a double-lumen tube may be necessary. Standard maintenance techniques are applicable, although this may have to be modified (e.g. no muscle relaxants) depending on surgical technique and spinal cord monitoring (see below).

Major blood loss is not uncommon and suitable intravenous access should be secured. Intraoperative blood loss may be dramatically reduced by careful patient positioning, the use of controlled hypotension (mean arterial pressure 60–70 mm Hg) and mild haemodilution to a haematocrit of 25–28%.

Intraoperative monitoring should include invasive blood pressure, central venous pressure, and urine output measurement. Evoked potentials are used to monitor spinal cord function (see below). If there is any indication of spinal cord ischaemia during surgery, normal blood pressure should be restored immediately and any traction on the cord relaxed. Strenuous efforts should be made to maintain normothermia.

Early extubation is desirable and good postoperative pain relief is essential. Epidural analgesia is considered by many to be the gold standard. An epidural catheter can be inserted before surgery or by the surgeon during the operation. Some patients require planned ICU admission for elective post-operative ventilation.

Postoperative complications include the risk of respiratory failure increased by thoracotomy, diaphragmatic injury and fat embolism. Great care should be exercised when moving and transferring patients to prevent dislodgement of spinal fix-ation. Careful documentation of neurological status is important because postoperative neurological deterioration is a major concern.

Spinal cord damage

Neurological damage during surgery and anaesthesia is not limited to the site of surgery. Paraplegia and quadriplegia have been reported as a result of poor patient positioning. There are reports of patients with spinal disease who have suffered neurological damage either at levels remote from the site of surgery or during surgery unconnected with their spinal disease. However, neurological damage is more likely at or near the site of surgery on the spine. Risk factors and methods for minimizing them are listed in Figure 3.

Risks of spinal cord damage

Risk related to:
- length and type of surgical procedure
- spinal cord perfusion pressure
- underlying spinal pathology
- pressure on neural tissue during surgery

Risk minimized by:
- careful positioning
- maintaining SCPP
  - SCPP = MAP – CSFP
  - CSFP can be reduced by CSF drainage
  - MAP manipulated by anaesthetist
  - ? keep systolic blood pressure > 90 mm Hg
- drugs
  - methylprednisolone given less than 8 hours after insult
  - NMDA antagonists (ketamine, magnesium)
- prevention of haematoma formation
  - careful haemostasis
  - stop anti-platelet medication preoperatively
  - withhold heparin immediately postoperatively

CSFP, cerebrospinal fluid pressure; MAP, mean arterial pressure; NMDA, N-methyl-D-aspartate; SCPP, spinal cord perfusion pressure

3

Spinal cord monitoring

The ‘wake-up test’ involves lightening anaesthesia at an appropriate point during the procedure and observing the patient’s ability to move to command. The technique requires practice and adds to the duration of surgery. In addition, it provides information at the time of the wake-up only and misses damage occurring at other times.

Neurophysiological monitoring using somatosensory evoked potentials (SEPs) provides a continuous picture and offers a more sophisticated approach. Electrical stimuli are applied to the lower limbs and appropriately placed electrodes can record cortical (SCEP) or spinal (SSEP) evoked potentials. The resulting trace can be analysed for wave amplitude and latency with respect to a reference ‘time zero’. SCEPs are affected by anaesthetic induction and inhalational agents, opioids and local anaesthetic drugs, and interpretation requires care and experience. Nevertheless, a decrease in amplitude or latency unrelated to drug administration of 35–50% is thought to be significant and indicate possible cord damage. However, even in skilled hands, interpretation can be difficult and a ‘wake-up test’ may still be required.

SSEPs can be recorded from electrodes placed into the epidural space either percutaneously or during surgery. SSEPs are affected less by inhalational agents, but are sensitive to temperature changes and local anaesthetic drugs. Their stability during anaesthesia allows them to be used with more confidence during surgery than SCEPs.

Motor evoked potentials can be obtained by stimulating the motor cortex with a transcranial electrode and eliciting a response from the distal spinal cord, peripheral nerves or muscle. They have not been used extensively for spinal cord monitoring because they are more difficult to achieve and are sensitive to inhalational anaesthetic agents. ◆

Preoperative Assessment in the Elderly

Malcolm Savidge

Malcolm Savidge is Consultant Anaesthetist in the Gloucestershire Hospital Trust, UK. He qualified from St Mary's Hospital, London, and trained in anaesthesia at Northwick Park Hospital, Harrow, Southampton and Wessex. His particular interests are medical ethics and within anaesthesia, chronic pain, regional anaesthesia and ophthalmic anaesthesia.

An increasing elderly population and advances in surgical technology are challenging anaesthetists to provide safe, effective anaesthesia. The mean age of the population continues to rise and half of all patients over 65 years will undergo surgery before they die. Osteoarthritis is almost universal and many of these patients will require joint replacement surgery. This article concentrates on elderly and arthritic patients and their associated problems.

Increased age and pre-existing illness both increase the incidence of complications. A successful outcome depends on meticulous attention to preoperative assessment and an intelligent choice of suitable anaesthetic techniques. An understanding of the limitations of physiological function in the elderly and rheumatic patient enables an accurate assessment of the likely response to the stress of surgery and therefore the final outcome to be made. The anaesthetic technique used and the choice of perioperative monitoring often makes the difference between success and failure. Similarly, the opportunity to improve physiological function preoperatively, where applicable, should never be missed.

Elderly patients often present with a baffling array of pathologies. Most are chronic effects of the ageing process and the residual effects of past illnesses. Signs and symptoms are often masked by limitation of movement and lack of exercise because of the pain of arthritis. This enforced immobility often leads to weight gain and obesity, making pre-existing pathology in other systems worse and adding to the risks of anaesthesia and surgery.

The elderly and ageing

Old age is not a disease. The elderly undergo physiological and anatomical changes that evoke different responses to stress and anaesthesia. In 1982, the United Nations recognized this: 'Support to the aged people must be provided by practitioners who are knowledgeable in the subject of ageing, are interested in ageing people and their families and are skilled in working with them as well as being concerned about the quality of care given'.

The process of ageing is one of continuous biological change. The number of parenchymal cells decreases, with a concomitant increase in inactive interstitial cells, triggering a progressive decline in physiological function. Gross morphological changes occur with contraction of vertebral bodies and discs. Kyphosis occurs and flexion of hips and knees. The long bones of the legs bow, but the arms remain unchanged in length. This reverses the height:span ratio. Muscle size and bulk decrease rapidly with advancing age, together with alterations in fat distribution. Skin becomes thinner and more fragile.

Cardiovascular system

In the heart, myofibrils enlarge but become less numerous. Collagen and fat replace a substantial volume of the muscle mass. Deposits of amyloid and subendocardial calcification impair conduction in the ventricle. This, combined with a reduction in pacemaker cells, makes the elderly prone to arrhythmias.

Progressive coronary arterial sclerosis leads to a reduction in maximal coronary artery blood flow. While the oxygen delivery is within the demand of the resting state, relatively small increases in cardiac work index or heart rate result in ischaemia. There is reduction in vasomotor tone; both vagal and sympathetic influences are minimized.

These changes make the heart less compliant. Stroke volume decreases; systole time is prolonged; and with a decrease in ventricular contractility, cardiac output and its reserve decline. Despite this, the average arterial pressure rises, with an increase in the systolic and a slight drop in the diastolic pressures, except in obesity. The mean arterial pressure remains unchanged. Peripheral vascular resistance increases progressively. Vessel walls become less compliant as smooth muscle is reduced and collagen replaces elastin. Major vessels become stretched and distended, damaging the endothelium and baroreceptors, making blood pressures labile. Importantly, any increase in intrathoracic pressure, passively or actively, causes greater decreases in blood pressure with little or no rebound elevation. Degenerative vasomotor control precipitates syncope in the presence of decreased cardiac output or peripheral resistance. Postural hypotension can be spontaneous or an effect of drugs.

Respiratory system

Dorsal kyphosis and curvature of the thorax alter the position of the ribs, forming a 'barrel chest'. There is associated weakness of intercostal muscles and chest wall rigidity. This increases the work, and reduces the efficiency, of breathing. Cellular changes also occur in the lung parenchyma. Elastic recoil of the lungs is reduced, increasing the lung volume at end-expiration, thus increasing the residual volume. There is a parallel decrease in the vital capacity. Widening of the airways increases the anatomical dead space, together with increase in the size of the alveolar ducts. Reduction in elastic fibres in these ducts may explain why airway closure occurs at resting functional residual capacity. This premature closure of the airways further contributes to increases in residual volume.

Loss of recoil, increasing dependence on the diaphragm and abdominal muscles and reduced vital capacity all produce an uneven distribution of ventilation, without change in tidal volume at rest. The alveolar–arterial oxygen tension difference increases causing a decrease in the partial pressure of oxygen in arterial blood (PaO_2). The $PaCO_2$ remains unchanged. However, a greater contribution to progressive reduction in arterial oxygen-ation comes from reduced perfusion. Fibrous replacement of the muscular arterial media and reduction in the number of capillaries increases the pulmonary vascular resistance and shunting. Maximal pulmonary blood flow, and therefore perfusion, is lowered. The additional oxygen demand caused by increased activity induces increased ventilation in the presence of a diminished maximum breathing capacity. This leads to dyspnoea in the absence of underlying pulmonary disease.

Progressive weakness of intercostal and accessory muscles reduces the ability to cough forcibly. The bronchial mucosa degenerate because of impaired blood supply and the cilia are not always able to keep the small airways clean. Suppressed glottic reflexes make pulmonary infections common.

Circulation

In addition to reduced haemoglobin and haematocrit, older people have reduced marrow iron stores and can suffer anaemia following small haemorrhages. The temptation to transfuse red cells immediately should be resisted. One large retrospective observational study showed no increase in mortality provided the haemoglobin concentration was kept above 8 g/dl, even in the elderly. It recommended that an indication for transfusion is haemoglobin below 7 g/dl. However, if elderly patients do not respond to treatment of anaemia other causes should be sought, such as occult malignancy, chronic infection or poor nutrition.

Other haematological changes include reduced cellular immune response because of thymic atrophy and reduction in the number of T cells. Lymphocytosis within the marrow results in susceptibility to proliferative disorders and infections.

Renal function

The nephron mass in the kidney can decline by 30% between 60 and 70 years of age. This is reflected in changes in lean body mass and basal metabolic rate as a result of loss of functioning tissue. Vascular changes may initiate this deterioration. As renal blood flow is reduced, glomerular filtration and concentrating ability decline linearly at 1% per annum from 30 to 80 years. Large acid or alkali loads can overwhelm the ability of the kidney to maintain acid–base homeostasis. The serum creatinine level can be misleading because it does not necessarily increase in response to declining creatinine clearance rates, but reflects muscle turnover when muscle mass is reduced.

Nervous system

Changes in cognitive function are multifactorial. 20% of octogen-arians have some degree of dementia, but this diagnosis should be made only when other causes have been excluded. Organic causes of dementia include hypoxia, infection, drugs, hypoperfusion, hypothyroidism, constipation and impaired sight or hearing.

Temperature regulation, together with heat and cold homeo-stasis, is impaired in the elderly; they do not often shiver. Hypothalamic hunger and thirst centres are down-regulated and antidiuretic hormone is less effective, leaving these people vulnerable to dehydration and malnutrition. The peripheral nervous system declines in a similar manner. Nerve conduction velocity decreases and appreciation of pain reduces; the elderly complain less of pain.

Care must be taken to ensure nerves are not compressed or stretched, particularly in the neck. Many elderly patients have a reduced cerebral blood supply as a result of atheroma or sclerosis. Vertebrobasilar insufficiency is not uncommon. Flexion or extension of the neck can compromise cerebral oxygen delivery. Osteoporosis and laxity of ligaments is common in old age. Care should be taken in moving the neck lest dislocation or fracture occurs in the cervical vertebrae.

Rheumatoid arthritis

Rheumatoid arthritis is an inflammatory proliferative disease of synovium with a familial association with the DRW 4 allogen. 70% of sufferers are female and 85% show anti IgG or IgM antibodies. It is thought to be caused by defective cell-mediated immunity, characterized by lymphocytic proliferation involving macrophages and complement activation on joint surfaces giving rise to symmetrical polyarthritis with a centrifugal distribution. Clinical features include insidious or sudden onset of pain, swelling and stiffness in peripheral joints. Weakening of the joint capsules leads to subluxation and permanent deformity. It is associated with tenosinovitis and muscle wasting.

Anaesthetic implications: advance of rheumatoid arthritis affects most systems. The airway is often compromised and involvement of the temporomandibular joint restricts mouth opening. Atlanto-occipital instability is not uncommon and 25% of patients admitted to hospital with rheumatoid disease have subluxation of that joint.

Hyperflexion of the neck may induce vertebrobasilar insufficiency or paraesthesia. Crico-arytenoid involvement may present with stridor. Associated lung conditions include fibrosing alveolitis, pleural effusion and Caplan's syndrome. Pericarditis can be associated with pericardial effusions. Valvular nodules cause aortic or mitral stenosis. These nodules are sometimes due to amyloid, which also causes nephrotic syndrome. Renal failure can occur through vasculitis or as a result of the drugs used to treat rheumatoid arthritis (e.g. penicillamine, non-steroidal anti-inflammatory drugs). Usually, these patients suffer anaemia, which may be haemolytic, chronic normochromic or iron-deficient. They may also have pancytopenia and hypersplenism (Felty's syndrome). Fragile skin and veins are also associated with this condition together with a predisposition to carpal tunnel syndrome, polyneuritis and neuropathy. Special care is needed when positioning these patients for surgery.

History

Obtaining a clear history may prove difficult in elderly patients. Sensory perception is impaired and misunderstandings occur because of failure to hear. Sight may be compromised, distorting perception of surroundings. There may also be age-related generalized neurological degeneration. Recall of past events is usually clear but recall of recent episodes of illness and their significance can be hazy. Relatives often fill in important gaps and reference to medical notes and letters is invaluable. The history should include:

- previous anaesthetics, especially any problems
- previous medical history, especially heart, lungs, kidneys, blood pressure, oesophageal reflux
- allergies
- current medicines
- social habits (e.g. smoking, alcohol intake)
- dentition.

The medical history and current medication provide important clues about the patient's underlying state of health.

Examination

The patient should be sufficiently exposed to enable accurate observation, palpation, percussion and auscultation, while ensuring warmth, comfort and dignity. Palpation of the pulses cannot be over-emphasized; it often reveals clear indications of severe cardiovascular disease. Thorough examination of the cardiovascular and respiratory systems is often rewarded by eliciting signs absent in younger patients. Cardiac murmurs should be carefully classified according to site heard loudest, pitch, length and timing in the cardiac cycle. Irregularities of the pulse should be noted as well as abnormalities of the jugular venous pulsation.

Tests of respiratory function include the ability to count to 10 in one breath, breathlessness on dressing and ability to walk up a flight of stairs. Palpation of chest expansion, percussion and auscultation should be performed on anterior and posterior aspects of the chest. Unexpected signs are often found, which prove important in future management decisions. A hyper-dynamic pulse may sometimes indicate hypercarbia.

Although cognitive function is not usually directly related to anaesthetic processes, postoperative confusion and delirium are not uncommon. A simple mental test score such as that given in Figure 1 can be a useful marker and may highlight patients at special risk.

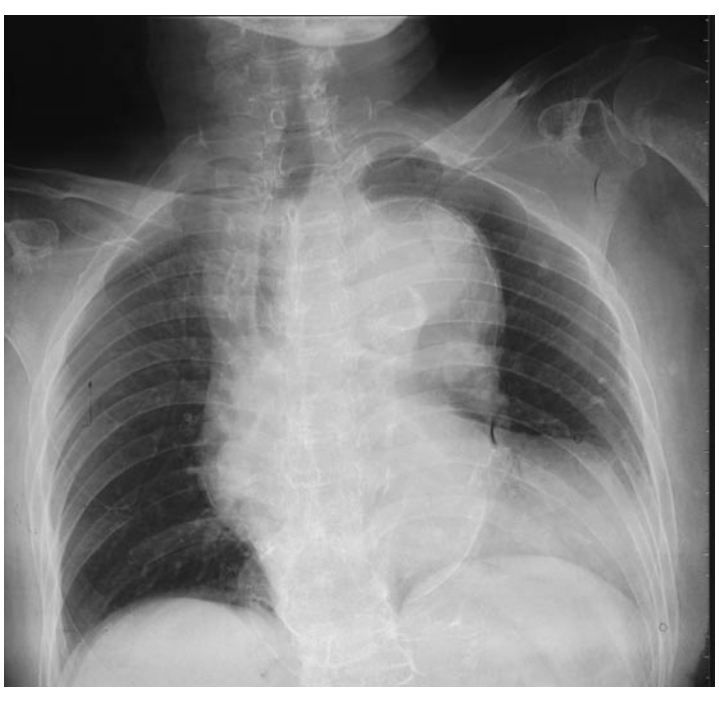
Mini-Mental State Examination

Section	Score	Task
Orientation	5	What is the date: year, season, date, day, month
	5	Where are we: country, county, town, hospital, floor
Registration	3	Name three objects – 1 second to say each, then ask the patient to recall all three. Repeat until the patient has learnt all three. Count and record trials
	5	Serial 7s – one point for each correct. Stop after 5 correct. Alternatively spell 'world' backwards
	3	Ask for the 3 objects repeated above – Give an example of each
Language	2	Name a pencil and watch
	1	Repeat the following 'no ifs, ands or buts'
	3	Follow a 3-stage command: 'take a piece of paper in your right hand, fold it in half and put it on the floor'
	3	Read and obey the following: 'close your eyes', 'write a sentence', 'copy a design'
Total score	30	
Score results:		30–29, normal 28–26, borderline cognitive dysfunction 25–18, marked cognitive dysfunction; dementia may be diagnosed < 17, severe dysfunction; severe dementia

From: Folstein M F, Folstein S E, McHugh P R. A Practical Method for Grading the Cognitive State of Patients for the Clinician. *J Psychiatr Res* 1975; **12:** 189–98.

Investigations

Together with haematology and biochemistry blood assays, a recent ECG should be available. Chest radiography may help to evaluate degrees of cardiac and respiratory disease. Occasionally surprise findings may occur (Figure 2).



2 Chest radiograph of a 71-year-old Chinese woman with a calcified dissected thoracic aortic aneurysm and aortic valve secondary to syphilis.

The value of 2D echocardiography is limited but can be useful in valvular heart disease in determining degrees of incompetence or stenosis. Assessment of hypokinetic ventricular damage in ischaemic heart disease is also possible. Ejection fractions are often not repeatable and can be misleading. If an estimation of ventricular function is required a multigated scintigraph scan (MUGA) may give a more reliable figure. Peak flow measurement can be easily performed. This simple test gives good quantitative estimates of pulmonary function, and in this context, is often as valuable as formal pulmonary function testing. ◆

Procedures under Tourniquet

Ivan N Ramos-Galvez
Alastair McCrirrick

Alastair McCrirrick is Consultant in Anaesthesia and Intensive Care at Gloucestershire Royal Hospital, UK. He qualified from Southampton University and joined the Royal Air Force. He completed his anaesthetic training in Bristol and the South West Region. He now specializes in intensive care and anaesthesia for major bowel and vascular surgery. His particular interests include anaesthesia for carotid endarterectomy.

Applying a pressurized pneumatic cuff to a limb can be used to prevent the central spread of local anaesthetic during intravenous regional anaesthesia. It may also be used to reduce bleeding and improve the surgical field when operating on an exsanguinated limb. Using a tourniquet can induce significant physiological changes depending on the duration of inflation and the general status of the patient.

Tourniquet application

Maintaining a bloodless field during limb surgery

The cuff should be wider than half the limb diameter and should be applied over smooth padding. The edges of the cuff must overlap to ensure it exerts even pressure all round the limb. Ideally, the overlap should be on the opposite side of the limb to the main neurovascular bundle. The limb is then exsanguinated either by elevation for 1 minute or by the application of Esmarch bandaging or a Rhys-Davies exsanguinator. (In the presence of infection or tumour, exsanguination by methods other than elevation is usually contraindicated.) When applied to the leg, the tourniquet is usually inflated to a pressure 100 mm Hg above systolic arterial blood pressure; on the arm it is inflated to 50 mm Hg above systolic arterial blood pressure. The pressure required depends on the size of the muscle mass to be compressed. During preparation of the surgical field, skin cleaning solutions should not come into contact with the tourniquet padding. If alcohol or iodine-based cleaning solutions soak into the padding they can cause skin irritation. Diathermy burns have also resulted from pooling of liquid around the tourniquet.

Intravenous regional anaesthesia

A machine equipped with two tourniquets is optimal for intravenous regional anaesthesia. Intravenous access is obtained in the limb before application of the tourniquet. Great care must be exercised during exsanguination to avoid dislodging the intra-venous cannula. After exsanguination, the proximal tourniquet cuff is inflated and local anaesthetic is introduced into the limb. (If the cuff were to fail at this stage the local anaesthetic would spread centrally resulting in a potentially toxic plasma concentration of local anaesthetic agent.) After a few minutes, the distal cuff is inflated and then the proximal cuff can be let down. The result is a tourniquet compressing a section of limb that has itself been rendered insensitive by intravenous regional anaesthesia. This is an attempt to reduce tourniquet-related pain (see below).
The tourniquet must remain inflated for a minimum of 20 minutes to allow the local anaesthetic time to bind to tissues. Deflation before 20 minutes may precipitate systemic local anaesthetic toxicity.

Physiological changes

Figure 1 summarizes the physiological changes that occur during inflation and deflation of a tourniquet.

Physiological changes

During inflation
- Rising volaemia and systemic vascular resistance lead to increased blood pressure, central venous pressure and heart rate
- Temperature reduction in non-perfused limb
- Anaerobic metabolites being produced

After deflation
- Reperfusion of limb
  – Reduction in volaemia and systemic vascular resistance lead to decreased blood pressure, central venous pressure and heart rate
  – Core temperature falls
  – Mixed acidosis, decrease in pO_2 and pH while pCO_2, K^+ and free radicals increase
- Reactive hyper-reperfusion

1

Cardiovascular

Increases in systemic blood pressure, central venous pressure and heart rate have been reported immediately after tourniquet inflation. These changes are related to the sudden increase in blood volume (up to 15%) combined with a reduction in the capacitance of the vascular bed. Reciprocal haemodynamic changes may be expected following tourniquet deflation due to a decrease in systemic vascular resistance and venous return while the limb is reperfusing. The magnitude of the haemo-dynamic changes can be reduced by the use of regional anaesthesia. Preoperative ketamine, 0.25 mg/kg, moderates the rise in blood pressure after tourniquet inflation. In some patients, who have been otherwise cardiovascularly stable, a sudden marked rise in arterial pressure may occur about 1 hour after tourniquet inflation. In these patients, the arterial pressure may continue to rise, despite increasing the depth of anaesthesia, and only resolves when the tourniquet is deflated. Severe hypertension and/or concerns about possible ischaemic limb damage are the two factors that most commonly limit the duration of tourniquet inflation. The exact physiological mechanisms involved in this late arterial pressure rise are unclear.

Generalized muscle perfusion remains above normal for up to 15 minutes after tourniquet deflation. This is caused by the release of anaerobic metabolites triggering reactive vasodilatation in capillary beds within the muscle fibres.

Temperature

While the tourniquet remains inflated, the temperature of the non-perfused limb falls. This has some protective effect against ischaemic damage. However, during reperfusion, blood is exposed to cold tissues and on deflation there can be a reduction in core temperature of up to 0.6°C for each hour the tourniquet was used.

Metabolic changes

Leaving the tourniquet on for more than 30 minutes produces anaerobic metabolism, resulting in a mixed acidosis with hypoxaemia, hypercapnia, hyperkalaemia and formation of free radicals. These changes are normally well tolerated by healthy individuals but may be detrimental to patients with poor cardio-pulmonary reserve. The acidosis can be partly corrected by a short period of hyperventilation immediately after tourniquet deflation. Maintaining anaesthesia with a propofol infusion rather than a volatile agent may significantly reduce the formation of free radicals. Nevertheless, caution is advised when bilateral tourniquets are required and, whenever possible, simultaneous inflation should be avoided.

Complications

The incidence of complications is related to the inflation pressure and the duration of inflation.

Limb ischaemia is the most serious complication. Current recommendations regarding the upper limit for the duration of inflation vary between 30 minutes and 4 hours (30 minutes is the time taken for the onset of anaerobic metabolism). Nevertheless, after 1 hour of ischaemia, electron microscopy can detect depletion of glycogen granules in the sarcoplasm of muscle fibres. After 2 hours, lesions associated with acidosis (e.g. mitochondrial swelling), myelin degeneration and Z-line lysis can be identified. These changes are reversible with reperfusion and it may be that intermittent reperfusion–exsanguination during surgery prolongs the safe limit of tourniquet application by preventing excessive anaerobic metabolism. This may, however, be at the expense of supplying more substrate for the production of free radicals.

Local anaesthetic toxicity: if the cuff is being used for intra-venous regional anaesthesia it must remain inflated for at least 20 minutes after local anaesthetic has been injected, if local anaesthetic toxicity is to be avoided. The risk of local anaesthetic toxicity is reduced if agents with low systemic toxicity are used. For prolonged procedures, the cuff can be deflated at intervals to prevent ischaemic damage and, if intravenous access in the operated limb has to be retained, further, smaller doses of local anaesthetic can be given.

Pressure-related nerve damage can be caused by a tourniquet with possible rupture of the Schwann cell membrane. This may lead to neuralgia paraesthetica, which usually resolves within a few weeks or months.

Excessive pressure can also damage underlying vessels, increasing the incidence of microemboli formation in the exsanguinated limb. This increases the risk of pulmonary microvascular injury (small pulmonary emboli). Prolonged tourniquet times have been related to respiratory failure requiring postoperative ventilation, especially in trauma. In a properly exsanguinated healthy limb, alterations in blood clotting physiology are usually minimal and theoretically should have no clinical impact. The incidence of deep vein thrombosis (DVT) may be higher when a tourniquet is used, but this has not been substantiated in arthroscopic knee surgery. Thromboprophylaxis must be considered in all patients aged over 40 years who have surgery performed under tourniquet (except for arthroscopic knee surgery), especially if there are other risk factors for DVT formation.

Tourniquet pain can occur 45–60 minutes after tourniquet inflation. Patients undergoing surgery under regional anaesthesia initially experience a dull ache in the exsanguinated limb after about 30 minutes of tourniquet application. This may occur even when a second cuff is inflated on an anaesthetized section of limb. As the pain worsens, patients may become restless and eventually the pain may become unbearable despite the presence of an otherwise satisfactory block. The pain may be transmitted through C fibres (slow, persistent, poorly localized pain), which are more resistant to local anaesthetic than Aδ fibres (sharp, fast pricking pain). At the onset of neural blockade, when the concentration of local anaesthetic is high, both are inhibited. As the local anaesthetic is metabolized, the concentration becomes insufficient to block C fibres despite continuing to anaesthetize Aδ fibres. This theory is supported by the observations that longer-acting local anaesthetic agents reduce the incidence of tourniquet pain and that its onset is delayed if a larger dose of local anaesthetic is used. There is also a reduction in the incidence of pain if clonidine is added to the local anaesthetic solution. Once tourniquet pain has developed it is difficult to treat, other than by releasing the tourniquet. General anaesthesia may need to be used if the surgery is continuing. Opiates alone are disappointing and tend to cause side-effects from excessive dose once the tourniquet is released and the afferent stimulus ceases.

Hypertension: patients undergoing general anaesthesia with a tourniquet *in situ* can develop signs of hypertension and tachy-cardia that mimic those seen during painful surgical stimulation. The reasons for the development of hypertension under these circumstances are unclear and it has been traditionally ascribed to the development of limb ischaemia, nerve compression or the development of tissue acidosis. Hypertension developing in these circumstances is often resistant to opiates and is relieved only when the tourniquet is deflated.

Treatment: Figure 2 lists treatments for complications. ◆

Treatment of complications

Easing the metabolic hurdle
- Whenever possible use a regional technique, even combined with general anaesthesia
- Preoperative ketamine, 0.25 mg/kg, prevents hypertensive response to tourniquet
- Total intravenous anaesthesia with propofol helps to scavenge the free radicals produced
- Hyperventilate after tourniquet deflation to reduce acidosis
- Caution with simultaneous tourniquets

Easing the tourniquet pain
- Reduce tourniquet time as much as possible
- Whenever possible use a regional technique, even combined with general anaesthesia
- Use longer-acting local anaesthetics to reduce incidence
- Use clonidine mixed with local anaesthetic
- Intrathecal opiates reduce incidence of pain
- If unbearable and patient awake, convert to general anaesthesia
- Caution with adjuvant systemic opiates in awake patient, they may lead to delayed respiratory depression

Local Anaesthetic Blocks in Ambulatory Orthopaedic Surgery

Patrick M Clarke

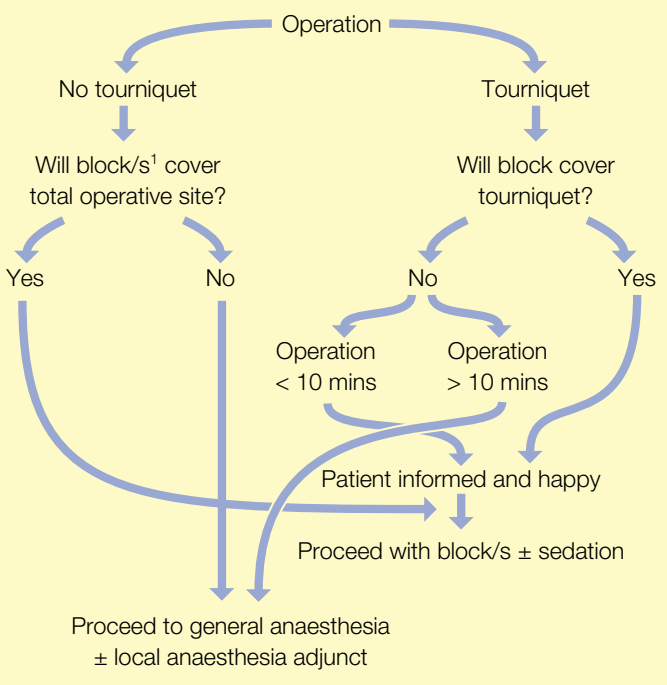
Patrick M Clarke is Consultant in Pain Management and Anaesthesia at Gloucester Royal Hospital. He qualified at Liverpool and trained in Liverpool, Birmingham and Bristol. He worked as Assistant Professor at Stanford University Medical Center, California, USA. His main interests are complex pain problems and orthopaedic anaesthesia.

More surgery is now being performed in an outpatient setting. The growing complexity of surgical procedures challenges the anaesthetist's ability to provide postoperative analgesia. Inadequate analgesia is a cause of delayed discharge and unexpected hospital admission. In a large prospective study, 16% of ambulatory orthopaedic patients had severe postoperative pain. Opi-oids are associated with nausea, vomiting and urinary retention, causing delayed discharge. Local anaesthetic techniques used as the primary anaesthetic or as an adjuvant to general anaesthesia can provide a safe and effective alternative to opioid analgesia.

Selection of local anaesthetic technique – orthopaedic surgery lends itself to peripheral and central neural blockade. Several questions need to be answered before deciding on a local anaesthetic technique (Figure 1).

- Can the block be used as the primary anaesthetic?
- Is sedation required as well?
- Can the block be used to supplement a general anaesthetic?
- Is the patient happy with a local technique?

Block decision algorithm



[1]If bone graft is being harvested from non-blocked site general anaesthesia is usually necessary (e.g. iliac crest graft).
If several blocks are being considered is this acceptable to the patient or is sedation required (e.g. ankle block)?

1

Selection of a particular block depends on surgical procedure, use of a tourniquet, patient acceptability and operator experience.

Sedation

Sedation is useful for block placement and intraoperative sedation. Some blocks take time to site successfully and patients may become irritable and anxious and lose confidence in the anaesthetist; sedation minimizes these problems. For block placement the patient should be relaxed but conscious enough to report any paraesthesia. In a paraesthesia-seeking technique less sedation should be administered than when using a nerve stimulator to obtain motor stimulation. When a nerve stimulator is used the patient may receive more sedation but must be conscious enough to report major paraesthesia, which may indicate intraneural injection. Suitable sedation for block placement may be achieved using a combination of a short-acting benzodiazepine such as midazolam, 0.025–0.05 mg/kg, and fentanyl, 0.5–1.0 μg/kg (i.e. midazolam, 2 mg, and fentanyl, 50 μg, for a 80 kg patient).

Intraoperative sedation may be achieved with a variety of pharmacological agents ranging from intermittent boluses of benzodiazepine/opioid combinations to an infusional drug such as target-controlled propofol. In an ambulatory setting success is easily achieved using bolus techniques owing to the short duration of surgery. There is a fine balance between patient relaxation and disinhibition. It is better to have a less sedated cooperative patient than one who is over-sedated and confused.

Patient information

Informed consent is paramount for local anaesthetic techniques used as the primary anaesthetic or adjuvant to a general anaesthetic. To gain the patient's confidence and minimize anxiety it is important to explain the sequence of events that will take place on arrival in the anaesthetic room or operating theatre.

Side-effects must be discussed when obtaining consent. Pain at the site of injection occurs in about 30% of patients. 10% may experience tingling or numbness for up to 48 hours. Patients must be advised not to go near hot or cold objects and to beware of trauma to a numb extremity for up to 48 hours. Rare complications such as infection and bleeding should also be mentioned. Complications specific to individual blocks should be discussed. For example, in interscalene block, hoarseness, Horner's syndrome or difficulty with coughing (secondary to phrenic nerve paralysis) should be outlined.

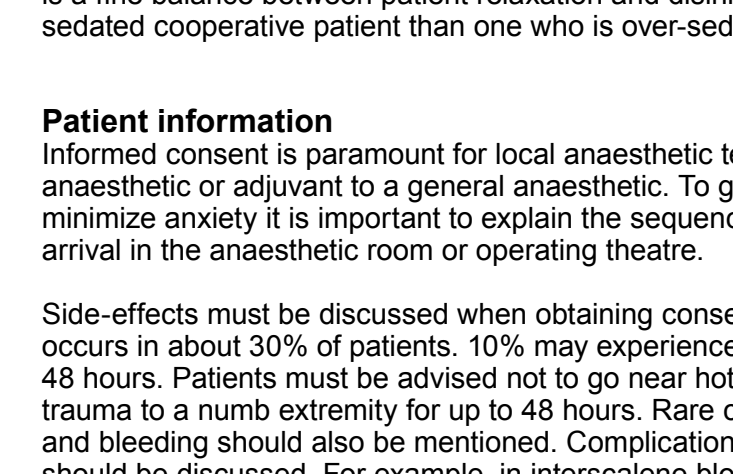
Patients must be told that even with a limb blocked satisfact-orily for surgery some sensation of movement and touch may occur otherwise they may panic when they feel touch during surgery. The sensation can be likened to that felt following dental local anaesthesia. "Touch may be felt but pinching is not painful".

Explain to the patient that pain will occur when the block wears off and give them advice about pre-emptive analgesia.

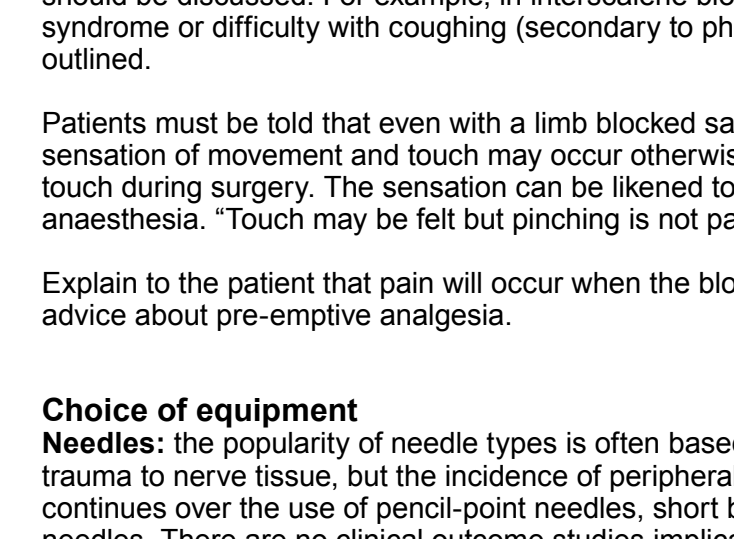
Choice of equipment

Needles: the popularity of needle types is often based on their likelihood of causing trauma to nerve tissue, but the incidence of peripheral nerve injury is small. Debate continues over the use of pencil-point needles, short bevelled needles or sharp needles. There are no clinical outcome studies implicating bevel design as a consistent factor in nerve injury. Evidence suggests that sharp needles cause less nerve damage, which is more rapidly repaired. Using a short bevelled block needle gives a better 'feel' of deeper tissue planes. Over-zealous seeking of paraesthesia should not take place.

When used in conjunction with a nerve stimulator in a conscious, relaxed patient, a carefully performed nerve block is unlikely to cause significant nerve injury. For single-shot techniques with needle and nerve stimulator, the Stimuplex short bevelled needle is excellent (Figure 2). It is available in various lengths, is well made and easy to hold. For a continuous catheter technique the combined Braun sheathed Tuohy needle, with side injection port and catheter is useful and well made (Figure 3). It is particularly useful following surgery when a continuous physiotherapy machine is required (e.g. post shoulder release).

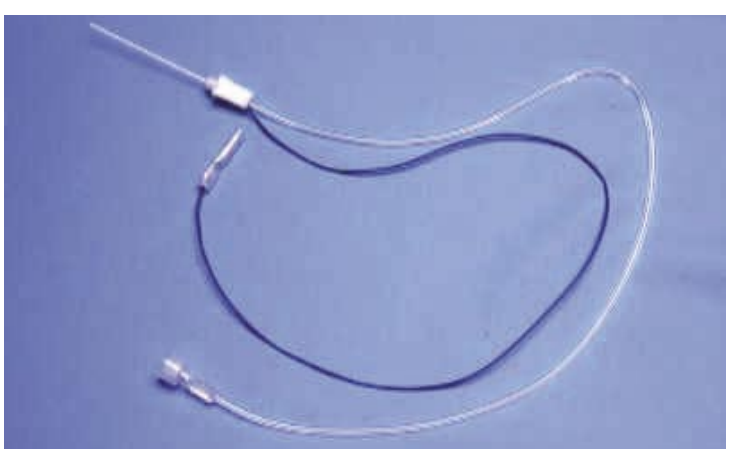


2 The Stimuplex short bevelled needle.



3 Braun catheter.

Nerve stimulator: there is little evidence that postoperative nerve injury is reduced by the use of nerve stimulators. There are also few studies to verify improved success of blocks. Ultrasound-guided block needles improve success in block placement. It is mandatory to use a nerve stimulator in some approaches to the brachial plexus (e.g. interscalene block because of proximity of the major blood vessels and CSF). The negative lead of the nerve stimulator should be attached to the needle and the positive lead attached to an ECG sticker at least 10 cm away from the limb to be anaesthetized (Figure 4). A current of 1 mA is used initially. Once the needle tip approaches the nerve/s to be blocked the current should be reduced to about 0.4 mA. Muscle twitching in the appropriate muscle group at this current indicates close proximity of the needle tip to the nerve. Muscle twitching at lower currents may indicate intraneural placement of the needle, though the patient will usually let you know if this occurs!



4 Patient attached to nerve stimulator.

Useful blocks in the ambulatory setting

Upper limb blocks: ambulatory orthopaedic surgery lends itself to the use of nerve blocks as both primary anaesthetic and as an adjunct to general anaesthesia (Figure 5). The main limiting factor for use as a primary anaesthetic is the use of tourniquets. The tourniquet must be placed on an anaesthetized part of the limb. With brachial plexus block this is easily accomplished, but with isolated nerve blocks the use of a tourniquet rules out blocks as the primary anaesthetic. If surgery takes less than 10 minutes a tourniquet may be tolerated, particularly with the use of sedation (e.g. carpal tunnel decompression under local infiltration).

For proximal upper limb surgery, the block of choice is the interscalene brachial plexus block. Shoulder arthroscopy, manipulation and arthroscopic rotator cuff repair may be extremely painful postoperatively. Interscalene anaesthesia is ideal. It is relatively easily performed using a nerve stimulator, the plexus usually being superficial at this level.

Most ambulatory orthopaedic surgery is performed on the distal part of the arm. In the forearm, removal of internal fixation devices is a commonly performed procedure. For forearm surgery the axillary approach to the brachial plexus is reliable and effective and may be used as the primary anaesthetic. Hand surgery is easily performed under axillary brachial plexus blockade.

The axillary approach is safe and reliable. Occasionally ab-duction at the shoulder joint is difficult, making an axillary approach impossible. In this situation, supraclavicular, infraclavicular or subcoracoid approaches to the brachial plexus may be used. Both supra- and infraclavicular approaches carry the risk of pleural puncture; the subcoracoid approach does not. In conjunction with a nerve stimulator the plexus is easily identified and block may be successfully achieved.

Nerve blocks at the elbow may be used to supplement brachial plexus blockade. Occasionally a nerve may be 'missed', requiring further block at the elbow. However, some anaesthetists consider that the likelihood of nerve damage is increased by attempting to block a 'partially' anaesthetized nerve because paraesthesia is decreased. The nerves at the elbow are superficial and paraesthesia must not be sought over-zealously.

Upper limb block

Block site		Primary anaesthesia	Adjunct to general anaesthesia	Advantages	Disadvantages	Volume of local anaesthetic
Plexus blocks	Interscalene Supraclavicular Infraclavicular Subcoracoid Axillary	Yes	Yes	Broad coverage	Variable block until experienced	20–40 ml
Block at elbow	Median Ulnar Radial	Possibly	Yes	Add on to brachial block if patchy	Does not cover tourniquet	5 ml/nerve
Block at wrist	Median Ulnar Radial	Possibly	Yes	Easy	Does not cover tourniquet	3–5 ml/nerve
Distal block	Ring block	Yes	Yes	Easy	None	5 ml
Other	Bier's block	Yes	No	Easy	Bloodless field not obtained	30–40 ml
	Local infiltration	Yes	Yes			

Distal nerve blockade at the wrist is usually used only as an adjunct to general anaesthesia due to use of a tourniquet. Surgery on the finger may be performed under ring block. A bloodless field is achievable using a finger tourniquet applied by the surgical team following block.

Bier's block is useful for simple forearm manipulations. Most surgeons do not use it for open procedures (e.g. excision of Dupuytren's contracture) because anaesthetic may ooze into the operative field.

Local infiltration is a useful anaesthetic tool. It may be used with a tourniquet for short procedures. It is valuable as an adjunct to general anaesthesia and for postoperative analgesia.

Lower limb blocks (Figure 6) are under-used. They are most appropriate when used with a general anaesthetic. Proximal lower limb surgery is unusual other than for removal of internal fixation devices (seldom performed in the ambulatory setting). Removal of small screws usually benefits from simple local infiltration by the surgeon. Most lower limb ambulatory orthopaedic surgery is distal. Commonly performed distal lower limb orthopaedic operations include bunion and bunionette excision, Zadek's procedure, removal of metalwork from distal tibia and fibula, excision of soft tissue lesions (e.g. Morton neuroma). Owing to the use of proximal tourniquets local anaesthetic techniques are not commonly used as the primary anaesthetic. However, local blocks are an excellent adjunct to general anaesthesia. ◆

Lower limb blocks

Block site		Primary anaesthesia	Adjunct to general anaesthesia	Advantages	Disadvantages	Volume of local anaesthetic
Proximal blocks	Femoral	Yes	Yes	Useful in avoiding central blockade	None	20 ml
	Sciatic	No	Yes		Experience required	20 ml
	Lateral cutaneous					
	3-in-1 block[1]	Yes	Yes		None	30 ml
At knee	Sciatic	No	Yes	Useful analgesia	Sometimes patchy	15 ml
	Saphenous	No	Yes			10 ml
	C.peroneal	No	Yes			10 ml
At ankle	5 nerves SSSPP[2]	Possibly	Yes	In sick patients	5 injections	20–30 ml
Distal	Ring	Yes	Yes	Easy	None	5 ml
Other	Bier's block	Yes	No	Easy	No bloodless field	30–40 ml
	Local infiltration	Yes	Yes

Acute and Chronic Airway Obstruction

Thandla Raghavendra
Robert Walker

Thandla Raghavendra is Specialist Registrar in Anaesthesia with an interest in paediatric anaesthesia. He has trained in anaesthesia in India and in the North West region of the UK.

Robert Walker is Consultant Paediatric Anaesthetist at the Manchester Children's Hospital, UK. He qualified from Glasgow University Medical School and trained in paediatrics and anaesthesia in Manchester. His main area of interest is the development of fibre-optic intubation techniques in infants and children.

A baby has a large tongue in relation to the oral cavity and the larynx lies higher than in an adult. Both features bring the tongue closer to the palate, predisposing to obstruction. Obstruction in a baby or child due to trauma from intubation is most likely to occur at the subglottic region because this is the narrowest part of the airway, has a complete ring of cartilage (the cricoid) and loose mucosa (making it particularly susceptible to oedema). Oedema can cause dramatic increases in airway resistance and the work of breathing (for laminar flow, a 50% reduction in airway radius causes a 16-fold increase in airway resistance – from Poiseuille's law). Uncuffed tracheal tubes are less likely to cause trauma and are therefore preferred.

Physiological factors

Babies less than 5 months of age are obligate nose breathers. Obstruction of both nasal passages (e.g. because of secretions or choanal atresia) can cause asphyxia. Babies, especially, have a limited ability to cope with an obstructed airway because:

- the chest wall, trachea and bronchi are pliable and easily deformed
- the diaphragm and intercostal muscles have fewer 'fatigue resistant' type I fibres and tire easily
- oxygen reserves are lower because of a smaller functional residual capacity (FRC) and higher oxygen consumption (4–6 ml/kg/minute compared with 2–4 ml/kg/minute in adults).

If the work of breathing increases, respiratory failure and hypoxaemia can develop quickly.

Acute airway obstruction

The site of airway obstruction determines the clinical features. Agitation and crying worsen airway obstruction by causing turbulent airflow and by worsening dynamic compression.

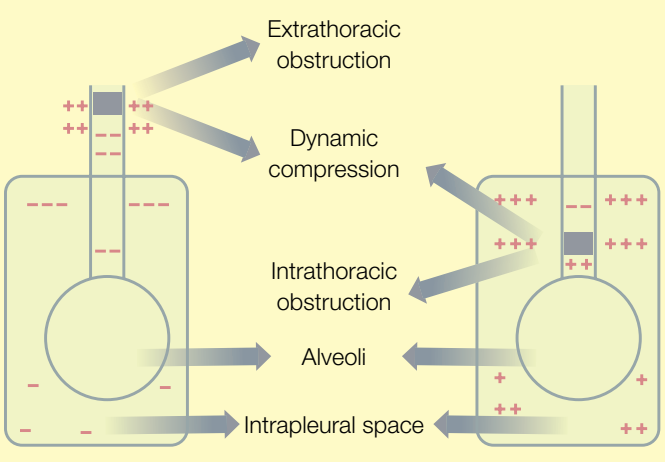
Extrathoracic obstruction – the calibre of the extrathoracic airways depends on the balance between the intraluminal and atmospheric pressures. Inspiratory efforts to overcome an extrathoracic obstruction generate large negative intrapleural pressures, which are transmitted to the extrathoracic airway as negative intraluminal pressure. The atmospheric pressure then exceeds the intraluminal pressure causing dynamic compression of the airway during inspiration (Figure 1a). Extrathoracic obstructions, therefore, cause inspiratory stridor, which may be improved by giving continuous positive airway pressure (CPAP) to help splint the airway open.

Intrathoracic obstruction – the patency of the intrathoracic airway depends on the balance of intraluminal and intrapleural pressures. Large positive intrapleural pressures generated during active expiration cause dynamic compression of the airways downstream of the obstruction (Figure 1b). Intrathoracic obstructions tend to cause expiratory stridor.

Sites of airway obstruction

a Extrathoracic obstruction causes dynamic obstruction during inspiration

b Intrathoracic obstruction causes dynamic obstruction during expiration



1

Figures 2–4 list the causes, clinical features and severity of acute airway obstruction.

Causes of acute airway obstruction

Congenital	Acquired
• Choanal atresia (congenital blockage of nasal passages)	• Epiglottitis[1]
• Laryngomalacia[2]	• Laryngotracheobronchitis[2]
• Subglottic stenosis	• Bacterial tracheitis
• Subglottic haemangioma	• Subglottic stenosis
• Webs	• Burns
• Cysts	• Peritonsillar abscess
• Tracheal stenosis	• Foreign body
• Vascular rings or slings	• Angioneurotic oedema
• Bilateral vocal cord paralysis	• Nerve palsies
	• Mediastinal masses

[1]Uncommon [2]Common

2

Clinical features of acute airway obstruction

Features	Implication
• Stridor (noisy breathing caused by turbulent air flow)	Airway obstruction
• Inspiratory stridor	Supraglottic obstruction
• Expiratory stridor	Infraglottic obstruction
• Biphasic stridor	Glottic obstruction
• Stridor when crying or feeding	Moderate airway obstruction
• Stridor at rest	Severe airway obstruction
• Wheeze	Small airways obstruction
• Muffled cry	Supraglottic obstruction
• Hoarse cry	Laryngeal obstruction
• Unable to cry	Severe obstruction
• Dysphagia	Supraglottic obstruction
• Nasal flaring • Sternal, intercostal, subcostal retractions • Paradoxical respiration • Head bobbing	Increased work of breathing
• Tachypnoea • Tachycardia • Agitation	Hypoxaemia
• Sitting up and unable to lie supine	Severe airway obstruction
• Cyanosis	Severe hypoxaemia
• Sweating	Hypercarbia and fatigue
• Altered consciousness	Severe hypoxaemia
• Bradycardia or arrhythmias	Collapse imminent

3

Dos and don'ts in stridor

Do	Don't
• Give oxygen	• Examine the pharynx
• Observe closely	• Sedate the child
• Minimize stress to the child	• Send for radiography
• Ask for experienced help	• Attempt intravenous access until help is present and anaesthesia induced
• Maintain spontaneous respiration	• Use muscle relaxants until the airway is secure

4

Airway management

The primary goal of management is to secure the airway safely, which requires general anaesthesia. The child should be kept calm, allowed to adopt a comfortable position and given oxygen to breathe (unless this upsets them). Oxygen saturation (SpO_2) should be monitored continuously. Heliox (oxygen in helium) decreases airway resistance during turbulent flow because of its lower density, and can be useful.

Parents should accompany the child to the induction room to avoid the distress of separation. Appropriate equipment for emergency cricothyroidotomy or tracheostomy, a range of tracheal tubes (including sizes smaller than that calculated) and an experienced surgeon should be available.

An unhurried inhalational induction using either sevoflurane or halothane in oxygen is started. Induction can be slow because of the effects of airway obstruction and V–Q mismatch caused by atelectasis. Standard monitoring is established and intra-venous access secured once anaesthesia has been induced. Spontaneous breathing should be preserved throughout induction (CPAP helps to keep the airway open by combating dynamic compression and preventing atelectasis) and laryngoscopy attempted only when the child is deeply anaesthetized. Muscle relaxants can be given safely only when the airway is secure. The important management points are given in Figure 4.

Treating the common causes

Viral croup (viral laryngotracheobronchitis) is usually caused by either the parainfluenza, influenza or respiratory syncitial virus. It affects children from 6 months to 6 years of age and occurs in epidemics in late autumn and early spring. Croup is usually preceded by several days of coryza. Respiratory obstruction develops gradually producing stridor, which is typically worse at night (Figure 5). The child presents with a low-grade temperature, a brassy cough and hoarse voice. About 2% of affected children are admitted to hospital but less than 2% need tracheal intubation. Most respond to oxygen and nebulized adrenaline (epinephrine), 5 ml of 1:1000, repeated as required. Corticosteroids (dexamethasone or nebulized budesonide) reduce the need for intubation. Dexamethasone, 0.6 mg/kg oral or i.v., is usually given as a single dose but can be repeated (0.15 mg/kg). Nebulized budesonide, 2 mg, is given as a single dose; it may be repeated but a single dose has been shown to improve outcome. The duration of intubation varies but is on average 3–5 days. There is no evidence to support the use of steam tents (which can also limit clinical observation).

Assessment of croup severity

Moderate	Severe	Life threatening
Alert	Quiet or agitated	Depressed consciousness
Stridor present	Stridor present	Stridor may be absent
Mild recession	Severe recession	Limited chest movement
No fatigue	Increasing fatigue	Exhaustion
Oxygen saturation > 92% in air	Oxygen saturation < 92% in air	Oxygen saturation < 92% in oxygen
Steady respiratory rate	Increasing respiratory rate	Periods of apnoea
Steady heart rate	Increasing heart rate	Bradycardia

5

Epiglottitis (supraglottitis) is a bacterial infection caused by *Haemophilus influenzae* type B (HiB), which generally affects children of 2–6 years. The recent introduction of universal vaccination against HiB has made this condition rare. The symptoms progress rapidly and affected children look toxic (pale, pyrexial and shivery), have a high temperature and inspiratory stridor. They usually sit up, leaning forward, with their mouths open and tongue protruding, drooling saliva. They are reluctant to swallow or speak. On laryngoscopy, the epiglottis and aryepiglottic folds appear inflamed and swollen. Often, the only clue to the glottic opening is a small mucous bubble. After securing the airway and obtaining blood for culture, intravenous cefotaxime, 30 mg/kg/dose 8 hourly i.v., is given (contacts are treated with rifampicin). Airway oedema resolves in 48–72 hours. A leak around the tracheal tube (appropriate for the child's age) is a reliable guide to timing extubation.

Bacterial tracheitis (membranous laryngotracheobronchitis) is caused by *Staphylococcus aureus*. Affected children look toxic and have a brassy cough. Respiratory obstruction can progress rapidly. On laryngoscopy, thick purulent secretions resembling a membrane are seen covering the subglottic mucosa. Nebulized adrenaline (epinephrine) is of little use. Anti-staphylococcal antibiotics (e.g. flucloxacillin, 25–50 mg/kg/dose 6 hourly) should be administered. Toxic shock syndrome is a rare complication.

Inhaled foreign bodies may lodge in the larynx, trachea, main bronchi or smaller airways. A previously well child presenting with paroxysmal cough and respiratory distress should arouse suspicion of foreign body aspiration. Peanuts are the most common inhaled organic objects. They absorb water, swell up, and become soft and friable. They also cause chemical irritation of the airway and should be removed urgently. Severe obstruction is life threatening and urgent management of the airway a priority (Figure 6). Rigid bronchoscopy under general anaesthesia is required for removal of a foreign body (see below). A child with a small foreign body in the larynx may present with hoarseness or stridor. A foreign body in the lower airway may present with persistent cough, unilateral collapse or unilateral wheeze on auscultation. Expiratory chest radiographs are indicated in less urgent cases to locate the position of a radio-opaque body and identify other features typical of an inhaled foreign body. There are three characteristic patterns.

Management of choking

If a child is breathing and talking do not intervene because this could worsen the situation

If obstruction is complete, action depends on age

< 1 year
- Position child face down on rescuer's lap or forearm and administer four back blows between scapulae
- If obstruction persists place supine and give 4 rapid chest thrusts
- If unsuccessful attempt mouth-to-mouth resuscitation

Small child
- Administer 6–10 abdominal thrusts with child supine and rescuer at victim's feet. Place heel of hand above umbilicus in midline and below xiphoid process

Larger child
- Treat as adult; administer Heimlich manoeuvre

If obstruction persists and medical staff are available attempt cricothyroidotomy

6

A 'stop valve' obstruction completely obstructs a smaller airway. A chest radiograph shows collapse of the affected lung, mediastinal shift (towards the affected side) and upward movement of the ipsilateral diaphragm.

A 'ball valve' obstruction permits air entry during inspiration but stops air leaving during expiration. This causes hyper-inflation on the affected side, pushing the mediastinum towards the opposite side and the ipsilateral diaphragm down.

A 'bypass valve' obstruction allows ingress and egress of air and causes no radiological changes.

Airway burns may accompany facial burns or occur in a victim burned in a confined space. Clinical clues include soot deposits in the mouth or nose. Other clues include stridor, facial burns or circumferential burns of the neck and oedema of the pharynx. When airway burns are suspected, the trachea should be intubated without delay because facial, oral and airway oedema can occur rapidly, making intubation difficult or impossible. It is wise to use an uncut tube to allow room for facial swelling, which may occur later.

Laryngomalacia is a congenital laryngeal anomaly and the most common cause of stridor in early infancy (it generally develops within a few days of birth). Obstruction is caused by either a floppy tubular epiglottis or flabby supraglottic structures prolapsing into the glottis, causing inspiratory stridor. Symptoms worsen during feeding, crying or with respiratory infections, but disappear when the baby lies prone. The condition improves with growth, usually resolving spontaneously by 1 year of age. Occasionally, laser aryepiglottoplasty is used to treat severe obstruction but tracheostomy is rarely indicated.

Laryngoscopy and tracheobronchoscopy

The diagnosis and evaluation of airway obstruction and removal of a foreign body involves laryngoscopy and tracheobronch-oscopy, usually under general anaesthesia. Preoperative imaging (CT or MR) may be required to ascertain the nature and extent of the obstruction. Sedative premedication is avoided because of the risk of compromising the airway further. Both laryngoscopy and tracheobronchoscopy involve sharing the airway with the endoscopist. Spontaneous breathing is required to evaluate a dynamic obstruction (e.g. laryngomalacia, tracheomalacia) and is safer during removal of a foreign body.

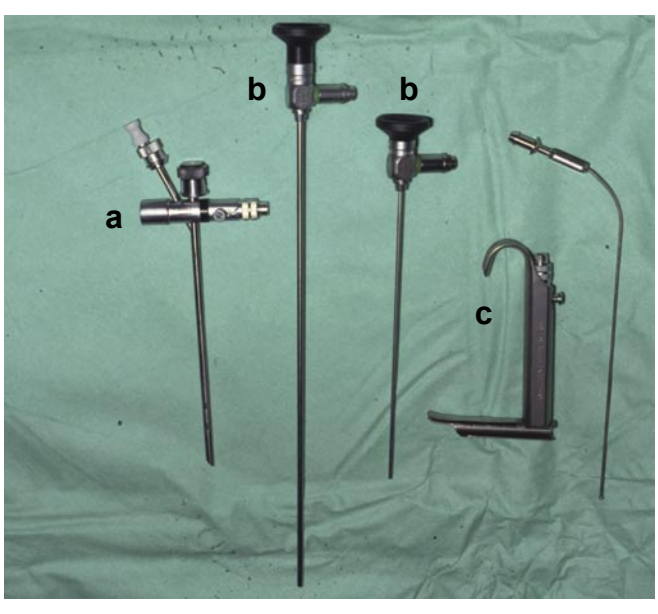
Induction can be performed with sevoflurane or halothane (Figure 7). Sevoflurane has a better cardiovascular profile but halothane is useful in the obstructed airway where deepening anaesthesia is difficult. Preventing undesirable responses to instrumentation of the airway, such as laryngospasm, breath-holding or coughing, requires a deep plane of anaesthesia. The incidence of these problems can be reduced further by topical anaesthesia with lidocaine (lignocaine), maximum of 3 mg/kg, to the cords (by the anaesthetist) or carina (by the endoscopist). Anticholinergic agents (glycopyrollate, 10 μg/kg, or atropine, 20 μg/kg), given intravenously at induction, may reduce secretions and prevent bradycardia (especially if using halothane).

Maintaining the airway: inserting a tube into the trachea obscures the surgeon's view and impairs the movement of laryngeal structures during breathing. There are no specific microlaryngoscopy tubes for children, but if a tube is necessary, a size or two smaller is selected. A common alternative is to flood the pharynx with oxygen and a volatile agent delivered through a T-piece attached through a face mask (allowing flexible bronchoscopy through a modified angle piece) or nasopharygeal airway inserted into a nostril, while maintaining spontaneous breathing(Figure 7). Correct placement of the nasopharyngeal airway (usually a softened cut-down tracheal tube) can be verified by occluding the mouth and observing unobstructed breathing or during bronchoscopy. Delivering anaesthesia through a nasopharyngeal airway allows easy access by the surgeon to examine the supraglottic structures or introduce a flexible or rigid bronchoscope through the mouth and into the trachea. Vasoconstrictor nasal drops are useful to prevent traumatic bleeding (e.g. otrivine paediatric nasal drops or spray which contains xylometazoline 0.05%).

7 An infant maintained on oxygen and halothane via a nasopharyngeal airway while undergoing rigid bronchoscopy.

Monitoring: close observation, including movement of the chest and reservoir bag (once the breathing system is attached to the rigid bronchoscope) and SpO_2 monitoring are essential during the procedure to ensure adequate ventilation and oxygenation. The patency of the airway and movement of the cords can also be assessed by watching the endoscopic image on the screen. Leak of gases from the mouth makes end-tidal CO_2 monitoring less reliable.

The bronchoscope: the T-piece can be directly connected to the side arm of the Storz bronchoscope (Figure 8), allowing the bronchoscope to function effectively as a tracheal tube once passed through the cords. Positive-pressure ventilation or assisted breathing can also be delivered if the lesion is fixed. However, other rigid bronchoscopes do not permit ventilation (e.g. the Hopkins rod). Anaesthesia is maintained with a nasopharyngeal airway delivering oxygen and a volatile gas.



8 Rigid bronchoscope showing: **a** the Storz ventilating bronchoscope; **b** the Hopkins rod; and **c** the Storz laryngoscope.

During removal of foreign bodies from smaller airways, inadequate ventilation and hypoxia can occur. The surgeon should withdraw the bronchoscope to the trachea to improve ventilation.

Chronic airway obstruction

Causes of chronic airway obstruction are given in Figure 9. Obstructive sleep apnoea syndrome may complicate chronic airway obstruction. The features include:
- snoring
- apnoea
- fragmented sleep
- daytime somnolence
- failure to thrive
- recurrent respiratory infections.

Causes of chronic airway obstruction

Adenotonsillar hypertrophy
Macroglossia
Down's syndrome
Beckwith-Wiedemann syndrome
Hypothyroidism
Glycogen storage disorders
Mucopolysaccharidoses

Neuromuscular disorders
Duchenne muscular dystrophy
Cerebral palsy
Syringobulbia
Arnold-Chiari malformation

Laryngomalacia

Micrognathia/retrognathia
Pierre Robin syndrome
Treacher-Collins syndrome
Goldenhar's syndrome
Moebius syndrome
Hallermann-Streiff syndrome

Obesity
Praeder-Willi syndrome

Maxillary hypoplasia
Apert's syndrome
Crouzon's disease

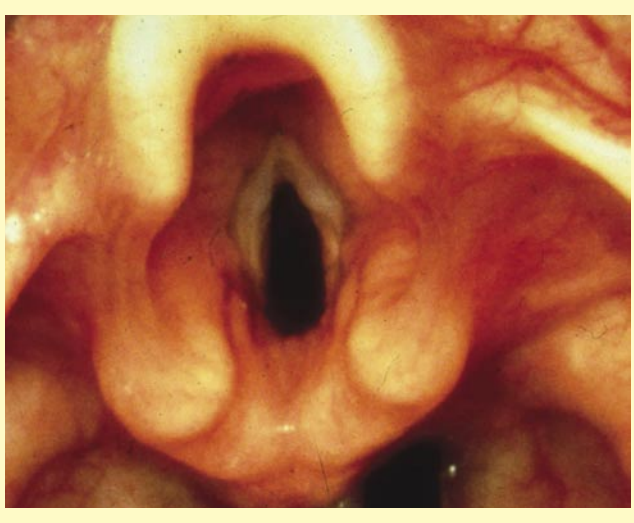
Laryngeal papillomatosis
(Figure 10)

9

Right heart failure may occur in severe obstructive apnoea, the pathophysiology of which is given in Figure 11.

If obstructive sleep apnoea is suspected, the ECG should be examined for signs of right ventricular hypertrophy. Echocardiography helps to assess right ventricular hypertrophy and pulmonary pressures and detect tricuspid regurgitation. If heart failure is present, preoperative nasal CPAP and diuretics may optimize the child's condition.

Surgery should be deferred, if possible, in the presence of respiratory infections. Sedative premedication should be avoided because of the risks of oversedation and airway obstruction.



a The normal infant larynx.

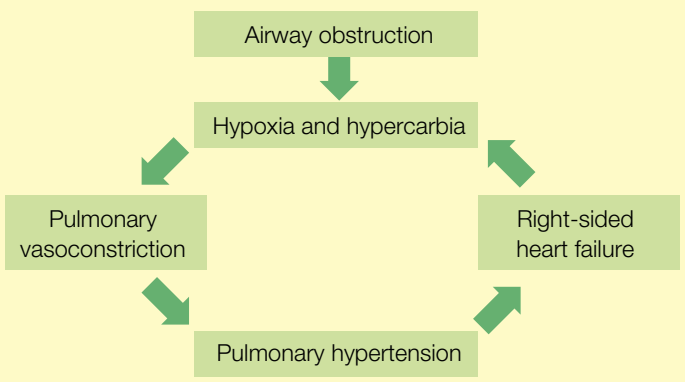
b Laryngeal papillomatosis.

10

Airway laser surgery

Laser beams are used to vaporize papillomata (see Figure 10b), and occasionally other pathology, but is associated with scarring. To enable the surgeon to aim the laser with precision, the target area should be still. Although neuromuscular blockade and tracheal intubation can ensure this, a laser beam can set fire to a normal polyvinyl chloride tube. Special metal-coated, laser-resistant tubes are expensive and their external diameter (ED) exceeds that of ordinary tracheal tubes of the same internal diameter (ID). The smallest laser tube has an ID of 3.0 mm and an ED of 5.2 mm (compared with 3.0 mm and 4.2 mm for a standard tube) and is suitable only for children over 1 year of age. Narrowing of the airways further limits their use. The dangers of airway laser surgery are discussed elsewhere.

Pathophysiology of right heart failure in obstructive sleep apnoea



11

Alternative anaesthetic techniques

Jet ventilation down the bronchoscope or operating laryngoscope, combined with total intravenous anaesthesia and muscle relaxants. The flow generated decreases with smaller injector needles. A 16G needle is commonly used in children, but great care must be taken to avoid barotrauma. A pressure-regulating device is now available which should be used to decrease the pipeline pressure (4 bar) to a lesser amount and thereafter deliver a more suitable volume to a small child. Pneumothorax, though rare, is a complication. Dissemination of the papilloma virus is a theoretical consideration but as yet is not described.

Apnoeic techniques: the surgeon uses the laser intermittently and the anaesthetist intubates and ventilates the patient for short durations between successive applications of laser.

Deep volatile anaesthesia delivered through a nasopharyngeal airway: for supraglottic and subglottic laryngeal lesions the combination of deep volatile anaesthesia with topical local anaesthetic (as described for laryngoscopy above) allows spontaneous respiration and can provide excellent conditions. ◆

Anaesthesia for ENT Surgery

Charles Stack

Charles Stack is Consultant in Paediatric Anaesthesia and Intensive Care at Sheffield Children's Hospital, Sheffield, UK. He qualified from the Middlesex Hospital, London, and trained in anaesthesia in Southampton, Nottingham and Great Ormond Street.

In the UK, routine ENT surgery accounts for a high proportion of children requiring anaesthesia. Tonsillectomy is undertaken in 2.3/1000 children under 12 years of age. Postoperative haemorrhage occurs in up to 4% and carries a risk of death.

Adenotonsillectomy

Indications for adenotonsillectomy include:

- recurrent tonsillitis
- recurrent otitis media
- obstructive sleep apnoea
- upper airway obstruction leading to pulmonary hypertension, right ventricular hypertrophy and right heart failure
- quinsy
- tuberculous cervical adenitis

The two main surgical techniques are guillotine tonsillectomy (which involves snaring the tonsil and excising it rapidly), and dissection tonsillectomy (which involves dissection and uses diathermy or surgical ties to control bleeding points). For either technique, the airway has to be secured, with a tracheal tube or a laryngeal mask airway (LMA). The surgeon inserts a Boyle–Davis mouth gag to keep the mouth open, the tongue blade of which (the 'Doughty tongue blade') has a groove to keep the tracheal tube or LMA out of the surgical field. It is important to ensure that the airway remains patent when the gag is opened because kinking of the tracheal tube or LMA can easily occur.

Preoperative assessment and premedication – it is important for the anaesthetist to ask specifically about:

- upper respiratory tract infections (adenotonsillectomy should be avoided during active infections because the risk of bleeding increases with adenoidal or tonsillar inflammation)
- features suggesting a bleeding diathesis
- obstructive sleep apnoea.

Children with obstructive sleep apnoea are particularly liable to respiratory depression after sedatives (therefore avoid sedative premedication) and general anaesthesia. Improvement after surgery is not immediate and takes several weeks. Postoperative care on a high dependency unit or ICU is usually required.

Airway protection – the standard method for maintaining the airway during tonsillectomy has been intubation with a south-facing, preformed, disposable tracheal tube followed by a spontaneously breathing anaesthetic technique. However, the results of a study using airway endoscopy showed no soiling of the trachea with blood when using an LMA compared with soiling in over 50% when using a tracheal tube. The LMA and tracheal tube for tonsillectomy are compared in Figure 1. The LMA is preferable because it affords better airway protection from blood until the patient is awake, but the choice depends on the anaesthetist and surgeon.

Use of tracheal tube or laryngeal mask airway (LMA) for tonsillectomy in children

Tracheal tube

Advantages

- Definite placement in trachea
- Smaller size
- Not in surgical field
- Easier to 'take over' respiration

Disadvantages

- Blood in trachea in > 50% of children
- Greater stimulation on insertion
- May need muscle relaxation for intubation
- Removal of airway protection when deeply anaesthetized if extubated 'deep'

LMA

Advantages

- Better airway protection
- No muscle relaxants required
- Protection of the lower airway until awake
- Reduced incidence of postoperative vomiting

Disadvantages

- Large size may impair surgical access
- Placement may encroach on surgical field
- Can be difficult to position correctly

1

Postoperative bleeding – the main complication of tonsil-lectomy is blood loss in the airway. If an anaesthetic technique that involves extubation under deep inhalational anaesthesia is used, it is important to suction the pharynx fully under direct vision (this also allows assessment of whether the surgeon needs to consider further attempts to control bleeding). The patient should be extubated head down on their left side (the 'tonsillar position') and should remain in this position to allow blood to trickle away from the larynx. Mean blood loss is about 4 ml/kg, but it is usually underestimated because most is swallowed.

Primary postoperative haemorrhage usually occurs within 8 hours of surgery. Children should be observed closely post-operatively to detect signs suggesting haemorrhage, such as:

- increased swallowing
- pallor or prolonged capillary refill time
- unexplained tachycardia
- restlessness
- sweating
- signs of airway obstruction
- hypotension (occurs late).

Bleeding tonsil

Death can occur from a bleeding tonsil (usually due to hypotension) following induction of anaesthesia after inadequate resuscitation. Mortality from tonsillectomy is about 1/10,000. The patient loses blood steadily, often quietly swallowing the blood before vomiting. Blood loss is always considerably more than that measured in the vomit; careful preoperative assessment is essential.

Before surgery the child should be given oxygen and resus-citated with intravenous fluids and blood (when available). A full blood count, clotting screen and cross match are required.

- Adequate fluid resuscitation with colloid and blood products is essential before inducing anaesthesia.
- Restlessness is often due to hypovolaemia, therefore sedation preoperatively should be avoided.
- Abnormal clotting may occur, therefore non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided and replacing clotting factors considered.
- Blood in the airway may cause obstruction or hinder the view at laryngoscopy.
- Blood in the stomach increases the risk of gastric aspiration at induction.
- The airway may be narrower due to tracheal edema, if so a tracheal tube half a size smaller should be considered.
- Care should be exercised when using anaesthetic agents that may cause vasodilatation and hypotension.
- The effects of the previous general anaesthetic and peri-operative opiates should be considered.

The recommended anaesthetic techniques are compared in Figure 2. Two suckers should be available at induction because haemorrhage can be brisk. Attempts should be made to empty the stomach before cessation of anaesthesia to reduce the risk of postoperative aspiration.

Uses of rapid sequence induction (RSI) or gaseous induction in the left lateral, head-down position for the child with a bleeding tonsil

RSI

Advantages

- Rapid induction
- Rapid control of the airway
- Less likelihood of regurgitation during induction

Disadvantages

- Blood in airway
- Patient may inhale blood
- May not visualize cords after paralysis
- Cardiovascular depression from induction

Gaseous induction

Advantages

- Maintenance of spontaneous respiration
- Inhalation of blood less likely

Disadvantages

- Blood in airway may precipitate laryngospasm
- Slow
- Less experience with this position therefore intubation difficult
- Restlessness during induction
- Respiratory depression from previous anaesthetic
- Cardiovascular depression from gaseous induction

2

Analgesia

Adenotonsillectomy is painful. Traditionally, opiates have been avoided because of their respiratory depressant and sedative effects (particularly in those with obstructive sleep apnoea) though codeine phosphate, 1 mg/kg i.m., has been used. NSAIDs are as effective as opiates but may increase the risk of primary postoperative haemorrhage (particularly ketorolac). Paracetamol alone is often insufficient.

In one study, the combination of paracetamol and ibuprofen as premedication reduced early requirements for supplementary analgesia compared with paracetamol alone (though pain scores were similar by 4 hours). Primary postoperative haemorrhage occurred but the numbers were too small to be significant. Median blood loss increased during adenotonsillectomy but was not statistically significant in the group receiving ibuprofen.

Most anaesthetists use perioperative opiates with a combination of NSAIDs and paracetamol at operation and then regularly postoperatively. A comparison of fentanyl (intravenous) and morphine (intramuscular) showed reduced frequency of vomiting in the fentanyl group (median: 1 episode versus 2 episodes) but not a reduced incidence (70 versus 78%). 52% of the fentanyl group and 41% of the morphine group required rescue opiate.

Postoperative nausea and vomiting occurs in 5–78% of patients. Vomiting causes distress, delayed discharge, dehydration and possibly bleeding from the tonsillar bed. Swallowed blood is emetogenic. Factors that reduce vomiting following surgery in children are:

- propofol induction and maintenance
- use of LMA
- routine use of anti-emetics
- midazolam, dexamethasone
- adequate analgesia
- avoidance of opioids
- intravenous fluids.

Day case tonsillectomy

The advantages of day case tonsillectomy are mainly socioeconomic; it involves less family disruption and reduces cost. The operation must be in the morning and a significant overnight admission rate may be expected. The disadvantages are the risk of primary postoperative haemorrhage (1–4%), the need for adequate analgesia (over 40% require postoperative opioids) and a significant rate of postoperative nausea and vomiting (5–78%). Distance from hospital, availability of transport and appropriate family circumstances also have to be taken into account. Children with a history of obstructive sleep apnoea should not be admitted as day case patients. Overall, it is probably safer for patients to remain in hospital overnight after tonsillectomy.

Myringotomy

Myringotomy with insertion of grommets is a common day case operation. An anaesthetic technique with spontaneous respiration (usually via a face mask) is used and the head held to the side during examination. Theoretically, nitrous oxide increases the pressure in the middle ear by diffusion of the gas into the air-filled cavity. Mild-to-moderate pain occurs afterwards for which perioperative paracetamol is useful. ◆

Assessment of Pain in Children

Neil S Morton

Neil S Morton is Consultant in Paediatric Anaesthesia, Intensive Care and Pain Management at the Royal Hospital for Sick Children, Glasgow, UK. He qualified from Aberdeen University and trained in Glasgow, Dundee and Montreal, Canada. His interests are in developing pain management services for children and improvements in the management of children undergoing diagnostic and therapeutic procedures.

Pain is difficult to measure precisely and reliably in children and many pain measurement tools and scores have been developed (Figure 1). The clinician needs a pragmatic system that reliably tracks both the child's pain experience and the efficacy of pain control over time.

Pain assessment is a broader concept than pain measurement and takes into account cognitive, physiological, sensory, behavioural, affective, sociocultural and environmental factors. The assessment must be appropriate for the child's stage of development, the severity and chronicity of the child's illness, the surgical or medical procedure and the medical environment.

- Self-reported assessment – pain assessment is most accurate when children can tell staff about their pain. It is possible for children from age 3 years to self-report the location, severity and nature of pain using words appropriate to their stage of development.
- Observed assessment – to detect the symptoms and signs of pain in the younger child (or in the older child with mental or physical disabilities), behavioural cues and physiological values are used. These are open to misinterpretation; for example the same changes may be caused by things other than pain (e.g. hunger). Experienced paediatric staff are better at interpreting these cues than novices, and parents are often better than nurses.

Pain assessment must be linked to appropriate interventions based on the assessment with the aim of ensuring that the child experiences no pain or only mild pain. Measurement with pain tools or scores should be regarded as an aid to this more complex holistic assessment process. For severe or acute pain that is likely to persist over a number of days it is important to assess anxiety and depression.

Whichever scoring system is used, pain assessments should be repeated regularly, appropriate interventions should be prescribed and their effectiveness should be documented.

Pain scoring

Pain measurement tool	Appropriate age range	Clinical utility	Indicators included	Advantages	Disadvantages
Behavioural and physiological signs of distress					
Objective Pain Scale (OPS)	< 3 years	• Acute postoperative pain	• Blood pressure • Crying • Movement • Agitation • Verbal expression • Body language	• Easy to use • Validated • Reliable • Tracks pain over time • Scores decrease with analgesia	
'CRIES' Score (Cry, Requires oxygen, Increased heart rate and blood pressure, Expression, Sleeplessness)	32–60 weeks' gestational age	• Neonates and infants • For acute procedural and postoperative pain	• Cry • Oxygen saturation and requirements • Heart rate and blood pressure • Expression • Sleeplessness	• Easy to remember and use • Validated • Reliable • Tracks pain over time • Scores decrease with analgesia	• Uses oxygenation as measure which can be affected by many other factors • Blood pressure measurement may upset the baby and falsely increase the score
COMFORT Score	0–17 years	• Distress in paediatric intensive care	• Alertness • Agitation • Calmness • Respiratory response • Physical movement • Blood pressure • Heart rate • Muscle tone • Facial tension	• Validated • Reliable • Tracks pain over time • Scores decrease with analgesia and/or sedation	• Complicated • Unsuitable for intubated or paralysed patients
CHEOPS (Children's Hospital of Eastern Ontario Pain Scale)	1–7 years	• Acute postoperative pain • Venepuncture pain	• Cry • Facial expression • Verbal expression • Torso position or movement • Touching wound • Leg position and movement	• Validated • Scores decrease with analgesia	• Complicated • May not track postoperative pain over time in 3–7 year age group because pain behaviours become inhibited or habituated
TPPPS (Toddler-Preschool Paediatric Pain Scale)	1–5 years	• Acute postoperative pain	• Verbal expression • Facial expression • Body language	• Tracks pain relief	• Seven categories to score
Self reporting tools					
Poker chip tool (Figure 2)	> 4 years	• Procedural pain • Acute postoperative pain	• Four tokens to indicate pieces of hurt corresponding to nil, mild, moderate and severe pain	• Validated • Easy to use	• Unsuitable for the critically ill or sedated child
Four faces scale (Figure 3)	> 4 years	• Procedural pain • Acute postoperative pain	• Four faces from neutral to sad corresponding to nil, mild, moderate and severe pain	• Validated • Easy to use	• Unsuitable for the critically ill or sedated child
Vertical colour analogue slide-rule (Figure 4)	> 4 years	• Procedural pain • Acute postoperative pain	• Vertically oriented coloured wedge • Calibrated 0–100	• Validated • Easy to use	• Unsuitable for the critically ill or sedated child
Horizontal linear analogue	> 7 years	• Procedural pain • Acute postoperative pain	• Horizontal 100 mm line • No markings as anchor	• Validated • Easy to use	• Unsuitable for the critically ill or sedated child
Adjectival self-report	> 4 years	• Procedural pain • Acute postoperative pain	• Key words with four choices	• Validated • Easy to use	• Unsuitable for the critically ill or sedated child

1

Children younger than 3 years

In the assessment tools used for children younger than 3 years, observations of behaviour (e.g. facial expression, body position, mobility, crying, sleep pattern), skin colour and vital sign measurements (e.g. arterial pressure, heart rate, arterial haemoglobin saturation) are given numerical scores that are added to give a total. This static assessment is much less useful than a dynamic one, in which the nurse is looking for the total score to improve in response to comforting, analgesia or sedation. This responsive (or interactive) scoring can be used to guide, for example, the titration of analgesic drugs. Good documentation of the score, the intervention used and its effect is important.

Many scores of this type are confounded in the less mature, sick or sedated, paralysed, intubated or ventilated child, so it is reasonable to assume that such children who have had surgery may be in pain and ensure that adequate analgesia is given.

Pain-related behaviour in toddlers may be 'all-or-nothing' in nature. They can often locate pain precisely (e.g. by grabbing at the site of operation). This suggests that a simple scoring system (e.g. pain present/absent) may be enough to guide analgesic therapy in this age group.

Children older than 3 years

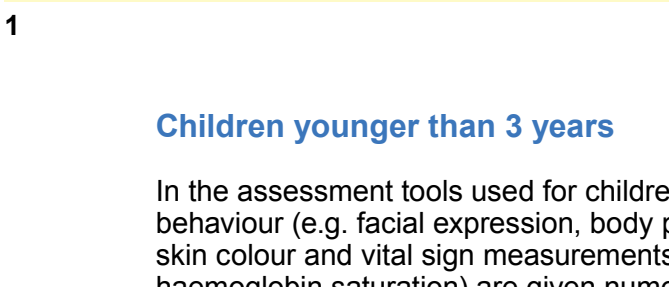
Many children over 3 years can differentiate between the presence or absence of pain, and indicate its nature, intensity and site. They can categorize pain reasonably accurately into one of four choices corresponding to nil, mild, moderate or severe.

Many children can explain whether they are feeling pain and indicate how bad it is providing they understand the language and phrases used. They can comprehend the concept of 'pieces of hurt' as used, for example, with the poker-chip tool (Figure 2).

Indicating severity using a faces scale can work well, but the choice of faces is best limited to four, with the first face appearing 'neutral' rather than 'happy' (Figure 3). Some children are unable to relate the faces to their own pain experiences, while others tend to choose those at the extremes of the scales.

Many children relate to previous pain experiences to indicate whether their current experience is worse or better, for example by comparing it with a previous injury. These earlier experiences may influence their assessments (e.g. the same injury may be scored as 'severe' by a young child with no previous pain experiences, while an older child, who has had a worse pain before, may score the pain as 'mild'). Some children who have undergone repeated, painful procedures may be sensitized and have a lowered pain threshold.

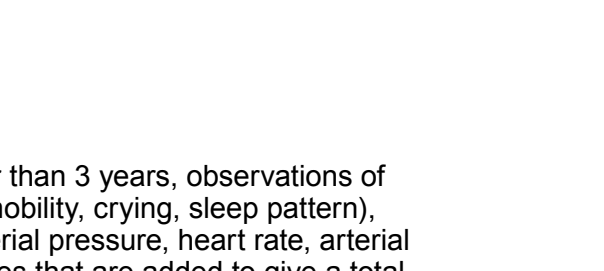
Poker chip tool



Tokens acting as pieces of pain are stacked by the child to indicate how much pain they are experiencing

2

The four faces scale



Note: the first face should be neutral, not happy

3

Children older than 5 years

Visual analogue tools and scales can be operated successfully by children from the age of 5 years, however, the classical 100 mm horizontal line is not well understood by younger children.

Adding colour gradations is helpful and making the scale into a vertical colour wedge is best (Figure 4).

Vertical colour analogue slide-rule tool

The child indicates the pain level with the slider. The obverse side is calibrated from 0 to 100

Central Blocks in Children

Edward Doyle

Edward Doyle is Consultant Paediatric Anaesthetist at the Royal Hospital for Sick Children, Edinburgh, UK. He qualified from Oxford University and trained in paediatric anaesthesia in Glasgow and Edinburgh. His research interests include postoperative analgesia and regional anaesthetic techniques in children.

The use of central neural blocks in children is now a routine part of paediatric anaesthesia. In selected children they reduce the morbidity associated with surgery and anaesthesia and can favourably influence the postoperative course. These techniques often result in dense intraoperative and postoperative analgesia, reduced requirements for volatile agents, minimal postoperative vomiting and a reduction in opioid use. The same standards of preoperative assessment used in adults, regarding contraindications, technical competence, sterility and postoperative monitoring are required in children. In most patients, a central block is combined with general anaesthesia. There is an incidence of predictable side-effects and a low incidence of potentially serious complications. Most of these are easily managed if competent personnel and appropriate facilities are available.

Subarachnoid and epidural blocks in young children seldom result in hypotension unless there is significant hypovolaemia or a high thoracic block. This is probably because children under 8 years of age have a reduced sympathetic tone and reduced blood volume in the splanchnic circulation and lower limbs, compared with older children and adults. Consequently, fluid loading or the administration of vasopressors are seldom necessary and this can make the practical conduct of central blocks easier than in adults. In older children, who have a more adult physiology, there is occasionally a variable decrease in both heart rate and blood pressure.

Subarachnoid (spinal) anaesthesia

Subarachnoid anaesthesia has a rapid onset, produces profound sensory and motor block without systemic effects, and when used alone avoids volatile anaesthetic agents or tracheal intubation. It provides definite benefits compared with general anaesthesia in certain children at high risk (e.g. infants born prematurely) but requires experience and the ability to manage any complications that may occur.

The most common indication is probably inguinal hernia repair in infants who were premature. 30% of premature infants with a birth weight less than 1000 g develop an inguinal hernia. Postoperative apnoea occurs in 30–40% of these babies if they undergo general anaesthesia for repair and is particularly common in those less than 44 weeks postconceptional age.

Three prospective, randomized, controlled studies have demonstrated a significant reduction in the incidence of postoperative apnoea, episodes of bradycardia and hypoxia, or requirement for postoperative ventilation, when subarachnoid anaesthesia rather than general anaesthesia is used in infants who were premature. In one study, in which a subgroup received sedation as well as subarachnoid anaesthesia, over 80% developed prolonged postoperative apnoeas with bradycardia and this technique probably offers no advantages over general anaesthesia in reducing the incidence of respiratory complications.

Other indications for subarachnoid blockade include most operations below the umbilicus (though it has also been used for upper abdominal or thoracic surgery). In combination with general anaesthesia, the technique has been used for spinal and cardiac surgery to reduce the requirements for opioids or postoperative ventilation in high-risk children, and to minimize the perioperative stress response to surgery. In many centres outside the UK, the technique is not restricted to high-risk patients but is also used in ASA I and II patients having lower- body surgery, simply because of the good anaesthetic and surgical conditions it provides.

Short narrow-gauge spinal needles ranging from 22 G to 24 G are available for use in children. Narrower-gauge adult needles may also be used in older children particularly if post-dural puncture headache is a concern. Hollow hypodermic needles or intravenous cannulae should not be used because they may introduce a core of epithelial tissue into the subarachnoid space. Injection should be performed at a low lumbar interspace because the neonatal spinal cord usually reaches the L3 vertebral level. Injection is often performed with the baby in the sitting position restrained by an assistant who also ensures that episodes of airway obstruction do not occur during the procedure.

Drugs

Bupivacaine is the local anaesthetic used most commonly in Europe whereas tetracaine (amethocaine) tends to be used in North America (Figure 1). Larger doses of local anaesthetic on a mg/kg basis are required than in adults. Children, and especially neonates, have a larger volume per kg of CSF than adults, with a higher proportion contained in the lumbar region, resulting in more dilution of the local anaesthetic. The greater cardiac output relative to body weight in infants and neonates results in more rapid systemic uptake of local anaesthetic contributing to a relatively short duration of subarachnoid anaesthesia compared with adults (usually about 50–120 minutes). The addition of adrenaline prolongs the duration of effective subarachnoid blockade by 20–40%.

There is limited pharmacokinetic data concerning subarachnoid bupivacaine in children. The mean plasma bupivacaine concentration in neonates 10 minutes after intrathecal administration of isobaric bupivacaine, 1 mg/kg, was 0.31 μg/ml (range 0.13–0.79 μg/ml) and 0.25 μg/ml (range 0.1–0.38 μg/ml) after intrathecal administration of isobaric bupivacaine, 1 mg/kg, with 1/200,000 adrenaline (epinephrine). Bupivacaine is extensively bound to plasma proteins, mainly albumin and α_1 acid glycoprotein. Neonates have lower levels of these proteins than adults, resulting in a decreased binding capacity for bupivacaine and an increased risk of toxicity from free bupivacaine. The mean free bupivacaine levels in this study were 0.047 μg/ml (range 0.01–0.11 μg/ml) in the group receiving bupivacaine alone and 0.062 μg/ml (range 0.03–0.1 μg/ml) in the group receiving bupivacaine and adrenaline (epinephrine). These values are reassuringly low.

Local anaesthetics and doses for subarachnoid anaesthesia in infants

Drug	Dose range[1] (mg/kg)
• 0.5% tetracaine hyperbaric plain	0.32
• 0.5% tetracaine hyperbaric plus adrenaline (epinephrine)	0.5–0.6
• 0.5% bupivacaine isobaric plain	0.75–1.0
• 0.5% bupivacaine plain with or without adrenaline (epinephrine)	0.6–1.0

[1]Recommendations from different authors

Problems

The technique of subarachnoid blockade in neonates and infants has a significant incidence of problems. The duration of the block is short and is reliable only for procedures lasting less than 1 hour. There is no significant postoperative analgesia and alternative analgesia must be provided. There is a failure rate of about 10% and an incidence of high blockade, which can cause respiratory compromise. These problems are well demonstrated in a series of 164 infants, who were premature, undergoing subarachnoid anaesthesia. In 137 patients (83.5%) there was a block that was adequate for surgery. Successful lumbar puncture could not be performed in 12 patients (7.3%). A further 15 (9.1%) required supplementation with infiltration anaesthesia, systemic analgesia or anaesthesia. Two patients became apnoeic during the lumbar puncture and five developed a high block producing respiratory weakness. Postdural puncture headache is seldom a clinical problem in children aged less than 10 years, but does occur in older children. Efforts to prevent this include the use of a pencil-type or a fine cutting needle. Hypotension during a subarachnoid block is also unusual in babies or children and if it occurs may indicate unanticipated hypovolaemia or a high block.

Epidural analgesia

The introduction of paediatric epidural needles (5 cm long, either 19 G or 20 G) and fine epidural catheters has made epidural analgesia feasible in the smallest of children. Single injection or infusion epidural analgesia at the thoracic or lumbar levels has become popular and often allows the use of light anaesthesia and minimal opioid administration, and may help avoid postoperative ventilation in some high-risk patients. Children in whom these techniques are particularly important include those with gastro-oesophageal reflux undergoing fundoplication, children with respiratory disabilities undergoing abdominal surgery or neonates undergoing repair of oesophageal atresia. In neonates and infants it is possible to thread a catheter from the sacral hiatus to the thoracic region and to provide analgesia for abdominal or thoracic surgery. This technique is popular because it allows the epidural space to be cannulated below the spinal cord. However, attempts to thread catheters to the thoracic region from the caudal hiatus or a low lumbar approach are generally ineffective in children aged over 2 years.

Conservative doses for epidural infusion in children after a loading dose of bupivacaine, 2–2.5 mg/kg, are a maximum of 0.2–0.25 mg/kg/hour in neonates or 0.3–0.4 mg/kg/hour in older children. Data from various sampling studies during continuous infusion of extradural bupivacaine of less than 0.5 mg/kg/hour are generally reassuring. Mean plasma concentrations are usually low and less than 2–4 μg/ml, a level often associated with the risk of toxicity. However, concentrations in individual patients may sometimes be high. There is particular concern about toxicity in children aged less than 6 months in whom drug elimination is variable as a result of diminished clearance and prolonged half-lives and prolonged infusions are associated with rising plasma levels of bupivacaine.

The simultaneous use of other analgesics such as opioids or non-steroidal analgesic drugs, increases the efficacy of epidural analgesia and reduces the dose of local anaesthetic required. After major surgery, an opioid (commonly fentanyl, morphine or diamorphine) is usually required in addition to local anaesthetic. This acts synergistically with the local anaesthetic to improve analgesia and to reduce the requirement for local anaesthetics. It will also treat discomfort from areas of the body that are not covered by the epidermal block and provide a mild degree of sedation. Opioids are conventionally given mixed with the local anaesthetic solution but may also be given systemically. Opioids have also been used alone by intermittent injection or continuous infusion to provide epidural analgesia.

Problems

Common problems associated with epidural anaesthesia in children are listed in Figure 2. The incidence of dural tap is variable and is influenced by various factors including the experience of the anaesthetist, the technique used, the age of the patient and the type of epidural needle used. More dural punctures occur if inappropriately large epidural needles are used or if air, rather than saline, is used to detect loss of resistance. The incidence of dural tap is usually quoted at less than 10%.

Technical problems with epidural catheters may occur and cause premature discontinuation of epidural analgesia. The incidence of problems is considerably higher with the fine catheters (e.g. 23 G) designed for babies or small children, than with the larger catheters (e.g. 21 G). Potential problems include leakage at the site of entry of the catheter through the skin, misplaced or occluded catheter and disconnection between the epidural catheter and the bacterial filter.

Common potential side-effects include urinary retention, leg weakness, nausea and vomiting. Intravenous or subarachnoid injection, epidural haematoma or infection are uncommon, but possible. Lack of sensation may cause problems if not anticipated and heel blisters or pressure sores may occur in analgesic skin unless patients are repositioned regularly.

When epidural opioids are used there is a possibility of respiratory depression. This is a particular risk if the child is aged under 1 year, is given concurrent parenteral opioids or large doses are used. Appropriate doses associated with a low incidence of respiratory depression are fentanyl, 0.1–0.5 μg/kg/hour, or morphine, 5 μg/kg/hour. The best method of detecting respiratory depression at an early stage is the use of continuous pulse oximetry while the patient is breathing air.

Postoperative nausea and vomiting in infants and young children tends to be less common and severe than in adults, though older children behave more like adults. The use of epidural opioids probably makes this problem worse, but it is impossible to quantify this effect in children. The incidence of postoperative nausea and vomiting during epidural infusions containing fentanyl has been reported as 0–80%. This should be compared with the significant incidence when systemic opioids are used to provide analgesia after major surgery.

The incidence of urinary retention is unknown because many patients are catheterized perioperatively. The reported incidence varies with age, opioid use and the criteria used to define urinary retention. The reported incidence is zero in neonates, 18% in infants and 62% in those aged 10–17 years. The relative contributions of opioid and local anaesthetic are difficult to determine because it occurs when both types of analgesic are used alone.

Epidural abscess or haematoma associated with the use of epidural analgesia for acute pain have not been reported in children. Other serious complications that result in permanent neurological deficit or death have a low incidence (5 of 7200 epidurals in a retrospective survey of practice between 1982 and 1991 of members of the Society of French Speaking Paediatric Anaesthetists). Risk factors for serious complications in this study included multiple traumatic attempts at epidural cannulation, age less than 3 months, or the use of the loss of resistance to air technique for identifying the epidural space.

Common problems of epidural analgesia in children

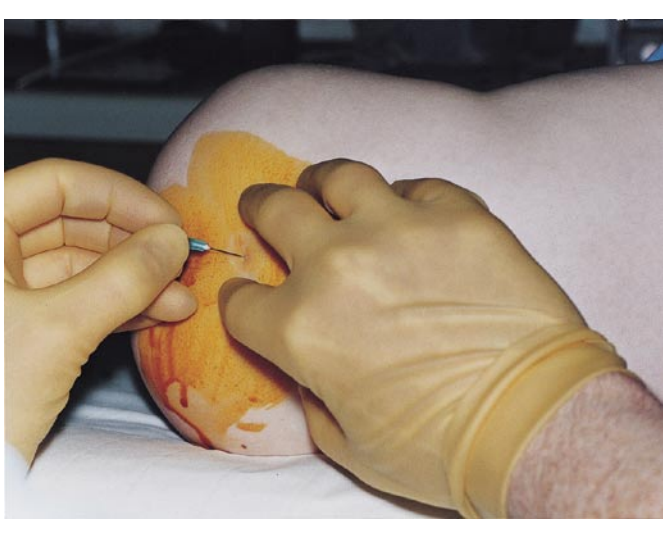
Problem	Incidence[1] (%)
• Dural puncture	< 10
• Catheter disconnection or obstruction	0–17
• Respiratory depression	< 1
• Hypotension	< 10
• Urinary retention	0–60
• Nausea and vomiting	0–80

[1]Composite figures from a number of series

Caudal epidural blockade

Single-injection caudal epidural blockade is a simple technique with a high success rate and a low incidence of serious complications. It can be used to provide intraoperative anaesthesia and postoperative analgesia for many operations below the umbilicus. It reduces the requirement for volatile anaesthetic agents and opioids, which reduces the incidence of postoperative nausea and vomiting. Children may then resume oral intake and take oral analgesics after quite major surgery without the need for parenteral analgesic drugs. In most patients, the caudal block is combined with light general anaesthesia, though it has been used as the sole technique for inguinal hernia repair in infants who were premature. It has also been combined with simultaneous subarachnoid block to provide prolonged anaesthesia after a subarachnoid block has worn off.

Injection is performed through the sacral hiatus, well below the termination of the spinal cord, therefore there is little risk of serious neurological damage during caudal epidural blockade. The main potential for serious complications comes from the possibility of intravenous injection or dural puncture followed by a subarachnoid injection. This is especially the case in small children in whom the termination of the dural sac may lie as low as the second sacral vertebra. Both of these problems can be almost eliminated if the initial puncture of the sacral hiatus is performed with a needle without the syringe of local anaesthetic attached (Figures 3 and 4). If this needle is left open to the atmosphere for a few seconds, blood or CSF will appear if there has been a puncture. This will prevent the injection of local anaesthetic into the CSF or a vein. If the needle is not left open to the atmosphere for a few seconds then it may be impossible to aspirate blood or CSF and an injection of local anaesthetic into the wrong compartment may be given.



3 Initial puncture of sacral hiatus performed with a needle without the syringe attached.

4 Slow injection of local anaesthetic without moving the needle.

Drugs

Local anaesthetics: bupivacaine is the local anaesthetic agent used most commonly for caudal epidural blockade. Pharmacokinetic data show that single epidural doses of bupivacaine, 2–2.5 mg/kg, are associated with low plasma levels of the drug (Figure 5).

Plasma levels of bupivacaine after caudal epidural injection

Drug	Dose (mg/kg)	Number of children	C_{max} mean (range) (μg/ml)	T_{max} mean (range) (minutes)
Bupivacaine	2.5	6	1.25 (0.96–1.64)	29 (19–38)
Bupivacaine	2.5	13	0.97 (0.55–1.93)	28 (10–60)
Bupivacaine	3.0	45	1.4 (maximum 2)	
Bupivacaine	2.0	14	0.9	16
Bupivacaine plus adrenaline (epinephrine)	3.7	10	0.67	45

Reprinted from Anaesthesia 1998; **53:** 980–1002 with permission from Blackwell Science Ltd, Oxford, UK.

Additives to local anaesthetic solutions have been used in an attempt to prolong the duration of caudal analgesia provided by a single injection of local anaesthetic.

Adrenaline (epinephrine) – vasoconstrictors decrease the rate of vascular absorption of local anaesthetic and increase the density and duration of the block. The most common is adrenaline (epinephrine) in a concentration of 5 μg/ml (1/200,000). When used for caudal epidural injection the effects of adrenaline (epinephrine) tend to be less pronounced with longer-acting local anaesthetics (e.g. bupivacaine) than with more hydrophilic drugs (e.g. lidocaine (lignocaine)). The high lipid solubility of bupivacaine causes it to be deposited in epidural fat and released slowly and adrenaline (epinephrine) tends to have little effect in prolonging its duration of action.

Opioids – the administration of caudal epidural opioids usually produces profound long-lasting analgesia. The median duration of analgesia after caudal morphine, 0.1 mg/kg, for lower-body surgery is 12 hours (range 4–24 hours) compared with 5 hours (range 3.5–24 hours) for 0.25% bupivacaine, 1 ml/kg, plus 1/200,000 adrenaline (epinephrine) and 45 minutes (range 0.3–24 hours) for intravenous morphine, 0.1 mg/kg. Side-effects of caudal epidural opioids include nausea, urinary retention, pruritus and respiratory depression. The latter is particularly worrying because its onset may be delayed for several hours after opioid administration, particularly if morphine is used. The largest reported series of children given caudal epidural morphine reported 11 cases of clinically important hypoventilation in 138 cases (8%). Of these, eight patients were younger than 3 months of age and seven received parenteral opioids in addition to caudal morphine. Assays of blood for plasma morphine levels after the administration of caudal epidural morphine show levels much less than those required for analgesia after systemic administration and strongly suggest that the synergistic effect of epidural opioids on analgesia results from a local action at spinal cord level as opposed to an effect after systemic absorption.

Clonidine also prolongs the duration of caudal epidural blockade produced with a local anaesthetic solution. Three groups of 15 patients undergoing lower-body general or urological surgery under combined general anaesthesia and caudal epidural blockade were given caudal injections of 0.25% bupivacaine. Two groups had added to this clonidine, 1 μg/kg, or adrenaline (epinephrine), 5 μg/ml. The quality and duration of postoperative analgesia assessed as the time to first analgesic requirement using an objective pain score was significantly longer with clonidine (mean 16.5 hours) than with bupivacaine (mean 7.6 hours) or bupivacaine plus adrenaline (epinephrine), (mean 6.3 hour). In a comparison of 0.25% bupivacaine, 1 ml/kg, with or without clonidine, 2 μg/kg, for lower-limb orthopaedic surgery, there was a significantly increased duration of postoperative analgesia in the group given clonidine (mean 9.8 hours) compared with the group receiving bupivacaine (mean 5.2 hours).

Ketamine – a comparison of ketamine, clonidine or adrenaline (epinephrine) added to 0.25% bupivacaine showed that ketamine, 0.5 mg/kg, provided a longer duration of postoperative analgesia after orchidopexy (median duration 12.5 hours) than clonidine, 2 μg/kg (5.8 hours) or adrenaline (epinephrine) 5 μg/ml (3.2 hours). There were no differences between groups in the incidence of urinary retention, motor block or postoperative sedation.

Problems

The incidence of failed caudal block has been reported to be as high as 11%. Failure appears to be more common in children weighing less than 10 kg in whom there may be difficulty identifying the sacral hiatus and in children aged over 7 years. Failure may also result from using an inadequate volume to block the required nerve roots.

The incidence of motor block as shown by leg weakness is variable after caudal blockade. Moderate weakness of the legs is common and occurs in about 30% of patients given 0.5% bupivacaine to block lumbar dermatomes. The incidence is less than 10% if more dilute solutions of bupivacaine are used. The optimal concentration of bupivacaine for caudal epidural blockade in children may be 0.125%. This has been shown to produce a block with an equal duration of analgesic effect and the same requirements for supplementary analgesia as 0.25%, but with a much lower incidence of leg weakness.

Venous puncture has an incidence of 1.6–10.6%. This is reduced when experienced anaesthetists, rather than trainees, perform the procedure and if short bevelled, rather than hypodermic, needles are used. There are no reports of extradural haematoma after caudal epidural blockade in children. The incidence of dural tap has been described as 1/500 and 1/1100 in various series. Negative aspiration for CSF is possible despite a dural puncture. A total spinal block is uncommon but has been reported.

The Child with Associated Medical Disease

Ann E Black

Ann E Black is Consultant Paediatric Anaesthetist at Great Ormond Street Hospital, London. She trained in anaesthesia in London and Philadelphia. Her interests include preoperative preparation, day care, audit and the strategies for management of the difficult paediatric airway.

Anaesthetists often have to deal with a child suffering from a common medical condition such as upper respiratory tract infection or asthma. Less commonly, a child may have a medical condition presenting early in life that may have important anaesthetic implications. This article addresses some common medical conditions; a textbook should be consulted for unusual or rare conditions.

Respiratory disease

Wheezing in children may be caused by:
- asthma
- infection (especially respiratory syncytial virus bronchiolitis in those less than 2 years of age)
- foreign body aspiration
- cystic fibrosis
- laryngotracheomalacia
- chronic lung disease (e.g. bronchopulmonary dysplasia, bronchiectasis, recurrent gastro-oesophageal reflux).

Asthma

Asthma affects about 10% of children, leading to reversible obstructive airways disease. Symptoms include wheezing, intermittent cough or dyspnoea. The incidence of asthma may be increasing owing to environmental changes and pollution. Most children with mild asthma become asymptomatic as they grow older. A smaller number continue to require long-term medication, including corticosteroids, and have severe exacerbations of the disease requiring repeated hospital admissions. Asthma attacks may be precipitated by respiratory infections, environmental factors, anxiety or stress.

Management: preoperative management of children with asthma includes optimizing lung function with bronchodilators, disodium cromoglycate and corticosteroids. Regular peak flow charts may be useful to assess the severity of the disease. An anaesthetic is planned to avoid histamine-releasing drugs. The use of diclofenac in asthmatic children has not been shown to be associated with drug-induced asthma or change in measured respiratory function therefore non-steroid anti-inflammatory drugs (NSAIDs) are not contraindicated for short-term use in children with mild asthma.

Upper respiratory tract infection (URTI)

On average, children have two to nine episodes of URTI per year. It may be difficult to decide whether to proceed with anaesthesia for elective surgery if a child has had a recent URTI. The evidence of additional morbidity associated with general anaesthesia is conflicting. Although severe morbidity, and even mortality, have been reported in children with URTI caused by severe lung infection, pulmonary collapse or myocarditis, this is rare. Most large studies have dealt with children undergoing day-case surgery, who are healthy or have mild systemic disease (ASA groups I and II), with minor symptoms of URTI. The adverse outcomes noted during anaesthesia in children with URTI include laryngospasm, apnoea, bronchospasm, cough, arterial desaturation, and postoperative stridor. Some studies suggest that complications with anaesthesia are 11 times more common if a child has an URTI or recent symptoms of URTI. The reasons include an increase in bronchial sensitivity, increased airway secretions and a tendency for closure of the small airways. Infants under 1 year of age are at increased risk of complications, particularly croup, and some studies have shown that children who are intubated may also be at additional risk.

Management: a child who is obviously systemically unwell with a high fever, chest signs or malaise, should have his surgery postponed. However, there is a large group of children in whom the benefit of cancellation is unclear. In general, the decision to postpone elective surgery can be made on history and examination (including WBC count and radiography), particularly taking into account the view of the parent. The length of postponement is also debated. It has been recommended that elective surgery is postponed for 3–6 weeks after an URTI. However, if this were implemented in some children with frequent mild URTI symptoms it would be difficult to find any period in the year when the child is considered free of the potential risk of complications associated with an URTI.

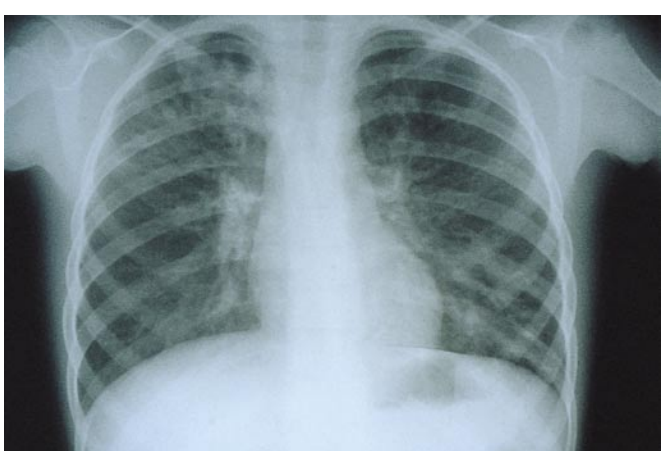
Cystic fibrosis

Cystic fibrosis is an autosomal recessive condition that affects 1/2000 live births. It is a progressive, multisystem disease affecting mainly the lungs and pancreatic exocrine function. Babies may present with meconium ileus, but infants tend to present with recurrent respiratory symptoms or failure to thrive. A diagnostic sweat test reveals a high sodium content of the sweat. The respiratory effects of cystic fibrosis include respiratory failure as a result of increasing ventilation–perfusion mismatch, bronchiectasis and pulmonary haemorrhage. Other sequelae include cor pulmonale, clubbing, cirrhosis, portal hypertension, malabsorption or failure to thrive. Diabetes occurs in about 10% of children with cystic fibrosis.

Management includes physiotherapy, bronchodilator therapy and systemic and inhaled antibiotics. Preoperative preparation involves maximizing these therapies. Pulmonary function tests show a mixed obstructive and restrictive pattern and quantify the degree of impairment. A chest radiograph reveals the extent of chronic lung damage (Figure 1). The ECG may indicate right heart hypertrophy. If liver function is affected, clotting may be abnormal and require preoperative correction.

Premedication is not contraindicated, but some of these children will not tolerate sedation and anticholinergics are often avoided because they make secretions more difficult to clear. Pancreatic supplements, salt supplements and vitamins are continued. Following intubation, physiotherapy and suctioning of the bronchial secretions in the anaesthetic room is useful, particularly if surgery is likely to take a long time. Tracheal tubes and suction catheters must be used with a careful aseptic technique. Intravenous fluids are given routinely and prolonged periods of fasting avoided.

Postoperatively, frequent chest physiotherapy and effective pain management are essential. Supplementary regional analgesia is useful if coagulation is normal.



1 Chronic changes of cystic fibrosis seen on a chest radiograph include hyperinflation of the lung fields, bronchiectasis and peribronchial thickening.

Neurological and muscular disease

Developmental delay and autism

Many conditions result in a child who has difficulties with understanding or behaviour, and the effects vary. Causes of developmental delay include genetic abnormalities, severe cerebral palsy, complicated epilepsy or following head injuries or trauma. Autism is a disease of unknown cause that has a distinctive pattern of behaviour, starting in early childhood, which results in the child being unable to relate to other people. Children with autism tend to be quiet, have a short attention span, be withdrawn and solitary and appear unconnected to their environment. These children may find the process of admission to hospital very stressful.

Management: regardless of their disability, children must be treated sympathetically. The family will be able to indicate the best way to help the child feel comfortable and prepare for anaesthesia. It is important to involve the child whenever possible and a play specialist can be helpful. Assessment of the cause of any apparent distress can be difficult and many systems in routine use (e.g. pain scores) are of little use in these children. Some children benefit from premedication, but in others behavioural difficulties may increase following sedation. Fasting policies may be difficult to implement and these children are often best treated early on a theatre list and allowed home as soon as their family feel ready to continue their care.

Cerebral palsy

Cerebral palsy is a non-progressive neurological disorder that results in abnormalities of motor function. Learning difficulties occur in over 50% of these children. The disorder can be associated with birth asphyxia, preterm delivery and cerebrovascular insults (including intraventricular haemorrhage, congenital infection or metabolic disorders); however, in many cases the cause is unknown. The resultant physical and neurological effect in the child is variable. Limb spasticity is common, as is scoliosis, poor mobility, restrictive lung disease secondary to chest abnormalities, seizure disorder, gastro-oesophageal reflux, feeding problems and failure to thrive. Intelligence may be normal, but speech may be seriously affected and there is often developmental delay. Particular issues to consider include respiratory compromise, restricted lung function, associated infection, frequency of fits, developmental delay, sensory compromise and nutritional status.

Management: preoperative respiratory care with physiotherapy and bronchodilators, if used, is beneficial. There may be an increased risk of respiratory depression and aspiration (owing to oesophageal incoordination), therefore sedative premedication should be used cautiously. Some children are sensitive to the respiratory and sedative effects of opiates. Anti-epileptic medication is continued. Positioning for surgery can be difficult. Postoperative apnoea can occur and oxygen saturation monitoring is useful. Analgesics, such as paracetamol, diclofenac and codeine, are advised. Assessment of postoperative pain can be difficult because routine pain assessment tools are often unusable. An epidural is often successful as an adjunct to general anaesthesia during major abdominal or hip surgery. Painful muscular spasms are common, particularly after orthopaedic surgery, and are best treated with benzodiazapines. Intensive care may be needed postoperatively and weaning from the ventilator following major surgery can be difficult if restrictive lung disease is significant.

Hydrocephalus

Hydrocephalus can be congenital (associated with meningomyelocele as in the Arnold–Chiari malformation), acquired (as in post-haemorrhagic ventricular dilatation) or less commonly the result of tumours, cysts or meningitis. In the neonate and young infant, the skull can increase in size to accommodate additional fluid, but in the child with fused cranial sutures, signs of raised intracranial pressure, such as vomiting, headache or decreased level of consciousness, occur earlier. Treatment requires insertion of a ventriculoperitoneal shunt if the cause cannot be cured.

Management: preoperative assessment of the child's level of consciousness is important. Excessive vomiting may result in electrolyte disturbance. A blood cross-match is usually required. Tapping the CSF in the neonate provides temporary relief and a ventriculoperitoneal shunt is usually inserted later when the neonate's naturally high CSF protein levels have decreased and the risk of obstruction of the shunt is reduced, though there is no consensus in management. If a temporary external ventricular drain is used, the resultant loss of CSF volume must be replaced with intravenous saline.

Neuromuscular disease

Neuromuscular disease includes muscular dystrophies, myotonias, myopathies and myasthenia. In many children the cause of the myopathic disease is unknown. Common operations in this group of children include muscle biopsy, surgery for scoliosis, squint or talipes repair.

General considerations include the presence of associated conditions, particularly respiratory, cardiac or airway abnormalities. Abnormal responses to anaesthetic drugs can occur, including the potential for severe reactions to suxamethonium or other relaxants, sensitivity to sedatives or the risk of precipitating malignant hyperthermia.

Duchenne muscular dystrophy

Duchenne muscular dystrophy is a dominantly inherited, sex-linked disorder. It produces progressive muscle weakness resulting in death in late adolescence, usually as a result of respiratory failure or cardiac disease. It is the most common muscular dystrophy and occurs in about 1/3300 live male births. Presentation is with weakness, slow walking, clumsiness and classically pseudohypertrophy of the calf muscles.The associated features significant to anaesthesia are summarized in Figure 2. It is not associated with malignant hyperpyrexia though there have been some reports of a malignant hyperpyrexia-like syndrome occurring in children with Duchenne muscular dystrophy. Suxamethonium is contraindicated because it can cause acute hyperkalaemia, resulting in cardiac arrest, and is also associated with rhabdomyolysis. Preoperative assessment includes ECG, echocardiography, pulmonary function test, physiotherapy review, full blood count and urea and electrolytes.

Myopathies

Myopathies are a mixed group of conditions and present a wide spectrum of disease, which can be difficult to diagnose. The potential for metabolic instability, drug sensitivity to opiates, sedatives or muscle relaxants, and the associated risk of malignant hyperthermia, must be considered. Specific types should be reviewed in specialist textbooks. Of the congenital myopathies, central core disease is of most relevance to the anaesthetist because it is associated with malignant hyperthermia.

Associated features in Duchenne muscular dystrophy

Features	Effect
• Respiratory muscle weakness	Recurrent chest infection, sputum retention, long-term ventilation
• Scoliosis	
• Cardiac	Arrhythmias, mitral valve prolapse, ventricular dysfunction, sudden death
• Gastric distension	Risk of aspiration
• Sensitivity to sedation	
• Suxamethonium	Produces hyperkalaemia, cardiac contraindicated arrest, muscle rigidity, rhabdomyolysis

2

Myopathies
Myopathies are a mixed group of conditions and present a wide spectrum of disease, which can be difficult to diagnose. The potential for metabolic instability, drug sensitivity to opiates, sedatives or muscle relaxants, and the associated risk of malignant hyperthermia, must be considered. Specific types should be reviewed in specialist textbooks. Of the congenital myopathies, central core disease is of most relevance to the anaesthetist because it is associated with malignant hyperthermia.

Other conditions

Down's syndrome
Down's syndrome is one of the most common chromosomal disorders. It results in characteristic facial features, developmental delay, and problems with the airway, heart and joints. Specific anaesthetic issues include behavioural problems and difficulty with vascular access.

Snoring or sleep apnoea may be present and preoperative sedation is sometimes contraindicated because of the risk of obstruction. Both post-intubation stridor and subglottic stenosis are more common in children with Down's syndrome. Congenital heart disease (e.g. atrioventricular septal defects, Fallot's tetralogy) is present in 40% of children with Down's syndrome. Assessment by a paediatrician or cardiologist and echocardiography or ECG are useful. Antibiotic prophylaxis for the prevention of bacterial endocarditis is essential for most cardiac lesions.

Laxity of the ligaments of the neck at the atlanto-axial joint occurs in 15–18% of patients with Down's syndrome and the risk increases with age. C1–C2 dislocation and spinal cord damage can occur (Figure 3). Some centres routinely screen the cervical spine at regular intervals, but this practice is not widespread. Any child with Down's syndrome who has neurological symptoms, such as paraesthesia of the hands or motor instability, must be screened with flexion and extension views of the neck. Additional care must be taken with positioning these children during anaesthesia.

3 MRI of a child with Down's syndrome showing C1–C2 instability with spinal canal narrowing (arrow).

Renal disease
The most common cause of renal impairment in infants is pelvic renal dilatation from either posterior urethral valves or pelviureteric obstruction. In children, the causes include congenital abnormalities, glomerulonephritis or nephrotic syndrome. In the child with established renal disease and a degree of chronic renal failure, symptoms are unusual until the glomerular filtration rate is less than 25% of normal. Then chronic anaemia, failure to thrive, renal osteodystrophy, hypertension, metabolic effects of uraemia, acidosis, salt loss or hyperkalaemia become more common.

Management: Preoperative assessment includes haemoglobin level, urea and electrolytes and creatinine. Fluid and electrolyte requirements are variable and should be assessed and discussed with the renal team before surgery. A child on dialysis will require post-dialysis bloods, including clotting studies (if heparin is used as in haemodialysis). Surgery should be avoided soon after dialysis so that time is given for fluid shifts to occur. Arm vessels are preserved because they may be required later for vascular shunts.

Drugs best avoided in children with significant renal impairment include known nephrotoxic drugs (e.g. aminoglycosides, diclofenac) and drugs dependent on renal excretion. Suxamethonium is contraindicated in the presence of hyperkalaemia because of the potential of producing severe hyperkalaemia. Renal patients should not be fasted excessively and fluid replacement should be maintained carefully. Perioperative hypotension should be avoided. Regular antihypertensive medication should be continued. If hypertension is poorly controlled a review of medical management before planned surgery is wise.

Diabetes
Type 1 diabetes occurs in about 1/500 children and most commonly presents at 6–7 years or at puberty. Control of blood sugar levels can be difficult because of the changing nutritional and insulin needs of the growing child and because older children may be non-compliant with their therapy. The long-term complications of diabetes (retinopathy, autonomic neuropathy or nephropathy) do not occur in children before puberty and good metabolic control minimizes their development in adulthood.

Management: routine surgery in diabetic children usually requires that they be admitted the day before surgery. Their diabetes should be under good control and ideally they should be scheduled first on the theatre list. Preoperative measurements of urea and electrolytes and blood sugar are taken. Preoperatively, bedside blood sugar estimates are checked regularly and the urine screened for sugar and ketones. The morning dose of insulin is omitted and an infusion of 10% dextrose with added potassium is started with an infusion of soluble insulin (e.g. 50 ml syringe with 1 unit of insulin per ml), with the rate adjusted according to hourly sugar results. This is continued until the child returns to a normal diet and his insulin regimen is restarted.

If diabetic control is poor, or emergency surgery is required and the child is systemically unwell and has a high blood sugar (with or without ketoacidosis) it is best to treat the metabolic condition first because surgery in the ketoacidotic child is associated with a high morbidity.

Sickle cell disease
All children from ethnic groups with a high incidence of sickle cell disease should be screened preoperatively, unless their sickle cell status is known. Routine screening is with a *Sickledex* test, which, if positive, must be followed by haemoglobin electrophoresis to identify the relevant haemoglobin types present. *Sickledex* tests are unreliable in babies less than 3 months of age because they have a high percentage of fetal haemoglobin, therefore electrophoresis should be carried out instead. Sickle haemoglobin may occur in association with other haemoglobinopathies, such as thalassaemia. Sickle cell trait is associated with a normal haemoglobin level and HbS and HbA on electrophoresis. These children are managed routinely and do not have additional risks during carefully conducted general anaesthesia.

Management: the preoperative management of children with sickle cell disease is under review. All cases should be discussed with the haematologist so that the risks and benefits of blood transfusion before surgery are considered. Blood transfusions are avoided if possible, so that the development of antibodies and other complications related to blood transfusion do not occur. These would make later management of the disease more difficult, particularly if a bone marrow transplant were required. Many children with sickle cell disease have a mild course and few symptoms.

For minor surgery, exchange or top-up transfusion is not routine, though some centres will give blood to increase the haemoglobin levels to 10 g/dl.

For more extensive surgery, or in children with a history of severe disease (e.g. painful crises of the bones, joints, spleen, lung or brain) a regimen of exchange transfusion is undertaken in the weeks before surgery to raise the haemoglobin level above 10 g/dl and the percentage of HbS to less than 30%. In all these patients, careful anaesthesia is essential, ensuring that the child is kept warm, well hydrated and that additional oxygen is administered perioperatively and even transient episodes of hypoxia avoided. Use of tourniquets is contraindicated owing to the risks of acidosis and tissue hypoxia in the exsanguinated limb. In these children, most surgery requires antibiotic cover. Effective pain management is important so that mobility is encouraged and early chest physiotherapy can be used to minimize the likelihood of a sickle crisis occurring.

Mucopolysaccharidosis
There are many different forms of mucopolysaccharidosis, which are genetic abnormalities resulting from an inborn error of metabolism. The most common are Hurler's syndrome and Hunter's disease. Children with Hurler's syndrome have characteristic facies and often have obstructive airway symptoms. Depending on the abnormality present they develop learning difficulties, cardiac disease, kyphoscoliosis, respiratory failure and neck instability. The airway can be difficult to manage during anaesthesia (Figure 4).

4 Child with Hurler's syndrome illustrating the typical coarsened facial features that are associated with difficulties in managing the airway.

Oncological disease and chemotherapy
Many children's cancers are now treated successfully. Common childhood oncological diseases include leukaemia (most commonly acute lymphocytic leukaemia), cerebral tumours, neuroblastoma and Wilms' tumour. In most patients, care is shared between the tertiary referral centre and the local hospital. Anaesthetic implications are related to the disease or to the effect of treatment such as corticosteroids or cytotoxic drugs, some of which have specific renal, haemopoietic or cardiac toxic side-effects.

Management: most children require chemotherapy, multiple blood tests, blood component therapy and repeat anaesthesia. To assist this management, indwelling catheters (e.g. Hickman catheters, Portacath) are placed early after diagnosis. Children can become quite fond of their catheters. An aseptic technique is essential when accessing these catheters and if carefully looked after they may be kept for many months. These children are frequent attenders at hospital and they often have particular requests about the conduct of their anaesthesia and need sensitive management.

A full blood count should be available preoperatively. Additional investigations may include urea and electrolytes and clotting studies. Blood component therapy is often required before or during surgery. Blood products may need to be leucodepleted and irradiated in these children, and this should always be discussed with the oncology team. The requirements depend partly on the intended surgery and on local clinical guidelines. A platelet count of at least 100,000 is required for the insertion of indwelling intravascular catheters or general surgery. For a lumbar puncture, a platelet count above 50,000 is acceptable, providing the clotting results are normal. Epidural and caudal anaesthesia are often contraindicated because of coagulation abnormalities. These children are often immunocompromised and great care is needed to avoid potential infection. Suppositories are contraindicated if the child is neutropenic owing to the risk of infection.

Latex allergy
Sensitivity to latex products is the most common cause of anaphylaxis during anaesthesia. It is a type 1, IgE-mediated hypersensitivity reaction and can be severe. Children most at risk include those with:

- a history of sensitivity to latex (e.g. balloons, toys)
- atopy
- specific food allergies (e.g. kiwi fruit, chestnuts, avocado, banana) owing to cross-sensitivity to specific food proteins
- a history of repeated surgery (particularly urological surgery)
- spina bifida.

Children at risk should be screened with a radioallergosorbent test (RAST) and enzyme linked immunosorbent assay (ELISA). These tests are non-specific and up to 45% of patients with negative RAST tests have a positive skin test to latex, so this should be considered if the history is strong. The management of children at risk from latex allergy is debated. In many centres, children at risk from latex allergy are admitted for preoperative treatment with methylprednisolone, ranitidine and chlorpheniramine, each given 6-hourly intravenously, started 12 hours preoperatively and continued for 24 hours postoperatively. This management precludes the use of day-care surgery and therefore the use of such regimens has been questioned and in some centres abandoned in favour of providing a latex-free environment for all children in the group at risk. It would seem wise to try to prevent sensitization of any patients by avoiding exposure of a child in an at-risk group to latex.

Long-term corticosteroid use

The long-term use of corticosteroids may occur in severe asthma, juvenile arthritis, nephrotic syndrome, in many chemotheraputic regimens and in replacement therapy for adrenal or pituitary failure or congenital adrenal hyperplasia. Long-term corticosteroid therapy can result in steroid facies, hypertension and diabetes. Children at risk of having inadequate endogenous corticosteroid production require additional cover during surgery. The dose of replacement corticosteroids is debated and more is probably given than is required.

- Give children taking regular corticosteroid therapy, hydrocortisone, 1 mg/kg i.v. on induction and 6-hourly until their routine corticosteroid treatment restarts.
- In children who have used corticosteroids in the last 2 months give hydrocortisone, 1 mg/kg i.v. until 24–48 hours postoperatively.
- Children who have had inhaled corticosteroids, for example in asthma medication, do not require additional corticosteroid perioperatively.

Cleft Lip and Palate

John Currie

John Currie is Consultant Anaesthetist at the Royal Hospital for Sick Children, Glasgow. He qualified from Liverpool University and trained in Paediatrics in Edinburgh, and then in anaesthesia in Liverpool; Great Ormond Street, London; and the Children's Medical Centre, Dallas, Texas. His interests include paediatric plastic surgery, spinal surgery and chronic pain in children.

Cleft lip and palate occur in 1.5/1000 live births. Cleft palate alone has an incidence of 0.5/1000 live births. Accompanying congenital abnormalities may be present (e.g. Pierre Robin syndrome). Often there are supernumerary teeth or absence of the incisor in line with the cleft. There may also be widening of the middle portion of the face (telecanthus) or even true hypertelorism. Several operations may be required to correct these abnormalities.

Cleft lip

Cleft lip is best repaired in the neonatal period. This produces a better scar and reduces the mother's emotional stress. Babies with congenital abnormalities are often premature and surgery should be delayed until feeding is well established and any other congenital abnormalities, respiratory problems or jaundice have been identified and treated. A detailed history of the baby's post-natal progress is essential.

Anaesthesia – babies with cleft palate tend to have enlarged tongues and micrognathia. Therefore, an inhalation induction may be preferred. Once the anaesthetist has confirmed that he can ventilate the lungs, a muscle relaxant may be given to facilitate intubation (a south-facing RAE tube is preferred to give good surgical access). A mouth pack is then inserted in case of intraoperative bleeding. Perioperative analgesia can be provided with an infra-orbital block, though the surgeon may prefer to inject local anaesthetic and adrenaline (epinephrine) to optimize the field. At the end of surgery, it is essential to remove the tracheal tube when the baby is awake to prevent laryngeal spasm.

Surgery also involves improving the appearance of the ipsilateral nostril (which is always flattened) by moving tissue medially from the lateral side of the cleft and repositioning the displaced cartilage. To maintain this position, the surgeon often sews a piece of sponge into the nostril. This may impair breathing postoperatively, so a small length of feeding tube should be included in the sponge, to provide an airway.

Postoperative care – babies may have difficulty feeding postoperatively and be unsettled (perhaps due to numbness of the lip from local anaesthetic). This can be helped by giving codeine phosphate, 1 mg/kg i.m., before extubation. Once feeding is re-established, paracetamol (regularly for 24 hours) maintains analgesia.

Cleft palate

Cleft palate should be repaired ideally at about 6 months of age. This is when the baby is learning to imitate speech, and is using the levator palatini and the aponeurotic tensor palatini muscles to close the velo-pharangeal aperture to make oral (as distinct from nasal) sounds. Modern techniques involve repositioning these muscles to obtain normal palatal function.

Anaesthesia – no premedication is required and (in the absence of other serious airway anomalies) intubation seldom presents a problem. A south-facing RAE tube is preferred. Before repair, the surgeon inserts a Boyle–Davies gag to open the mouth and provide access. It is essential to check the tracheal tube position carefully because it is often kinked or pushed into a main stem bronchus by the gag. Bilateral air entry should be checked by listening with a stethoscope after the gag has been positioned. Local anaesthetic and adrenaline (epinephrine) help to produce a dry field and analgesia. However, it is also wise to give an opiate (e.g. fentanyl, 1 μg/kg) to avoid tachycardia if the surgeon strays beyond the 'blocked' area (particularly likely when making lateral 'relieving' incisions to facilitate a difficult repair). Codeine, 1 mg/kg i.m., before extubation is useful, especially if combined with rectal diclofenac at induction. Diclofenac and paracetamol should then be given regularly for 24 hours, with paracetamol 'as required' thereafter.

Postoperative care – the repair tends to lift the palate towards the roof of the nasopharynx, narrowing the airway (which may be worsened by spasm of the levator palatini) and causing upper airway obstruction after extubation. The obstruction may be overcome by inserting a nasopharyngeal airway (usually a tracheal tube one size less than that used for intubation). Ideally the surgeon should insert this before removing the gag if the repair is 'tight'. The nasopharyngeal airway must be kept patent postoperatively (e.g. by suction). These babies should be nursed on a high dependency unit.

Fistula repair

The child may require further operations if it is impossible to close the cleft completely or the repair breaks down. Occasionally, a tongue flap is needed to provide enough tissue to close an anterior fistula. Initially, the surgeon fashions the flap and attaches it to the defect in the roof of the mouth. These children should be nursed on a high dependency unit for 24 hours. The child returns 2 weeks later for division of the flap. Intubating a child with its tongue attached to the roof of the mouth is challenging and best achieved fibre-optically by the nasal route. This can be practised during anaesthesia for the first stage to determine the most suitable nostril and the optimum position for the best view.

Alveolar bone graft

The final stage of repair is to close the defect in the alveolar arch (usually at about 8–9 years of age) using bone from the iliac crest. Postoperatively, infusion of local anaesthetic subcutaneously at the donor site provides excellent analgesia. ◆

Common Local Anaesthetic Techniques in Children

Pam Cupples
Roddie McNicol

Pam Cupples is Fellow in Paediatric Anaesthesia at the Royal Hospital for Sick Children, Glasgow, UK.

Roddie McNicol is Consultant in Paediatric Anaesthesia at the Royal Hospital for Sick Children, Glasgow, UK.

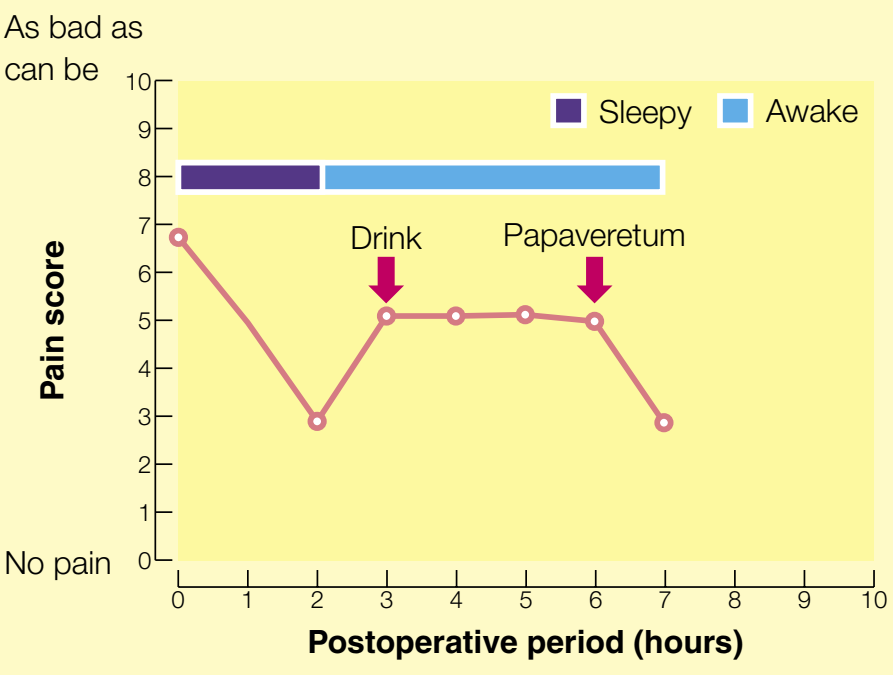
Paediatric regional anaesthesia is not a scaled-down version of adult practice. It is important to be aware of the anatomical and pharmacological differences between children and adults and to apply that knowledge appropriately so that regional anaesthesia becomes an integral part of day-to-day practice.

In children, regional analgesia is usually combined with a general anaesthetic to provide balanced anaesthesia. The depth of anaesthesia can be reduced because regional blocks provide excellent intraoperative analgesia and a predictable period of postoperative pain relief. Local anaesthetic techniques combined with mild-to-moderate oral analgesics, such as paracetamol or non-steroidal anti-inflammatory drugs (NSAIDs), decrease the requirements for opioids and reduce the incidence of unwanted side-effects (e.g. nausea and vomiting, respiratory depression, excess sedation).

The advantages of regional anaesthesia in the postoperative period are shown in Figure 1. Both children received similar anaesthetics, but different analgesics. The boy given the penile block had excellent pain relief for almost 8 hours before he became uncomfortable and required simple analgesics. The girl given papaveretum had poorer pain control complicated by side-effects (e.g. vomiting).

Contribution of regional anaesthesia during and after surgery

12-year-old girl given papaveretum during and after surgery



5-year-old boy given a penile block

Applying local anaesthesia

Topical anaesthesia

The ability of local anaesthetics to penetrate intact skin and produce anaesthesia and analgesia proved to be a difficult pharmacological challenge until the development of a eutectic mixture of local anaesthetic (*Emla* cream) in the 1980s. *Emla* is an oily emulsion containing 25 mg/ml each of lidocaine (lignocaine) and prilocaine. 'Eutectic' refers to the lowering of the melting points, the physical transformation that occurs when lidocaine (lignocaine) and prilocaine crystals are mixed together in equal quantities. When applied to the skin under an occlusive dressing for 60–90 minutes, the emulsion produces analgesia of the skin which is useful for:

- venepuncture
- division of prepucial adhesions
- myringotomy and ventilation tube insertion when applied to the tympanic membrane
- minor surgical procedures when given before superficial infiltration of local anaesthetic.

Emla occasionally causes transient blanching of the skin owing to vasoconstriction of blood vessels, and erythema and oedema, which can make cannulation difficult. Ingestion of the occlusive dressing and *Emla* cream have both been described, and methaemoglobinaemia has occurred in a child following application of *Emla* cream over a large area, leading to systemic absorption and toxicity.

A new alternative to *Emla* is tetracaine (amethocaine) 4% gel (*Ametop*), which provides more rapid and longer-lasting analgesia before venous cannulation.

Mucosal analgesia

Topical analgesia of mucosal surfaces is simple and effective, and can be used for the following indications:

- strabismus surgery, using 0.4% oxybuprocaine hydrochloride eye drops into the conjunctival sac before the conclusion of surgery
- circumcision, using 2% lidocaine (lignocaine) gel applied at the end of surgery or during the postoperative period
- anal stretch for the treatment of anal fissures, using lidocaine (lignocaine) gel.

Instillation of local anaesthetics

Local anaesthetics can be instilled directly into wounds (e.g. inguinal hernia). The analgesia is of shorter duration, but can equal that produced by an iliohypogastric/ilioinguinal nerve block.

Local anaesthetic can also be instilled before cleaning or suturing small superficial wounds in the Accident and Emergency Department. The local anaesthetic can be applied either by dropping it on to the wound or applying a swab soaked in the local anaesthetic. Solutions of either lidocaine (lignocaine) or bupivacaine combined with a vasoconstrictor, such as adrenaline (epinephrine), are most commonly used.

The technique of instillation can be useful in children requiring regular dressing changes (e.g. split skin graft donor sites); the wound dressing can be soaked with a combination of local anaesthetic and adrenaline (epinephrine). Alternatively, an epidural catheter can be incorporated into the wound dressing and local anaesthetic (e.g. 0.125% or 0.25% bupivacaine with 1:400,000 adrenaline (epinephrine)) can be continuously infused on to the wound at a rate of 1–3 ml/hour. Care must be taken not to exceed the maximum recommended dose of 0.5 mg/kg/hour or 2 mg/kg/4 hours.

Infiltration

The infiltration of local anaesthetics, alone or combined with vasoconstrictors, is used regularly to provide anaesthesia and analgesia for many operations (e.g. suturing superficial wounds, or excision of cysts, accessory auricles, naevi). It is particularly useful in the neonate undergoing pyloromyotomy; infiltrating the wound edge before completion of surgery can produce excellent postoperative analgesia. Combined with paracetamol, this avoids the use of opioids and reduces the incidence of side-effects, particularly respiratory depression or apnoea.

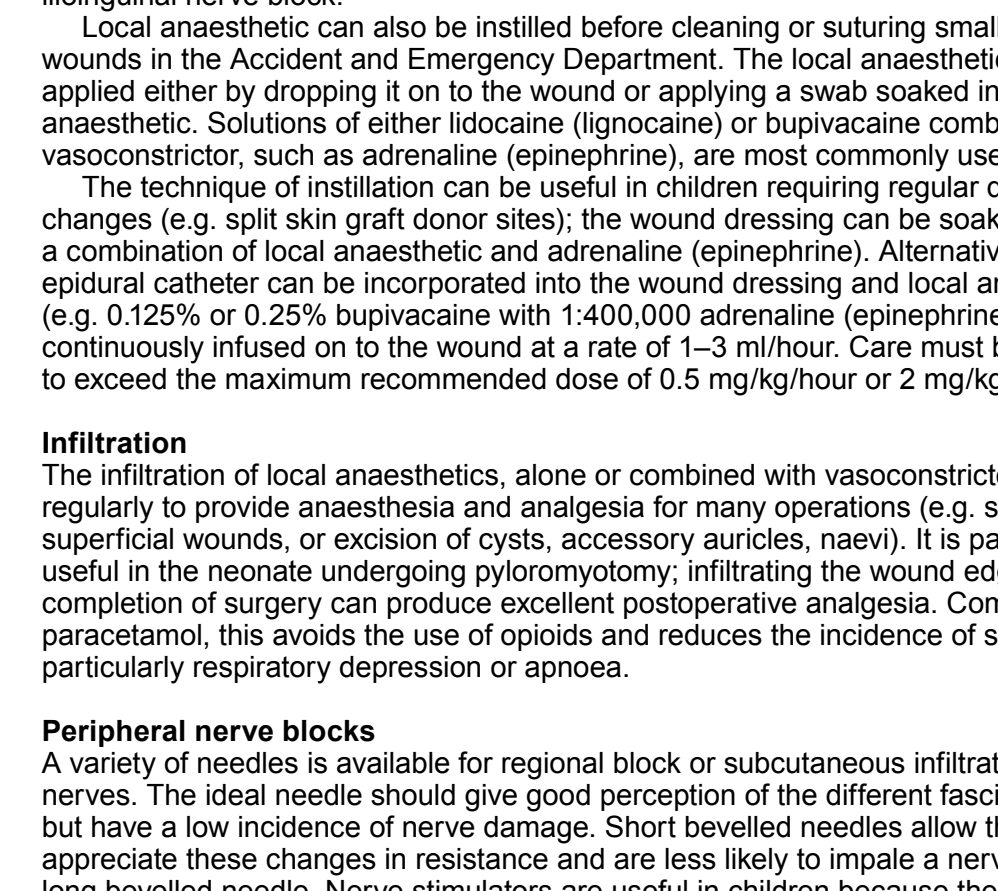
Peripheral nerve blocks

A variety of needles is available for regional block or subcutaneous infiltration of nerves. The ideal needle should give good perception of the different fascial planes, but have a low incidence of nerve damage. Short bevelled needles allow the user to appreciate these changes in resistance and are less likely to impale a nerve than a long bevelled needle. Nerve stimulators are useful in children because their anatomy is variable and most children are anaesthetized before the block therefore the technique of paraesthesia cannot be used.

Great auricular nerve block is used for pinnaplasty; a common operation in children. The sensory supply of the ear is largely from the great auricular nerve derived from the superficial cervical plexus (Figure 2).

The great auricular nerve divides into pre- and post-auricular branches, which can be blocked by infiltrating the tip of the mastoid process anteriorly and posteriorly with 2–3 ml of local anaesthetic (Figure 3). A branch of the mandibular division of the trigeminal nerve, the auriculotemporal nerve, supplies the external auditory meatus and the temple region. This can be blocked by infiltrating a further 2–3 ml of local anaesthetic anterior to the external auditory meatus.

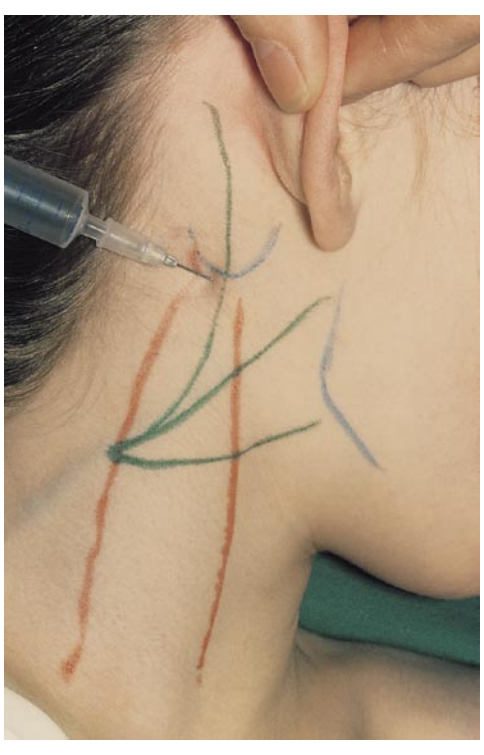
Great auricular nerve block



2

Infraorbital nerve block is excellent for providing analgesia for neonates undergoing cleft lip repair. It removes the need for opioids and reduces the risk of respiratory depression or apnoea. This is particularly important because these neonates are often either preterm or have associated congenital anomalies.

The infraorbital nerve is a branch of the maxillary division of the trigeminal nerve and provides the sensory innervation to the skin and mucus membranes from upper lip to the lower eyelid and medially to the side of the nose. The landmark for locating the infraorbital nerve is found by drawing a line from the angle of the mouth to the midpoint of the palpebral fissure; the nerve is situated about halfway along this line and can be approached either percutaneously or buccally (Figure 4). For the percutaneous technique a 25 G needle is used and is introduced perpendicular to the skin and advanced until bony resistance is felt. The needle is then withdrawn slightly and, following a negative aspiration test, the local anaesthetic (usually 0.5% bupivacaine, 0.5–0.75 ml with 1:200,000 adrenaline (epinephrine)) is injected.



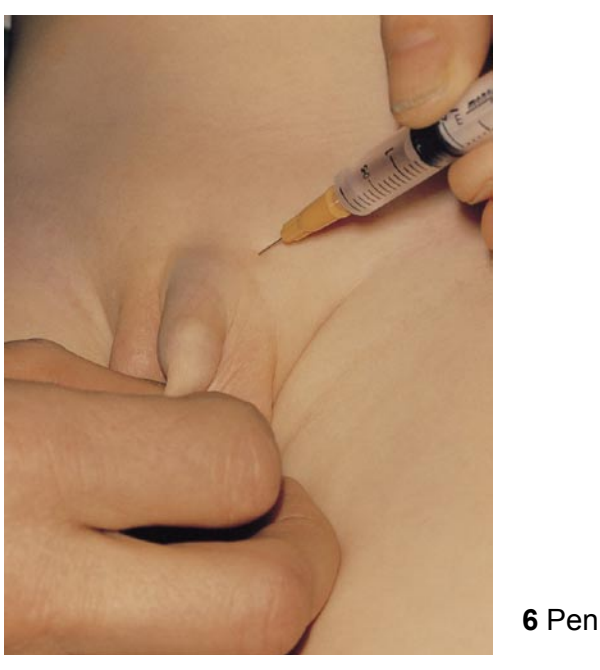
3 Site of great auricular nerve block.

4 Landmarks for infraorbital nerve block. A line is drawn from the angle of the mouth to th emidpoint of the palpebral fissure. The nerve is situated about half way along this line.

5 Ilioinguinal and iliohypogastric nerve block. X marks the position of the anterior superior iliac spine.

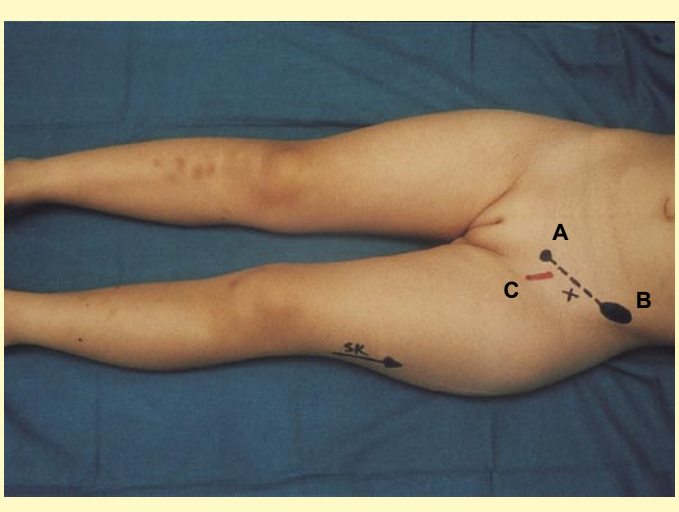
Combined ilioinguinal and iliohypogastric nerve block provides anaesthesia and postoperative analgesia for operations in the groin. These nerves are derived from T12, L1 and L2. A 22 G short bevelled needle is inserted at a point one patient's fingerbreadth medial to the anterior superior iliac spin (Figure 5). The needle is inserted perpendicular to the skin. A 'pop' is felt as the needle passes through the aponeurosis of the external oblique. After a negative aspiration test, about one-third of the local anaesthetic is injected at this point. The needle is then withdrawn and redirected caudally and laterally until it strikes the ilium, and a further third of the solution is injected. The remaining local anaesthetic is injected as the needle is withdrawn.

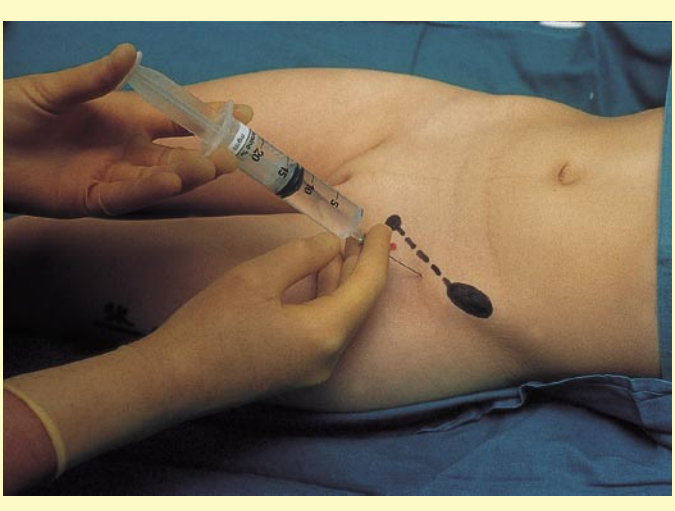
Genitofemoral nerve block: if the child is undergoing an orchidopexy, the genital branch of the genitofemoral nerve has to be blocked. Depositing one-third of the solution adjacent to the pubic tubercle and infiltrating subcutaneously across the midline blocks the genital branch and any innervation from the contralateral nerve. 0.25% bupivacaine, 2 mg/kg, is the recommended safe dose. In the older child, 0.5% bupivacaine may be used.



6 Penile block.

Penile block: the dorsal nerve of the penis is the terminal branch of the pudendal nerve (S2, 3 and 4) and is commonly blocked to provide postoperative analgesia following circumcision. The patient lies supine and a short bevelled needle is inserted 0.5–1.0 cm lateral to the pubic symphysis (Figure 6), depending on the age of the child. The needle is advanced posteriorly, caudally and medially; a 'pop' is felt twice as the needle penetrates the superficial fascia then Scarpa's fascia. Plain 0.5% bupivacaine, 0.1 ml/kg, is then injected. Vasoconstrictors should never be added to the local anaesthetic solution because of the risk of ischaemia.
Fascia iliaca block: the femoral, lateral cutaneous and obturator nerves can be blocked with a single injection using the fascia iliaca compartment block devised by Dalens. It has superseded the femoral '3 in 1' block because it is a simple technique with a high success rate (particularly in children) and lower complication rate. The fascia iliaca block can be used for a number of operations on the hip and thigh, for example femoral osteotomy, reduction of femoral fracture, surface operations on the thigh, femoral biopsies and the removal of metal screws and plates from the femur. The child lies supine and an imaginary line is drawn between the anterior superior iliac spine and the pubic tubercle (Figure 7).





7

This line is divided into thirds and the junction of the lateral with the medial two-thirds is located. A short bevelled needle is inserted at an angle of 60° about 0.5 cm below this point. As the needle is advanced, two 'pops' are felt as the needle penetrates the fascia lata then the fascia iliaca. The needle is aspirated to ensure that it is not lying intravascularly and the local anaesthetic is then injected. 0.25% bupivacaine can be used alone or in combination with 1:200,000 adrenaline (epinephrine) and the recommended doses are given in Figure 8.

Dosing guidelines for fascia iliaca nerve block

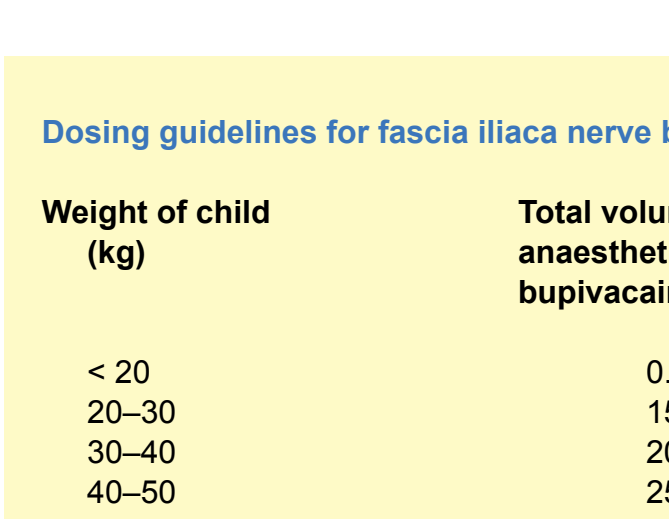
Weight of child (kg)	Total volume of local anaesthetic (0.25% bupivacaine ml/kg)
< 20	0.7
20–30	15
30–40	20
40–50	25
> 50	27.5

8

Metacarpal and metatarsal blocks are used for operations on the fingers and toes, respectively. These techniques are simple and provide good intraoperative and postoperative analgesia. They are preferred to blocks within the digits because the digits are small and injecting large volumes into a confined space can damage the end artery, producing ischaemia or distorting anatomy and impairing surgical access. The common digital nerves are derived from the ulnar and median nerves, and divide into dorsal and ventral branches in the distal palm. They run on the dorsolateral and ventrolateral aspects of the digit, respectively, and are accompanied by the digital vessels.

To perform a metacarpal block, a short bevelled needle is inserted through the skin on the dorsal aspect of the hand adjacent to the proximal end of the metacarpal bone and advanced until it can be felt by the operator's hand on the palmar surface (Figure 9). Following a negative aspiration test, 0.25% bupivacaine , 0.5–1.0 ml, is injected until a small swelling is felt. The technique can be repeated at several interspaces, depending on the number of digits involved.

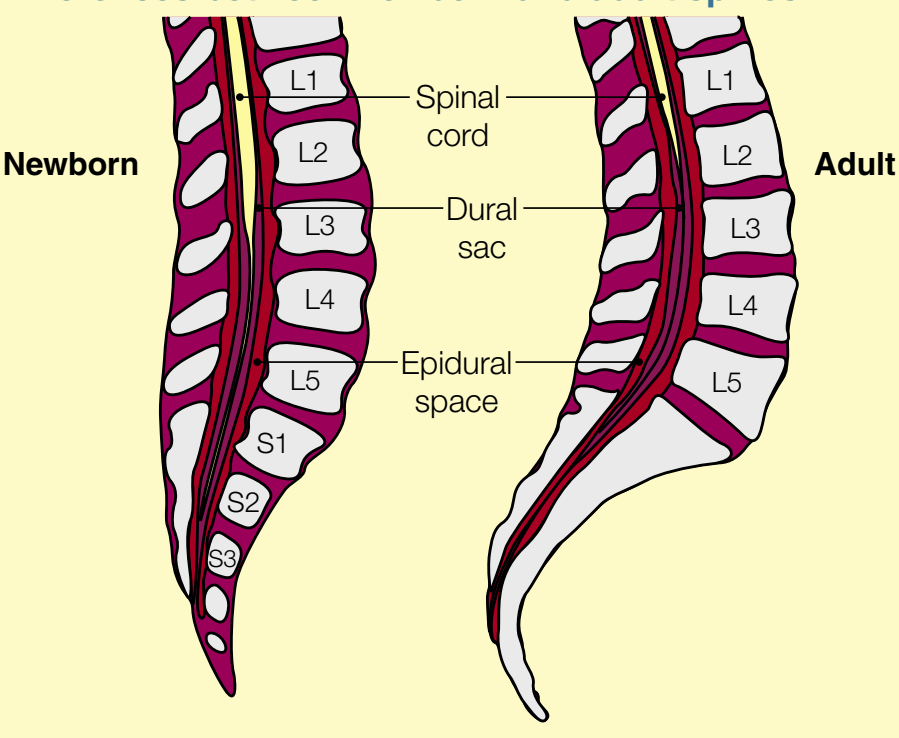
Analgesia of the toes can be obtained similarly with a metatarsal block. A needle is inserted through the skin on the dorsum of the foot at the proximal end of the metatarsal bone. 0.25% or 0.5% bupivacaine, 0.5–1.0 ml, is injected. Vasoconstrictors should not be added because of the risk of ischaemia.



9 Metacarpal block.

Central neuroaxial blocks
There are important anatomical differences between babies, children and adults (Figure 10). Following neuroaxial blockade in children, there is less haemodynamic instability because of the immaturity of the sympathetic nervous system and less pooling of blood in the legs.

Differences between newborn and adult spines



The tip of the spinal cord lies at L3 at birth and the dura extends to S2–3. Only at the age of 1 year does the cord assume the adult position of the L1–2 interspace and the dural level of S2. The intercristal line in the neonate lies at the level of L5–S1 and in the slightly older child at L5

10

Spinal anaesthesia
Spinal anaesthesia is most commonly used in neonates or ex-premature babies for operations of short duration on the lower abdomen (e.g. hernia repair, orchidopexy). There is a 10% absolute failure rate for this technique as well as a 10% rate of inadequate blockade.

In the neonate, the CSF pressure is low and many therefore recommend the use of a 22 G Quincke point needle, which allows better flow of CSF once in the spinal canal. A short bevelled needle allows better perception of the 'pops' as the needle traverses the posterior spinal ligaments and dura. Atraumatic tipped spinal needles (Whitacre needles) are not recommended for neonates because of the tendency of the orifice of the needle to straddle the dura. The incidence of post-dural puncture headaches is low in neonates, but increases as the child ages. It is therefore prudent to use a smaller-gauge needle (e.g. 26 G) in older children and adolescents.

Either hyperbaric or isobaric 0.5% bupivacaine can be used. If hyperbaric bupivacaine is used, the appropriate dose can be calculated using the formula: 0.06 ml/kg + 0.1 ml. If isobaric bupivacaine is used, the dose is 1 mg/kg. As a guide, the distance from the skin to the subarachnoid space is 10 mm in a full-term baby and 7 mm in a premature baby. Spinal anaesthesia lasts for 20–110 minutes, but the block is unreliable for operations longer than 40 minutes.

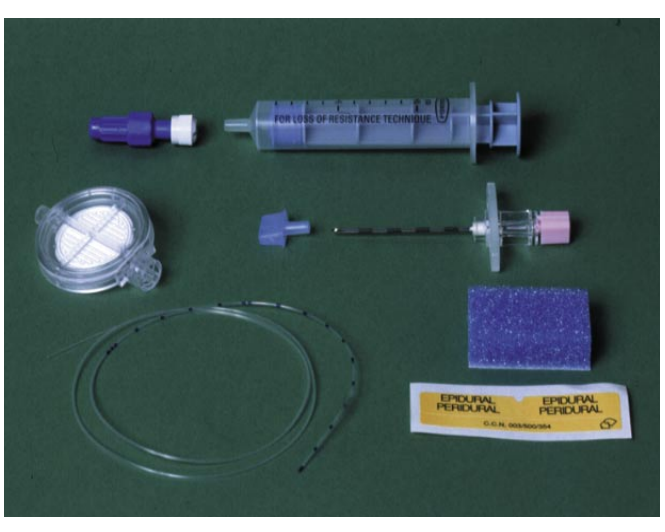
One of the main indications for performing spinal anaesthesia is to reduce the incidence of postoperative apnoea, which can be a problem following general anaesthesia. If spinal anaesthesia is used, it is of paramount importance to monitor the baby postoperatively for oxygen saturation and apnoea.

Epidural anaesthesia
Epidural analgesia (usually combined with general anaesthesia) is useful for orthopaedic surgery on the legs, orchidopexy and operations involving the perineum. Commercially available paediatric epidural kits are available (i.e. 18, 19, 20 G Tuohy needles with 21 G, 23 G and 24 G catheters, respectively; Figure 11). The 18 G Tuohy needle with its 21 G catheter can be used in babies weighing more than 3 kg; the larger gauge of catheter allows better flow of blood, if the catheter has breached an epidural vessel, or CSF, if the catheter has traversed the dura inadvertently. There are fewer technical problems, such as kinking and blocking, with the larger gauge of catheter.

A guide to the depth of the lumbar epidural space in children can be calculated according to either their age or weight (e.g. (body weight in kg + 10) x 0.8 mm). Alternatively, for children 6 months to 10 years of age, the distance to the epidural space is about 1 mm/kg body weight.

In children, the epidural space can also be accessed through the sacral intervertebral spaces, because the sacrum does not ossify until the age of 25–30 years.

The complications following epidurals in children are similar to those seen in adults and include:
- dural puncture with total spinal block
- post-dural puncture headache – age increases incidence
- hypotension – uncommon in children less than 6 years old
- nerve damage – occasionally the catheter may press against nerve roots
- infection
- urinary retention
- unilateral or patchy blocks.



11 Paediatric epidural kit containing 19 G, 5 cm Tuohy needle with 23 G catheter.

Epidurals are most commonly inserted in the lumbar region and then threaded to the appropriate dermatomal level. The epidural space in children contains gelatinous fat globules instead of the densely packed fat divided by fibrous bands found in adults. This allows more longitudinal spread of local anaesthetic within the space and makes it possible to thread a catheter the entire length of the vertebral column. The volume of local anaesthetic required can be calculated using the formula devised by Takasaki for caudal anaesthesia (Figure 12), which may also be applied to lumbar epidural anaesthesia. Alternatively, 0.25% bupivacaine, 0.5–1 ml/kg can be used for lumbar epidurals and half this dose for a thoracic block.

Formulae for calculating the volume of local anaesthetic for caudal block

Armitage
- Lumbosacral blocks = 0.5 ml/kg of 0.25% bupivacaine
- Thoracolumbar = 1 ml/kg of 0.25% bupivacaine
- Mid-thoracic = 1.25 ml/kg of 0.25% bupivacaine

Takasaki
- Volume = 0.05 ml x body weight x no. of spinal segments to be blocked

12

Caudal anaesthesia
Caudal anaesthesia is a simple and safe technique. It is performed by injecting local anaesthetic through the sacral hiatus, which is easily palpated as a dimple flanked by the sacral cornua (Figure 13).

Single-shot caudal blocks can be performed using either a short (2.5 cm) 23 G intramuscular needle, a short bevelled needle with a solid obturator, or a 22 G cannula. However, the risks of vascular penetration or the production of a dermoid cyst due to implantation of skin are recognized problems that favour the use of the cannula technique. The technique of insertion is different depending on the age of the child. In babies, the needle should be inserted in the centre of the hiatus at an angle of 15° to the skin because of the flatness of the sacrum. In older children, the needle is placed at the apex of the hiatus at an angle of 45° to the skin. For continuous caudal anaesthesia, a 20 G intravenous cannula can be used ensuring the cannula is not advanced too far up the caudal space for fear of damaging the dura. A catheter (23 G) from a 19 G epidural set can then be passed easily through the cannula to the desired dermatomal level.

Congenital Heart Disease

Monica Stokes

Monica Stokes is Senoir Lecturer in Paediatric Anaesthesia and Honorary Consultant at University Hospital, Birmingham, UK, and Birmingham Children's Hospital. She qualified from the University of Nottingham and trained in anaesthesia in Cambridge, Bristol and Birmingham. She has held Fellowships in Australia and the USA. Her clinical interests include anaesthesia for paediatric cardiac surgery, neonatal surgery and ethical issues in contemporary anaesthesia practice.

The incidence of congenital heart disease (CHD) is about 6–8/1000 births, and is more common in premature infants. There is a broad range of lesions and severity, with differing implications for morbidity and life expectancy. The multifact-orial causes include known teratogens such as maternal alcohol, rubella, and diabetes. In some instances there is an association with a chromosomal abnormality (e.g. trisomy 21, Down's syndrome), or other recognized pattern of malformation or syndrome. Significant musculoskeletal defects such as diaphragmatic hernia, exomphalos, tracheo-oesophageal fistula, and imperforate anus may co-exist.

The pathophysiological effects of CHD vary with the nature of the lesion and change as time passes. Some septal defects, for instance, close spontaneously without medical intervention. Other lesions tend to worsen as the child grows, and some are lethal without intervention. Therefore, regular evaluation of anatomical and functional status is essential. There is often an optimal time for surgical intervention to achieve the best outcome, and many defects are palliated or treated at an early age.

Pathophysiology

Classifications of CHD based on detailed anatomical descriptions are unhelpful for practical purposes because it is the pathophysiology that determines the presentation, natural history and management of a particular condition. A simple distinction between cyanotic and acyanotic is too broad, however, because it gives no sense of the potential for systemic and pulmonary circulatory patterns to change. It is more useful to consider whether the dominant lesion is a shunt between systemic and pulmonary circulations, with increased or decreased pulmonary blood flow, or obstruction to systemic or pulmonary blood flow (Figure 1).

Simple classification of congenital heart disease

Lesions causing primary left-to right shunts
- Patent ductus arteriosus
- Atrial septal defect
- Ventricular septal defect

Lesions causing primary right-to-left shunts
- Transposition of the great vessels
- Tetralogy of Fallot
- Tricuspid atresia

Lesions obstructing ventricular function
- Left heart
  - Coarctation of the aorta
  - Aortic stenosis
  - Mitral stenosis
- Right heart
  - Pulmonary stenosis

1

Shunts

A shunt is a communication between systemic and pulmonary circulations. It may occur outside the heart (e.g. collateral vessels, patent ductus arteriosus) or within it (at atrial, ventricular, or great artery level). It may be a component of the congenital heart lesion or be created to palliate it. (A conduit, by contrast, is a channel fashioned between vessels or chambers normally in continuity.)

The magnitude and direction of blood flow across a shunt are determined primarily by the size of the communication and by the relative resistances of the pulmonary and systemic circulations.

• A dependent shunt is one where the flow varies according to the relative resistances of the vascular beds. It may be left-to right or right-to-left.

• A small communication may be restrictive in that systemic and pulmonary vascular resistances are less important in determining the amount of shunting. This is usually the case in children with mild heart disease that is asymptomatic or minimally symptomatic (e.g. small artial septal defect, ventricular septal defect, patent ductus arteriosus).

• A non-restrictive defect is defined as one across which no pressure gradient exists, the direction and degree of shunting being determined by the relative compliances of the two atria and ventricles.

• An obligatory shunt occurs when resistances are fixed and flow occurs because of pressure differences of an order of magnitude.

Shunting may be essential for survival: a patent ductus arteriosus for instance, may supply the pulmonary blood in pulmonary atresia or the systemic flow in aortic atresia. In other words, where there is partial or complete obstruction to a circulatory path, a communication at another level is necessary.

Left-to-right shunts

Children with left-to-right shunts are typically pink with pulmonary plethora on chest radiography. The physical signs reflect the shunt volume. The cardiac chambers enlarge and hypertrophy to cope with the excessive volume and increased flow across a valve causes a murmur.

Unchecked, volume overload can lead to ventricular failure, and sustained high pulmonary blood flow damages small peripheral pulmonary arteries. This damage consists of medial hypertrophy of the arterial wall, followed by intimal damage and ultimately elevated pulmonary vascular resistance, which may be irreversible. At this point, flow through the shunt diminishes and eventually reverses, the patient becoming cyanosed (Eisenmenger reaction).

Atrial septal defect

The secundum atrial septal defect is the most common type of interatrial communication. It is a true defect of the atrial septum, unlike the more complex ostium primum septal defect. The direction of blood flow is determined by the relative compliances of the two atria and ventricles, which in the newborn are equally thick walled. Shunting between the atria does not occur until the pulmonary vascular resistance has fallen after birth, and the right ventricle has become more compliant.

Of the excessive blood returning to the left atrium, enough enters the left ventricle to sustain a normal systemic output
but a greater volume is recirculated through the atrial defect, right heart and lungs. Flow through the pulmonary circulation can be three times that through the systemic circulation, producing the characteristic mid-diastolic tricuspid flow murmur, pulmonary ejection murmur, and prolonged right ventricular ejection.

Some infants with isolated interatrial communications develop symptoms of intractable congestive heart failure and failure to thrive. Many children are initially asymptomatic but with time, particularly if a large shunt (2:1 or greater) persists through childhood, pulmonary vascular disease and arrhythmias can develop.

Large defects may be closed surgically but it is possible to occlude smaller defects with devices placed percutaneously under radiological imaging, avoiding the need for cardiopulmonary bypass.

Ventricular septal defect

In ventricular septal defect, blood flows from the left to the right ventricle in systole and recirculates through the lungs. Both ventricles and the left atrium dilate and the liver enlarges secondary to right ventricular volume overload.

A large defect may present in early infancy with tachypnoea and failure to thrive, because the lungs are stiff and non-compliant. The high left ventricular pressure is transmitted to the pulmonary circulation and the hypertensive pulmonary arteries may compress small airways. Therefore, respiratory tract infections are common. Both ventricles enlarge making the chest wall bulge and the apical beat is typically forceful.

The characteristic murmur is pansystolic, and when the pulmonary flow is more than about twice systemic, a mitral diastolic murmur appears. As pulmonary vascular resistance increases, the pulmonary artery diastolic pressure rises; pulmonary flow decreases, and the mitral diastolic murmur disappears. Eventually, when the pulmonary vascular resistance approaches systemic levels, the pansystolic murmur shortens and disappears. On chest radiography the enlarged heart becomes small and the plethoric lung field become oligaemic with pruning of the peripheral vessels.

Medical management depends on the size of the defect. Most defects are small and close spontaneously. About 10% of the larger defects will also close. In some patients, obstruction to the right ventricular outflow tract develops. These patients become cyanosed, the physiology coming to resemble that of tetralogy of Fallot. Pulmonary vascular disease develops if the defect remains large so surgery is often performed in infancy.

Patent ductus arteriosus

Patent ductus arteriosus is a shunt at arterial level and flow occurs during both systole and diastole. The magnitude of shunting is dependent on the size of the duct and the relative resistance of the pulmonary and systemic vascular beds. There is a continuous flow of blood from the aorta to the pulmonary artery, producing a continuous murmur. If the ductus is large, pulmonary venous return is high, the left heart is overloaded and so the apical impulse is prominent and a mitral mid-diastolic flow murmur is heard. During diastole the blood 'steals' from the aorta to the pulmonary artery, and therefore the aortic diastolic pressure is low and the upstroke of the pulse is abrupt as blood is ejected into an empty aorta. This produces the characteristic bounding pulse.

Most children with patent ductus arteriosus are asymptomatic. Premature babies, however, are often symptomatic. The work of breathing is increased and attempts to wean from mechanical respiratory support are unsuccessful.

Treatment with indomethacin is often successful in promoting closure of the ductus but when it fails, surgical ligation is indicated via a left thoracotomy. It is extremely unlikely that a patent ductus arteriosus will close spontaneously after 1 year.

A large duct can lead to progressive pulmonary vascular disease, while those with smaller shunts are at risk for endocarditis, aneurysm, calcification and paradoxical emboli. Nowadays, it is common for ducts in older children to be occluded by devices placed percutaneously at cardiac catheterization.

Pulmonary venous obstruction

Patients with pulmonary venous obstruction may be cyanosed or acyanotic but have signs of pulmonary oedema clinically and on chest radiography.

Obstruction to pulmonary venous return can occur at several places; in the pulmonary venous pathway (obstructed total anomalous pulmonary venous drainage), within the atrium (cor triatriatum) or by obstruction to left ventricular inflow at supravalvar, valvar, or submitral level. Children with pulmonary venous obstruction usually present in early infancy with cyanosis and dyspnoea caused by pulmonary oedema. In less severe cases, presentation is with failure to thrive and respiratory symptoms.

The major effect of total anomalous pulmonary venous drainage is that all systemic and pulmonary venous return is to the right atrium. The pulmonary veins drain into a confluence behind the heart and from there to the right atrium, usually indirectly via the innominate vein, coronary sinus or portal system. Saturated and desaturated blood mixes in the right atrium; sufficient oxygenated blood crosses an atrial sepal defect to support the systemic circulation while the remainder re-enters the right ventricle. The long pulmonary venous pathway is usually obstructive, causing pulmonary venous hypertension and pulmonary oedema and contributing to a high pulmonary vascular resistance. This is a life-threatening situation requiring emergency corrective surgery.

Obstruction to systemic perfusion

The dominant features of an obstruction to systemic perfusion are poor peripheral pulses and metabolic acidosis. This can be a result of aortic obstruction (interrupted aortic arch and coarctation) left ventricular outflow tract obstruction (aortic valve stenosis) or low left ventricular stroke volume (hypoplastic left heart syndrome). Even when the anatomical obstruction is severe, the fetus survives because the right ventricle can provide systemic perfusion through the ductus arteriosus. Once the duct starts to close in early neonatal life, systemic hypoperfusion, or lower body hypoperfusion in coarctation, develops. The pulses become impalpable, urine output diminishes, metabolic acidosis develops and a vicious cycle of generalized organ dysfunction develops.

Resuscitation includes maintaining the patency of the ductus with prostaglandin infusion. Mechanical ventilation and inotropic support of the failing left ventricle is often required.

Coarctation of the aorta

Narrowing of the aortic lumen usually occurs at the level of the insertion of the ductus arteriosus. In neonates, the pressure load on the left ventricle may produce congestive failure, metabolic acidosis and respiratory insufficiency.

Older children are usually asymptomatic but have diminished femoral pulses and upper limb hypertension. Collateral vessels tend to be well developed: enlarged intercostal arteries produce the characteristic rib notching seen on chest radiography in older children and adults with coarctation.

Tetralogy of Fallot

The tetralogy of Fallot is the combination of a ventricular septal defect and obstruction to pulmonary blood flow (usually at the outlet of the right ventricle, the infundibulum). There is secondary right ventricular hypertrophy and an abnormally positioned aortic outflow, which 'overrides' the ventricular septal defect.

Blood flow to the lungs is reduced but by variable amounts – some children have very few symptoms unless stressed, whereas others present early in infancy with cyanosis, particularly if the pulmonary arteries are also small. Cyanotic 'spells' are a result of spasm of the infundibular muscle and cause an increased shunt across the ventricular septal defect to the systemic circulation (right to left). It is this dynamic aspect of the obstruction to pulmonary blood flow that accounts for both the intermittent nature of 'spells', and therapeutic interventions that may curtail them. Intraoperative spells are detected by desaturation, a reduction in end-tidal carbon dioxide and systemic hypotension.

Management is directed towards improving forward pulmonary blood flow including:

- hyperventilating with 100% oxygen to reduce pulmonary vascular resistance
- optimizing intravascular volume with a bolus of colloid
- increasing venous return by elevation of the legs
- increasing systemic vascular resistance by administering phenylephrine or noradrenaline (norepinephrine).

Analgesia and β-blockade are also helpful (Figure 2).

Transposition of the great arteries

In transposition of the great arteries, the aorta arises from the right ventricle and the pulmonary artery comes off the left ventricle. To be compatible with life, mixing must occur through a septal defect or patent ductus. If the neonate has an intact septum, an atrial communication is made by percutaneous balloon septostomy.

Transposition of the great arteries is usually lethal without cardiac surgery. There are two surgical approaches.

Anaesthetic considerations in tetralogy of Fallot

- Give preoperative hydration (see right-to-left shunts)
- Prescribe sedative premedication (helps reduce 'spells')
- Hypoxia and hypotension on induction should be avoided because they tend to increase shunting
- Intraoperative desaturation and reduced end tidal carbon dioxide tension values occur in other acute situations such as hypovolaemia and air embolus
- Treatment of infundibular spasm
  - Oxygen
  - Pain relief
  - β−blockade (propranolol, 0.1 mg/kg i.v.)
  - Intravascular volume replacement
  - α−agonist (e.g. phenylephrine, noradrenaline (norepinephrine)) to increase systemic vascular resistance
- Risk of embolization

2

Physiological correction: a physiological correction involves making channels in the atria such that venous blood returning from the body is diverted into the left ventricle, and then into the pulmonary artery (the Mustard or Senning procedures). Longer term, the right ventricle is unable to power the systemic circulation indefinitely and right ventricular failure eventually occurs.

Anatomical correction: an anatomical correction can be made, in which the aorta and pulmonary arteries are 'switched' and the coronary arteries are reimplanted. Although technically complicated, cardiovascular function is usually good afterwards.

Perioperative management

Anatomy and function of the heart are variable, therefore each patient must be assessed individually (Figure 3). A thoughtful approach to anaesthetic management will avoid unnecessary upset of the child's cardiorespiratory balance. Sedative, anxiolytic premedication is very useful, for instance, but large doses of opioid premedication should be avoided because of the potential for respiratory depression. The aim is for a smooth induction of anaesthesia, with impeccable airway control and balanced pulmonary and systemic vascular resistances.

Children with mild-to-moderate functional impairment tolerate inhalation induction and intravenous induction well. Intravenous ketamine is a useful alternative for more severely impaired patients because it has little effect on either systemic or pulmonary vascular resistance.

Preoperative assessment

History and examination

- Level of activity (cardiac reserve) and symptoms
- Murmurs, peripheral pulses and skin temperature

Investigations

- Chest radiography (heart position, size and shape; increased or decreased pulmonary vascular markings)
- ECG (R axis deviation is normal in infancy; evidence of ventricular hypertrophy)
- Echocardiography (anatomy, function, cardiac output)
- Cardiac catheterization (site and size of shunts, pressures, saturations)
- Haematocrit (increased in cyanotic lesions; significant risk of thrombosis if > 60%).

Medications

- Diuretics, digoxin, captopril
- Warfarin, aspirin
- Antibiotics (endocarditis prophylaxis)

Previous surgery

- Review records
- Note airway problems
- Review dental hygiene

3

Left-to-right shunts

- An increase in systemic vascular resistance increases left-to-right shunting. An increase in pulmonary vascular resistance reduces left-to-right shunting.
- Intravenous induction may be prolonged because of recirculation in the lung.
- Uptake of inhalational agents is not really influenced by left-to-right shunt unless there is poor cardiac output. An agent with low blood gas solubility coefficient will then show increased speed of uptake. Pulmonary congestion increases the risk of atelectasis.

Right-to-left shunts:

- Prolonged starvation times should be avoided. Dehydration produces haemoconcentration, worsening the effects of the high haematocrit associated with cyanotic heart disease (e.g. increased risk of thrombosis and stroke). Consider starting intravenous fluids if the time of surgery is uncertain.
- Accidental air embolization should be avoided.
- The aim is not to make the shunt any worse (e.g. by hypoxia or hypotension).
- Raised intrathoracic pressure decreases pulmonary blood flow.
- Cyanotic patients have an abnormal response to hypoxia because they do not increase breathing rate in the same way as healthy individuals.
- Intravenous induction is rapid, however, the dose should be reduced to avoid a large drop in systemic vascular resistance.
- Uptake of volatile anaesthetic gases is slow

Equipment for Paediatric Anaesthesia

Christopher J Vallis

Christopher J Vallis is Consultant Anaesthetist at the Royal Victoria Infirmary, Newcastle upon Tyne, UK. He works full time in paediatric anaesthesia and intensive care, and is also involved in medical education.

There are physiological and anatomical differences between babies, children and adults, therefore the anaesthetic equipment required for each needs to be different. Differences are greatest for neonates (under 4 weeks old) and infants (under a year). The laws of physics also determine that the behaviour of some equipment depends on size. However, cultural differences between centres, which sometimes seem to have little scientific basis, may dictate which anaesthetic equipment is used.

Environment

A child-friendly environment is important. However, when designing paediatric anaesthetic or recovery areas, it should be remembered that 13-year-olds may be insulted if they are put in an area better suited to 3-year-olds. Fashions change and durable cartoon characters are more suitable than current fads that may soon be outdated.

Temperature maintenance

Infants have a high surface area/body mass ratio and therefore lose heat rapidly, mainly by radiation, though convection, conduction and evaporation also have a role. Strategies to maintain temperature should take account of all these. In general, the following factors should be considered:

- warming the patient's environment
- warming and humidifying inhaled gases
- limiting evaporative heat loss
- warming topical and intravenous fluids.

Even within the hospital, neonates should travel in a heated incubator. Paediatric theatres should be warm, but temperatures above 25°C are uncomfortable for staff; therefore, the microenvironment of the patient needs attention. For infants, a radiant overhead heater should be used during induction and reversal of anaesthesia and during application of skin preparation, when heat loss (through the latent heat of vaporization) is high. Manufacturer's guidelines concerning patients' proximity to the heater should be followed to avoid overheating or burns. Forced-air warming systems blow filtered, warm air from a cover or mattress and can be used throughout the operation. When draped, the patient lies in a microenvironment of warm air. Simple techniques are also available; for example, partial wrapping in aluminium foil reduces radiant heat loss, and wrapping in cotton wool padding reduces conductive and convective losses.

Humidification of gases

Some active water-bath humidifiers incorporate a heating wire in the patient tubing. This reduces 'rain-out' – condensation that occurs when gases cool below the dew point. A temperature sensor at the patient end of the tubing prevents the gases overheating beyond 35°C. Use of sterile water and disposable components reduces bacterial colonization.

The heat and moisture exchanger (HME), or condenser humidifier, is a passive humidifier using a membrane that is hygroscopic (water absorbing) or hydrophobic (water collects as surface droplets). The membrane warms during expiration, both from the expired gases and the release of latent heat of evaporation. HMEs are efficient with small tidal flows (with larger tidal volumes the membrane may saturate before expiration ends). Efficiency over short periods is limited but improves with time – after 1 hour the humidity of the inspired gases may be 30 g/m^3 (equivalent to 95% relative humidity in the trachea at 32°C). Modern HMEs are small, adding less dead space and less flow resistance (even when saturated), and are suitable for paediatric use.

Viruses can be transmitted via the breathing system, mainly in liquid secretions. Heat and moisture-exchanging filters act as barriers to all microorganisms and may allow 'single-use' systems to be re-used. However, their volume adds dead space and they are not suitable for neonates.

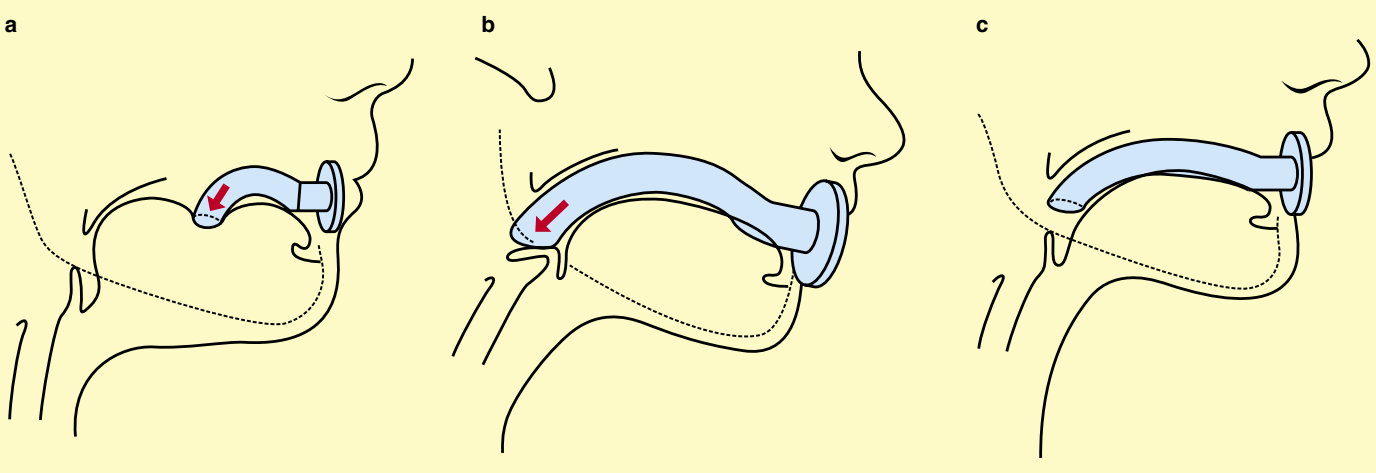
Intravenous infusions

Cannulae
Cannulae are available in sizes as small as 26 G. Nicking the skin before insertion reduces the chance of a fine cannula buckling. An extension set can be attached via a three-way tap to facilitate drug administration. Using a narrow-bore extension (100 cm long, 0.8 ml volume) avoids having to give large volumes of flush each time a drug is given. Giving fluids to babies by syringe (either manually or using a syringe driver) allows small volumes to be given accurately and reduces the possible danger of the fluid from a full burette inadvertently running into the patient.

Intravenous filters
Care should be taken to exclude bubbles from the system. In the case of a patient with a known atrioventricular malformation or atrial septal defect, an air filter is recommended because there is a risk of air emboli entering the left side of the circulation. However, blood cannot be given through air filters.

Fluid warmers
Various types are available. Some use a special concentric double-tubing system. The infusion in the central tube is kept warm by heated water circulating in the outer tube, which also prevents gases coming out of solution and forming bubbles. However, the tubing sets are expensive.

Guedel airway



A Guedel airway is unnecessary if the airway can be managed without it. Sizing guide: with the flange at the centre of the lips, the end should be nearly at the angle of the jaw (**c**). An incorrectly sized airway will make matters worse (**a** and **b**). Sizing and colour-coding is not consistent between manufacturers.

Anaesthetic machines

An air flowmeter allows mixtures containing less than 100% oxygen to be given when nitrous oxide is contraindicated. Availability of carbon dioxide is controversial, but is some-times useful in preventing hypocarbia. Some flowmeters are limited to 0.5 litre/minute to prevent excessive carbon dioxide administration.

It is a good idea to have a pressure blow-off valve at the fresh gas port of the anaesthetic machine, functioning at 5–6 kPa, to avoid inadvertently exposing the patient to high pressures.

Equipment for managing the airway

Face masks
The Rendell-Baker–Soucek mask, designed specifically for babies, is shaped to give a low dead space, but can be difficult to use. Because most anaesthetists intubate babies, a face mask is used principally during ventilation before intubation, so a good seal is more important than low dead space. Round masks with moulded face seals, often made of clear silicone rubber, are increasingly popular for this reason.

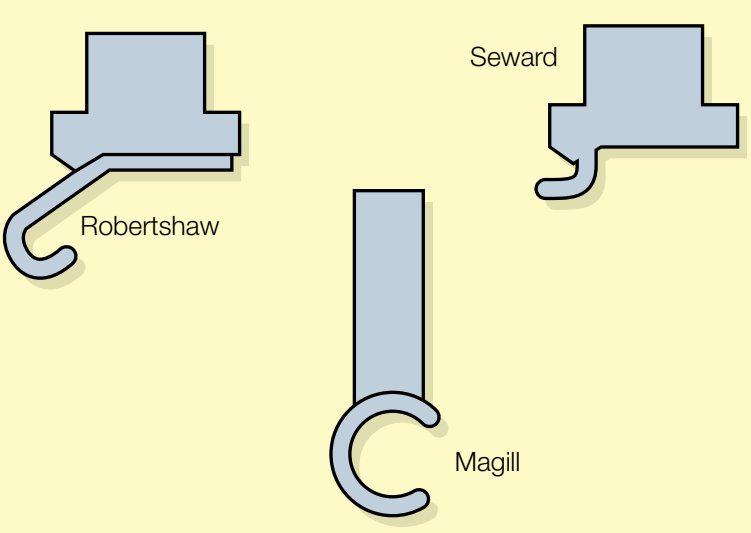
Laryngeal mask airways (LMAs)
The wide LMA tube has a low resistance to gas flow during spontaneous breathing compared with a small tracheal tube, thus reducing the work of breathing. This is indicated by a lower incidence of paradoxical respiratory movements. (The Hagen–Poiseuille equation states that the laminar flow is proportional to the fourth power of the radius.)

A range of sizes is available, down to size 1, recommended by the manufacturers for babies less than 6.5 kg (see Figure 1, *Anaesthesia and Intensive Care Medicine* **1:1:** 33). However, LMAs are not used routinely in neonates because dead space is excessive, obtaining a laryngeal seal is difficult, and most anaesthetists use intermittent positive-pressure ventilation (IPPV) delivered through a tracheal tube. However, LMAs have been used for neonatal emergencies and difficult airways such as the Pierre Robin syndrome.

In small children, it has been suggested that the LMA is easier to insert with the cuff partially inflated, or inserted sideways and then rotated 90°. Positioning is not always satisfactory, and gas leaks are common. Reinforced LMAs have made their use practicable for adenotonsillectomy.

In view of the potential for distending the stomach with gas, LMAs are not recommended for IPPV in small children.

Laryngoscope blades



1

Intubation equipment
Straight-bladed laryngoscopes are usually preferred in younger patients. There are several designs (Figure 1), which may be broadly divided into open designs (e.g. the Robertshaw and Seward), and those with a semi-circular blade (e.g. the Magill). Open blades are often easier to use, especially when using forceps to place nasal tubes. Laryngoscopes are better balanced if a lightweight paediatric handle is used. Fibre-optics give superior illumination. Green bands indicate International Standards Organization compatibility with interchangeable blades and handles from different manufacturers. The age of the child at which the straight blade is replaced with a curved adult blade is a matter of personal preference, but is often around 5 years.

Infants have relatively large heads, therefore the traditional adult 'sniffing the morning air' position with the head on a pillow is inappropriate. An infant's head should be flat on the trolley or table. A rolled-up pillowcase under the nape of the neck helps stabilize the head.

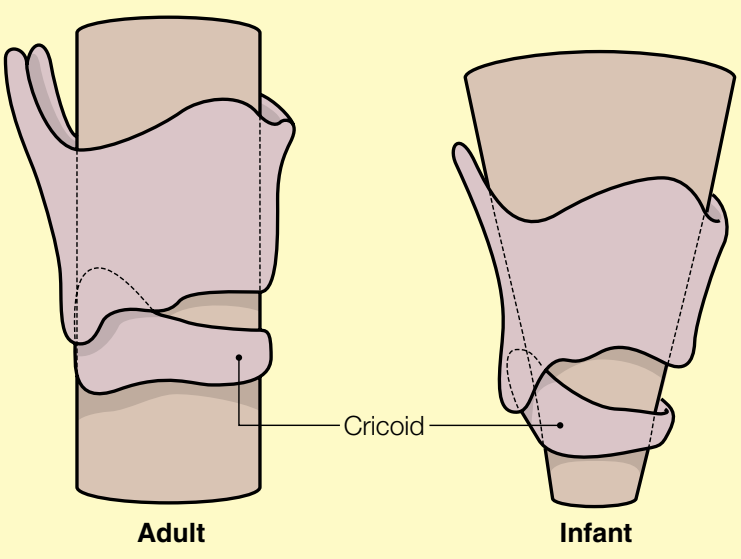
With straight open blades, intubation technique is a matter of choice. There are three possible techniques:

- the tip of the blade placed in the vallecula
- the epiglottis lifted with the blade
- the tip of the blade initially placed in the oesophagus, then withdrawn until the cords appear.

Tracheal tubes
In infants and children the airway narrows beyond the cords, at the cricoid ring (Figure 2), and the tracheal mucosa may be damaged by excessive tube or cuff pressure, resulting in temporary swelling or even permanent subglottic stenosis. With modern materials and soft cuffs it is debatable whether cuffed tubes do much harm for short-term use. However, absence of a cuff may allow a slightly larger tube size, improving gas flow. It is still normal practice to use uncuffed tubes and there are no rigid rules about the age at which to switch to cuffed tubes, though 8–10 years is reasonable.

Disposable tubes are often made of polyvinyl chloride (PVC), which is implantation tested in rabbit paravertebral muscle or tested in cell culture. Tubes are marked IT or Z-79 to indicate this. PVC softens at body temperature, conforming to the patient's airway. (Tubes soften when repeatedly handled. If practising intubations on manikin heads, they are best kept in iced water). Thin-walled paediatric tubes kink easily.
Tube sizing: a correctly sized tube passes easily through the cords, giving a slight leak at maximum, or just over maximum, inflationary pressure. The necessity for significant leaks at normal ventilator pressures is less emphasized than previously. Suggested tube sizes for infants are shown in Figure 3.

Infant airway anatomy showing narrowing at cricoid



2

Tube sizes for infants

Age	Weight (kg)	Tube size (internal diameter, mm)
Small premature	< 0.7	2.0
Premature	0.7–1.5	2.5
Small term	1.5–3.0	3.0
Term	3.0–4.0	3.5
6 months	7	4.0
1 year	10	4.5

3

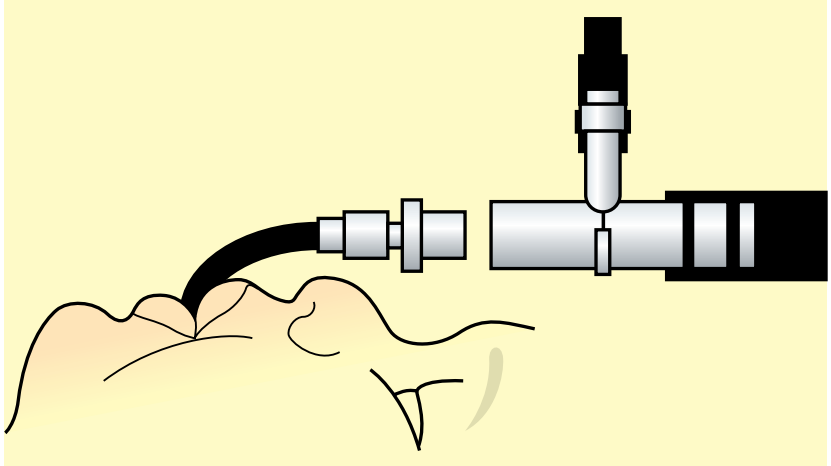
For older children: tube size (mm) = age (years)/4 + 4.5. For emergencies, a tube size of age/4 + 4 should be used (a small tube is usable, whereas one that is too big is useless). It is also sensible to have ready a smaller and a larger tube than the one planned.

A formula for the length of an oral tube in a child older than 12 months is: [½ (age in years) + 12] cm. In some countries it is usual to leave a length protruding from the mouth and different formulas are used. In emergencies it may better to leave a tube uncut, because one cut too short is useless.

The ideal position for the tip of the tube is the mid-trachea. This can be obtained by passing a 3.0 or 3.5 mm tracheal tube 3 cm, a 4.0 or 4.5 mm tube 4 cm, or a 5.0 or 5.5 mm tube 5 cm through the cords. However, the tube position should always be checked by auscultation (and radiography for long-term ventilation).

Reinforced tubes can simply be folded over the lip and stuck down, making adjustment of the intratracheal length simple (Figure 4). Some anaesthetists use them routinely. An intubation stylet is needed for insertion. Overall tube diameter depends on wall thickness, therefore reinforced tubes (with thick walls) may need to be half a size smaller than predicted.

Reinforced tracheal tube



The use of a reinforced tube allows easy adjustment of length, and the tube can be securely stuck down to the upper lip

4

Other tubes: double-lumen tubes do not exist in infant sizes and single lung anaesthesia is achieved by endobronchial intubation. Cole pattern tubes have wider bores, narrowing at a shoulder to a section that passes the cords. They may be easier to use for neonatal emergency intubation but have associated problems. Airflow is turbulent at the shoulder, increasing flow resistance. If the tube slips and the shoulder presses on the glottis, there is a risk of damage.

Connectors: standard 15 mm connectors are bulky when used with small tracheal tubes. For this reason, neater 8.5 mm systems were developed. However, the small demand has led to limited commercial success and their future is uncertain. Nevertheless, awareness of different connectors is important, particularly for transportation between centres.

Breathing systems

Paediatric breathing systems should be lightweight with low dead space. For spontaneously breathing patients, resistance to flow should be low (though the greatest resistance will be at the narrow endotracheal tube). It is desirable to have a low compressible volume of gas, particularly for ventilation at small tidal volumes, and stiff, non-compliant tubing.

Breathing systems may be divided into absorber and non-absorber systems. Non-absorbing systems have had greater use in paediatrics.

Mapleson classification: this is the usual classification of semi-closed systems . There are no unidirectional valves to direct gas flow, and no absorbant, so the fresh gas flow (FGF) must wash away the carbon dioxide.

The Mapleson A system is efficient for spontaneously breathing patients, and low gas flows, equivalent to the alveolar ventilation, may be used (alveolar ventilation in litre/minute 0.6 √bodyweight in kg). However, the system is inefficient for ventilated patients.

The Mapleson D and F systems are the most efficient for use with IPPV. The Humphrey ADE system is a combination of three systems – Lack (Mapleson A), Mapleson D and Mapleson E, and has been used successfully in paediatric anaesthesia.

The T-piece

Ayre's original form was a Mapleson E system. It was later modified by Jackson Rees, by including an open-ended reservoir bag and using a longer reservoir tube. In this form it is a Mapleson F. The Jackson Rees modification is commonly used for patients under about 20 kg, though with a high enough FGF and an expiratory limb greater than tidal volume there is no upper weight limit. It has several advantages:

- lightweight
- low flow resistance
- suitable for spontaneous or controlled ventilation
- simple design with no valves.

It also has some disadvantages:

- exhaust gases difficult to scavenge
- obstruction of expiratory limb exposes patients to high pressures
- high FGF required in larger patients.

Carbon dioxide elimination is affected by several factors:

- FGF
- tidal volume
- rate of ventilation.

Classically it was taught that an FGF of two-and-a-half to three times the patient's minute ventilation should be used. The patient's minute ventilation is not known, thus the FGF is estimated from bodyweight (BW); for example: FGF = 3 x (1000 + 100 ml/kg) for an intubated patient who is breathing spontaneously. Alternative formulas are: FGF = 2√BW for spontaneous respiration; FGF = √BW for controlled ventilation. It is now usual to monitor end-tidal carbon dioxide and make adjustments accordingly.

Increasing FGF pushes expired alveolar gas further down the reservoir tube, reducing rebreathing of exhaled gases during inspiration. Above a certain FGF there is no rebreathing of alveolar gas. Increasing FGF beyond this point is wasteful. The use of high gas flows in a T-piece results in a degree of positive end-expiratory pressure, as a result of the pressure needed to expel gas through the expiratory limb.

At low FGFs it is largely the FGF that determines the degree of rebreathing and hence the elimination of the patient's carbon dioxide. If the patient is ventilated, increasing the tidal volume may have little effect on carbon dioxide. This characteristic allows generous tidal volumes to be given to the patient, reducing basal atelectasis, without blowing off excessive carbon dioxide.

Increasing the rate of ventilation may not increase carbon dioxide exhaled gases to be driven out of the reservoir tube.

A simple increase in rate may even lead to paradoxical carbon dioxide retention unless the FGF is also increased.

Circle systems

Paediatric circle systems are not widely used in the UK because of concerns about flow resistance, dead space and leaks around the uncuffed endotracheal tube. Disposable circle systems are also expensive. However, many of these concerns are spurious. Recognition of physiological differences has led most anaesthetists to use controlled ventilation during anaesthetia in infants. The use of filters reduces infection risk and small paediatric soda lime canisters and narrow-bore tubing reduce compressible volume.

It is important to monitor gases within the circle, because there may be significant differences between the composition of fresh gas compared with gas in the circle.

Ventilators

Paediatric ventilators can be classified under familiar headings (e.g. power source, cycling mechanism, pressure or flow generator). Most mechanical ventilation in small children is defined by the fraction of oxygen in inspired air (Fi_{O_2}), inspiratory and expiratory times (or inspiratory/expiratory ratio and rate), and the pressures (maximum, mean and end-expiratory). Ventilation is not usually defined by setting tidal volume. Tidal volume is unknown with pressure-controlled ventilation, but will be reasonably constant with unchanging compliance. In practice, ventilation is set up according to sensible predicted values and then modified according to the monitoring figures.

T-piece occluding ventilators

Ventilation requirements in the operating theatre are different from those in the ICU. In the ICU, compliance changes are usually gradual, and the chest wall can be observed. The lowest acceptable mean airway pressure is used to prevent barotrauma. ICU ventilators are often time cycled, pressure limited, pressure pre-set and of the T-piece occluder type (e.g. Sechrist). There is no separate driving gas. Gas flows continually in the T-piece and the ventilators function by occluding the T-piece outflow, when gas flows into the patient. The patient can always make spontaneous breaths, with low resistance to flow. In effect, the patient is always given intermittent mandatory ventilation. High fresh gas flows are often used in the ICU to maintain a rapid upsweep in inspiratory pressure, allowing optimal recruitment of alveoli.

In the operating theatre, ventilators with a separate driving gas are favoured, because simple T-piece occluders are not ideal. Compliance and tidal volume can fall if one of the surgical team leans on the chest or splints the diaphragm. The endotracheal tube may block or kink and this may cause tidal volume to fall without much change in the ventilator pressure display.

Bag squeezer

Gas-driven, 'bag-squeezing', ventilators are easily connected to a T-piece or Bain system, replacing the anaesthetist's hand squeezing the bag. Some are pure flow generators and produce a constant tidal volume (provided the safety blow-off pressure is not exceeded).

The Penlon–Nuffield anaesthesia ventilator is used in many centres in the UK and Australasia, and in some centres in the USA. It is a gas-driven flow generator. It is fitted with a Newton valve for use in infants, which introduces a fixed leak and has a pressure relief valve set at 40 cm H_2O. With the Newton valve the Nuffield ventilator works predominantly as a flow generator at low pressures and as a pressure generator at higher pressures. A drawback is the slow inspiratory pressure rise, because with short inspiratory times this gives sub-optimal alveolar recruitment.

A bag squeezer can provide stable ventilation that is unaffected by small changes in compliance. As discussed earlier (see page 58), at low fresh gas flows it is the FGF that governs the elimination of carbon dioxide in the T-piece or Bain system, not small changes in patient tidal volume. In contrast, using high gas flows with no rebreathing, where carbon dioxide elimination is determined by adjusting minute ventilation, may produce unstable ventilation that needs frequent fine-tuning in theatre.

Other ventilators

Complex intensive care ventilators with a variety of volume or pressure modes may be used for theatre ventilation. However, these ventilators, though flexible, are not always ideal because the alarms are easily triggered.

Adult circles, with bag-in-bottle ventilators using volume control, are not recommended for infants because accurate control of tidal volume is impossible as a result of the large compressible volume of gas in the system. Smaller bellows and tubing are used to reduce compressible volume in paediatric circles.

Disconnection alarms
Some T-piece occluders require a separate alarm that detects pressure cycling. The alarm limits are adjusted by the user; if set incorrectly, system leaks may not be sensed. It is also possible that a high flow rate through a small tracheal tube will generate sufficient pressure for an accidental extubation to go undetected.

Hand ventilation
Once practised, hand ventilation is easy and reliable with the T-piece.

Advantages
- Pressure on the chest or diaphragm is felt immediately.
- The 'educated thumb' can detect disconnection, or occlusion of the tube (assuming the system is non-compliant).
- The anaesthetist stays near the patient.
- There is useful back-up in case of ventilator problems.

Disadvantages
- The anaesthetist will need assistance for some manoeuvres (e.g. giving drugs or changing fluid bags).
- The technique is suitable for the T-piece only. Hand ventilation is possible with other circuits, but the higher compressible volumes mean that problems are detected less reliably.

Resuscitation equipment

Pocket resuscitation masks
Pocket resuscitation masks are of one 'adult' size only, but may be used upside down in infants by forcibly folding the nose end over the chin.

Self-inflating bags
Three sizes are available: neonatal (240 ml), child (500 ml) and adult (1600 ml). With care, the child size may be used on neonates. It is essential to have one available during transportation, when exhaustion of the oxygen cylinder would render a T-piece unusable. A reservoir limb or bag should be attached to deliver a high inspired oxygen concentration.

Defibrillators
Defibrillators are seldom needed in paediatrics. If the patient is less than 10 kg, paediatric (4.5 cm) paddles are used, often revealed by sliding off the adult paddles. Separate paediatric paddles clipped over adult ones are easily lost.

Fluid and Electrolyte Balance for Children

Grant Rodney

Grant Rodney is Consultant Anaesthetist and Honorary Senior Lecturer at Ninewells Hospital, Dundee, UK. He qualified from the University of Cape Town, South Africa, and trained in anaesthesia in Cardiff, with a year of paediatric anaesthesia in Vancouver. His interests are in paediatric anaesthesia and resuscitation.

Applied physiology

Renal function matures rapidly from 34 weeks' gestation. At birth, term babies have a glomerular filtration rate one-third that of the adult, rising to mature values by 12–18 months of age. Infant tubular function is poorly developed at birth and matures over the first months of life. Function can be regulated only under physiological conditions. Neonates in the first week of life are unable to tolerate large acute water or salt loads. Equally, faced with fluid restriction, neonates are able to concentrate to only half of the adult capacity. Preterm neonates have a much slower increase in glomerular and tubular function after birth. Greatly reduced renal function persists until at least 18 months postconceptional age, reaching mature values only by 8 years of age.

Glucose homeostasis: neonates have reduced hepatic glycogen stores and are at risk of developing hypoglycaemia. They usually require fluids containing 10% glucose. Critically ill neonates may require greater concentrations of glucose. However, the stress response to surgery or illness may cause hyperglycaemia. With reduced glomerular filtration, the ensuing glycosuria may cause an osmotic diuresis. Neonates should be closely monitored for both hypo- and hyperglycaemia.

Body water: total body water of a term neonate is 80% of body weight or 800 ml/kg. This value falls to 60% (600 ml/kg) by 1 year of age. The intracellular fluid (ICF) volume is constant, at about 40% of body weight. The extracellular fluid (ECF) comprises the plasma volume within the circulation and the interstitial fluid volume. In relative terms, the ECF volume falls to 20% by 1 or 2 years of age (Figure 1). Most of the decrease in ECF results from a decrease in interstitial fluid. Plasma volume within the circulation is one-third to one-quarter of the total ECF volume, the remainder consisting of the interstitial fluid volume. Blood volume is 90–100 ml/kg at birth, falling to 80 ml/kg at 1 year of age and to 70 ml/kg by adulthood.

Fluid compartments as percentage of body weight

	Total body water (%)	Extracellular fluid (%)	Intracellular fluid (%)
Neonate	80	40	40
Child (2 years)	60	20	40

1

Acute loss of circulating fluid as in blood loss (trauma, surgery) or plasma loss (burns) can be replaced with rapid infusion of relatively small volumes of fluid (i.e. 20 ml/kg boluses). Dehydration is usually of slower onset with loss of fluid from all fluid compartments. The vascular compartment is maintained unless fluid loss is rapid (overwhelming diarrhoea in small children) or has exceeded compensatory mechanisms. Evidence of dehydration is not clinically apparent until the overall loss is greater than 5% of body weight (50 ml/kg).

Normal fluid and electrolyte requirements

Normal daily fluid intake is variable. Urine output is adjusted to account for diminished or excessive fluid intake. Maintenance fluids are required to compensate for water losses from skin, respiratory tract and stools, water for essential urine output and growth, and to maintain a reasonable diuresis. Water requirements can be calculated by one of three methods.

Body surface area (BSA) – this requires measurement of weight and height and the use of nomograms. Measuring height in neonates and infants is difficult and in children under 3 kg BSA errors of 20% occur.

Calorie requirements – metabolism of 1 calorie requires 1 ml of water, therefore knowledge of a child's calorie requirement can be used to determine fluid requirement.

Body weight is the simplest method of calculating fluid and electrolyte requirements (Figure 2). Continuing measurement of body weight also gives a reliable indication of changing volume status.

The examples in Figure 3 show that maintenance fluid volumes are easily calculated. However, calculated requirements are an initial estimate and, when based on body weight, do not take account of variations in lean body mass, metabolic rate and variable growth rates.

Normal fluid and electrolyte requirements

Body weight	Daily requirement (ml/kg)	Hourly requirement (ml/kg)	Sodium[1] (mmol/kg/day)	Potassium[1] (mmol/kg/day)
First 10 kg	100	4	2–4	1.5–2.5
Second 10 kg	50	2	1–2	0.5–1.5
Subsequent 10 kg	25	1	0.5–1	0.2–0.7

2

Calculating daily maintenance fluid and electrolyte requirements

5 kg infant

- Water100 ml/kg for the first 10 kg of body weight = 500 ml
- Sodium 2–4 mmol/kg for the first 10 kg of body weight = 10–20 mmol
- Potassium1.5–2.5 mmol/kg for the first 10 kg of body weight = 7.5–12.5 mmol

The fluid that best meets this requirement is 500 ml of 0.18% saline in glucose, which would supply 15 mmol sodium (0.18% saline contains 30 mmol/litre of sodium). Potassium requirement could be met by addition of 10 mmol KCl to each 500 ml bag of fluid, assuming adequate urine output and need for continuing parenteral fluid

16 kg child

- Water100 ml/kg for the first 10 kg of body weight
  + 50 ml/kg for the second 10 kg of body weight
  = 1000 ml + 300 ml = 1300 ml
- Sodium2–4 mmol/kg for the first 10 kg body weight
  + 1–2 mmol/kg for the second 10 kg body weight
  = (20–40) + (6–12) mmol = 26–52 mmol
- Potassium1.5–2.5 mmol/kg for the first 10 kg of body weight
  + 0.5–1.5 mmol/kg for the second 10 kg body weight
  = (15–25) + (3–9) = 18–34 mmol

1300 ml of 0.18% saline would supply 39 mmol of sodium/day
Adding 20 mmol/litre of KCl would supply 26 mmol of potassium

3

Dehydration

Dehydration reflects whole body fluid loss in excess of fluid intake and compensatory mechanisms. Severity of dehydration is classified as mild (5% of body weight or less), moderate (5–10%), or severe (10% or greater) (Figure 4).

Clinical signs of dehydration

Signs/symptoms	Mild < 5%	Moderate 5–10%	Severe > 10%
Decreased urine output (beware watery diarrhoea)	+	+	+
Dry mouth (mouth breathers are dry)	+/–	+	+
Decreased skin turgor (use several sites)	–	+/–	+
Sunken anterior fontanelle (crying increases pressure)	–	+	+
Sunken eyes	–	+	+
Decreased eyeball turgor (difficult in young)	–	+/–	+
Tachypnoea (acidosis and pyrexia worsen this)	–	+/–	+
Tachycardia (hypovolaemia plus pyrexia and irritability cause this)	–	+/–	+
Drowsiness, irritability	–	+/–	+

4

Mild dehydration is associated with up to 50 ml/kg fluid deficit and can usually be managed with oral rehydration.

Moderate to severe dehydration always requires intravenous fluid replacement. It is important that an initial assessment of circulatory status is performed. Most of the child's body weight consists of water, therefore 10% dehydration equates to a 10% reduction in body weight caused by fluid loss. This value in grams is equivalent to millilitres of fluid deficit (Figure 5). Large volume and/or particularly rapid fluid loss may precipitate shock. When dehydration exceeds 10%, shock is invariably present. The child with sunken eyes, dry mouth, tachypnoea, tachycardia, cool peripheries, prolonged capillary refill and drowsiness or irritability requires rapid intravascular volume replacement. Treatment of shock involves administration of high flow oxygen, attention to airway and breathing, and administ-ration of a fluid bolus (20 ml/kg). Crystalloids, either 0.9% saline or Ringer's lactate are given initially. These fluids are isotonic and restore the ECF volume. Once the circulatory status has improved (based on continuing assessment and repeat fluid bolus if necessary) further fluid therapy is initiated to correct the associated dehydration. This requires calculation of fluid deficit and maintenance fluid requirements (Figure 6). Blood samples are taken to calculate electrolyte values to guide fluid therapy, particularly speed of rehydration.

Estimating fluid deficit in a dehydrated child

A 10 kg child with diarrhoea is estimated from clinical assessment to have 10% dehydration

The fluid deficit is therefore 10% of 10 kg = 1 kg = 1000 g
1000 g = 1000 ml of fluid deficit (100 ml/kg)

This can be more easily calculated as % dehydration × body weight (kg) × 10 ml

5

Types of dehydration

The three types of dehydration are isotonic, hyponatraemic and hypernatraemic. All are associated with water and sodium loss but the speed of replacement depends on serum sodium values.

Calculating fluid requirements in dehydration

Fluid requirements for a 4 kg baby with pyloric stenosis and an estimated 10% dehydration

Maintenance fluid requirement (see Figures 2 and 3)
100 ml/kg/day = 400 ml/day
Ideally given as 0.18% saline in glucose

Deficit fluid requirement (see Figure 5)
4 (wt in kg) × 10 (% dehydration) × 10 = 400 ml/day

This should be given as 0.9% saline, reflecting the predominant loss of extracellular fluid volume in dehydration (gastric fluid is isotonic and has large quantities of sodium, chloride and hydrogen ions)

Combined fluid requirement = 800 ml

The deficit can be replaced over 24 hours, assuming the child is not hypernatraemic. Continuing fluid type and volume needs adjustment based on clinical assessment of hydration status and electrolyte values

Isotonic or hyponatraemic dehydration: the baby with pyloric stenosis (Figure 6) could be given maintenance fluid using 400 ml of 0.18% saline (which gives 12 mmol sodium ions/30 mmol/litre) while replacing the fluid deficit caused by de-hydration with 400 ml 0.9% saline (150 mmol/litre), to give an additional 60 mmol of sodium ions. A total of 72 mmol sodium ions would then be infused over 24 hours. However, it is more practical to infuse a single type of fluid to provide both maintenance and deficit volumes and sodium requirements. By calculating the sodium ion concentrations, it can be seen that a solution of 0.45% saline (75 mmol/litre) matches best. For example, giving 800 ml of 0.45% saline in 5% glucose would deliver 60 mmol sodium ions and provide adequate sodium requirement for fluid maintenance and deficit requirements. This solution is isotonic and prevents hypoglycaemia.

For more complex situations (e.g. children with severe cardiac or renal dysfunction, particularly the critically ill) it may be appropriate to provide separate infusions for maintenance requirement, fluid deficit and continuing losses. In these situations, frequent measurements of serum and urinary electrolytes and clinical assessments of hydration are required.

Hypernatraemic dehydration: if the serum sodium concentration is above 145 mmol/litre, rapid infusion of fluid causes the serum sodium concentration to fall. Water then moves into cells to maintain osmotic equilibrium and there is a risk of cerebral oedema and death. The serum sodium concentration should be lowered by no more that 5 mmol/day to avoid this and the values measured every 4 hours. The aim is to correct dehydration over 48 hours.

Colloids or crystalloids?

The relative merits of colloids and crystalloids for volume replacement during surgery and intensive care are still debated.

Isotonic crystalloids (e.g. normal saline, Ringer's lactate) are used to restore the intravascular volume but are distributed evenly within the ECF volume. As plasma makes up only one-third to one-quarter of the ECF volume, only one-third of the infused fluid remains in the intravascular space, the remainder lying in the interstitial fluid space. Therefore, if crystalloid is used to replace blood loss, then three times the volume of blood lost is required as crystalloid therapy. There is concern that excessive crystalloid fluid administration may result in overhydration of the interstitial space with resultant oedema formation. On the other hand, faced with plasma volume depletion, fluid shifts from the interstitial space into the circulating volume so that in hypovolaemic states there is generalized depletion of ECF volume. The whole of the ECF volume requires resuscitation and therefore crystalloids are most appropriate.

Crystalloids are readily available, cheap and generally free of adverse reactions. They are widely used as first choice therapy in the USA. In other countries, colloids are preferred to treat hypovolaemia, particularly in neonates who have large body water volumes, susceptibility to oedema and inability to deal with water and solute loads. Human albumin solution is most widely used because there is concern about the effects of synthetic colloids such as gelatin and hydroxyethyl starch (accumulation in the reticuloendothelial system) on the newborn and young children. A recent review of 30 published studies suggested a higher mortality in patients receiving albumin. However, there is criticism of some of the studies included and no published comparisons of crystalloids with colloids in children. Albumin is still preferred for intravascular volume replacement in critically ill children, especially neonates. For older children, the choice of initial fluid is less important than recognizing circulatory compromise and treating it promptly.

Perioperative fluid requirements

The volume and type of fluid required perioperatively depends on:

- the duration of preoperative fasting
- additional preoperative deficits from abnormal loss of fluid and electrolytes (e.g. diarrhoea, vomiting, ileus, burns, blood loss)
- intraoperative losses include evaporation from the wound (e.g. during laparotomy) or airway (if anaesthetic gases are not humidified), blood loss, and third-space loss associated with surgical manipulation and tissue trauma
- retention of water and sodium postoperatively, due to the stress response to surgery.

The stress response to major surgery includes release of aldosterone and antidiuretic hormone with retention of salt and water. It is important to limit the use of non-crystalloid solutions (e.g. 5% glucose) because of a tendency to cause haemodilution and hyponatraemia. This is particularly relevant because third-space fluid losses, blood loss and the circulatory effects of anaesthesia (including reduced cardiac output and vasodilatation) mandate crystalloid fluid therapy.

Intraoperative fluids are given based on maintenance fluid requirements and replacement of pre-existing deficits (e.g. because of fasting) and additional losses during surgery (e.g. bleeding or extravasation of fluids in major surgery). For simple surgical procedures, the fluid deficit can be replaced by resuming oral fluid intake postoperatively. For more major surgery, starvation fluid deficit can be calculated by multiplying hourly maintenance fluid requirement by the duration of fast in hours. Half the deficit is replaced in the first hour and a further quarter in the subsequent 2 hours given in addition to the hourly maintenance fluid.

Perioperative administration of glucose: neonates have inadequate glycogen stores and a tendency to hypoglycaemia. They require infusion of 10% glucose at maintenance rates. Additional crystalloid and colloid may be needed depending on the type of surgery. Sick neonates may require higher concentrations of glucose. If fluid restriction is required, glucose may have to be given centrally in 20% or 50% concentrations. Sometimes, the stress response causes hyperglycaemia. It is important to monitor blood sugar concentrations closely to avoid hypo- or hyperglycaemia.

Older children, unless fasted for prolonged periods, or critically ill, are able to maintain adequate blood sugar levels by metabolism of glycogen stores. Crystalloids are indicated for perioperative fluid infusion. Infusion of crystalloid with low concentrations of glucose (2%) avoids hypo- and hyperglycaemia in children receiving variable fluid infusion rates. Such fluids are not available commercially and must be prepared, as required, by adding 20 ml of 50% glucose to 500 ml of 0.9% saline.

Practical fluid administration in the operating room
Neonates should receive 10% glucose at maintenance rates and additional crystalloid, colloid or blood, as necessary. The blood glucose should be monitored carefully.

Children having day case or body surface surgery do not require intravenous fluids because of liberal fluid fasting policies (2 hours preoperatively for clear fluids), minimal fluid loss and the ability to take oral fluids rapidly after surgery.

Children having prolonged surgery (over 1 hour duration) or those having major surgery (especially within a body cavity or associated with blood loss exceeding 10% of the circulating volume) require intravenous fluids perioperatively. Other factors to consider include the age of the child and the likelihood of rapid return to oral intake. If large intraoperative fluid losses are not anticipated, then 0.18%/0.45% saline in glucose can be infused at maintenance rates. If larger losses or fluid shifts are predicted, Ringer's lactate (with or without additional glucose) may be administered. Hourly fluids infused at up to 2–3 times maintenance rates may be required. It is important that the cardiovascular variables (e.g. peripheral perfusion and capillary refill time, heart rate and blood pressure) are continually reviewed in the light of fluid administration. Invasive monitoring of arterial and central venous pressures may be indicated if large fluid shifts are predicted.

Hypervolaemia
Hypervolaemia is usually secondary to cardiac or renal failure. Occasionally, it results from deliberate excessive ingestion of water. The signs of hypervolaemia are those of heart failure, which is treated by fluid restriction and diuretics. Patients with water intoxication present with confusion, convulsions and coma from cerebral oedema and hyponatraemia. The treatment is to restrict fluids and manage the symptoms.
Specific electrolyte abnormalities

Sodium abnormalities are linked with dehydration or over-hydration, and are considered above.

Potassium – the usual daily requirements are listed in Figure 2. The upper limit of normal is 5.8 mmol/litre for neonates and 5.0 mmol/litre for infants and children. High values are found at birth and are tolerated without ECG changes. The clinical features (especially the ECG abnormalities) and causes of hypo- and hyperkalaemia are given in Figure 7. Treatment for hyperkalaemia is described in Figure 8.

Features and management of hypo- and hyperkalaemia in children

Hypokalaemia	**Hyperkalaemia**
Clinical features	
Muscle weakness	Tingling
Hypotonicity	Paraesthesia
Ileus	Muscle weakness
Ventricular and atrial tachycardias	Flaccid paralysis
ECG changes	
Prolonged PR interval	Peaked T waves
T wave inversion	Prolonged PR interval
Prominent U waves	Widened QRS complex
	Deep S wave and eventually asystole (arrhythmias rare < 7.5 mmol/litre)
Causes	
Inadequate intake	***Excessive intake***
Abnormal losses	***Endogenous release***
Gastrointestinal (e.g. diarrhoea)	Burns
Renal (e.g. hyperaldosteronism, diuretic therapy, volume depletion)	Rhabdomyolysis
	Haemolysis
Compartmental shift	***Decreased renal excretion***
Alkalosis	Renal failure
Insulin therapy	Drugs (e.g. potassium-sparing diuretics, ACE inhibitors)
β_2-agonists	***Compartmental shift***
	Acidosis
	Insulin deficiency
	Succinylcholine administration
Treatment	
KCl, oral or i.v. slowly (centrally if concentration > 40 mmol/litre)	See Figure 8

Guidelines for potassium administration
Total daily maintenance dose = 2 mmol/kg (0.08 mmol/kg/hour)

K to be replaced = weight x (C_D–C_M) x 0.3 = mmol required
where C_D = serum concentration desired; C_M = serum concentration measured

Max concentration for i.v. administration = 20 mmol/500 ml fluid

KCl, 2 mmol/ml, is diluted in 5% dextrose or 0.9% saline

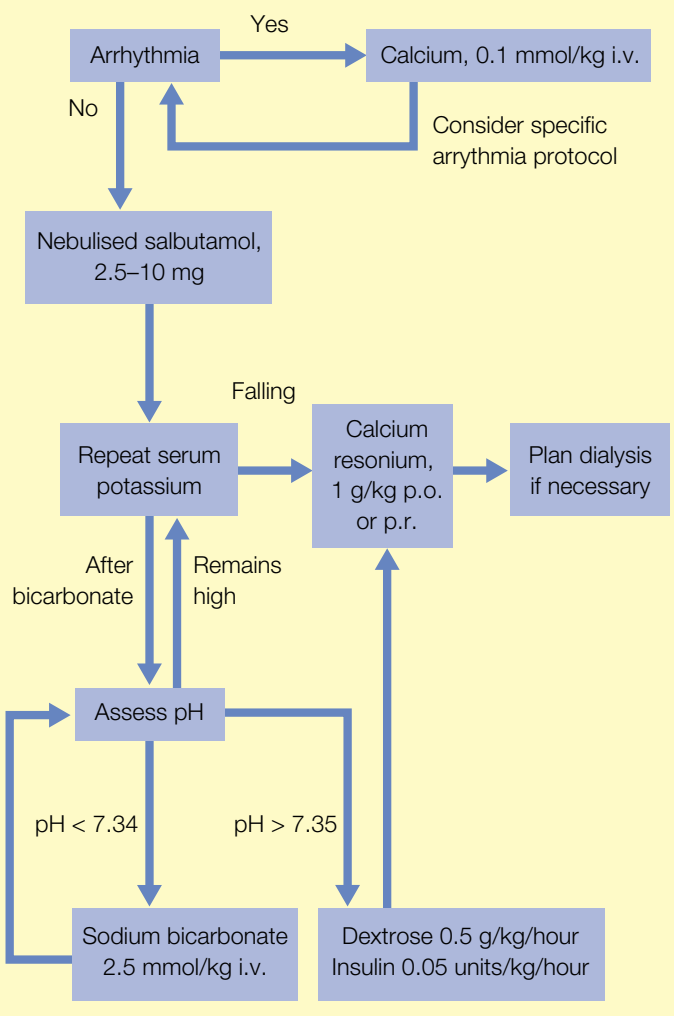
Maximum infusion rate = 0.5 mmol/kg/hour

Higher infusion rates (up to 2 mmol/kg/hour) used in cardiac ICU

Electrolyte status and ECG should be monitored

Oral K supplements can be given as effervescent or slow release tablets 1–2 mmol/kg/day in up to 3 divided doses given with or after food

Algorithm for the management of hyperkalaemia



Salbutamol dose by age

< 2.5 years 2.5 mg
2.5–7.5 years 5 mg
> 7.5 years 10 mg

Calcium abnormalities, particularly hypocalcaemia, are associated with acute illness including septicaemia or renal failure. Hypocalcaemia can produce muscle weakness, tetany, hypotension and arrhythmias, or convulsions. Treatment is of the underlying condition but intravenous calcium may be required. It is best administered as a continuous infusion via a central line using calcium gluconate 10% (0.225 mmol calcium/litre). The total daily dose is 1 mmol/kg given as 0.2 ml/kg/hour of 10% solution. However, calcium gluconate should be diluted in 5% dextrose or 0.9% saline to at least a 2% (20 mg/ml) solution. Doses for neonates are halved. Hazards include precipitation, if given with sodium bicarbonate, tissue necrosis, if the drug extravasates, and the possibility of cardiac arrhythmias, if given with cardiac glycoside drugs. Hypercalcaemia is treated with volume expansion using 0.9% saline. ◆

Cardiorespiratory Arrest

Pauline M Cullen

Pauline M Cullen is Consultant in Paediatric Anaesthesia and Intensive Care at the Royal Hospital for Sick Children, Glasgow, UK. She qualified from National University of Ireland, Dublin, and trained in anaesthesia in Glasgow, Bristol and Melbourne, Australia. Her special interests include paediatric intensive care and paediatric resuscitation.

Cardiorespiratory arrests in children are uncommon and their aetiology differs from those in adults. Progressive respiratory insufficiency accounts for 60% of all paediatric arrests. This may result from upper or lower airway disease (e.g. croup, bronchiolitis, pneumonia, asthma, foreign body aspiration) or respiratory depression caused, for example, by prolonged convulsions, raised intracranial pressure, neuromuscular disease or drug overdose. Other important causes include sepsis, dehydration and hypovolaemia.

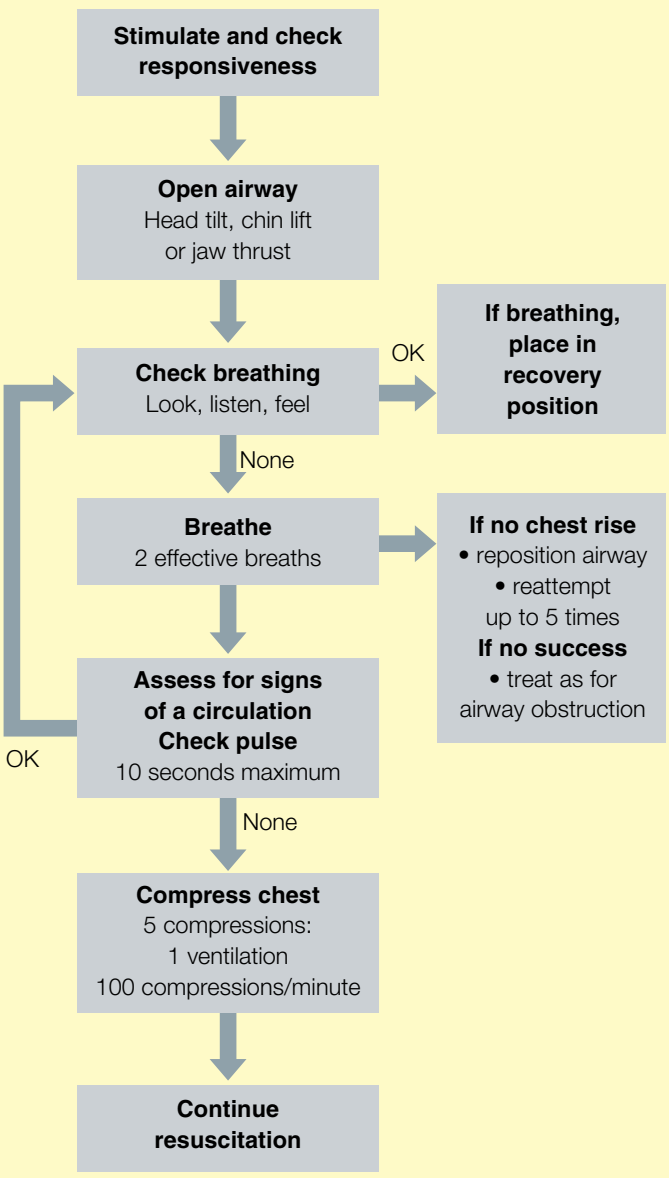
Primary cardiac arrest in children is rare and ventricular fibrillation has been reported in less than 10% of cases. Many children have a relatively long 'pre-arrest' phase (i.e. cardiac arrest following prolonged physiological deterioration). Impending cardiopulmonary arrest may be averted by early recognition of the child's distress and prompt intervention. Once cardiac arrest occurs, the outcome is dismal with survival rates of 3–17%. Often the child is resuscitated only to die of multi-organ failure in the ICU or to survive with significant neurological impairment.

Guidelines for paediatric life support are published by several national organizations. The most recent recommendations are those of the International Liaison Committee on Resuscitation (ILCOR) in 1997 and the European Resuscitation Council in 1998. The cardiopulmonary resuscitation (CPR) algorithms described in this article are based on these guidelines. The CPR sequence and general resuscitative principles are similar for infants and children. An artificial line is generally drawn between infants (< 1 year) and children (1–8 years). Older children and teenagers should be resuscitated using adult algorithms and techniques.

Basic life support

Basic life support (Figure 1) refers to maintenance of the airway and support of respiration and circulation without the use of equipment.

Paediatric basic life support



1

Initial approach and assessment of responsiveness

Before starting resuscitation it is important to evaluate the site for any danger or physical hazards. Only in extreme situations should the child be moved. The first step in any resuscitation is to assess the level of responsiveness. If the child does not respond to voice or gentle shaking, a rapid cardiopulmonary assessment should be performed (Figure 2). Assessment should take no longer than 10 seconds. Infants should not be shaken vigorously. If trauma is suspected, the cervical spine should be immobilized. Resuscitation should start immediately and help should be summoned.

Rapid cardiopulmonary assessment

A Airway
- Patency

B Breathing
- Respiratory rate
- Work of breathing
- Stridor
- Wheeze
- Air entry
- Skin colour

C Circulation
- Heart rate
- Pulse volume
- Capillary refill
- Skin temperature
- Mental status

D Disability
- Conscious level
- Posture
- Pupils

2

Airway

The tongue is the most common cause of airway obstruction in children. Simple head tilt, chin lift or jaw thrust manoeuvres may relieve the obstruction. Infants are primarily nose breathers; this is an inbuilt mechanism to overcome obstruction caused by a relatively large tongue. Only the jaw thrust procedure is recommended in suspected spinal injury. If a foreign body is obstructing the airway it should be removed carefully under direct vision. The blind finger sweep technique used in adults is not recommended because it may cause trauma and bleeding or displace the foreign body further into the trachea.

Breathing

The adequacy of breathing should be assessed by looking for chest movement, listening over the airway for breath sounds and feeling for exhaled air over the mouth and nose. If the child is not breathing despite an adequate airway, expired air ventilation should be started. The mouth of the rescuer should cover the nose and mouth of the infant. In the child, mouth-to-mouth expired air ventilation is recommended. A minimum of two, but up to five breaths, may be required for effective ventilation in the hypoxic child. The breaths should be delivered slowly, over 1–1.5 seconds, with a force sufficient to make the chest rise. By giving the breaths slowly, an adequate volume is delivered at the lowest possible pressure thereby avoiding gastric distension and possible regurgitation of gastric contents. If chest movement does not occur or is inadequate, the airway position should be readjusted and the possibility of a foreign body considered.

Circulation

Check the presence, rate and volume of the pulse. In infants, the brachial or femoral pulse is easiest to feel. In older children, the carotid should be palpated. It may be difficult to locate a pulse in a collapsed child owing to the intense vasoconstriction. If no detectable pulse is felt within 10 seconds or the rate is less than 60 beats/minute in an infant, chest compressions should be started.

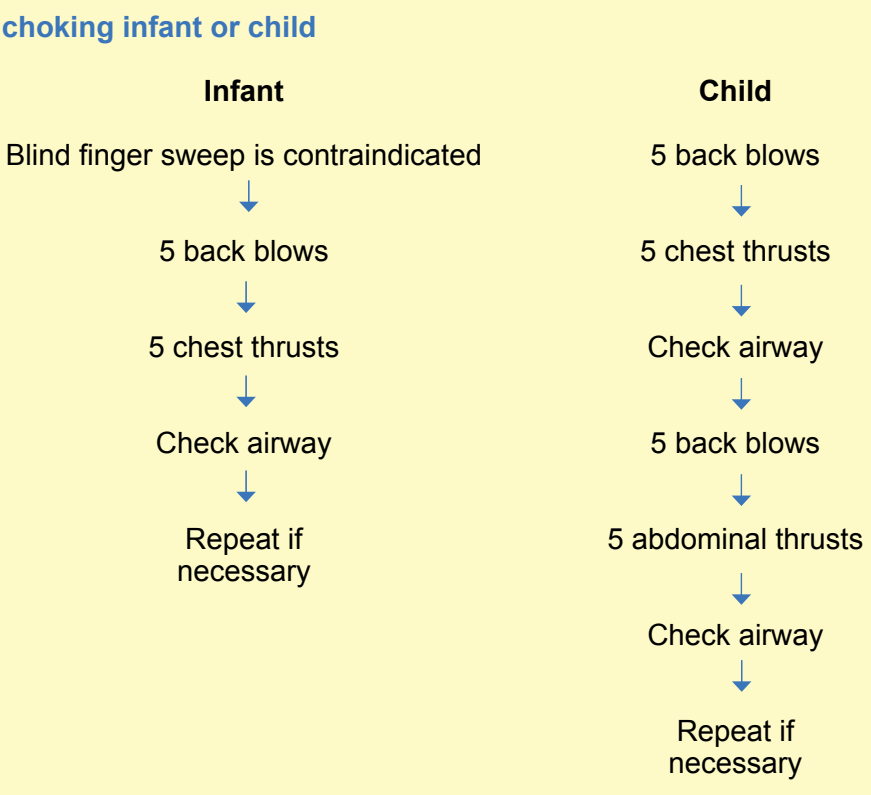
The chest is compressed over the lower half of the sternum and the technique differs slightly between age groups.
- In infants, the chest is compressed using two fingers placed one finger's breath below an imaginary line joining the nipples.
- In the child, the heel of the hand is used and positioned one finger's breath up from the xiphisternum.
- In the child over 8 years, the two-handed compression technique is recommended.

The chest should be compressed to one-third its resting diameter at a rate of 100/minute. One breath should be given after each five compressions.

Airway obstruction from a foreign body

If upper airway obstruction due to foreign body aspiration is witnessed or strongly suspected, special measures to clear the airway must be undertaken (Figure 3). If the child is breathing spontaneously, their own efforts to clear the obstruction should be encouraged. Intervention is necessary only if these attempts are ineffective and respiration is inadequate. The manoeuvres suggested for removing impacted foreign bodies are:
- back blows
- chest thrusts
- abdominal thrusts.

The choking infant or child



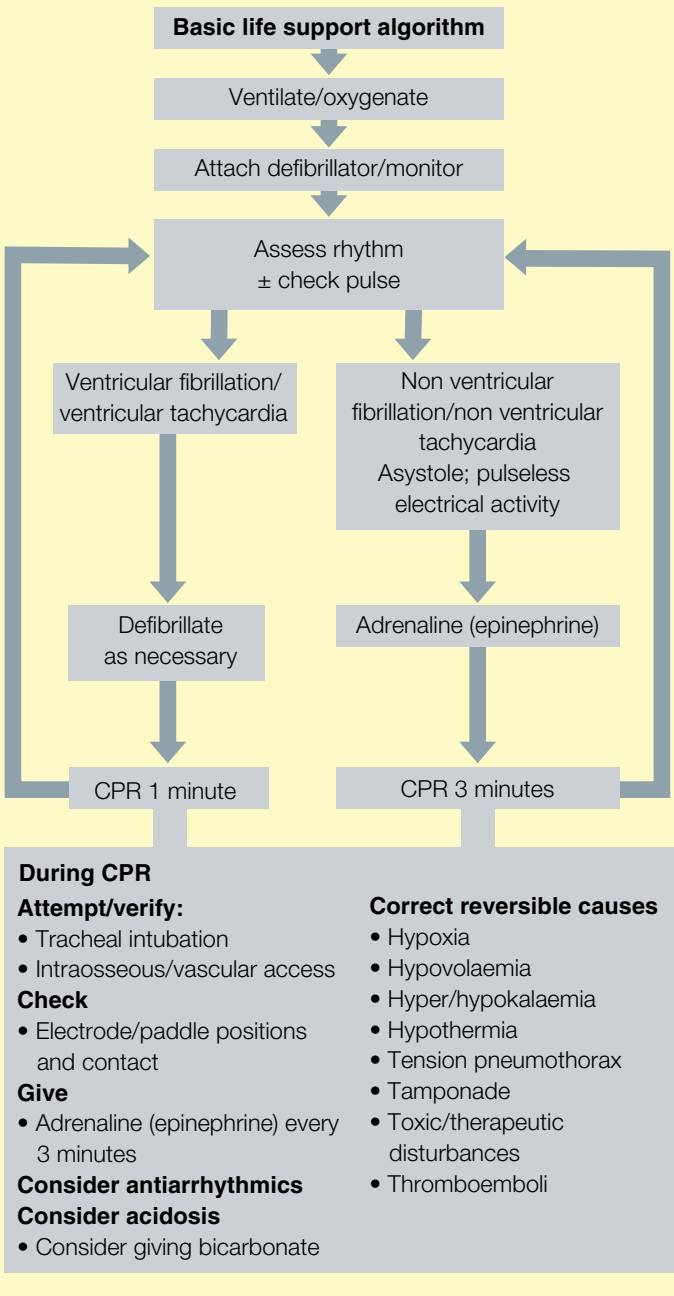
3

A combination of back blows and chest thrusts are recommended for infants. Abdominal thrusts are not recommended because damage to the abdominal contents may occur. In children, back blows with alternate cycles of chest thrusts and abdominal thrusts are preferred. After each cycle, the mouth should be checked for the presence of a foreign body and ventilation attempted.

Advanced life support

As soon as skilled help and equipment arrive, advanced life support should be started (Figures 4 and 5). The aim of advanced life support is to restore spontaneous cardiac activity. Asystole is presumed to be the primary arrhythmia because ventricular fibrillation has been documented in less than 10% of paediatric cardiac arrests. Monitoring equipment (including a pulse oximeter, ECG and end-tidal carbon dioxide analyser) should be attached as soon as possible. The priorities are to secure the airway and provide adequate oxygenation and ventilation followed by vascular access and drug administration.

Paediatric advanced life support



4

Advanced life support

- Perform basic life support algorithm
- Ventilate the lungs with 100% oxygen
- Establish a secure airway by intubating the trachea
- Establish reliable vascular access
- Administer adrenaline (epinephrine) every 3–5 minutes
- If resuscitation attempts exceed 15 minutes, consider giving sodium bicarbonate
- Correct reversible causes

5

Airway and ventilation
A secure airway and effective ventilation are vital in advanced life support. Respiratory failure is the primary cause of paediatric cardiac arrest, therefore the highest available oxygen concentration should be given immediately by bag, valve mask ventilation. An oropharyngeal airway may be used to aid airway management in the short term.

Tracheal intubation is the most effective method of securing the paediatric airway during CPR. It allows optimum ventilation, protects the airways from aspiration of gastric contents, and provides a route for drug administration. Intubation should be achieved rapidly. Any attempt lasting longer than 30 seconds should be abandoned and the child's lungs reoxygenated before further attempts are made. The position of the tracheal tube should be checked and the tube secured to prevent dislodgement or displacement. The place of the laryngeal mask airway in paediatric resuscitation has yet to be established.

Circulation
Rapid vascular access is critical in paediatric resuscitation for drug and fluid administration. In small children this may be difficult owing to the extreme vasoconstriction. The intravenous or intraosseous routes are preferred for drug delivery.

Intravenous access: the choice of venous access is determined by the skill of the resuscitator and the relative risks of the procedure. In practice, the largest, most accessible vein that does not require the interruption of CPR is used. Attempts at peripheral venous cannulation should be limited to 90 seconds. Useful central venous routes during resuscitation include the femoral and external jugular veins. The internal jugular and subclavian routes require interruption of external cardiac compressions and are prone to serious complications in young children. Drugs administered centrally act more rapidly than those administered peripherally.

Alternative routes of drug and fluid administration: when rapid venous access is impossible an intraosseous cannula should be inserted. This is relatively easy to perform, safe and usually rapidly achieved. Drugs and fluids can be administered by this route and gain rapid access to the central circulation.

The trachea is often intubated early in the resuscitation and is a useful alternative route for drug administration. It is best used when there has been, or is likely to be, a significant delay in establishing venous access. Lipid-soluble drugs, adrenaline (epinephrine), atropine, lidocaine (lignocaine), naloxone and diazepam are suitable for this route. Animal studies suggest that peak plasma concentrations of drugs are significantly lower than those achieved by intravenous administration, hence a tenfold increase in the adrenaline (epinephrine) dose is recommended for the tracheal route. Depot storage of adrenaline (epinephrine) in the lungs may cause prolonged post-arrest hypertension.

Drug and fluid therapy
Adrenaline (epinephrine) is the most useful drug during paediatric CPR. The α-adrenergic action increases systemic vascular resistance, elevates aortic diastolic pressure and thereby improves coronary perfusion. The recommended initial dose is 0.01 mg/kg, intravenously or intraosseously, or 0.1 mg/kg by the tracheal route. Because the outcome of asystolic arrest in children is poor and a beneficial effect of higher dose adrenaline (epinephrine) has been demonstrated in some studies, second and all subsequent doses should be 0.1 mg/kg regardless of route of administration. As the action of adrenaline (epinephrine) is short lived, it should be repeated every 3–5 minutes during resuscitation. If there is no return of spontaneous cardiac activity after two doses, despite adequate CPR, the outlook is likely to be dismal.

Sodium bicarbonate: after the initial treatment of cardiac arrest (ventilation, chest compression, adrenaline (epinephrine)), severe acidosis is treated with sodium bicarbonate. Its use remains controversial because it has not been shown to improve survival. Nevertheless, during prolonged resuscitation (i.e. over 15 minutes), sodium bicarbonate, 1 meq/kg, may be administered intravenously or intraosseously.

Other drugs: neither calcium chloride nor atropine is recommended in the treatment of asystole or pulseless electrical activity.

Fluids: expansion of the circulating blood volume is vital in children who are hypovolaemic secondary to fluid loss or fluid maldistribution. The intravascular fluid of choice is isotonic crystalloid. An initial bolus of 20 ml/kg is given and repeated until there is an improvement in circulatory status.

Treatment algorithms
Non-ventricular fibrillation/non-ventricular tachycardia: asystole and pulseless electrical activity are the most common rhythms in childhood cardiac arrest. Profound bradycardia should be treated in the same way as asystole. The drug of choice is adrenaline (epinephrine), 0.01 mg/kg, intravenous or intraosseous or 0.1 mg/kg via the tracheal route. This should be followed by 3 minutes of CPR. If the child does not respond to the initial dose of adrenaline (epinephrine), another dose of 0.1 mg/kg should be given. All subsequent doses should be the higher dose of 0.1 mg/kg intravenous or intraosseous.

Any underlying reversible cause of the arrest should be treated and resuscitation should not be abandoned until reasonable attempts have been made to do so. Reversible causes of pulseless electrical activity include:
- hypovolaemia
- tension pneumothorax
- cardiac tamponade
- drug overdose
- electrolyte imbalance.

Ventricular fibrillation and ventricular tachycardia are relatively uncommon in infants and children; they are treated by defibrillation. The recommended sequence is to give two rapid defibrillatory shocks of 2 joules/kg, followed by a single shock of 4 joules/kg. If the initial third shock fails, CPR should be continued for 1 minute and adrenaline (epinephrine), 0.01 mg/kg, given. The heart is then defibrillated with three further shocks at 4 joules/kg. The cycle of defibrillation and 1 minute of CPR is repeated until defibrillation is achieved. In children there is often an underlying cause and correction of hypothermia, drug overdose and electrolyte imbalance should be considered.

Post-arrest stabilization
Following a cardiac arrest, children are often poorly perfused, hypotensive and very acidotic. Most require continuing pharmacological support to maintain blood pressure and improve tissue perfusion. Management is similar to the general management of critically ill infants and children in cardiogenic shock. The goals are rapid restoration of blood pressure, effective organ perfusion, and correction of hypoxia and acidosis. Normocapnic ventilation should be continued until cardiorespiratory stability is achieved.

Cerebral resuscitation aims to provide a sufficient supply of oxygenated blood to the brain to meet its demands. Hypo-glycaemia and hyperglycaemia should be avoided, and factors that increase cerebral oxygen requirements (e.g. hyperthermia, inadequate analgesia, seizures) should be treated. Mild hypothermia (34°C) is beneficial after global brain ischaemia. In animal studies, lowering brain temperature from 36° to 33°C with local cranial cooling during the first hour of post-ischaemic recirculation improves neuronal survival. The protective effect of mild hypothermia is presumably multifactorial as it cannot be explained by the modest reduction in oxygen consumption. The clinical impact of mild hypothermia on long-term outcome remains to be tested. It is probably wise to avoid aggressive rewarming of patients in the early post-arrest period. Cerebral resuscitative strategies such as thiopental (thiopentone), calcium channel blockers and steroids do not improve outcome.

Outcome
The combined mortality and morbidity rate of children who are pulseless on arrival in the accident and emergency department approaches 100%. Children who have a delayed response to resuscitation have little chance of surviving without neurological damage. The length of resuscitation is another predictor of outcome. Prolonged resuscitation requiring more than two doses of adrenaline (epinephrine) leads to a dismal outcome and attempts beyond 25 minutes are unsuccessful. Respiratory arrest alone is associated with a better outcome. The most effective treatment of cardiorespiratory arrest is prevention. The early recognition and aggressive treatment of impending cardiac or respiratory failure in children is essential. ◆

Intraosseous Cannulation

Jane M Peutrell

Jane M Peutrell is Consultant Paediatric Anaesthetist at the Royal Hospital for Sick Children, Glasgow, UK. She qualified from the University of Newcastle upon Tyne in 1982 and after a medical SHO post in Durham, trained in anaesthesia in Leeds, the South West of England, and the Netherlands. Her main interest is regional anaesthesia in babies and children. She also instructs regularly on APLS courses.

The technique of obtaining vascular access through intraosseous cannulae became popular during the 1940s but was forgotten as equipment and methods for venous cannulation improved. The technique was rediscovered in the 1980s for use during paediatric resuscitation and quickly became accepted practice because:

- access is rapid
- landmarks are easily identified
- success rates are high (85% of babies, 50% of adults) and complications infrequent
- a variety of drugs and fluids (including all those given during resuscitation) can be injected.

Intraosseous cannulation is now indicated in babies or children during resuscitation or in an emergency when intravenous access cannot be obtained quickly or after two failed attempts. However, it is essentially a resuscitation technique and conventional intravenous access should be obtained as soon as possible (certainly within 24 hours) to reduce the risk of complications, particularly osteomyelitis.

Applied anatomy

The marrow cavity in long bones contains a spongy mesh of non-collapsible venous sinusoids, which drain into a wide central venous canal. The central canal leaves the bone through nutrient veins (running with the arteries) or sometimes through independent emissary veins that pierce the shaft elsewhere.

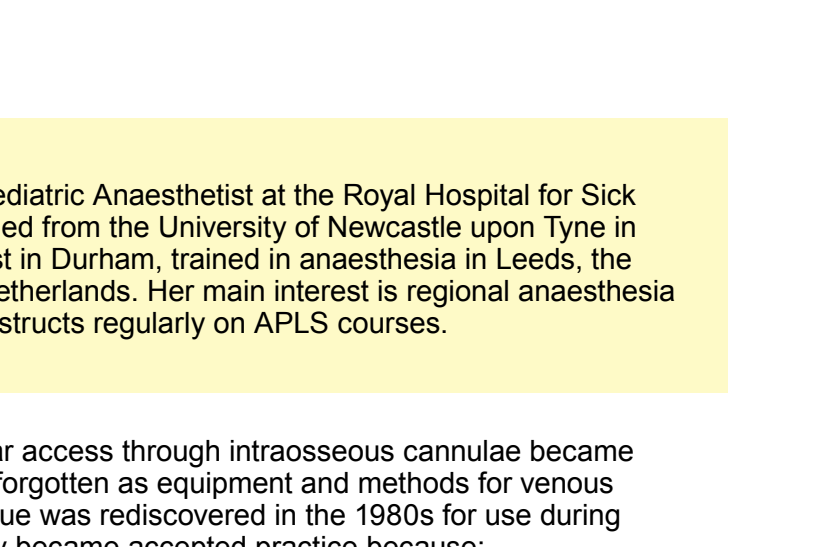
The skeleton of a baby contains very vascular red marrow, which is gradually replaced by less vascular yellow marrow from about 5 years of age. Although intraosseous cannulation is recommended for children less than 6 years of age, it is useful throughout childhood. Even adults have numerous venous sinusoids, allowing infusion rates of 20–25 ml/minute (sufficient for drug administration).

Technique

Equipment: intraosseous cannulation using hypodermic, spinal, or standard bone marrow needles has been described, though specifically designed equipment is also available. Cook® have developed two types (Figure 1).

Intraosseous needles developed by Cook®

a A smooth external, non-threaded needle with inner stylet showing the standard tip (left) and one with two lateral side ports (right). This needle is available in different gauges (18/16/14), lengths (2.5/3/4 cm) and tips (35° lancet/pencil-point/45° trochar). Having two laterally opposed side ports allows flow if the end-hole obstructs. **b** Threaded, self-tapping needles with large or small handles are available in either 15G, 1.8 cm (for babies < 9 months) or 12G, 2.3 cm (for children > 9 months). They have trifaceted cutting tips, relatively short lengths (therefore low centre of gravity making them easier to handle) and two lateral side ports. The screw thread allows controlled and atraumatic access to the marrow and better stabilization (reducing the risks of dislodgement, leakage, or penetration of both cortices)



1

Site: the proximal tibia is the most common site for insertion (Figure 2). The sternum is no longer used because of the risk of mediastinal damage.

Cannulation: as far as practicable, use an aseptic technique. The landmarks and technique of insertion in the proximal tibia are shown in Figure 3.

Recommended sites for intraosseous cannulation

Common

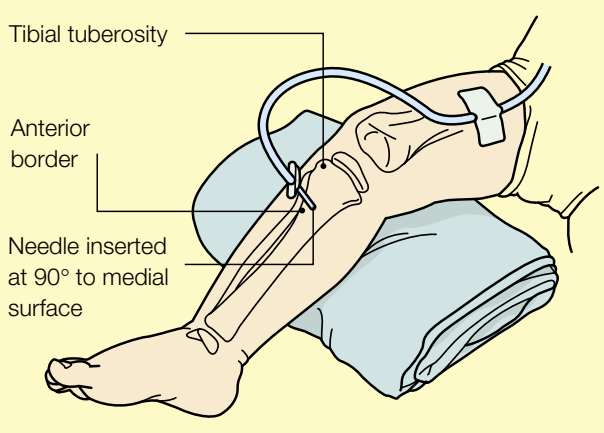
- Proximal tibia – most common site in children, but difficult to access in adults
- Distal tibia – just above the centre of the medial malleolus, better access to red marrow in adults
- Distal femur – approached from the anterior aspect

Others

- Clavicle
- Humerus
- Ilium

2

Intraosseous cannulation at the proximal tibia



The site of needle insertion is 1–3 cm (children) or 0.5–1 cm (babies) below and just medial to the tibial tuberosity on the flat, medial aspect of the tibia where the bone lies subcutaneously. Support the leg on a firm surface, grasping the thigh and knee above and lateral to the site of insertion. Insert the needle at right angles to the coronal plane, directing the needle tip slightly caudally and away from the tibial growth plate. To prevent dislodgement, carefully immobilize the cannula and splint the limb

3

To insert the needle, use a boring, twisting, or screwing action (depending on design), applying axial pressure through the needle shaft. Avoid rocking movements (which produce a larger diameter hole than the needle) or repeated attempts, which can cause leakage of drugs or fluid during infusion. Stop once there is a loss of resistance and then unscrew the cap or handle. Try aspirating to confirm correct placement and to obtain marrow for laboratory investigations. Test the position by injecting 10 ml of 0.9% saline. Signs suggesting correct placement include:

- a sudden loss of resistance as the needle tip passes through the cortex into the marrow (does not occur with screw-threaded needles)
- aspiration of marrow (reassuring, but not always possible despite correct placement)
- the needle remains upright without support
- fluid can be injected easily, without evidence of extravasation (e.g. increased limb circumference or tissue firmness).

Intraosseous cannulation should take about 2 minutes. If unsuccessful on one side, make the second attempt on another limb or bone to prevent leakage through the original hole.

Contraindications include fracture of the ipsilateral, proximal limb; repeated attempts in the same bone; local infection; osteogenesis imperfecta; osteoporosis; osteopetrosis and osteomyelitis.

Complications are uncommon, but include:

- dislodgement of the cannula (10%)
- extravasation around the needle or through a secondary site (e.g. previous attempts in the same bone, penetration through the posterior cortex) or failure to penetrate the cortex, producing:
  - haematoma
  - severe tissue necrosis, particularly with hypertonic solutions (e.g. bicarbonate, glucose), catecholamines or cytotoxic drugs
  - compartment syndrome
- subcutaneous abscess or skin infection (0.7%)
- osteomyelitis with prolonged infusion (0.6%)
- tibial fracture (in babies).
  Growth plate injury or fat emboli are not problems unless osteomyelitis occurs.

Intraosseous infusions or injections: all drugs and fluids used in a sick child can be given (Figure 4). Circulation times are similar to standard intravenous delivery and drugs should be given in the same doses.

Drugs reported given by the intraosseous route

- Adenosine
- Analgesics
- Antibiotics
- Anticonvulsants
- Atropine
- Blood products
- Calcium gluconate
- Digitalis
- Fluids
- Glucose
- Heparin
- Inotropes, including adrenaline (epinephrine)
- Lidocaine (lignocaine)
- Muscle relaxants
- Sedatives
- Sodium bicarbonate

4

Flow rates for gravity-driven infusions are low (1–25 ml/minute), but can be doubled by infusing under pressure (40 ml/minute through a 13G needle at 40 kPa/300 mm Hg). Bone and marrow vessels have vasomotor responses to humeral and neurological stimuli and flow is significantly and unpredictably reduced in shock (because of the physiological stress response or locally injected catecholamines). To prevent local sequestration and ensure systemic uptake, drugs should be infused under pressure or 'flushed in' with saline.

To prevent dislodgement, carefully secure the needle, immobilize the limb in a splint and avoid transferring the child until conventional intravenous access has been obtained.

Assess the distal pulses, limb diameter and tissue turgor every 10–15 minutes to identify extravasation or vascular compromise.

Using marrow for laboratory investigations

The acid–base status of marrow can be used as an estimate for mixed venous blood during haemorrhagic shock and the early stages of cardiac resuscitation (< 15 minutes). During longer periods, the correlation deteriorates because of local stasis and intraosseous delivery of drugs (especially bicarbonate or catecholamines).

Other biochemical variables (Na^+, Cl^-, Ca^{2+}, K^+, Mg^{2+}, urea, creatinine and glucose) are similar to central venous values in stable patients or during less than 30 minutes of cardiopulmonary resuscitation if no intraosseous drugs are given. Once drugs have been delivered, differences develop as resuscitation progresses, but are unlikely to lead to erroneous treatment, except for glucose and K^+.

Haemoglobin values are consistently lower than for mixed venous samples (especially after 30 minutes of resuscitation), perhaps because of 'wash-out' of red cells. Marrow samples also poorly predict mixed venous platelet and leucocyte concen-trations, but can be used to group and cross-match blood. ◆

The Law and Ethics of Consent and Research in Children

Robyn Smith
Nick Pace

Robyn Smith is Specialist Registrar in Anaesthetics at the Western Infirmary, Glasgow, UK. She qualified in New Zealand. Her main interests are emergency and trauma medicine.

Nick Pace is Consultant Anaesthetist at the Western Infirmary, Glasgow, UK. He qualified from Glasgow University and trained at the Glasgow Western and Royal Infirmaries, University Hospital of South Wales and Parkland Memorial Hospital, Dallas, Texas. His interests include airway management and anaesthesia for renal and adrenal diseases. He is currently completing a PhD in medical law.

Consent

Most of the ethical and legal issues in caring for children arise from uncertainties about consent. In common with adults, if no legally effective consent has been given, the doctor is liable for criminal or civil charges of assault if he makes contact with the patient. The five preconditions of consent are given in Figure 1.

The five preconditions of consent

- The person has to be of competent mind
- There must be full disclosure of information regarding the nature of the procedure, including the associated risks
- The person must understand the information they have been given
- The decision must be made voluntarily
- The person must give authorization

The law gives a child's parents authority to make decisions on behalf of the child (a form of proxy consent). In addition, a child may make decisions about their own treatment. In 1997, The United Nations Convention on the Rights of the Child stated that the child's views should 'be given weight in accordance with the age and maturity of the child'. The age at which a child is considered a 'mature minor' or 'emancipated minor' in legal terms differs between various legal systems.

In England and Wales the age of majority is 18 years. However, the Family Reform Act of 1969, section 8, clearly states that once a person reaches the age of 16 years, he or she can consent to any surgical, medical or dental treatment. The principle of the 'mature minor' in English law was defined in the Gillick case (Gillick v. West Norfolk AHA (1984)). This case concerned the validity of a minor's consent to contraceptive treatment without parental knowledge. It was held that consent would be legally valid when the child, in the opinion of the doctor, had sufficient maturity and intelligence to understand the implications of the treatment proposed. Furthermore, since it would be the doctor who would decide whether the minor was mature enough, legal authority regarding treatment would appear to have passed from the parents to the doctor. In his judgement in the Gillick case, Lord Templeman gave as examples the removal of tonsils or an appendix as occasions when parental consent might not be required. On the other hand, it has been suggested that when the minor's own future welfare is at stake and the consequences of a procedure might be serious, traumatic or irreversible, parents should probably be involved. There is little doubt that the law would distinguish between the requirements for consent for an adenoidectomy and consent for cancer chemotherapy. A child may be deemed mature enough to appreciate fully the nature and consequences of an adenoidectomy but not mature enough to give effective consent for cancer chemotherapy. In delicate cases concerning a minor consenting to treatment, it may be prudent to seek the opinion of a colleague, and document this clearly in the patient's notes.

Scottish law explicitly gives those over the age of 16 years the right of consent, through the Age of Legal Capacity (Scotland) Act 1991 and Children (Scotland) Act 1995. Similarly, a child under the age of 16 who meets the requirements of the 'mature minor' test has the legal capacity to consent to medical treatment.

The immature minor: consent by one parent is sufficient because parents may act independently, unless a Court order has been made restricting his or her right to consent (Figure 2). Thus, if the parents disagree, the doctor may proceed with treatment provided the consent of one parent has been given.

The following people may give consent on behalf of an incapable child

- The child's natural mother whether married to the father or not
- The child's natural father whether married or divorced
- An unmarried father who has entered and registered a formal parental responsibilities and rights agreement with the mother
- A legal guardian nominated in writing by a parent before the parent's death
- A person holding a Court order giving them the right to consent on the child's behalf
- A person who has had delegated to them by a parent or legal guardian the right to consent to medical procedures or treatment of the child
- A person aged 16 years or more who has care and control of the child (e.g. foster carers) except those involved in the school setting and procedures such as organ donation, non-therapeutic research or treatment (e.g. cosmetic surgery)

Refusal of elective or emergency treatment

Refusal by parents: parents have the authority to make decisions on behalf of their legally incompetent children, but this authority is a form of 'proxy consent' and must be used reasonably. It may be taken away if the Courts believe that the parents are abusing the power given by the law.

From the anaesthetist's point of view, the two most common situations when this arises are:

- when parents refuse to consent to the surgical treatment proposed for their children
- when parents who are Jehovah's Witnesses refuse to allow a blood transfusion to be administered to their child.

In a free society it is a major step to override religious convictions. It significantly interferes with the principle that parents should have the freedom to choose the religious and social upbringing of their children. However, parental refusal to agree to life-saving treatment for their child on religious grounds has been regularly overridden in the courts. Courts, however, have not endorsed every medical judgement, and there have been occasions when the Courts have upheld parental refusal of treatment. Medical staff cannot assume that the Courts will always endorse their view.

If urgent life-saving treatment is required doctors should proceed with treatment. Justification stems from the defence of 'necessity'. The reasons for proceeding and confirmation of the urgency by another doctor should be entered in the case notes. The prevailing ethical principle is the child's right to live, and it has been asserted that in the case of Jehovah's Witnesses the civil law will protect doctors who administer a blood transfusion despite parental opposition. If treatment is not urgent, then doctors cannot proceed without parental consent.

If treatment is not required immediately the medical team can proceed in one of two ways. The clinical staff may elect to try to resolve the matter through discussions with the parents. Particularly in cases concerning religious beliefs, this may require the parents to act in a way that is not in keeping with their principles. The implications for them within their religious communities may include a belief that they have sinned, and for this reason, these discussions should be undertaken with tact and diplomacy. The second approach is to make the child a ward of Court. If the Court agrees with the medical evidence, treatment can then be given with official authorization.

Refusal by the child: the situation is more complex when a mature, under-age child refuses treatment that has been accepted as necessary by the parents and the medical staff.

In England and Wales it would appear that, following the House of Lords decision in Gillick (1985), the child has every right to refuse treatment, provided he has sufficient maturity and intelligence to understand the implications of refusing the treatment proposed. If one is legally entitled to consent, one must be legally entitled to dissent. The problem, however, is not so clear cut because the Courts have the responsibility to act in the child's best interests. They may therefore hold that a child who refuses treatment (especially if life saving) cannot be mature enough to fully understand the implications of such a refusal. Thus, it would appear that a child is mature enough to decide on treatment only if his decision agrees with the view of the Courts. Some believe that section 8(3) of the Family Law Reform Act 1969 gives parents the right to consent to treatment against the expressed wishes of the minor. This has been tested in case law. The Courts are prepared to ignore the statutory rights of legally competent 16-year-olds following the case of a 16-year-old girl suffering from anorexia nervosa who was ordered to be treated against her will.

In Scotland the Age of Legal Capacity (Scotland) Act 1991, and, later, the Children (Scotland) Act 1995 gave young people aged 16 years or over the same right to consent or refuse as adults. Furthermore, in contrast to English law, it would appear that a legally competent minor has the same right to refuse medical treatment as an adult. Thus, in the elective situation, the wishes of a child under 16 years of age who satisfies the 'mature minor' test should prevail, even when their refusal of treatment is counter to the wishes of both their parents and doctors. This has never been tested in a court of law. However, one can foresee a child under the age of 16 who refuses treatment and appears competent bringing a case against medical staff who fail to honour his wishes. In an urgent life-saving situation, a legally competent minor, it could be argued, cannot be overruled if they refuse treatment. However, one could doubt the competency of a child refusing treatment that is clearly in his best interests. That child would then fail the 'mature minor' test and the refusal of treatment overruled due to incompetency. It must be pointed out, once again, that these issues have not been tested in a court of law. As always in such situations, if possible, legal advice should be sought.

Research

Undertaking research in children creates many legal and ethical dilemmas. The importance of advancing medical knowledge must be balanced against the potential risks to a vulnerable group. It must be remembered that for a child a simple procedure, such as taking blood, may be distressing and therefore cause harm. Research should be done on children only if comparable research on adults could not answer the same question. Older children should be involved in preference to younger ones. All proposals involving medical research on children should be submitted to a research ethics committee, and legally valid consent should be obtained. Consent should be given voluntarily, with a full explanation of all risks. Consent may be withdrawn at any time.

Simplistically, research can be considered as therapeutic or non-therapeutic. In therapeutic research it is hoped that the research will directly benefit the patient. Non-therapeutic research will not directly treat the patient, though the results may benefit other patients. The ethical approach to these two types of research differs in children.

In therapeutic research the general rule applies that it is the duty of the doctor to act in the best interests of the patient and not to do harm. It would be wrong for the doctor to withhold information about experimental therapy for fear that the patient might refuse that treatment, even though the doctor believes it is in the patient's best interests to receive it. If the child fulfils the criteria for maturity and understands the risks and implications of a particular experimental treatment, then his consent would appear to be legally valid. This has never been debated in a court of law. However, the consent of an immature child is insufficient. In this situation, the parents appear to have the legal right to consent because it could be argued that the therapeutic research is in the child's best interests. For therapeutic research to be undertaken on their child, the parents (or guardian) must give voluntary consent. They must fully understand the principles of research and believe the risk:benefit ratio of that research favours their child. Good medical practice dictates that the child should also assent to being involved in the research. If he dissents, depending on the degree of discomfort to the child, he should be withdrawn from the study.

In non-therapeutic research in babies and children, consent is more complex. The child would appear not to gain from this research, and indeed may be harmed. Although parents have been given legal authority to consent on behalf of their children, they cannot use this power to harm their child. Therefore, it can be argued that parents cannot consent to their children being involved in non-therapeutic research.

The Medical Research Council in 1964 stated that parents could not give legal consent on behalf of their children to any procedure that would be of no benefit to them. However, this is not based on any solid legal foundation. There are no statutes or Court decisions on this matter in the UK, and so general ethical principles have to be invoked. The extreme arguments advocate either no research at all, as legally valid consent can never be given, or justifying non-therapeutic research on an altruistic basis.

The Royal College of Paediatrics and Child Health has issued guidelines for the ethical conduct of medical research involving children (*Ethics Advisory Committee Archives of Diseases in Childhood* 2000; **82:** 177–82). These include guidelines for the conduct of non-therapeutic research. Risks are estimated to be minimal, low or high. It is claimed that it would be unethical to submit children to more than minimal risk when the procedure offers no benefit to them, or only a slight or very uncertain one. Minimal risk describes procedures such as questioning, observing and measuring children, provided that procedures are carried out in a sensitive way, and that consent has been given. Procedures with minimal risk include collecting a single urine sample, or using blood from a sample that has already been taken as part of treatment. The College states that for many children injections and venepuncture are classified as low rather than minimal risk. This recognizes the fear with which many children regard needles. It may be possible for a child to allow blood to be taken following careful explanation and the use of local anaesthetic cream. The College is clear that it is completely inappropriate to insist on taking blood for non-therapeutic reasons if a child indicates significant unwillingness before the start or significant stress during the procedure. Despite the ethical framework and Royal College guidelines, it is still unclear whether proxy consent for non-therapeutic research is legally valid. Local research ethics committees have an important part to play in ensuring that research in children continues, but that due to their vulnerability, they are not exploited.

Non-therapeutic surgery

Male circumcision: one of the few occasions when one is asked to anaesthetize healthy children who appear not to benefit from the procedure is when young boys undergo circumcision for religious reasons. The child obtains no immediate benefit and yet is exposed to all the risks of surgery and anaesthesia. The legality of parental consent in these cases has never been challenged in a court of law but in the UK it would probably be upheld on grounds of religious toleration. However, the ethical debate is more complex, with two opposing views being taken. Brazier has commented that male circumcision is a matter of medical debate and that for Jewish and Muslim parents it is an article of faith. The child suffers momentary pain and though medical opinion may not regard it as beneficial, it is not medically harmful if properly performed. The community as a whole regards it as a decision for the infants' parents. The counter-argument claims that there is an extensive literature on the harm of circumcision and that everyone has a right to bodily integrity and proxy consent must be used reasonably and in the interests of the child. Giving consent to medical treatment of a child is a clear example of parental responsibility arising from a duty to protect the child. How can a parent be said to be protecting the child while exposing him to such risk? How can the procedure be ethically justified? Why cannot the procedure wait until the child is old enough to make his own decision?

In the UK, female circumcision is prohibited by the UK Prohibition of Female Circumcision Act of 1985.

Transplantation: the first kidney transplants were undertaken between identical minors. Couples are now having children for the express purpose of providing genetically compatible sibling donors of, at present, regenerative tissues. Whether these practices are ethically and legally acceptable is debatable, but they appear likely to increase. While different legal jurisdictions have come to different conclusions about their acceptability, the UK situation is unclear. A strong argument can be made to distinguish between various types of donation. The risk assessment depends in part on the regenerative capacity of the tissue or organ being donated.

It would appear, from the arguments discussed earlier, that the 'Gillick' competent minor would be able to consent, subject to the restrictions of the minor understanding the risks and benefits involved. Clearly, donation of non-regenerative organs involves greater risks than removal of those that can be replaced. Similarly, the risks inherent in the surgery to obtain the organs are relevant. It is far riskier to obtain a part of a liver than to obtain bone marrow, even though both are capable of regeneration. Thus, blood donation is ethically acceptable whereas kidney or skin is probably not. In common with non-therapeutic research, it would be foolish to proceed without parental consent, even when the minor has consented to the procedure. If this situation were to arise, it would be wise to seek the guidance of other doctors, and to apply to the Courts for guidance.

The situation regarding incompetent minors is even less clear. The debate hinges on whether parents have the right to consent on behalf of their child to something that will not benefit, and may harm, the child. Once again, the separation into regenerative and non-regenerative tissue helps to assess the risk. Assessment of what benefit would accrue to the child, such as the survival of a sibling or parent, also has to be undertaken. In the UK, application to the Courts would be needed in most cases. ◆

Managing the Difficult Airway

Robert Walker

Robert Walker is Consultant Paediatric Anaesthetist at the Manchester Children's Hospital, UK. He qualified from Glasgow University Medical School and trained in paediatrics and anaesthesia in Manchester. His main area of interest is the development of fibre-optic intubation techniques in infants and children.

In normal infants, anatomical differences, compared with those of older children or adults, can make airway management and intubation slightly more difficult. These differences give rise to the 'high anterior larynx' and include:

- a more cephalad larynx (lying at the level of C3/4, compared with C5/6 in adults)
- a relatively large tongue, which is displaced posteriorly into the oropharynx, thus obscuring laryngeal structures
- a large, floppy, inverted, Ω-shaped epiglottis that is firm and lies at 45° to the long axis of the pharynx.

In addition, the mandible (and the space defined by it) is relatively deficient, so there is little space anteriorly in which to push the tongue and other tissues during laryngoscopy, making laryngeal structures more difficult to see.

Preoperative assessment

There are no tests that accurately predict difficult tracheal intubation in babies or children, though some features of history and examination alert the anaesthetist to potential problems (e.g. congenital or acquired abnormalities, previous anaesthetic difficulties). Features suggesting obstructive sleep apnoea (e.g. snoring, apnoea during sleep, day-time somnolence) may suggest a difficult airway, and examining mouth opening and mobility of the cervical spine can be helpful. Obstructive sleep apnoea indicates a high likelihood of airway obstruction during induction of anaesthesia but does not indicate any likelihood of difficulty to intubate the trachea. The presence of cervical spine disease makes positioning the head into the desired 'sniffing the morning air' position difficult.

For any child with a difficult airway, the anaesthetist must discuss the anaesthetic risks fully with the parents (and child, if appropriate), including the possibilities of tracheostomy or failure to secure the airway. The benefit of the procedure should always outweigh the risk of the anaesthetic.

Patient characteristics

Congenital and acquired problems associated with difficulty in airway management and tracheal intubation are listed in Figure 1.

Causes of difficulty in airway management and tracheal intubation in babies and children

Congenital

Craniofacial disorders
- Pierre Robin syndrome
- Treacher-Collins syndrome
- Goldenhar's syndrome
- Cleft palate

Lysosomal enzyme defects
- Mucopolysaccharidoses
- Mucolipidoses

Congenital swellings
- Cystic hygroma
- Haemangioma

Cervical spine abnormalities
- Klippel–Feil syndrome (congenital synostosis of cervical vertebrae)

Acquired

Inflammatory
- Acute epiglottitis
- Croup
- Diphtheria
- Retropharyngeal abscess

Others
- Trauma
- Burns
- Still's disease
- Radiotherapy
- Malignancy of the head and neck

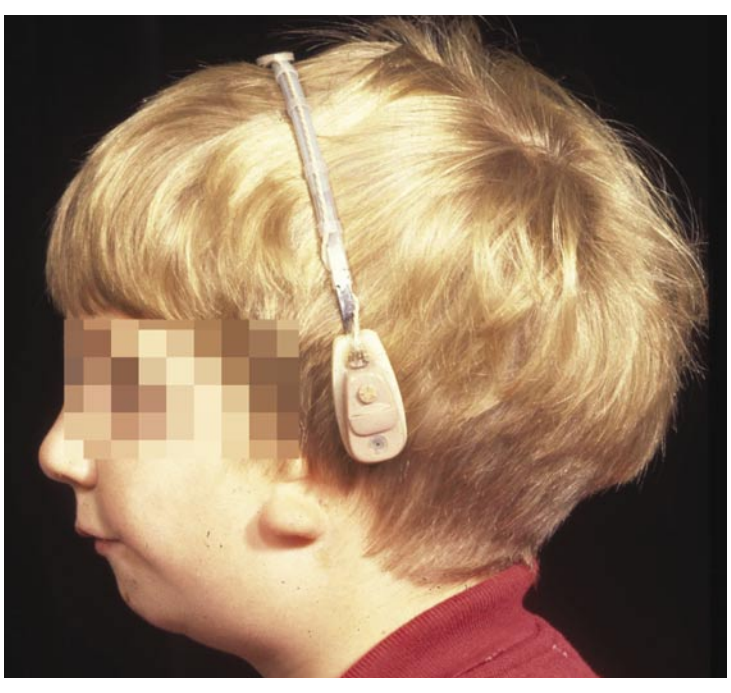
1

Craniofacial abnormalities: the most common are the Pierre Robin syndrome, Treacher-Collins and Goldenhar's syndromes. Both Treacher-Collins and Goldenhar's syndromes present major airway challenges to the anaesthetist, similar to those found in the Pierre Robin sequence.

The Pierre Robin syndrome consists of micrognathia and relative macroglossia, with or without cleft palate. In severely affected babies, airway obstruction develops in the first 4 weeks of life. When supine, the nasopharynx fills with the tongue, causing varying degrees of obstruction. When the baby then struggles, an even greater negative intrathoracic pressure is generated, sucking the tongue into the nasopharynx (via the cleft palate, if present). The obstruction is often ameliorated by nursing these babies prone, though a tracheostomy may be necessary. Children with this problem often have feeding difficulties and failure to thrive and may require nasogastric or gastrostomy feeding.

The combination of severe micrognathia with relative macroglossia and the cephalad displacement of the larynx can make visualization of the larynx with conventional laryngoscopes almost impossible.

The Treacher-Collins syndrome (mandibulofacial dysostosis) (Figure 2) consists of abnormalities of the external, middle and inner ear with hearing loss, mandibular deformities and minor eye abnormalities. The facial bones may be hypoplastic (typically the zygoma and mandible). These children may also have macrostomia (with or without a cleft palate), high arched palates and abnormal dentition.



2 Lateral view of a child with Treacher-Collins syndrome.

Goldenhar's syndrome (oculoauriculovertebral dysplasia) consists of mandibular hypoplasia, eye and ear abnormalities sometimes with hearing loss. In addition, 40% have a Klippel–Feil anomaly (congenital fusion of the bodies of two or more cervical vertebrae), which makes appropriate positioning of the head and neck difficult.

Mucopolysaccharidoses (e.g. Hurler's, Hunter's, Marateaux–Lamy syndromes) (Figure 3) are hereditary progressive disorders caused by a deficient lysosomal enzyme, resulting in excessive intralysosomal accumulation of glycosaminoglycans (mucopolysaccharides). There is progressive, generalized infiltration and thickening of soft tissues making anaesthesia and airway management hazardous. Particularly important clinical features include:

- a large tongue (and sometimes hypertrophied tonsils) that obstructs the oropharynx
- progressive narrowing of the nasal airway ed by thickened mucous membranes, adenoidal hypertrophy and redundant 'granulomatous' tissue
- a typically short and immobile neck that may be unstable
- temporomandibular joint involvement with fibrosis, stiffness and limited mouth opening
- progressive thickening of the supra- and infra-glottic regions.

Difficulties with anaesthesia and intubation worsen with age.

3 A child with Hurler's syndrome.

Anaesthesia

Premedication decreases the child's anxiety and improves cooperation at induction and dries airway secretions. It can be achieved safely with oral midazolam, 0.5 mg/kg, and oral atropine, 20 μg/kg. Sedative premedication is best avoided in patients with pre-existing severe airway obstruction.

Induction

Induction using a spontaneous breathing technique with oxygen and either halothane or sevoflurane is the technique of choice. The anaesthetist should aim to attain a sufficiently deep level of anaesthesia to attempt to visualize the larynx using conventional laryngoscopes and then intubate the trachea. If this proves impossible, the anaesthetist must have a clear plan of how to proceed, either to abandon the procedure or to use alternative means to aid tracheal intubation (see below).

Following inhalational induction of anaesthesia and loss of consciousness, airway obstruction may occur rapidly. This can be treated by laying the patient in the lateral or semi-prone position to clear the airway. Other helpful manoeuvres to clear the airway further and allow deepening of anaesthesia before laryngoscopy include:

- inserting an oral airway (may precipitate coughing, and even laryngospasm, if inserted too early) or nasal airway (may cause bleeding, but better tolerated at an earlier stage than an oral airway)
- anterior traction of the tongue to clear the pharynx (e.g. with a tongue suture or forceps)
- inserting a laryngeal mask airway (LMA) when the child is sufficiently deeply anaesthetized.

Muscle relaxants should never be given until the airway is secure because this may result in the anaesthetist being unable to inflate the patient's lungs manually or to intubate the trachea and having to attempt a surgical airway rapidly. Maintaining spontaneous breathing allows the anaesthetist a way out should securing the airway prove impossible.

Equipment

Conventional laryngoscopes: a full range of curved and straight-bladed laryngoscopes should be available. Experienced practitioners often prefer straight-bladed instruments. The normal technique of intubation involves placing a laryngoscope into the mouth over the right side of the tongue, compressing the structures into the mandibular space and lifting to reveal the glottis. If the mandible is small or the tongue is large, a straight-bladed laryngoscope can be used lateral to the tongue in the paraglossal sulcus. Popular blades include the Miller and Wisconsin. The Storz laryngoscope (favoured by ENT surgeons) is also an excellent instrument and anaesthetists working with children with difficult airways should obtain experience using it. The smaller straight-bladed laryngoscopes, preferred by many paediatric anaesthetists, take up less space in the mouth and can be used to lift up the epiglottis and provide clear views of the glottis.

Fibre-optic bronchoscopes: although certain manoeuvres using conventional equipment can succeed, fibre-optic intubation techniques are often necessary.

Adult bronchoscopes – many flexible fibre-optic bronchoscopes are available. It is relatively easy to attain competency using one with an outer diameter of 3.5–3.8 mm, and these have good suction channels. However, they are only suitable for railroading tracheal tubes of internal diameter 4.0 mm or more, which limits their use to children less than 1 year of age.

Ultrathin flexible bronchoscopes have outer diameters of 2.2 mm, allowing a 2.5 mm internal diameter tracheal tube to be railroaded over them. Their optical quality is superb, but they have no suction channel (secretions must be aspirated with normal suction catheters), are 'whippy' to handle (requiring practice to become competent) and easily damaged.

Fibre-optic intubation techniques

Before attempting fibre-optic intubation, the baby or child must be deeply anaesthetized, well oxygenated, and have a clear airway to give the operator time to visualize the structures. Fibre-optic intubation is (almost) never done in babies or children who are awake. Topical anaesthesia is useful. A second anaesthetist is desirable to monitor the patient and check the airway during the fibre-optic intubation. Successful intubation is confirmed by capnography.

General strategies

Preloading the tube onto the bronchoscope, then railroading it into the trachea necessitates careful selection of the tube. If the tube is too large for the larynx, then the bronchoscope must be removed and the procedure repeated with a smaller tube.

A guide-wire technique has the advantage of being able to use an adult-sized bronchoscope for all sizes of tubes. A guide-wire is passed through the suction channel of the bronchoscope and guided into the trachea under direct vision. The bronchoscope is then removed and the tube passed over the wire. Pre-selection of the tube is not an issue because it is easily changed for a smaller one without having to re-insert the bronchoscope. A stiffening device is generally required using this technique prior to railroading of the tube.

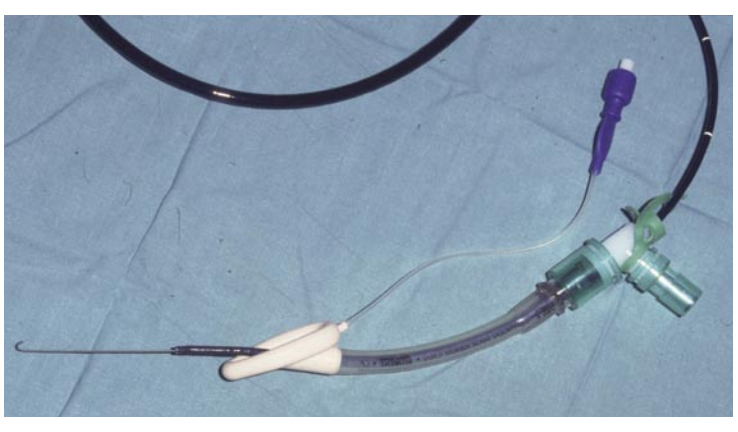
Route of intubation

The nasal route is often favoured in adults and can be used in children. Despite the belief that the angles to the larynx are easier when the fibre-optic bronchoscope is introduced through the nose, the risk of bleeding (caused either by the bronchoscope or railroading of the tube) can make this hazardous. Therefore, if the nasal route is chosen, careful preparation with vaso-constrictor solutions is essential. Adrenaline (epinephrine) 1:10,000, 1–2 ml, can be used before fibre-optic examination. Cocaine is best avoided.

The oral route is often preferred in children. The airway is commonly maintained during intubation through a nasal airway, a specially adapted face mask or an LMA.

The use of the LMA

The LMA is an extremely effective method of maintaining a difficult airway in a baby or child, allowing good oxygenation and a deep level of anaesthesia while affording the anaesthetist time to bronchoscope through the lumen of the device (Figure 4). However, it is difficult to railroad a tracheal tube through an LMA because it may stick in the lumen or at the distal bars of the LMA, or at the level of the glottis. A good alternative is to use a guide-wire inserted into the trachea through the suction channel of the bronchoscope, which is then removed. The guide-wire should be very long (in excess of 120 cm). These wires are often found in cardiac catheter laboratories. A 'stiffening' device (e.g. *Cook* airway exchange catheter) is passed over the wire and the wire, followed by the LMA, are then removed allowing the tracheal tube to be railroaded over the stiffening device and into the trachea. ◆



4 A laryngeal mask airway with a flexible bronchoscope inserted through it and a long guide-wire emerging from the suction channel of the bronchoscope.

Monitoring during Paediatric Anaesthesia

Franco Moscuzza

Franco Moscuzza is Consultant Anaesthetist at Guy's and St Thomas' Hospitals NHS Trust, London, UK. His special interests are anaesthesia for congenital heart disease and paediatric airway surgery.

Monitoring during paediatric anaesthesia should comply with the recommendations of the Association of Anaesthetists. The most important 'monitor' is the presence of an appropriately trained and vigilant anaesthetist whose role is to interpret the information obtained from a range of sources. There are also many subtle physical and clinical signs that are either not detectable by electronic or electrical methods or may precede equipment warnings. Examples include observation of the eyes (pupillary dilation and divergence of gaze), capillary refill time, changes in the character of peripheral pulses, and early signs of airway obstruction (which may occur before changes in capnography or oxygen saturation). Because of the physiological differences between children and adults, changes in cardiovascular and respiratory variables occur more rapidly in children (particularly in babies), and monitoring assumes a greater role in safe management.

Cardiovascular monitoring

Precordial and oesophageal stethoscope

Auscultation with a precordial or oesophageal stethoscope is a cheap and simple method of obtaining direct and continuous information about the respiratory and cardiovascular systems. Both types of stethoscope can be connected to a conventional or a moulded monaural earpiece.

The precordial stethoscope can give continuous information about heart rate and some indication of blood pressure (the heart sounds can become 'muffled' with a major fall in cardiac output). The best position is usually at the left sternal border at the second or third intercostal space where both breath sounds and heart sounds can be heard. However, this does not exclude endo-bronchial intubation of the ipsilateral lung or provide information about the adequacy of gas exchange. Wheeze or secretions are generally easily detected. Background noise in the operating theatre may interfere with auscultatory monitoring.

The oesophageal stethoscope is a soft catheter with holes in the distal 2–3 cm covered by a balloon cuff. To position the catheter appropriately, connect it to the distal tubing of a stethoscope and then advance it into the oesophagus (through a nostril or the mouth) until the heart and breath sounds are loudest. The tip then lies in the mid-oesophagus. It should be used only in intubated patients and it can also incorporate a thermistor or ECG electrode. Contraindications include laser surgery of the airway and oesophageal atresia.

ECG

Myocardial ischaemia is uncommon in children except those with congenital heart disease having cardiac surgery. Therefore, the principal function of the ECG is to monitor heart rate and detect arrhythmias, particularly bradycardia. Primary cardiac arrhythmias are rare but secondary arrhythmias (caused by hypoxia, hypercarbia, surgical stimulation or anaesthetic agents) occur more commonly. Ensuring an adequate heart rate is essential in babies because cardiac output is largely rate dependent.

Lead II is the most useful for detecting arrhythmias because it provides the most information about the P wave. In neonates and young infants the right ventricle is dominant (precordial leads V1 ± V2 according to age) and there is right axis deviation. The T wave is large because of the proximity of the electrodes to the heart and the monitor can mistake this for another QRS complex resulting in an erroneous double counting of the heart rate. Electrolyte disturbances can occur rapidly in babies and the first clue may be a change in the morphology of the ECG (e.g. peaked T waves with hyperkalaemia, increased QT interval with hypocalcaemia). Monitoring the ECG during regional analgesia may also help to detect inadvertent intravenous injection of local anaesthetics.

Blood pressure

Non-invasive: systolic and diastolic blood pressure can be measured by auscultation of the Korotkoff sounds using a sphygmomanometer. However, this is impractical during surgery in babies or small children and has long been replaced by automated devices using Doppler or (more commonly) oscillometry.

Oscillometry (e.g. the Dinamap – device for indirect non-invasive mean arterial pressure) is the most common technique for automated blood pressure measurement in paediatrics and is generally accurate for systolic, diastolic and mean pressures if an appropriately sized cuff is chosen. If the cuff is too narrow, the blood pressure reads falsely high and if too wide, falsely low. Care should be taken to ensure that the cuff does not cause nerve injury (for example, by over-frequent measurement) and that the tubing does not cause pressure damage. An appropriate blood pressure cuff should cover two-thirds of the length of the upper arm or thigh or have a width equivalent to 40% of the circumference of the limb (4 cm width is recommended for a term neonate).

Invasive: direct, intra-arterial monitoring is the most accurate measure of blood pressure and provides a 'beat to beat' assessment. However, it is usually restricted to critically ill children or those undergoing major surgery with significant blood loss or fluid shifts because of the associated risks (e.g. thrombosis, embolism). Possible sites for arterial cannulation include all the proximal and distal arteries of the arms and legs (e.g. radial, brachial, femoral, dorsalis pedis) and the umbilical artery in a newborn baby up to 3 days old, though this cannot be used in cases of intra-abdominal surgery. Care should be taken to try to ensure that a collateral blood supply is present although Allen's test is difficult in young children and the efficacy debatable. The size of catheter varies according to the site but as an approximation a 24G is used in neonates, 22G in infants and young children up to about 20 kg and 20G in older children. A solution of heparinized saline (heparin, 0.5 or 1 iu/ml) is flushed through the transducer mechanism at a constant rate (usually 3 ml/hour) to maintain patency. However, 0.5 ml/hour delivered through a syringe driver, rather than a pressurized bag, is more appropriate in infants, especially premature babies whose maintenance fluids need to be carefully regulated.

Inaccuracies are minimized by ensuring that the tubing between the cannula and the transducer is rigid and as short as possible to prevent high-frequency harmonic interference. Other causes of a 'damped' trace include air bubbles, arterial spasm and kinking of the tubing or cannula. Care needs to be taken in babies or small children to avoid retrograde flow into the cardiac or cerebral circulations (which can occur with as little as 0.5–1 ml of injectate) or the inadvertent administration of large volumes of fluid during flushing. It is preferable to inject a small amount of fluid through a syringe at relatively low pressure rather than 'flush' directly through the transducer (which will deliver an unmeasured volume at relatively high pressure). Other complications of arterial cannulation include local haematoma, haemorrhage from inadvertent disconnection, infection (local or generalized sepsis), thrombosis and distal embolization.

Central venous pressure monitoring

Indications for direct central venous pressure monitoring include:

- major surgery with anticipated large fluid shifts
- massive blood loss
- cardiac surgery
- critically ill children.

As in adults, the trend of readings is more important than absolute values. If right ventricular function is normal, then values are a reasonable indication of intravascular volume. Measurements are accurate when made from either the superior (SVC) or inferior vena cava (IVC) provided there is no obstruction to drainage. The SVC is usually accessed via the internal jugular or subclavian vein and the IVC is approached through the femoral (or in the newborn, umbilical) vein. Care must be taken in neonates to ensure that the tip of a central line does not extend into the right atrium because there have been reports of lines eroding though the atrial wall. As with arterial pressure monitoring, the tubing between the transducer and line should be short and rigid. The zero baseline is crucial and should be taken at the mid-axillary level. Measurement is influenced by respiration and should be made at the end of expiration, which corresponds to the lowest level on the wave form.

Pulmonary artery pressure and cardiac output monitoring

Although pulmonary artery catheters are available for children, in the author's experience they are seldom used. Accurate positioning is harder to achieve in the small child than in adults and data interpretation is more difficult. Complications (e.g. catheter knotting, infection, bleeding) though uncommon, are a significant source of morbidity. In surgery for congenital heart disease, the catheter often lies directly in the surgical field and left-sided filling and pulmonary artery pressures are better measured (if required) from lines placed by the surgeon at the end of the procedure.

Alternatives for measuring cardiac output accurately in children are becoming increasingly available though most are confined to the paediatric ICU. The systems most likely to develop more widespread use are transoesophageal Doppler, transpulmonary thermodilution (COLD Z-021) and pulse contour analysis. Measurement of mixed venous oxygen saturation is also used to determine changes in cardiac output indirectly.

Respiratory monitoring

Pulse oximetry

Hypoxia, usually associated with airway problems, is the most common critical incident in paediatric anaesthesia. Hypoxia develops quickly, particularly in babies in whom the functional residual capacity is low and oxygen consumption high. Clinical evaluation by detecting cyanosis is difficult even for the most experienced anaesthetist. Oximetry provides an invaluable early warning of hypoxia.

The pulse oximeter provides no information on the adequacy of ventilation. For example, a baby with severe respiratory failure and hypercarbia may have normal saturations if breathing oxygen-enriched air. Nor does it measure the partial pressure of oxygen, which may vary for the same saturation according to shifts in the oxyhaemoglobin dissociation curve. Because of the plateau of the oxyhaemoglobin dissociation curve, saturation monitoring is an inappropriate monitor for avoiding hyperoxia in preterm neonates at risk of retinopathy. Although calibrated for adult haemoglobin, the absorption spectrum is virtually identical for fetal haemoglobin and pulse oximeters can be used reliably in neonates. Other forms of haemoglobin may introduce errors in the saturation obtained. For example, carboxyhaemoglobin is detected by the oximeter as normal oxyhaemoglobin therefore the oxygen saturation is overestimated. Figure 1 indicates factors that may affect the accuracy of pulse oximeters. Thermal injury and pressure necrosis due to too tight application of the sensor probe have been described (Figure 2).

Limitations of pulse oximetery

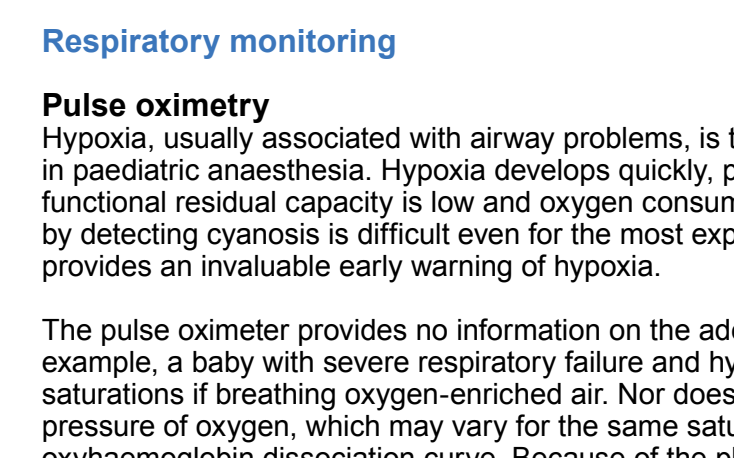
Physiological

- Abnormal haemoglobin (oxyhaemoglobin dissociation curve shift)
  – methaemoglobin decreases oxygen saturation (SpO_2 – to 85% with high concentrations)
  – anaemia causes no problem if haemoglobin > 5 g/dl
  – carboxyhaemoglobin produces a falsely high SpO_2
- Poor perfusion (from hypovolaemia, low cardiac output or hypothermia)
- Dyes (e.g. methylene blue causing transient low SpO_2)
- Venous pulsation (e.g. tricuspid regurgitation causing a falsely low SpO_2)

Technical

- Accuracy decreases with SpO_2 < 80% (e.g. cyanotic congenital heart disease)
- Response delay/motion artefacts
- Light interference (especially fluctuating light sources)
- Electrical or magnetic interference

1



2 Injury sustained from saturation probe.

Capnography

Capnography is the measurement of PCO_2 in inspired or expired gases during breathing. In fit babies and children, the end-tidal carbon dioxide ($EtCO_2$ or alveolar PCO_2) provides a good measure of arterial PCO_2 ($EtCO_2$ is usually 2–5 mm Hg lower), but the difference may be increased if there is a large V/Q mismatch, particularly with a large dead space (e.g. bronchopulmonary dysplasia). Children with congenital heart disease, particularly those with large shunts, also show larger variations. Capnographs use infrared absorption for measurement.

Main-stream analysers have a sensor placed in the breathing system, preferably as close to the patient as possible, and give an instantaneous reading. However, they are heavy and can significantly increase the dead space of small paediatric circuits. Sensors with smaller dead spaces are available.

Side-stream analysers have a line leading to the analyser from a sampling port and consequently, there is a lag time for measurement. Gas can be monitored more proximally than with a main stream, the tubing is narrow and lightweight, and has no effect on dead space. However, there is a greater potential for obstruction either from kinking, external compression or blockage of the tube due to water condensation from the expired gases. When using a side-stream analyser to monitor a low-flow circle system, allowance must be made for the volume of gases removed for sampling or the exhaust gases from the analyser must be returned to the circuit. Side-stream analysers can also measure other gases such as nitrous oxide and volatile agents.

Capnography is not only a monitor of the adequacy of ventilation but also gives warning of disruption in gas supply (e.g. disconnection of the circuit), inadequate fresh gas flow, and oesophageal intubation. A falling $EtCO_2$ may indicate a sudden decrease in cardiac output or a pulmonary embolus (both reduce pulmonary blood flow) and a rapid rise may be the earliest warning sign of malignant hyperpyrexia. Changes in the capnographic trace may indicate recovery from muscle relaxation. Some characteristic changes are described in Figure 3.

Some causes of abnormal end-tidal CO_2 readings

Decrease

Complete disappearance

- Disconnection
- Complete obstruction (either airway or sampling line)
- Cardiac arrest

Slow decrease

- Hyperventilation
- Pulmonary hypoperfusion
- Leak around tracheal tube (may be variable)

Increase

Slow

- Hypoventilation
- Rebreathing (may become rapid)
- Faulty unidirectional valve in circle (causing rebreathing)
- Muscle relaxation reversal

Rapid

- Malignant hyperpyrexia (progressive despite adequate ventilation)

Temperature

Measuring temperature is important in babies and children because of the increased risks of hyperthermia and hypothermia. In infants, thermoregulatory mechanisms are poorly developed and the relatively large surface area to weight ratio means that hypothermia may develop rapidly. It is also easy to overheat children with the enthusiastic use of modern warming devices. Temperature monitoring is also indicated because of the potential risk of malignant hyperpyrexia. Temperature probes may be thermistors, thermocouples or liquid crystals.

Thermistors are metal semiconductors and the resistance varies with temperature. They can be covered by plastic tubing and placed in the nasopharynx, oesophagus or rectum or incorporated into catheters (e.g. urinary or pulmonary artery catheters).

Thermocouples work on the principle that the potential difference generated at the junction of two different metals varies according to the temperature – the tympanic thermometer is a good example of this type.

Liquid crystal thermometers are often incorporated into adhesive strips, which are applied to skin. The crystals change colour with changes in temperature.

Neuromuscular blockade

In young children, particularly infants and neonates, there is a much greater individual response to muscle relaxants. Variability may be increased by underlying medical conditions and interactions with other agents. Monitoring neuromuscular blockade with a peripheral nerve stimulator is, therefore, essential in paediatric anaesthesia and highly recommended in intensive care, particularly if infusions of relaxants are given. ◆

Preoperative Assessment and Preparation

Peter Stoddart

Peter Stoddart is Consultant Paediatric Anaesthetist at the Bristol Royal Hospital for Sick Children and the Bristol Eye Hospital, Bristol, UK. His main interest is the prevention and control of acute pain in children.

Admission to hospital for surgery is stressful for a child and his or her family. The preoperative assessment allows the anaesthetist to establish a rapport with the child and parents, allaying many fears and concerns. In addition, the anaesthetist must assess the child, then plan and discuss the anaesthetic and analgesic management with the family, surgeon and nurses. This time is crucial to the subsequent success of the anaesthesia and is a rewarding component of paediatric practice.

Assessment

Most children requiring anaesthesia are healthy, have large physiological reserves, and are having relatively uncomplicated surgery. However, they all require a full history and examination to exclude any potential hazards or difficulties for the anaesthetist. The importance and relevance of these may change with the age of the child; for example, the airway in a child with Pierre Robin syndrome often becomes easier to manage as the mandible grows.

With the increasing numbers of day-case and same-day admissions, many hospitals have established successful pre-admission clinics. These are usually run by nurses and play therapists who obtain a standardized anaesthetic history. They also help families to become familiar with the sights and sounds of the hospital environment. The routines are explained, especially the fasting requirements, and the child is able to play, ask questions and learn what to expect on admission.

The child must also be seen by an anaesthetist, preferably the one giving the anaesthetic on the day of the surgery. It is important to review the notes and speak to the nurses and surgeon before seeing the child. The anaesthetist should gain the family's confidence before obtaining a more detailed history. Making eye contact with children by, for example, sitting at their level, involving them in the discussion, or asking them about other non-medical, and therefore less-threatening topics (e.g. their favourite toy/doll, television programme, football team), helps to reduce their anxiety, makes them feel important and increases their trust. Children will often listen to an anaesthetist who is speaking to their parents while appearing to play close by. These children should be drawn into the discussion and certainly should not be ignored.

History – the following factors must be noted in the history:

- age
- weight
- diagnosis
- starvation time
- important factors in the medical history that are of relevance to the anaesthetist (see Figure 1)
- past anaesthetic history – airway problems, endotracheal tube size, behavioural problems in anaesthetic/recovery room, previous premedication and its effect, nausea/vomiting
- family history – malignant hyperthermia, muscle disease, pseudocholinesterase deficiency, porphyria, sickle cell disease
- drug history – current medication, recent corticosteroid therapy, previous chemotherapy
- allergies (including latex).

Examination – much of the examination and assessment, especially of small children, can be done by watching and observing the child while taking the history. School-age children are usually happy to be examined once the anaesthetist has gained their trust, though some can be easily embarrassed and require more time and privacy. Toddlers and preschool children may be more of a challenge and are best examined while sitting on their parent's knee rather than laid flat on a bed or in a cot. Examining the child's hands first allows the anaesthetist to look for potential venous access and makes an initial contact in an open, non-threatening way. The features that should be assessed in the examination are listed in Figure 2.

Investigations – few children about to undergo routine minor surgery require further investigations. However, if they have a significant underlying history (e.g. recent chemotherapy) or are having major surgery (e.g. a fundoplication, multilevel osteotomies), then blood should be taken for a full blood count, urea, blood sugar and electrolytes, and a blood group and save or cross-match (if appropriate). Further tests such as an ECG, echocardiography, haemoglobin electrophoresis, clotting studies, chest radiograph and lung function tests may be required if indicated by the history or examination.

The child with a runny nose is a common problem in paediatric anaesthetic practice. The indications for cancelling elective surgery are signs of active viraemia (i.e. the child is unwell and miserable or has a fever) or signs of lower respiratory tract infection. A child who is obviously recovering from an upper respiratory tract infection or who has an allergic rhinitis has an increased risk of laryngospasm and bronchospasm but should not present difficulties for an experienced anaesthetist.

Factors in the medical history of relevance to the anaesthetist

Perinatal
- Maternal health and delivery
- Prematurity and management on neonatal ICU
- Congenital anomalies or syndromes

Respiratory
- Respiratory distress syndrome, apnoeas, bradycardias
- Recent upper respiratory tract infection
- Asthma
- Croup
- Snoring, sleep apnoea
- Cystic fibrosis

Cardiovascular
- Hypertension (e.g. secondary to renal or endocrine disease, or associated coarctation of the aorta)
- Murmurs, pulmonary hypertension
- Cyanotic episodes
- Dyspnoea/exercise tolerance

Gastrointestinal
- Vomiting
- Gastro-oesophageal reflux
- Diarrhoea
- Liver disease
- Nutritional requirements – total parenteral nutrition, enteral supplements

Renal
- Thirst, urine output, wet nappies
- Renal failure

Neurological
- Cerebral palsy
- Developmental delay
- Seizures – frequency, type, treatment
- Hydrocephalus – shunts
- Meningomyelocele

Metabolic/endocrine
- Inborn errors of metabolism
- Diabetes, thyroid, pituitary, adrenal disease

Haematological
- Sickle cell disease
- Bruising/bleeding tendency
- HIV

Oncological
- Leukaemias
- Solid tumours (e.g. nephroblastoma, neuroblastoma)
- Recent chemotherapy or marrow suppression

Dental
- Loose teeth – these may need to be extracted, if so the child should be informed

1

Examination of the preoperative child

Vital signs (especially before emergency surgery)
- Colour/cyanosis
- SpO_2 with a pulse oximeter
- Hydration (assessed by examining fontanelle, mucous membranes, skin)
- Pulse rate and volume
- Capillary refill time
- Conscious level/activity
- Temperature

Head and neck
- Dysmorphic features, especially craniofacial
- Dentition – loose teeth
- Size of tongue
- Cervical lymphadenopathy
- Tracheal deviation

Respiratory
- Respiratory pattern
- Work of breathing – look for nasal flaring, tracheal tug, sternal recession
- Use of accessory muscles
- Wheeze/stridor/grunting
- Breath sounds

Cardiovascular
- Murmurs
- Peripheral pulses
- Venous access

Abdominal
- Distension
- Hepatic/splenic enlargement

Neurological
- Neurodevelopment
- Spasticity
- Scoliosis
- Myelomeningocele

2

Psychological preparation

The psychological needs of both the child and the parent must be considered. Time invested in preparing the family will improve cooperation and behaviour before surgery and cause fewer upsets and long-term behavioural changes afterwards.

The nature of the child's fears will be related to their age, stage of neurodevelopment, emotional maturity, previous anaesthetic experience and parental support. Toddlers and pre-school children are unhappy if they are separated from their parents and may benefit from bringing a favourite toy or comforter into the anaesthetic room. Schoolchildren are less concerned about leaving their parents but may be needle-phobic, fear a loss of control, be embarrassed by the loss of privacy, or be concerned that they will wake up during the surgery or not at all. Adolescents have similar fears that they may suppress, appearing calm and controlled on the ward only to revert to an immature state in the anaesthetic room. They can be very concerned about their body image, loss of autonomy, the long-term consequences of the surgery and the potential complications of the anaesthesia.

Most parents are extremely anxious and stressed during the perioperative period, which can add to the child's apprehension. Parents may experience a sense of guilt because their child needs surgery and worry that the child may have pain postoperatively. They can become very upset when separated from the child and embarrassed by their loss of control. Parents are concerned for their child's safety while they are anaesthetized and worry about the outcome of the surgery.

The fears and reservations of each child and their parents must be addressed and individualized for that particular family. A careful explanation of what is planned, with their involvement, must be given using appropriate language. Care should be taken not to use condescending phrases that can be taken out of context (e.g. the innocent reference to 'being put to sleep'). Postoperative pain control should be discussed, including epidural analgesia and patient-controlled analgesia if these techniques are required, as should the need for catheters or drains. Children and parents expect and accept a truthful description of any discomfort or pain they may experience. If the need for postoperative intensive care is anticipated, the family should be allowed to visit the unit before surgery.

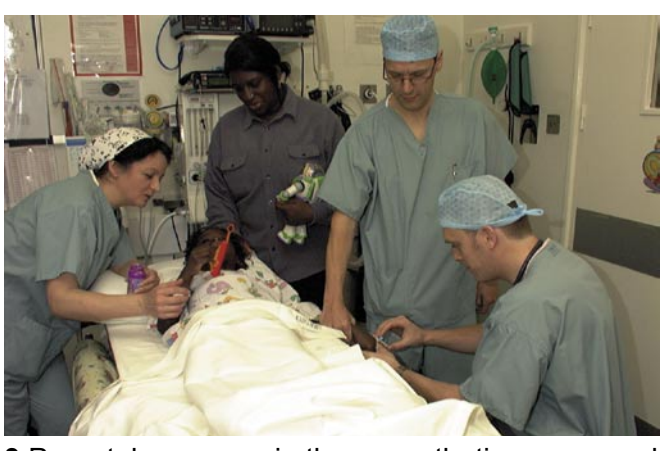
Having established a rapport and gained the trust of the child, subsequent induction of anaesthesia is achieved in a much more simple and peaceful fashion. Additional anxiolysis may be induced by judicious premedication, but simple distraction using musical books, bubbles or enlisting a play therapist is often as effective for the nervous child. The induction room should have a relaxed, 'child-friendly' atmosphere with one person (i.e. the anaesthetist) obviously in control.

Parents are usually encouraged, and have an expectation that they should come to the anaesthetic room (Figure 3). This may be helpful if the parent is calm and reassures an anxious child, especially if a small child prefers to sit on the parent's knee. However, parental presence is not beneficial to all children. Indeed, parents may hinder the smooth induction of anaesthesia by upsetting the child, distracting the anaesthetist and requiring nurses to look after them. Many parents dislike the feeling of their child being induced in their arms and worry that the child looks lifeless. Some parents panic or faint.

After explaining what to anticipate during induction, the relative merits, or otherwise, of a parent being in the anaesthetic room should be discussed. If parents do not wish to come to the anaesthetic room they should be encouraged to stay on the ward and reassured so that they do not feel guilty or inadequate. Additionally, if the child is a small baby or has potential anaesthetic difficulties, the anaesthetist should not be forced to have the parents present; the child's safety is paramount.

Emergency surgery is acutely stressful for most children and their families. There may be little time to counsel them fully preoperatively. Often they are tired and may have travelled a long distance to a specialist centre. However, many families are also relieved that something positive is being done for their child.

Some children require repeated anaesthesia (e.g. radiotherapy, repeated oesophageal dilatations). They need careful consideration and may develop obsessional behaviour in the anaesthetic room. These children are best treated by the same anaesthetic team members or, if this is impossible, by discussing their needs, preferences and routines well in advance of anaesthesia.



3 Parental presence in the anaesthetic room may help in achieving a smooth induction of anaesthesia.

Premedication

Premedication may be used to assist the induction of anaesthesia by providing:

- anxiolysis, amnesia and sedation
- topical analgesia before venepuncture
- reduced airway secretions and vagolytic action
- analgesia
- anti-emesis.

Sedative premedication – many sedatives have been used over the years as premedicants for anxious children. Their use has reduced as the rate of day-case surgery has increased and the emphasis is now on gaining the child's confidence before induction of anaesthesia, allowing parents to accompany the child, using distraction techniques, and applying topical analgesia before venous cannulation. However, some children benefit from sedation. Commonly used drugs are shown in Figure 4.

Oral premedication is the most acceptable, and many children's nurses are now unwilling to administer intramuscular injections. However, some children refuse an oral premedicant and exhibit such combative behaviour in the anaesthetic room that intramuscular sedation is the only option.

Topical local anaesthesia with *Emla* (a eutectic mixture of lignocaine and prilocaine) or *Ametop* (amethocaine gel) has simplified and increased the acceptance of awake, venous cannulation, enabling a smooth intravenous induction. However, both need to be applied 30–60 minutes before venepuncture. *Emla* has a slower onset time, may cause marked venoconstriction, and has been reported to cause methaemaglobinaemia. *Ametop* can occasionally cause local allergic skin reactions.

Anticholinergics – atropine, 20 µg/kg i.m. or 40 µg/kg p.o., reduces the incidence of hypoxic episodes or bradycardias secondary to laryngospasm or excessive airway secretions during induction and emergence from a halothane anaesthetic. However, its routine use has decreased since the introduction of sevoflurane for gaseous induction and the more widespread use of intravenous induction.

Analgesics – paracetamol, 20–30 mg/kg, and/or non-steroidal anti-inflammatory drugs such as ibuprofen, 5 mg/kg, or diclofenac, 1 mg/kg, are often given orally before elective surgery. This reduces the requirement for postoperative opioids and supplements intraoperative local anaesthetic blocks by ensuring adequate absorption before the end of surgery.

Anti-emetics – children with a history of postoperative nausea and vomiting or having high-risk surgery (e.g. strabismus or middle ear surgery) should be given preoperative anti-emetics such as ondansetron, 0.1–0.2 mg/kg, or metoclopramide, 0.15 mg/kg.

Fasting guidelines

All patients are fasted before elective surgery to reduce the risk of pulmonary aspiration of acidic gastric contents, which may lead to a pneumonitis or occlusion of the airway with solid material. Balanced against these risks is the danger of occult hypoglycaemia or dehydration, especially in small babies following a prolonged fluid fast. Residual gastric acid content and volume are not increased by allowing children to drink clear fluid (apple juice, squash or oral dehydration fluid) until 2 hours before anaesthesia and these more liberal guidelines have improved compliance and comfort. The Bristol Children's Hospital fasting guidelines for elective surgery in otherwise normal children are shown in Figure 5.

These guidelines are not appropriate for children needing emergency surgery or if the child is known to have delayed gastric emptying as a result of, for example, pyloric stenosis, ileus or peritonitis. A nasogastric tube must be inserted on the ward before children with bowel obstruction come to theatre and this should be aspirated before inducing anaesthesia. Following trauma, the time between the last meal and the subsequent injury gives a more useful guide to the probability of an empty stomach, rather than the duration of fasting, because of the frequent development of gastric paresis exacerbated by opioid administration. Many children, especially those with cerebral palsy, have marked gastro-oseophageal reflux. They are usually taking medicines such as H_2-antagonists or a proton pump inhibitor (e.g. omeprazole) and these should be continued preoperatively. In children with a high risk of aspiration, anaesthesia should be induced using a rapid sequence technique.

Sedative premedicants

Drug	Route and dose	Comments
Benzodiazepines		
• Midazolam	Oral, 0.5–0.75 mg/kg, max. 20 mg	Intravenous preparation actually used. Has an unpleasant taste, therefore disguise in blackcurrant juice or paracetamol elixir. NB Syrups are available (e.g. the Alder Hey recipe). Onset 20–30 minutes
	Intranasal, 0.2–0.3 mg/kg	Irritant. Onset about 10 minutes
• Temazepam	Oral, 0.5–1.0 mg/kg, max. 20 mg	
• Diazepam	Oral, 0.2–0.4 mg/kg, max. 15 mg	
Opioids		
• Morphine	Intramuscular, 0.2 mg/kg	Especially before cardiac surgery. Intramuscular injection painful
• Oral transmucosal fentanyl citrate	Oral, 10–15 µg/kg	*Oralet* in North America. Associated with vomiting and pruritus
Others		
• Triclofos	Oral, 50–75 mg/kg, max. 1000 mg	Pleasant taste compared with parent compound chloral hydrate
• Trimeprazine	Oral, 2 mg/kg	This dose often ineffective but has potentially useful anti-emetic properties
• Methohexitone	Rectal, 30 mg/kg	Popular in North America. Induces anaesthesia in a child while in parent's arms before transfer to theatre
• Ketamine	Oral, 5–6 mg/kg; intramuscular, 2–5 mg/kg	Associated with increased salivation, hallucinations and emergence delirium

4

Fasting guidelines – Bristol Children's Hospital

Age (months)	Food (hours)		Clear fluid (hours)
< 12	Solids	6	2
	Formula milk	4	
	Breast milk	3	
> 12	6	3

Principles of Anaesthesia for Common Elective and Emergency Operations in Children

Alison S Carr

Alison S Carr is Consultant Paediatric Anaesthetist at Derriford Hospital, Plymouth, UK. She qualified from St Bartholomew's Hospital, London, and trained in paediatric anaesthesia in Bristol, Toronto, Canada, and Charlottesville, USA. Her research interests are paediatric regional analgesia and methods of controlling postoperative vomiting in children.

This article describes the principles of anaesthesia for children and discusses the important considerations and anaesthetic techniques for specific elective and emergency surgical procedures. Principles of anaesthesia for babies and techniques for ENT surgery are discussed in other issues of *Anaesthesia and intensive care medicine*.

General considerations

Standards for the delivery of a surgical service for children in the UK are summarized in Figure 1.

Standards for the delivery of a surgical service for children in the UK

Clinicians
Anaesthetists and surgeons should have adequate training and continuing experience in the management of children. Occasional paediatric practice has been widely condemned

Specialist paediatric centres
Children are managed by specialist paediatric surgeons and anaesthetists

District general hospital
Surgeons treating children must:
- have a minimum of 6 months' training in paediatric surgery
- care for a sufficient number of children annually to maintain a high level of competence
- operate on children on at least one operating list every fortnight

Anaesthetists treating children must:
- have a minimum of 6 months' training in paediatric anaesthesia
- anaesthetize children on at least one operating list per week

It has been recommended that adequate continuing paediatric experience requires the anaesthetist to anaesthetize per year:
- 12 children < 6 months
- 50 children < 3 years
- 300 children < 10 years

Paediatricians should be involved in the care of children when appropriate

There must be close liaison with a specialist paediatric surgical centre

Other staff and facilities
- In all areas, staff should include nurses with special paediatric training
- An accident and emergency department must have appropriate children's facilities
- Protocols must be in place for prompt access to paediatric ICU beds

Environment
- Children should be nursed on children's wards and should not be cared for alongside adults
- Separate safe and appropriate facilities should be available for children perioperatively including a preoperative play area, designated theatres and a paediatric recovery bay
- Surgery for day-case patients should take place on designated paediatric lists in the day-case unit

Equipment
- Suitable, appropriately organized paediatric equipment must be available, arranged on trolleys or in designated anaesthetic rooms

Induction of anaesthesia
The choice of induction method depends on several factors, including the wishes of the child, parent or anaesthetist and the general condition of the child. A rapid-sequence induction is indicated if there is bowel obstruction, an acute abdomen or significant gastro-oesophageal reflux. Gaseous induction is essential if there is airway obstruction. Total intravenous anaesthesia may be used in children susceptible to malignant hyperthermia or to reduce vomiting after specific operations.

Perioperative intravenous fluid therapy is summarized in Figure 2.

Temperature regulation: body temperature preservation is important particularly

Perioperative intravenous fluid therapy

Replacement of starvation deficit
- Depends on length of starvation
- Equals hourly maintenance intravenous fluids (ml/hour) x duration of starvation (hours)

Maintenance intravenous fluids
- 4 ml/kg/hour for first 10 kg body weight
- 2 ml/kg/hour for next 10 kg body weight
- 1 ml/kg/hour for every additional kg body weight
- Use 5% dextrose,1/2 strength Hartmann's solution or lactated Ringer's solution, depending on age

Replacement of third-space losses
- Depends on site of operation and extent of surgical exposure
- Use lactated Ringer's solution

Suggestions:
- Laparotomy, 6 ml/kg/hour
- Thoracotomy, 4 ml/kg/hour
- Femoral osteotomy, 2 ml/kg/hour

Replacement of blood loss
- Type of intravenous fluid used depends on haemoglobin (Hb)

Calculate allowable blood loss

$$\frac{(\text{preoperative Hb} - \text{acceptable Hb}) \times \text{circulating blood volume}}{\text{mean Hb}}$$

Acceptable Hb
- Depends on clinical condition of child
- Suggest Hb = 8 g/dl in a healthy child

Circulating blood volume
- 72 ml/kg for children > 2 years old

Replacement intravenous fluids
- Give 1 ml colloid/blood or 3 ml crystalloid for every ml blood loss
- Use colloid or crystalloid if Hb > 8 g/dl
- Use blood if Hb ≤ 8 g/dl

during major surgery. Children are at greater risk of heat loss than adults because of their higher surface area to mass ratio. Core temperature should be monitored during anaesthesia in small children or those undergoing major surgery. It should also be monitored continuously in children at risk of malignant hyperthermia.

The main method of cutaneous heat loss is thermal radiation. Conduction and convection from exposed tissues are less important. Evaporation may be substantial from large incisions. Methods of preserving body temperature perioperatively are summarized in Figure 3.

Analgesia: perioperative analgesia for different procedures is summarized in Figure 4. **Preventing postoperative vomiting** is described in Figure 5. Side-effects of some of the frequently used anti-emetics are more common in children. Metoclopramide and cyclizine are associated with extrapyramidal effects. Cyclizine may cause anticholinergic effects. Droperidol, particularly in large doses, may cause drowsiness, sedation, dysphoria or restlessness. Ondansetron is comparatively free of side-effects and is the first-line treatment for postoperative vomiting at Derriford Hospital, Plymouth.

Methods of preserving body temperature perioperatively

Prevent heat loss from the body to adjacent structures
- Keep child covered during procedures (e.g. wrap body and head in an insulating cover, gamgee or polythene)
- Lay the child on a warming mattress or a mattress of low thermal conductance
- Use a forced-air patient-warming system

Reduce evaporative losses
- Keep large surgical incisions covered up
- Use 'bowel bags' during laparotomy
- Use water-repellent surgical drapes

Warm intravenous fluids
- Use a blood and intravenous fluid warmer

Prevent heat loss from the respiratory tract
- Humidify and (if necessary) warm inspired gases using a heated humidifier or a heat and moisture exchange filter

Perioperative analgesia in children

	At induction	Intraoperatively	In recovery	Postoperatively
Minor surgery (no opioids required)	Diclofenac, 1–1.5 mg/kg p.r. Local block or infiltration if applicable		Paracetamol, 40 mg/kg p.r. or 20 mg/kg p.o., if required	**a** Paracetamol, 15–20 mg/kg p.o. or p.r. 6 hourly (max. 90 mg/kg/day) **b** Diclofenac, 3 mg/kg/day in divided doses
Intermediate surgery (opioids required for ≤ 24 hours)	Paracetamol, 40 mg/kg p.r. and diclofenac,1–1.5 mg/kg p.r. Regional or local block if indicated Opioid boluses[1]	Opioid boluses[1] as required	Morphine, 50 µg/kg i.v. boluses every 10 minutes (max. 200 µg/kg i.v.)	*Oramorph*, 0.5 mg/kg 4 hourly p.o., as required or morphine, 50 µg/kg i.v., as required and regular prescriptions of **a** and **b** as above
Major surgery (opioids required for > 24 hours)	Paracetamol, 40 mg/kg p.r. and diclofenac, 1–1.5 mg/kg p.r. Epidural if indicated Opioid boluses[1]	Opioid boluses[1] as required	As for intermediate surgery	Epidural infusion ± *Oramorph* or patient-controlled morphine or morphine i.v. infusion and regular prescriptions of **a** and **b** as above

[1]Opioid boluses are fentanyl, 1–2 µg/kg i.v. or morphine, 50–100 µg/kg i.v., at induction, and fentanyl, 1 µg/kg i.v., or morphine, 50 µg/kg i.v., boluses as required intraoperatively.

4

Reducing postoperative vomiting

Give prophylactic intravenous anti-emetics at induction to children:
- scheduled for surgery associated with a high incidence of postoperative vomiting (e.g. squint correction, major ear surgery, adenotonsillectomy, emergency abdominal surgery)
- with a history of motion sickness or previous postoperative vomiting

Give prophylactic anti-emetics to children receiving perioperative opioids
- For example, a single dose intravenously before commencing patient-controlled analgesia or an intravenous morphine infusion

Suggested anti-emetic regimen

First-line therapy	*Receptor antagonism site*
• Ondansetron, 0.15 mg/kg i.v. 8-hourly	• Serotonin (5-HT)
Second-line therapy	
• Metoclopramide, 0.15 mg/kg i.v. 8-hourly	• Dopamine
• Droperidol, 25–50 µg/kg i.v.	• Dopamine
• Cyclizine, 1 mg/kg i.v.	• Histamine

5

Major elective surgery

Childhood tumours
Nephroblastoma and neuroblastoma are the most common extracranial solid childhood tumours, each occurring in about 1/30,000 children.

Nephroblastoma (Wilms' tumour) arises from embryonic cells in the kidney. It usually presents as an asymptomatic renal mass in children under 5 years, and is more common in boys. Bilateral disease occurs in 10% of those affected. Nephroblastoma is associated with aniridia, other genitourinary abnormalities and hemihypertrophy of the body. The tumour may spread to lymph nodes or, via the blood stream, to the lungs. Treatment is nephrectomy either before or after chemotherapy. Children may also require urgent anaesthesia for investigations (e.g. bone marrow or scans). The anaesthetic considerations for excision of a nephroblastoma are summarized in Figure 6.

Anaesthesia should be induced with a rapid-sequence induction. Large-bore intravenous cannulae and central lines should be inserted into the upper body because venous drainage from the lower body may be impaired. Considerable haemorrhage and third-space losses may occur and adequate intravenous fluids must be given to maintain normovolaemia and to ensure adequate urine output. Urinary output should be measured hourly via an indwelling catheter. Blood pressure may vary considerably because of major blood loss, inferior vena cava compression and catecholamine release. Blood pressure should be monitored from an arterial line. Central temperature should be measured because there are large intraoperative heat losses. Intravenous fluids should be warmed. Perioperative analgesia may be provided by an epidural if the platelet count and coagulation studies are normal. Alternatively, morphine may be given either as an intravenous infusion or by a non-continuous method.

Anaesthetic considerations for excision of nephroblastoma

The child may:
- be anaemic
- have a coagulopathy
- vomit frequently
- have lung and liver metastases
- be hypertensive
- have impaired cardiac function, haematology and immunology secondary to chemo-therapy

The presence of a large abdominal mass may:
- predispose the child to regurgitate on induction
- compress the inferior vena cava (IVC) pre- or intra-operatively
- compromise ventilation by diaphragmatic splinting

Blood pressure changes may be marked owing to:
- intermittent IVC compression
- large blood loss
- catecholamine release

Ventilation may be compromised by lung metastases

The tumour may embolize in the IVC

6

Neuroblastomas arise in sympathetic nervous tissue. The primary tumour is retroperitoneal in 50% of patients and arises from either the adrenal medulla or the sympathetic ganglion. It generally presents as an abdominal mass in children under5 years and has usually metastasized at presentation. Prognosis worsens with increasing age. Treatment is surgical excision with chemotherapy and radiotherapy as required.

Preoperative assessment identifies the symptoms and signs detailed in Figure 7. The anaesthetic management of excision of neuroblastoma is similar to that for nephroblastoma. Children with catecholamine-secreting tumours may become tachycardic and hypertensive when the tumour is handled. Treatment with α and β-blockers may be required perioperatively.

Anaesthetic considerations for excision of neuroblastoma

The child may:
- be anaemic and thrombocytopenic owing to bone marrow infiltration
- have metastases in bone, lymph nodes, bone marrow, the brain and spinal cord, and less commonly, in the liver or skin
- have impaired cardiac function, haematology and immunology secondary to chemotherapy

The tumour may secrete vasoactive peptides and catecholamines (adrenaline and noradrenaline) resulting in:
- sweating, pallor and diarrhoea
- hypertension
- cardiac arrhythmias
- an increased level of vanillyl mandelic acid in the urine

Local invasion and compression by the retroperitoneal mass may:
- predispose the child to regurgitate on induction
- compress the inferior vena cava pre- or intra-operatively
- compromise ventilation by diaphragmatic splinting

Blood pressure changes may be marked owing to:
- intermittent inferior vena caval compression
- large blood loss
- catecholamine release

7

Fundoplication
Fundoplication is used for severe, persistent gastro-oesophageal reflux. A hiatus hernia may be associated and cerebral palsy is common. Nissen's fundoplication, in which the lower oesophagus is encircled by the fundus of the stomach, is the usual technique. The effects of severe reflux and indications for fundoplication are given in Figure 8. Usually an open operation through a limited incision is used, though a laparoscopic technique is increasingly used.

An antacid and ranitidine, 2 mg/kg orally, should be prescribed as premedication. Anaesthesia should be induced with a rapid-sequence technique. Suxamethonium is safe for children with cerebral palsy. Anaesthesia is usually maintained with an inhalation agent. A non-depolarizing muscle relaxant is given as indicated. There is evidence that epidural analgesia is associated with less morbidity than an opioid technique. A nasogastric tube is inserted after induction to act as a stent to guide the surgeon. It should be secured carefully so that it can be used postoperatively.

Effects of severe oesophageal reflux and indications for fundoplication

Severe oesophageal reflux may cause:
- malnutrition, producing failure to thrive, particularly in young children
- oesophagitis
- bleeding
- heartburn or chest pain in older children
- pulmonary aspiration particularly in children with total body cerebral palsy who have impaired bulbar control

Reflux commonly occurs in children with chronic disease
- Cerebral palsy

Indications for surgery
- Failure to thrive
- Failure to respond to medical treatment
- Oesophagitis or oesophageal stricture formation
- Anaemia

8

Urinary tract surgery
Children undergo major elective surgery to correct congenital malformations of the urinary tract. Examples are nephrectomy, pyeloplasty, reimplantation of the ureters into the bladder or hypospadias surgery. Most children are generally well and have normal renal function. In addition, many children with spina bifida undergo urological surgery. Compared with other children, they have 500–1000 times the risk of latex allergy and should be treated as being allergic to latex.

Inhalational or intravenous induction may be used. A general anaesthetic combined with a regional analgesic technique, usually an epidural, is common. Anaesthesia is usually uncomplicated but blood loss may be large during nephrectomy. The anaesthetic considerations are those of major surgery: adequate replacement of fluid, body temperature preservation and adequate perioperative analgesia. Non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided if renal function is impaired.

Orthopaedic surgery

Open reduction of a congenital hip dislocation or femoral osteotomy: children having osteotomies are otherwise healthy with congenital deformity (e.g. a congenital dislocation of the hip or Perthes' disease) or have cerebral palsy or muscular disease and may be scheduled for single or multiple procedures. Open reduction for congenital dislocation of the hip is becoming less common owing to improved neonatal screening and ultrasound, but is indicated if the hip is unstable in a spica or if diagnosis is late. Femoral osteotomy may occur from early childhood to adolescence.

The anaesthetic management for open reduction of a hip or femoral osteotomy is similar. Induction may be intravenous or by inhalation. A large-bore intravenous cannula should be inserted. Although not always required, blood should be cross-matched. Tracheal intubation (facilitated by muscle relaxants) and positive-pressure ventilation is common because the procedure may take several hours. Anaesthesia is usually maintained with a volatile agent in nitrous oxide/oxygen or air/oxygen. During surgery the child is usually supine but sometimes may lie prone (Figure 9).

9 A child scheduled for femoral osteotomy in the prone position.

Care must be taken to replace blood loss, preserve body temperature and provide adequate analgesia. A regional technique such as a continuous lumbar epidural or a fascia iliaca block is preferable. Clonidine, 1–2 μg/kg, may improve the quality of block obtained from local anaesthetics during the first 12 hours and can be used safely in children older than 12 months of age. Analgesia is also improved by giving NSAIDs (e.g. diclofenac, paracetamol). After an open reduction, the surgeon applies a hip spica, for which the child is raised on a box or special frame to allow access around the trunk and buttocks.

Cerebral palsy is a non-progressive brain disorder in young children causing impaired motor function. It has a spectrum of severity from spastic diplegia (where the child, commonly born prematurely, is often intellectually normal and seldom epileptic) to total body cerebral palsy (where the child may be blind, deaf, epileptic, have severe learning and communication difficulties, quadraparesis, pseudobulbar palsy and feeding difficulties). Children with cerebral palsy may have complex multilevel surgery at one operation, such as bilateral femoral and tibial osteotomies, and multiple tendon and soft tissue releases. Children with cerebral palsy benefit from regional analgesic techniques. They often experience postoperative muscle spasm, which is inadequately controlled with epidural infusions alone. A low-dose intravenous midazolam infusion, 25–50 μg/kg/hour, or diazepam, 0.1–0.3 mg/kg 3-hourly p.o. or p.r., effectively reduces tone and relieves spasm.

Correction of talipes equinovarus (club foot): babies with congenital talipes equinovarus usually have surgery before they are weight bearing, often at 5–7 months of age. They are usually otherwise healthy. Operations to revise a correction of talipes equinovarus may be required later.

Induction of anaesthesia may be intravenous or by inhalation. Intravenous access is obtained and tracheal intubation is usual. The child lies supine or prone, depending on surgical preference. Maintenance of anaesthesia is usually by inhalational agents (e.g. isoflurane, 0.75–1% in nitrous oxide/oxygen or air/oxygen) using positive-pressure ventilation facilitated by muscle relaxation. During surgery, the lower leg is exsanguinated with a tourniquet. Blood loss, when the tourniquet is released, is usually easily replaced with appropriate crystalloid or colloid and blood transfusion is seldom required for unilateral surgery. At the end, an above-knee plaster of Paris is usually applied.

Regional analgesia techniques are ideal for operations on the foot. Options include a continuous lumbar epidural, a caudal or blocks of the sciatic nerve (and femoral nerve at the groin or saphenous nerve at the knee, if necessary). In addition, paracetamol and NSAIDs should be given at induction and regularly postoperatively. Care should be taken to observe the foot in plaster carefully after a regional block because the leg may be totally anaesthetized initially.

Minor elective surgery

Eyes

Examination of the eyes may be performed to assess parts of the eye or to measure intraocular pressure. It is usually carried out under general anaesthetic. A light general anaesthetic is required to maintain the intraocular pressure at as normal a level as possible (e.g. gaseous induction and maintenance with sevoflurane in nitrous oxide/oxygen or intravenous induction with propofol, 3–4 mg/kg). The airway can be maintained with a laryngeal mask airway or a face mask. Postoperative analgesia is not required.

Strabismus surgery is usually a day-case procedure. A suitable and effective anaesthetic technique for strabismus surgery is intravenous induction with propofol, 3–4 mg/kg, and glycopyrrolate, 3–5 μg/kg, insertion of a laryngeal mask and maintenance by spontaneous respiration of a volatile agent in nitrous oxide and oxygen. Analgesia is provided by topical anaesthesia and by NSAIDs and paracetamol given at induction. There are several special considerations for anaesthesia for strabismus surgery.

Postoperative vomiting occurs in up to 88% of children. It is the most common complication and the most frequent cause of hospital admission overnight. Anaesthetic techniques used to try to reduce this problem include: a propofol infusion for induction and maintenance of anaesthesia; giving a prophylactic intravenous anti-emetic at induction (e.g. ondansetron, 0.1–0.15 mg/kg, granisetron, 40 μg/kg, metoclopramide, 0.1–0.25 mg/kg, droperidol, 25 μg/kg); or avoiding opioids if possible.

Pain is mainly conjunctival in origin. Topical analgesia using amethocaine, oxybuprocaine or a NSAID (e.g. diclofenac) can be used instead of parenteral opioids. Non-opioid systemic analgesia, provided by a NSAID (e.g. diclofenac, ketorolac) and paracetamol is usually adequate and associated with a lower incidence of postoperative vomiting.

Oculocardiac reflex or 'trigeminal vagal reflex' is caused by traction on the extraocular muscles. It usually produces bradycardia, but occasionally chaotic arrhythmia or sinoatrial arrest with serious complications may result. It is managed by stopping traction and injecting intravenous anticholinergics. This reflex is common and a prophylactic intravenous anticholinergic drug is often injected at induction (e.g. atropine, 10 μg/kg, or glycopyrrolate, 3–5 μg/kg).

Associated diseases – squint surgery may be required in children with generalized muscle disorders associated with malignant hyperthermia. However, the risk of malignant hyperthermia in other children undergoing strabismus surgery is no greater than in the general population.

Otoplasty

The anaesthetic technique aims to reduce postoperative vomiting and provide adequate perioperative analgesia. Anaesthesia for otoplasty is summarized in Figure 10.

Anaesthesia for otoplasty

Otoplasty is associated with:

Postoperative vomiting

- Incidence 50–85%
- May require hospital admission
- Multifactorial
- Increased by:
  - Perioperative opioids
  - Packing the ears after surgery (a similar mechanism to that used by Romans to induce vomiting after large meals: stimulation of the vagal branch to the external auditory meatus and conchal hollow of the ear)

Severe postoperative pain

Suggested anaesthetic techniques

- Local infiltration or regional block only (suitable for the older child)
- Light general anaesthetic with preoperative local infiltration/ regional block
  - Give a prophylactic intravenous anti-emetic at induction
  - Airway maintenance with a laryngeal mask or an endotracheal tube
  - Avoid opioids
  - NSAID and paracetamol suppositories at induction and regular NSAIDs postoperatively

10

Scrotum and groin surgery

Elective scrotal and groin surgery includes inguinal herniotomy, orchiopexy, removal of hydrocele, circumcision, or hypospadias repair. Many of these are day-case procedures.

Anaesthesia is induced by intravenous or inhalational agents and maintained by inhalation via a face mask or a laryngeal mask airway. Muscle relaxation is not required. Analgesia is best provided by a regional technique (e.g. a caudal epidural) combined with diclofenac and paracetamol suppositories. Bupivacaine, 0.125%, 0.5 ml/kg, for operations on the penis or scrotum or 1 ml/kg for groin surgery or orchiopexy, provides good analgesia but avoids prolonged motor block and delayed hospital discharge. Adding preservative-free clonidine, 1 μg/kg, or ketamine, 0.5 mg/kg, increases the median duration of caudal analgesia from 4–6 hours to over 8 hours. Caudal ketamine, 0.5 mg/kg, does not produce behavioural side-effects or sedation and is more suitable for day surgery than clonidine, which causes marked sedation postoperatively. Local anaesthetic infiltration or ilio-inguinal nerve block is also satisfactory for analgesia for groin surgery. A penile block may be used for circumcision.

Community dentistry

Every year, deaths and critical incidents occur in dental anaesthesia. They usually occur in young, apparently healthy patients, often children, and are associated with shortfalls in clinical practice. The General Dental Council and the Royal College of Anaesthetists (RCA) have recently issued guidelines to change practice. The RCA expects anaesthesia for dentistry to be of the same standard as for all other procedures. The prerequisites for general anaesthesia for dentistry are summarized in Figure 11.

Standards required for general anaesthesia for dentistry

The anaesthetist

- Is on the Specialist Register (Anaesthetics)
  OR is a trainee working under his/her supervision
  OR is a non-consultant career grade doctor with a NHS appointment working under the responsibility of a named consultant anaesthetist
- Must have had appropriate experience of and training in dental anaesthesia
- Paediatric anaesthetists should anaesthetize very young children
- Dentists can no longer provide general anaesthesia for dental surgery

Anaesthetic assistance

- Skilled assistance is mandatory

Anaesthetic equipment

- All anaesthetic equipment, monitoring and resuscitation equipment must be available as in theatre

Resuscitation training

- All personnel working where general anaesthesia is used for dental surgery must be capable of basic life support
- The anaesthetic team must have expertise in advanced life support and regular updates in resuscitation

The community dental facility

- Centralization is recommended to a dental anaesthetic facility in the district general hospital (with emergency services immediately available and direct access to intensive care beds)

Where this is impossible

- Clear written protocols must be agreed in advance by both parties, on the provision of additional support if resuscitation or transfer become necessary
- The site of the dental department must allow easy access for emergency services

11

The risks of general anaesthesia must be explained to the parents. General anaesthesia should be used only if there are no alternatives (e.g. very young children, those with infected teeth in whom local anaesthetics may not be effective, older children requiring orthodontic extractions, or children with special needs). The responsibility for recommending dental treatment under general anaesthesia rests with the referring dentist, the dentists performing the procedure and the anaesthetist administering the anaesthetic. Routine dental surgery for children is usually an outpatient service. Inpatient general anaesthetics are required for children with specific medical problems or severe learning difficulties.

Paediatric dental anaesthesia is often challenging. The children arrive 'off the street', about 15–20 minutes before anaesthesia, having been starved at home. There is seldom time to apply topical local anaesthetic for venepuncture and premedication is seldom used. These children have often experienced failed attempts to extract teeth under local anaesthetic and may be uncooperative. They are often discharged within 30 minutes of completing the dental procedure.

A health questionnaire, accurately completed at home, speeds up preoperative assessment. It must be confirmed that fasting guidelines have been followed. The anaesthetist should specifically examine for a heart murmur and give prophylactic antibiotics if indicated; see guidelines in Figure 12.

Antibiotic prophylaxis for prevention of bacterial endocarditis during dental surgery

Standard regimen

Indications

All children with structural abnormalities of the heart undergoing procedures causing gingival bleeding

Exceptions not requiring prophylaxis

Uncomplicated secundum atrial septal defects (ASD2)

Repaired ASD2, repaired patent ductus arteriosus, and repaired ventricular septal defect do not require prophylaxis

Children not allergic to penicillin

1 hour preoperatively give amoxicillin, 50 mg/kg orally, and 6 hours later give amoxicillin, 25 mg/kg orally

Children allergic to penicillin

1 hour preoperatively give clindamycin 10 mg/kg orally, and 6 hours later give clindamycin 5 mg/kg orally

Regimen for high-risk patients

Indications

Children with prosthetic valves, systemic–pulmonary shunts or previous endocarditis

Children not allergic to penicillin

At induction give ampicillin, 50 mg/kg i.v. and gentamicin, 3 mg/kg i.v., 6 hours later give amoxicillin, 25 mg/kg orally

Children allergic to penicillin

1 hour before procedure give vancomycin, 20 mg/kg as an intravenous infusion over 1 hour, and gentamicin, 3 mg/kg i.v.

Consent for suppositories, if required, should be obtained from the parent (and the child, if appropriate). The anaesthetic technique usually involves short-acting agents, for example, induction with sevoflurane 1–8% in nitrous oxide and oxygen, or propofol, 3–4 mg/kg, and maintenance with sevoflurane or isoflurane. Halothane may no longer be used in remote sites because of the increased incidence of cardiac arrhythmias. An intravenous cannula should always be inserted for safety. The child usually lies supine on a trolley. Paracetamol, 20 mg/kg orally 1 hour preoperatively, or rectal diclofenac, 1–1.5 mg/kg, and/or paracetamol, 40 mg/kg, at induction provides adequate postoperative analgesia. Local anaesthetic infiltration is beneficial after extracting permanent molars. Monitoring is usually by ECG, pulse oximetry and a capnograph, but a blood pressure monitor should be available.

In dental anaesthesia, the airway is shared between the anaesthetist and the dentist and outcome depends on the skill of both. Anaesthesia is usually maintained with an inhalational agent delivered through a nasal mask, but a laryngeal mask may be preferred during extraction of permanent molars or multiple teeth. The airway is protected from blood and tooth fragments with a dental pack. At the end of the procedure, the dentist places gauze swabs over the tooth sockets for haemostasis and the child recovers in the left lateral position with the head down. The child may be discharged when he or she is awake, able to stand, and bleeding has ceased.

Imaging

Anaesthetizing children in remote locations is challenging. Skilled assistance and familiarity with the anaesthetic equipment and monitoring are vital. Children often require heavy sedation or a general anaesthetic for imaging. Spiral CT scans usually take several minutes. MRI lasts 20–60 minutes and the child must remain still for several 10-minute episodes to avoid image distortion.

Specific considerations for MRI scanning: the magnetic field strength poses hazards to everyone near the scanner. All equipment containing ferromagnetic components is strongly attracted to the magnet and is a potential projectile. Patients with metal implants (e.g. a pacemaker, an aneurysm clip, a ferromagnetic artificial heart valve, a metal prosthesis or plates) cannot undergo MRI scanning. A strong electrical current may be induced in any wire coil placed within the magnetic field and may cause burns. Routine monitors and motorized equipment (i.e. syringe infusion devices) do not function reliably. A non-ferromagnetic anaesthetic machine is required in the scanner room and monitoring equipment must be carefully selected. All monitors applied to the child must be MRI-compatible to avoid burns. Usually the monitors are located outside the scanner room and connected to the patient via extension tubing. Standard hospital trolleys are unsuitable and a special trolley made of non-ferromagnetic materials (e.g. aluminium, stainless steel, brass or other alloys) must be used in the scanner room.

Anaesthetic techniques: several anaesthetic or sedative techniques have been described for MRI or other painless radiological procedures in children. Inhalational anaesthesia via a laryngeal mask is common, though propofol sedation is sometimes used for MRI or CT scanning, with oxygen administered via nasal cannulae or a clear plastic mask. Recovery is rapid, with little postoperative vomiting. Intravenous sedation is particularly useful for MRI because it permits careful titration of sedatives to achieve clinical effect, does not require a non-ferromagnetic anaesthetic machine or scavenging of waste gases and can be given to a child requiring several scans in different sites on the same occasion. The infusion pump is housed outside the scanner room and long lengths of tubing are threaded through a hole in the scanner room wall to be attached to an indwelling intravenous cannula.

Other sedative techniques include oral or rectal midazolam, intramuscular ketamine or barbiturates (e.g. rectal methohexitone). Disadvantages are an unpredictable onset, a variable depth of sedation or anaesthesia and prolonged recovery.

Oncology procedures

Children with malignancy may require sedation or general anaesthesia for haematological investigations (lumbar puncture and bone marrow aspiration and trephine biopsy) or for insertion of a central line. The anaesthetic considerations and suitable techniques are summarized in Figure 13.

Oncology procedures

The child may have:

- anaemia, neutropenia or thrombocytopenia
- lung and liver metastases
- impaired cardiac function, haematology and immunology secondary to chemotherapy

Suitable sedation and anaesthetic techniques:

- ketamine, 0.5–1 mg/kg boluses and oxygen via plastic mask
- intravenous propofol or inhalational induction and inhalational maintenance

Perioperative analgesia may be provided by:

- local anaesthetic infiltration
- paracetamol, 20 mg/kg orally 1 hour preoperatively

Emergency surgery

There are several important considerations when anaesthetizing a child for emergency surgery.

- The child may be unwell, vomiting and dehydrated, and in pain.
- Vital signs, urine output and electrolytes must be assessed carefully to determine fluid and electrolyte requirements. It is essential to correct electrolyte abnormalities and fluid deficits before anaesthesia and to provide adequate analgesia.
- The theatre and anaesthetic equipment should be prepared thoroughly before the child's arrival.
- Before induction, intravenous access with a good working drip must be confirmed and full monitoring applied. The child is considered to have a full stomach and induction with a rapid-sequence technique using suxamethonium must be performed.
- A parent may be present if the anaesthetist agrees and the parent understands the importance of leaving quickly as soon as the child has lost consciousness.
- Anaesthesia is maintained using air/oxygen or nitrous oxide/oxygen with a volatile agent and muscle relaxation is obtained with a short-acting muscl relaxant (e.g. atracurium, vecuronium).•Intraoperative analgesia is usually provided by opioids.• The child must emerge from anaesthesia in the left lateral head-down position with tracheal extubation when awake.

Appendicectomy

Acute appendicitis usually presents in older children. Severity of the illness ranges from mild abdominal symptoms to peritonitis, secondary to perforation. Although these children usually present to the emergency surgical team, avoiding operating during the night does not increase morbidity or mortality. This is consistent with the recommendations of the authors of NCEPOD 1990.

Intravenous opioid analgesia should be provided at diagnosis (either by boluses, continuous infusion or with patient-controlled analgesia). Additional intravenous opioids are given perioperatively as necessary. NSAIDs and local anaesthetic injected into the peritoneum and skin may reduce postoperative opioid requirements. With regular NSAIDs, patient-controlled morphine is often discontinued after 24 hours. Urine output must be adequate postoperatively (i.e. greater than 0.5 ml/kg/hour), particularly if NSAIDs are given.

Some surgeons remove the appendix laparoscopically. To date, this prolongs surgery and intraoperative opioid requirements without significantly improving postoperative analgesia or allowing earlier discharge.

Perforated Meckel's diverticulum

A Meckel's diverticulum is the persistent proximal portion of the vitelline duct. It is usually situated on the anti-mesenteric surface of the ileum about 25 cm from the ileocaecal junction. It contains all layers of intestinal wall and often ectopic gastric mucosa. Ileal peptic ulceration may occur adjacent to the diverticulum producing perforation or haemorrhage. A perforated Meckel's diverticulum is a differential diagnosis of acute appendicitis and the anaesthetic management is similar.

Torsion of the testis

Torsion of a testis is a surgical emergency, usually occurring in older boys. Anaesthesia is induced without waiting for the usual 6-hour starvation period because of the risks of testicular damage and necrosis if surgery is delayed. A rapid-sequence induction is used to protect the airway because gastric emptying may be delayed because of pain. Muscle paralysis is unnecessary for surgery.

A one-shot caudal epidural provides good analgesia in combination with rectal NSAIDs and paracetamol at induction. Alternatives are opioids or local anaesthetic infiltration.

Principles of Day Surgery for Children

Paul M Spargo

Paul M Spargo is Consultant Anaesthetist at Southampton General Hospital, UK. He qualified from St Mary's Hospital Medical School, London. His research interests include training and education in anaesthesia.

Day surgery was first used extensively for children by Nicholl in Glasgow as early as 1909. Since the 1970s, there has been a resurgence of interest. Although the main drive for expansion during recent years has been economic, day surgery remains in the best clinical interests of many children. They are particularly suited to day surgery because they are usually healthy with no serious concomitant disease and generally require only minor or intermediate surgical procedures. The advantages of paediatric day surgery are:

- minimal disruption of the family
- reduction in behavioural disturbance
- cost effectiveness
- reduction in hospital-acquired infection.

Almost without exception, children are accompanied by a parent or adult who provides support.

Organizational aspects

In 1991, a report *Just for the Day; Children Admitted to Hospital for Day Treatment*, was published by Thornes on behalf of Caring for Children in the Health Services (CCHS). The authors of the report made recommendations for the improvement and expansion of day services for children, emphasizing the importance of a child-friendly environment and covering all aspects of day care.

Design of the day surgery unit: a day ward should provide separate facilities for the admission and recovery of children; they should not be admitted or treated alongside adults. The design should separate day case patients from in-patients and provide a safe but pleasant environment in which healthy children can play while awaiting treatment. The anaesthetic and recovery rooms should also be child friendly. Facilities for unexpected overnight stay must be available.

Pre-admission education pays dividends. Patients and their parents are invited to attend the ward a few weeks before admission to familiarize themselves with the environment, 'play' with simple equipment (e.g. stethoscopes, face masks), and visit the theatre suite (particularly the recovery room). Short videos can also be shown and comprehensive written and oral information given to parents and children, preparing them for admission and discharge.

All nursing staff working in the paediatric day unit should be trained in the care of children and be specifically and regularly designated to the day ward, theatres and recovery area. The service should be consultant based (though there are excellent teaching opportunities) and both the anaesthetist and surgeon should have appropriate training and a regular commitment to the care of children.

Preoperative assessment and selection

Careful preoperative assessment by questionnaire or telephone some weeks before admission helps to reduce cancellation rates. However, it does not obviate the need for preoperative assessment by both the surgeon and anaesthetist on the day of surgery. Routine preoperative investigations are generally unnecessary.

Selection criteria can be categorized into surgical, patient and social factors. Procedures suitable for day surgery are listed in Figure 1. The list is not comprehensive. Any procedure that is associated with a risk of postoperative bleeding, swelling, pain or vomiting or which requires specialized postoperative care is unsuitable as a day case. Prolonged surgery of more than 1 hour is probably unsuitable though tracheal intubation is not a contraindication. Some units perform adenotonsillectomy on a day case basis.

Procedures suitable for day surgery

General surgery
Inguinal or femoral herniotomy, ligation of patent processus vaginalis (excision of hydrocele), circumcision, orchidopexy, epigastric or umbilical hernia, division of tongue tie, excision of skin lesions, examination under anaesthesia (EUA), anal dilatation, endoscopy, muscle biopsies

Urology
Cystourethroscopy, meatotomy, urethral dilatation, change of urinary catheter, minor hypospadias repair

ENT/dental
Myringotomy and grommets, foreign body removal (aural or nasal), EUA, nasal cautery, antral lavage, pack removal, (possibly) adenotonsillectomy, conservation or extraction of teeth

Orthopaedics
Removal of metal work, change of plaster cast, arthroscopy

Plastic surgery
Removal of minor skin lesions, suture removal, dressing changes, removal of scars, otoplasty

Oncology
Bone marrow biopsy, lumbar puncture, intrathecal injections, radiotherapy

Ophthalmology
EUA, strabismus correction, lacrimal duct probing

Radiology/investigations
CT, MRI

1

Patient factors

Most children are healthy (ASA I or II) and well suited for day surgery. Occasionally, ASA III patients are also admitted to the day ward, for example those with cystic fibrosis or immunodeficiency following chemotherapy, who may benefit from avoiding contact with in-patients. Frequent attenders with stable concomitant diseases who have behavioural problems or learning difficulties may also benefit from treatment in a day unit.

Age – the lower age limit depends on postconceptional age, the experience of the anaesthetist, the facilities of the day unit and certain social factors. Outside specialized centres, the lower age limit may be as high as 6 or even 12 months. In larger units with the appropriate facilities, healthy full-term neonates may be treated as day cases. All preterm or ex-preterm babies of up to 60 weeks' postconceptional age are generally considered unsuitable because they are vulnerable to postoperative apnoeic spells. They require overnight admission and close respiratory monitoring.

Family history of sudden infant death syndrome (SIDS) or near-SIDS – although there is no association with postoperative apnoea, siblings of babies who have been the victim of SIDS or near-SIDS should probably not be treated as day cases.

Upper respiratory tract infections (URTI) – many small children have a 'runny nose' for much of the time and cancellation of a minor procedure is unnecessary if the child is otherwise well. If there are more florid symptoms (e.g. fever, general malaise or irritability, or an unpleasant nasal discharge) the procedure should be cancelled. Such patients are at greater risk of perioperative respiratory complications, particularly if less than 1 year of age or if the trachea is intubated. Surgery should also be delayed for patients with lower respiratory signs on auscultation (e.g. bronchospasm, persistent 'crackles'). Postponement for 4–6 weeks is usually recommended.

A previously undetected heart murmur is a common dilemma. A flow murmur must be distinguished from a pathological murmur, which may require specialized assessment. However, children with stable uncomplicated congenital heart disease can often be managed as day patients, provided they are given endocarditis prophylaxis (if indicated).

Miscellaneous conditions – children with mild well-controlled asthma or epilepsy can be admitted for day surgery. Those with diabetes or metabolic disorders are unsuitable because of the problems associated with pre-operative fasting.

Social factors

Parents should be capable of coping with the pre-procedure instructions and with the post-discharge care of their child and be willing to do so. Home facilities should be adequate. In some units, a travelling time of less than 1 hour is a requirement for day case surgery and should be by private car or hospital transport. Community paediatric nurses can provide invaluable support.

Preoperative preparation

Fasting guidelines: clear written instructions about the period of preoperative fasting should be issued and the importance of compliance stressed. Solids, cows' milk or formula feeds are usually permitted until 6 hours before surgery, breast milk until 4 hours and clear fluids until 2 hours beforehand. It is often more practical to issue simple instructions to parents in relation to the time of admission rather than the time of operation.

Psychological preparation: pre-admission educational programmes reduce the stress of admission for parents and children. On the day ward, plenty of space and toys and a relaxed atmosphere are essential. Avoiding separating the child from the parent is also important.

Premedication*:* it is unusual for sedative premedication to be necessary in children undergoing day surgery, particularly if a parent is present at the induction of anaesthesia, as is now widely accepted. Separation anxiety is not usually a problem until about 8–9 months of age, therefore parental presence at induction is usually not necessary or desirable before this age. Oral midazolam, 0.5 mg/kg (maximum 10–15 mg), is occasionally indicated for the particularly anxious child and has the advantage of rapid onset with minimal delay in recovery. It is bitter and should be flavoured with undiluted blackcurrant juice or paracetamol elixir. Midazolam may also be given by the intranasal route, though this can be unpleasant. Anticholinergic premedication is seldom used. Topical local anaesthetic creams such as *Emla* or *Ametop* are routinely used to enable virtually painless cannulation. Concerns that they make cannulation more difficult are largely unfounded.

Anaesthesia

Induction

Induction is via the intravenous or inhalational route. Having a parent present is often helpful, though anxious parents may transmit their anxiety to the child. It is often preferable to allow the child to sit on the parent's lap during induction.

Intravenous induction: the use of *Emla* or *Ametop* cream has made intravenous induction the most common mode of induction and there are advantages to having intravenous access from the start of anaesthesia, provided this is not at the expense of distressing the child. Anaesthesia can be induced intravenously with thiopental (thiopentone) or propofol. In unpremedicated children, thiopental (thiopentone), 5–6 mg/kg, is required and, compared with propofol, may be associated with delayed recovery (though probably not in children less than 5 years of age). An advantage of thiopental (thiopentone) is that the onset of sleep is clear, which is reassuring to the accompanying parent about to leave the anaesthetic room. Propofol induction may be associated with involuntary movements that may be alarming to the parent. Such movements are usually overcome by additional doses of propofol. The dose requirement for propofol is higher in unpremedicated children (3–4 mg/kg) than in adults. Propofol obtunds airway reflexes facilitating the insertion of an oropharyngeal airway or laryngeal mask airway (LMA), though it is also associated with respiratory depression, breath holding, and hiccups. Pain on injection is the main drawback but can be minimized by adding lidocaine (lignocaine), 0.2 mg/kg. In the UK, the rectal route for induction is uncommon.

Inhalational induction is useful for the child with a needle phobia or in whom intravenous access is difficult. Using a transparent face mask impregnated with food flavouring or the 'cupped hand' is more acceptable than the old-style opaque masks. Halothane has been used for many years, though its use may have been superseded by sevoflurane which, although expensive, has a pleasant smell, is non-irritant and has a rapid onset. The inspired concentration can be increased rapidly, though marked respiratory depression and breath holding occur unless the concentration is reduced immediately after induction. Isoflurane is pungent, more irritant to the airway and requires considerable skill to effect a smooth induction.

Maintenance of anaesthesia

Most day case procedures do not require intubation of the trachea or muscle relaxation. Spontaneous ventilation with oxygen, nitrous oxide and a volatile agent via a face mask or LMA is common. An LMA provides a patent airway, freeing the anaesthetist to carry out local anaesthetic blocks, but does not prevent soiling of the airway. When surgery is completed there seem to be fewer transient airway complications if the LMA is removed while the patient is deeply anaesthetized. Any accumulated secretions are removed if the LMA is removed gently with the cuff inflated.

Tracheal intubation is occasionally required and is not a contraindication to day case surgery. Although suxamethonium pains are less common in young children than in adults its use should be kept to a minimum in ambulant children (it may be necessary if laryngospasm occurs). Alternatively, tracheal intubation can be facilitated by deep halothane or sevoflurane anaesthesia.

Modern guidelines for preoperative starvation and the early resumption of oral intake postoperatively make the routine use of intravenous fluids unnecessary. Significant fluid loss is not a feature of day case surgery. An intravenous infusion of a balanced salt solution may sometimes be indicated if starvation has been prolonged, if there is a history of postoperative nausea or vomiting or if the procedure is associated with a higher incidence of postoperative vomiting (e.g. orchidopexy, strabismus surgery).

Analgesic techniques

Analgesia is best provided by an appropriate regional or nerve block combined with simple analgesics. Opioids should be avoided, if possible, because they delay recovery and markedly increase postoperative vomiting.

Simple analgesics

Early administration of simple analgesics is preferable, either in the form of oral premedication or per rectum after induction. It is good practice to obtain consent from a parent (and/or, if appropriate, the child) for the rectal administration of any drug.

Non-steroidal anti-inflammatory drugs (NSAIDs) are widely used because of their lack of serious adverse effects. The lower limits for NSAIDs are 1 year of age for diclofenac, 1–3 mg/kg/day in divided doses, either orally or rectally, and 7 kg in weight for ibuprofen, 20–30 mg/kg/day in divided doses orally. NSAIDs may be given to patients with mild well-controlled asthma but should be avoided in those with severe asthma or renal impairment.

Paracetamol is a valuable adjunct and can be given to children initially as an oral loading dose of 30 mg/kg then 15 mg/kg 4 or 6 hourly (maximum total daily dose of 90 mg/kg) for a limited period. Alternatively, a rectal loading dose of 30 mg/kg followed by 20 mg/kg 4–6 hourly per rectum (again, not exceeding a daily dose of 90 mg/kg) may be given, though absorption is more erratic. Doses for neonates are reduced with a maximum daily dose of 60 mg/kg.

Local anaesthetic techniques

Many procedures performed on a day surgical unit are suitable for supplementary local anaesthetic blocks, which are virtually always undertaken after induction of anaesthesia. Contra-indications include:

- refusal of consent
- infection at the injection site
- allergy to local anaesthetic agent
- coagulopathy.

Anatomical abnormalities or pre-existing neurological abnormalities are relative contraindications. Blocks commonly used are listed in Figure 2.

Commonly performed local anaesthetic techniques

- Local infiltration
- Caudal extradural block
- Ilioinguinal-iliohypogastric block
- Penile block
- Periumbilical or rectus sheath block
- Fascia iliaca block
- Greater auricular block

2

Caudal blockade is commonly used for surgery below the umbilicus. The procedure is safe and simple. Full aseptic precautions should be taken. The type of needle used depends on operator preference. The use of a 22G intravenous plastic cannula allows removal of the needle immediately after puncture of the sacrococcygeal membrane. Advancing the plastic cannula only may reduce the chances of intravascular or intrathecal puncture. It may also permit a more cephalad delivery of local anaesthetic, which is useful if higher levels of blockade are needed. 0.25% bupivacaine is commonly used up to a maximum of 2–2.5 mg/kg and the duration of action is about 4–6 hours. Levobupivacaine and ropivacaine have a reduced potential for systemic toxicity but experience with these agents in children is limited. The duration of effect of local anaesthetic solutions following single-shot caudal blockade is not significantly increased by the addition of adrenaline (epinephrine) and the use of other additives (opioids, ketamine or clonidine) is best confined to in-patients.

Practical guidelines relating the spread of analgesia to the dose of local anaesthetic injected, originally described by Armitage, are still in widespread use. He recommended 0.25% bupivacaine, 0.5 ml/kg, for a lumbosacral block (e.g. circumcision or hypospadias operations), 1.0 ml/kg for thoracolumbar blockade (e.g. inguinal herniotomy), and 1.25 ml/kg for a mid-thoracic block (e.g. orchidopexy). If the calculated volume exceeds 20 ml, Armitage recommended diluting the bupivacaine to 0.19% (3:1). However, spread to the inguinal and thoracic dermatomes becomes inconsistent in patients who weigh more than 20 kg and, for an orchidopexy, the combination of ilioinguinal/iliohypogastric block and NSAIDs may be more effective. Dalens found the caudal injection of 0.75–1.0 ml/kg to be appropriate for a variety of operations and more recently 0.25% bupivacaine, 0.75 ml/kg, for herniotomy or orchidopexy was found to produce 4 hours of postoperative analgesia in almost 70% of patients. Venous and dural puncture are rare complications of caudal blockade. Motor blockade, as manifested by leg weakness, may occur and can be distressing to the patient. Urinary retention is almost unknown in children who are well hydrated.

Complications of day surgery

The incidence of postoperative complications is low and hospital admission rates are generally quoted as 1–2%. The more common complications include:

- nausea and vomiting
- pain
- unsteadiness of gait
- delayed micturition
- unexpected bleeding necessitating a return to theatre.

Nausea and vomiting

The incidence of postoperative nausea and vomiting (PONV) varies according to age, previous history of PONV or motion sickness, the type of surgical procedure and the anaesthetic technique. Children have a higher incidence than adults, but it is lowest during childhood in infants or pre-school children. Adenotonsillectomy, strabismus surgery, otoplasty and orchidopexy are associated with a high incidence. Opioids significantly increase the probability of vomiting, and nitrous oxide may be a contributory factor. The use of total intravenous anaesthesia in certain circumstances, such as strabismus surgery, may be beneficial. Avoiding prolonged preoperative fasting and maintaining good perioperative hydration may help to reduce the incidence of PONV. Encouraging oral fluids early postoperatively may be counterproductive. Early mobilization should also be avoided. The routine use of anti-emetics in children is uncommon because of sedation or extrapyramidal effects. The introduction of 5-HT_3 antagonists (e.g. ondansetron, granisetron) has reduced the incidence of PONV. They have few adverse effects and offer significant advantages over other anti-emetic agents. They should be used prophylactically in situations associated with a high risk of PONV. Dexamethasone reduces postoperative vomiting following tonsillectomy either alone or in combination with other anti-emetic agents. The mechanism of action is unknown.

Discharge and follow-up

Guidelines for the discharge of patients to home should be in place (Figure 3). It is desirable but not essential for patients to drink before discharge. Some units require children to have passed urine, though retention of urine is uncommon. After certain types of surgery (e.g. hypospadias repair) there may be surgical reasons for insisting that the patient has voided before discharge. Community paediatric nurses or health visitors should carry out home visits. Some units telephone the parent the day after surgery to check satisfactory progress and answer questions. This also provides a good opportunity for audit. ◆

Criteria for discharge from hospital

- Vital signs and conscious level normal
- No respiratory distress/croup/stridor[1]
- No bleeding or other surgical complications
- Minimal or no pain
- Minimal or no nausea or vomiting
- Minimal or no unsteadiness of gait
- Written/verbal instructions issued
- Lines of contact established
- Appropriate transport arranged

[1] If tracheal intubation is performed it is generally recommended that patients should be kept a minimum of 2 hours following extubation before discharge from hospital.

Managing Trauma

Peter Oakley

Peter Oakley is Consultant in Anaesthesia and Trauma at the North Staffordshire Hospital, Stoke-on-Trent, UK. He qualified from Cambridge and undertook training posts in anaesthesia in Bristol and Oxford, and in emergency medicine and trauma in Toronto, Canada.

The priorities for the initial assessment and intervention in trauma are the same for adults and children.

The primary phase involves a rapid physiological assessment to identify immediate threats to life in a structured order: airway, breathing, circulation and disability. Plain radiographs of the chest and pelvis and an ultrasound scan of the abdomen should be instantly available as adjuncts to the clinical examination. At this stage the focus is on physiological control.

The secondary phase – the focus shifts to the control of damaged anatomical structures. A more detailed clinical examination (head to toe, front and back, including the orifices, cavities and skeleton), complemented by imaging and other investigations, should be carried out. Pain relief should be given as soon as possible after completing the primary assessment.

Primary assessment and intervention

Airway (with cervical spine control)

In serious blunt trauma, the spine should be maintained in a neutral position from the outset. Applying a hard collar, blocks and straps safely in a bewildered young child requires gentle coaxing, reassurance and subtle distraction. Force should not be used to immobilize an agitated child, because the neck may inadvertently act as a fulcrum in the struggle, increasing the risk of further damage. In small children lying on a flat surface, the relatively large head tends to leave the neck in flexion. Neutral neck positioning may be achieved by placing a folded towel beneath the shoulders.

The child's airway is smaller and floppier than an adult's. Care should be taken not to cause obstruction by compressing the floor of the mouth with inaccurate hand positioning under the chin. It is conventional to insert an oropharyngeal airway without rotation. The size of the airway may be estimated by placing its concavity over the child's face and measuring from the centre of the teeth to the angle of the mandible (or, equivalently, from the angle of the mouth to the external auditory meatus). The diameter of a nasopharyngeal airway is the same as a tracheal tube (internal diameter age/4 + 4 in mm), and is about the same size as the child's little finger. The nasal route is contraindicated in basal skull fracture.

The subglottic segment is the narrowest part of the upper airway and is vulnerable to critical narrowing from mucosal oedema or scarring. A cuffed tracheal tube and surgical cricothyroidotomy are contraindicated before puberty.

If a child whose spine has not been cleared starts to vomit, it is tempting to turn them on to their side. This is feasible in an infant but impossible in a larger child unless he is still on the spinal board with the body straps done up tightly. Even then, several attendants are needed instantly. It is far easier (and safer) to tip the trolley head-down temporarily, while the airway is sucked out.

Orotracheal intubation with manual in-line mobilization following rapid sequence induction should be used to secure the airway in blunt trauma with an uncleared spine. The collar and blocks should be removed before intubation and replaced afterwards. Intubation is indicated immediately in head-injured children with a GCS less than 9. If the GCS is 9–12 it may still be necessary, to protect against deterioration or to facilitate investigations, particularly if the child is restless. In extreme situations (e.g. a very low GCS or severe shock) it may be necessary to intubate with minimal analgesia or sedation (e.g. fentanyl, 0.25–0.5 μg/kg, and/or midazolam, 20–40 μg/kg) or even without drugs. The circulatory state and the conscious level must be taken into account when choosing the induction agents and their dose.

Thiopental (thiopentone) in a reduced dose (e.g. 1–2 mg/kg) is suitable for induction in those with a low GCS or circulatory shock. Etomidate is not licensed for use in those less than 10 years. Ketamine, 1–2 mg/kg, is safe for all ages. Its use in head injury has often been dismissed unfairly, but it is popular in circulatory compromise without head injury.

Suxamethonium is widely used in children. It is not contra-indicated at initial presentation in burns or spinal cord injury, but can produce severe hyperkalaemia and cardiac arrest after the first day. It is contraindicated at the outset in major crush injury because of the risk of massive potassium release from damaged muscle. Rocuronium, 1–1.2 mg/kg, is an alternative but the consequences of prolonged paralysis in the event of failure to intubate must be considered.

If the airway is damaged or distorted (e.g. in airway burns), there is a risk of losing the airway and alternatives (e.g. gas induction) should be considered.

Cricothyroidotomy is indicated for failed tracheal intubation. The surgical method is contraindicated in children below 12 years. Following needle cricothyroidotomy a Y-piece breathing system may be used to supply oxygen for 1 second followed by expiration for 4 seconds (or less in a small child). To reduce the risk of barotrauma, the initial inspiratory flow should be set at the child's age in litres/minute and increased according to chest movement. Expiration occurs through the upper airway, not through the cannula: the peak inspiratory pressure in the chest is insufficient to push gas back through the cannula.

Breathing

Children have greater oxygen consumption and a smaller residual volume, predisposing to earlier hypoxia. They have less developed musculature so that accessory muscle use is less obvious, but sternal and intercostal recession is more noticeable. They are also prone to apnoea after head injury. Tables of normal ranges for resting respiratory rate with age (Figure 1) are useful in assessing respiratory distress.

Tension pneumothorax must be identified clinically and treated by needle decompression using a 14–18G cannula in the second intercostal space in the mid-clavicular line. The size of the subsequent drain may be found in tables (Figure 1); estimated by the diameter of the child's little finger; or the largest size that will just fit between the ribs can be used. If the child is obese the 'mating forceps' technique is useful to guide the drain into the pleural cavity; an artery clip is inserted through the incision and held open while the other, grasping the tip of the tube, is rotated into position between the open jaws.

Variation of respiratory rate, chest drain size, pulse rate and blood pressure with age

Age	Respiratory rate (breaths/minute)	Chest drain size (French gauge)	Pulse rate (beats/minute)	Systolic blood pressure (mm Hg)
< 1 year	30–40	12–16	110–160	70–90
1–4 years	25–35	16–20	95–150	80–100
5–11 years	20–25	20–24	80–120	90–110
≥ 12 years	15–20	24–32	60–100	100–120

1

An open pneumothorax (or 'sucking chest wound') allows air to be sucked in through the chest wall defect at the expense of inspiratory flow through the trachea. Temporary treatment with an Ashermann chest seal (Figure 2) is generally more effective than an occlusive dressing, taped on three sides. The base encloses the defect, while the pipe acts as a one-way valve. Massive haemothorax is distinguished from tension pneumothorax by the dull percussion note. Venous access should be secured before inserting a chest drain.

2 Ashermann chest seal.

Circulation

Children compensate well after major haemorrhage, but can deteriorate suddenly. Tachycardia is a valuable sign, though it may also reflect pain and fear. In small children, intravenous access is often easier in the hands and feet than in the antecubital fossae. If not achieved within 1 minute in a severely injured child less than 7 years of age, intraosseous access is appropriate.

It is vital to warm infusion fluids. Boluses are given according to conventional guidelines: 2 x 20 ml/kg of saline-based crystalloid or colloid, then blood 20 ml/kg. Weight is obtained from the parents or estimated from the body length (e.g. Broselow tape) or age (weight in kg = 2 x (age + 4) up to age 11 years). Fluid loading may be harmful in the face of uncontrolled haemorrhage particularly after penetrating trauma. It can exacerbate bleeding and contribute to coagulopathy and hypothermia. Fluid restriction (or permissive hypotension) may then be appropriate, providing it is combined with immediate surgical intervention to control the bleeding. Fluid loading with normal saline can also cause hyperchloraemic acidosis with an abnormal base excess. This can lead to the erroneous diagnosis of inadequate tissue perfusion requiring more fluid, leading to fluid overload. Lactate is a more appropriate end-point than base excess in this situation.

Sources of haemorrhage should be sought externally and internally. In an infant, scalp bleeding or an intracranial haematoma may cause shock. Major bleeding from an unstable open-book pelvic fracture may be significantly reduced by a pelvic sling. A sling can be made from sheets twisted round at the level of the greater trochanters with the legs internally rotated. If no bleeding source can be identified or if the shock does not respond as expected look for alternative causes (e.g. cardiac tamponade, spinal cord injury, overwhelming head injury). Distended neck veins, warm peripheries, bradycardia, priapism or fixed dilated pupils may provide clues.

Disability

The primary assessment comprises the GCS, which is modified in children under 4 years (Figure 3), and examination of the pupils. To minimize the risk of secondary insult in a decompensating, head-injured child, the PaO_2 should be above 12 kPa, the $PaCO_2$ at 4–4.5 kPa and the mean blood pressure normal. Provided that uncontrolled bleeding has been excluded or treated, fluids may be used liberally and inotropes introduced early to maintain the blood pressure. Mannitol, 0.3–0.5 g/kg, should be considered if the conscious level deteriorates, especially if there are focal signs. Hypoglycaemia is a cause of obtundation or fitting, particularly in adolescents after alcohol binging and in infants.

Modified Glasgow Coma Scale in children

Best eye opening

4 Spontaneously
3 To voice
2 To pain
1 None

Best motor response

6 Obeys commands (spontaneous movements aged < 4)
5 Localizes
4 Withdraws
3 Flexes abnormally (decorticate)
2 Extends (decerebrate)
1 None

Best verbal response

	Age ≥ 4	*Age < 4*
5	Orientated	Alert, babbles, coos, words to usual ability
4	Confused	Less than usual words, spontaneous irritable cry
3	Inappropriate	Cries only to pain
2	Incomprehensible	Moans to pain
1	None	No response to pain

3

It is important to minimize the time to surgical decompression of an intracranial haematoma. This requires prompt assessment by CT scan and timely referral to a neurosurgeon.

Secondary assessment and intervention

Exposure

During the secondary assessment, it is vital to examine the whole body surface. Children cool rapidly when exposed. Any benefit from hypothermia in preserving brain function is offset by platelet dysfunction, cardiac arrhythmias, myocardial depression and impaired resistance to infection. An overhead radiant heater should be available for infants and a convective air heater for older children.

Analgesia

For the child in pain, intravenous increments of an opioid are appropriate as soon as possible after the primary assessment. It is now accepted that carefully titrated opioids enhance the clinical evaluation of injuries. Morphine, 25–50 μg/kg, in increments of up to 0.15–0.2 mg/kg is the standard. Fentanyl, 0.5 μg/kg, repeated as necessary, has a faster onset, causes little histamine release or haemodynamic instability, is easy to titrate and, in larger children, can be given without diluting the 50 μg/ml neat solution. In the presence of hypovolaemia or drowsiness, it is wise to halve the incremental dose of these drugs.

Head and neck

Children have large heads and almost adult-sized brains by the age of 3 years. They shed their primary teeth between 7 and 12 years and have a disproportionately small face until after puberty. Up to the age of 9–18 months, the fontanelle is present, allowing a crude evaluation of intracranial hypertension. The elasticity of the skull and the ability of the sutures to widen offer little protection against acute rises in intracranial pressure. Children with diffuse brain injury are more prone to cerebral oedema, punctate haemorrhage and intracranial hypertension than adults.

The scalp, face and neck must be carefully inspected and palpated with the collar removed. The orifices should be examined for signs of basal skull fracture. Evidence of retinal and conjunctival haemorrhage is important if there is any suspicion of non-accidental injury. The GCS should be re-checked and a more detailed neurological examination carried out. If the GCS is less than 9, a CT scan should be obtained immediately the child has been intubated, ventilated and stabilized. If the GCS is 9–13, or there are focal signs, fitting or persistent vomiting, an emergency CT scan is indicated. If the GCS is 14, a CT scan may be deferred overnight and the child carefully observed.

Chest

The elasticity of children's ribs reduces the risk of rib fracture, but allows the transfer of energy to internal structures and pulmonary contusion without rib fracture is common. If there are multiple rib fractures with a flail segment, such is the force involved that mechanical ventilation is usually needed. Simple pulmonary contusions tend to resolve within 72 hours and can usually be managed without intubation though continuous positive airway pressure may be needed.

The chest is re-examined in more detail and the chest radiograph studied. In young children, the thymus may be confused with the mediastinal widening of aortic disruption. A pneumo-thorax identified after trauma should be treated with a chest drain. A drain that bubbles persistently suggests tracheobronchial or oesophageal disruption. If the nature and extent of the thoracic injuries are uncertain, a contrast CT scan should be considered, especially if the mediastinal contour is abnormal.

Abdomen

The child's under-developed thoracic cage and anterior abdominal wall musculature offer less protection to upper abdominal organs. Distressed children are prone to air swallowing and acute gastric dilatation is common in multiple injuries or severe burns. Inserting a gastric tube makes examination more reliable, reduces the risk of aspiration and improves comfort. The urine must be inspected for macroscopic haematuria. Urine collection bags are appropriate in babies. Catheterization of small boys should not be undertaken lightly because of the significant risk of urethral stenosis.

Clinical examination of the abdomen is unreliable. Ultrasonography allows rapid identification of free intraperitoneal fluid and may be repeated without the accumulated radiation risk of CT scanning. A contrast CT scan is more discerning but is contraindicated if the child is haemodynamically unstable.

In blunt injuries to the liver, spleen, kidney or the mesentery, bleeding is often self-limited; free intraperitoneal fluid is no longer an automatic indication for laparotomy. However, conservative management is only appropriate if haemodynamic stability can be achieved and the child observed in an HDU with a capable paediatric surgeon and anaesthetist immediately available. Careful haemodynamic monitoring, frequent clinical examination, repeated blood sampling and further ultrasound scans are essential if the child is treated conservatively. Perforation of the hollow organs (bladder or bowel) indicates laparotomy.

Spine

The cartilaginous vertebral bodies, elastic ligaments and horizontal facet joints contribute to the increased spinal mobility in children compared with adults. This tends to protect the spinal cord from injury by dispersing energy over several segments, but when cord injury does occur, it is more likely to be complete. Spinal cord injury without radiological abnormality is well recognized in children, implying severe ligamentous disruption without demonstrable fracture. The value of steroids in cord injury in children remains uncertain. Cervical spinal injuries tend to occur at a higher level than in adults and often affect adjacent vertebrae. Subluxations and dislocations are more common.

In major blunt trauma, spinal precautions must be taken from the outset (i.e. immobilization on a firm surface and the use of collar, blocks and straps). A spinal board is intended for transfer to hospital and should be removed soon after arrival to avoid pressure injuries.

Clinical examination is similar to adults. If the child is alert and orientated with no spinal symptoms or signs and no distracting pain, the spine may be cleared clinically without imaging. Otherwise, three plain views are required for radiological assessment: the lateral, AP and odontoid peg views (the latter can be omitted in a severe head injury and CT of the occiput to C3 obtained instead). Even if the plain films and/or CT are normal, the spine still cannot be cleared in the persistently obtunded child.

Limbs

Children's bones are more flexible than adults', producing different fracture patterns (e.g. greenstick fractures). Most fractures can be managed without surgery and some deformities accepted without manipulation. Fractures involving the growth plate are of particular concern and accurate repositioning is essential for future growth. Supracondylar humeral fractures and fractures around the knee may damage the brachial and popliteal arteries, respectively, requiring meticulous monitoring of distal pulses and perfusion.

Particular patterns of injury, such as fractured shaft of femur in a child aged less than 3 years, bruising in a finger mark pattern, bite marks or cigarette burns, suggest non-accidental injury. Other supporting evidence includes delay in seeking help, discrepancy between different versions of the history or between the professed mechanism of injury and the resulting injuries, injuries of different ages, abnormal demeanour in the child ('frozen watchfulness'), retinal haemorrhage and injury to the frenulum of the lip or genitalia. Paediatric referral is essential in suspicious circumstances.

In older children, femoral shaft fractures can be immobilized with a Thomas splint. Femoral nerve block provides excellent analgesia, facilitating splint application but a nerve stimulator is inappropriate because of pain caused by muscle twitches.

Initial analgesia for limb injuries can be achieved with intravenous opioids. Long-acting nerve blocks are occasionally useful (as above), but some fractures (e.g. closed tibial fractures) are associated with a higher risk of compartment syndrome, which may be masked by neural blockade. A nitrous oxide/oxygen mixture may be used for immediate pain relief (contraindicated in pneumothorax or significant head, eye or abdominal injuries). Ketamine in subanaesthetic doses (0.2 mg/kg repeated if necessary) given with low-dose midazolam to reduce dysphoria allows simple manipulation, suturing and dressing changes. Ketamine can be given with fentanyl (although synergism should be anticipated), which is useful at the accident scene when extricating from entrapment.

Burns

Children's skin is thinner than adult skin, making them prone to deeper burns. Their higher surface area to body weight ratio makes them susceptible to heat and fluid loss. Particular patterns, compatible with cigarette burns or immersion in very hot water, should raise the possibility of non-accidental injury.

In burns to the head and face, an associated airway burn may be suggested by the history or by peri-oral burns, carbonaceous sputum and hoarseness. Airway oedema is typically maximal at 36 hours, but can cause airway obstruction with little warning. Laryngospasm can occur immediately. If an airway burn is suspected, early intubation by an experienced paediatric anaesthetist should be planned.

Assessing burns – the depth of a burn should be assessed visually. Pin-prick testing of sensation is inappropriate in children. In general, the blistering, weeping appearance and obvious pain of a partial thickness burn distinguishes it from a leathery, charred, non-blanching full-thickness burn. However, some deep dermal burns can be difficult to identify initially. Electrical burns often involve neurovascular bundles and may cause myoglobinuria and cardiac arrhythmias. The 'rule of nines' does not apply to children. Lund and Browder charts (Figure 4) allow more accurate mapping at different ages. The palm of the child's hand also approximates to 1% of the body surface area.

C = ½ of one leg	2½	2½	2¾	3	3¼	3½

4

Fluid management – fluid loss is crudely predictable after major burns. A widely accepted guideline for the first day's crystalloid requirements is 4 ml/kg/% burn, giving half of this in the first 8 hours and the remainder in the next 16 hours. Alternative colloid-based guidelines recommend 2–4 ml/kg/% burn in the first day. Maintenance fluids are also given. These formulae are only rough estimates and the fluids should be adjusted depending on haemodynamic state and urine output. In the presence of myoglobinuria, after an electrical burn, the fluids should be further increased to promote a diuresis. It is also important to remember that physical injuries (e.g. from an associated explosion or fall), with extra blood and third-space losses, may accompany burns.

Further stabilization

In small children who are mechanically ventilated, a positive end-expiratory pressure of 3–5 cm H_2O is acceptable, even with a severe head injury. Invasive arterial blood pressure monitoring should be established in severe head injury before transfer to the CT scanner, allowing beat-to-beat blood pressure measurements and repeated PaO_2 and $PaCO_2$ estimations. Initially, the blood pressure should be kept (or left) at or above normal. Once intra-cranial pressure monitoring is established, it should be adjusted to maintain a cerebral perfusion pressure of 65–70 mm Hg.

In severe multi-system trauma, the haemoglobin or haematocrit should be monitored hourly initially and clotting checked every few hours. As haemodynamic stability is achieved maintenance fluids should be added according to standard recommendations. If extra third-space losses are predicted, additional fluids are required. A urine output of 2 ml/kg/hour is adequate in infants, 1 ml/kg/hour in older children and 0.5 ml/kg/hour in adolescents.

Two-thirds fluid restriction was conventional after serious head injury. With the current emphasis on maintaining an adequate blood pressure, this is no longer recommended. Inadequate tissue perfusion, indicated by a lactate concentration over 2 mmol/litre, must be avoided which may require extra fluid with careful monitoring. It is also important to avoid inadvertent fluid overload with severe head or chest injuries by accounting for the volumes of all infusions and drugs in fluid balance measurements.

Diabetes insipidus is a particular problem after severe head injury (though seldom evident in the first few hours) which must be distinguished from the diuresis following liberal fluid resuscitation. In diabetes insipidus, urine output may exceed 30 ml/kg/hour, causing severe hypernatraemia and dehydration. The diagnosis should be confirmed by plasma and urine osmolality measurements and treated promptly with desmopressin (DDAVP). Replacing losses with hypotonic or glucose-based fluids (to correct the sodium) may cause cerebral oedema.

Sedation after intubation and ventilation is best achieved with the combination of benzodiazepine and opioid infusions. Muscle relaxants may be added but can mask seizures.

Anaesthesia
In children with a severe head injury, propofol by infusion is contraindicated. Nitrous oxide is no longer favoured because it causes cerebral vasodilatation and increases the cerebral metabolic rate of oxygen consumption slightly and expands any air in the skull. Remifentanil infusion can be used in children and its rate may be rapidly adjusted to match the changes in the surgical stimulus. If it is not planned to wake the child up immediately, it offers few other advantages over opioids (e.g. fentanyl, alfentanil) and has a greater tendency to cause hypotension and bradycardia.

Volatile agents (e.g. isoflurane), though little favoured in head-injured adults because of cerebral vasodilatation, are commonly used in low concentrations in paediatric neuroanaesthesia. If there is evidence of severe intracranial hypertension, it may be best to avoid them or severely limit the inspired concentration. If the surgical stimulus is modest (as it is for a burr hole, especially when local anaesthetic infiltration has been used), an opioid-benzodiazepine combination may suffice until initial decompression has been achieved. If the stimulus is greater, thiopental (thiopentone) by infusion, 2–4 mg/kg/hour, with an opioid infusion, is useful if it is not planned to wake the child up immediately.

If a child with a severe head injury needs urgent surgery for other injuries, similar considerations apply. In these circumstances, ICP monitoring is essential. In comparison, maintaining anaesthesia in injured children without a head injury is relatively straightforward. Opioid infusions should be continued and increased according to the stimulus. Nitrous oxide is permitted if the risk of unrecognized pneumothorax or perforated bowel is small. A volatile agent may be used (reducing the concentration in the face of unavoidable hypovolaemia). When using paralysing agents, it may be difficult to achieve the balance between not exacerbating hypovolaemia and preventing awareness. Once surgical haemo-stasis has been achieved, vigorous warm blood/fluid therapy allows the inspired concentration of the volatile agent to be increased. ◆

Special Considerations in Paediatric Intensive Care

Peter T Hutchings
Mark Darowski

Peter T Hutchings is Specialist Registrar in Anaesthesia in the Yorkshire Region, UK.

Mark Darowski is Consultant in Paediatric Anaesthesia and Intensive Care at the Leeds General Infirmary, Leeds, UK.

In the UK, about 15,000 children under 16 years of age are admitted to paediatric intensive care units (PICUs) each year. Half of them are under 2 years of age. Mortality is 5–17% depending on the case mix of the individual unit. Admissions include children who were previously well but develop an acute life-threatening illness, those requiring support after complex surgical procedures and others with chronic conditions (congenital or acquired) who develop a superimposed acute illness. More admissions occur in winter, mainly because of an increase in respiratory infections. Compared with adults, children decompensate quickly when severely ill, but if appropriately treated they recover quickly.

Intensive care delivered to children differs from adult care because of the different social and patient factors. The role of the child's parents or guardians has to be considered as do the legal and ethical considerations relevant to children (see *Anaesthesia and Intensive Care Medicine* **4:1**). Compared with adults, children have different patterns of illness and specific physiological and pharmacological developmental differences.

Organization of care
The specialist, low volume nature of paediatric intensive care medicine has led to the centralization of services in lead centres. These centres must meet defined standards of throughput, staffing, training and facilities and operate a retrieval service for the safe transfer of critically ill children from referring hospitals.

Some intensive care for children continues to be delivered in major acute hospitals, often hospitals with specialist services (e.g. neurosurgery). These must also meet the appropriate standards and care for children within protocols developed in partnership with the local lead centre. Occasional intensive care of children in district general hospitals should no longer occur, except in unusual circumstances and after discussion with the local lead centre.

Care of parents and family
Parents rightly expect to be involved in their child's care. When appropriate, they should be encouraged to participate in routine nursing care. This is often reassuring for child and parents. They also expect to be informed about, and usually participate in, any decisions concerning their child. Since PICU services are usually centralized, it is essential to provide accommodation for parents needing to stay.

Siblings may have considerable difficulty coming to terms with the patient's illness. Their needs have to be considered and it may be appropriate for them to visit regularly.

The death of a child is relatively rare. Many deaths on PICU are because of the elective withdrawal of care. Deaths need to be handled with sensitivity to the families' cultural and religious values. To help with the grieving process, many PICUs offer a bereavement counselling service. The Royal College of Paediatrics and Child Health has produced useful guidance on issues relating to end-of-life decisions.

Audit
In order to compare performance between PICUs, a number of case-mix adjustment tools have been developed. Adult tools (e.g. APACHE) are unsuitable for children because they do not take account of age-related normal ranges for physiological variables or the different patterns of disease. The two most commonly used case-mix adjustment tools are Paediatric Risk of Mortality (PRISM) and Paediatric Index of Mortality (PIM). These were developed in the USA and Australia, respectively, and need to be adjusted for the UK population. The MRC-funded Paediatric Intensive Care Outcome Study (UK PICOS) is being completed to determine and calibrate the most appropriate case-mix adjustment tool for PICU in the UK. The Department of Health has recently funded a national audit database, the Paediatric Intensive Care Audit Network (PICANET).

Airway management
Most children undergoing intensive care require tracheal intubation. Aspiration of gastric contents can increase morbidity and mortality and in the non-arrest, emergency situation, a rapid sequence intubation should be considered. After intubation, a gastric tube should be placed to decompress the stomach. Uncuffed tubes are traditionally used to minimize the risk of subglottic damage. Cuffed tracheal tubes are available in small sizes and their use on PICU is being re-evaluated, especially in situations where lung compliance is poor and the presence of a leak impairs lung recruitment and ventilation.

Nasotracheal intubation: nasotracheal tubes are easier to secure, allow better mouth toilet and are tolerated at lower levels of sedation. They are used unless contraindicated (e.g. possible basal skull fracture, coagulopathy). Tube length is crucial and should be checked with an AP chest radiograph (the tip should be opposite T2). Too long a tube is associated with endobronchial intubation and one too short increases the risk of accidental extubation.

Some children with airway obstruction can be woken once intubated. Nasotracheal tubes are often well tolerated in these situations and avoiding sedation and ventilation reduces complications. These children still require care in an ICU because of the hazards of accidental extubation. Nasotracheal tubes can be used for prolonged periods without apparent sequelae.

Tracheostomy is not usually discussed until after 3–4 weeks of intubation, though it may be indicated earlier in specific circumstances (e.g. in children after head injury who have poor or absent upper airway reflexes). When making the final decision about tracheostomy in a long-term ventilated child, non-invasive modes of ventilation must be carefully considered first, because tracheostomy precludes their use. Surgical tracheostomy remains the method of choice (we have used a percutaneous approach in teenagers, but abandoned the technique because of complications). A percutaneous gastrostomy may be considered at the same time.

Management of respiratory failure
Respiratory failure is the most common cause of emergency admission to PICU (Figure 1). Many children with respiratory failure have predisposing factors that complicate the course of their illness:
- bronchopulmonary dysplasia
- trisomy 21
- congenital anomalies (especially cardiac and respiratory)
- congenital or acquired immunodeficiencies (especially after cancer chemotherapy or organ transplantation).

Successful treatment of severe respiratory failure requires a package of measures that includes physiotherapy and meticulous attention to nutrition, infection control, cardiovascular status and fluid balance.

Causes of respiratory failure in children

Anatomical site	Diseases
Upper airway obstruction	Croup, epiglottitis, foreign body, laryngomalacia, subglottic stenosis
Lower airway obstruction	Asthma, bronchiolitis
Interstitial lung disease	Infective pneumonia/pneumonitis, aspiration pneumonia, acute respiratory distress syndrome from any cause
Pleura and chest wall	Trauma, empyema, kyphoscoliosis,
Neuromuscular diseases	Muscular dystrophy, spinal muscular atrophy, Guillain–Barré syndrome, spinal injury
Central hypoventilation syndromes	'Ondine's curse' (reduced ventilatory drive following neurosurgery)

1

Positive-pressure ventilation
Continuous positive airway pressure (CPAP) and non-invasive positive-pressure ventilation (NIPPV) can be delivered in a number of ways. Nasal prongs are suitable for neonates, while infants and young children may tolerate a short nasal tube (an uncuffed tracheal tube with the tip in the oropharynx). Tight-fitting face or nasal masks in sizes suitable for children are also available and surprisingly well tolerated by some. Positive pressure can be applied either by a CPAP circuit, flow driver, or by attachment to an appropriate ventilator.

Non-invasive pressure support (either NIPPV or CPAP) is becoming increasingly popular. CPAP may be indicated in babies with bronchiolitis and may avoid the need for intubation, but its role in other forms of acute respiratory failure requires further evaluation. Non-invasive support is also used for long-term ventilatory support in children with neuromuscular diseases or central hypoventilation syndromes.

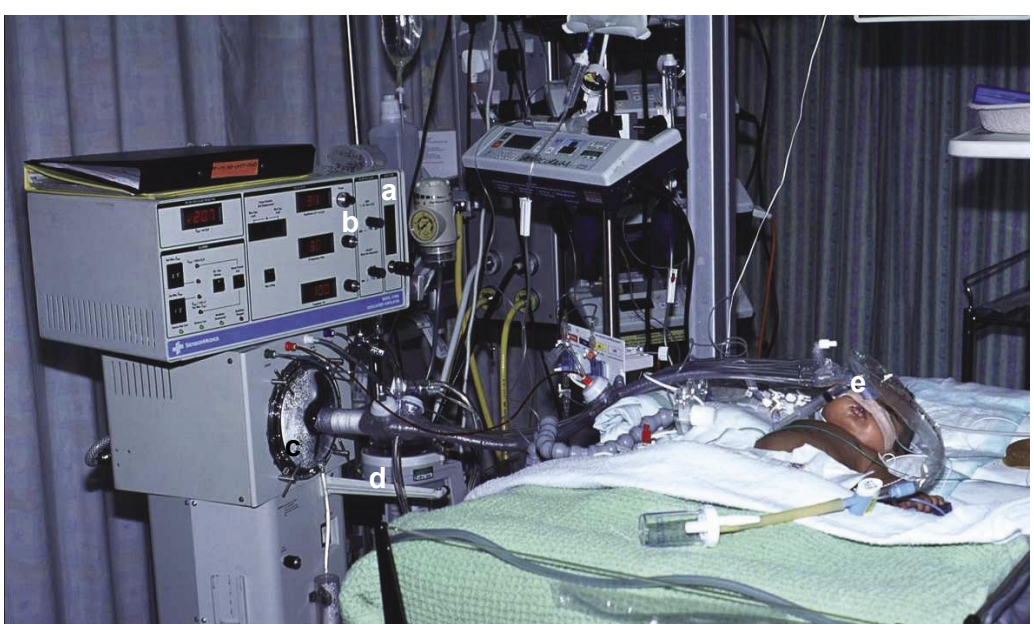
Negative-pressure ventilation: adult intensive care started with the use of cuirass ventilators during the polio epidemics of the middle of the last century. In the last 15 years, similar devices have been developed for use in infants, which can deliver continuous (CNEP) or intermittent (INEP) negative expiratory pressure. A more recent development is the Hayek oscillator, which encloses the trunk only and can be used in all age groups. Theoretically, these devices provide more physiologically normal respiratory support. Although they have enthusiastic proponents, they are not established in mainstream paediatric intensive care.

Pressure-controlled ventilation: most children admitted to PICU receive conventional respiratory support with time-cycled, pressure-controlled ventilation. The objectives of ventilatory support for children with acute respiratory failure are the same as those in adults:
- alveolar recruitment without over-distension
- limitation of tidal volume and pressure to avoid volutrauma and barotrauma
- the acceptance of permissive hypercarbia and possibly hypoxaemia to meet the requirements of the above.

Several ventilators deal successfully with children of all ages. The authors prefer those with near-patient flow sensors, which have allowed improved triggering and tidal volume monitoring. These are particularly useful in the ventilation of infants.

Adequate humidification is essential to prevent heat and moisture loss from the patient and drying of secretions, which crust the lumen of the tracheal tube and encourage blockage. Heated water humidifiers are generally used.

High frequency oscillatory ventilation (HFOV) was popularized by neonatologists. Its main advantage is to allow alveolar recruitment at relatively constant, but often lower, peak pressures than IPPV. Outcome is better in acute respiratory distress syndrome (ARDS) compared with IPPV, presumably because of reduced ventilator-associated lung injury. Ventilation is delivered through a conventional endotracheal tube and adequate humidification is possible in contrast to earlier technologies such as high frequency jet ventilation. Oxygenation and carbon dioxide excretion are independent. Oxygenation depends on FiO_2 and mean airway pressure. Carbon dioxide is removed by imparting energy into the system via an oscillating diaphragm. The threshold for progressing to HFOV has decreased as paediatric intensivists have become increasingly familiar with the technology. The Sensormedics oscillator (Figure 2) is the only machine commercially available in the UK with sufficient power to ventilate children older than neonates. There are two models: one for neonates and smaller children, the other for older children and adults. Some units now use HFOV as the ventilatory mode of first choice for children presenting with moderately severe respiratory failure.



2 The Sensormedics high frequency oscillatory ventilator in use. **a** Flowmeter, **b** amplitude, percentage inspiratory time and frequency controls, **c** oscillating diaphragm, **d** heated humidifier, **e** airway connector with closed suction device.

Nitric oxide
Some years ago nitric oxide became popular as a therapy in severe respiratory failure but with experience its use has declined. In respiratory failure, its main indication appears to be to improve oxygenation before and during transportation of children requiring extracorporeal membrane oxygenation. However, nitric oxide improves outcome in neonates with idiopathic pulmonary hypertension of the newborn and is used to treat pulmonary hypertension in children with congenital heart disease after corrective surgery.

Surfactant
Exogenous surfactants have revolutionized the management of neonatal respiratory distress syndrome. In older patients, many pulmonary disease processes are associated with surfactant deficiency. Clinical trials suggest that there may be some benefit from surfactant administration to babies with bronchiolitis but the authors are not aware of any other evidence to support its use in respiratory failure beyond the neonatal period.

Liquid ventilation
Liquid perfluorocarbon is used to transport oxygen and carbon dioxide through the respiratory tract. In full liquid ventilation, the lung is completely full of fluid and an external pump and gas exchanger are required. Partial liquid ventilation is simpler to use. The lung is filled to the end of the tracheal tube at expiration and the patient attached to a conventional ventilator. The FRC is thus filled with liquid and the gas/liquid interface is intrapulmonary. Although the technique was described over 10 years ago, clinical trials are not completed. The role of liquid ventilation in treating children with respiratory failure is unknown.

Extracorporeal membrane oxygenation (ECMO)
It is unlikely that a randomized controlled trial of the use of ECMO for the treatment of respiratory failure in children will ever take place. However, it has been accepted as an effective rescue therapy for severe acute respiratory failure in children.

Sedation and analgesia
All children in pain, from whatever cause, must receive adequate analgesia. Many routine ICU procedures are painful and the use of local anaesthetics should be considered when indicated.

Sedation of children on PICU remains a problem. It is often needed, but complications are relatively frequent (Figure 3). Sedation scoring is difficult in young children. There are numerous sedative regimens, and the choice of drug may be less important than the philosophy behind its administration. Before sedating a child, other causes of agitation should be sought and, if possible, eliminated. Paramount among these is pain. Others include bladder distension, hypoxaemia, hypercarbia, cold, hunger and separation from parents. Once these issues are addressed, it is appropriate to administer sedation that is titrated to a defined endpoint. The judicious use of restraints may also reduce the need for sedation, but they are considered unacceptable by many nurses.

Advantages and disadvantages of sedation

Advantages
- Comfort
- Safety (retention of lines and tubes, prevention of injury to patient and carers)
- Therapeutic (attenuate rises in intracranial pressure, blood pressure)
- Psychological (reduces distress, may reduce long-term psychological disturbance)

Disadvantages
- Hypotension
- Immobility (pressure area problems, fluid retention)
- Reduced secretion clearance (ventilator-associated pneumonia)
- Immunosuppression (hospital-acquired infection)
- Withdrawal phenomena
- Pharmacodynamic (side-effects, toxicity)

3

Intravenous opiates and benzodiazepines by continuous in-fusion remain popular. Following a directive from the Committee for Safety of Medicines, propofol should no longer be used for the sedation of children because there have been a number of cases of progressive myocardial failure following long-term, high dose propofol infusions in children with respiratory failure. Some units are returning to intermittent boluses of longer acting agents because of the risks of overdose and accumulation with infusions. Once gastric absorption is established many prescribe enteral sedation with chloral hydrate, trimeprazine or clonidine. Muscle relaxants are often used in the acute stages of critical illness. Their use is associated with complications and needs to be carefully considered in each case.

Fluids, electrolytes and nutrition
Resuscitation fluids
Resuscitation fluids are usually given in increments of 20 ml/kg. The type of fluid has been the subject of considerable debate. Human albumin solution remains the most popular agent for large volume resuscitation in babies and small children. Artificial colloids can be used, but with appropriate limits on the volume administered. Normal saline is increasingly used for the first 20–40 ml/kg.

Maintenance fluids
Maintenance fluids need to supply water, electrolytes and energy. The standard formula of 4 ml/kg/hour for the first 10 kg body weight, 2 ml/kg/hour for the second 10 kg, and 1 ml/kg/hour thereafter (see page 459) works reasonably well in children weighing 5–50 kg. However, in smaller babies it considerably underestimates fluid and energy requirements and overestimates them in older children. Fluid requirements per kg increase with decreasing weight and gestational age. The smallest infants admitted to a PICU may require more than 180 ml/kg/day.

0.18% NaCl in 4% dextrose remains a popular first-line maintenance fluid. However, it will just supply basal sodium requirements, and in the face of deficits or losses its use will lead to hyponatraemia (deaths from hyponatraemia and cerebral oedema have resulted). There are strong arguments for replacing it with a fluid with a higher sodium content (e.g. 0.3%) for routine use.

Renal replacement therapy
Haemofiltration is commonly used in paediatric intensive care to manipulate fluid and electrolyte balance. The technique is possible in all but the smallest of babies, but the technical challenges are substantial. Peritoneal dialysis is technically simpler and may give more gradual control of metabolic disturbances.

Nutrition
Children have a high metabolic rate because of the energy costs of temperature homeostasis, growth and (often) the work of breathing. They may have very limited energy reserves, particularly because up to 40% are malnourished on admission to PICU.

Adequate nutrition is vital, but can be difficult to achieve because of concerns about fluid retention and volumes of drugs and other fluids. The authors are more liberal with fluids, and therefore nutrition, and control fluid balance with diuretics if necessary. Enteral feeding is preferable, if possible. If full enteral feeds cannot be established within 48 hours, the authors start parenteral nutrition, but, unless contraindicated, continue to deliver small volumes (3–5 ml/hour) of enteral feed.

Monitoring
Monitoring modalities in PICU are broadly the same as those used in adult intensive care. The main difficulties in children arise because of the diameters of the various intravascular catheters available. Most, including intravascular blood gas sensors, are now available in miniature forms. Cardiac output can be measured satisfactorily with proprietary tools that use a variety of indicator dilution methods. Conventional pulmonary artery catheters can be used but, as in adult ICU, their use is declining. The authors have found the cerebral function analysing monitor useful.

Some specific clinical conditions
Sepsis
The systemic inflammatory response syndrome is similar in adults and children but mortality is lower in children. Neonates, premature babies, the immunosuppressed and those children with congenital cardiac or renal anomalies are particularly at risk. Children under 2 years of age are particularly susceptible to polysaccharide-encapsulated bacteria such as *Meningococcus*, *Pneumococcus* and *Haemophilus influenzae*. Surgical sepsis is relatively uncommon.

Meningococcal disease (Figure 4) is the leading infectious cause of death in children. It is hoped that the vaccination programme against Group C disease will reduce the mortality. The disease is often difficult to diagnose in the early stages but can have a fulminant course resulting in death within a few hours of the appearance of the characteristic rash. Most cases occur in children less than 5 years of age, with a peak incidence between 3 months and 2 years of age.

4 A child with meningococcal septicaemia. The characteristic rash is non-blanching and may have necrotic areas surrounded by erythema. This child had fasciotomies to all four limbs and went on to have bilateral below knee amputations.

Initial treatment consists of antibiotics, aggressive fluid resuscitation, inotropic support, intubation and ventilation, treatment of hypoglycaemia, electrolyte imbalances (especially hypocalcaemia) and coagulopathy. A detailed protocol can be found at ***www.meningitis.org***. Several experimental agents have undergone clinical trials with mixed results. PICU mortality is below 20% and it is unlikely that any trial with mortality as a primary endpoint will recruit sufficient numbers to prove efficacy. Fluid requirements can exceed 200 ml/kg in the first 24 hours. Human albumin solution remains the most commonly used colloid, and there is some experimental evidence to support its use. The children remain very oedematous until the systemic inflammatory process and capillary leak have resolved, at which point most will diurese spontaneously. During this period, there may be florid pulmonary oedema, which requires treatment with high positive end-expiratory pressure, HFOV or occasionally extracorporeal membrane oxygenation. Despite the pulmonary oedema, fluid resuscitation may need to continue if the patient shows signs of intravascular volume depletion. The role of treatments such as early haemofiltration, prostacyclin infusion, steroids, plasmapheresis or plasma exchange remains unclear. Death occurs either in the first 24 hours as a failure to stabilize or later as a withdrawal of treatment when catastrophic sequelae (e.g. cerebral infarction) manifest themselves. In survivors, further treatment may include dialysis/haemofiltration for electrolyte imbalance or renal failure and debridement, amputation or skin grafting of necrotic limbs or areas of skin.

Acute brain insults
The response of children to acute brain injury differs from that in adults in a number of ways. Babies with unfused cranial sutures are able to tolerate rises in intracranial volume without the degree of intracranial hypertension seen in older patients. In traumatic brain injury, the response is often predominantly hyperaemic (so a degree of cerebral vasoconstriction may be indicated) and extradural haematoma is less common than in adults. For any severity of injury, the outcome for children appears to be better than for adults, presumably because of the greater adaptability of the developing CNS.

In only a small number of children is a reduced conscious level associated with a structural intracranial injury. In most there has been a diffuse insult, such as hypoxaemia, ischaemia or metabolic insult (commonly hypoglycaemia) (Figure 5).

Traumatic brain injury (TBI) in babies is often non-accidental. Babies with non-accidental injury may have a diffuse injury, with multiple petechial haemorrhages throughout the brain, and/or intracranial haemorrhage. Petechial retinal haemorrhages are pathognomonic of a shaking injury. Care of children with non-accidental injury requires close liaison with the child protection team and careful clinical examination (including photography) to document other injuries. Clotting studies (to exclude a bleeding diathesis), a skeletal survey and fundoscopy (to document retinal haemorrhages) should be obtained. Subdural haematoma may require evacuation, usually by needle puncture.

In older children a more adult pattern is seen. Extradural haematoma is less common, but requires urgent attention if present.

Causes of non-traumatic coma in children

Nature of insult	Disease process
Hypoxic-ischaemic injury	Cardiac arrest Immersion incidents Near miss sudden infant death syndrome Suffocation
Infection	Meningitis, encephalitis Cerebral effects of generalized sepsis
Metabolic injury	Hypoglycaemia Hyper- or hyponatraemia Hepatic encephalopathy Reye's syndrome Haemolytic uraemic syndrome Poisoning Inborn errors of metabolism

Intensive care management is similar to that of adults with head injury with general resuscitative measures and acute reduction in intracranial pressure (ICP). The authors measure ICP and manipulate therapy to maintain cerebral perfusion pressure (CPP), despite the fact that there is little evidence that ICP measurement and the management strategies deriving from it are of any benefit. The targets for CPP need to be age related, but there is a paucity of data to support any particular set of values. Trials are continuing to evaluate moderate hypothermia in the early post-injury period and the role of newer monitoring modalities (e.g. tissue pO_2) needs evaluation. Data obtained from adults may not be directly applicable to children.

Blocked ventriculo-peritoneal shunt: there are increasing numbers of children with shunt devices and blockage can be a neurosurgical emergency (there have been several deaths in our region recently because clinicians did not appreciate the urgency of the situation). If a child with a shunt starts to lose consciousness, urgent referral to a paediatric neurosurgical centre is required. While transfer is being arranged, emergency management must be instituted (i.e. removing CSF through the reservoir, osmotic diuretics to reduce ICP and controlled ventilation to maintain $PaCO_2$ at 3.5–4.5 kPa).

Cardiovascular disease
Acquired cardiac disease is relatively uncommon in childhood, but children with congenital heart disease account for a large proportion of the workload of a PICU. Most are admitted for postoperative care after corrective surgery. They also present with heart failure or arrhythmias at other times. There is also an increasing population of older patients who had surgery for congenital lesions as children. These patients can present with intercurrent illness or for revision of their original surgery.

Children with cyanotic congenital heart disease are prone to respiratory tract infections and can pose management problems. It is important to determine their normal oxygenation status and to set appropriate targets for ventilatory management. Some of these children normally have oxygen saturations below 70%.

Diabetic ketoacidosis
Diabetic ketoacidosis is often the first presentation of diabetes in children. These children can be profoundly acidotic and severely dehydrated. Their conscious level may be impaired and their airway may require protection. Deaths occur from cerebral oedema. The precise cause of this is unclear, but it is thought to be a result of the maintenance of a high intracranial osmotic pressure as glucose and ketones are cleared from the blood. The imperative, therefore, is a gradual normalization of blood sugar, achieved by replacing fluid deficits over 24–48 hours with normal saline. Potassium replacement is also necessary once a urine output is established. A low dose intravenous insulin infusion of 0.1 unit/kg/hour is started. The blood sugar is monitored closely and if the rate of fall is greater than 5 mmol/litre/hour, then either the rate of insulin infusion should be reduced to 0.05 IU/kg/hour or dextrose should be added to the maintenance fluid or both. Once the blood glucose is below 12 mmol/litre, the normal saline is replaced with a solution containing 4% or 5% dextrose. The choice of solution depends on the serum sodium concentration. A detailed management protocol can be found at http://www.diabetes.org.uk/dka_paed/dkapaed.pdf ◆

Stabilization and Transport of Critically Ill Children

David A Rowney
David L Simpson

David A Rowney is Consultant in Paediatric Intensive Care and Anaesthesia at the Royal Hospital for Sick Children in Edinburgh. He qualified from Edinburgh University and trained in anaesthesia in Edinburgh, paediatric anaesthesia at HSC Toronto and paediatric intensive care, including transport of critically ill children, in Edinburgh and Glasgow. His research interests include paediatric neuroanaesthesia and anaesthesia for paediatric laparoscopic surgery.

David L Simpson is Consultant in Paediatric Anaesthesia and Intensive Care and Head of the Department of Anaesthesia and Intensive Care at the Royal Hospital for Sick Children in Edinburgh. He qualified from the University of Edinburgh. He is a member of the Scottish Colleges Committee on Children's Surgical Services and has a particular interest in the organization of care for and the transfer of critically ill children. He was a member of the Acute Services Review (Scotland) Working Party on the Transport of Critically ill Children which led to the establishment of a national service in Scotland.

Development of Paediatric Intensive Care Unit (PICU) transport services
In the UK, during the last decade, there has been a drive to centralize paediatric intensive care in a small number of large tertiary centres to try to improve the outcome of critically ill children. Centralization has resulted in increasing numbers of critically ill children requiring inter-hospital transportation. The report, *Standards of Practice for the Transportation of the Critically Ill Child,* published in 1996 by the Paediatric Intensive Care Society (PICS), recommended that transportation should be undertaken by specialized PICU transport teams functioning as an 'intensive care bed on the move'. Alternatives include transportation by the local ambulance paramedic team or by the referring physician and/or nurse. However, critically ill children transported by non-specialized teams suffer significantly more critical incidents during transportation than those transported by specialized teams. The main advantages of specialized teams are that they:

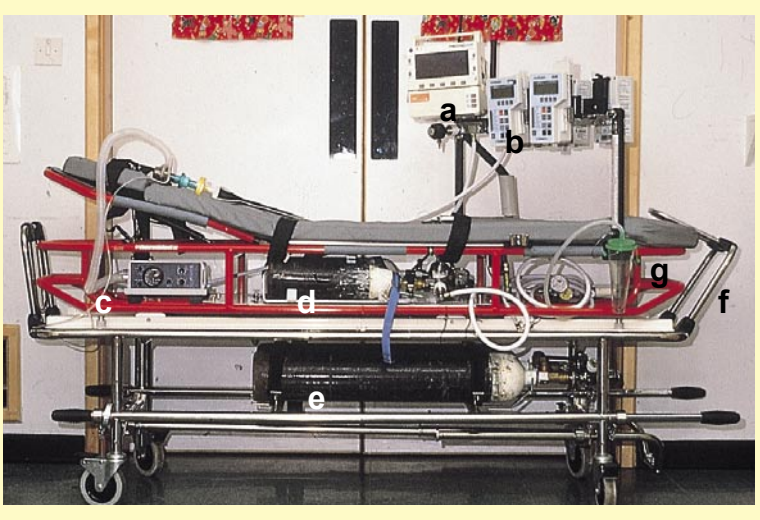
- have training and experience in paediatric intensive care and transportation
- use dedicated transportation equipment
- can operate without rendering the PICU base or referring hospital short staffed.

The transport team
A specialized PICU transport team usually comprises an experienced PICU doctor and nurse. Ideally, the doctor should be a senior trainee with 2 years' experience in anaesthesia, adult or paediatric intensive care medicine, neonatal intensive care or equivalent discipline (including a minimum of 3 months' PICU experience). Nurses have independent professional responsibility towards the child and should have undergone PICU training (ENB 415 or equivalent) and have 2 years' PICU experience. Ideally, these transport personnel should have specialist transport training. Consultants often travel with difficult patients or when new personnel are being trained. The transport service is usually managed by a PICU consultant (the 'Transport Director') and a senior PICU nurse (the 'Transport Coordinator'). They approve equipment and medical supplies, develop transport protocols, establish outreach education programmes, implement audit and a risk management pro-gramme, manage the transport budget and organize staff training.

Equipment (Figures 1–4)
The team should be self-sufficient and carry all the necessary equipment and drugs for stabilization and transportation (smaller hospitals may not be equipped with the full range of consumables for babies and children). These can be pre-packed in special bags with multiple, labelled compartments to allow rapid access to the contents (Figure 1). Important additional equipment includes a mobile telephone, warm protective high-visibility clothing for staff and a sharps disposal box.

Transport equipment and drugs bags (the Paediatric Intensive Care Society has guidelines about equipment and drugs for transport). a Circulation and monitoring; b airway and breathing; c emergency equipment; d suction apparatus; e drugs for resuscitation, anaesthesia, sedation and cardiovascular support; f multiple compartments.

1

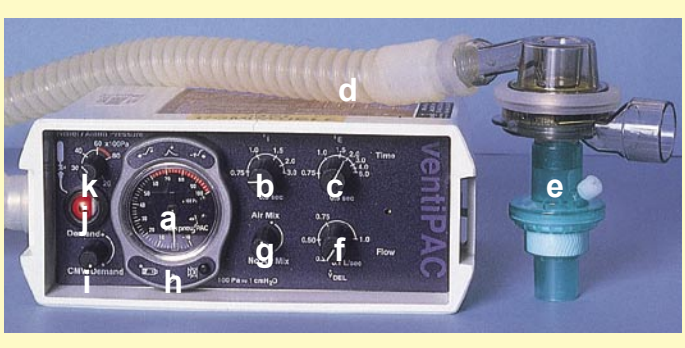


Custom-built transport trolley. **a** Monitor, essential features:
- operates from battery, 12 V DC and 240 V AC power
- visual and audible alarms
- illuminated display with wide viewing angle screen
- suitable for neonates and children
- includes ECG, oxygen saturation, end-tidal CO_2, non-invasive blood pressure, temperature, respiratory rate, central venous pressure, invasive blood pressure and facilities for data storage, download or printing; **b** syringe pumps with visual and audible alarms; **c** ventilator; **d** size D oxygen cylinders (340 litre); **e** size F oxygen cylinder (1360 litre) – take twice the estimated oxygen requirement (O_2 consumption = minute volume + driving gas (specified by the manufacturer) ml/minute). Note: hand ventilating requires more oxygen; **f** modified standard ambulance trolley; **g** Aerosled (red frame) separates from the trolley for air transport.

2

The baby PAC™ ventilator (SIMS pneuPAC Ltd), which is suitable for babies ≤ 10 kg. It is a gas-driven, time-cycled, pressure-controlled ventilator. **a** Pressure gauge; **b** inspiratory time; **c** expiratory time; **d** on/off switch; **e** inspiratory and expiratory circuit; **f** heat and moisture exchanger; **g** pressure control; **h** positive end-expiratory pressure; **i** fraction of oxygen in inspired air; **j** alarm module with visual and audible alarms for high pressure and low pressure (disconnection); **k** air failure visual alarm; **l** oxygen failure visual alarm; **m** pressure relief and audible alarm.

3



The ventiPAC™ ventilator (SIMS pneuPAC Ltd), which is suitable for babies and children > 5 kg. It is a gas-driven, time-cycled, flow generator. **a** Pressure gauge; **b** inspiratory time; **c** expiratory time; **d** inspiratory circuit only; **e** one-way valve heat and moisture exchanger; **f** flow control adjusted to achieve the desired peak airway pressure (NB set pressure relief just above this pressure to protect lungs if leak around the tube decreases); **g** fraction of oxygen in inspired air; **h** alarm module with visual and audible alarms for high pressure and low pressure (disconnection); **i** on/off switch; **j** oxygen failure visual alarm; **k** pressure relief and audible alarm.

4

Modes of transportation
Transportation is either by road (emergency ambulance, dedicated mobile PICU) or air (helicopter or fixed wing (aeroplane) aircraft). The choice depends on the severity of illness, urgency of transportation, availability of vehicles, distance involved, proximity of the hospitals to airfields, time of day, weather conditions and the amount and type of equipment to be carried.

Road transportation is rapidly organized and door-to-door. It is usually more time efficient for distances of less than 75 miles. Some teams use a dedicated mobile PICU, which is designed for easy patient loading, and has adequate lighting and heating, sufficient space for the transport team at the head and both sides of the child, adequate oxygen supplies, 240 V AC electricity and storage space. They also have adequate restraints for the transport team, child, trolley and equipment and an effective communications system.

Air transportation takes longer to organize and requires secondary road transportation to and from the aircraft. It is a realistic option for distances over 75 miles or when road transport will take more than 2 hours. A variety of helicopter (Figure 5) and fixed wing (Figure 6) aircraft are available from the Ambulance Service, the Royal Navy and RAF Search and Rescue Services and charter companies. In transit, the transport team is in charge of patient management decisions but the pilot is in command of the aircraft and all passengers. The pilot decides when to fly, the route, how many passengers to carry and whether to divert in poor weather conditions. Effective communication and discussion between the team and the pilot is essential.

5 The Scottish Ambulance Service EC 135 helicopter ambulance is unpressurized, which limits its altitude, affecting routing and fuel consumption and increasing the importance of weather conditions.

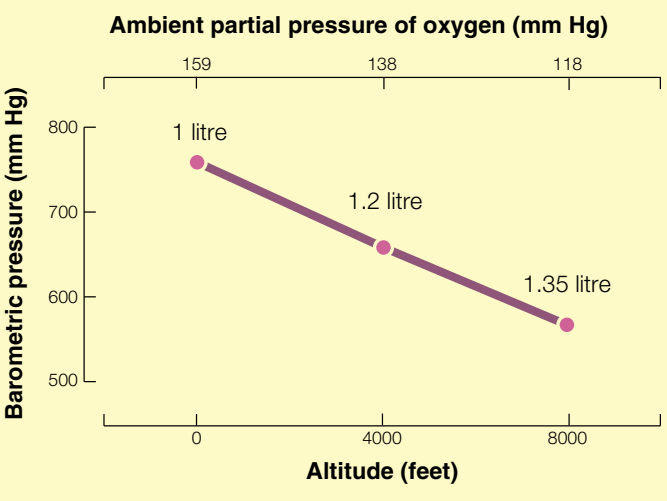
6 The Scottish Ambulance Service Air King fixed wing air ambulance, which is pressurized and can therefore fly higher, above bad weather, faster and further than unpressurized air ambulances (e.g. the Islander).

Special transport considerations
Isolation and the unfamiliar environment: the transport team is isolated from assistance and working in a relatively unfamiliar environment. These effects can be minimized by training, experience and using expertise at referring hospitals. The use of mobile telephones in aircraft is often prohibited.

Movement (including acceleration, deceleration, head up/down tilt and vibration) has significant physiological effects. If the child's head is towards the front of the vehicle, acceleration causes venous pulling in the legs and reduces cardiac output. Baroreceptor-induced vasoconstriction increases systemic vascular resistance maintaining arterial pressure. This normal response is obtunded in children with septicaemia, hypovolaemia or CNS injury. Deceleration (e.g. sharp braking) increases venous return and intracranial pressure, which is exaggerated by head-down tilt when travelling down hill. The effects of these forces can be minimized by good communication with the driver and using a police escort to negotiate traffic congestion at a steady speed. Procedures such as intubation or cannulation are easier in a stationary ambulance (ideally before commencing the journey). Aircraft transmit vibration to passengers, exacerbating motion sickness, impairing co-ordination and interfering with the vestibulo-ocular and pursuit reflexes, which are important when trying to visualize a monitor display. Children with fractures may require additional analgesia. Movement and vibration can also cause displacement of tracheal tubes, chest drains and venous and arterial cannulae.

Altitude: pressurized aircraft usually fly with a cabin altitude of 6000–8000 feet (1800–2500 m). Barometric pressure falls with altitude from 760 mm Hg (100 kPa) at sea level to 565 mm Hg (74 kPa) at 8000 feet, which affects enclosed gas spaces and patient oxygenation (Figure 7). Boyle's law states that volume is proportional to 1/pressure. Therefore, enclosed air spaces could expand by up to 35% at 8000 feet with the risks of ear, sinus and dental pain, expansion of pneumothoraces and tracheal tube cuffs and abdominal distension. Altitude affects equipment containing gas spaces (including non-invasive blood pressure cuffs, glass intravenous giving bottles, pressure bags and vacuum mattresses). The percentage of oxygen in atmospheric air remains unchanged with altitude, but as barometric pressure falls the partial pressure of oxygen in dry air falls from 159 mm Hg (21 kPa) at sea level to 118 mm Hg (16 kPa) at 8000 feet. This is important for children with high oxygen requirements at sea level, especially if the fraction of oxygen in inspired air (FiO_2) cannot be increased readily during transportation (e.g. those breathing spontaneously on high flow oxygen or ventilated with 100% oxygen). To compensate, the cabin altitude of pressurized aircraft can be reduced to near sea level and military helicopters can fly as low as 500 feet (150 m), weather permitting.

Effects of changing barometric pressure on partial pressure of oxygen and gas volume



7

Excessive ambient noise makes communication in aircraft difficult and tiring. Auscultation with a stethoscope is usually impossible and the detection of auditory alarms is inhibited. Children and the transport team should be protected from the damaging effects of noise with helmets and ear defenders.

Motion sickness is caused by the mismatch of afferent visual and vestibular information and is made worse by excessive head movement and reading in transit. Anti-emetics (e.g. antihistamines, ondansetron) are generally effective.

Distraction by alternative stimulation (e.g. looking out of the aircraft window or at the aircraft instrumentation) combined with difficulty hearing audible alarms means that transport personnel must be particularly vigilant.

Communication
Effective communication is important at all stages of transportation. Every PICU should have a dedicated telephone 'hotline'. Referrals should be made direct from the referring consultant to the PICU consultant, who should complete a comprehensive evaluation sheet covering the pertinent aspects of the child's location, clinical condition and treatment and give advice on further management. The ambulance service is contacted to arrange transportation and the referring hospital notified of the team's estimated time of arrival. The PICU consultant remains in regular contact with the referring physician to give additional advice and to receive clinical updates that can be passed on to the transport team, in transit, by mobile telephone. Once the transport team has assessed the child, they inform the ambulance service about the expected stabilization time to facilitate scheduling of the return journey and notify the PICU staff about the child's condition, treatment requirements and expected time of arrival in the PICU. During the child's stay in PICU, staff should provide regular feedback to the referring hospital and send a formal discharge letter to all consultants involved and the patient's GP.

Resuscitation and initial referral
Referrals should be made as soon as it is evident that the child is critically ill and needs transportation to a PICU. Children compensate and appear well in the early stages of critical illness, then rapidly deteriorate when their capacity for compensation is exceeded. The main criteria for PICU referral are given in Figure 8. The referring hospital is responsible for resuscitation and stabilization until the transport team arrives (Figure 9). This should be undertaken by the most senior staff available, following accepted PALS/APLS principles, in an appropriate location in the hospital equipped for high dependency or intensive care (usually ICU, high dependency unit, theatre or theatre recovery).

Main criteria for PICU referral

Deteriorating airway
- Chest wall recession
- See-saw breathing
- Stridor

Respiratory distress
- Rate > 60/minute
- Chest wall recession
- Oxygen saturation in arterial blood (SaO_2) < 94% or partial pressure of oxygen in arterial blood (PaO_2) < 8 kPa (on high flow face mask oxygen)
- Partial pressure of carbon dioxide ($PaCO_2$) in arterial blood > 6 or < 3.5 kPa

Shock
- Heart rate > 180 or < 80/minute (< 5 years) > 160 or < 60/minute (> 5 years)
- Absent peripheral pulses
- Cold peripheries
- Capillary refill > 2 s
- Systolic blood pressure < 70 + (age in years x 2) mm Hg

Deteriorating level of consciousness

Recurrent seizures

Burns > 10%

Multiple trauma

8

Responsibilities of the referring hospital

- Optimize resuscitation with advice from the PICU staff
- Copy clinical notes for the transport team
- Obtain cross-matched blood if required
- Communicate changes in clinical condition to the PICU staff
- Consider transport arrangements for the parents

9

Stabilization
Meticulous preparation and stabilization of the child before departure minimizes the risks during transportation. This encompasses adequate resuscitation, initiation of all supportive therapies and monitoring, cessation of deterioration (ideally, improvement) in the clinical condition and pre-emptive management to avoid problems in transit. A systematic ABC approach, including assessment, optimization and preparation for transportation, of the airway, breathing, circulation, neurological status, temperature and blood glucose is useful. The child is transferred to the transport equipment to provide continuous therapy and monitoring throughout the transportation. Children must be regularly assessed to evaluate the impact of treatment and recognize further deterioration, which can be rapid.

Airway and breathing should be assessed in the context of the full clinical picture. Respiratory compromise can be the cause or result of multi-system dysfunction in children. Aspects to be clarified in the history include the speed of deterioration, duration of intubation, volume of secretions and suction requirement. Important points of examination include airway patency, level of consciousness, degree of exhaustion, and adequacy of ventilation, sedation and neuromuscular blockade. Monitoring and investigations should include oxygen saturation, capnography, airway pressures, ECG, arterial blood gas analysis and chest radiograph to confirm the correct position of a tracheal tube. The airway must be reliable before transportation. The decision to intubate can be difficult. There should be a lower threshold for intubation and ventilation for transportation than in routine PICU practice, to optimize the clinical condition before transportation. Effective tracheal tube fixation is essential and intubated children should be given sedative and neuromuscular blocking drugs throughout transportation to reduce the likelihood of accidental extubation, decrease awareness and anxiety, and facilitate controlled ventilation with the transport ventilator. All children intubated with an uncuffed tracheal tube require a gastric tube to decompress the stomach. Pneumothoraces should be drained before departure. Intermittent positive-pressure ventilation or flying at altitude can expand pneumothoraces, resulting in respiratory and cardiovascular compromise. One way flutter (Heimlich) valves should be used in preference to bottles with underwater seals for chest drains during transportation.

Circulation: hypovolaemic children tolerate transport badly. It is important that hypovolaemia (characterized by tachycardia, poor peripheral perfusion and, if severe, hypotension and acidosis) is corrected with fluid before transportation. Children with continuing haemorrhagic shock should not be transported until the bleeding has been controlled. Commencing inotrope infusions in transit is difficult so there should be a low threshold for doing this before departure. Some types of congenital heart disease require a prostaglandin infusion to sustain life by maintaining patency of the ductus arteriosus, for example interrupted aortic arch (duct dependent systemic circulation) or pulmonary atresia (duct dependent pulmonary circulation). The requirement for a central venous line and an arterial line depends on clinical condition and is not required for transport *per se*. However, non-invasive blood pressure recordings may be affected by motion artefact, can be unreliable in shocked children and are a significant drain on the battery life of the monitor. It is advisable to have at least two functioning, securely fixed intravenous cannulae because critically ill children are difficult to cannulate in transit. A urinary catheter is usually inserted and hourly urine output monitored.

Patient packaging: the difficulties of working in the confined space of an ambulance are evident in Figure 10. The child's head and tracheal and ventilator tubes should be securely fixed while ensuring easy access for airway management. Intravenous line extension tubing is useful for administering drugs or fluid without needing to move around or unwrap the child. The transport environment can be hostile (e.g. on an airport runway in mid-winter) making heat loss a problem when transporting infants who have a large surface area to weight ratio, a large head, thin skin and neuromuscular blockade preventing shivering. The use of a vacuum mattress (Figure 11), gamgee, foil blankets, chemical warming packs (which can be placed directly against the skin of an infant without causing thermal injury), a hat and warm ambient temperature within the vehicle are sufficient to maintain body temperature in infants over 1.5 kg body weight. (Babies less than 1.5 kg are usually transported by neonatal intensive care teams using a portable incubator to maintain body temperature.) All equipment, syringe pumps and the monitor must be secured and readily visible to the team while seated. Emergency drugs, fluids, airway and ventilation equipment (including a self-inflating resuscitation bag, valve and mask system) must be available immediately. A pre-departure checklist prevents accidental omissions in stabilization or inadvertently leaving equipment behind.

10 Interior of an ambulance, which provides limited space to perform procedures such as intubation or intravenous cannulation.

Baby and transport equipment packaged in a vacuum mattress. This secures the child and prevents pressure areas and heat loss. A transport incubator is unnecessary for full-term babies and infants and is heavy, complicated to operate and offers less access to the baby. **a** Head securely fixed; **b** carrying handle; **c** security straps; **d** monitor; **e** ventilator; **f** syringe pump.

11

Documentation should include a comprehensive medical, nursing and operational record from the initial telephone referral until the child arrives in the PICU (Figure 12). It should form the basis of debriefing sessions, audit and risk management.

Transport documentation

- Demographic data
- Clinical data
- Advice given by the PICU
- Treatment by the transport team
- Mode of transport, personnel and timings
- Critical incidents in transit
- Checklists
- Drug infusion and resuscitation charts
- Consent forms
- Parent information booklets

12

Critical incidents in transit
Transferring the child between trolleys, around the hospital, into and out of vehicles, with the associated switching of oxygen supplies are risk factors for critical incidents. Despite the best preparation and stabilization, children may deteriorate in transit and the transport team should be able to respond. Published series highlight the critical incidents that can occur during transportation of children, which can be classified as physiological deterioration or equipment problems (Figure 13). Transport teams should have regular audit and risk management meetings to discuss these events.

Common critical incidents during transportation of children

	Avoidable	Early recognition and treatment
Physiological deterioration		
• Hypoxia		✓
• Cardiac dysrhythmia		✓
• Hypotension		✓
• Deterioration in Glasgow Coma score		✓
• Hypothermia	✓	
• Hypoglycaemia	✓	
Equipment problems		
• Tracheal tube blockage	✓	
• Accidental tracheal extubation	✓	
• Loss of intravenous access	✓	
• Loss of monitoring	✓	
• Ventilator malfunction		✓
• Exhaustion of oxygen supply	✓	

13

During transportation the child should be reassessed regularly using a systematic ABC approach. The position, patency and fixation of the tracheal tube are confirmed. Capnography is a sensitive way of monitoring airway security in the intubated child especially during periods of maximal risk such as loading and unloading from vehicles when clinical observation is difficult. There is a high risk of tracheal tube (< 5.0 mm internal diameter) blockage by secretions, which is reduced by humidifying inspired gas using a heat and moisture exchanger and by regular tracheal suction. Adequacy of ventilation is assessed by observing chest movement, the airway pressure gauge on the ventilator and the capnograph trace. The ventilator settings, connections and oxygen source are regularly observed. The mnemonic, DOPE, is a useful method of troubleshooting (consider **D**isplacement or **O**bstruction of the tube, **P**neumothorax and **E**quipment problems). Assessment of circulation includes evaluation of heart rate, peripheral and central pulses, capillary refill, blood pressure and central venous pressure (if monitored). Intravenous access sites are inspected regularly. Neurological status is assessed by evaluating pupil size and reactivity and fontanelle pressure. Seizure activity, which is masked by neuromuscular blockade, should be suspected if tachycardia, hypertension or pupil dilatation occur suddenly. Body temperature and blood glucose in babies can fall during transportation and should be measured regularly.

Caring for the parents
The distress to parents caused by the critical illness of their child is extreme and is exacerbated by the news of transportation to a different hospital. The transport team has limited time to gain the trust and confidence of the parents, who require verbal and written information. Most transport teams have booklets for parents and some have websites containing this information. The transport team should explain the need for transportation and the risks involved. Parents often want to accompany their child during transportation. Considerations include the available space within the vehicle, the distance to be travelled, availability of alternative transport and the severity of illness of the child. It is usual for a parent to accompany a conscious child. If the parents are not travelling with their child, alternative transportation should be arranged.

Special considerations
Occasionally it is impossible to stabilize a child before transportation because of an unstable surgical pathology such as intracranial haemorrhage. The severity and urgency of the situation should be addressed during the initial referral telephone call and a decision made whether the referring hospital should expedite transportation to the PICU or whether the transport team should collect the child. Occasionally the child is so severely ill that stabilization is impossible or futile and the child dies. This is distressing for all concerned but should be considered before attempting to transport an unstable child. Cardiac arrest or death occurring in transit is uncommon. The duration of attempted resuscitation and whether to proceed towards the PICU or return to the referring hospital should be decided in discussion with the referring consultant and the PICU consultant. Occasionally it is appropriate to divert to another hospital *en route*. ◆

Systemic Analgesics in Children

David Fell

David Fell is Consultant Paediatric Anaesthetist at Leicester Royal Infirmary, Leicester, UK. He qualified in Edinburgh, and undertook training posts in anaesthesia in Edinburgh, Leicester and Canada.

Systemic analgesics are used to treat acute or procedural pain, postoperative pain and chronic painful conditions. They can be divided broadly into opioids or non-opioid analgesics (e.g. non-steroidal anti-inflammatory drugs – NSAIDs, tramadol; or paracetamol).

Opioids

Opioids are either synthetic compounds or derived from opium (opiates) and have affinity for and activity at μ, κ and δ opioid receptors.

Pharmacokinetics: opioids may be administered intravenously, intramuscularly, subcutaneously or orally. Conscious children dislike intramuscular injections and this route should be used only intraoperatively. Gastrointestinal absorption after oral administration involves hepatic first-pass metabolism, and bioavailability (e.g. morphine – 20%, codeine – 60%) determines effectiveness.

The volume of distribution of morphine at steady state is similar throughout infancy, childhood and adulthood, despite differences in body water distribution. Opioids are bound to plasma albumin and α_1-acid glycoproteins, the concentrations of which are lower in infants and neonates than in adults; thus, more free drug is available to receptors.

Metabolism takes place in the liver microsomal system, and phase I metabolism, for example, dealkylation (morphine and fentanyl), demethylation (pethidine), deacetylation (diamorphine) precedes phase II metabolism (conjugation). Morphine is conjugated to morphine 3-glucuronide and morphine 6-glucuronide. Conjugation is immature in early infancy, but sulphation can occur during the neonatal period. Glucuronidation, however, matures at about 3 months. As metabolism matures with age, the half-life of morphine decreases while total clearance increases to a maximum at 2–3 years. Renal function also matures during the first year and excretion is limited during this period until adult values are reached at 2–3 years. Smaller bolus doses and infusion rates should be prescribed in infants less than 6 months of age.

Opioids can be classified according to their duration of action (Figure 1). Initial redistribution determines the short clinical action of fentanyl; in higher doses (10 μg/kg) its terminal half-life is apparent.

Terminal half-life of commonly used opioids

Drug	Terminal (β) half-life
• Morphine	2.5 hours
• Pethidine	3.4 hours
• Diamorphine	1–4 hours
• Codeine	1–4 hours
• Methadone	25–45 hours
• Fentanyl	3–6 hours
• Alfentanil	1–3 hours
• Remifentanil	9.5 minutes

1

Side-effects and toxicity: side-effects of opioids include respiratory depression, sedation, nausea, vomiting, pruritus, urinary retention and stasis of gastrointestinal smooth muscle leading to delayed gastric emptying or intestinal paralysis and constipation.

Untreated respiratory depression has serious consequences in children. It occurs as a result of μ_2 receptor activation, is dependent on plasma concentration and occurs equally with all opioids at equianalgesic doses. Opioids shift the ventilatory response to carbon dioxide line to the right and decrease the slope of the line. Ventilatory rate is reduced, but in children the ventilatory depth also decreases, and somnolence supervenes. Naloxone, a μ receptor antagonist, can be used to reverse opioid respiratory depression and 10 μg/kg should be prescribed whenever opioid infusions or patient-controlled analgesia (PCA) are used, to be given if needed.

Nausea and vomiting are less common in children less than 2–3 years of age compared with teenagers, but the consequences (e.g. dehydration, electrolyte imbalance, delayed oral nutrition) are more severe. Postoperative nausea and vomiting (PONV) are associated with certain procedures (e.g. strabismus surgery, ENT procedures, orthopaedic, dental, penoscrotal or gastrointestinal surgery), but more especially with use of opioid analgesia which can cause vestibular stimulation as well as stimulation of the chemoreceptor trigger zone. Preventing PONV with intravenous anti-emetics at the end of surgery (e.g. with intravenous ondansetron, 100 μg/kg, or cyclizine, 1 mg/kg) is preferable to treating established PONV. Children are more susceptible to the extrapyramidal side-effects of anti-emetics than adults; therefore, anti-emetics with differing mechanisms of action should be given for any additional treatment. Combination therapy with dexamethazone may prove successful in the future. Rectal prochlorperazine, 5 mg, is also useful for treating established PONV in children.

Morphine is the most commonly used opioid in children. Dose–response curves for children are not established, but recommended doses are based on considerable experience in children (Figure 2). Preoperative use of morphine (e.g. in a child with acute abdominal pain) can relieve pain and assist diagnosis. Intravenous morphine may be administered in conscious children in increments of 20–50 μg/kg. Intraoperatively, 100–150 μg/kg i.v., provides morphine loading before postoperative use of PCA or intravenous infusions. Morphine causes histamine release

Recommended doses of opioids in children

Drug	Intravenous bolus	Intravenous infusion	Patient-controlled analgesia	Oral	Subcutaneous
• Morphine	50–150 μg/kg	10–30 μg/kg/hour	20 μg/kg bolus + 4–5 μg/kg/hour background	300 μg/kg	100–150 μg/kg
• Pethidine	1–1.5 mg/kg	–	–	–	1–1.5 mg/kg
• Diamorphine	25–50 μg/kg	12.5–25 μg/kg/hour	–	600 μg/kg	–
• Codeine	n/r[1] (1–1.5 μg/kg i.m.)	n/r	n/r	0.5–1 mg/kg	–
• Fentanyl	1–10 μg/kg	–	–	–	–
• Alfentanil	10–15 μg/kg	–	–	–	–
• Remifentanil	n/r	0.25 μg/kg/minute	–	–	–

[1] n/r – not recommended.

2

Pethidine is metabolized to norpethidine, which can cause excitation or convulsions in children. It has greater lipid solubility than morphine and a slightly shorter duration of effect. At equianalgesic doses it has a respiratory depressant effect similar to that of morphine. There are few indications for the use of pethidine instead of morphine.

Diamorphine (diacetylmorphine) has greater lipid solubility than morphine and undergoes rapid phase I metabolism in the liver to monoacetyl morphine and morphine. Diamorphine is sometimes given by intravenous infusion, 12.5–25 μg/kg/hour, to children in intensive care. Systemic use of diamorphine intraoperatively or postoperatively provides little advantage over morphine.

Codeine is a μ receptor partial agonist with a ceiling effect for analgesia. It has a high oral bioavailability (60%) and a rapid onset (20 minutes) after oral administration. A proportion of codeine is converted by the liver to morphine, and genetic variation results in absence of this action in about 10% of individuals. Intravenous use is contraindicated because of cardiac depressant effects. Codeine is a potent cough suppressant, and inhibition of gastrointestinal motility may cause constipation. In children, codeine is used during tonsillectomy (e.g. 1–1.5 mg/kg i.m.) or following neurosurgery. In combination with paracetamol it is an effective mild oral analgesic with morphine-sparing effects superior to paracetamol alone.

Fentanyl is a short-acting opioid with a potency 100 times that of morphine. It is lipid soluble, and has a rapid onset and short duration of action in low doses (e.g. 1 μg/kg). Its terminal half-life is greater than that of morphine in high doses (e.g. ≥ 10 μg/kg), and clearance is higher than in adults. Side-effects of intravenous fentanyl include bradycardia (as a result of central sympathetic depression) and chest wall muscle rigidity, which responds to neuromuscular blockade. Fentanyl may be used in children by intravenous bolus injection for analgesia for short surgical procedures, or as part of a balanced technique for major surgery where postoperative ventilation is considered.

Alfentanil is an ultra-short-acting opioid with moderate lipid solubility and a short half-life. Clearance in children is higher than in adults and volume of distribution is lower. An intravenous bolus, 10–15 μg/kg, provides analgesia for short surgical procedures (e.g. anal dilatation) without residual effect.

Remifentanil is a synthetic ultra-short-acting opioid with a unique mode of metabolism. It is a piperidine derivative with a side chain that undergoes rapid metabolism by RBCs and plasma esterases. Kinetics in infants and children are similar to those in adults. Its rapid metabolism and short half-life dictate its use by intravenous infusion intraoperatively. A loading dose is not recommended in children and the initial dose of 0.25 μg/kg/minute is lower than in adults. The infusion is then adjusted according to response. Remifentanil causes no histamine release but leads to rapid apnoea and can cause chest wall muscle rigidity. The intravenous line must be dismantled or flushed carefully when the infusion is discontinued to avoid even small residual volumes of remifentanil being inadvertently injected by subsequent infusions. Adequate 'follow on' analgesia with other opioids or regional analgesic techniques must be ensured because of its short action.

Postoperative opioid administration

Intravenous infusion – a loading dose of intravenous morphine is given intraoperatively and the intravenous delivery system maintains a therapeutic blood concentration of the drug – the so-called 'analgesic corridor'. The initial rate of infusion is set at 20 μg/kg/hour for children, but lower in infants and neonates, with a range of 10–30 μg/kg/hour (Figure 2).

The intravenous infusion should be given through a dedicated cannula. Alternatively, a non-return valve can be included in the line to prevent retrograde infusion of morphine into another infusion line.

Morphine infusions may be used in the ICU for sedation during mechanical ventilation or for children breathing spontaneously after surgery for whom PCA is inappropriate. Breakthrough pain can be treated with a bolus injection of morphine, 20 μg/kg, after suitable assessment and evaluation of the child's discomfort. Concurrent monitoring of vital signs during morphine infusions is important.

PCA has been employed successfully both postoperatively and for other acute pain control in children as young as 4 years, but a realistic target age is 5–6 years. The PCA system should be explained to the child preoperatively. The importance of only the child pressing the demand button should be stressed, but they may be encouraged to do this by parents or nurses. A loading dose of morphine should be given intraoperatively. A dedicated intravenous cannula is attached via a non-return valve to a delivery system. Figure 3 lists the essential practical components of the technique. A bolus dose of morphine, 20 μg/kg, is an optimum dose, with a lockout period of 5 minutes and a maximum 4-hourly delivery of 400 μg/kg. If morphine, 1 mg/kg, is diluted in 50 ml saline, then 1 ml contains 20 μg/kg which is used as a standard volume bolus.

In contrast to the case in adults, younger children will benefit from a background infusion rate of 20% of the bolus dose (4 μg/kg/hour).

Nurse-controlled analgesia is advocated by some, but the rate of background infusion is closer to that of a constant rate infusion (20 μg/kg/hour) and the nurse demands equate to a 'top-up' intravenous bolus.

Subcutaneous administration – bolus subcutaneous administration may be used to avoid a painful needle injection. A small-gauge (23 SWG) intravenous cannula is inserted during general anaesthesia beneath the skin of the chest, abdominal wall or deltoid area. When covered with a transparent dressing, this provides a suitable means of painless administration postoperatively. Morphine, 100–150 μg/kg, is used. Alternatively, subcutaneous infusions can be attached via a delivery tube to a syringe pump containing morphine, 1 mg/kg in 20 ml saline solution. Infusion of 0.4 ml/hour results in a dose of 20 μg/kg/hour. Subcutaneous PCA can be used with a demand bolus of 0.4 ml (20 μg/kg) of the above solution with a lockout of 5 minutes.

Requirements for safe use of intravenous morphine infusions

- Clear labelling and prescription
- Lockable syringe pump
- Infusion pump < 80 cm above patient
- Dedicated intravenous cannula
- Antisyphon or one-way valve in line
- Regular pain and side-effect monitoring
- Prescription for naloxone (10 μg/kg) available
- Patient-controlled analgesia for those over 5 years
- No intracranial pathology

Monitoring during opioid treatment: it is important to monitor pain, respiratory frequency, sedation, pulse oximetry and side-effects in patients receiving opioid analgesia. Pain evaluation (see page 138) using a system appropriate to the age of the patient should be recorded on the patient's chart along with pulse rate and arterial blood pressure. Respiratory frequency is age-dependent and, though a potentially poor indicator of respiratory depression in some age groups, is important to monitor during sleep. The thresholds for alert according to age are given in Figure 4. A simple sedation score can be charted with other 'vital signs'.

Respiratory rate and age

Age	Threshold respiratory rate (breaths/minute)
• < 6 months	20
• 6 months–2 years	16
• 2–10 years	14
• > 10 years	12

4

Non-opioid analgesics

Tramadol is a synthetic codeine derivative which is a racemic mixture. Delta tramadol has opioid μ receptor affinity and both delta and laevo tramadol inhibit monoamine uptake. The active metabolite (O-demethyl tramadol) has similar pharmacokinetics in children and adults, and a half-life of 6.4 hours. Tramadol, 2 mg/kg i.v., given intraoperatively results in less respiratory depression in children than pethidine, 1 mg/kg, and provides postoperative analgesia. It may have a role in paediatric day- case anaesthesia for minor to moderate surgery. Initial fears of intraoperative awareness in adults with tramadol have subsided with modern techniques. Tramadol should be avoided in epileptic patients because seizure activity has been reported following rapid intravenous injection.

Ketamine is an N-methyl-D-aspartate receptor antagonist which is useful in subanaesthetic doses as an analgesic. Ketamine, 0.5 mg/kg i.v., may be given intraoperatively to provide analgesia equal to that of morphine. Recovery may be slower. Anaesthetic doses can cause severe emergence phenomena that are attenuated with concomitant use of a benzodiazepine (e.g. midazolam, 0.5 mg/kg). Analgesic doses of ketamine produce fewer side-effects, but can cause catecholamine stimulation. Ketamine is useful in children undergoing burns dressings and skin grafts and intramuscular ketamine, 0.5 mg/kg, can be given during tonsillectomy.

Paracetamol is an acetanilide derivative. It is an inhibitor of cyclo-oxygenase in the CNS and has no peripheral anti-inflammatory effects. In children, oral or rectal paracetamol is widely used to control pain of mild or moderate intensity and its side-effects are minimal. An intravenous preparation, propacetamol, has been available in Europe for some time but is not available in the UK. Propacetamol is acetylparaminophenol diethyl aminoacetic ester, which is hydrolysed in vivo by esterases and converted to paracetamol. Propacetamol, 1 g, is equivalent to paracetamol, 500 mg.

Oral paracetamol is absorbed from the small intestine and results in peak blood concentrations after 30–60 minutes. Rectal absorption is slower because of a two-stage process of suppository dissolution and rectal absorption, and peak plasma concentrations are reached only after 1.5–4 hours. Paracetamol is unbound to plasma proteins and undergoes hepatic phase I n-oxidation and phase II conjugation with glucuronide, sulphate and glutathione. Sulphation is an important pathway of excretion in babies and children, indicated by lower glucoronide: sulphate ratios (Figure 5). Its half-life is 1.5–3 hours across age groups despite differences in the way it is conjugated.

The pharmacodynamics of paracetamol in children have undergone recent re-evaluation. Recommended traditional doses of paracetamol of 10–15 mg/kg are for its antipyretic effect, and associated blood concentrations are about 10–20 mg/litre. However, analgesic blood concentrations of paracetamol exceed this value, and are achieved only at higher doses. Initial loading doses are required followed by a maintenance (4-hourly) dose (Figure 6). Provided a maximum dose of 90 mg/kg/24 hours is not exceeded, toxic effects are uncommon and may not occur until 120 mg/kg/24 hours.

Paracetamol exists in palatable preparations in syrup form, and soluble paracetamol may be used in older children. Discrete suppository sizes demand an approximation of doses for rectal use. Contraindications to the use of rectal suppositories include anorectal pathology or surgery and patient preference. Preoperative paracetamol has been advocated before day-case or dental surgery. During anaesthesia, rectal paracetamol can be administered after parental and patient consent obtained preoperatively. Suppositories are best given immediately after induction of anaesthesia to allow time for absorption and for adequate therapeutic blood concentrations to be present on waking. Postoperative oral paracetamol can be given after return of gastrointestinal function, or rectal doses can be continued.

Paracetamol conjugation – glucuronide:sulphate ratios

Age	Glucuronide:sulphate
Neonate	0.34
3–9 years	0.75
12 years to adult	1.6–1.8

5

Paracetamol doses for analgesia

	Oral (mg/kg)	Rectal (mg/kg)
Loading dose	20	30–40
Maintenance dose (4-hourly)	15	20
Maximum dose in 24 hours	90	90

NSAIDs

NSAIDs are chemical derivatives of acetic acid, propionic acid, anthranilic acid or oxicams with anti-inflammatory, antipyretic and analgesic properties. NSAIDs are often used in inflammatory arthritis, and only a few (ibuprofen, mefanamic acid, diclofenac, piroxicam) have dose recommendations for children. However, some drugs have been used to control acute postoperative pain in children and can significantly decrease postoperative opioid requirements.

NSAIDs reversibly block the action of cyclo-oxygenase on arachidonic acid released at injured cell membranes and inhibit peripheral prostaglandin production. This mechanism also accounts for the side-effects of NSAIDs (i.e. exacerbation of asthma, peptic ulceration, renal impairment, platelet function inhibition). There are few side-effects in children when NSAIDs are used for acute pain relief, but short-acting NSAIDs (flurbiprofen, diclofenac, ibuprofen) are preferred to medium-acting or long-acting drugs. Contraindications include renal immaturity (e.g. in infants), actively treated asthma and coagulation defects.

Absorption from the gastrointestinal tract is rapid because NSAIDs are weak acids. Rectal administration results in comparable, but delayed, plasma concentrations. There is little first-pass metabolism, and oral bioavailability is high (55–80%). NSAIDs are bound to plasma proteins and have a low volume of distribution; they undergo hepatic metabolism and conjugation. Pharmacokinetics of NSAIDs used for juvenile rheumatoid arthritis indicate no differences from those of adults. NSAIDs are 'opioid-sparing', and reduce morphine requirements after major surgery.

Diclofenac is short acting (terminal half-life about 1 hour). It may be given orally or rectally using an acute dosing regimen of 1–2 mg/kg 8-hourly. Acute postoperative pain (e.g. after day- case herniotomy, orchidopexy or minor surgical procedures) can be anticipated by rectal administration intraoperatively after obtaining appropriate parental and patient consent. After tonsillectomy, diclofenac may be associated with bleeding, but is probably safe in a single dose.

Ibuprofen has weak anti-inflammatory properties, low potency, and fewer side-effects than other NSAIDs. It has a short half-life (1–4 hours). As a sole analgesic after surgery, its potency is insufficient, but it is useful for mild postoperative pain and after opioid requirements have declined following major surgery. Regular oral doses (4–6 mg/kg) of up to 40 mg/kg/24 hours may be used.

Ketorolac has a higher clearance in children than in adults but a larger volume of distribution resulting in a similar half-life (about 6 hours). It may be used intraoperatively at a dose of 0.5 mg/kg i.v. (maximum 10 mg) to augment opioid analgesia or during minor surgery in children. After tonsillectomy, early blood loss can be significant in children given ketorolac.

Piroxicam is a long-acting NSAID with a half-life more than 30 hours. Its merit in children is that it is recommended for use in juvenile rheumatoid arthritis at a dose of 0.3–0.6 mg/kg, and it is available in a lingual melt preparation. It has been used for analgesia in dental surgery.

Anatomical and Physiological Development: from the Fetus through Childhood

Lynley Marshall
Andrew R Wolf

Lynley Marshall is Specialist Registrar in Paediatrics in the South West of England. She completed her undergraduate and early paediatric training at the University of Witwatersrand, South Africa, working at the Baragwanath and Johannesburg Hospitals.

Andrew R Wolf is Consultant Paediatric Cardiac Anaesthetist and Intensive Care Physician at Bristol Children's Hospital. He qualified from Cambridge University and St Thomas' Hospital, London. His research interests are understanding stress and inflammatory responses in infants undergoing cardiac and non-cardiac surgery.

As the future human being develops from a single cell into the mature adult the physiology of each individual organ and the integrated systems of the body undergo many developmental changes. Although performance in the early stages may seem crude, fragile and poorly controlled, this usually reflects a stage needed to cope with the challenges of the current environment. For example, the presence of fetal haemoglobin *in utero* allows oxygen to be extracted from the placenta in a very low oxygen environment compared with that after birth. In considering developmental physiology (ontogeny) it is necessary to see fetus, preterm newborn, neonate, infant, child and adolescent as almost separate organisms that merge into each other, but with sometimes very different physiology. Moreover, different systems mature at different rates.

Birth is a stressful event but it is this stress that acts as a stimulus for initiating extrauterine physiological changes and sustaining essential functions in the newborn, such as respiration, suckling, glucose metabolism and thermoregulation. The physical stress of delivery (vaginal squeeze), loss of the nourishing placenta, and the accompanying hormonal stress response are jointly responsible for these physiological adaptations.

Cardiovascular system

Changes in the circulation at birth

During fetal life the placenta is the primary organ of oxygenation. Pulmonary vascular resistance is high and less than 10% of cardiac output passes through the lungs. The two ventricles are effectively in parallel, with the dominant right ventricle pumping about two-thirds of the combined ventricular output via the pulmonary artery, through the ductus arteriosus and into the aorta. In addition, relatively oxygenated blood from the placenta (saturation 65%) passes preferentially through the foramen ovale, left atrium and left ventricle to supply the heart, brain and upper body. Venous blood from the superior vena cava passes through the right ventricle and ductus arteriosus, supplying the lower body with blood of reduced saturation (55%). The ductus venosus shunts blood from the umbilical vein to the inferior vena cava, thus bypassing the liver and preventing desaturation of blood by the liver. This series of shunts (the ductus venosus, foramen ovale and ductus arteriosus) act to protect the brain and heart by allowing optimal oxygenation, with locally produced prostaglandin E_2 (PGE_2) maintaining patency of the ductus arteriosus.

At birth, with onset of spontaneous ventilation and loss of the placenta, the circulation changes dramatically. With the first breath, pulmonary vascular resistance falls rapidly, allowing blood to flow from the right ventricle through the lungs. As placental blood flow ceases with clamping of the umbilical cord, systemic vascular resistance rises, resulting in a reversal of right to left blood flow through the ductus arteriosus. Exposure to oxygenated blood and reduced PGE_2 production stimulates ductal constriction, with functional closure by 24 hours (a shunt murmur may be audible before closure). Histological obliteration occurs by 3 weeks in most normal term infants. Preterm babies have a higher incidence of patent ductus arteriosus, and may require medical treatment with a prostaglandin synthetase inhibitor such as indometacin (indomethacin), a cyclooxygenase inhibitor such as ibuprofen, or surgical ligation.

After the first breath, pulmonary venous blood returns to the left atrium, causing pressure in the left atrium to exceed that in the right. The valve-like foramen ovale closes, thus preventing deoxygenated blood from the right atrium crossing to the left. The ductus venosus closes passively owing to absent blood flow.

Persistent pulmonary hypertension of the newborn: although pulmonary vascular resistance is much reduced after birth, the pulmonary arteriole medial walls are muscular. If the neonate becomes hypoxic or acidotic, pulmonary vasoconstriction can lead to significant shunting through the foramen ovale and reversion to a fetal-type circulation. This condition is called persistent pulmonary hypertension of the newborn. Oxygen, hyperventilation or nitric oxide may be needed to reverse the condition, and extracorporeal membrane oxygenation has been used successfully in severe cases.

The heart as a pump

The newborn heart consists of cardiac myofibrils that are poorly organized and lack the structured architecture of the mature heart. The increased ratio of connective tissue to contractile tissue compared with adults results in limitation in myocyte contractility and ventricular compliance. In addition, calcium metabolism is immature in neonatal myocytes. Consequently, there is a relatively flat Starling curve, and while inadequate preload is poorly tolerated, overloading results in early cardiac failure. The stroke volume is relatively fixed and increases in cardiac output are achieved largely by increases in heart rate (cardiac output = heart rate x stroke volume). Conversely, bradycardias secondary to hypoxia, acidosis or cold adversely affect cardiac output. Normal heart rate at birth lies in the range 100–170 beats/minute, decreases with age, and reaches adult values by puberty (Figure 1).

Both ventricles weigh the same at birth, though the right ventricle is dominant in fetal life, possessing a thicker wall at delivery. The left ventricle enlarges rapidly after birth, and by 6 months the relative sizes of the ventricles are similar to adults. This change is demonstrated by the ECG, which shows right axis deviation at birth (up to +180°) changing to +90° by 6 months.

Normal values in childhood

Age	Blood pressure Systolic (mm Hg)	Blood pressure Diastolic (mm Hg)	Heart rate (beats/minute)
Preterm or 750 g[1]	45	25	>120
Birth	60	35	>120
Neonate	70–80	40–50	120–150
3–6 months	80–90	50–60	120–140
1 year	90–100	60–80	110–130
5 years	95–100	50–80	90–100
12 years	110–120	60–70	80–100

[1]A good rule of thumb for preterm infants is that mean arterial blood pressure is less than or equal to gestational age in weeks.

Cardiac rhythm

Oxygen rather than atropine should be the anaesthetist's first response to bradycardia; indeed giving atropine before intubation in infants may mask bradycardias occurring as a warning sign of hypoxia.

Supraventricular tachycardia is the next most likely arrhythmia, and usually responds to vagal manoeuvres or first-line pharmacol-ogical intervention with adenosine.

Circulating blood volume

The average neonatal circulating volume is 80–85 ml/kg, falling to 75 ml/kg between the ages of 6 weeks and 2 years, and about 72 ml/kg thereafter. Infants tolerate fluid overload poorly because they are unable to redistribute or excrete extra volume. They also cope badly with sudden or massive fluid loss, such as diarrhoea and vomiting. Sinus tachycardia of 200 beats/minute or more can occur in dehydrated or septic infants. Low blood pressure is a late sign of cardiovascular compromise in young children.

Respiratory system

Airway anatomy

Infants have relatively large heads and short necks, and hyperextension compromises rather than assists visualization of airway structures during intubation. As the tongue is large and the mouth small, the insertion of an oropharyngeal airway may reduce pharyngeal obstruction in infants under 6 months of age. Infants are obligate nose breathers with narrow nasal passages, therefore any increase in secretions or airway oedema significantly compromises airflow. Resistance is proportional to 1/radius to the power of 4; according to the Hagen–Poiseuille law. Children and infants are also more prone to laryngospasm than adults.

Tonsils and adenoids, especially when inflamed, may impinge on airway patency and in severe cases cause sleep apnoea and pulmonary hypertension.

The trachea is short in infants and children (average length in a term neonate is 4 cm), and care must be taken to avoid inadvertent endobronchial intubation. A long tube intermittently stimulating the carina causes vagal effects (e.g. bradycardia), which may be marked in neonates. The main differences in airway anatomy at different ages are given in Figure 2. Appropriate endotracheal tube lengths are given in Figure 3.

Airway anatomy

	< 1 year	1–8 years	> 8 years
Upper airway	Narrow nasal passages Relatively large tongue	Tonsillar and adenoidal hypertrophy	More adult type features
Larynx	Anterior position C3–4 level	More posterior position C4–5 level	Posterior position C4–5 level
Epiglottis	Narrow, U-shape Long and thin Angled posteriorly	Wider and flattened Shorter Angled horizontally	More adult type features
Trachea	Average diameter 5 mm Narrowest point: cricoid (hence uncuffed endotracheal tube)	Average diameter 10 mm Narrowest point: cricoid (hence uncuffed endotracheal tube)	Average diameter 15 mm Narrowest point: vocal cords (hence uncuffed endotracheal tube)
Bronchioles	Average diameter 0.1 mm	Average diameter 0.15 mm	Average diameter 0.2 mm
Alveoli	Average diameter 0.075 mm	Average diameter 0.15 mm	Average diameter 0.3 mm

Recommendations for endotracheal tube length and diameter (> 1 year olds)

The Advanced Paediatric Life Support (APLS) formulae

Internal diameter (mm) = Age/4 + 4

Oral tube length (cm) = Age/2 + 12

Nasal tube length (cm) = Age/2 + 15

Lung development and the first breath

In utero the fetal lung is filled with fluid essential for lung maturation and development. The fetus makes irregular breathing movements which help the development of respiratory muscles, including the diaphragm and intercostal muscles.

As full term approaches, catecholamines and triiodothyronine (T3) stimulate the reabsorption of pulmonary fluid by reversing the chloride pump. Final reabsorption is stimulated by passage through the birth canal. This is less effective in babies born by caesarean section, often leading to transient tachypnoea of the newborn. Invasive ventilatory support is seldom required when this exists in isolation.

When newborns enter the world, somewhat hypoxic and hypercarbic, they are greeted by a barrage of sensory stimuli, resulting in the first breath, and usually followed by lusty crying. The first breath generates a negative pressure of about 50 cm H_2O, drawing in about 80 ml of air and expanding the functional residual capacity. Failure to do this efficiently results in ventilation–perfusion mismatch. The first breath initiates pulmonary vasodilatation, coinciding with the increase in systemic vascular resistance.

The bronchial tree is fully developed at birth, in contrast to the alveoli, which continue to expand in size and number, increasing the surface area of the lung up to 25 times. This partially explains why the respiratory function of infants who had severe lung damage as neonates may improve significantly with age, though some residual damage usually persists.

Surfactant: endogenous surfactant is a protein-bound phospholipid molecule produced by the endoplasmic reticulum of type 2 pneumocytes from about 26 weeks' gestation, although in inadequate amounts until 32–34 weeks' gestation. Secretion is stimulated by endogenous cortisol, β-adrenergic drugs (via the cAMP pathway), thyroid hormone, prolactin and *ex utero* by gas inhalation and alveolar distension. Surfactant acts to reduce surface tension at the air–fluid interface, thus reducing opening pressures and maintaining alveolar distension.

Extreme preterm infants are surfactant deficient, leading to the respiratory distress syndrome and often the need for ventilatory support. Studies have shown that elective intubation at birth with administration of surfactant by the endotracheal route in the first hour produces better respiratory outcomes than attempted reversal of respiratory distress syndrome once it has developed. Thus, a prophylactic dose of 4 ml/kg via the endotracheal tube should be considered in all babies born at less than 30 weeks' gestation or preterm babies under 1.5 kg.

Improvement in lung compliance following surfactant is rapid and vigilance is essential to prevent severe over ventilation and air leaks. A further dose of surfactant may be given after 6 hours if the infant's fraction of oxygen in inspired air remains above 30%, but further doses are seldom required.

Term babies may also be surfactant deficient if they suffer severe acidosis or hypoxia and secondary surfactant deficiency may occur in babies with Group B streptococcal pneumonia or meconium aspiration syndrome. Infants of diabetic mothers are vulnerable to the condition because insulin delays type 2 pneumocyte maturation and prostaglandin production, Hyperglycaemia similarly delays lung development.

The use of maternal antenatal steroids has helped to prevent respiratory distress syndrome. Two doses of intramuscular betamethasone or dexamethasone given 12 hours apart before delivery significantly reduce the likelihood of severe respiratory distress in the newborn.

Mechanics of breathing
Babies, especially preterm neonates, have extremely compliant chest walls with compressible, horizontally aligned ribs. The diaphragm is the main respiratory muscle in infancy, leading to subcostal (and intercostal) recession during periods of respiratory distress. As the infant grows in the first year of life, the percentage of type 1, slow-twitch muscle fibres that fatigue more slowly, increases from 10% to 25% (adult level). The fairly protuberant abdomen of the small child can also affect respiration by impinging on lung volumes.

Static lung volumes in infants are proportionately similar to those of adults, though alveolar ventilation is larger and closing volume is higher. During mechanical ventilation, infants require higher volumes by weight; up to 150 ml/kg/minute in neonates compared with 60 ml/kg/minute in adults. Although infants may require similar pressures to adults, they require higher rates of ventilation, mimicking normal physiology (Figure 4).

Respiratory physiology

	Neonate	Adolescent
Respiratory rate (breaths/min)	25–40	12–18
Airway compliance (ml/cm H_2O)	5	100
Airway resistance (cm H_2O/litre/sec)	30	2
Vital capacity (ml/kg)	30–35	50–55
Minute ventilation (ml/kg)	200	100
Tidal volume (ml/kg)	5–7	7–10
Alveolar ventilation ml/kg/min)	130	60
Metabolic rate (ml O_2/kg/min)	6.5	3.5
PaO_2		
(kPa)	9	12.5
(mm Hg)	68	95
$PaCO_2$ (kPa)	4.5	5.3

Control of breathing
Newborns are sensitive to changes in the partial pressure of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) in arterial blood, though many other factors such as gestational and postnatal age, temperature, wake–sleep cycles and drugs all affect their responses and respiratory drive is easily lost. Preterm newborns are less responsive to increased inspired carbon dioxide than healthy term infants. Neonates react to hypoxia in a different way from older infants. In the first week of life, in well, awake babies, hypoxia produces brief hyperpnoea followed by centrally mediated respiratory depression and reduced minute volume. In the following weeks, as chemoreceptors mature, the infant develops a predominantly hyperpnoeic response to hypoxia, with apnoea and bradycardia being more ominous signs. Hypothermic babies show respiratory depression without an initial hyperpnoea response. In sleeping infants, the arousal response to hypoxia (normal in adults) is diminished, and often completely absent during rapid-eye movement (REM) sleep. Intercostal muscle activity is inhibited during REM sleep, as are the lung and chest wall reflexes responsible for determining respiratory rate and tidal volumes.

Periodic respiration, in which rapid shallow breathing alternates with apnoeas of up to 10 seconds, is normal in many infants. More prolonged apnoeas, lasting more than 20 seconds, may be associated with bradycardia and require stimulation or even bag-and-mask ventilation. In preterm babies, apnoeas usually respond to oral xanthines (e.g. caffeine, theophylline), though occasionally continuous positive airway pressure is needed until central chemoreceptors mature. Apnoeas may also have non-respiratory causes such as gastro-oesophageal reflux, seizures, sepsis or intracranial haemorrhage.

Fluid homeostasis

Body fluid composition changes with age, gender and amount of adipose tissue. Neonates have a higher percentage of total body water than older children, with a relatively higher extracellular to intracellular fluid ratio. This makes them particularly sensitive to fluid loss and dehydration. Fluid output depends on metabolic rate, urine, stool and insensible losses. These are high in small infants, particularly when under radiant warmers or phototherapy lights.

Normal fluid shifts occur in the first few days of life. Up to 5% of body weight shifts from the extracellular to the intracellular compartment, with excess fluid being excreted. This results in loss of up to 10% of birth weight in the first week, usually regained by day 10. Careful attention to fluid replacement is essential in infants and small children, particularly when starved perioperatively. The APLS formula for intravenous maintenance fluid calculations is:

- 4 ml/kg/hour for the first 10 kg of body weight
- + 2 ml/kg/hour for the second 10 kg of body weight
- + 1 ml/kg/hour for each subsequent kg of body weight.

Preterm babies need extra fluid because of their high surface area to body weight ratio; often more than 200 ml/kg/24 hours.

Renal function

The first nephrons form in the embryo during week 5 and are functional from week 8, reaching their full complement by week 36. After this there are no new nephrons; the existing nephrons grow in size and cell number.

Renal blood flow comprises 5% of cardiac output at birth, but as renal vascular resistance falls with time, this increases to 20% by 1 month of age, with increased flow to cortical areas. The glomerular filtration rate (GFR) escalates logarithmically in the first 2 years of life. Nonetheless, infants remain ill-equipped to handle massive water loads, and common neonatal problems such as hypoxia, hypothermia and low-output states may all compromise GFR. Because of this renal immaturity, levels of renally excreted drugs (e.g. aminoglycosides) should be measured regularly and doses adjusted accordingly.

In the mature kidney, water is reabsorbed in the proximal convoluted tubule with glucose, amino acids, phosphate, sodium and bicarbonate. Water is also absorbed more distally under the influence of antidiuretic hormone (ADH), with sodium reabsorbed under the influence of aldosterone in exchange for excreted potassium and hydrogen ions. Infants have immature renal tubular systems with a relative inability to handle solute loads, notably sodium and glucose. They have difficulty excreting sodium in the first week of life, and trouble reabsorbing it thereafter. Preterm neonates tend towards hypernatraemia, often reflecting fluid deficit and increased fluid requirement. After the first month of life, the reference ranges for sodium (135–145 mmol/litre) and potassium (3.5–5.5 mmol/litre) for different age groups vary little.

Preterm infants are unable to effectively excrete hydrogen ions or retain bicarbonate as compensation for acidosis; indeed bicarbonate levels remain lower on average in those under 5 years compared with older individuals (18–25 compared with 23–26 mmol/litre).

Phosphate levels are high in those less than 1 year old, with the highest levels in preterm infants (up to 2.65 mmol/litre). This is optimal for bone growth and prevention of metabolic bone disease; this level drops to about 1.5 mmol/litre by adolescence.

Calcium homeostatic mechanisms are sluggish in preterm infants. Calcium levels must be adjusted for albumin level and temperature and pH should also be considered when interpreting calcium levels.

Measures of renal function on the first day of life reflect maternal values, with more accurate results obtained from day 2 onwards. Urea levels change with age from 0.7–6.7 mmol/litre in term and preterm newborns, 1.8–8.2 in those aged 1–52 weeks, 2.1–6.4 in those 1–13 years to 2.9–7.5 in those over 13 years. Creatinine levels in preterm infants are 100 μmol/litre on day 2, 80 on day 7, and 50 on day 28. In term infants they are 70 on day 2, 45 on day 7, and 30 on day 28. They are 50 μmol/litre until 1 year of age. In those aged 1–9 years they are 35 and 75 in those over 9 years.

Hepatic function and metabolism

During intrauterine life, the fetus receives glucose via the placenta for growth, deposition of stores and maintenance of basal metabolic rate. Fetal glucose regulation is independent of maternal hormonal control and in the case of placental insufficiency endogenous fetal glucose production occurs. The fetus also utilizes ketone bodies and lactate.

At birth, following placental separation, the infant must find alternative energy sources. Aerobic metabolism is rapidly replaced by anaerobic metabolism. Fat from adipose tissue stores and from feeds becomes the key substrate. Plasma insulin levels drop while catecholamine and glucagon levels rise rapidly stimulating glycogenolysis (in heart muscle, liver and brain), gluconeogenesis (in liver from alternative energy sources such as ketones, fatty acids and lactate), lipolysis and ketogenesis.

In the immediate postnatal period, glucose remains the main metabolic substrate for most organs, except for the brain which may prefer lactate. Later in the neonatal period, ketones are preferred to glucose for cerebral metabolism. The neonatal brain uses ketones more efficiently than older brains do.

If establishment of enteral feeding is slow, hypoglycaemia may occur. Neonates may be asymptomatic at blood glucose levels below 2.5 mmol/litre, or they may appear jittery, lethargic, sweaty, or apparently 'septic'. Changes in auditory evoked potentials on EEG are demonstrable at blood glucose levels of 2.5 mmol/litre and less.

Prolonged hypoglycaemia must be avoided, by cup feeds or intravenous dextrose if necessary. An initial intravenous bolus of 10% dextrose, 5 ml/kg, should be given over 1–2 minutes, checking the blood glucose response soon after. If a dextrose infusion is required to maintain the blood glucose above 2.5 mmol/litre, 10% dextrose at the physiological rate of 3 ml/kg/hour (i.e. 5 mg/kg/minute) is given. The use of 50% dextrose in not recommended because rebound hypoglycaemia may occur and sudden osmotic fluid shifts in the brain predispose to cerebral oedema.

Infants at risk of hypoglycaemia include preterm infants, small (2.5 kg) or large (over 4 kg) babies, infants with intra-uterine growth retardation caused by lack of subcutaneous fat and muscle wasting, infants of diabetic mothers and cold or asphyxiated babies. Septic babies may demonstrate hypoglycaemia, but hyperglycaemia may also be an early warning sign of sepsis in ill preterm neonates.

Older children may also be prone to hypoglycaemia when unwell. Any child with acute neurological symptoms should have their blood glucose level checked urgently, with 10% dextrose, 5 ml/kg i.v., given as a bolus if levels are below 3.5 mmol/litre.
Few normal children have very low blood sugars even when extremely unwell. Inherited metabolic disorders may be unmasked by illness and are worth considering especially if hypoglycaemia is associated with a metabolic acidosis.

Feeding
Breast milk is the feed of choice for the first 4–6 months of life because it has immunological benefits and is more easily handled by the immature gut. Newborns have enzymes for the breakdown of carbohydrates such as sucrase, lactase, maltase and isomaltase, but amylase and proteases develop after 3 months of age, reaching adult levels by 2 years. Introducing solids too early is poorly tolerated, often causing diarrhoea.

Bilirubin
During intrauterine life, the fetus excretes fat-soluble unconjugated bilirubin via the placenta and maternal liver. There is a physiological rise in bilirubin soon after birth, owing to an increased bilirubin load and immaturity of the hepatic enzymes. The peak occurs on days 3–4, owing to immature oxidation–reduction reactions (phase I), with levels dropping in the second week of life as conjugating enzymes needed for glucuronidation mature (phase II). This drop takes longer in preterm babies. Lower treatment thresholds for phototherapy are used in preterms, because the blood–brain barrier is less developed and the risk of kernicterus or bilirubin encephal-opathy (damage to basal ganglia, auditory and occulomotor pathways) is higher than in term infants at similar bilirubin levels. Phototherapy works by detoxifying bilirubin and promoting its excretion by non-conjugatory means (e.g. urinary excretion).

Factors that may exacerbate physiological jaundice include polycythaemia or haemorrhage (due to increased red cell breakdown and turnover), hypoalbuminaemia (reduced protein binding), dehydration and breast feeding.

Drug excretion
Infants handle hepatically excreted drugs differently from older children and adults because of immature enzyme systems and the difference in blood supply to the liver. Infants receive a higher proportion of their hepatic blood supply from the portal vein than from the hepatic artery. Any increase in intra-abdominal pressure (e.g. post-abdominal surgery) reduces clearance of hepatically excreted drugs such as morphine or fentanyl.

Thermoregulation
Infants lose heat more readily than older children or adults because of their higher surface area to body weight ratio and relative paucity of subcutaneous fat. Heat loss occurs by evaporation, radiation, convection and to a lesser extent, conduction, as well as by insensible losses (e.g. through respiration). Newborns should be nursed in a thermoneutral environment, at an ambient temperature that minimizes oxygen consumption and heat loss. Preterm infants in the first week of life have particularly thin skin and high evaporative losses of heat energy and water (skin matures as a function of post-natal age). They therefore require higher ambient temperatures and humidity.

Unlike older children and adults who generate heat involuntarily by shivering, newborns rely on non-shivering thermogenesis to increase their basal metabolic rate. This is a function of their unique brown fat, present in the first few weeks of life as an adaptive, protective entity. These specialized adipose cells are situated around the kidneys and adrenals, in the mediastinum and around the scapulae. They are abundant in mitochondria and have a rich blood and autonomic nerve supply. Noradrenaline in sympathetic nerve endings stimulates the hydrolysis of triglycerides to fatty acids and glycerol, resulting in oxygen consumption and heat production. The resting metabolic rate is high in newborns, reaching a maximum of 50 kcal/m^2/hour by 3–6 months, then levelling off.

CNS
The newborn brain is immature, and though most responses are reflex or instinctive, it is extremely sensitive to hypoxia, hypercarbia and metabolic derangements, especially hypoglycaemia. Any such insult may cause jitteriness, seizures, acute collapse or chronic neurological deficit. Neonates have relatively impaired cerebral autoregulation of blood flow, and sudden fluctuations in blood flow can be extremely harmful. Preterms, in particular, have friable blood vessels in the germinal matrix and periventricular area, with intraventricular haemorrhage occurring easily. Obsessive attention to PaO_2 and $PaCO_2$ is essential in ventilated babies because hypocarbia, hypercarbia and hypoxia are all detrimental to newborn brains. Paradoxically, despite this ‘fragility’, infant brains are more plastic than those of older children or adults, and if an injury is moderately severe but not devastating, recovery may be better than expected, with different parts of the brain apparently taking over the functions of damaged areas.

Pain pathways
Nociceptive pathways and their neurophysiological responses are present even in extremely preterm infants. At 6 weeks’ gestation the dorsal horn cells in the spinal cord are forming synapses in the developing sensory neurons. These grow peripherally, reaching the skin of the limbs by 11 weeks, the trunk by 15 weeks and the remaining skin and mucosal surfaces by 20 weeks. The term neonate has at least as many peripheral nerve endings as an adult. Specific neurotransmitter vesicles are developing by 13 weeks, with completion by 30 weeks.

From week 24 the neurons start to mature biochemically, with production of glial-specific proteins and enzymes. Gyral formation and dendritic growth in the cerebral cortex begin at week 28. The newborn brain weighs about 350 g, increasing in size dramatically over the first 4 years of life to about 1000 g. This is largely due to the processes of myelination and dendrite formation, which is most rapid in the first 6 months of life.

The nerve tracts for nociception are fully myelinated to thalamic level by 30 weeks, with myelination of the thalamocortical tracts by 37 weeks. This lack of myelination does not imply lack of function; indeed the lack of inhibitory pathways increases rather than decreases afferent nociceptor transmission in the spinal cord. In other words, neonates may display hypersensitive responses to unpleasant stimuli because they lack the maturity in their inhibitory pathways needed to dampen down the response.

Auditory and visual evoked responses, though immature, are present by 28 weeks, and positron emission tomography scans have shown that increased glucose uptake, and thus increased cerebral metabolism, is highest in sensory areas of the fetal brain.

These factors lead to the conclusion that even extreme preterms experience pain and discomfort, though interpreting its expression may be difficult for the observer. Noxious stimuli such as heel pricks, generally produce physiological changes in variables such as heart rate and blood pressure and alter facial expression and behaviour. These changes may be of assistance in scoring the severity of neonatal pain and discomfort, as changes can be objectively measured when local anaesthetic or other analgesic measures are used. There is evidence that newborns may develop hypersensitivity and hyperalgesia to repetitive painful stimuli. Fitzgerald suggested that infants born at 26 weeks' gestation show a flexion withdrawal response to painful stimuli and although they are not cortically equipped to experience the unpleasant emotional aspect of pain, it is likely that this same sensitivity is true of a 26 week fetus *in utero*. Inadequate analgesia in newborns may cause long-term behavioural effects. It has been shown that circumcised infants display exaggerated pain responses months later following vaccination. These responses could be attenuated by the use of local anaesthetic agents, suggesting the existence of a pain memory even in very young infants.

Use of appropriate sedation and analgesia in infants, especially neonates, requires careful planning and consideration. In neonates, the pharmacodynamic susceptibility to opioids increases with decreasing gestational age, with changes in the number and type of opioid receptors. It is difficult, however, to separate true receptor-based or effector-based sensitivity from the effects due to selective distribution to the brain following administration.

Influence of age on the delivery of drugs to the brain
Lipid-soluble drugs (e.g. fentanyl) are redistributed rapidly out of the central compartment at a rate depending on cardiac output, regional blood flow, presence of shunts, protein binding, sequestration within peripheral tissues and membrane permeability of the drug. The neonatal brain receives a much higher proportion of cardiac output than does the adult brain. As a result, lipid-soluble drugs enter the CNS rapidly, reaching effectively high peak levels at effector sites (biophase). Offset is much slower than in adults because of slow peripheral uptake. (The brain forms 50% of the vessel-rich group in neonates, compared with only 25% in adults, resulting in drugs remaining in the CNS for longer.) This, together with immature elimination systems, leads to an overall increased drug half-life. The elimination half-life of fentanyl may thus be extended to 15 hours in neonates, as opposed to the normal 3–4 hours in adults. This should be remembered when using fentanyl in ventilated newborns close to the time of planned extubation, because failure to wean sedation sufficiently early may lead to delayed or failed extubation, with its associated increased morbidity. Delivery of morphine into the biophase may also be enhanced in newborns and young infants compared with older individuals owing to immaturity of the blood–brain barrier.
As a water-soluble drug, however, onset is still slower than fentanyl, making it a less appropriate drug to use for neonatal intubation.

Fentanyl is most useful peri-intubation for rapid ablation of the stress response and intense analgesia at the time of surgery, or for treatment and prevention of pulmonary hypertension during induction of anaesthesia. Morphine is more appropriate as an infusion drug postoperatively, particularly in ventilated patients, however, tolerance develops rapidly in neonates.

Hormonal changes
Noradrenaline (released from sympathetic nerve terminals) and adrenaline (produced by the adrenal medulla) are elevated in the first week of life. Together with cortisol (from the adrenal cortex), they regulate the perinatal adaptation of major systems, including changes in the cardiovascular system and circulation, structural lung maturation and surfactant production by type 2 pneumocytes, smooth muscle activity (and thereby pulmonary and systemic vascular resistance), energy production and temperature control. A sharp rise in thyrotropin-stimulating hormone (TSH), T3 and thyroxine (T4) just before delivery assists in respiratory control, regulation of metabolic rate and development of β-adrenergic receptors in the myocardium, thus improving contractility of maturing myocytes. Preterm infants have lower levels of cortisol, adrenaline and noradrenaline in cord blood compared with term infants, though baseline levels in unstressed babies, irrespective of gestation are similar. This implies an inability of preterm infants to cope with stressors such as hypoxia, acidosis or the birth process itself.

Haematology

Erythropoiesis
Early erythropoiesis in fetal life begins in the yolk sac during the first few weeks following conception. From the fifth week of gestation the liver is the predominant site of erythropoiesis, though minimal red cell production occurs in the bone marrow from week 9. Shortly before birth, the erythroid cells enter the bone marrow, and erythropoiesis continues there.

Haemoglobin
Newborn blood volume is about 80 ml/kg (and up to 20% higher in preterms). Neonates are relatively polycythaemic with a normal haemoglobin of 18–19 g/dl and haematocrit of 0.6 at term, depending on the timing of cord clamping.

At birth, 70–90% of haemoglobin is fetal haemoglobin (HbF). This has a much higher affinity for oxygen than adult haemoglobin (HbA), and it therefore carries more oxygen but releases it to the tissues less readily (see Figure 1, page 70). Polycythaemia improves oxygen delivery up to a point, although haematocrits greater than 0.65–0.7 increase the risk of hyperviscosity and associated sludging with microthrombi formation and organ hypoperfusion.

As HbF is gradually replaced by HbA by 3–6 months of age, the haemoglobin drops to about 8–9 g/dl. This drop occurs more quickly and to lower levels in preterms. These are normal values in this age group and though ‘top-up’ blood transfusions or prophylactic erythropoietin may be needed in sick, ventilated or oxygen-dependent infants, this is not the case in well babies even before surgery. This physiological anaemia makes preterm infants prone to postoperative apnoea and they are more likely to require positive pressure or ventilatory support after surgery.

The most common haemoglobinopathies are sickle cell disease and β-thalassaemia major; both disorders of b-chains and consequently appearing after 3–6 months of age as HbF levels fall and HbA levels rise.

Coagulation
The coagulation system in newborns differs from that in older children and adults. Haemorrhage occurs more often than thrombosis and most disorders are acquired rather than hereditary. Preterm or ill infants are more prone to coagulopathies than healthy term babies and often develop disseminated intravascular coagulopathy in response to hypoxia or sepsis. Thrombocytopenia is common in the first week of life, but recovery is usually spontaneous.

Haemorrhagic disease of the newborn is unique to the newborn and is caused largely by deficiency of vitamin K dependent clotting factors. Vitamin K crosses the placenta poorly, and neonates have immature livers that absorb fat, and therefore fat-soluble vitamins, poorly. Breast-fed infants are at higher risk because formula milks are supplemented with Vitamin K.

The condition manifests as early (in the first 48 hours), classic (days 2–6) or late (up to 6 months of age) haemorrhagic disease, with gastrointestinal bleeding, oozing from the umbilical stump and mucosal surfaces or severe bleeding into the CNS. Treatment is with fresh frozen plasma, intravenous vitamin K and blood transfusion as required. Prophylaxis is by administration of vitamin K soon after delivery, either intramuscularly (1 mg for those over 2 kg; 0.5 mg for those under 2 kg) or orally. If a breast-fed baby receives oral Vitamin K, further doses are recommended on days 3 and 7 of life, and then monthly until 3 months of age. An alternative oral regimen would be 2 mg on days 1, 10 and 28 of life. ◆

Age-related Pharmacology

George H Meakin

George H Meakin is Senior Lecturer in Paediatric Anaesthesia at the University of Manchester and Honorary Consultant Anaesthetist at Royal Manchester Children's Hospital. He qualified in medicine from Manchester University and trained in anaesthesia in Plymouth before undertaking specialist paediatric anaesthesia training in Montreal, Canada. His research interests include the clinical pharmacology of muscle relaxants and anaesthetic drugs in infants and children.

Children differ from adults in the way they respond to drugs. These differences became apparent during the 1950s following a number of therapeutic disasters such as an increase in kernicterus among newborns treated with sulphonamides and fatal cardiovascular collapse in infants treated with chloramphenicol. Research into these conditions revealed that the responses of babies and children to drugs are determined by a large number of factors that change rapidly and independently during development. This article relates those factors to the developmental pharmacology of commonly used anaesthetic drugs.

Factors affecting responses in babies and children

Pharmacokinetic factors affect absorption, distribution and elimination.

Cardiac output per kg is higher in babies and children than in adults. This means faster circulation times, therefore drugs are distributed to and from their site of action more rapidly.

Plasma protein binding limits the amount of free drug available to interact with tissue receptors. In the neonate, the concentrations of plasma proteins (e.g. α_1-acid glycoprotein) are decreased and their affinity for drugs reduced.

The blood–brain barrier may be immature in newborns, resulting in a greater uptake of partially ionized drugs such as morphine.

Body water compartments vary with age (Figure 1). The reduction in extracellular fluid volume in the first year of life has a profound effect on the volume of distribution of highly ionized drugs such as muscle relaxants.

Drug metabolism – the liver is the principal organ of drug metabolism. The activity of enzymes catalysing these reactions is reduced in infants leading to an increase in the duration of action of some drugs (e.g. morphine and aminosteroidal muscle relaxants).

Excretion – drugs and their metabolites are excreted mainly by the kidney. Both glomerular filtration rate (GFR) and tubular secretion rate are low at birth, reaching adult levels by 5 and 7 months, respectively.

Variation in body water compartments with age

1

Pharmacodynamic factors: the interaction between a drug and its receptor can be influenced by developmental changes in receptor number, type, affinity and availability of ligands. Such changes have been implicated in the neonate's sensitivity to non-depolarizing muscle relaxants and susceptibility to opioid-induced respiratory depression.

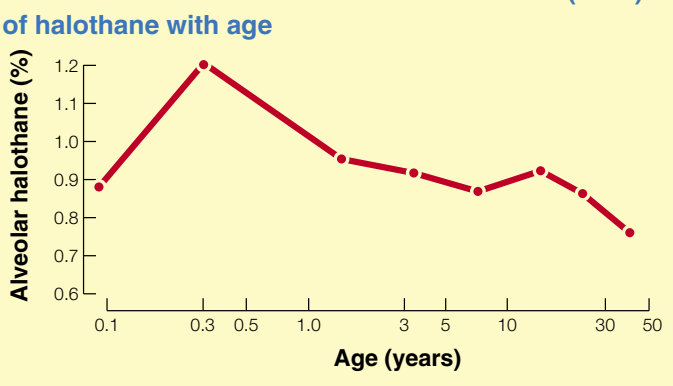
Inhaled anaesthetics

Uptake and elimination of inhaled anaesthetics occur more rapidly in babies and children than in adults owing to increased ventilation in relation to functional residual capacity, an increase in cardiac output in relation to body weight and reduced solubility of inhaled anaesthetics in blood. The increased rate of uptake in infants correlates with more rapid induction of anaesthesia and earlier development of cardiovascular side-effects. The minimum alveolar concentration (MAC) of inhaled anaesthetics varies with age, being generally lower in neonates and adults than in infants and young children.

Halothane has a sweet, non-pungent odour allowing smooth induction and maintenance of anaesthesia. Induction is rapid owing to its relatively low blood solubility and high potency. About 20% of halothane is metabolized in the liver, mainly by oxidation. Metabolism appears to be an important factor in the aetiology of halothane hepatitis, which occurs in 1 in 10,000–30,000 of exposed adults. By contrast, halothane hepatitis is rare in children and there have been no fatalities.

In neonates, the MAC of halothane is 0.9%, increasing to a maximum of 1.2% at 1–6 months, thereafter declining to 0.76% in the adult (Figure 2). The lower MAC of halothane in neonates compared with infants may be related to immaturity of the CNS. The higher MAC in infants compared with older children may reflect an increase in brain water.

Variation of minimum alveolar concentration (MAC) of halothane with age



Data from: Lerman J *et al. Anesthesiology* 1983; **59:** 421–4 and Gregory G A *et al. Anesthesiology* 1969; **30:** 488–91.

2

Halothane anaesthesia is associated with hypotension and bradycardia. Neonates and infants are susceptible owing to a reduction in active tension of the myocardium, reduced compliance of the ventricles and relative under-development of sympathetic innervation. Treatment consists of giving atropine, 20 μg/kg i.v. or i.m.

Isoflurane has an irritant odour, making it unsuitable for induction of anaesthesia. The rate of metabolism is about one-hundredth that of halothane (0.2%) and there have been no reports of hepatotoxicity in children. At 32 weeks' gestational age the MAC of isoflurane is about 1.3%, while at 32–37 weeks it is 1.4% increasing to about 1.6% at term and 1.9% at 1–6 months. It then declines to 1.2% in adults.

Isoflurane and halothane produce similar reductions in blood pressure in infants and children, though heart rate is either unchanged or increased with isoflurane. In contrast with halo-thane, the reduction in arterial blood pressure during isoflurane anaesthesia appears to be mainly the result of decreased peripheral resistance rather than myocardial depression.

Sevoflurane has a slightly pungent but not unpleasant odour, allowing rapid, smooth induction of anaesthesia. The MAC of sevoflurane is 3.3% in neonates, 2.5% in infants and children aged over 6 months and 2.0% in adults. The cardiovascular responses to sevoflurane are similar to those of halothane.

Concerns with sevoflurane include its relatively high rate of metabolism (2%), its chemical instability with soda-lime and high levels of agitation in children during recovery (67–69%). In view of the latter, some authors recommend restricting the use of sevoflurane in children to induction of anaesthesia.

Desflurane has a pungent ethereal odour, making it unsuitable for induction of anaesthesia. However, by virtue of its low blood solubility, recovery after desflurane anaesthesia is faster than that after halothane or sevoflurane. The MAC of desflurane is 9.2% in neonates, 9.9% in infants aged 6–12 months, thereafter declining to 6.0% in adults. The haemodynamic responses to desflurane are similar to those reported for halothane, metabolism is negligible (0.02%) and the drug is stable with soda-lime. Desflurane may be a useful maintenance agent for low-flow anaesthesia in infants and children.

Nitrous oxide: the low MAC of nitrous oxide gas (105%) precludes its use as a sole anaesthetic, but it is a useful adjunct to potent volatile anaesthetic agents during induction and maintenance of anaesthesia. Low blood solubility results in rapid uptake and elimination, and there is little biotransformation. Premature and sick neonates may not tolerate the cardiovascular effects of nitrous oxide, in which case air may be substituted. The main contraindications to nitrous oxide are the presence of air pockets within the body and the need for a high inspired oxygen tension.

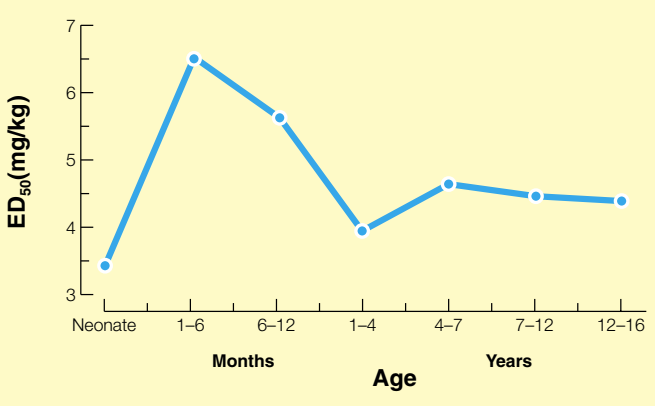
Intravenous anaesthetics

Intravenous anaesthetics are highly lipid-soluble substances that produce hypnosis in one arm–brain time when injected intravenously. Rapid recovery occurs predominantly by redistribution. Induction doses vary with age in a similar manner to the MAC of volatile anaesthetics.

Thiopental (thiopentone): plasma protein binding of thiopental (thiopentone) is reduced in neonates, so that the fraction of unbound drug is almost twice that in older children and adults. The elimination half-time is also over three times longer in newborns compared with older children; however, as recovery occurs predominantly by redistribution, the duration of effect of an induction dose should not be significantly prolonged.

The ED_{50} sleep dose of thiopental (thiopentone) varies with age (Figure 3). For smooth induction of anaesthesia using thiopental (thiopentone), neonates require 4–5 mg/kg, infants 7–8 mg/kg and children 5–6 mg/kg. The reduced requirements in neonates can be explained by a decrease in plasma protein binding. The increased requirements in infants and children compared with adults (usual dose 4 mg/kg) may be a result of their large cardiac output, which reduces the concentration of thiopental (thiopentone) arriving at the brain. Induction doses of thiopental (thiopentone) may be reduced by up to 50% by sedative premedication. The most important side-effects of thiopental (thiopentone) are respiratory and cardiovascular depression.

Variation in the ED_{50} sleep dose of thiopental (thiopentone) with age



Sources: Westrin P *et al. Anesthesiology* 1989; **71:** 344–6 and Jonmarker C *et al. Anesthesiology* 1987; **67:** 104–107.

3

Methohexitone has a shorter distribution half-time than thiopental (thiopentone), which is reflected in a shorter recovery time. The usual dose is 1–2 mg/kg for infants and children. The respiratory and cardiovascular effects of methohexitone are similar to those of thiopental (thiopentone). In addition, methohexitone may cause muscular twitching and hiccough due to CNS excitation.

Propofol: the distribution half-time of propofol is less than that of thiopental (thiopentone) but similar to that of methohexitone; accordingly, the recovery time after propofol is similar to that after methohexitone. Because of its prompt recovery characteristics and anti-emetic effects, propofol has largely displaced methohexitone as the induction agent of choice for outpatients.

Average induction doses of propofol are 4 mg/kg for infants and 3 mg/kg for children. The average infusion dose of propofol in children is 10 mg/kg/hour. This is about twice the rate required for adults (5 mg/kg/hour) and reflects a greater plasma clearance of propofol in children.

The respiratory and cardiovascular effects of propofol appear to be greater than those of thiopental (thiopentone). Pain on injection with propofol can be minimized by adding lidocaine (lignocaine), 20 mg, to each 200 mg of propofol.

Opioid analgesics

In the past, opioids were avoided in neonates and young infants because of their increased susceptibility to respiratory depression. This susceptibility may be due in part to increased penetration of the CNS by opioids, reduced drug elimination and changes in the proportions and affinities of opioid receptors in early infancy.

Morphine remains the most commonly used opioid for the management of severe pain in children. It is metabolized mainly by conjugation with glucuronide in the liver. Hence, deficiency of microsomal enzymes may be responsible for prolongation of its clinical effect in infants aged less than 6 months.

A regimen consisting of a loading dose of 100 μg/kg followed by a maintenance dose of 25 μg/kg/hour provides excellent intraoperative and postoperative analgesia in children aged over 6 months. Reduced doses are required in infants aged less than 6 months. A single dose of 25 μg/kg usually provides adequate intraoperative and postoperative analgesia in neonates undergoing relatively brief (45 minute) procedures. After longer surgery in neonates, postoperative analgesia may be supplemented with a continuous infusion of morphine, 5–10 μg/kg/hour. All infants aged less than 6 months receiving morphine infusions require high dependency nursing and respiratory monitoring.

Fentanyl is a highly lipid-soluble, synthetic opioid with a rapid onset of action. It is usually administered in a dose of 1–2 μg/kg at the start of anaesthesia followed by further bolus doses as clinically indicated, or continuously infused at 1 μg/kg/hour. After a dose of 1–2 μg/kg, its duration of action should be short in all age groups (20–30 minutes), being terminated predominantly by redistribution. After higher doses, repeated doses or an infusion, its effect may last for several hours and is terminated predominantly by elimination. Fentanyl may produce chest wall rigidity and bradycardia.

Naloxone is used to antagonize opioid-induced respiratory depression. The recommended dose is 5–10 μg/kg i.v. In view of its relatively short duration of action a supplementary dose of 10 μg/kg i.m. may be co-administered. Severe opioid overdose may require a much larger initial dose of naloxone followed by an infusion.

Muscle relaxants

Neonates and infants appear to be sensitive to non-depolarizing relaxants and resistant to depolarizing relaxants. Sensitivity to non-depolarizing drugs may be due to a reduction in acetylcholine in immature motor nerves. As this sensitivity is almost exactly countered by an increase in the volume of distribution (extracellular fluid volume), the clinical dose of non-depolarizing relaxants is unaffected by age. However, the elimination of aminosteroidal relaxants is delayed in infants with a resulting increase in their duration of action. The increased requirements for succinylcholine in babies and children may be the result of an increase in its volume of distribution (extracellular fluid volume).

The muscle relaxants described below are variously classified as ultrashort (less than 8 minutes), short (8–20 minutes) or intermediate (20–50 minutes) clinical duration drugs, where clinical duration describes time to 25% recovery of control twitch height after a 2 x ED_{95} dose. Rapid onset is defined as a time to maximum twitch depression of 1–2 minutes.

Succinylcholine is unique in having both a rapid onset and an ultrashort duration of action. In view of its side-effects, its use is reserved for emergency intubation or where immediate securing of the airway is necessary. Following 2–3 mg/kg in infants and 1–2 mg/kg in children, 100% block occurs within 1 minute with 25% recovery in about 5 minutes. Laryngospasm can be relieved in under 1 minute with succinylcholine, 4–5 mg/kg i.m., and full recovery occurs in about 20 minutes. As elimination of succinylcholine depends on hydrolysis by plasma cholinesterase, a deficiency in this enzyme may result in prolonged block.

Atracurium is a benzylquinolium diester that undergoes spontaneous degradation at body pH and temperature in a process known as Hofmann elimination. Although the volume of distribution of atracurium (extracellular fluid volume) is greater in infants compared with older children, this is accompanied by an increase in plasma clearance so that recovery rates are comparable in all age groups.

Following a standard intubating dose of 0.5 mg/kg, 100% block occurs in 1–2 minutes with 25% recovery in 29–36 minutes. Adverse effects relate mainly to histamine release, most commonly resulting in a rash along the course of the vein. Occasionally, the rash may be accompanied by more serious histamine-mediated effects such as hypotension, tachycardia or bronchospasm.

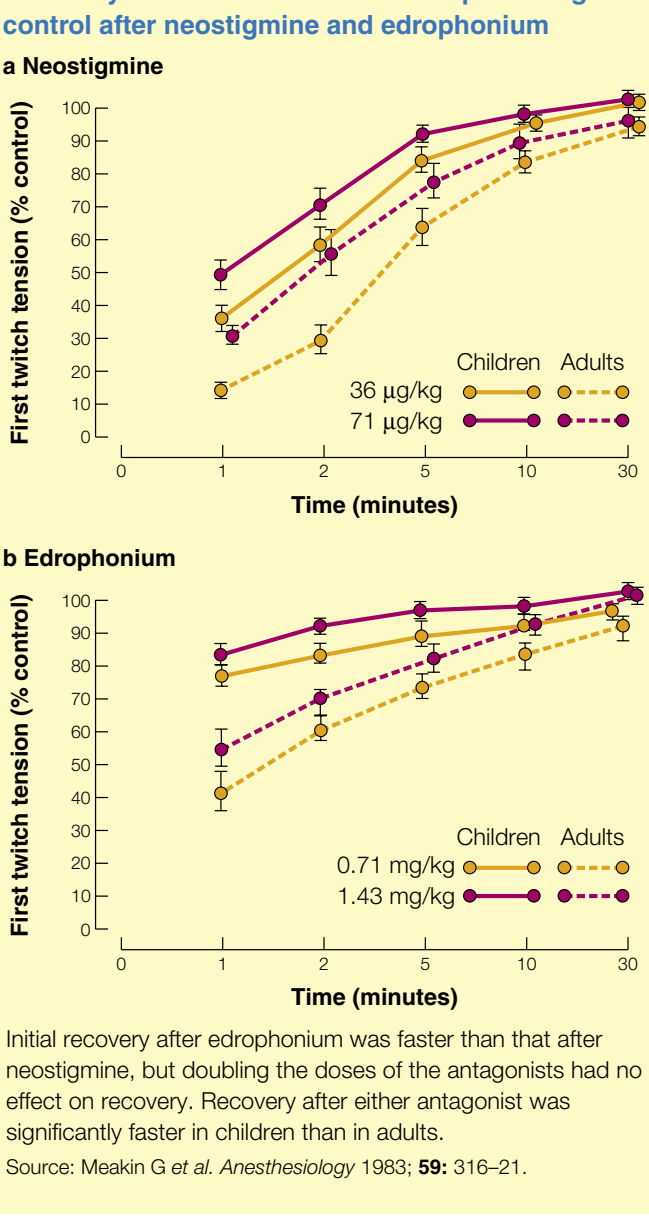
Mivacurium has a structure similar to atracurium but a shorter duration of action due to its metabolism by plasma cholinesterase. Following 0.2 mg/kg in infants and children, onset of complete block occurs in 1–2 minutes, while 25% recovery of twitch occurs in 8–9 minutes. As with atracurium, the absence of prolonged activity in infants compared with children may be due to an increase in plasma clearance. Histamine-releasing properties are similar to those of atracurium. The duration of action of mivacurium may be greatly prolonged in infants with plasma cholinesterase deficiency.

Rocuronium (*r*apid *o*nset *curonium*) is an aminosteroidal relaxant similar to vecuronium, but having a more rapid onset of action (due to its reduced potency), stability in solution and an intermediate duration of action in both infants and children. It has virtually replaced vecuronium in clinical practice.

The onset and duration of action of rocuronium, 0.6 mg/kg, have been determined in infants and children. While there was no difference in time to maximum block between the groups (64 versus 78 seconds), recovery of T1 to 25% of control was much slower in the infants than in the children (41.9 versus 26.7 minutes). Increased duration of action in infants is typical of aminosteroidal relaxants and may be due to slower elimination by the liver. In view of its intermediate duration of action, rocuronium should be used in place of succinylcholine for rapid- sequence induction only when no difficulties with the airway are anticipated.

Antagonism of muscle relaxants: in the presence of 10% recovery of twitch height, neostigmine, 35 μg/kg, or edrophonium, 0.7 mg/kg, will provide maximal antagonism in all age groups (Figure 4). For convenience, and to provide a margin of safety, neostigmine, 50 μg/kg, or edrophonium, 1 mg/kg, are usually given. Atropine, 20 μg/kg, or glycopyrrolate, 10 μg/kg, should be co-administered to counter any muscarinic effects.

Recovery of first twitch tension as a percentage of control after neostigmine and edrophonium



Initial recovery after edrophonium was faster than that after neostigmine, but doubling the doses of the antagonists had no effect on recovery. Recovery after either antagonist was significantly faster in children than in adults.

Local anaesthetics

Local anaesthetics are well tolerated by babies and children in whom they are often used to provide intra- and postoperative analgesia. Drugs of the amide type are used most often. Plasma protein binding of these drugs is reduced in infants, increasing the risk of toxicity. Total body clearance is also reduced in infants, which in conjunction with an increase in the volume of distribution leads to a prolonged elimination half-time. Accordingly, single doses of local anaesthetics should be kept strictly within the maximum recommended, and infusion doses reduced in the very young.

Bupivacaine is commonly used for wound infiltration and nerve blocks in infants and children. Its main advantage is its long duration of action (up to 8 hours following a single injection). Its toxic effects are similar to those of other local anaesthetics, though bupivacaine has a narrower safety margin between CNS and cardiovascular effects. Bupivacaine is particularly dangerous if cardiac effects occur, because dissociation from the myocardium is slow. For this reason, bupivacaine is not recommended for intravenous regional anaesthesia.

The maximum recommended dose of bupivacaine (plain or with adrenaline (epinephrine)) as a single injection is 2.5 mg/kg. The maximum recommended infusion rate is age dependent: less than 4 months, 0.2 mg/kg/hour for less than 48 hours; over 4 months 0.4 mg/kg/hour.

Ropivacaine is a new amide local anaesthetic with a chemical structure resembling that of bupivacaine. Compared with bupivacaine, ropivacaine offers a wider margin of safety, with lower potential for CNS and cardiovascular side-effects, and less motor block. The clinical indications, dose and duration of action of ropivacaine are similar to those of bupivacaine. ◆

Anaesthesia for Specialist Surgery in Infancy

Jane M Peutrell
Philip Bolton

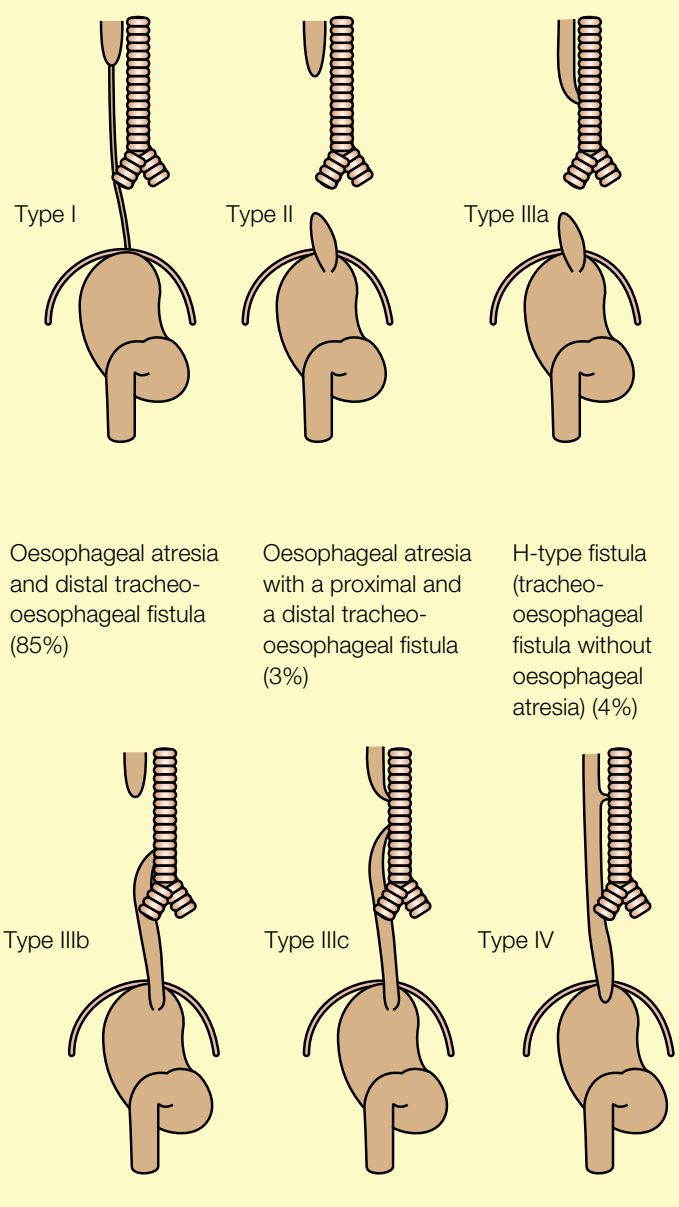
Jane M Peutrell is Consultant Paediatric Anaesthetist at the Royal Hospital for Sick Children, Glasgow, UK. She qualified from the University of Newcastle upon Tyne in 1982 and after a medical SHO post in Durham, trained in anaesthesia in Leeds, the South West of England, and the Netherlands. Her main interest is regional anaesthesia in babies and children.

Philip Bolton is Consultant Paediatric Anaesthetist at the Royal Hospital for Sick Children, Glasgow, UK. He qualified from Dundee University in 1991. After working in medicine and A&E he trained in anaesthesia in Dundee, Vancouver (Canada) and Glasgow.

Oesophageal atresia and/or tracheo-oesophageal fistula

Oesophageal atresia is usually associated with a fistula between the oesophagus and trachea (Figure 1). Occasionally a tracheo-oesophageal fistula occurs without oesophageal atresia (an 'H-type' fistula). A fistula, if present, usually lies on the posterior wall of the mid (60%) or distal (33%) trachea.

Classification of tracheo-oesophageal fistula and/or oesophageal atresia



Isolated oesophageal atresia (7%) – either with obliteration (type I) or atresia of the oesophagus (type II)

Oesophageal atresia with a proximal tracheo-oesophageal fistula (1%)

Oesophageal atresia and distal tracheo-oesophageal fistula (85%)

Oesophageal atresia with a proximal and a distal tracheo-oesophageal fistula (3%)

H-type fistula (tracheo-oesophageal fistula without oesophageal atresia) (4%)

1

Presentation: oesophageal atresia may be suspected antenatally because of maternal polyhydramnios or characteristic ultrasound findings (small or absent gastric bubble, little intestinal fluid). After delivery, these babies characteristically drool saliva and cough, splutter or become cyanosed with feeding. The diagnosis is confirmed when a gastric tube cannot be passed into the stomach, appearing 'curled up' in the upper oesophageal pouch on radiography. Air in the stomach confirms a fistula. Contrast studies are contraindicated because of the risks of pulmonary aspiration. 'H-type' fistulas often present late, usually with recurrent ventilatory distress or chest infections.

Preoperative assessment and preparation: oesophageal atresia is often associated with prematurity, intrauterine growth retardation or other anomalies (Figure 2), which should be identified before surgery. Soiling of the lungs and pulmonary infection are the main preoperative risks. Aspiration can be reduced by nursing the baby 'head up' and continuously draining the upper pouch using a large suction catheter. Surgery is usually not required immediately and pulmonary function, hydration and plasma electrolytes should be optimized first. Antibiotics and chest physiotherapy are indicated for aspiration or pulmonary infection.

Congenital anomalies associated with oesophageal atresia with or without a fistula

	Comments	Action
• Prematurity	Affects about 33%	
• Congenital heart disease	Affects 20–50%, of which half are major lesions (e.g. Fallot's tetralogy, coarctation)	Obtain cardiological opinion and echocardiograph preoperatively
• Cleft lip and palate		
• Concurrent syndrome	VATER/VACTER sequence (Vertebral, Anal, Cardiac, Tracheo-Esophageal, Renal abnormalities) 13%	Examine plain abdominal radiograph Obtain cardiological opinion and echocardiograph preoperatively
—	CHARGE syndrome (Colombomata – a congenital anomaly of the eye, Heart disease, choanal Atresia, growth and developmental Retardation, Ear abnormalities and deafness) 6% Retrognathia common and intubation may be difficult	Obtain cardiological opinion and echocardiograph preoperatively Choanal atresia may cause significant ventilatory distress Plan strategy for difficult intubation if babies have CHARGE syndrome and retrognathia
• Other complex abnormalities of the airway	Potentially fatal anomalies (e.g. tracheal agenesisor stenosis, laryngeal atresia) are uncommon but associated with tracheo-oesophageal fistula with oesophageal atresia (but not H-type fistulas)	

2

Specific anaesthetic considerations

Leakage of gas through the fistula may cause preferential ventilation of the stomach during intermittent positive-pressure ventilation (IPPV), compromising pulmonary ventilation and causing gastric distension (with the risks of pulmonary aspiration or diaphragmatic splinting). Clinically, however, this is seldom a problem and most anaesthetists use a gaseous or intravenous induction, facilitating tracheal intubation with a non-depolarizing relaxant. Because of the rare association with other significant airway abnormalities, some prefer to insert the tracheal tube while the baby breathes spontaneously, anaesthetized with a volatile agent. 'Awake intubation' is seldom used because it is difficult, distressing for the baby and associated with significant oxygen desaturation. Leakage through the fistula is reduced by acurate positioning of the tracheal tube (see below) and using the lowest possible inflation pressure.

Positioning the tracheal tube – most fistulas lie posteriorly in the mid or low trachea. Commonly, the tube is positioned with the bevel facing forwards, so the tip occludes the fistula while allowing ventilation of both lungs. In practice, the anaesthetist often inserts the tube 'too deep', slowly withdrawing it until both lungs are ventilated. Because the tip then lies low, inadvertent bronchial intubation during surgery is more likely. Bilateral air entry should be confirmed after intubation and whenever the baby is re-positioned.

Nitrous oxide may distend the stomach, compromising ventilation, and is best avoided.

Fluids – two intravenous cannulas are advisable, though significant bleeding is uncommon. Third-space losses can be replaced with suitable colloid (about 5 ml/kg/hour).

Monitoring – a precordial stethoscope may help to detect bronchial intubation or attempted ligation or compression of a major airway.

Surgical technique: primary repair of oesophageal atresia and/or tracheo-oesophageal fistula is an extrapleural procedure through a right thoracotomy. The baby lies in the left lateral position with the upper arm abducted against the head. Oxygen desaturation commonly occurs during surgery because of lung compression, airway kinking and V:Q mismatch. The lungs are usually ventilated by hand using a T piece because the pulmonary compliance changes continuously and it is easier to detect sudden airway obstruction, and to coordinate ventilation with the surgeon's activity.

During surgery the proximal oesophagus is identified by distending the upper pouch with the large suction catheter. When the anastomosis is almost complete, a smaller nasogastric tube is advanced to act as a stent and is then carefully secured.

A primary repair may be impossible with a 'long gap' between the proximal and distal oesophagus. The surgeon then usually fashions a feeding gastrostomy, draining the upper pouch with either an oesophagostomy or a suction tube, until definitive repair is feasible.

Anaesthetic technique depends on the intended postoperative care. Some clinicians routinely paralyse and ventilate the lungs of all babies after oesophageal atresia repair. Others do this only in those with 'long gaps' or associated significant anomalies. Epidural block provides excellent analgesia, allowing early extubation, and probably improving outcome. In those electively ventilated, an opioid anaesthetic technique (e.g. fentanyl, 20–100 μg/kg in increments) is appropriate.

Postoperative complications are common (Figure 3).

Complications after repair of a tracheo-oesophageal fistula in a neonate

	Comments	Treatment
• Tracheomalacia	Common at the fistula site. Affects about 25%. Presents with a 'seal like' cough, stridor and variable degree of ventilatory distress, which becomes worse after anaesthesia or when upset. Improves with age	
• 'Death attacks' or 'dying spells' (episodes of severe airway obstruction causing cyanosis, bradycardia and apnoea)	These spells usually occur in babies aged 2–3 months during or shortly after feeding. The cause is probably compression between the aorta/innominate artery and the oesophagus of the area of tracheomalacia	Aortopexy (suspension of aortic arch from posterior sternum) required in about one-third of babies with tracheomalacia
• Gastro-oesophageal reflux	A common association. May cause ventilatory distress and be difficult to distinguish from tracheal compression. Associated with pulmonary aspiration	May require fundoplication
• Oesophageal stricture	May cause pulmonary aspiration	May require repeated dilatation
• Abnormal oesophageal peristalsis	A common association. May cause dysphagia	
• Recurrent fistula	Affects about 13%	
• Anastomotic leak	Particularly after primary repair of a 'long gap'	Risk in association with a 'long gap' probably reduced if the baby is paralysed and its lungs ventilated mechanically postoperatively

3

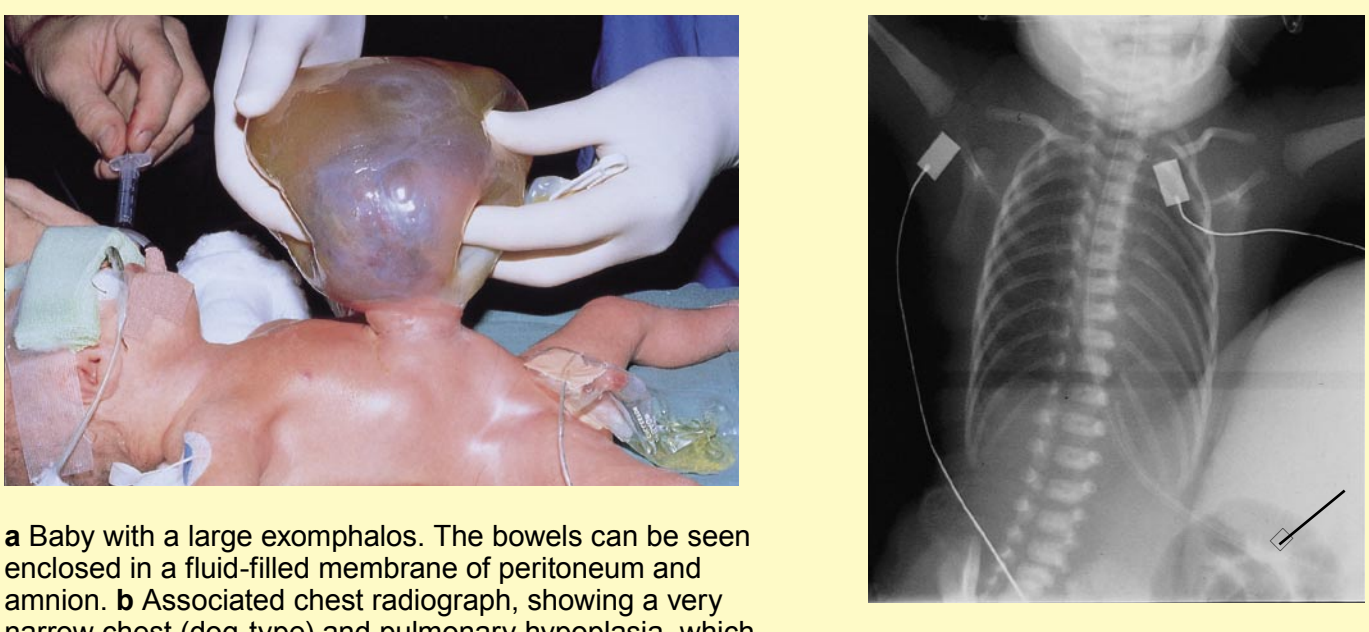
Gastroschisis and exomphalos

Gastroschisis and exomphalos have different embryological aetiologies causing herniation of abdominal contents through a defect in the abdominal wall. Their features are compared in Figure 4. Exomphalos is associated with serious congenital abnormalities. 60% of fetuses are therapeutically or spontaneously aborted (those with the most complex problems), therefore survival rates for live births are now higher. In the absence of other significant anomalies, a small exomphalos enclosed in a sac causes little disturbance. A large ('giant') exomphalos (Figure 5) or gastroschisis produces large amounts of fluid and heat loss. Preoperative assessment and management are summarized in Figure 6.

Comparison of gastroschisis with exomphalos

	Gastroschisis	Exomphalos (omphalocoele)
• Incidence (of live births)	1/5000–1/10,000	1/30,000
• Bowels	Often thickened, shortened, damaged, and enclosed in thick fibrous peel. Complications include intestinal atresia, stenosis, ischaemia, perforation, malrotation or volvulus	Usually normal structure and function, though other gastrointestinal abnormalities (e.g. malrotation, imperforate anus) can occur
• Abdominal wall defect	Lateral to the umbilicus, usually small and on the right side. Bowels not enclosed with a membranous sac	Midline defect (through the umbilical ring) often large. Bowels enclosed within a membranous sac of amnion and peritoneum
• Associated congenital anomalies	Uncommon	Common (but most fetuses with complex anomalies recognized antenatally are aborted; see Figure 6)
• Prematurity	33%	33%
• Intrauterine growth retardation	60%	37%
• Determinants of outcome	State of the bowel	Associated anomalies
• Survival (of live births)	90%	80% (but 60% of fetuses aborted)

4



a Baby with a large exomphalos. The bowels can be seen enclosed in a fluid-filled membrane of peritoneum and amnion. **b** Associated chest radiograph, showing a very narrow chest (dog-type) and pulmonary hypoplasia, which may be associated with ventilatory failure. Extra-abdominal alimentary gas shadows (arrowed).

5

Preoperative assessment and management of a baby with gastroschisis or exomphalos

	Comments	Action
• Identify associated congenital anomalies	Associated anomalies common in (congenital heart disease 25–35%; exomphalos Beckwith-Wiedemann syndrome 10%; chromosomal abnormalities, especially trisomy 13 or 18, in 10%), but not in gastroschisis	For exomphalos, obtain preoperative cardiological opinion and echocardiograph and check blood glucose regularly
• Recognize and treat ventilatory insufficiency	Large exomphalos associated with poor lung growth and pulmonary hypoplasia (see Figure 5b)	Consider mechanical ventilation
• Assess shock, reduce fluid loss	In gastroschisis or a large exomphalos, large volumes of fluid are often sequestrated within the bowel lumen Gastroschisis or ruptured exomphalos associated with greater evaporative losses because the bowels are not enclosed in a membranous sac	Site two intravenous cannulas and give warmed colloid, 20 ml/kg. Give further boluses of fluid according to clinical signs
• Reduce heat loss and prevent hypothermia		Wrap the bowels in a sterile polythene bag or 'cling film'. Nurse baby in a 'thermoneutral environment'
• Reduce bowel distension and the risk of aspiration		Pass a nasogastric tube and leave on 'free drainage'
• Prevent damage to the bowel or its blood supply		Wrap the bowels in a sterile polythene bag or 'cling film' Position a large exomphalos carefully to prevent kinking of the blood vessels. Sometimes best to lay the baby in the lateral position
• Prevent infection	Infection is a risk in gastroschisis or a ruptured exomphalos because the bowels are not enclosed in a membrane	Give prophylactic antibiotics. Wrap the bowels in a sterile polythene bag or 'cling film'

6

Specific anaesthetic considerations
Pulmonary aspiration of gastric contents – see bowel obstruction below.

Nitrous oxide is contraindicated because it causes bowel distension, which can prevent abdominal closure.

Intra-abdominal pressure – primary repair is preferable because infection rates are lower. Although a small exomphalos causes few problems, reducing a large gastroschisis or exomphalos may produce unacceptable increases in intra-abdominal pressure with serious clinical effects (Figure 7). If pressure is excessive, the surgeon sutures a silastic silo around the defect to enclose the bowels in a protective bag. The bowels are gradually returned to the abdomen over several days, after which the abdomen is closed. The decision to defer closure is often made indirectly (Figure 8), but some clinicians measure intravesical or intragastric pressures, deferring closure if these exceed 20 mm Hg.

Clinical effects of excessive intra-abdominal pressure

	Cause	Clinical features
• Hypoperfusion of intra-abdominal organs	Decreased venous return, reducing cardiac output Compression of aorta	Acute renal failure Bowel infarction Acidosis Ischaemia of the legs
• Decreased pulmonary compliance	Increased intra-abdominal pressure	'Stiff lungs' Hypoxia, hypercarbia, acidosis

7

Features supporting delayed closure of a gastroschisis or exomphalos

Significant discrepancy between abdominal cavity and volume of herniated organs
- Small abdominal cavity and/or large herniation of intra-abdominal contents
- Marked dilatation or oedema of bowels (particularly in gastroschisis)

Abdominal skin tension and perfusion (at attempted closure)
- Tense abdominal wall
- Dusky appearance

Altered cardiovascular variables (at attempted closure)
- CVP rise greater than 4 mm Hg
- Significant hypotension or tachycardia

Impaired ventilation (at attempted closure)
- Significantly decreased pulmonary compliance
- Hypoxia
- End tidal carbon dioxide tension > 50 mm Hg (6.7 kPa)

Significant associated anomalies (e.g. pulmonary hypoplasia)

8

Technique – postoperative muscle paralysis and IPPV are usual after repair of a moderate or large exomphalos or gastroschisis to optimize ventilation and reduce intra-abdominal pressure. An opioid anaesthetic with a low concentration of volatile agent and full muscle paralysis is common. For a small exomphalos, light general anaesthesia combined with epidural analgesia may facilitate early extubation.

Congenital diaphragmatic hernia

The diaphragm normally forms by 10 weeks' gestation. If proper development fails, abdominal viscera may enter the chest through the hernia (usually on the posterolateral aspect of the left hemi-diaphragm), impairing lung development (particularly ipsilaterally) and causing pulmonary hypoplasia and abnormal capillary growth.

Specific anaesthetic considerations
Associated congenital abnormalities, particularly cardiac, are common.

Ventilatory failure is a result of pulmonary hypoplasia, which is not corrected by urgent repair. These babies should be stabilized and pulmonary function optimized preoperatively.

Severe pulmonary hypertension and worsening hypoxia often develop after a 'honeymoon period'. The babies are initially treated preoperatively with muscle relaxation, tracheal intub-ation, hyperventilation, and a high fractional concentration of oxygen in inspired gas (FiO_2). However, excessive inflation pressures may further damage lungs or cause a pneumothorax and more complex ventilatory support (e.g. extracorporeal membrane oxygenation (ECMO), nitric oxide) may be necessary. Babies occasionally have surgery before weaning from ECMO.

Bleeding – if babies are receiving ECMO, bleeding may be severe because they will be heparinized.

Technique – anaesthesia is usually a continuation of intensive care. Additional analgesia is often provided with fentanyl, 20–100 μg/kg, in 10 μg/kg increments.

Necrotizing enterocolitis

Necrotizing enterocolitis is characterized by intramural air and bowel wall necrosis, sometimes leading to perforation. It has a mortality of 10–30%. 90% of affected babies are preterm (generally those who have survived the immediate post-natal period). The aetiology is multifactorial and incompletely understood. The three factors usually implicated are intestinal injury, primary ischaemia and substrate (usually formula milk) within the lumen of the bowel.

Presentation: the early stages are indistinguishable from sepsis and treatment is initially supportive with appropriate fluids, inotropes, antibiotics and IPPV. Ventilation is often compromised by splinting of the diaphragm (secondary to abdominal distension) and apnoea is common. About 50% require surgery, usually babies with more severe disease who are systemically ill (Figure 9). They should be rapidly, but carefully, resuscitated before surgery. Some very small premature babies may be too ill for laparotomy, in which case the surgeon may simply insert an intraperitoneal drain (under local anaesthetic) to drain the necrotic material.

Clinical features of severe necrotizing enterocolitis

Cardiovascular instability
- Hypotension, bradycardia
- Hypovolaemia (secondary to sequestration into dilated bowels, haemorrhage or ascites)

Respiratory failure and respiratory acidosis
- Severe apnoea
- Impaired ventilation because of abdominal distension

Haematological failure
- Thrombocytopenia
- Neutropenia
- Disseminated intravascular coagulation

Abdominal signs
- Abdominal distension and tenderness, ileus, blood per rectum
- Bilious vomiting, peritonitis, perforation

Others
- Metabolic acidosis
- Temperature instability

Specific anaesthetic considerations
Cardiovascular instability and haemorrhage – these babies may be septic and are often unstable. They have large intraoperative fluid requirements because of bleeding and third-space losses, often needing more than 100 ml/kg fluid during surgery (including platelets and fresh frozen plasma). In severely affected infants, cardiac function is poor, leading to reduced organ perfusion, decreased urine output and metabolic acidosis. Hypotension often occurs when the abdomen is opened. The anaesthetist should establish adequate venous access with two relatively large cannulas. Monitoring of intra-arterial and central venous pressures is essential. Because of associated coagulopathy, the central venous line may be best inserted using a formal surgical technique. The intraoperative course is often stormy and a second anaesthetist may be helpful. Inotropic support may be required.

Friable liver capsule – the liver capsule is often distended and can bleed profusely at laparotomy. Hepatic distension has been attributed to over-zealous resuscitation and venous engorgement.

Citrate toxicity – infusing blood products containing citrate (e.g. fresh frozen plasma) at a rate greater than 1 ml/kg/minute may produce citrate toxicity, hypocalcaemia and refractory hypotension. Ionized calcium should be measured, and, if low, corrected with intravenous calcium chloride 10%, 0.1 ml/kg, given over about 30 minutes through the central line.

Nitrous oxide is absolutely contraindicated because of intra-mural air and the risk of intestinal perforation. It also significantly depresses cardiovascular function (60% nitrous oxide has as much effect as 0.6 minimum alveolar concentration (MAC) of halothane).

Technique – intubation and ventilation are usually part of the supportive care before surgery. Anaesthesia can be maintained with a low inspired concentration of a volatile agent in oxygen or air. Regional techniques are contraindicated because of coagulopathy and/or bacteraemia. Fentanyl, 10–50 μg/kg (in divided doses), provides analgesia, reducing the physiological stress of surgery. Alternatively, ketamine, 4 mg/kg/hour, can be infused.

Postoperative care: aggressive intensive care (including IPPV, meticulous management of fluid balance, and, often, inotropic support) are required. Morphine infused continuously provides sedation and analgesia.

Bowel obstruction

Babies presenting with bowel obstruction soon after birth are usually well and easily resuscitated. Others may be dehydrated and have significant acid–base and electrolyte abnormalities, which should be corrected preoperatively. Ventilatory function is more easily impaired compared with adults (Figure 10) because babies have relatively horizontal ribs and are mainly diaphragmatic breathers. Pulmonary function may be further compromised by aspiration of gastric contents.

10 Abdominal distension can easily cause respiratory compromise in a baby.

Preoperative assessment
Associated anomalies are common in newborn babies (Figure 11).

Fluid and electrolyte resuscitation is vital. Dehydration should be assessed clinically (Figure 12). Hypovolaemia produces cool peripheries, tachycardia and slow capillary refill (over 2 seconds). Blood pressure is a poor indicator of shock and does not fall until 25% of circulating blood volume has been lost.

Coagulopathy is common in unstable, septic babies.

Congenital causes of bowel obstruction and their associations

Condition	Incidence	Clinical features	Associated abnormalities	Specific anaesthetic considerations
Obstructed inguinal hernia			Prematurity. Low birth weight	Large aspiration risk
Duodenal atresia or obstruction	1/6000–1/20,000	Copious and forceful vomiting within days of birth (may be bile stained) 'Double bubble' on abdominal radiograph	Prematurity. 33% have Down's syndrome. May be caused by malrotated caecum compressing the duodenum with Ladd's bands	
Meconium	1/20,000	No passage of meconium after 48 hours. Meconium may be 'milked out' at laparotomy or bowel resection may be required. Perforation can lead to severe peritonitis with large fluid shifts and blood loss	Presenting sign in 15% of children with cystic fibrosis	Avoid prophylactic atropine because of thick secretions Humidify gases intra- and post-operatively
Hirschsprung's disease	1/5000–1/10,000	Caused by lack of parasympathetic ganglia in rectal mucosa, producing a functional obstruction. Vomiting and abdominal distension usually within 48 hours of birth, but may occur much later. Diagnosed by mucosal biopsy	Uncommon	
Imperforate anus		May be low with small defect may end above levator muscle. Genitourinary fistulas common with high defects	VACTER (Vertebral, Anal, Cardiac, Tracheo-Esophageal atresia, Radial abnormalities and other limb abnormalities)	Obtain cardiological opinion and ECG preoperatively
Volvulus		May involve all of small bowel owing to malrotation. May present with obstruction and bloody stools		
Mucosal cyst	Rare	May cause obstruction or intussusception		

Clinical assessment of dehydration

Degree of dehydration (% of body weight lost) as fluid	Mild (5%)	Moderate (5–10%)	Severe (> 10%)
Decreased urine output	+	+	+
Dry mouth	+/–	+	+
Decreased skin turgor	–	+/–	+
Tachypnoea	–	+/–	+
Tachycardia	–	+/–	+

Data taken from: Advanced Paediatric Life Support. London: BMJ Books, 2001.

Specific anaesthetic considerations
Preventing pulmonary aspiration of gastric contents – there may be a significant residual volume in the stomach immediately before anaesthesia. The risks of pulmonary aspiration are reduced by aspirating the nasogastric tube carefully (with the baby lying in several positions) and using a rapid-sequence induction. Cricoid pressure is effective in babies, but may make intubation difficult if applied incorrectly.

Nitrous oxide worsens bowel distension and is contra-indicated.

Invasive monitoring (central venous and arterial pressure) is indicated for sick or unstable babies and a central line if intravenous nutrition is required postoperatively.

Technique – sick babies can be managed as for necrotizing enterocolitis. For stable babies, light general anaesthesia combined with epidural analgesia often allows early extubation.

Intussusception

Intussusception usually affects boys aged 5–9 months who may become very sick. A portion of bowel (usually the ileo-caecal valve) 'telescopes' into the next, causing obstruction, bloody diarrhoea and often vomiting. Generally, intussusception can be reduced with a barium enema, but 25% require surgery, sometimes including bowel resection.

Bleeding and fluid loss can produce significant anaemia, electrolyte abnormalities and shock, which should be corrected preoperatively. Other anaesthetic considerations are similar to those for bowel obstruction.

Pyloric stenosis

Pyloric stenosis most commonly affects first-born males. The circular muscles of the pylorus become thickened, inhibiting passage of gastric contents into the duodenum. Babies classically present with projectile vomiting and a palpable tumour. The diagnosis is often made by ultrasound. Pyloric stenosis has no specific associations with other congenital anomalies.

Pathophysiology: Cl^-, H^+ and water, and smaller amounts of Na^+ and K^+, are lost causing dehydration, metabolic alkalaemia, and hypochloraemia. Initially, the kidneys attempt to compensate by excreting bicarbonate with Na^+ and K^+. Later aldosterone (released in response to hypovolaemia) conserves Na^+, causing paradoxical aciduria, worsening alkalaemia, and renal loss of K^+. Plasma Na^+ and K^+ concentrations are usually normal at presentation (despite marked loss of total body K^+). Cl^- concentration falls (usually to 80–85 mmol/litre) once plasma bicarbonate exceeds 30 mmol/litre.

Preoperative assessment and preparation: babies with established vomiting are dehydrated and have significant electrolyte and acid–base disturbances. Pyloric stenosis is not an emergency and affected babies should be resuscitated before operating.

Dehydration should be assessed clinically (Figure 12) and corrected over 24–48 hours. Intravenous water and sodium chloride are the mainstay of treatment.

Electrolyte and metabolic disturbances – major electrolytes and acid–base abnormalities are corrected by rehydration with normal saline in addition to maintenance fluids. Apnoea lasting for over 15 seconds occurs in alkalotic babies with pyloric stenosis; it may be potentiated by general anaesthesia. Surgery should be delayed, therefore, until plasma electrolytes and pH are normal. Cl^- concentration is a useful guide to adequate resuscitation, but alkalosis persists until the Cl^- is at least 105 mmol/litre. In dehydrated babies, total body K^+ is low, despite a normal plasma concentration, and 20 mmol/litre should be added to the intravenous fluids.

Reducing the volume of gastric contents – a nasogastric tube should be inserted preoperatively and aspirated regularly.

Anaesthesia and surgery: pulmonary aspiration should be prevented by suctioning the nasogastric tube immediately before anaesthesia and using a rapid-sequence induction (see bowel obstruction, above). Anaesthesia can be maintained with a volatile agent (e.g. desflurane) in oxygen and nitrous oxide/air, using a relatively short-acting drug (e.g. atracurium) for muscle relaxation. Adequate analgesia can be provided with wound infiltration and regular paracetamol.

During the operation, the surgeon makes a small incision in the right upper quadrant, and then splits the circular muscles of the pylorus. Sometimes the anaesthetist is asked to inject air through the nasogastric tube to check that the pyloric mucosa remains intact.

Inguinal herniotomy

Inguinal hernias are common in babies born prematurely (30% of those with a birth weight less than 1000 g). Surgery should not be delayed unreasonably because of the risks of incarceration and bowel infarction. An incarcerated hernia should be managed as for bowel obstruction. Healthy, term infants generally have small, unilateral hernias and can be admitted for day surgery if they are older than 50 weeks' postconceptional age. Light general anaesthesia (using sevoflurane followed by desflurane) combined with caudal or ilioinguinal block is commonly used.

Ex-premature babies often have large bilateral hernias. The anaesthetic plan must take account of the specific implications of prematurity.

Ventriculo-peritoneal shunt

In the neonate, hydrocephalus is usually 'obstructive' and caused by clot debris (after intraventricular haemorrhage) or an Arnold-Chiari malformation (commonly associated with spina bifida). The slow accumulation of CSF in the ventricles destroys brain tissue and dilates the skull. CSF is commonly drained with a ventriculo-peritoneal shunt inserted into a cerebral ventricle and passed subcutaneously along the chest wall into the abdomen.

Specific anaesthetic considerations

Intracerebral pressure remains relatively normal if CSF accumulation is gradual because the cranial bones are unfused. Acute rises in intracranial volume, however, increase pressure because the dura is tough and relatively inelastic. If the baby has significant neurological signs or symptoms preoperatively, the ventricles can be 'tapped' under local anaesthetic to reduce the intracranial pressure before inducing general anaesthesia.

Prematurity is commonly associated with intraventricular haemorrhage.

The large head flexes the neck, which may make intubation difficult (Figure 13).

Heat loss from the large, exposed head may be significant and can be minimized by using a radiant overhead heater.

Bleeding is usually minimal, but blood should be available in case an epidural vein is damaged.

Technique depends on the child's condition. Inhalational induction is relatively contraindicated because of the increased intracerebral pressure associated with high concentrations of volatile agents and spontaneous breathing. Babies with preoperative symptoms generally improve after CSF drainage and most are extubated immediately after surgery.

a The large head in hydrocephalus flexes the neck making intubation difficult.

b This can be improved by raising the baby's body on a towel, which brings the head into a neutral position.

Postoperative care: analgesia is provided by regular paracetamol and wound infiltration with local anaesthetics. Non-steroidal anti-inflammatory drugs are contraindicated because of renal immaturity in babies less than 6 months.

Myelomeningocoele (spina bifida)

Myelomeningocoele results from failed fusion of the vertebral arches with variable loss of neural function below the lesion. It is commonly associated with hydrocephalus. There is a high risk of infection because the CNS is covered only by dura, pia and arachnoid mater and surgery is indicated within the first days of life.

Specific anaesthetic considerations

The position during intubation must not damage the sac. The baby can be laid either partially or completely on one side or supine with padding beneath the thorax, lower pelvis and head, leaving an adequate gap for the sac.

Position for surgery – the baby lies prone during surgery. The chest and pelvis must be supported to allow free abdominal movement and the tracheal tube position confirmed carefully after positioning the baby.

Latex allergy in later life is common and many hospitals provide a latex-free environment for anaesthesia and surgery from the outset.

Bleeding can be substantial with large lesions, and difficult to assess because blood is mixed with CSF. Good intravenous access must be obtained and blood cross-matched. ◆

Managing Pain in Babies

Deborah Duce

Deborah Duce is Clinical Fellow in Paediatric Anaesthesia at the Hospital for Sick Children in Toronto, Canada. She qualified from the London Hospital Medical College and trained in anaesthetics in North East Thames Area and at Great Ormond Street, London.

It is now generally accepted that neonates (the first 28 days of life) and infants (the first year of life) have cortical awareness of pain, and may have increased nociception owing to incomplete development of inhibitory pathways.

Importance of controlling pain
It has been argued that even if neonates and infants feel pain they do not remember it, and therefore the consequences of inadequate analgesia are unimportant. However, neonates who have undergone circumcision without analgesia or anaesthesia have higher behaviour pain scores and cry for longer when immunized at 4 or 6 months of age compared with other infants. In addition, ex-preterm babies who have undergone multiple painful procedures have an increased incidence of somatization (the reporting of symptoms that cannot be explained by, or are in gross excess of, physical findings) in later childhood. It is also possible that untreated pain in the neonate may result in a detrimental structural and functional reorganization of the developing nervous system.

Assessment
Assessing pain is a complex, multidimensional entity, especially in infants who are incapable of articulating feelings. In clinical practice, it can be carried out by a nurse experienced in pain management using simple sedation scores and pain scales. Many different scoring systems have been developed, none of which is ideal and many of which have not been validated. Most scoring systems use a combination of changes in observed behavioural and physiological variables (see *Anaesthesia and Intensive Care Medicine* **1:4:** 138). The ideal pain scoring system is easy and quick to use, distinguishes well between pain and other forms of distress, gives reproducible results and does not cause discomfort. It is important to repeat measurements at regular intervals to assess response to therapeutic interventions. The following two systems are in widespread use.

The CRIES neonatal scoring system is an acronym for five variables with scores of 0 to 2 for each (Figure 1). It has a maximum pain score of 10 and a minimum of 0. It is commonly used for neonates, is easy to remember and use, and has been validated down to the age of 32 weeks' postconception. However, it does not distinguish well between pain and distress (a common problem with all systems for this age group), and increased oxygen requirement can be caused by many factors other than pain. It also involves blood pressure measurement, which can be distressing for the neonate.

CRIES neonatal scoring system used to assess postoperative pain in babies

	0	1	2
Crying	No	High pitched	Inconsolable
Requires oxygen for SpO_2 > 95%	No	< 30%	≥ 30%
Increased vital signs pressure	Heart rate and blood pressure above preoperative values	Heart rate or blood pressure increased but not greater than 20% of preoperative levels	Heart rate or blood increased by over 20% of preoperative levels
Expression	None	Grimace	Grimace/grunt
Sleepless	No	Wakes at frequent intervals	Constantly awake

1

The Objective Pain Scale (OPS) has been validated for use in neonates and infants. It scores five behavioural and physio-logical signs of distress (Figure 2), is easy to use and reliable.

Objective Pain Scale

Observation	Criteria	Points
Blood pressure	± 10% preoperatively	0
	10–20% preoperatively	1
	20–30% preoperatively	2
Crying	Not crying	0
	Crying but responds to care	1
	Crying and unresponsive to care	2
Moving	None	0
	Restless	1
	Thrashing	2
Agitation	Patient asleep or calm	0
	Mild	1
	Hysterical	2
Body language	Patient asleep	0
	Mild pain (cannot localize)	1
	Moderate pain (can localize)	2

2

Techniques of postoperative pain management

Simple analgesia
Paracetamol is the most widely used analgesic in this age group because of its well-established safety profile. It is effective as sole analgesia after minor procedures, and as an adjuvant to opioid or local anaesthetic techniques for more painful procedures. The route of administration and dose have been widely discussed. Absorption is variable following rectal administration and the immaturity of hepatic glucuronidation in neonates may increase the risks of toxicity. The drug should be given 1–2 hours preoperatively to be effective at the time of surgery. Current recommended doses are given in Figure 3.

Paracetamol dosing in healthy children

Age	Oral initial dose (mg/kg)	Rectal initial dose (mg/kg)	Maintenance oral/rectal dose (mg/kg)	Maximum daily dose (mg/kg)	Duration at maximum dose (hours)
Preterm	20	20	15	60 (40 in 28–32 weeks)	48
0–3 months	20	20	15	60	48
> 3 months	20	40	15	90	72

3

Non-steroidal anti-inflammatory drugs (NSAIDs) are not recommended for neonates because they are vulnerable to the side-effects of impaired renal perfusion and fluid retention. Ibuprofen is the only NSAID licensed for use in infants over 7 kg for the treatment of postoperative pain; it is given orally at 30–40 mg/kg/24 hours in divided doses.

Opioids
Codeine and morphine are the mainstays of opioid therapy in neonates and infants because there is more extensive clinical experience and published data about them than other opioids, not because they are more effective. Neonates and infants are vulnerable to the same opioid side-effects as older children. Neonates are at particular risk of convulsions and myoclonic jerks with morphine. There are similar incidences of respiratory depression, constipation and pruritus at all ages, but nausea and vomiting are less common in infants and neonates.

Codeine is indicated for the treatment of mild-to-moderate pain. Its duration of action is 4–6 hours and it has good oral bioavailability. Codeine is metabolized mainly by conjugation to codeine-6-glucuronide and partly biotransformed by demethylation to morphine and norcodeine; morphine may be responsible for the analgesic actions of codeine. The glucuronidation pathway is immature in preterm babies and neonates; this leads to an increased half-life of the drug and proportionally higher serum concentrations. Codeine given at therapeutic doses in combination with other sedative agents in cold remedies has resulted in fatal intoxication in infants and it should be used with caution in this age group. The recommended postoperative oral or rectal dose is 1 mg/kg given 8 hourly in neonates and 6 hourly in infants. Higher peak plasma levels are achieved with the intramuscular route when compared with rectal administration but with an equal duration of action. A single intramuscular injection is commonly given intraoperatively with further doses given orally or rectally. It should not be given intravenously because it causes histamine release and hypotension.

Morphine is used for severe postoperative pain. Neonates and infants metabolize morphine differently from adults. The half-life decreases and the clearance increases with age, with values approaching those of an adult by 2 months. However, there is large interpatient variability in opioid metabolism, which may be exaggerated by surgery and critical illness. These differences may lead to accumulation of morphine with infusions or repeated doses and it should be used only in neonates given high dependency care.

Morphine can be given by the same routes as in adults though intramuscular injections are seldom used. The intravenous route by infusion or nurse-controlled analgesia (NCA) is the most common in neonates and infants. Data comparing the efficacy and complication rates of the two regimens are limited, but NCA is more popular with nursing staff; the overall morphine consumption is similar.

NCA involves the use of programmable syringe pumps that provide a background infusion of morphine and allow nurses to give bolus doses regulated by a lockout time. Although morphine infusions provide constant plasma concentrations, the rates used for NCA are inadequate for the fluctuations in pain occurring postoperatively. Bolus doses can therefore be administered if necessary by a trained nurse. A lockout time of 20 minutes between boluses is recommended. Because of the variability in morphine metabolism in babies under 2 months and the increased risk of respiratory depression, background infusions are not recommended in babies weighing less than 5 kg, except those ventilated postoperatively. Recommended doses are given in Figure 4.

Recommended maximum doses of morphine in babies

Route	Preterm	Term	Infant
I.v. bolus	4 µg/kg 2 hourly	15 µg/kg 2 hourly	40 µg/kg 2 hourly
Infusion	2 µg/kg/hour	7 µg/kg/hour	20 µg/kg/hour
I.v. nurse controlled analgesia	Not recommended No background	10 µg/kg bolus 4 µg/kg/hour infusion	20 µg/kg bolus background
Epidural	Not recommended	Not recommended	30 µg/kg 8 hourly

4

All babies should have a pain chart with hourly recording of vital signs, pulse oximetry, sedation and pain scores. The results of these observations should guide emergency measures, administration of boluses, or review by the pain team and a change in the NCA programme. When supervised by a pain service, NCA has a 1% incidence of respiratory depression.

Prescriptions for naloxone in the event of respiratory depression together with a threshold respiratory rate for its administration should be included on the same drug chart as the NCA prescription. The intravenous naloxone dose is 2–4 µg/kg which may be repeated at 2 minute intervals.

Local anaesthetic techniques
Data are limited on the absorption, distribution and metabolism of local anaesthetics in neonates and infants, but they are more vulnerable to toxicity and accumulation. There are several reasons for this. Concentrations of the plasma proteins α_1-acid glycoprotein and albumin are lower in babies less than 3–6 months of age, and further reduced in preterm neonates. These proteins bind amide local anaesthetics and reduced binding increases the concentration of free drug and the potential for CNS and cardiovascular toxicity. Hepatic metabolism by dealkylation and hydroxylation (the degradation pathways for amide local anaesthetics) is slower in young babies. Elimination half-lives are therefore prolonged in this age group, increasing the risk of accumulation with infusions or repeated doses. Smaller doses with increased dose intervals are recommended.

Lidocaine (lignocaine) and bupivacaine are well established for use in children (Figure 5). There are few data about the use of ropivacaine and levobupivacaine in this age group. They have similar properties to bupivacaine, but may prove safer and supersede it in clinical practice.

Dose of lidocaine (lignocaine) and bupivacaine for regional analgesia

	Lidocaine	Bupivacaine
Neonate (up to 44 weeks' postconceptional age)	3 mg/kg 4 hourly	2 mg/kg 6 hourly
Infant (over 44 weeks' postconceptional age)	4 mg/kg 4 hourly	2.5 mg/kg 6 hourly

5

Topical application of local anaesthetic has limited use for postoperative pain, though *Emla* (eutectic mixture of local anaesthetics) has been used for neonatal circumcision, and is recommended for use before a range of painful procedures such as venous and arterial puncture, lumbar puncture, and subcutaneous or intramuscular injections. It should be applied 60 minutes before a procedure is started. Concerns have been raised over an increased risk of prilocaine toxicity in neonates and preterm infants. Neonates have a thinner stratum corneum layer of the skin, allowing increased absorption of prilocaine and hence higher plasma levels. They also have reduced activity of the methaemoglobin reductase enzyme which converts methaemoglobin to haemoglobin. In practice, though methaemoglobin levels are raised they remain below toxic levels, however caution is advised with repeated doses. Maximum doses are given in Figure 6.

Maximum dose and application area for Emla assuming intact skin and normal hepatic and renal function

Age	Body weight (kg)	Maximum *Emla* dose (g)	Maximum area
30–37 weeks	Mean 1.9	0.5	Unspecified
Over 37 weeks	More than 2.5	1	Unspecified
1–3 months	Up to 5	1	10 cm^2
4–12 months	5–10	2	20 cm^2

6

Wound infiltration and peripheral nerve blocks are a valuable supplement to general anaesthesia, providing analgesia well into the postoperative period. Bupivacaine is the local anaesthetic of choice because of its long duration of action. The safe dose varies according to the site of administration. Peripheral nerve blocks are particularly suitable for surface and peripheral surgical procedures, and are widely used for day case surgery. They avoid the problems of central blocks but carry the risk of intraneural injection and subsequent nerve damage. Commonly performed peripheral nerve blocks include penile, ilioinguinal, axillary, intercostal and femoral (see *Anaesthesia and Intensive Care Medicine* **1:4:** 132). Blocks should be sited and working before skin incision to allow an opioid-free and low volatile anaesthetic technique; this leads to more rapid emergence from anaesthesia.

Central blocks: the epidural space can be accessed via the thoracic, lumbar and sacral intervertebral spaces and the sacral hiatus (caudal epidural). The use of epidural analgesia improves outcome in adults and may do so in babies, with benefits from improved respiratory function, reduced postoperative apnoea, and attenuation of the neuroendocrine stress response to surgery. Retrospective studies show reduced mortality and less need for postoperative ventilation in neonates having diaphragmatic hernia repair with epidural analgesia, and reduced hospital stay in children having Nissen's fundoplication with epidural analgesia. Prospective studies are required to demonstrate this benefit. Complications from epidurals in this age group include convulsions related to bupivacaine toxicity and venous air embolism. Technical problems resulting from the use of finer bore catheters (e.g. catheter occlusion, disconnection, leakage round the epidural site) lead to premature discontinuation in about 10% of infusions. The incidence of neurological complications is low.

Caudal epidurals are increasing in popularity in babies. A single dose of local anaesthetic may be given or a catheter threaded to the desired level and an infusion commenced. A single dose caudal can provide analgesia for surgery below the umbilicus and a catheter may be threaded up as high as T6 for upper abdominal or thoracic surgery. The potential hazards of accessing the epidural space at spinal cord level (the spinal cord extends to L3 in neonates) have led to many centres using caudal catheters rather than thoracic or lumbar approaches. Threading caudal catheters is most successful in neonates and infants under 5 kg and is made easier with styletted catheters. The catheter position can be confirmed by fluoroscopy which has the side-effect of radiation exposure to the patient, or by using a metal styletted catheter and nerve stimulation guidance.

The sacral hiatus is usually easy to identify in this age group and can be found using the same anatomical landmarks as in adults. In neonates, the dural sac may extend as low as S3–4 making accidental dural puncture more likely. For this reason, a technique using a cannula that is threaded over the needle as soon as the membrane is pierced is commonly used. Recommended doses of local anaesthetic for epidurals are given in Figures 7 and 8. A block from L5–S5 is suitable for penile surgery (e.g. circumcision, hypospadius repair), a T9–S5 block is adequate for herniotomy or orchidopexy. A single dose provides analgesia for up to 4–6 hours. The resultant immobility in the early postoperative period is not a problem in infants. Clonidine and ketamine have been used successfully in combination with local anaesthetics to prolong the duration and improve the quality of caudal block in older children. Data about their use in children under the age of 1 year are limited.

Volumes of bupivacaine for caudal, lumbar and thoracic epidural analgesia

Injection site	Dose
Caudal	*L5–S5 block:* 0.25% bupivacaine, 0.5 ml/kg *T9–S5 block:* 0.25% bupivacaine, 1.0 ml/kg (volume to be made up with normal saline once safe dose limit reached)
Lumbar	0.25% bupivacaine, 0.75 ml/kg
Thoracic	0.25% bupivacaine, 0.5 ml/kg

7

Infusion rates of bupivacaine for epidural analgesia

Age	Infusion rate (mg/kg/hour)
Preterm/neonate (up to 44 weeks' postconceptional age)	< 0.2
Infants (44–56 weeks' postconceptional age)	< 0.25
Infants (56 weeks' postconceptional age)	< 0.4

8

Lumbar and thoracic epidurals provide analgesia for abdominal and thoracic surgery, and have been used in babies as small as 900 g. Lumbar catheters may also be threaded into the thoracic region. In some centres, lumbar or thoracic approaches are preferred to caudal catheters because it is easier to keep the entry site clean postoperatively. Studies have shown increased bacterial colonization in caudal as compared with lumbar catheters, but there is little evidence to suggest a difference in clinical infection rates between the two sites.

A loss of resistance to saline technique is recommended for identifying the epidural space because of the potential for venous air embolism and reports of patchy blocks if air is used. A smaller gauge needle and catheter are used. The size of catheter used varies, but the following is suggested: 20 G needle with 24 G catheter for babies under 2 kg, 19 G needle with 23 G catheter for babies 2–10 kg, 18 G needle and 21 G catheter for larger babies. The finer the catheter the higher the technical difficulties threading it into the epidural space. The depth from skin to epidural space is not predictable by weight in neonates and infants under the age of 6 months but can be as little as 3 mm; in older infants it is about 1 mm/kg. Recommended doses of bupivacaine are given in Figure 8. Adding opioids is not recommended in neonates because of concerns about respiratory depression. They may be used in older infants if they are nursed in a high dependency setting.

Infants with epidural catheters postoperatively should be nursed on wards with nursing staff trained in their management and complications. Infusions are usually discontinued 24–72 hours after surgery. Standardized forms should be used for recording pain and sedation scores, respiratory rate, vomiting, urinary retention and pruritus, with instructions for treating these complications should they occur. The infants should be assessed at least daily by a member of the pain team and the epidural site inspected with each change in nursing shift.

Spinal anaesthesia can provide analgesia into the early postoperative period and is widely used. When used without supplementation it reduces the incidence of postoperative apnoea in former preterm infants compared with general anaesthesia. It can be used as sole anaesthesia for lower abdominal, lower limb and urological procedures lasting less than 90 minutes. Limitations of the technique include a variable success rate with a significant requirement for additional sedation, a second spinal injection or conversion to general anaesthesia. Bupivacaine, 0.3–0.6 mg/kg, tetracaine (amethocaine) or lidocaine (lignocaine) are used. Central blocks in young children do not cause the haemodynamic changes seen in adults, but the reasons for this are unclear. ◆

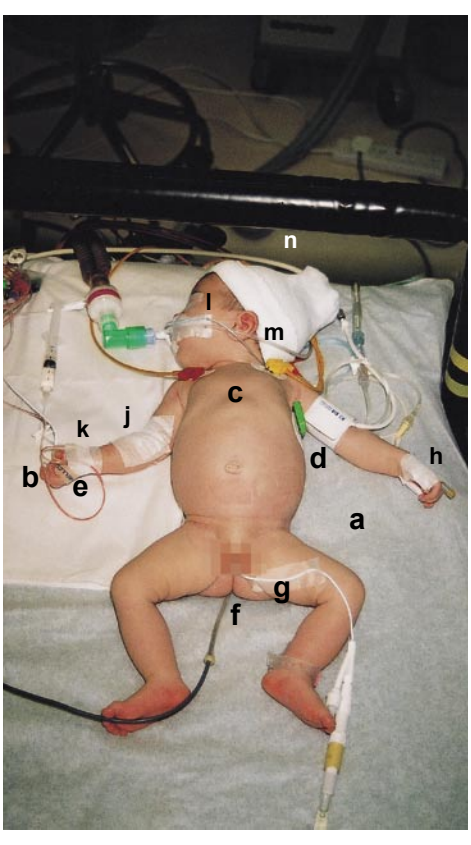
Principles of Anaesthesia for Babies

Declan J Warde

Declan J Warde is Consultant Anaesthetist at the Children's Hospital, Temple Street, Dublin. He qualified from University College, Dublin, and trained in anaesthesia and paediatric intensive care in Dublin and Toronto, Canada.

Successful outcomes in babies requiring surgery (Figure 1) demand that anaesthetists, surgeons and intensivists work together to ensure the best possible patient care before, during and after the operation. Complex surgery should be carried out in specialized centres. If minor and intermediate procedures are undertaken elsewhere, it is essential that all involved are appropriately trained and have continuing experience managing babies.



1 A baby prepared for surgery:

a covered warming matress; **b** peripheral perfusion assessed from the hand;

c ECG electrode; **d** non-invasive blood pressure cuff; **e** pulse oximeter probe; **f** rectal (core) temperature probe;

g urinary catheter measures urine output;

h intravenous access in hand;

j supplementary intravenous access in right antecubital fossa; **k** right radial (preductal) arterial catheter; **l** nasogastric tube;

m oesophageal stethoscope; **n** bar lifts the surgical drapes and allows the anaesthetist access to the airway.

Preoperative preparation

Environment

Temperature: once anaesthesia has been induced the infant's response to cold is suppressed. The operating theatre should be warmed to 24–25°C before the infant arrives. A water or air mattress should be heated to 40°C and covered with flannelette. Servocontrolled overhead radiant heaters are helpful in main-taining body temperature but must be used strictly in accordance with the manufacturer's recommendations (e.g. position a safe distance from the baby's body surface and monitor skin temperature to avoid hyperthermia. Other useful measures include warming intravenous and skin preparation fluids, and ensuring that anaesthetic gases can be warmed and humidified.

Equipment

The anaesthetic machine should incorporate the facility to deliver air in situations in which nitrous oxide is contraindicated and hyperoxia undesirable (e.g. gastroschisis, bowel obstruction).

Breathing systems – anaesthetic circuits for babies should be light, have minimal resistance and dead space, and be adaptable for spontaneous, assisted or controlled ventilation. The T piece system designed by Ayre and modified by Jackson Rees is the most widely used, though the circle absorber semi-closed system can be adapted for babies by incorporating smaller diameter breathing tubes.

Ventilators for babies should have a low internal compliance and be able to deliver small tidal volumes and rapid respiratory rates. Inspiratory flow rates and the inspiratory:expiratory (I:E) ratio should be adjustable so that peak airway pressure is kept low. Suitable ventilators can be either pressure or volume cycled. With the former, suitable settings for term babies include a fresh gas flow of 2–3 litres/minute, I:E ratio of about 1:1.5, positive end-expiratory and peak airway pressures of 5 and 20 cm H_2O, respectively, and a ventilatory rate of 30–40/minute. If volume cycling is used, a tidal volume of 10 ml/kg at a rate of 30–40/ minute is appropriate. Preterm babies (born before 37 weeks' gestation) are prone to pulmonary barotrauma; the risks are reduced by using lower peak airway pressures and faster ventilatory rates, often with an I:E ratio of 1:1.

Laryngoscopes – the larynx is higher (C4) and more anterior in babies than in adults and a laryngoscope with a straight blade (e.g. Seward or Robertshaw) provides a better view than one with a curved blade. The epiglottis is large and floppy and often obscures the larynx unless lifted by the tip of the laryngoscope blade (for which the straight blade was specifically designed).

Monitoring equipment – a complete range of monitoring equipment of suitable size for babies must be available.

Face masks are generally used for brief periods only in babies, but should provide a good fit and have a low dead space. Oral airways are not widely used.

Tracheal tubes – a cuff limits the diameter of tube that can be used and increases the risk of trauma, particularly to the cricoid mucosa, therefore, uncuffed tubes are preferred. Recommendations for the diameters and lengths of tubes for babies of different postconceptional ages are given in Figure 2, but a range of sizes should be available.

Laryngeal mask airway (LMA) – the incidence of airway complications associated with the LMA in babies is high, but it is useful if intubation is difficult. The seal achieved may not be adequate to permit controlled ventilation.

Drugs – both anaesthetic and emergency drugs should be drawn up before anaesthesia is commenced, either in finely graduated 1 ml syringes or suitably diluted in 2 or 5 ml syringes. All air bubbles should be removed to minimize the risk of air embolus.

Approximate diameter and length of oral tracheal tubes in babies

Postconceptional age (weeks)	Internal diameter (mm)	Length (cm)
< 30	2.0–2.5	7–8
30–40	2.5–3.0	8–9
> 40	3.0–3.5	9–10

2

The baby

History – even in very young babies, considerable information will have accumulated by the time of the anaesthetist's visit. This should be obtained from the parent(s) and health centre staff. Attention should be paid to birth history, gestational age at delivery and age at surgery, which is usually expressed as postconceptional age.

Trends in blood pressure and heart rate, body weight, fluid intake and output, laboratory measurements, radiographic appearances and the extent of any respiratory support required are normally available and are helpful to plan the anaesthetic technique and to anticipate problems. Knowledge of recent or current drug therapy is also important.

Physical examination – the anaesthetist should make a brief assessment of the baby's overall condition and carefully examine the individual body systems. Many surgical conditions presenting at birth are associated with other congenital anomalies, particularly congenital heart disease. Overhydration or hypovolaemia can be detected by assessing skin turgor, anterior fontanelle tension and liver size. Peripheral vasoconstriction (delayed capillary refill time) may indicate either hypovolaemia or acidosis. Jaundice is usually self-evident, but anaemia and cyanosis can be difficult to detect. Pulmonary function is also less easily evaluated than in older children and adults, but impending respiratory failure may be identified by nasal flaring, tachypnoea, chest wall recession, grunting respiration or apnoeic spells. Airway anatomy should be assessed so that potential difficulties with tracheal intubation can be anticipated.

Homeostasis – the minimum laboratory data required for most babies aged less than 44 weeks' postconceptional age includes a full blood count, blood urea and serum electrolytes, blood glucose and calcium, coagulation profile and urine specific gravity. Any abnormalities should be corrected preoperatively. If significant blood loss is expected during surgery, the infant should have blood typed and cross-matched. Body temperature should be normalized. Estimated blood volume, allowable blood loss and maintenance fluid requirements should be calculated.

Fasting – to prevent hypoglycaemia or dehydration, babies having elective or non-urgent surgery should not be starved excessively. Recommended fasting periods are generally shorter than in children (2 hours from clear non-particulate and non-carbonated fluids, 4 hours from breast milk and 6 hours from infant formula or other milk).

Coagulation – stores of vitamin K are low at birth and bleeding can occur because of depletion of factors II, VII, IX and X. Vitamin K partially reverses hypothrombinaemia rapidly and 0.5–1.0 mg is usually injected intramuscularly at birth. It is important for the anaesthetist to check that this has been given to newborns needing surgery.

Premedication – sedative premedication is not used in babies. However, many anaesthetists give an anticholinergic drug at induction to reduce secretions and protect against bradycardia. Atropine, 20 μg/kg i.v., is the most widely used drug.

Transfer to the operating theatre

Risks are minimized if the baby is accompanied to theatre by experienced personnel. Transfer should be in an incubator or an isolette with overhead heater to reduce heat loss. Any treatment in progress (e.g. intravenous fluid or drug infusion, respiratory support) and appropriate monitoring should be continued using battery-operated infusion pumps and portable equipment.

Anaesthesia

The anaesthesia plan

The anaesthetist must choose between spontaneous and controlled ventilation for maintenance of anaesthesia – it is acceptable for healthy infants to breathe spontaneously for minor procedures. Controlled ventilation should be employed when using a circle system for infants. An analgesic plan for both intra- and postoperative periods should be formulated and its potential side-effects considered. Drugs and techniques in common use are summarized in Figures 3 and 4. Intraoperative monitoring requirements must be decided in advance because access to the baby may be limited once surgery commences.

Drugs used for perioperative pain control in babies

Opioids	
• Morphine	Clearance prolonged in babies Beware respiratory depression
• Fentanyl	Well tolerated haemodynamically Care with dosing if baby is expected to breathe spontaneously postoperatively
• Alfentanil	Rapid onset, short duration of action, minimal accumulation
• Remifentanil	Ultra-short acting May be used intraoperatively by continuous infusion
• Codeine phosphate	Relatively safe; never give i.v.
Local anaesthetics	
• Lidocaine (lignocaine)	Short acting, seldom used
• Bupivacaine	Cumulation in babies after 6–12 hours if given by continuous infusion
• Levobupivacaine	May be safer than bupivacaine
Paracetamol	Useful for minor pain
Non-steroidal anti-inflammatory drugs	Seldom used, renal maturation still occurring

3

Administration of drugs used for perioperative pain control

Opioids	
• Intravenous bolus injection	Often used intraoperatively
• Intramuscular injection	Avoid if possible
• Oral	May be useful in weaning from lengthy intravenous infusion
• Per rectum	Codeine most often used
• Continuous intravenous infusion	Widely used for postoperative analgesia in ventilated infants and those nursed in high dependency areas Respiratory monitoring required
• Epidural infusion	Synergistic effect when added to local anaesthetics Risk of delayed respiratory depression
• Nurse-controlled analgesia	Becoming popular, using patient-controlled analgesia devices
Local anaesthetics	
• Wound infiltration	Can be useful
• Peripheral nerve blocks (e.g penile, ilioinguinal)	More difficult to perform than in older children
• Single-shot central block (e.g. caudal)	Action may be prolonged by clonidine or ketamine
• Intrathecal block	May be used alone for short procedures, especially in ex-preterm babies
• Epidural infusion (e.g. caudal, lumbar, thoracic)	Complication rate relatively high in babies If used alone, lack of sedation may be a problem despite good analgesia
Paracetamol	
• Oral or rectal	Use reduced doses in babies

4

Induction of anaesthesia
Intravenous access should be established before induction, preferably in a vein that the anaesthetist can check to ensure patency during surgery (e.g. the back of the hand). The anaesthetist must ensure that access to an injection port will be easy once the baby is draped so that volume expanders can be given conveniently during surgery. The dead space of the line between injection port and cannula should be minimal. Basic monitoring (ECG and pulse oximetry) should be applied. The induction technique depends on the age, size and physical status of the infant, the relative risk of regurgitation, and the personal preference of the anaesthetist.

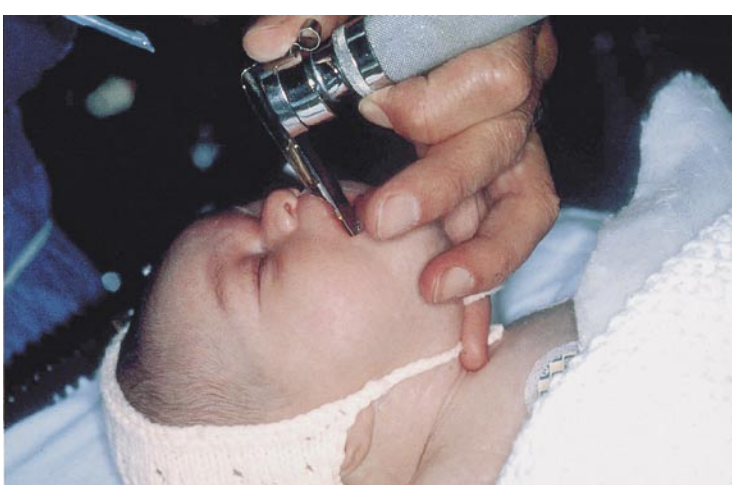
Intravenous induction – thiopental (thiopentone) sodium is the most widely used agent in infants. The induction dose (ED_{50} 3.4 mg/kg) is lower in neonates less than 14 days of age than in older babies. Experience with propofol is limited; the induction dose in infants aged 1–6 months is 25% more than that in older children. Propofol is more effective than thiopental (thiopentone) in obtunding the hypertensive response to intubation and recovery is faster. It also suppresses pharyngeal and laryngeal reflexes to a greater degree, and this has been used to facilitate LMA insertion or intubation when there is a need to avoid muscle relaxants. However it is not currently licensed for use in children below 3 years of age. Ketamine has a profound analgesic effect and is associated with greater cardiovascular stability than many other anaesthetic drugs. However, its metabolism is delayed in infants.

Inhalation induction remains popular. For many years, halothane was the most widely used volatile anaesthetic in babies. Sevoflurane is now advocated by many because it provides rapid induction with minimal airway irritation or cardiovascular effects. Induction time with sevoflurane is shorter than with halothane in older children but not in babies. Sevoflurane causes more respiratory depression than halothane in babies and young children. Desflurane, enflurane and isoflurane are unsuitable for inhalation induction because of their irritant effects on the airway. Nitrous oxide is used as a carrier to supplement volatile anaesthetics, reducing the concentration required and minimizing cardiovascular depressant effects. However, it is more soluble in blood than is nitrogen, and inhalation and diffusion of the gas causes an increase in the volume of compliant spaces. Therefore, air should be used as the carrier gas in babies with congenital diaphragmatic hernia, lobar emphysema or necrotizing enterocolitis.

Tracheal intubation
Babies should be intubated and ventilated for most surgical procedures because of their limited respiratory reserve. Most anaesthetists recommend giving a muscle relaxant (e.g. succinylcholine, 2 mg/kg, or atracurium, 0.6 mg/kg) after induction of anaesthesia to facilitate tracheal intubation. Awake intubation is seldom used because it is distressing and may be associated with intraventricular haemorrhage in preterm babies.

In babies, the epiglottis is long and floppy and should be displaced anteriorly from behind with the tip of the laryngoscope blade to aid visualization of the larynx. The view is often improved by application of cricoid pressure by either the intubator or an assistant (Figure 5). If difficulty is encountered, use of an atraumatic (but rigid) bougie can also be helpful but care should be taken to ensure that the tip of the bougie does not protrude significantly beyond the tip of the tracheal tube to reduce the risk of laryngeal or tracheal perforation.

The optimal diameter of tube is the largest that will pass easily through the glottis and subglottic region and will allow a slight leak when 20 cm H_2O positive pressure is applied. Once satisfactory positioning has been confirmed the tube should be taped securely. The anaesthesia circuit must be carefully positioned and supported.



5 A straight laryngoscope blade inserted from the right-hand side of the mouth keeps the large tongue out of the way of the intubator. A finger placed on the skin over the larynx pushes the anterior and tilted laryngeal entry in a posterior direction to give a good view and easier insertion of the tracheal tube.

Thanks are extended to Andrew R Wolf for the use of this photograph.

Maintenance of anaesthesia
Although it is acceptable for healthy babies to breathe spontaneously during anaesthesia for minor operations, prolonged anaesthesia in spontaneously breathing babies is associated with airway closure, atelectasis and increasing alveolar–arterial oxygen tension gradient.

Manual ventilation using the Jackson Rees modification of Ayre's T piece is used at times, especially when there is doubt about the adequacy of ventilation or pulmonary compliance is changing rapidly (e.g. during repair of an oesophageal fistula). Most paediatric anaesthetists revert to hand ventilation if there is any concern about the adequacy of chest wall movement or possible obstruction of the tracheal tube.

Mechanical ventilation helps to ensure adequate gas exchange and leaves the anaesthetist's hands free. Both end-tidal carbon dioxide concentration and peak airway pressure are more easily controlled. Because the amount of ventilation lost by compression of the ventilator tubing and leakage around the tracheal tube in babies is significant, readings of volume observed on a ventilator bellows are relatively meaningless. The adequacy of ventilation must be judged by auscultation, chest movement and end-tidal or arterial carbon dioxide tensions. Inspired gases should be warmed and humidified. Passive heat and moisture exchangers (HMEs) are satisfactory in most cases. Active systems such as heated water-bath humidifiers are more effective in preventing hypothermia but require the use of a servomechanism to control the temperature of the water heater.

Traditionally, halothane was the most widely used agent for maintenance of anaesthesia in babies. However, isoflurane, sevoflurane and desflurane all offer improved cardiovascular stability along with more rapid recovery. They are usually combined with 50% oxygen in air or nitrous oxide. Atracurium is an attractive neuromuscular blocking agent because its metabolism is independent of hepatic and renal function. Vecuronium should be considered long-acting in babies. Mivacurium is shorter-acting and the onset of block is more rapid in younger patients. Rocuronium causes more neuromuscular depression and has a longer duration of action during halothane anaesthesia in infants less than 2 years of age than in older children.

Termination of anaesthesia
If a volatile agent has been used during maintenance of anaesthesia it should be discontinued before the end of surgery. Residual muscle relaxation is reversed by neostigmine, 60 μg/kg, combined with atropine, 20–30 μg/kg, or glycopyrollate, 10 μg/kg. Controlled ventilation is continued with 100% oxygen or with oxygen in air until spontaneous respiration returns. Babies should not be extubated until fully awake and breathing adequately. Postoperatively they should be nursed in a warmed environment or under a thermostatically controlled radiant heater.

Monitoring
The condition of the anaesthetized baby can deteriorate rapidly with little warning. Therefore careful and continuous monitoring is essential. Figure 6 lists the minimum equipment required.

ECG electrodes designed for infants should be used. The advent of neonatal non-invasive monitors and appropriately sized cuffs has made blood pressure measurements easier. Pulse oximetry allows close observation of changes in heart rate and oxygen saturation, and reduction of inspired oxygen concentration to the minimum required to maintain adequate oxygenation (important in very preterm babies). At least one central temperature should be monitored. The precordial or oesophageal stethoscope remains valuable and is considered essential by many. It allows continuous monitoring of respiration, heart rate and rhythm, and also the intensity of heart sounds (the latter becoming muffled with hypovolaemia).

The anaesthetist should supplement monitoring with clinical observation. Assessing peripheral perfusion or palpating a peripheral pulse may prove difficult because of limited access. Even with oximetry, a light should be available to assess skin colour and perfusion. Chest wall movement should be observed continuously if possible. It should be possible to gain access to the tracheal tube.

Minimum monitoring for anaesthetized babies

- ECG
- End tidal carbon dioxide
- Non-invasive blood pressure monitor
- Pulse oximeter
- Core temperature probe
- Precordial or oesophageal stethoscope (considered by many to be essential)

6

Additional monitoring should comply with the Association of Anaesthetists' guidelines. If either the infant's physical status or the type of surgery necessitates continuous monitoring of blood pressure or regular arterial blood gas analysis, a suitable vessel should be cannulated with a 22 or 24 G cannula. The right radial artery is usually preferred because it is representative of preductal blood flow. The hand is secured with slight extension at the wrist. The fingertips are left exposed so that any peripheral ischaemic changes can be observed. Fibre-optic light sources and Doppler devices may assist in identifying the course of the artery. Cannulation is accomplished by direct entry at an angle of 15–20° or on withdrawing the cannula after transfixion of the vessel. The brachial artery is an end-artery and percutaneous puncture is more hazardous.

Central venous cannulation is useful when major shifts in intravascular volume are anticipated. The right internal jugular vein is usually the simplest and safest to cannulate. The high approach at the apex of the triangle formed by the two heads of the sternocleidomastoid muscle and the clavicle is associated with the most success. The most common complication (arterial puncture) is easily recognized and usually managed uneventfully. A 4 French gauge double-lumen catheter 5 cm in length inserted using the Seldinger technique is suitable for most babies.

Monitoring cardiac output, left atrial pressure and/or pulmonary capillary wedge pressure is seldom indicated but can be performed if necessary. For babies undergoing complex cardiac surgery, intermittent use of intraoperative trans-oesophageal echocardiography is becoming common.

Fluid balance
Maintenance fluid requirements vary in the neonatal period (Figure 7) but are about 5 ml/kg/hour for fullterm babies older than 5 days of age. 10% glucose in water is the usual starting fluid; the glucose concentration can subsequently be adjusted depending on blood glucose measurements. After 24 hours, electrolytes should be added (Figure 8). Assuming there is no fluid deficit, an intravenous infusion set at the appropriate maintenance rate should be commenced before induction of anaesthesia. The composition of the fluid administered varies according to the maturity of the baby and preoperative glucose and electrolyte levels. Fluid administration must be monitored carefully. During prolonged surgery, blood glucose levels should be checked often, especially in smaller babies, and corrected if necessary. If the surgical procedure involves significant tissue trauma and/or exposure, additional fluid must be given to replace extracellular (third-space) fluid loss. Lactated Ringer's solution is suitable in most cases. The volume required is related to the type of surgery; as little as 1 ml/kg/hour during peripheral procedures, 2–3 ml/kg/hour for thoracotomy and as much as 5–10 ml/kg/hour during major intra-abdominal surgery. There are few published data on the relative merits of crystalloid and colloid solutions in newborn surgery, and while concerns have been expressed about the cost:benefit ratio of the use of albumen (4: 5 or 20%), it remains widely used as a safe and effective volume expander. Because of the relatively high haematocrit at birth, red-cell replacement is seldom needed in newborn babies. The need for transfusion can be determined more accurately from serial haematocrit measurements than by other methods; blood loss can be extremely difficult to measure accurately. Haematocrit should be maintained at 35–40%.
When required, the blood used should be as fresh as possible. Adequacy of volume replacement can be assessed by monitoring blood pressure, central venous pressure, peripheral circulatory state and urine output (at least 1 ml/kg/hour).

Daily maintenance fluid requirements in newborns

Day	Volume (ml/kg)
1	50–80
2	80–100
3	100–120
4	120–150

7

Daily electrolyte requirements in mmol/kg

Sodium	2–4
Chloride	2–4
Potassium	1–3
Calcium	0.5–1
Magnesium	0.25
Phosphate	2–3

8

Day-case anaesthesia for babies
The lower age limit for day-case management depends on several factors including postconceptional age. Healthy fullterm babies may safely be scheduled for minor surgery as outpatients within a few days of birth provided that access to inpatient care is available should it become necessary. Preterm or ex-preterm infants are at increased risk of postoperative complications (e.g. apnoea). Most anaesthetists will not consider day-case management for these babies at less than 50 weeks' postconceptional age or even older if the infant still exhibits lung disease. ◆

Resuscitation of the Newborn

Jonathan Wyllie

Jonathan Wyllie is Consultant Neonatologist at the James Cook University Hospital, Middlesbrough, UK. He qualified from Manchester University and trained in paediatrics and neonatology in Manchester and Newcastle upon Tyne. His research interests include neonatal and paediatric resuscitation and neonatal cardiological assessment.

In the UK, about 650,000 babies are delivered each year and mostmake the transition to extrauterine life without problems. A fewrequire assistance in establishing adequate respiration and both the Royal College of Paediatrics and Child Health and the Royal College of Midwives, state that 'anybody attending a delivery should be able to deliver basic resuscitation to the baby'.

The main difference between resuscitation in adults and in children is that most adult arrests are a result of myocardial infarct or dysrhythmia, while most paediatric arrests are respiratory in origin.

Physiology

In pregnancy, the fetal lungs are net exporters of fluid. The onsetof normal labour stimulates the production of adrenaline (epinephrine) by the fetus and thyrotrophin-releasing hormone by the mother causing cells within the fetal lung to cease secretion and to begin re-absorption of fluid from the alveolar spaces.

During vaginal delivery at term, about 35 ml of fluid is expelled from the lungs by uterine contraction and passage through the birth canal. The first breath usually occurs within 60–90 seconds of clamping or obstruction of the umbilical cord. The first breaths are important in aerating the fluid-filled fetal lungs.

The healthy term baby may generate a negative pressure of between –0 and –100 cm H_2O (–3.9 and –9.8 kPa) to aerate the lungs for the first time. This pressure is 10–15 times greater than that needed for later breathing, but is necessary to overcome the viscosity of fluid filling the airways, the surface tension ofthe fluid-filled lungs and the elastic recoil and resistance of thechest wall, lungs and airways. These powerful chest movementscause fluid to be displaced from the airways into the circulation.

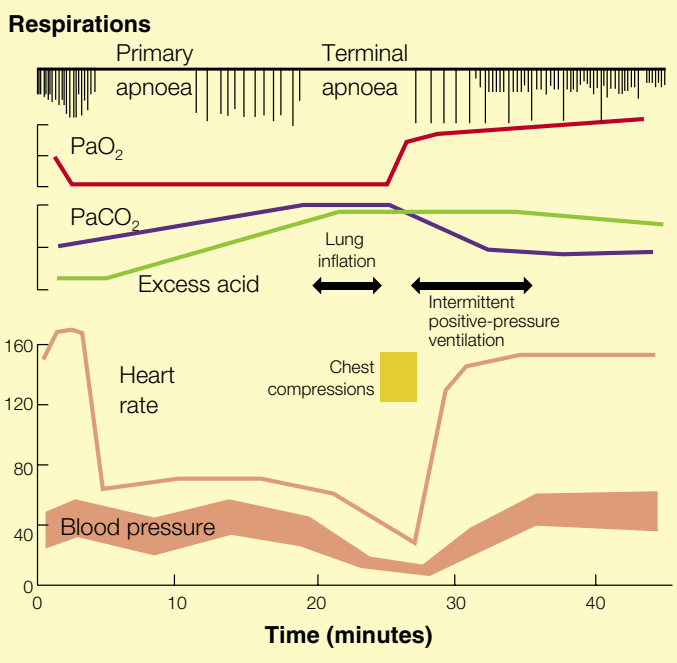
In a 3-kg baby, about 100 ml of fluid is cleared from the airways following the initial breaths, a process aided by full inflation and prolonged high pressure on expiration (i.e. crying). Delivery by section before the onset of labour may slow the clearance of pulmonary fluid from the lungs and reduce the initial functional reserve capacity. Lung inflation and alveolar distension release mediators that affect the pulmonary vasculature, reducing pulmonary resistance and increasing oxygenation.

Pathophysiology

Understanding of the pathophysiology of fetal hypoxia is based on pioneering animal work by Geoffrey Dawes, Kenneth Cross and others in the early 1960s.

When the placental oxygen supply is interrupted, the fetus initiates breathing movements. Should these fail to provide an alternative oxygen supply, the baby loses consciousness. If hypoxia is prolonged, the respiratory centre can no longer initiate breathing and stops functioning, usually within2–3 minutes (primary apnoea: Figure 1). Babies have several automatic reflex responses to such a situation. Bradycardia ensues secondary to hypoxia and vagal mediation, but peripheral vasoconstriction and an increased cardiac stroke volume usually maintain blood pressure. After a period of primary apnoea, primitive spinal reflexes initiate gasping breaths, similar to Cheyne-Stokes respiration. These deep spontaneous gasps are easily distinguishable from normal respirations because they occur 6–12 times per minute and involve all accessory muscles in a maximal inspiratory effort. If hypoxia continues, this activity eventually ceases (terminal apnoea; Figure 1). The time taken for such activity to cease is longer in the newborn (up to 20 minutes) than in later life.

Physiology of acute hypoxia and resuscitation in the newborn



PaO_2, partial pressure of oxygen in arterial blood; $PaCO_2$, partial pressure of carbon dioxide in arterial blood.

Reproduced with permission from the Northern Neonatal Network.

1

The circulation is almost always maintained until all respiratory activity ceases. This circulatory resilience is a feature of all newborn mammals at term, largely because of the reserves of glycogen in the heart. Therefore, resuscitation is relatively easy if undertaken before respiratory activity has stopped. If the circulation is still functioning then, once the lungs are aerated, oxygen is carried to the heart causing an increase in heart rate. Oxygenated blood then flows to the brain and recovery is rapid.

Once gasping ceases, the circulation starts to fail owing to the combined effects of hypoxia and acidosis and these infants may need more extensive resuscitation.

General care of the newborn

Most mature babies breathe or cry within 90 seconds of birth and few need resuscitation, even after an operative delivery. However, every newborn should be assessed at birth. Because of their small size and relatively large surface area, babies become cold very quickly. Evaporation and convection are the most important routes of heat loss for the newborn, and so the baby should be dried and wrapped in a pre-warmed towel and protected from draughts.

Resuscitation (Figure 2)

Newborn life support

Remove any wet cloths, dry the baby and cover

↓

Initial assessment at birth
Start the clock or note the time
Assess: colour, tone, breathing, heart rate

↓

If not breathing

↓

Control the airway
Head in the neutral position

↓

Support the breathing
If not breathing give five inflation breaths
(each 2–3 seconds' duration)
Confirm a response – increase in heart rate or visible chest movement

↓

If there is no response:
• double check head position and apply jaw thrust
• give 5 inflation breaths
• confirm a response – increase in heart rate or visible chest movement

↓

If there is still no response:
• use a second person (if available) to help with airway control and repeat inflation breaths
• inspect the oropharynx under direct vision and repeat inflation breaths
• insert an oropharyngeal (Guedel) airway and repeat inflation breaths
• Consider intubation
• Confirm a response – increase in heart rate or visible chest movement

↓

When the chest is moving
Continue with ventilation breaths if no spontaneous breathing

↓

Check the heart rate
If the heart rate is not detectable or slow (less than about 60 beats/minute) and not increasing

↓

Start chest compressions
First confirm chest movement – if not moving return to airway
3 chest compressions to 1 breath for 30 seconds

↓

Reassess heart rate
If improving – stop cardiac compressions, continue ventilation if not breathing
If heart rate still slow, continue ventilation and chest compressions
Consider venous access and drugs

At all stages consider whether help is required
In the presence of meconium, remember:
• screaming babies have an open airway
• floppy babies have a look

Reproduced with the permission of the Resuscitation Council (UK).

2

Equipment: all healthcare staff working in the maternity department should be familiar with the equipment available for the resuscitation of babies.

Preparation: if there is time, introduce yourself to the parents, study the obstetric notes and prepare the resuscitation equipment and area. Wash your hands and put on gloves.

Drying, covering and assessing: whatever the problem, first ensure the cord is securely clamped, then dry the baby (removing any wet towels) and cover the baby with dry towels. Drying the baby provides stimulation and allows time to assess the baby's colour, tone, breathing and heart rate. Reassess these observations about every 30 seconds throughout the resuscitation process. Consider and reconsider whether help is required and, if so, ask for it immediately.

A healthy baby is born blue but has good tone, cries within a few seconds of delivery, has a good heart rate (usually about 120–150 beats/minute) and rapidly becomes pink. A less healthy baby is blue at birth, has poor tone, may have a slow heart rate (less than 100 beats/minute) and may not establish adequate breathing by 90–120 seconds. An ill baby is born pale and floppy, not breathing and with a slow or very slow heart rate. The heart rate is best judged by listening to the chest with a stethoscope – palpating the cord does not necessarily give an accurate heart rate.

Airway: for a baby to breathe, the airway must be open. The bestway to achieve this is to place the baby on his back and to supportthe head in the neutral position. Most newborn babies have a relatively prominent occiput, which tends to flex the neck and obstruct the airway if the baby is supine. This can be avoided by placing some support under the baby's shoulders. If the baby is very floppy it may also be necessary to apply jaw thrust.

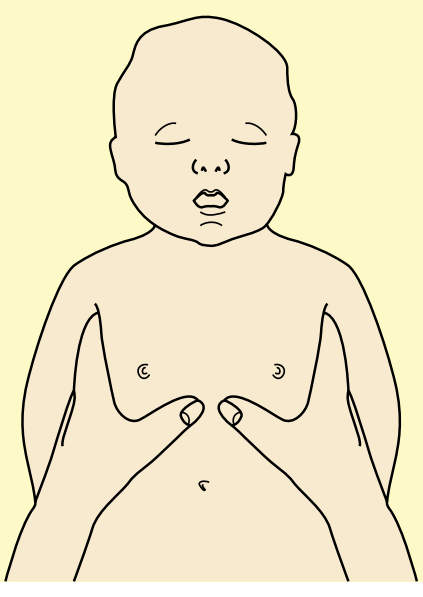
Breathing: if the baby is not breathing adequately by about 90 seconds consider giving five inflation breaths. Until this point, the baby's lungs have been filled with fluid. Lung aeration therefore requires sustained application of pressures of about 30 cm H_2O for 2–3 seconds for about five breaths – these are 'inflation breaths'. The heart rate usually increases in response to inflation breaths. If it does, assume the chest has been inflated successfully. If the heart rate increases but the baby does not start breathing for himself, continue to provide regular breaths at a rate of about 30–40 per minute until he starts to breathe on his own. If the heart rate does not increase following inflation breaths, then the chest is not inflated or the baby needs more help. It is most likely that inflation of the chest has failed. To ensure the lungs are inflated consider the following while checking for chest movement.

- Is the baby's head in the neutral position?
- Is jaw thrust required?
- Is a longer inflation time needed?
- Is a second person's help with the airway required?
- Is there an obstruction in the oropharynx (laryngoscope and suction)?
- Consider an oropharyngeal (Guedel) airway.
- Consider intubation.

If, following five inflation breaths, the heart rate remains slow or absent despite good chest movement, consider chest compressions. Make certain that breaths are being delivered because neither chest compression nor drugs will work without oxygenated blood.

Chest compressions: almost all babies needing help at birth respond to successful lung inflation with an increase in heart rate and the onset soon after of normal breathing. However, in some cases, chest compressions are necessary. In babies, the most efficient method of delivering chest compressions is to grip the chest in both hands such that the thumbs of both hands can press on the sternum at a point just below an imaginary line joining the two nipples and with the fingers over the spine at the back (Figure 3). Compress the chest quickly and firmly to reduce the antero-posterior diameter of the chest by about one-third. The currently recommended ratio of compressions to inflations in newborn resuscitation is 3:1.

Hand encircling technique for infant chest compression



3

Drugs: in a few babies (perhaps 1/1000 births), inflation of the chest and effective chest compressions are insufficient to produce an effective circulation. In these babies, drugs may be helpful. Drugs are needed only if there is no significant cardiac output despite effective lung inflation and effective chestcompression. They are listed in Figure 4 and are usually given viaan umbilical venous line. The place of drugs in the resuscitation of babies less than 28 weeks' gestation remains controversial.

Records should be clear and factual, noting the timing and sequence of events (Figure 5).

Drugs used in resuscitation of babies

Drug and dose	Route
Adrenaline (epinephrine)	
First dose, 10 μg/kg (0.1 ml/kg of 1:10,000 solution)	Via umbilical venous line
Second dose, 30 μg/kg (0.3 ml/kg of 1:10,000 solution)	Possible via tracheal tube but unproven at birth
Sodium bicarbonate,1–2 mmol/kg 2–4 ml/kg of a 4.2% solution	Via umbilical venous line
10% Glucose, 2.5 ml/kg	Via umbilical venous line

4

Records to be kept during resuscitation of the newborn

- When were you called, by whom, and why?
- The time you arrived, who else was there, and the condition of the baby on your arrival
- What you did, when you did it, and the timing and details of any response from the baby
- Assessment of the baby at birth
- The baby's heart rate at birth and when it first exceeded 100 beats/minute
- Whether gasping respiration preceded the onset of rhythmical breathing, when gasping started and how long it lasted
- When the baby started to breathe evenly, regularly and effectively 30–60 times per minute (even if gasping still occurred intermittently)
- The date and time of writing your entry and your signature

5

Special cases

Meconium: 'meconium stained liquor' is seldom a major problem in resuscitation, though it may cause problems for continuing care. Hypoxia *in utero* in the infant approaching term (over 37 weeks), leads to gut vessel vasoconstriction, increased peristalsis and a relaxation of the sphincters. This can result in passage of meconium *in utero*. In addition, fetal hypoxia, if severe, may lead to gasping and aspiration of meconium into the trachea before birth.

After delivery, meconium can cause problems if it obstructs the airway. Combined with asphyxia it causes a multi-organ problem, which is relatively uncommon in the UK. The original insult is the cause of this rare, but significant, problem. Slight coloration of liquor with meconium is not significant.

Prematurity: babies born prematurely are smaller, more likely to get cold and have fewer reserves than term babies. They may also be deficient in surfactant. Surfactant reduces alveolar surface tension and prevents alveolar collapse on expiration. Initial inflation pressure should be less (20–25 cm H_2O) to avoid lung damage, but if this pressure is inadequate it may need to be increased.

Congenital abnormality: most abnormalities are detected antenatally and only orofacial abnormalities (e.g. micrognathia, cleft lip and palate) and occasionally diaphragmatic hernia cause problems at resuscitation. The latter may be one of the few indications for intubation.

Prognosis

After resuscitation, parents will want to know the likely outcomefor their baby. Following any significant resuscitation the mostsenior person present should discuss events with the parents.

The prognosis for the full-term baby subjected to sudden acute asphyxia is usually good, provided the episode does not last for long. Most babies resuscitated from primary apnoea have no sequelae secondary to the resuscitation. Many babies who start to breathe again regularly within 20 minutes of the circulation being restored recover completely, but it is rare for a baby who is still gasping after 30 minutes to recover.

The prognosis for the preterm baby of less than about 34 weeks'gestation subjected to severe acute anoxia is less predictable. This is because of the risk of secondary intraventricular haemorrhage or periventricular intracerebral haemorrhage and/or infarction, after even a relatively brief asphyxial episode, especially in the period immediately before and after birth.

The effects of chronic hypoxia are also difficult to predict, but a reasonably clear idea of the extent of the problem should be obtainable within 36–48 hours of the original chronic asphyxial insult. A mild short-lasting state of hyperexcitability usually carries a good prognosis even if there is seizure activity, but moresevere symptoms can be associated with permanent handicap.

If no cardiac output has been established after 15 minutes, then the outcome is dire and consideration should be given to ceasing efforts. This should be a team decision; led by a senior person and with involvement of the parents. ◆

Special Considerations for Anaesthesia in the Premature Baby

Peter M Crean

Peter M Crean is Consultant Paediatric Anaesthetist at the Royal Belfast Hospital for Sick Children. He qualified from Queen's University, Belfast, and spent 2 years training in paediatric anaesthesia and intensive care in Canada. He has interests in the care of the premature infant and postoperative analgesia.

Babies are considered premature if born before 37 weeks' gestation and represent 6% of births. 7% of newborns weigh less than 2500 g. Babies weighing less than this are referred to as low birth weight (LBW) and those below 1000 g as extremely low birth weight (ELBW). ELBW babies constitute 0.5% of live births. Neonatal intensive care units (NICU) mainly cater for babies less than 28 weeks' gestation. Many of these babies are critically ill and can develop respiratory distress syndrome, life-threatening infections, intraventricular haemorrhage, heart failure or necrotizing enterocolitis.
In many premature infants scheduled for surgery, the conduct of anaesthesia is an extension of neonatal intensive care management. For this reason an understanding of the basic principles of neonatal care is essential.

Respiratory system

During fetal life the bronchial tree grows by dichotomous branching to produce 16 to 25 generations that form the future airways. Structures then develop by branching and budding to form respiratory bronchioles by 24 weeks' gestation, at which stage extrauterine survival is possible. Production of surfactant begins at about this time, though surfactant concentrations may remain inadequate until 36 weeks' gestation. The neonatal lung contains few alveoli, but alveolar growth accelerates after birth and continues until 8 years of age. Respiratory difficulties are common in preterm infants (Figure 1).

Respiratory difficulties in premature infants

- Deficiency of pulmonary surfactant leading to respiratory distress syndrome
- Risk of aspiration because of poor gag and cough reflexes, uncoordinated suck and swallow
- Compliant chest wall and weak respiratory musculature resulting in less efficient ventilation
- Periodic breathing and apnoea because of immaturity of the respiratory centre in the medulla

1

Respiratory distress syndrome

Respiratory distress syndrome is caused by surfactant deficiency and mainly affects the premature infant. The incidence is inversely related to gestational age and affects 90% of infants born at 26 weeks' gestation. Surfactant is produced by type 2 alveolar cells and, by reducing surface tension, prevents alveolar collapse at end-expiration. Deficiency of surfactant leads to reduced lung volumes, decreased lung compliance and ventilation/perfusion abnormalities. In severe cases, this results in hypoxaemia, tachypnoea and a mixture of metabolic and respiratory acidosis. Medical treatment includes oxygen delivered through a headbox, continuous positive airway pressure, mechanical ventilation and exogenous surfactant. In babies with severe respiratory distress syndrome, surfactant replacement therapy reduces mortality and morbidity and decreases complications such as pneumothorax and pulmonary interstitial emphysema. It is also beneficial when used prophylactically in babies of less than 30 weeks' gestation.

Anaesthesia may cause low lung volumes and ventilation/perfusion mismatch. The combination of immature structural development, disease and anaesthesia increases the chance of hypoxia and an anaesthetic technique based on mechanical ventilation with the use of positive end-expiratory pressure should avoid this complication. The risks of oxygen toxicity and barotrauma should also be considered during anaesthesia and the goal should be to maintain adequate oxygenation and ventilation, with the minimum oxygen concentration and peak inspiratory pressure necessary. Occasionally, surgery is required in infants suffering from respiratory distress syndrome and advice about optimal ventilator settings should be sought from a neonatologist. However, during anaesthesia with muscle relaxation, peak inspiratory pressures often need to be increased above preoperative values.

Chronic lung disease

Chronic lung disease is defined as a need for supplemental oxygen in babies of a postconceptional age of 36 weeks or term (postconceptional age = gestational age at birth + postnatal age). It is becoming more common as increasing numbers of immature babies survive. It develops in 25–30% of babies following treatment with intermittent positive-pressure ventilation on the NICU and in 5–10% of all babies less than 1500 g. Affected infants have continued oxygen requirement, indrawing, wheezing, cyanotic spells and right heart failure.

Subglottic stenosis

Acquired subglottic stenosis is a rare complication of long-term intubation in premature babies and is related to the number of intubations. Less than 1% of ventilated babies require a tracheostomy. Surgery to split the cricoid cartilage is an alternative.

Cardiovascular system

The premature infant is at greater risk of cardiovascular compromise during anaesthesia and surgery than the term infant. The fetal heart has fewer contractile units with more connective tissue than that of the infant, resulting in poor diastolic function and a decreased responsiveness to changes in intracellular calcium. The left ventricle is less compliant and cardiac output depends more on heart rate than in the term infant. Premature babies have small absolute blood volumes, therefore relatively minor blood loss during surgery can rapidly lead to hypovolaemia, hypotension and shock. Autoregulation is not well developed in premature babies and the heart rate may not increase with hypovolaemia. Also, anaesthesia blunts the baroreflexes in premature infants, further limiting the ability to compensate for hypovolaemia.

Patent ductus arteriosus

Physiological closure of the ductus arteriosus usually occurs 10–15 hours after delivery and depends on a complex process involving raised partial pressure of oxygen in arterial blood and falling prostaglandin levels. As gestational age increases, the muscular wall of the ductus becomes more sensitive to these stimuli so the ductus of a term infant tends to close more effectively than that of a premature infant. In term babies, permanent closure with obliteration of the duct lumen may take several weeks. Delayed ductus closure is more common in premature infants, occurring in 20–40% of those less than 1000 g. The clinical features are given in Figure 2.

Signs of a patent ductus arteriosus

- Bounding pulses
- Active precordium
- Loud systolic or continuous murmur at left sternal edge
- Widened pulse pressure
- Metabolic acidosis
- Apnoea

2

Congestive heart failure with pulmonary hypertension may develop in some infants, producing a large left-to-right shunt that leads to severe recurrent apnoea, intractable metabolic acidosis and the need for prolonged mechanical ventilation. Initial treatment includes fluid restriction and diuretic therapy, which may control symptoms until spontaneous closure occurs, usually at a postconceptional age of 40 weeks. However, in severely affected babies who remain in congestive heart failure and are 'ventilator dependent', surgical closure of the duct should be considered. Indometacin (indomethacin), a prostaglandin synthetase inhibitor, should be tried first. However, it is relatively common for a patent ductus arteriosus to reopen following a course of indometacin (indomethacin), especially in babies less than 1000 g, often during an episode of sepsis. Further courses of indometacin (indomethacin) are worth considering, but if severe symptoms persist, surgical ligation may be necessary. Babies with a patent ductus arteriosus, managed by chronic fluid restriction and diuretic therapy, are at increased risk of hypotension during anaesthesia.

Intraventricular haemorrhage

Intraventricular haemorrhage is common in ELBW babies and occurs in 25–30% of babies less than 1200 g; the incidence reduces with increasing gestational age. In the premature infant, the cerebral vessels are supported by a loose lattice-work of connective tissue. Under certain conditions (e.g. asphyxia), there is a loss of autoregulation of cerebral blood flow. With hypoxia, hypertension occurs and cerebral flow is not kept constant when the arterial pressure increases. Under these circumstances, bleeding can occur from capillaries in the germinal plate and blood may rupture into one or both lateral ventricles. The prognosis depends on the extent of haemorrhage with a high risk of disability if the brain parenchyma is involved.

Intraventricular haemorrhage during anaesthesia should be preventable. Abrupt fluctuations in cerebral blood flow, cerebral blood volume and cerebral venous pressure play a role in its development, therefore values should be maintained at normal levels during anaesthesia. Arterial and central venous pressures should remain constant, and rapid fluid administration, hypoxia and hypercarbia should be avoided.

Retinopathy of prematurity

In retinopathy of prematurity, marked retinal vasoconstriction occurs, which may be followed by new vascular proliferation. This leads to fibrosis, scarring and retinal detachment. Oxygen therapy is a main cause of its development but the duration and extent of high oxygen tension required are unknown. During anaesthesia, the lowest inspired oxygen concentrations should be used while avoiding fluctuations in oxygen saturation. Babies developing retinopathy of prematurity are usually born very prematurely and often have associated medical problems. By the time laser therapy for retinopathy is considered, the baby may be many weeks old and, although extubated, may have developed chronic lung disease requiring low flow oxygen therapy. An alternative to tracheal anaesthesia is ketamine sedation, which may be carried out in the NICU under full monitoring. Postoperative apnoea in these infants is discussed below.

Necrotizing enterocolitis

Necrotizing enterocolitis is an inflammatory condition that may affect the large and small bowel; about 90% of cases occur in premature infants. These babies are often very sick, requiring aggressive intensive care; 50% require surgery. Perioperative management is discussed on page 84.

The former premature infant

Inguinal hernia occurs most often in babies born before 32 weeks' gestation with a birth weight of less than 1250 g. Repair of inguinal hernia is the most common surgical operation in these babies. The operation is usually performed when the infant has been weaned from mechanical ventilation, has grown and is medically stable. This often corresponds to the time when the baby is ready to be discharged home from the NICU. Infants born prematurely are more at risk of developing complications after anaesthesia and surgery; the most serious being apnoea.

Postoperative apnoea

Although the incidence of apnoea has been reported to be as high as 81%, most investigators have found that 20–30% of otherwise healthy premature infants undergoing inguinal hernia repair under general anaesthesia develop one or more apnoeic episodes in the postoperative period. Babies are at risk of apnoea for the first 12 hours postoperatively.

Predisposing factors

Gestational age and postconceptional age – the incidence of apnoea is inversely related to gestational age and is less common when postconceptional age is more than 43 weeks. However, apnoea can occur as late as 55–60 weeks' postconceptional age.

Weight – infants born small for gestational age are less likely to develop apnoea. These infants undergo significant intrauterine stress, which can induce accelerated maturation and may offer protection against postoperative apnoea.

Anaemia – premature infants experience a decrease in haemoglobin level, which reaches its lowest level at 1–3 months of age. This is known as the 'physiological anaemia of prematurity' and is usually benign and self-limiting. Former premature infants with anaemia (Hct < 30%) are particularly vulnerable to postoperative apnoea, even up to a postconceptional age of 60 weeks.

Anaesthesia: all general anaesthetic agents, including ketamine, can cause postoperative apnoea. The methylxanthines, aminophylline and caffeine, have been used for many years for the treatment of apnoea of prematurity. Caffeine, 10 mg/kg, given at induction of general anaesthesia, reduces the incidence of postoperative apnoea.

Regional anaesthetic techniques are popular for former premature infants undergoing inguinal hernia repair. These babies can be managed successfully with spinal, caudal or combined spinal/caudal block for surgery. Regional techniques without sedation have been reported to have a reduced incidence of postoperative respiratory complications and may be more suitable than general anaesthesia in the very young.

Recommendations

- Former premature infants must be carefully observed following anaesthesia and surgery.
- Infants less than a postconceptional age of 60 weeks should be managed only as in-patients.
- The age at which these babies outgrow this anaesthetic risk is ill-defined and must be made on an individual basis taking into account factors such as growth, development and co-existing medical problems.
- If possible, surgery in otherwise healthy premature infants should be delayed until the infant's respiratory control mechanism is more mature. This corresponds to a postconceptional age of 44–46 weeks.
- In younger infants, measures should be taken to minimize respiratory problems in the postoperative period.
- Surgery should be delayed in anaemic infants and feeds supplemented with iron until the haematocrit is at least 30%. If surgery cannot be delayed, anaemic infants must be closely observed in the postoperative period. ◆

Pain

Anaesthesia
and intensive care medicine
on CD-ROM

Anatomy, Physiology, Pharmacology and Psychology of Pain

Mick Serpell

Mick Serpell is Consultant and Senior Lecturer in Anaesthesia at the Western Infirmary, Glasgow, UK. He qualified from Dundee University where he undertook most of his anaesthetic training. He specialized in regional anaesthesia and pain management at Orebro, Sweden, and Dartmouth-Hitchcock, NH, USA, and these subjects continue to be his research interests.

Pain is not simply a biological response, it is a complex interaction that involves sensory, emotional and behavioural factors, and its definition and treatment must include all these aspects. The International Association for the Study of Pain (IASP) defines pain as 'an unpleasant sensory and emotional experience associated with potential or actual tissue damage'. It is a fundamental component of the stress response to injury and therefore needs to be managed to improve patient recovery and minimize complications (Figure 1).

Pathophysiological associations of pain

- Neurohumoral alterations at site of injury[1]
- Alteration in synapses and nociceptive processing at the dorsal horn of the spinal cord[1]
- Neuroendocrine
  – increased catabolic: cortisone, glucagon, growth hormone, catecholamines
  – decreased anabolic: insulin, testosterone
  – increased plasminogen activator inhibitor (increased coagulation)
- Sympathoadrenal via adrenal gland and lateral horns of spinal cord

All of the above result in the following clinical effects

- Misery, anxiety, depression, sleep disturbance
- Increased blood pressure, heart rate and vascular resistance, increased cardiac ischaemia
- Cough inhibition (pneumonia), hyperventilation (respiratory alkalosis)
- Ileus, nausea, vomiting
- Urinary retention, uterine inhibition
- Restlessness, increased oxygen consumption
- Immobility, increased incidence of pulmonary thromboembolism

[1]Can lead to persistent pain states

1

Anatomy
Pain can no longer be viewed in terms of a simple pathway transmitting traffic from the periphery to the cortex. Although these pathways exist, the system is adaptable and dynamic. Nociception is transmitted and modulated at three levels; the peripheral nociceptor, the dorsal horn (spinal), and supraspinal (brain) levels.

Somatic pain

Physiological pain
Physiological pain, also known as first or 'fast' pain is a protective event that enables the organism to localize pain rapidly and accurately and withdraw from the stimulus in order to avoid or reduce tissue damage. It is produced by stimulation of high-threshold thermo/mechanical nociceptors and is transmitted by fast conducting Aδ fibres (Figure 2). The Aδ primary afferent enters the dorsal horn of the spinal cord and synapses at laminae I, V and X. Conduction continues along the secondary afferent fibres via the neospinothalamic tract which is monosynaptic as it ascends to the posterior thalamic nuclei. From there it synapses with tertiary afferents to the somatosensory postcentral gyrus at the cortex. If this short-duration stimulus does not result in tissue damage, the pain disappears when the stimulus stops.

Spinal and supraspinal pathways of fast and slow pain

2

Pathophysiological pain
Pathophysiological pain, sometimes called second or 'slow' pain, is responsible for the delayed pain sensation that occurs after tissue injury, which encourages tissue healing by eliciting behaviour to protect the damaged area. This is the type of pain that occurs after surgery, trauma and inflammation, and which doctors endeavour to manage in the clinical setting. It originates from stimulation of the high-threshold polymodal nociceptors (free endings) present in all tissues. The nociceptors respond to mechanical, chemical and thermal stimuli and are transmitted via slow-conducting C fibres, which synapse at laminae II and III (substantia gelatinosa) of the dorsal horn. Secondary afferents ascend cranially via the paleospinothalamic tract which is polysynaptic as it ascends to medial thalamic nuclei. It has collaterals that also project to the midbrain, pontine and medullary reticular formations, the periaqueductal grey and the hypothalamus, where they synapse on to neurons that project to forebrain limbic structures (Figure 2). This system is primarily involved with reflex responses concerned with respiration, circulation and endocrine function. They also engage descending modulatory systems. Spinoreticular tracts and spinomesencephalic tracts also supply afferent impulses. All are involved in producing the emotional and behavioural response to pain.

In addition to the two types of nociceptors mentioned above, there are 'silent' or 'sleeping' nociceptors. They are present in the skin and visceral organs and account for about 15% of C fibres. They become active only under inflammatory conditions when they may respond spontaneously or become sensitized to other sensory stimuli.

Visceral pain

Visceral pain is less well understood than somatic pain. There are functional differences between the two systems. The density of visceral nociceptors is less than 1% compared with somatic afferents and the cortical mapping of visceral afferents is also less detailed. Visceral pain is poorly localized, diffuse and often in the midline; exceptions are joints and the mesentery.

The qualitative nature of the pain is also different because the viscera are sensitive to distension. Afferent fibres respond in a graded fashion to intensity of stimulation rather than to individual stimulating modalities. Visceral pain exhibits spatial summation in that if a large area is stimulated, the pain threshold is lowered; this does not occur in cutaneous nociception.

Visceral pain can also be referred to a site away from the source of stimulation. It is often segmental and superficial, and frequently shows hyperalgesia (bladder pain can produce these effects in the peri-anal S2–4 dermatomes).

Neuropathic pain

Injury of nerve fibres can lead to abnormal functioning of the nervous system. Complete destruction, for example if a nerve is severed, usually results in complete loss of sensation and muscle power. Partial damage, which may occur after physical trauma (crush injury or surgery) or medical conditions (diabetes and shingles), can result in the preservation of gross motor and sensory function but produce subtle abnormalities such as altered temperature sensation, unusual or unpleasant feelings or even pain. This altered function occurs because the overall activity of the nervous system results from the balance between excitatory and inhibitory components. Partial damage often leads to increased activity of the nerve fibres. Treatment is aimed at suppressing the hyperactivity of the abnormal nerves.

Physiology and pharmacology

Peripheral level
Most pain originates from tissue damage. The release of inflammatory mediators from tissues, immune cells and sympathetic and sensory afferent nerve fibres results in an 'inflammatory soup' bathing the nociceptors (Figures 3 and 4). These chemicals sensitize the high-threshold nociceptors so that they can be activated by low-intensity stimuli. This results in sensitization at the site of injury or 'primary hyperalgesia'.

Some mediators act directly on ion channels in the membrane (protons and serotonin (5-HT)) but most bind to membrane receptors and act via regulatory intermediates (G-proteins and second messengers) to produce changes in membrane ion channels or enzymes. These inflammatory mediators also interact to form a complex process of events, which not only changes the short-term function of sensory afferent fibres but can also alter gene transcription. This can result in long-term alterations in intracellular biochemistry, receptor and transmitter production, which in effect changes the phenotype and behaviour of the neuron.

There are many potential pharmacological targets in the periphery (Figure 3). Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin production and are among the most common analgesic drugs used. Other targets being explored are bradykinin, substance P and nerve growth factor. Drugs blocking the action of histamines, adenosine and nitric oxide have not proved clinically useful.

Common inflammatory mediators and their effect on the primary afferent fibre

	Comments
Activate	
Potassium (K^+)	
Serotonin (5-HT)	
Bradykinin	Most potent endogenous alogenic substance known acts at the bradykinin 2 (B2) receptor
Protons (H^+)	Stimulate same receptor as capsaicin
Histamine	
ATP, Adenosine (A)	Cause pain via A2 receptor, A1 receptor analgesic
Sensitize	
Prostaglandins	Inhibited by cyclo-oxygenase (COX) inhibitors, inhibition of COX-2 accounts for the analgesic and anti-inflammatory effects
Leukotrienes	
Cytokines	Secreted from immune cells, stimulate interleukin synthesis
Nerve growth factor	Increases production of neuropeptides
Neuropeptides	Substance P, neurokinin A and B and calcitonin gene-related peptide released from sensory afferent nerves
Noradrenaline	
Nitric oxide	Sensitizes nociceptors to bradykinin
Reactive oxygen species

Spinal level

The dorsal horn of the spinal cord is the site where complex interconnections occur between local excitatory and inhibitory interneurons and the descending inhibitory tracts from the brain. The second-order neurons are of two types, some are nociceptive specific, located in the substantia gelatinosa, responding selectively to high-threshold nociception. Others are wide dynamic range (WDR) neurons or convergent neurons located in deeper laminae (V and VI) responding to a wide range of input, both nociceptive and non-nociceptive.

The gate-control theory was proposed in 1965 by Melzack and Wall to explain the variable and non-linear relationship between injury and response to pain. They proposed that primary nociceptive cells synapsed with a WDR neuron (called a T cell in the original hypothesis) which carried the impulse to higher centres. This T cell could also be excited by Aβ fibres, depending on the configuration and intensity of firing, thus proposing a hypothesis for mechanical allodynia (painful response to non-painful stimuli). Crucial to this theory was the presence of an inhibitory interneuron in the substantia gelatinosa, that prevented activation of the T cell. This interneuron could be activated by Aβ fibre firing and inhibited by the small nociceptor fibres (Aδ and C fibres). The theory proposed that pain would be 'gated-out' by stimulating the large Aβ fibres in the painful area. This is the working mechanism behind transcutaneous electrical nerve stimulation (TENS) in pain control.

However, this theory does not explain the presence of secondary hyperalgesia, which is the result of the following three spatiotemporal characteristics.

- Radiation – the area of pain enlarges past the receptive field of the primary nociceptive afferent (usually less than 1 cm^2) through recruitment of WDR neurons at caudal and rostral levels. This is termed 'secondary hyperalgesia' because it occurs outside the area of injury as opposed to 'primary hyperalgesia'.
- After response – the pain response outlasts the peripheral impulses that evoke it (hyperpathia).
- Slow temporal summation – the intensity of the pain increases if the stimulus is repeated (every 3 seconds or faster) despite the stimulus remaining at the same intensity.

These three phenomena result in a widened receptive field that exhibits exaggerated responses to noxious stimulation and increases the spontaneous discharge rate. In general, this situation is temporary and resolves with tissue healing. However, if significant tissue injury has occurred or there is nerve injury, the nervous system may dysfunction permanently and produce a chronic pain state.

Neurotransmitters at the dorsal horn

Multiple neurotransmitters play a role in the transfer of nociceptive information in the dorsal horn. The mediators fall into two categories; excitatory amino acids (EAAs) and neuropeptides. These transmitters activate the ionotropic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) and neurokinin 1 (NK-1) receptors to produce ionic depolarization of the cell. They both also activate a metabotropic receptor, which results in the production of secondary cellular messengers that prime the N-methyl-D-aspartate (NMDA) receptor to be activated. As a result, the EAAs and neuropeptides can stimulate the NMDA receptor, resulting in sustained depolarization. This receptor is pivotal to the maintenance of spinal cord hyperalgesia and therefore is a strong potential target for analgesia. NMDA receptor antagonists such as ketamine or memantine reduce allodynia and hyperalgesia but because they act on all four subtypes of the receptor, side-effects of hallucinations, sedation and amnesia are troublesome. Therefore, development of selective NMDA antagonists is required if they are to be acceptable for clinical use.

Many other neuropeptides are involved in the nociceptive process described above. Some enhance nociception, such as substance P acting at the NK-1 receptor, neurokinin A and B, cholecystokinin (CCK), calcitonin gene-related peptide (CGRP), bombesin and vasoactive intestinal peptide (VIP). Other neuropeptides are antinociceptive such as somatostatin, galanin, γ-aminobutyric acid (GABA) and glycine. These are all promising potential targets for modulation but at present there are no useful agents available for clinical use.

Currently the main form of clinical management aimed at the spinal cord level includes local anaesthetic agents and opioids. The former produce nonspecific conduction blockade of neuronal tissue though the concentration of drug can be titrated to produce a mainly analgesic effect. The opioid drugs are specifically analgesic and act on receptors that can be pre- or post-synaptic, however their predominant action is at the more numerous pre-synaptic sites. All the endogenous opioids (enkephalin, endorphin, dynorphin A) are rapidly inactivated by peptidases, therefore administration of exogenous opioids (morphine, fentanyl) is the most commonly practised technique. The opioid receptors are subject to plasticity, being down-regulated by CCK and reduced in number following nerve injury. The effects of opioids can be potentiated by α_2 agonists and NMDA antagonists and these agents may be better given in combination.

α_2-adrenergic agonists include endogenous noradrenaline, involved in the descending inhibitory pathways, or exogenous clonidine and dexmedetomidine. The latter two can be given systemically or by epidural. They offer the advantage of analgesia without the risks of respiratory depression, addiction, nausea and vomiting induced by the opioids. However, their use is limited by side-effects such as sedation, bradycardia and hypotension. Cholinergic agonists seem to enhance noradrenergic-mediated analgesia and neostigmine has been used with some beneficial effect.

CCK differs from the other nociceptive neuropeptides by indirectly antagonizing the effect of opioid μ agonists at the receptor. The amount is increased in neuropathic pain and decreased in inflammatory pain. This may explain the relative opioid resistance and sensitivity, respectively, of these two pain syndromes. Antagonists to CCK are not useful analgesics on their own but could enhance the effects of opioids. They may also be useful in tolerance and addiction and clinical trials are under way.

Midazolam produces segmental spinal analgesia probably via the benzodiazepine receptor which, once activated, forms a complex with the GABA receptor. Benzodiazepines also react with the opioid receptors, but further studies are needed to determine their potential role.

Supraspinal level

The supraspinal organization and function in nociception is largely unknown. However, it is commonly agreed that the perception of pain is associated with changes in activity of the thalamus, primary and secondary cortex and particularly the anterior cingulate cortex.

Various regions of the brain are involved with descending inhibition. These pathways originate at the level of the cortex and thalamus, and are mediated via relay stations in the brain stem such as the periaqueductal grey, nucleus raphe magnus and locus coeruleus subcoeruleus complex.

The inhibitory pathway descends the spinal cord via the dorsal columns and terminates at the dorsal horn where neurotransmitters noradrenaline, 5-HT and the endogenous opioids are released to provide antinociception. All three receptors (μ, δ, κ) play a role in the ascending pathways but the μ and δ receptors are mainly responsible in the descending component.

Noradrenaline and 5-HT synthesis and release are increased by the action of opioids and they in turn enhance the action of opioids. This may be the mechanism by which tramadol and the antidepressants work as analgesics. GABA and acetylcholine appear to be other mediators.

Psychology

Pain always has physical and psychological components. The gate-control theory was suggested to account for some of the clinical observations made about pain. For example, the observations that pain sometimes occurs without apparent cause or does not occur despite obvious injury (e.g. wounded soldiers on the battlefield), or often persists after tissue healing or fails to respond to appropriate treatment. The theory proposed that there were mechanisms in the spinal cord (see above) that increased or decreased pain signals. An example of this is the placebo response whereby an inert treatment can produce good pain control. The converse is the nocebo response in which pain can be experimentally induced despite there being no nociceptive stimulus, only a suggestion of one.

The pain experience and amount of suffering depends on many psychological parameters such as anxiety, past experience, the meaning to the patient of the pain, injury or illness, their beliefs about treatment and medications (e.g. fear of dependence, addiction, tolerance, organ damage) and self-management strategies. This applies equally to acute and chronic pain. Pain services should screen patients to address any critical psychological issues as an integral component of medical management.

One of the most commonly used techniques is cognitive behavioural therapy, in which the patient is trained to behave differently towards the pain experience by a combination of preparatory information, diaphragm breathing, muscle relaxation, guided imagery and/or hypnosis, leading to greater self-control.

Motivation and positive attitudes can be just as important to pain control and recovery, as illustrated by the phrase 'People who have something better to do don't suffer as much' (W E Fordyce, 1988).

Assessment of Acute and Chronic Pain

Gordon McGinn

Gordon McGinn is Consultant in Anaesthesia and Pain Management at the Victoria Infirmary, Glasgow, UK.

Why assess pain?
Effective control of pain requires accurate assessment. Pain is a subjective, private experience and must be made 'visible' through measurement and assessment.

Who should assess pain?
Pain is a subjective experience, therefore the patient is the most reliable assessor. Health professionals and family members can help but health professionals tend to underestimate the level of pain a patient is experiencing and family members tend to overestimate. Some patients (e.g. infants, children, the mentally impaired) are less able to communicate their pain experience. In these cases, more responsibility passes to health professionals and carers to adapt the assessment accordingly.

What to measure and assess?
The essence of pain measurement is to assign a value to pain. This can aid the overall assessment. Pain can be measured only indirectly using one of three strategies: what a patient reports about their experience (self-report); the way a patient reacts in response to pain (behavioural measures); and how the body responds to pain (physiological and biological measures).

Patient self-report is the most reliable and valid measure of pain in the clinical situation. Self-report in conjunction with appropriate measurement tools, history and examination, produces comprehensive assessment. This process requires clear communication. Those involved should have some idea of the potential barriers to communication, including: under-reporting by patients, under-assessing by health professionals or carers, language and cultural differences, impaired hearing or cognition, incorrect attitude and knowledge deficit in health professionals.

Behavioural observations have been used extensively in animal studies to infer the presence of pain. The same principles can be applied to neonates and pre-verbal children (e.g. observation of facial expression, movements, quality of cry, and sociability). However, scales relying on behavioural observations depend on context, because they are often based on patterns of behaviour during specific procedures or circumstances.

Physiological and biological measures: physiological measures include heart rate and blood pressure. Heart rate may increase in the presence of pain but alone it is not a reliable indicator of pain. At best, physiological parameters improve the discriminatory power of other measures. Some biological changes (e.g. endocrine responses) occur in association with pain, but are not used clinically.

Acute and chronic pain

Pain is a multidimensional experience that includes physical, psychological and spiritual factors. In the acute setting it may be sufficient to acknowledge the patient's anxiety and fear, attempt to reassure them and provide an explanation. The pain intensity is assessed with an expectation of a return to normality. Concentrating on the measurement of pain intensity using unidimensional scales (Figure 1) is the norm and is usually, but not always, sufficient.

In a patient with chronic pain, depression, interference with activities of daily living or interpersonal relationships, or fears regarding the future may cause more distress, suffering and disability than the pain itself. In such a situation, concentrating on pain intensity alone is inadequate. Multidimensional tools (Figure 2) look at factors in addition to pain intensity.

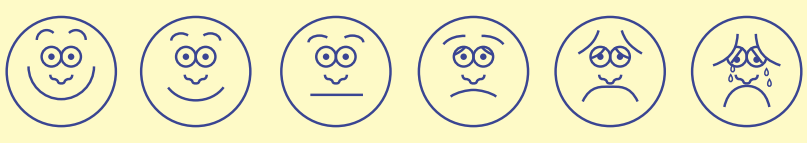
Unidimensional measures of pain intensity

Verbal rating scale
The patient rates the pain verbally (e.g. none, mild, moderate or severe)

Numerical rating scale
The patient rates pain on a scale typically from 0 (no pain) to 10 (severe pain)

Visual analogue scale
The patient indicates intensity of pain on a line typically 10 cm long marked from 'no pain' at one end to 'severe pain' at the other end. The pain is then scored in cm or mm, often with a sliding marker to aid measurement

Faces scale
The child indicates which face represents how much pain they have. Clearly this may measure other factors such as general distress rather than pain exclusively



1

Multidimensional tools for pain assessment

McGill Pain Questionnaire (MPQ)
Descriptive words are grouped into sets containing between two and six words. The words are in ranked order with a numerical score. There are 20 sets grouped into sensory, affective, evaluative and miscellaneous

Wisconsin Brief Pain Inventory (BPI)
Measures intensity and relief of pain, psychological distress, and functional impairment

Memorial Pain Assessment Card (MPAC)
A brief measure that uses 100 mm visual analogue scales to characterize pain intensity, pain relief and mood. Plus a further 8-point verbal rating scale to further characterize pain intensity

2

How to assess acute pain
Pain intensity is the main focus of acute pain, therefore it is usually, but not always, appropriate to concentrate on the biomedical model. Pain intensity is assessed from the patient's report usually aided by unidimensional measures (Figure 1).

History, examination and investigations should be tailored to the underlying cause of the pain. However, what appears as an obvious source of pain may not be what the patient is reporting. A patient who has had a laparotomy may have pain from several sites, such as the throat from tracheal intubation, the bladder from a urinary catheter, or the chest from myocardial ischaemia. Assuming the wound is the problem may lead to inappropriate treatment.

Scoring tools: the verbal rating scale (Figure 1) is a category scale. It makes a minimal demand on the patient and can be applied to individuals with some mental impairment. It is commonly used in the postoperative period, often with a score attributed to each descriptor (e.g. 0 no pain, 1 mild pain, 2 moderate pain, 3 severe pain). However, it is not a ratio scale because the increase from mild to moderate pain is not necessarily the same as the increase from moderate to severe.

Figure 3 shows an example of a postoperative pain chart using a verbal rating scale. The pain score, on movement, is plotted against time, with analgesic interventions noted. Documenting pain on movement, deep breathing or coughing helps to ensure that analgesics are used to aid appropriate mobilization and rehabilitation. The chart renders the pain and the response to analgesics 'visible'.

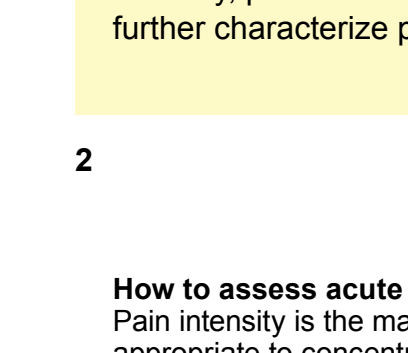
Moderate or severe pain requires analgesic interventions to be considered with reassessment. Consistent scores of no or mild pain allow progressively longer assessment intervals. There is a score 's' for sleeping. It is usually inappropriate to awaken a patient to determine pain intensity.

The numerical rating scale asks the patient to score their pain as a number whereas the visual analogue scale asks them to indicate a point on a line. Both scales are anchored at either end with descriptors, which can be altered to measure other variables such as anxiety.

The visual analogue scale is a ratio scale and is widely used in research as well as in clinical practice. A sliding marker is often incorporated, which the patient moves to the appropriate point on the line. On the reverse side, there is a scale in cm or mm that can be read off directly. These scales require more patient understanding, although, with appropriate explanation, they can be used by children as young as 5 years.

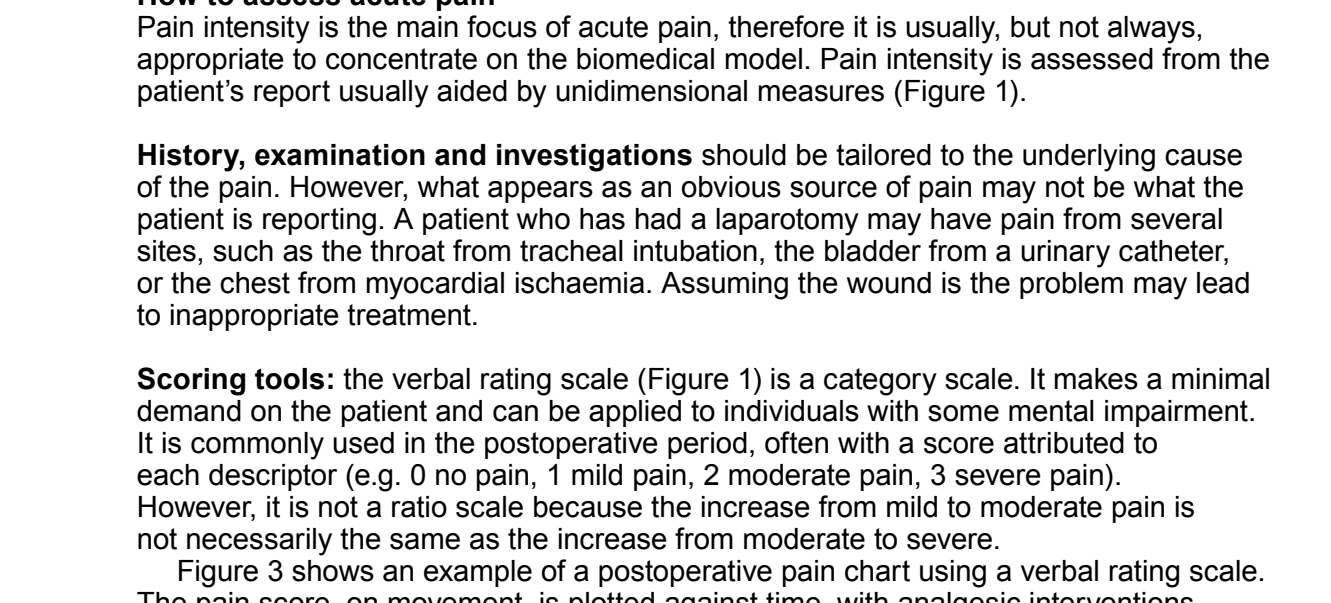
Typical pain assessment chart used in the postoperative setting

Pain score guidelines



Ask the patient: 'When you move, which of the following words best describes your pain?'

	Score
Sleeping	S
None	0
Mild pain	1
Moderate pain	2
Severe pain	3



Drug reactions and contraindicated drugs (e.g. NSAIDs) _____

3

Children: the assessment of pain in children is discussed in elsewhere in *Anaesthesia and Intensive Care Medicine*

Comparing scoring tools: mild pain corresponds to a score of less than 30 mm on a visual analogue scale ranging from 0 mm (no pain) to 100 mm (worst possible pain), moderate pain is 31–54 mm and severe pain above 55 mm.

The exact method of assessment and choice of scale is pragmatic. The choice depends on general circumstances and individual patients. However, pain intensity and its response to treatment is usually the focus.

How to assess chronic pain
In the patient with chronic pain, pain intensity is only one of many areas that require assessment. There is only a moderate correlation between pain intensity and the patient's disability, distress and suffering. Classically the domains involved are:

- sensory-discriminative (the nature, location, intensity and temporal aspects)
- affective-motivational (comprising emotions and their arousing, compelling nature to escape and avoid)
- cognitive-evaluative (how the person perceives, interprets and relates to pain).

The inclusion of psychological and social variables is described as the biopsychosocial model.

Multidimensional scoring tools: many tools are available to aid assessment of the various domains. This suggests that no single one is ideal for all situations. Some are designed for specific applications, others to assess specific aspects of a problem and some may be of use to one practitioner and not to another. Three of the more commonly used multidimensional tools (measuring more than one domain) are outlined in Figure 2.

The McGill Pain Questionnaire (MPQ) attempts to assess the multidimensional nature of pain. Scores can be obtained for the sensory, affective and evaluative descriptors as well as a total. Body diagrams allow different pain sites to be documented. The MPQ has been widely used, with versions in many languages. It takes time to complete, though a short form is available (SF-MPQ).

The Wisconsin Brief Pain Inventory (BPI) is widely used across different cultures. Numerical rating scales indicate the intensity of pain in general, at its worst and at its least and at the time of assessment. A percentage scale quantifies relief from current therapies. A body diagram allows the patient to indicate the areas involved. Seven questions, using a numerical rating scale, determine the degree to which pain interferes with general activity, mood, walking, work, relations with other people, sleep and enjoyment of life. The BPI is self-administered and easily understood.

The Memorial Pain Assessment Card (MPAC) is the briefest of the three tools outlined. The mood scale, which is correlated with a measure of global psychological distress, depression and anxiety, is considered to be a brief measure of global symptom distress.

Continuing records – asking the patient to maintain a continuing record of pain scores and other variables such as activities and sleep pattern is of great value. A patient's recall of how they were feeling days or weeks earlier varies depending on their mood and perceived pain at the time of questioning.

History, examination and investigations: a detailed history should include the medical complaint, treatments and any interaction with other health workers. It is important to gauge the patient's overall expectations because these may differ from what is felt to be realistic. The focus should then move to wider issues including their social, financial and employment situation, as well as physical and functional limitations.

Physical examination is essential as a baseline, to document the present medical condition, and to exclude other pathology. However, the absence of findings does not infer the absence of pain, because the correlation between somatic findings and pain is poor. The findings from physical examination should be added to the information gathered from assessment, with appropriate weighting. Concentrating on examination and the biomedical model may detract from assessment of the other relevant domains.

Investigations may be useful to assess the underlying disease process and to exclude other pathology. Recent advances have allowed the imaging of different parts of the brain involved in pain processing. At present, however, investigations have little clinical role in assessing chronic pain.

Multidisciplinary assessment: ideally, assessment of a chronic pain problem involves a multidisciplinary team approach. Health professionals from different backgrounds, possessing different skills, contribute to holistic assessment and management. The make-up of such teams is variable and depends on circumstances and resources. Typical teams include a physician, nurse, psychologist and physiotherapist.

Control of Acute Pain in Postoperative and Post-traumatic Situations

Carolyn M Smith
John R Colvin

Carolyn M Smith is Senior Registrar in Anaesthesia in Tayside. She qualified from Glasgow University and trained in general medicine and anaesthetics in Stirling and Falkirk, UK. Her research interests are acute pain management and intensive care medicine.

John R Colvin is Consultant in Anaesthesia and Intensive Care Medicine at Ninewells Hospital, Dundee, UK. He is also an Honorary Senior Lecturer in Anaesthesia at the University of Dundee. He qualified from Aberdeen University and trained in anaesthesia and intensive care medicine in Glasgow and Dundee. He set up the first Acute Pain Service in Scotland and was the chairman of the Scottish Acute Pain Interest Group from 1994 to 1999.

Historical perspective

During the late 1980s there was mounting concern about the treatment of acute pain. In the UK, this concern culminated in the setting up of a joint working party by the Royal College of Surgeons and the College of Anaesthetists. Their report on *Pain after Surgery* was published in 1990. The report cited papers dating back 40 years that revealed postoperative pain was badly treated, with up to 75% of patients reporting moderate to severe pain. The reasons for the poor treatment are based on inadequate and inappropriate education, poor organization and infrastructure, and other institutional issues. The report highlighted the low priority given to postoperative pain in the ward routine, the lack of education among medical and nursing personnel and the failure to provide responsible personnel to manage postoperative pain. Recommendations for improvement are listed in Figure 1.

Recommendations of Joint Colleges' Working Party Report, 1990

- A named responsible consultant with appropriate training in pain management
- Development of an interdisciplinary approach to all areas of pain management
- Continuing education of clinical staff; challenge traditional attitudes
- Continuing audit and performance appraisal
- Introduction of a scoring system to enable formal, regular assessment and recording of pain in all patients
- The provision of trained staff, equipment and facilities
- Introduce new techniques and improve use of existing techniques
- Encourage research and innovation
- Development of Acute Pain Teams

1

Progress during the 1990s
The past 10 years have seen some advancement in our understanding of the physiology of acute pain and the introduction of some new analgesics, but improvements in the quality of acute pain management have tended to focus on using existing drugs and techniques more effectively. These efforts centre on the introduction of patient-controlled analgesia (PCA) and epidural infusion analgesia, and challenge traditional thinking with improved programmes of education for clinical staff and the introduction of regular assessment and scoring of pain. In the UK, progress has been patchy, with several examples of good practice in the development of dynamic Acute Pain Teams contrasting with many hospitals where little has changed. A report from the UK Audit Commission in 1997 on provision of anaesthesia and associated services identified Acute Pain Teams in only 57% of hospitals. Studies continue to report significant levels of poorly treated pain in acute hospital patients.

More recently, the Royal College of Anaesthetists outlined guidelines for pain management services. It is of interest to note that their recommendations differ little from those of the 1990 report though there is an emphasis on integration of acute and chronic pain services.

Two other recently published guidelines relate their findings and recommendations to best available evidence. *Acute Pain Management – Scientific Evidence* from the Australian National Health and Medical Research Council (NHMRC) emphasizes the multidisciplinary approach to the treatment of acute pain and highlights many areas of acute pain outside the postoperative period requiring the services of the Acute Pain Team. In the UK, the Royal College of Anaesthetists recently issued guide-lines on the use of non-steroidal anti-inflammatory drugs (NSAIDs).

The Acute Pain Service

An anaesthesia-based multidisciplinary team approach to acute pain relief was first described by Ready in Seattle, USA. This has been developed in the UK and Wheatley and his colleagues from York District General Hospital have described one of the better examples of such an Acute Pain Service.

Various models of acute pain service delivery have been described. Generally, they come under the auspices of the anaesthesia department. In some services, the Acute Pain Team is predominantly nurse based while others are physician orientated; there are advantages and disadvantages for each. National or local resources determine which model is optimal in a given setting. UK hospitals have largely adopted the anaesthetist-based service with dedicated specialist nurse input.

Generally, analgesics are under-prescribed by doctors, under-delivered by ward nursing staff and under-demanded by patients. This results from a long-term deficit in the education of healthcare staff over many years, with what little effort there was on education about pain control under-emphasizing the benefits of good analgesia, while exaggerating the adverse effects of analgesic drugs and techniques. One of the factors inhibiting improvements in acute pain control is the requirement for extra resources. Improvements in postoperative pain control have been demonstrated following the sequential introduction of a staff education programme, pain scoring and a more proactive regimen for administering intramuscular morphine. Further, though less dramatic, improvement was seen when the more expensive ‘high-tech’ interventions, such as PCA and epidural infusion analgesia were added.

Rationale for treating postoperative pain

Pain should be treated on humanitarian grounds, though this can be difficult to prove in terms of evidence-based medicine. It is also difficult to measure patient satisfaction. However, effective postoperative pain relief is fundamental to good quality patient care and is a legitimate therapeutic goal. There is increasing evidence relating good postoperative analgesia to reduced clinical morbidity. Some authorities suggest that there may be economic benefits associated with enhanced patient well-being and early rehabilitation.

The aim of postoperative pain relief is to provide subjective comfort in addition to inhibiting trauma-induced nociceptive impulses that induce autonomic and somatic reflex responses to pain. The physiological changes brought about by pain result from activation of both central and peripheral nervous systems. Bradykinin and other peptides produce the pain, tissue oedema and hyperaemia associated with the peripheral inflammatory response. Effective analgesia may modify these responses, and may reduce the stress response to surgery.

Pain induces stress hormone responses, with activation of cytokines, adhesion molecules and coagulation factors. These responses result in numerous physiological changes promoting catabolism, sympathetic activation, hypercoagulability and immunosuppression. Hypertension, tachycardia and increased cardiac work are among the adverse cardiovascular effects of acute pain, which may compromise precarious myocardial oxygen balance in the ‘at-risk’ cardiac patient. The respiratory effects of unrelieved pain can result in significant reductions in respiratory function including the reduced ability to cough and clear secretions. Treatment of acute pain results in better cardiovascular stability, decreased respiratory complications, less gastrointestinal upset and quicker mobilization after surgery.

Less readily observed, but no less harmful, are the psychological effects of pain. Two recent guidelines stress the importance of preparing the patient psychologically for surgery and the positive value this has on patient well-being. Psychological effects may interact with physical parameters, leading to a vicious cycle of anxiety, pain and sleeplessness. This is a role that probably requires expansion in the future and would be appropriately managed by the Acute Pain Team.

There is now a significant body of opinion suggesting that effective pain control reduces the incidence of chronic post-surgical and traumatic pain.

Pain assessment

To treat pain effectively its severity must be measured (see page 428). Several scoring systems and methods are available (Figure 2). In UK wards, the observer rating generally meets with greater acceptance. Pain must be assessed at rest and during activity to allow appropriate function. Frequent pain scoring drives analgesic management and improves pain management. Many studies confirm that clinical staff underestimate patients’ pain levels unless a formal scoring system is used. Introduction of universal pain charting is facilitated by incorporating the scoring into the general observations chart.

More information on patient well-being can be obtained if a sickness scoring system and a sedation score are used in conjunction with the pain score. The sedation score is thought to be a better indicator of respiratory depression than the respiratory rate.

Pain assessment tools

- Verbal rating scale – different descriptions are used to rate the patient's pain (i.e. no pain, mild pain, moderate pain, severe pain, worst possible pain)
- Visual analogue scale – uses a 10 cm line rated from ‘no pain’ at the left to worst possible pain on the right and requires the patient to mark their pain on this line. The score is the distance from the ‘no pain’ point to the patient’s estimate
- Verbal numerical rating scale – requires the patient to rate their pain from 0 (no pain) to 10 (worst possible pain)
- Observer rating is carried out by the nurse looking after the patient – pain is rated 0, 1, 2 or 3, corresponding to no pain, mild, moderate and severe pain. This scale mixes rest and movement in its assessment, and its scientific validity can be criticized, however it provides useful language for clinical staff and has been shown to correlate well with visual analogue scale scoring
- Complex multidimensional methods – applicable to research but too cumbersome for routine use
- Inferential methods (e.g. respiratory rate or depth, cardiovascular response) are unreliable

2

Therapeutic options

In most cases, acute pain is managed solely with drugs. New drug advances have tended towards the development of agents with a better safety profile or a novel delivery route rather than more analgesic efficacy. There is increasing use of multi-modal analgesic strategies in which several analgesics are used in combination to maximize efficacy and minimize side-effects.

Opioids
Opioids are the first-line treatment for severe postoperative pain in most patients. Their use must balance the efficacy of analgesia against the occurrence of side-effects. Individual opioid requirements vary. In adults, age rather than weight has been shown to be a better predictor of opioid requirement. Morphine requirements after abdominal surgery vary by a factor of 30.

Common side-effects of opioids include sedation, pruritus, nausea, vomiting, slowing of gastrointestinal function and urinary retention. Respiratory depression, hypoxia, dysphoria, hallucinations, miosis and muscle rigidity also occur. Most side-effects are dose dependent.

Adequate doses of opioids are often withheld because of traditions, misconceptions, ignorance or fear. Both doctors and nurses fear addiction and respiratory depression, but addiction is not a problem with opioid use in severe pain. For safe and effective use the dose of opioid should be titrated to the desired effect while minimizing side-effects.

Intramuscular opiates: the dose should be based on the patient's age and medical condition, though absorption varies with muscle mass and blood flow. There is a 30-fold variation in morphine requirements after abdominal surgery, therefore a conventional regimen is unlikely to be effective in many patients. The onset of analgesia following intramuscular morphine begins after about 20 minutes with a peak effect at about 60 minutes. Injections should be given in the context of an algorithm that takes account of pain scores and potential side-effects. One such algorithm permits repeat injections on an hourly basis subject to satisfactory respiratory and sedation parameters.

Intravenous opiates: intermittent intravenous bolus doses of morphine allow titration to effect, though care must be taken not to 'overshoot'. The peak effect of intravenously injected morphine is reached at about 15 minutes and most of the effect by 5 minutes. Thus incremental titration with a 1–2 mg bolus each 5 minutes generally represents the best compromise between rapid pain relief and safety. Continuous infusion may be used to avoid peaks and troughs in pain relief. Reliable infusion devices, frequent assessment and monitoring with adjustment of infusion rates and bolus dose administration are essential for optimum safe analgesia. In UK practice, this level of care may not be achievable in a general ward setting.

Intravenous PCA allows patients to adjust the level of analgesia to their own level of comfort and tolerance of side-effects. PCA requires sophisticated infusion devices, adequate preoperative instruction, and an understanding of and ability to activate the device. PCA use has been shown to provide better patient satisfaction and improved ventilation than conventional routes of administration. Background infusions in adult patients increase the amount of opioid delivered and increase the risks of side-effects without improving analgesia.

Peripheral effects of opioids: opioid receptors are synthesized in the dorsal root ganglion and are transported centrally in C-fibre afferents to become presynaptic receptors. In the presence of inflammation, peripheral axonal transport of opioid receptors also occurs. Therefore, it might be expected that local application of opioids may have an analgesic action in damaged tissue, however, recent meta-analyses have not demonstrated significant clinical effects attributable to peripheral receptors, except perhaps in the knee joint.

Tramadol
Tramadol is a synthetic analgesic with minimal sedation, respiratory depression, gastrointestinal stasis or abuse potential. It is a weak μ agonist but it has important non-opioid spinal and CNS effects via norepinephric and serotonergic pathways. It has both opioid and non-opioid analgesic properties. The disadvantages of its use are its relative expense and the side-effects of dizziness, nausea, sedation, dry mouth and sweating. Efficacy shows a clear dose response increasing up to 150 mg, but at this dose there is a high incidence of side-effects.

NSAIDs
NSAIDs do not relieve severe pain when used alone but they are valuable in multimodal analgesia because they decrease the opioid requirement and improve the quality of opioid analgesia. They have the benefit of improved analgesia without sedation or respiratory depression and are of particular use in day case surgery, or in combination with other drugs for more major surgery.

The use of NSAIDs is limited by their side-effects, which are an extension of their pharmacological actions. Both NSAIDs and aspirin act by preventing prostaglandin production through inhibition of the cyclo-oxygenase system. New-generation NSAIDs have a more selective effect on cyclo-oxygenase 2 (COX-2), which is associated with trauma-related inflammation, and less effect on COX-1 which relates to gastrointestinal and renal prostaglandin production. These selective COX-2 inhibitors are associated with fewer gastrointestinal side-effects though they may have a similar incidence of renal and liver toxicity.

The Royal College of Anaesthetists published evidence-based guidelines on the perioperative use of NSAIDs in 1998; the key recommendations are described in Figure 3.

There is little evidence to suggest that one route of NSAID administration is superior unless fast onset is required when an intravenous preparation should be used. They are more effective when prescribed regularly and provide a useful adjunct to opioid therapy.

Recommendations of Royal College of Anaesthetists guideline on perioperative NSAID use

- NSAIDs are not sufficiently effective as the sole agent after major surgery
- NSAIDs alone are often effective after minor or moderate surgery
- NSAIDs often decrease opioid requirement
- The quality of opioid-based analgesia is often enhanced by NSAIDs
- NSAIDs increase bleeding time and some studies have shown increased blood loss

Oral analgesics
Paracetamol is effective for mild-to-moderate pain because it is analgesic and antipyretic. It is thought to act by inhibiting cyclo-oxygenase enzyme in the CNS, while sparing peripheral prostaglandin production. It is rapidly absorbed from the gut, and peak plasma levels are achieved 30–60 minutes after administration. The dose must be reduced in renal and hepatic impairment. The active component, acetoaminophen, has been introduced in some European countries. Paracetamol may be given rectally if the oral route is unavailable.

Paracetamol is more effective when combined with other compounds such as codeine, dihydrocodeine or dextropropoxyphene. Numerous different compound preparations are available. Care should be taken to avoid paracetamol overdose by mixing these compound preparations.

Relative efficacy of commonly used oral drugs and intra-muscular morphine: relative analgesic efficacy can be expressed in terms of the number needed to treat (NNT); that is the number of patients who need to receive the active drug for one to achieve at least 50% relief of pain compared with placebo over a treatment period of 6 hours. For analgesics to be considered effective they require an NNT of 2–3 or less. Because the comparison is with placebo, the NNT represents the analgesic effect over and above placebo. The total percentage of patients experiencing effective pain relief will be correspondingly greater. Of 100 patients treated with an analgesic with an NNT of 2, 50 would be expected to gain more than 50% pain relief because of the intrinsic analgesic effect of the drug. However, another 20 would be expected to gain a similar reduction in pain score owing to the placebo effect. Thus, 70 of the 100 patients would get at least 50% pain relief. In addition, others would get less than 50% relief. In many circumstances this would also represent a useful clinical effect. Caution must be exercised when interpreting such results. Figure 4 shows the relative efficacy of some common analgesics. The results have been gleaned from many meta-analyses of hundreds of clinical trials in thousands of patients. Its apparent simplicity hides the vast resource and expertise required to produce it. On the other hand, the results must be interpreted with caution because they may hide effects such as non-standardization in the pain being treated.

Relative efficacy of common analgesics

	Number needed to treat
Paracetamol, 1 g	4.6
Paracetamol, 1 g + codeine, 60 mg	3
Codeine, 60 mg	18
Dihydrocodeine, 30 mg	10
Tramadol, 50 mg	8.9
Tramadol, 100 mg	4.8
Tramadol, 150 mg	2.9
Diclofenac, 50 mg	2.3
Diclofenac, 100 mg	2.1
Ibuprofen, 200 mg	5.5
Ibuprofen, 400 mg	2.9
Ibuprofen, 600 mg	1.8
Morphine, 10 mg (single i.m. dose)	2.9

Local and regional analgesia
Simple methods include the use of topical agents such as *Emla* (eutectic mixture of local anaesthetics) or *Ametop* to provide surface analgesia. Infiltration of the operative site is well established in paediatric surgery but is of limited benefit after major surgery.

In a comprehensive qualitative systematic review of wound infiltration, 26 randomized trials were reviewed. Unequivocal benefits were reported for hernia surgery only. In other groups (e.g. hysterectomy, cholecystectomy) results were equivocal or clinically insignificant.

Nerve blocks, with or without the use of catheters, may be used for the surgical procedure or as a form of postoperative analgesia. Coexistent sympathetic blockade may be problematic or advantageous. Motor block is less troublesome with some of the newer local anaesthetic agents (e.g. ropivacaine, levobupivacaine).

Epidural infusions have the potential to improve postoperative analgesia and reduce adverse physiological changes associated with surgery. Postoperative epidural analgesia can significantly reduce the incidence of pulmonary morbidity. When combined with active convalescence, epidural analgesia may improve overall outcome. Uncommon, but important, risks relate to catheter insertion (neurological injury) and the potential for life-threatening complications (intravascular or subarachnoid injection of large doses of local anaesthetic). These factors must be considered to determine the risk:benefit ratio for each patient.

It is generally recommended that, where possible, epidurals should be placed in the awake patient. Aspiration and test doses should be used to detect subarachnoid or intravascular placement. The catheter should be placed as close as possible to the level of dermatomes affected by the surgical incision. Patients must be closely supervised with an anaesthetist readily available for advice and management of occasional life-threatening complications.

Postoperative epidural infusions may be of local anaesthetic alone or combined with opioids. Epidural analgesia, particularly when both local anaesthetic and opioids are used in the infusion, reduces postoperative morbidity and mortality. Epidurals are discussed in more detail elsewhere.

Adjuncts to drug therapy

Simple methods of pain relief include splinting or immobilizing painful areas. The application of cold compresses occasionally has a role. Transcutaneous electrical nerve stimulation (TENS) is largely in-effective for acute postoperative pain relief. Acupuncture is used particularly in Chinese medical practice. Few randomized trials exist to support the efficacy of acupuncture postoperatively.

Many factors influence the perception of pain, including past experience, personality, cultural background, anxiety and fear. Coping strategies and the ability to control events may modify the pain experience.

Relaxation training, procedural information, cognitive coping methods and behavioural instructions have been shown to improve pain scores and reduce consumption of analgesics.

Specific patient groups

Opioid tolerance and addiction
Tolerance describes the decrease in efficacy of a drug as a result of its previous administration. This is manifest as a high requirement for opiate analgesia and relative resistance to side-effects. Patients taking chronic opiate therapy require significantly increased doses of opiate in the acute situation. If the oral route is available, chronic oral opiates should be continued with parenteral supplementation as required. Intravenous PCA with frequent review of settings can help to define opiate requirements. Every opportunity should be taken to use non-opioid alternatives as adjunct or sole therapy. Surgical review is warranted if opioid requirements appear to increase rapidly, in order to rule out any surgical complication.

Addiction is unlikely following the use of opioids for postoperative pain in opioid naïve patients. When treating patients with opioid dependence or addiction it is important to realize that pain-scoring systems are unreliable. It is essential to obtain a measure of the opioid problem and to work out a management plan to return the patient to oral medication as soon as possible, using a long-acting opioid if appropriate. Patients on a methadone programme may require a slow reduction of their opioid doses and continuing assistance for total withdrawal after resolution of the acute episode. In patients still using opioids, PCA may be advantageous because it allows the use of high doses of opioids and may reduce confrontation with staff members. Background infusions are a reasonable method of delivering the patient's daily requirement. Non-opioid therapies should be considered, either as adjuncts to opioids or as alternatives, and epidural infusion analgesia may be valuable after major surgery. In the reformed addict there is significant onus on clinical staff to avoid re-establishing dependency. Patients in this category presenting for major surgery are a particular challenge but every effort should be made to avoid opiates without subjecting the patient to unrelieved pain.

Elderly patients
Pain management in the elderly should recognize their generally reduced reserve and high incidence of concomitant disease and polypharmacy. Pain assessment may be complicated by a background painful disease state, cognitive impairment and altered pain responses. NSAIDs should be used with caution because the elderly have an increased incidence of gastric and renal toxicity. Co-administration of a proton pump inhibitor should be considered if gastric ulceration is of particular concern. Opioid drugs are effective analgesics in the elderly. Patients experience a higher peak and longer duration of pain relief but they are also more sensitive to sedation and respiratory depression, probably as a result of altered drug distribution and excretion. Opioid dose titration should take into account analgesic effects and side-effects, including an awareness of possible cognitive impairment. Use of PCA should ensure careful titration of the initial dose, avoidance of accumulation by not using background infusions, and setting a longer lockout period. Regional techniques may be associated with cognitive impairment from high blood levels of opiate, when standard bolus and infusion doses are used, orthostatic hypotension from sympathetic blockade and clumsiness from partial motor or sensory anaesthesia may also occur. When regional techniques are used the dose of any opioid should be reduced accordingly.

Children
The assessment of pain in children requires modification of pain scoring systems. Preparation of the patient starts at home, psychological support may decrease fear and anxiety of surgical procedures. Familiarization with equipment and procedures preoperatively enhances the use of PCAs postoperatively. The presence of parents or carers in the anaesthetic room decreases postoperative pain and reduces adverse psychological sequelae.

Drug therapy is the mainstay of postoperative analgesia in children, but non-drug modalities may be useful. Analgesia should be given by the least painful route and regular assessment of analgesic efficacy is required. It has been clearly demonstrated that children as young as five can understand the principles and workings of PCAs.

Trauma patients
Various studies have shown that analgesia in the Accident and Emergency Department is often inadequate. Appropriate techniques are listed in Figure 5. All patients require formal assessment of pain.

Various groups require special attention; it is important to reduce the distress associated with analgesic administration in children. Insertion of an intravenous cannula allows rapid control of pain and repeated doses can be given by subcutaneous cannula to avoid repeated intramuscular injection. In the elderly, an increased frequency of adverse drug interactions warrants cautious treatment.

It was traditionally thought that pain relief masked the clinical signs of pathology, but early administration of opioids to patients with an ‘acute abdomen’ does not reduce the detection rate of serious pathology and may facilitate it.

The Acute Pain Team may make a significant contribution to the continuing management of trauma patients. The use of intercostal blocks or epidural infusion may significantly reduce pulmonary morbidity after chest trauma.

Patients with multiple injuries who are initially managed with sedation and ventilation in the ICU require considerable effort in the management of analgesia during the early stages of recovery.

Analgesia in the Accident and Emergency Department

Local anaesthetics
Used in the form of wound infiltration or nerve blocks, such as femoral nerve block for a fractured neck of femur

Entonox
An inhaled 50:50 mixture of oxygen and nitrous oxide, which may be of some use for minor procedures

Opioid analgesics
Best used intravenously with careful titration of the dose. The intramuscular route may be used, but caution is required if tissue perfusion is less than optimal

Non-opioid analgesics
Generally inadequate in severe pain but non-steroidal anti-inflammatory drugs (NSAIDs) are of value in certain conditions (e.g. renal and biliary colic) or as an adjunct to opioid therapy

Physical methods
Fracture stabilization with splints, plaster and early recourse to operative fixation if indicated

Burns
Burn pain has been underestimated and inadequately treated. The belief that third degree burns are painless is fallacious, because damaged nerve endings may result in neuropathic pain. Inadequate pain management may lead to exacerbation of the hypermetabolic state and may increase the incidence of psychological disturbances in the form of depression or post-traumatic stress disorder.

Provision of analgesia deserves high priority in patients with acute burns; analgesia improves cooperation allowing clearer assessment of burns and other injuries. Careful titration of intravenous opiate followed by PCA or intravenous infusion for maintenance is required. Standard pain scoring may require modification in these patients.

During the healing phase adequate background analgesia must be supplemented by intense analgesia for incident pain related to procedures, mobilization and physiotherapy. Again PCA is useful for background pain while a variety of techniques including peripheral nerve blocks, ketamine, benzodiazepines, *Entonox*, regular paracetamol and NSAIDs are useful for incident pain.

Future developments

The future of acute pain management lies in better education of healthcare staff, universal introduction of pain scoring and improved use of existing facilities. The challenge lies in disseminating knowledge and expertise to ensure that best practice is adopted universally.

Novel concepts such as early postoperative restoration of function and ‘fast track’ surgery require further exploration. This approach may have economic benefits in terms of reduced hospital stay, reduced convalescence, and shorter absences from work and other social benefits. The use of effective pain control in facilitating this seems obvious, but the reasons why these results have not been widely replicated remains to be determined.

A further area of evolution in UK practice is the issue of nurse prescribing, which like other aspects of traditional demarcations between health professionals is likely to come under scrutiny.

The developments of evidence-based medicine and systematic review have many applications in pain management. There is room for increased cooperation between acute and chronic pain clinicians and several national trends and initiatives will lead to greater integration.

The development of more sophisticated methods of defining quality and patient satisfaction relating to pain management will allow us to test new pain therapies and innovations in a meaningful way.

Implantable Technology for Pain Management

John Hodkinson

John Hodkinson is Consultant in Anaesthetics and Pain Management at Furness Hospital, Cumbria, UK. He qualified from Manchester University and trained in anaesthesia and pain management in Manchester, Liverpool and New Zealand. He is Director of the Morecambe Bay Trust Pain Management Programme and Neuromodulation Service with research interests in both specialist units.

Implantable devices for managing chronic pain by neuro-modulation evolved from spinal regional anaesthesia. Their use was assessed by the European Federation of Chapters of the International Association for the Study of Pain in 1998 and a consensus from this task force stated 'Neuromodulation procedures offer a non-destructive reversible alternative to the treatment of severe chronic pain where less invasive therapies and/or neurodestructive procedures are not effective or contraindicated.'

The procedures involve stimulation of the peripheral nerve, spinal cord, deep brain or motor cortex and drug delivery by the intraspinal or intracerebroventricular route. They should be performed in Pain Treatment Centres by a multidisciplinary team trained in patient selection and education, behavioural and psychological assessments and therapy, surgical implantation of the devices and continuous aftercare.

General selection criteria
Patients are suitable for an implantable device if other conservative or interventional (surgical) treatments have failed and there is no intention of pursuing those routes. The patient must give informed consent, have a realistic expectation of the outcome and a high degree of cognitive motivation.

Patients are unsuitable if they have a severe coexisting medical disease, a major psychiatric disorder or illness-seeking behaviour, poor understanding, social support and compliance, or if they abuse drugs.

Neuromodulation by stimulation

In 1965, Melzack and Wall demonstrated the gate control theory of pain. According to the theory, electrical stimulation of large diameter low threshold Aβ proprioceptive sensory nerve fibres causes suppression of small diameter high threshold Aδ and C sensory fibre activity within the dorsal horn of the spinal cord. Antidromic and summation loops are involved following stimulation of the peripheral nerve, spinal cord, deep brain and motor cortex. Stimulation of the spinal cord also influences sympathetic and parasympathetic activity with an autonomic response. Neuromodulation within the CNS by stimulation is governed by the gene–peptide link and the release and reuptake of neuropeptides within groups of wide dynamic range neurons, particularly of the dorsal horn. Release of vasoactive peptides influences peripheral vascular tone and myocardial perfusion. The types of stimulation required for each clinical group are listed in Figure 1. Specific selection criteria for the most commonly treated conditions are given in Figure 2.

Patient selection by clinical group

Site of lesion	Clinical group
Peripheral nerve	
• Peripheral nerve lesion	Trauma, incision, amputation, stump pain
• Complex regional pain syndrome (CRPS)	
Spinal cord	
• Mixed neuropathic nociceptive	Chronic mixed spinal pain, failed back syndromes
• Peripheral nerve lesion	Entrapment, trauma, amputation
• Neuralgias	Post-herpetic
• Plexopathies	Traumatic avulsion, post-radiation
• Radiculopathies	Cervical, lumbar disc, osteoarthritis
• Myelopathies	Spinal cord incomplete lesion, injury
• Polyneuropathies	Diabetes, post-chemotherapy
• CRPS	CRPS type 2
• Refractory angina	Occlusive coronary artery disease, syndrome X
• Peripheral vascular disease	Atherosclerosis, vasospastic, Raynaud's disease, Buerger's disease, CRPS type 1
Deep brain	
• Thalamic nuclei	Trigeminal neuralgia, post-herpetic neuralgia, stump or phantom pain, spinal cord lesion, post-stroke pain
• Periventricular, aqueductal grey matter	Chronic mixed failed back, neuropathic pain
Motor cortex	
• Neuropathic	Post-herpetic neuralgia, cluster headache, post-stroke, phantom pain

1

Specific selection criteria for spinal cord stimulation

Chronic low back pain
- Failed conservative therapies
- Pain experienced correlates with observed pathology
- No further surgical intervention indicated
- Drug habituation has been treated
- Psychological evaluation clearance
- No contraindications (e.g. sepsis, coagulopathy)
- Successful trial screening

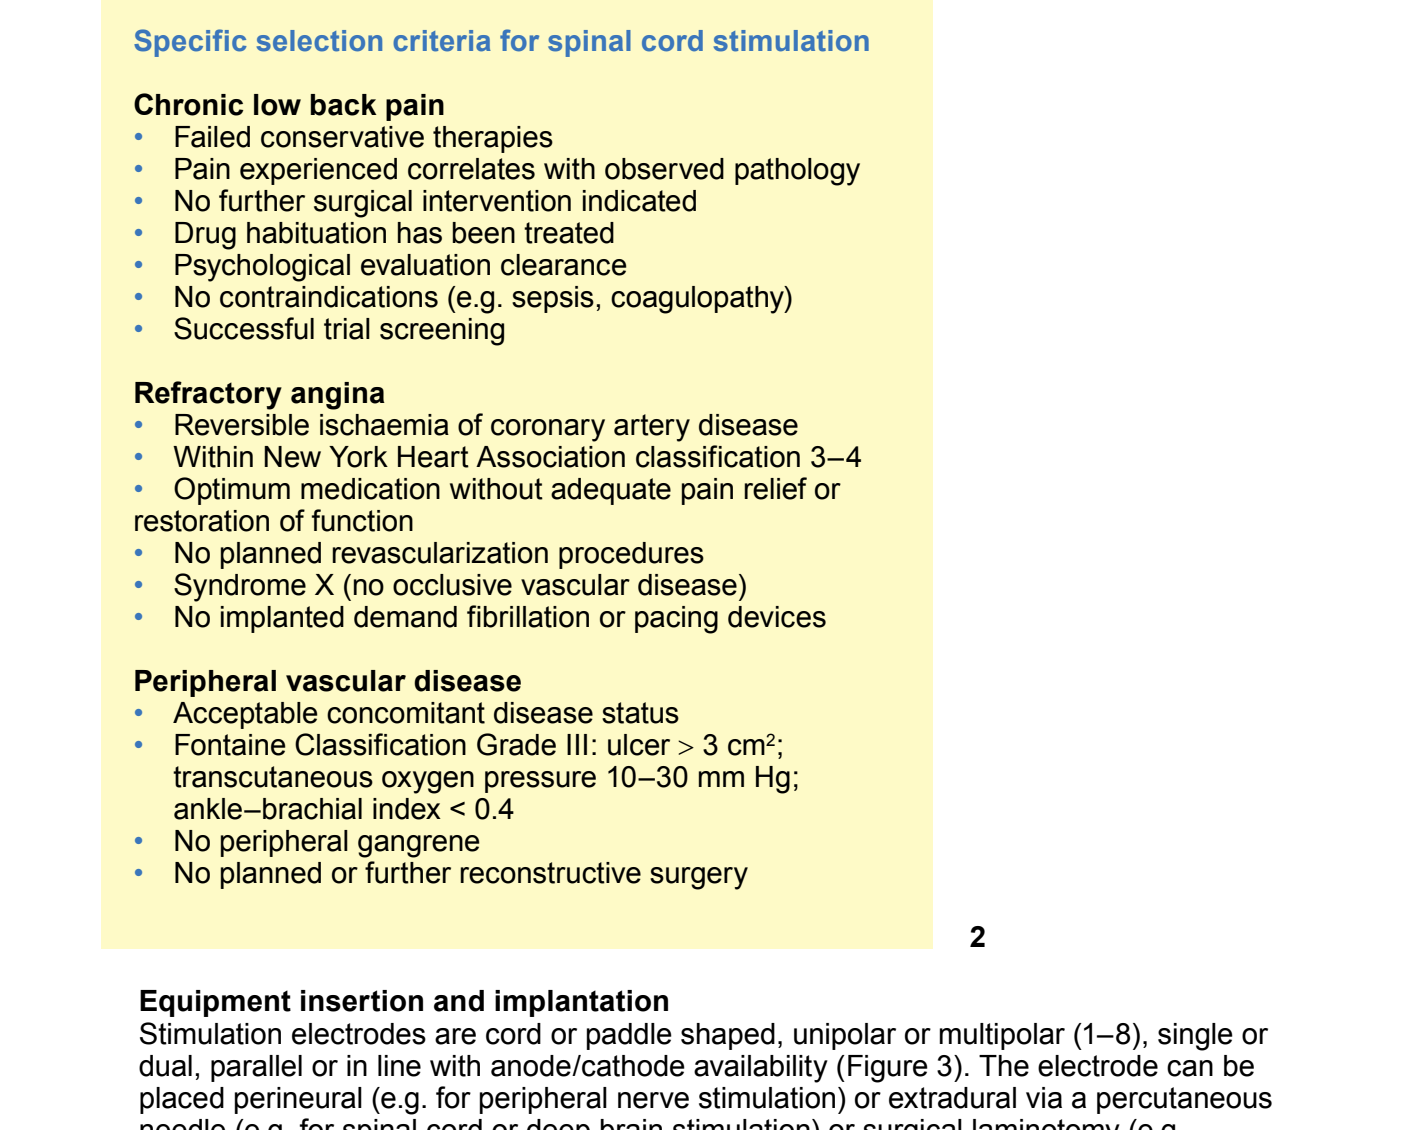
Refractory angina
- Reversible ischaemia of coronary artery disease
- Within New York Heart Association classification 3–4
- Optimum medication without adequate pain relief or restoration of function
- No planned revascularization procedures
- Syndrome X (no occlusive vascular disease)
- No implanted demand fibrillation or pacing devices

Peripheral vascular disease
- Acceptable concomitant disease status
- Fontaine Classification Grade III: ulcer > 3 cm^2; transcutaneous oxygen pressure 10–30 mm Hg; ankle–brachial index < 0.4
- No peripheral gangrene
- No planned or further reconstructive surgery

2

Equipment insertion and implantation
Stimulation electrodes are cord or paddle shaped, unipolar or multipolar (1–8), single or dual, parallel or in line with anode/cathode availability (Figure 3). The electrode can be placed perineural (e.g. for peripheral nerve stimulation) or extradural via a percutaneous needle (e.g. for spinal cord or deep brain stimulation) or surgical laminotomy (e.g. spinal cord stimulation) or craniotomy (e.g. motor cortex stimulation). Computer-aided stereotactic imaging and cortical mapping are used to guide the placement of deep brain and motor cortex stimulation. Electrode placement for spinal cord stimulation uses continuous fluoroscopy and evoked sensory stimulation (paraesthesia) as experienced by the patient at the time of placement. Figure 4 lists the common electrode placement sites. A trial period of stimulation precedes implantation of the pulse generator, which is usually placed in the abdominal wall within a subcutaneous pocket with a hardwire connection lead to the electrode through a percutaneous tunnel. An aseptic technique with broad-spectrum antibiotic prophylaxis for *Staphylococcus* is used.

Spinal cord stimulation



3

Electrode placement for stimulation

	Stimulation mapping
Spinal cord stimulation	
• Chronic mixed low back pain	D9–L1
• Chronic mixed neck pain	C2–D1
• Angina chest wall pain	C7–D2
• Peripheral vascular disease of arm	C6–D1
• Peripheral vascular disease of leg	D11–L1
Deep brain stimulation	
• Central pain	Periaqueductal and periventricular Thalamic projections
Motor cortex stimulation	
• Central pain	Broca motor cortex projections

4

There are a variety of implantable programmable devices activated by internal battery or transcutaneous radiofrequency induction, operated by the patient using a hand set (Figure 3). Operation parameters vary widely, some commonly used ranges are amplitude 2–7 volts, frequency range 30–50 Hz (motor cortex or deep brain stimulation), 50–85 Hz (spinal cord stimulation), 100–150 Hz (peripheral nerve stimulation), and a pulse width of 200–500 microseconds. Various waveform, operational and cycling modes are available and combinations of stimulation arrays within multipolar channels. Interesting effects of concentrated stimulation ('sweet spot') can be achieved by anode/cathode variation across the dorsal columns with parallel dual electrodes. Follow-up evaluation is essential. Usage guidance is provided by audit of patient experience and demand and reprogramming of parameters is often required. Fully internalized battery-operated electronic systems are reprogrammed by transcutaneous computerized telemetry.

Complications
Wound infection occurs in 5% of cases and 3% of implants require removal. Epidural abscess or haematoma may require surgical decompression.

Electrode migration occurs in 35% of cases and 23% require re-implantation. Electrode fracture occurs in 5%, and discomfort at the implantation site occurs in 13%.

Other complications include seroma formation of the pocket, a foreign body immune response causing allergic phenomena either local to the implant or systemically, and CSF leakage.

Failure of the implantable device can occur through technical failure or battery failure. Batteries commonly last for 2–6 years depending on usage and power delivery.

Neuromodulation by implantable drug delivery systems

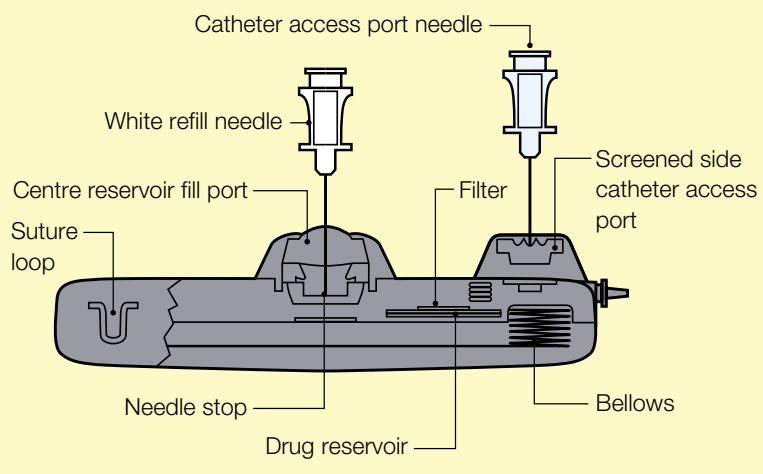
Delivery routes are intraspinal (extradural or intrathecal) and less commonly intracerebroventricular. The general indications for use are a failure of conventional treatments including stimulation, or if the oral and systemic administration of analgesic drug(s) at appropriate dose as recommended by the World Health Organization ladder does not control pain or is associated with unmanageable side-effects. A good response to a screening trial and life expectancy over 3 months is necessary. The types of pain treated include somatic, visceral, neuropathic and mixed. The clinical distribution includes failed back syndrome (42%), cancer (32%), complex regional pain syndrome (5%), post-herpetic neuralgia (5%), peripheral nerve injury (3.7%), multiple sclerosis (2.1%), spinal cord injury (1.4%) and others (8%).

Equipment, insertion and implantation

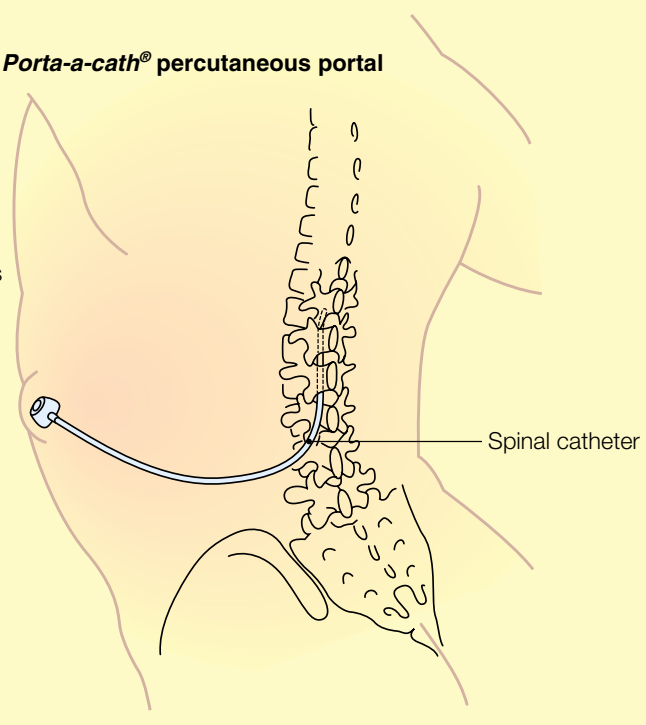
A trial epidural, intrathecal or intraventricular catheter is percutaneously inserted using an aseptic technique. Dose reductions of up to 300:1 are achieved in some cases. When titration to effect and pain control are acceptable, reinsertion of a long-term indwelling silastic catheter is performed percutaneously, tunnelled and connected to the implanted delivery device. An aseptic technique and broad-spectrum antibiotic prophylaxis is essential for the trial and implant procedures and the immediate aftercare period. The various systems used include a subcutaneous portal for continuous or bolused treatments via needle access (*Porta-a-cath*), or totally implantable pumps consisting of a primed chamber with a reservoir manually operated by patient palpation for refill and delivery of a fixed volume and dose (*AlgoMed*). The *IsoMed* is fully internalized with a primed reservoir under pressure giving constant flow delivery, and the *SynchroMed* has a primed reservoir with a battery-operated, electronically programmable, constant flow pump. All the devices are accessible percutaneously for priming the pump or reservoir, changing the drug or concentration and for a test bolus, sometimes through a separate portal (Figure 5). Drugs in common use include opioids (e.g. diamorphine, morphine, hydromorphone, fentanyl, sufentanyl, buprenorphine), local anaesthetics (e.g. bupivacaine) and α_2-agonists (e.g. clonidine). Combinations of opioid drugs, local anaesthetic and α_2-agonists are used synergistically for their dose-sparing effect, though all drugs have an analgesic property and can also be used separately.

Implantable drug delivery systems

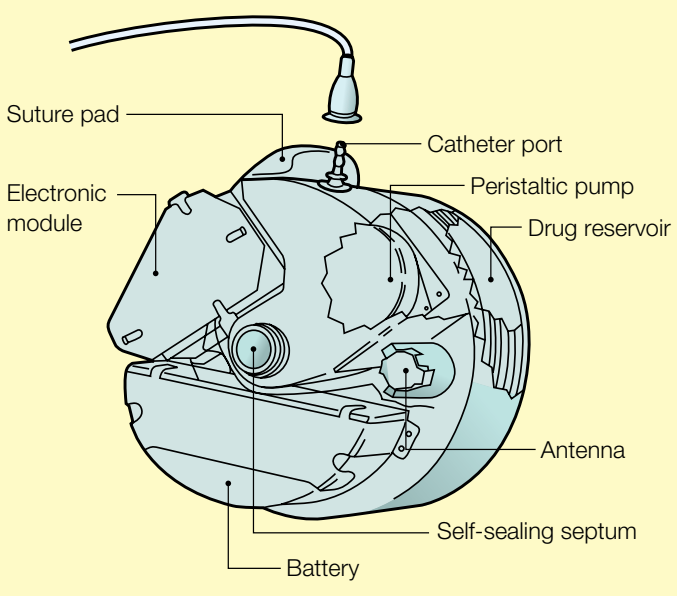
***IsoMed*® pressure chamber continuous delivery pump**



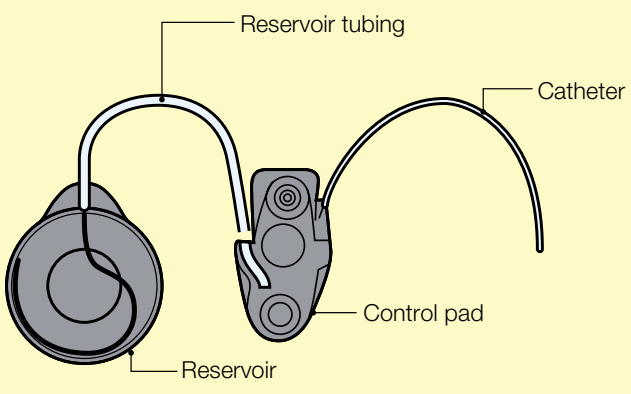
***Porta-a-cath*® percutaneous portal**



***SynchroMed*® programmable infusion system pump**



***AlgoMed*® manual peristaltic pump**



The devices require continual patient monitoring, re-priming, dosage re-adjustments or re-programming of battery-operated devices, which can be performed by transcutaneous computerized telemetry.

Complications

Complications can occur with surgery or the implantation procedure as described above. Drug overdose, tolerance and postural hypotension may occur. Side-effects of the drugs include constipation, micturition disturbance, nausea, vomiting, dysfunction of sexual potency and libido, pruritus, sweating, oedema, weakness, weight gain and nightmares. Catheter complications include migration of catheter tip, fibrosis at the delivery site and nerve root irritation. Mechanical or electrical failure of the pump device can also occur.

Clinical efficacy stimulation and pumps

Data on clinical efficacy are derived from personal and clinical practice supported by case reports and internal audit. Patient series longtitudinal data and retrospective non-randomized and randomized controlled trials have been performed, and repeated measures of sensory, psychological and qualitative dimensions show improvement of quality of life with less social dependence. The usual measurement tools and outcome predictors are visual analogue scores and psychometric questionnaires. Implantable devices are cost-effective because they reduce hospitalization and the use of medication. ◆

Inhalational Analgesia

Mick Serpell

Mick Serpell is Consultant and Senior Lecturer in Anaesthesia at the Western Infirmary, Glasgow, UK. He qualified from Dundee University where he undertook most of his anaesthetic training. He specialized in regional anaesthesia and pain management at Orebro, Sweden, and Dartmouth-Hitchcock, NH, USA. These subjects continue to be his research interests.

The advantage of administering analgesic agents via the respiratory tract is that it is a non-invasive method of achieving high plasma levels.

Analgesic agents that have a low blood-gas solubility coefficient produce analgesia of rapid onset and equally rapid elimination. These are the ideal requirements for managing intermittent and short-term pain problems. The requirements are that the substance must be either a gas, volatile substance or aerosolized. Many different agents have been used in this way, but the one most commonly used employs nitrous oxide (laughing gas); one of the earliest anaesthetic agents (Figure 1).

Most inhalational agents are anaesthetic agents used at sub-anaesthetic doses. Although the technique is inherently safe because the patient self-administers the drug, it is sometimes possible to receive an overdose resulting in depressed consciousness. Therefore care must always be taken, and the technique is contraindicated if there is no one present skilled in airway management.

Inhalational analgesics

Agent	Comments
Entonox	Nitrous oxide (N_2O) mixed with oxygen in a 50:50 mixture
Trilene	Trichloroethylene 0.35–0.5% in air. Administered via a temperature compensated *Emotril* or *Tecota* drawover vaporiser. Central Midwives Board withdrew approval for use in 1984. Slow onset owing to high blood–gas solubility coefficient, slow recovery owing to accumulation and therefore use was limited to less than 6 hours
Methoxyflurane	Methoxyflurane 0.35% in air. Administered via the Cardiff Inhaler. Even higher blood-gas solubility than Trilene, therefore slow onset and recovery. Excessive exposure can lead to 'high output renal failure'. Restrict use to less than 2 minimum alveolar concentration (MAC) hours (MAC 0.16)
Isonox	Isoflurane 0.2–0.75% in *Entonox.* The lower concentrations of isoflurane produce less drowsiness
Isodesox	Desflurane 1%, isoflurane 0.25% and oxygen 60% in nitrogen produced inferior analgesia but significantly less hypoxia than intravenous analgesia with fentanyl and midazolam

1

Nitrous oxide

Nitrous oxide is a weak anaesthetic agent (minimum alveolar concentration (MAC) 105) but a good analgesic. *Entonox* is a 50:50 mixture of nitrous oxide and oxygen and comes in a pre-mixed blue cylinder. Both substances are in the gaseous form but nitrous oxide can liquefy if the cylinder is cooled to –7° C. The cylinder would then initially deliver a high oxygen-containing mixture, but eventually hypoxic pure nitrous oxide would emerge. If accidentally exposed to low temperatures, the cylinder must be warmed up and agitated to ensure thorough mixing of the gases. The gas is administered through a demand valve that is activated by an inspiratory effort of–3 to –5 cm H_2O.

Since the mid 1930s, *Entonox* has been popular in the labour suite as a form of patient-controlled analgesia because it can be self-administered through a mask or mouthpiece. Onset of analgesia occurs within 30 seconds, peaks in 40–120 seconds and dissipates rapidly after discontinuation. For this reason, it is very useful for intermittent pains such as labour contractions and renal colic, or procedural pain such as change of burns dressing, removal of chest drains, insertion of cardiac pacemakers or oocyte recovery. The side-effects of *Entonox* are listed in Figure 2.

Side-effects of *Entonox*

- Drowsiness, nausea
- Augments the effects of respiratory depressant drugs
- Excitability
- Diffuses rapidly into and increases air-containing cavities (i.e. could exacerbate pneumothorax, blocked sinuses, air embolism)

Prolonged and excessive exposure may lead to

- Inhibition of B_{12} coenzyme, methylcobalamin, which results in depression of haematopoietic cell proliferation in bone marrow
- Megaloblastic anaemia, leukoplastic anaemia
- Myeloneuropathy resembling subacute combined degeneration of the spinal cord
- Environmental pollution

2

Other volatile anaesthetic agents

Other volatile anaesthetic agents used for analgesia (Figure 1) include isoflurane and desflurane. They are suitable because they have a low blood-gas solubility coefficient and therefore rapid onset and are the least metabolized of all the volatile anaesthetic agents. Owing to the fact that they are mixed with at least 50% oxygen, desaturation occurs less frequently compared with intravenous analgesic methods. Nitrous oxide produces analgesia for experimental pain in humans but isoflurane does not seem to exhibit any specific effects on pressure, heat or cold induced pain. Isoflurane may produce clinical analgesia by its potent hypnotic and sedative properties.

Opioid drugs

Opioid drugs can also be administered by inhalation. Butor-phanol, 1 or 2 mg, delivered intranasally by a metered dose spray pump relieves pain within 15 minutes after dental impaction surgery. Fentanyl can also be administered intranasally with good short-term effect. The drugs are principally absorbed systemically via the highly vascular nasal mucosa although there may be some direct central absorption through the cribriform plate to the brain.

Alternatively, fentanyl and morphine have been given in an aerosolized form for pulmonary absorption. Fentanyl, 100–300 µg, administered either in the intravenous or aerosol form, produced similar plasma concentrations of rapid onset. These non-invasive and transportable techniques have strong potential for field and domicillary use, and for patient-controlled analgesia without the need for intravenous cannulae.

Environmental exposure

The recommended upper limits for environmental exposure of inhalational agents averaged over an 8 hour period are 100 parts per million (ppm) for nitrous oxide and 50 ppm for isoflurane. These values are more stringent in North America, where for example the values are 25 ppm for nitrous oxide and 2 ppm for other halogenated agents. Inhalation analgesia will undoubtedly cause some pollution due to leakage round the mask, but this can be minimized by using a well-fitting face mask and an operational scavenging system. One group recorded 85 ppm for nitrous oxide in a maternity unit without scavenging and could not identify any significant haematological effects.

Management of Severe Pain in Advanced Cancer

Alison C Mitchell

Alison C Mitchell is Senior Registrar in Palliative Medicine in the Beatson Oncology Centre, Glasgow, UK. She qualified from Dundee University and trained in anaesthesia before embarking on higher specialist training in palliative medicine. Her research interests include neuropathic pain and its treatment in advanced cancer.

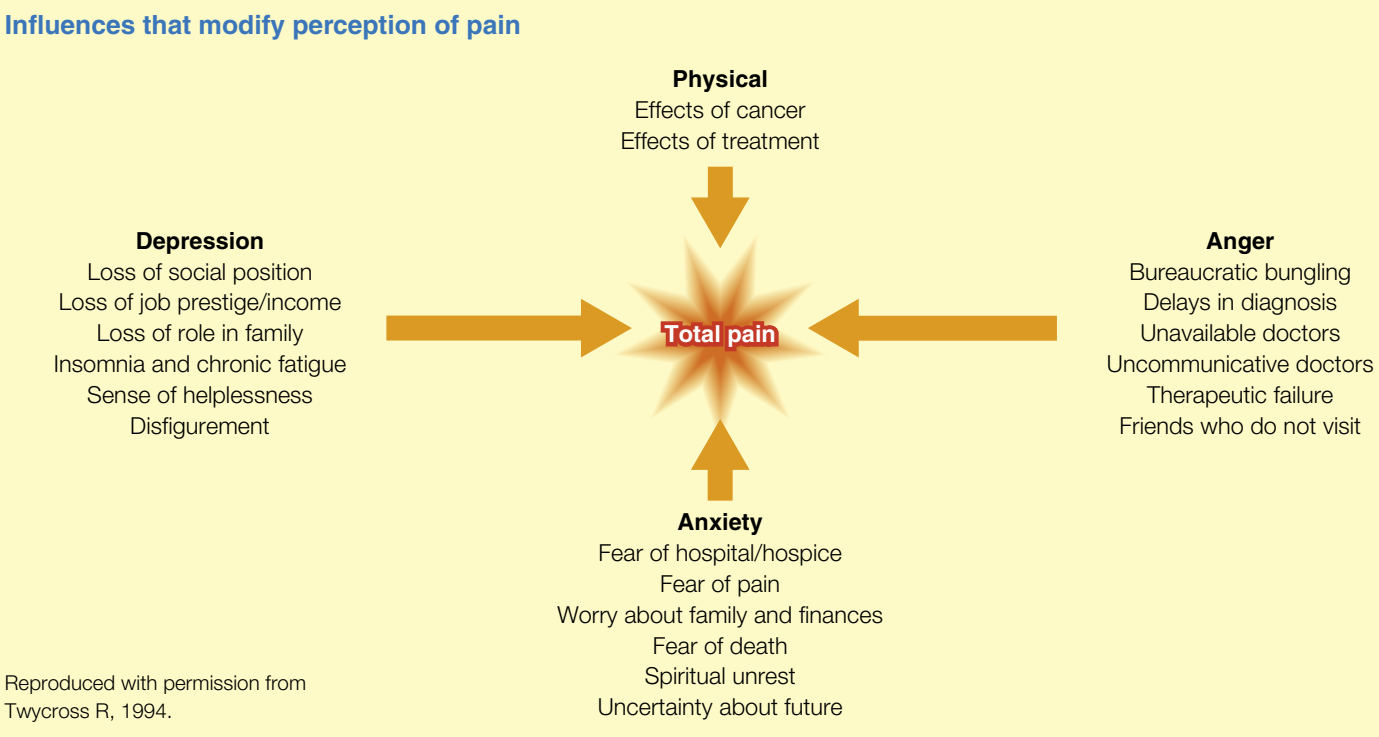
Worldwide there are estimated to be 17 million patients living with cancer. One-third of these patients who receive anti-cancer treatment will experience pain. In patients with advanced disease, more than two-thirds experience pain, and symptom management becomes the principal aim of treatment. In this group of patients, more than 80% can experience pain relief with regular oral analgesia, if a systematic approach to pain management is adopted.

Pathophysiology
Pain in advanced cancer can be caused by a variety of patho-physiological mechanisms. These can be divided into three main groups.

- The pain can be associated directly with the tumour itself. Metastatic bone disease, nerve compression or infiltration and visceral infiltration are the most common causes of pain from direct tumour involvement.
- The pain can be related to the anti-cancer treatment. This group includes pain secondary to surgical intervention, chemotherapy and radiotherapy.
- The pain is unrelated to the cancer or cancer treatment.

The pain experienced by cancer patients is multidimensional (Figure 1) and recognizing this is essential for effective pain management. The spiritual, psychological and social aspects of the patient's suffering must be addressed along with the physical symptoms, or the pain may continue unrelieved.

Influences that modify perception of pain



Reproduced with permission from Twycross R, 1994.

1

Evaluation of pain
A careful history and examination of the patient are essential to determine the most likely cause of the pain (Figure 2). Two-thirds of patients with advanced cancer have two or more distinct pains, and these should be dealt with individually. It is vital to take a detailed history of the analgesic medications that have been tried and a measure of their effectiveness. This will include details of the dose used, whether it was taken on a regular or 'as required' basis, over what period and any side-effects experienced. It may be appropriate to order further investigations to elucidate the cause of the pain.

Evaluation of pain in cancer (WHO, 1994)

- Believe the patient's report of pain
- Initiate discussions about pain
- Evaluate the severity of the patient's pain
- Take a detailed history of the pain
- Evaluate the psychological state of the patient
- Perform a careful physical examination
- Order and personally review any necessary investigations
- Consider alternative methods of pain relief
- Monitor the results of treatment

2

Pain relief in advanced cancer requires a multidimensional and often a multiprofessional approach (Figure 3). It may be appropriate to try to modify the pathological process with surgery, chemotherapy or radiotherapy.

Pain management in advanced cancer

Examination

Explanation
- Reduces psychological impact of pain

Modification of disease process
- Surgery
- Chemotherapy
- Radiotherapy
- Hormone therapy

Analgesia
- Non-opioids
- Opioids
- Adjuvant drugs

Non-drug pain-relieving procedures
- Physical
  - TENS (transcutaneous electrical nerve stimulation)
  - Heat pads
  - Acupuncture
- Psychological
  - Relaxation techniques
  - Cognitive behavioural therapy
  - Psychodynamic therapy

Modification of pain pathway
- Peripheral nerve blockade
- N-methyl-D-aspartate (NMDA) receptor blockade
- Neurolytic procedures
- Neurosurgery

Lifestyle modification
- Immobilization
- Walking aids
- Wheelchair
- Hoist

3

Drug treatment

Morphine remains the strong opioid of choice for the treatment of cancer pain. However, newer synthetic opioid analgesic drugs may be more appropriate in individual patients.

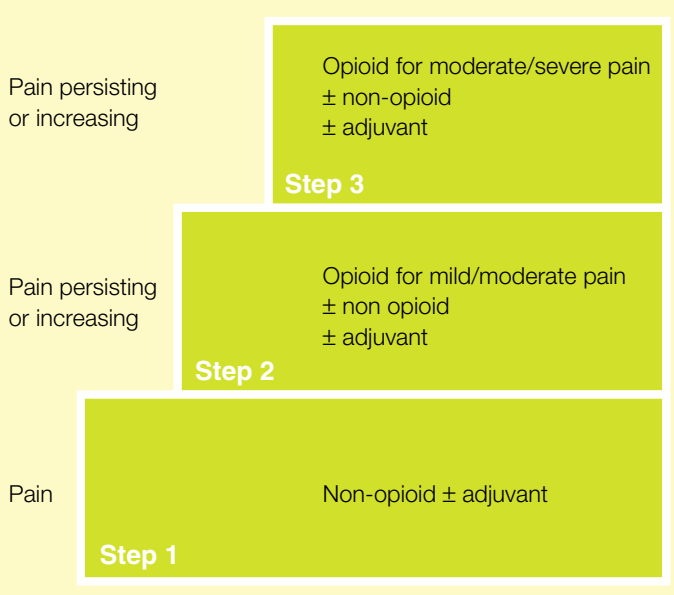
Over 80% of patients with advanced cancer can achieve complete pain control by application of six basic principles for cancer pain relief set out by the World Health Organization (WHO).

By mouth – morphine and several other strong opioid preparations are effective orally and should be taken orally for as long as gastric absorption is unimpaired. This allows patients control of their own medication.

By the clock – analgesia should be prescribed at regular intervals and not on an 'as required' basis because this necessitates that the patient must be in pain before requesting a further dose of analgesia. If the analgesia is given on a regular basis the drug plasma concentration remains relatively stable and the patient experiences more constant pain relief.

By the ladder – the WHO recommended titration of analgesic strength to severity of pain is shown in Figure 4. As the pain increases so should the strength of the analgesia prescribed, with appropriate use of adjuvant analgesia. If a step 2 analgesic drug given regularly does not provide adequate analgesia, it is not appropriate to change to an alternative step 2 drug; a step 3 drug should be commenced.

WHO analgesic ladder



4

Individual treatment – there are no standard doses for opioid drugs. The 'right' dose for a patient is the dose that relieves that patient's pain.

Supervision – the response to analgesic treatment should be monitored carefully to achieve a balance between therapeutic benefit and unwanted side-effects.

Adjuvant drugs fall into three groups, secondary analgesic drugs, psychotropic medication, and drugs to combat predictable opioid side-effects (Figure 5). A laxative is nearly always necessary and an anti-emetic is required in up to 50% of patients when commencing strong opioid analgesia.

Adjuvant drugs

Secondary analgesic drugs
- Corticosteroids
- Anticonvulsants
- Antidepressants
- N-methyl-D-aspartate (NMDA) receptor antagonists
- Membrane stabilizing drugs

Psychotropic medication
- Anxiolytic agents
- Night sedation

Drugs to counteract adverse effects of analgesics
- Laxatives
- Anti-emetics

5

Dose titration
It is important to titrate the dose of opioid required to the individual patient. This can be achieved by starting a regular dose of a short-acting formulation of morphine (either tablets or elixir). An appropriate starting dose for patients stepping up from a regular step 2 analgesic is morphine, 10 mg every 4 hours. The patient should also be prescribed a dose equivalent to that of the regular 4-hourly morphine to be given as often as needed between the regular doses of morphine. This makes allowance for the occurrence of 'breakthrough' pain.

After 24–48 hours, the patient and the analgesic requirements are reassessed and the regular and breakthrough doses of morphine adjusted. Generally the dose of morphine (both regular and breakthrough) is increased by 25–30% at each dose adjustment, though this will be guided by the number of breakthrough doses of analgesia that the patient has required. By titrating the dose of morphine against the effect, the various factors that contribute to the variability in dose are accounted for. These include the type and severity of the pain, any psychological component of the pain and individual variations in pharmacokinetics.

Once the patient has achieved good analgesia and requires a maximum of two breakthrough doses of morphine in 24 hours, it may be appropriate to convert to a long-acting morphine preparation. These are available as slow-release preparations either as a once daily dose lasting 24 hours or a twice daily preparation lasting for 12 hours.

Opioid side-effects
The common side-effects of strong opioid analgesics are well recognized and predictable (Figure 6). The initial side-effects of nausea and vomiting, drowsiness, delirium and unsteadiness tend to wear off after the first few days, but they may reappear temporarily after a dose escalation. Patients should be warned about the potential side-effects and given appropriate medication to counteract them. Occasional side-effects include sweating, myoclonus and urinary retention.

Adverse effects of opioid analgesics

Common initial
- Nausea and vomiting
- Drowsiness
- Unsteadiness
- Delirium (confusion)

Common continuing
- Constipation
- Nausea and vomiting

Occasional
- Dry mouth
- Sweating
- Pruritus
- Hallucinations
- Myoclonus

Rare
- Respiratory depression
- Psychological dependence

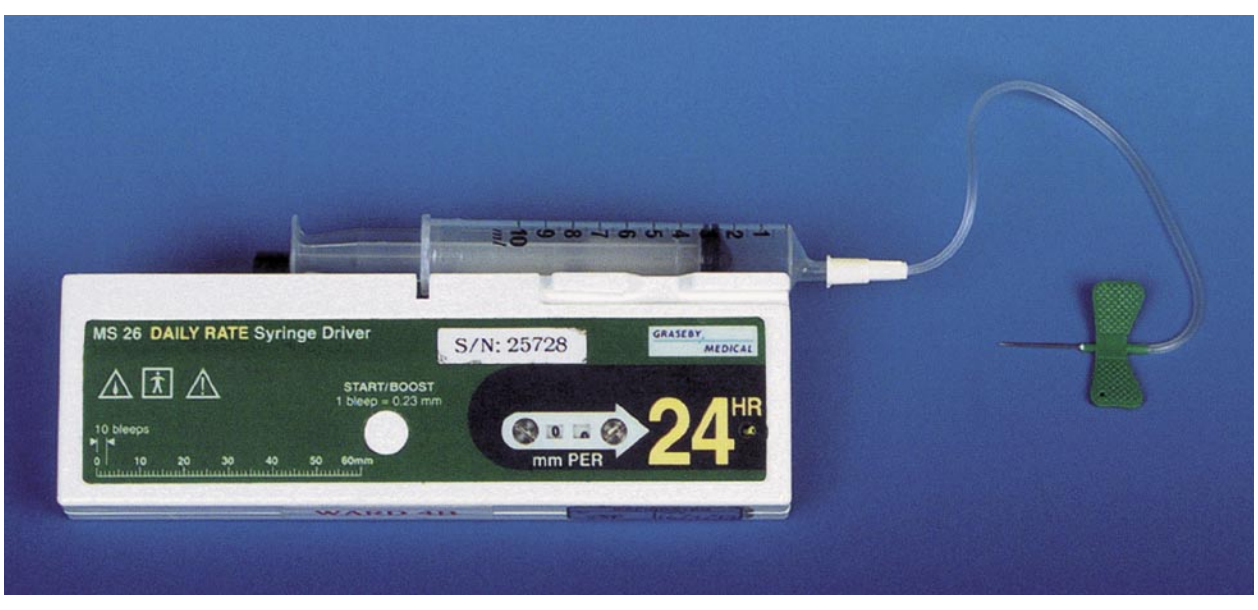
6

In particular, it is important that patients are not dehydrated while taking morphine because impaired renal function increases and prolongs the therapeutic and adverse effects of this drug.

Nausea and vomiting occur in 33–50% of patients taking oral morphine. In most patients, this resolves after the first few days of use, but for a few it may persist and be difficult to control. Suitable anti-emetics are metoclopramide, 10–20 mg q.d.s., or haloperidol, 1.5 mg at night. They can be given subcutaneously using a syringe driver if vomiting persists.

Constipation and a dry mouth continue for the duration of opioid treatment. Laxatives should be given prophylactically and should include a stool softener (e.g. docusate sodium, glycerol) and a peristaltic stimulant (e.g. bisacodyl, senna). Dry mouth should be dealt with by maintaining good oral hygiene and ensuring adequate hydration either orally or parenterally by the intravenous or subcutaneous route.

Alternative routes of administration
It may be necessary to use an alternative route of administration if the oral route becomes difficult or impossible. Morphine can be delivered rectally in suppository form at a dose equivalent to that taken orally. However, it may be more convenient to convert directly from the oral route to the subcutaneous route using a portable syringe driver (Figure 7). This delivers a continuous infusion of the required drug (usually morphine or diamorphine). The relative potency of the opioid delivered increases when it is given parenterally. Therefore the 24-hour dose of oral morphine should be divided by two to reach an equianalgesic dose of subcutaneous morphine, and by three to reach the equianalgesic dose of diamorphine.



7 Portable syringe driver.

The transdermal route can also be used to deliver fentanyl in patients unable to take oral medication.

Patient-controlled analgesia can make effective use of the intravenous route, particularly when the patient can anticipate the pain (e.g. dressing changes).

Opioid alternatives to morphine
In patients with opioid-sensitive pain who cannot tolerate the side-effects of morphine, it may be appropriate to try an alternative strong opioid. As these vary in potency in relation to the equianalgesic dose of morphine, care is essential. For patients who have had good pain control the starting dose of the new drug should be reduced to 50–75% of the equianalgesic dose to allow for incomplete cross-tolerance. If pain control was poor on the previous regimen, the starting dose of the new drug can be about 75–100% of the equianalgesic dose.

Hydromorphone is a synthetic morphine congener that is about seven times more potent than morphine. It is available in oral quick-release and long-acting preparations as well as parenterally.

Oxycodone is a synthetic derivative of thebaine. It is twice as potent as oral morphine. It is available in oral quick-release and long-acting preparations.

Diamorphine is a semi-synthetic analogue of morphine. It is classified as a pro-drug because it is biotransformed to 6-acetylmorphine and morphine to achieve its analgesic effect. It is delivered parenterally, and in this form is about three times as potent as oral morphine.

Transdermal fentanyl is a semi-synthetic opioid, which is released gradually from self-adhesive patches. The patch is changed every 72 hours. There is a slow onset of effect because it takes 12–24 hours to reach steady plasma fentanyl concentration. There is an equally slow decline in plasma drug concentration when the patch is removed. It is therefore suitable only for patients with stable pain.

Opioid responsiveness
Opioid responsiveness is not an all-or-nothing phenomenon, but a continuum. Not all pains respond well to opioid analgesia. Although a therapeutic trial of opioids should be given, bone pain, visceral pain and neuropathic pain are less likely to respond completely to opioids. Radiotherapy should be considered if the pain is caused by a bone metastasis. It can often be given as a single treatment, and results in partial or complete pain relief in over 80% of patients.

Neuropathic pain
Neuropathic pain in advanced cancer usually results from either nerve compression or infiltration. The pain may be in a neurodermatomal distribution, and the patient may complain of a 'shooting' or stabbing sensation. There is an area of altered sensation, and the pain does not respond well to opioid analgesia. If the pain is thought to be secondary to nerve compression, a corticosteroid is the drug of choice. If the pain is thought to be secondary to nerve infiltration, then the anticonvulsant gabapentin can be tried. Gabapentin is a structural analogue of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). The dose of gabapentin should be titrated up gradually. The principal limiting side-effect of gabapentin is drowsiness.

Other classes of drug useful in neuropathic pain are antidepressants, antiarrhythmics, and the N-methyl-D-aspartate (NMDA) receptor antagonist ketamine. It is important that these adjuvant analgesic drugs are tried in conjunction with regular analgesia following the WHO analgesic ladder (Figure 4).

It may be appropriate for some patients to consider a nerve-blocking procedure if the pain is localized to the distribution of a single nerve. Commonly used nerve blocks include intercostal nerve blocks for chest wall pain and coeliac plexus blocks for pain secondary to pancreatic carcinoma.

Opioids, local anaesthetics, and other adjuvant drugs for neuropathic pain (e.g. ketamine) can be given spinally using the epidural or intrathecal route. A successful local anaesthetic nerve block reduces the afferent input to the dorsal horn of the spinal cord, and reduces the amount of opioid analgesia required by the patient. If opioids are given spinally the dose required reduces (e.g. diamorphine 100 mg s.c = 10 mg epidurally = 1 mg intrathecally). ◆

Medico-legal Aspects of Pain

Charles Pither

Charles Pither trained as an anaesthetist and has been working full time in pain management for 5 years. His particular interest is the treatment of chronic benign pain by interdisciplinary approaches. He has been providing medico-legal reports for 8 years.

The pain specialist professionally encounters the legal system in three circumstances.

- The practitioner is the subject of legal action or censure as a result of negligence or malpractice.
- The practitioner is requested to provide a medical report for litigation purposes.
- The practitioner is undertaking the treatment of patients involved in litigation.

This article focuses on the latter two aspects.

The legal system

The legal system has its own rules and language. Experienced lawyers function in ways better understood by their colleagues than by outsiders. The point you feel most strongly about in a case may not be the point the solicitor is most interested in. Interacting with the legal system involves learning its language and recognizing that it knows best. Doctors who fail to appreciate this can become frustrated when lawyers do not listen to them. The best approach is to listen to what the lawyers want and do your utmost to provide it – save your fascinating point for your medical friends. It is helpful to remember that you are an outsider, but nevertheless providing the court with something it cannot do without.

In civil law, the legal system works on likelihood not on certainty. Thus the burden of proof is not 'beyond reasonable doubt', but 'on balance of probabilities'. Herein lies a conceptual leap for the medical mind: your view need not be proven if it is the most likely explanation. Doctors are interested in rarities and small print; lawyers are interested only in winning the case. This can be harsh and at times disconcerting, but it is crucial to remember it when writing medical reports.

Medical reports

You may be requested to write a medical report about one of your patients as their treating physician or as an expert witness. In either case your report will have to conform to the civil procedure rules as modified following the recommendations of Lord Woolf in 1999 (Figure 1). These changes aim to speed cases through the courts by active management and encourage communication between experts. In all cases, the medical report is directed to the court, which implies a lay readership, thus the use of complex medical terms is to be avoided. Although you will have been instructed to prepare the report by a firm of solicitors, you are not preparing the report for them, but for the court. It is implicit in this arrangement that the expert is impartial. As treating physician, the court will respect the position you hold in your hospital, whatever your grade, but to be accepted as an expert witness the court requires a copy of your curriculum vitae and it should be included with your report.

Important aspects of a medico-legal report as proposed by Lord Woolf

The report is addressed to the court

In your report you must

- State your qualifications
- State the sources of material instructions on which you base your report
- Give references and provide literature where used to support your arguments
- Say who carried out any tests or investigations referred to
- If a range of opinion is expressed this must be summarized and reasons given for your own opinion
- Conclude with a summary
- Contain a final statement saying that you understand your duty to the court and have complied with it
- Conclude with the statement of truth 'I believe the facts I have stated in this report are true and that the opinions I have expressed are correct'

1

The court is interested in two main aspects of the case, often dealt with separately:

- liability and causation
- condition and prognosis.

It is often the case that the former is not in dispute but the latter cannot be agreed. Pain clinicians are not commonly asked to provide medical reports on their patients, compared with, for example, orthopaedic surgeons. In simple factual medical reports the essence is clarity and certainty. Reports need not be long-winded; simple explanations suffice, especially when the diagnosis is not in doubt. For example, if you performed various nerve blocks on a patient who developed a clear-cut complex regional pain syndrome following a wrist fracture, it is important to state clearly that in your view, this is the condition from which the patient is suffering. Reasons why you believe this (for example, in terms of matching up to internationally agreed criteria) are important. Similarly, a brief sentence or two explaining the condition is in order but complex explanations of the putative dysfunctions within the CNS are unnecessary. If a reference is appropriate, as in the above case, a photocopy of the paper should be included with the report.

In musculoskeletal pain syndromes, such as whiplash injury and low back pain, the situation is more complicated, not least because the diagnostic systems are more arbitrary. In many ways the legal system is overly simplistic about diagnosis. For an award of damages to an individual, something must have happened to them in the form of an injury or the development of a diagnosable medical condition. Cases run into difficulty when doctors either cannot agree on what condition the person has, or it is disputed whether they have a condition at all. Doctors may not be satisfied by the term 'whiplash-associated disorder' in a medical meeting, finding it nonspecific and not representing a clear pathological entity. However, the diagnosis may have considerable utility in court especially when accompanied by a referenced learned paper on the subject. All the court has to do is to decide whether the person in question has this condition and then act accordingly. Your task as treating doctor or expert is to help them make that decision.

Most plaintiffs with claims relating to chronic pain are also depressed, anxious or both. They may also have a post-traumatic stress disorder. Psychiatric consequences of an accident are no different from other injuries and can be compensated for. If a clear medical diagnosis is difficult to identify it can be helpful to invoke a DSM IV diagnosis such as 'somatoform pain disorder' or pain disorder with psychological factors. The ubiquitous term 'chronic pain syndrome' can also be useful. I have never been cross-examined on the point that this term is no longer recognized by the International Association for the Study of Pain.

Joint reports

Under the Woolf rules, experts are now appointed jointly by solicitors for both the plaintiffs and defendants, to avoid the previous lunacy of two groups of experts producing opposing reports. In time this will simplify matters but there are still many cases in the system with two sets of experts. In this situation, the Woolf recommendations allow the experts to produce a joint report. This can be interesting and can help to resolve difficult cases. It can also serve to demonstrate the differences in approach between different specialties.

Those interested in learning more about writing medical reports within clinical practice or as an expert witness should consider attending one of the courses organized by the BMA and others. The Pain Society has a special-interest group on the legal aspects of pain.

The question of fees always arises and is usually the first thing on the mind of the specialist asked to provide a report. Guidelines are published by the BMA, and other bodies have recommended fees. If in doubt ask a colleague.

The treatment of patients involved in litigation

The old dictum that the symptoms of people involved in litigation resolve with settlement has been challenged. Numerous studies have examined the fate of plaintiffs following the award of compensation and shown that, contrary to the enduring opinion of Henry Miller, subjects are not 'cured by a verdict' and do not make a speedy return to function once the case is settled. This is not to say that seeking compensation does not influence function and outcome. Several studies have demonstrated adverse outcome in subjects pursuing compensation. Without doubt, seeking compensation is stressful, prolonged and causes individuals to become expert in rehearsing the wrongs done to them. Furthermore, the more disabled they are and the greater their suffering the more they stand to gain. The biopsychosocial model is in essence a multivariate system and thus it would be surprising if these effects did not have an influence on disability and distress. What is more surprising is that these effects are seldom reversed once the award has been made, suggesting that the physical and mental influences are not feigned but become reality for the sufferer. The effects are not as prominent if compensation is paid in the form of regular payments rather than a lump sum, which supports the concept of 'no fault' workers' compensation schemes that do not require fault to be proven in an adversarial system.

A common question is whether patients involved in litigation should be treated vigorously in pain management centres before resolution of the case. The answers are conflicting. Much anecdotal information supports the notion that patients can and do make positive changes even in the face of litigation and thus withholding treatment is harsh and ethically questionable, especially because it is difficult to predict which patients will make changes. The author's recommendation is to ensure a multidisciplinary assessment before treatment in order to maximize the chance of detecting those for whom the award is more important than the restoration of quality of life.

However, there is often an impetus from the solicitors to obtain all possible treatment for the patient in an effort to 'mitigate the loss'. The interests of the solicitor are often to close the case rather than to maximize the patient's rehabilitation potential. In fact the reverse may be true, because the worse the plaintiff is, the more work the solicitor has to do, the larger the settlement will be, and the larger the potential fees. ◆

Neurobiology of Chronic Pain States

Lesley A Colvin
Ian Power

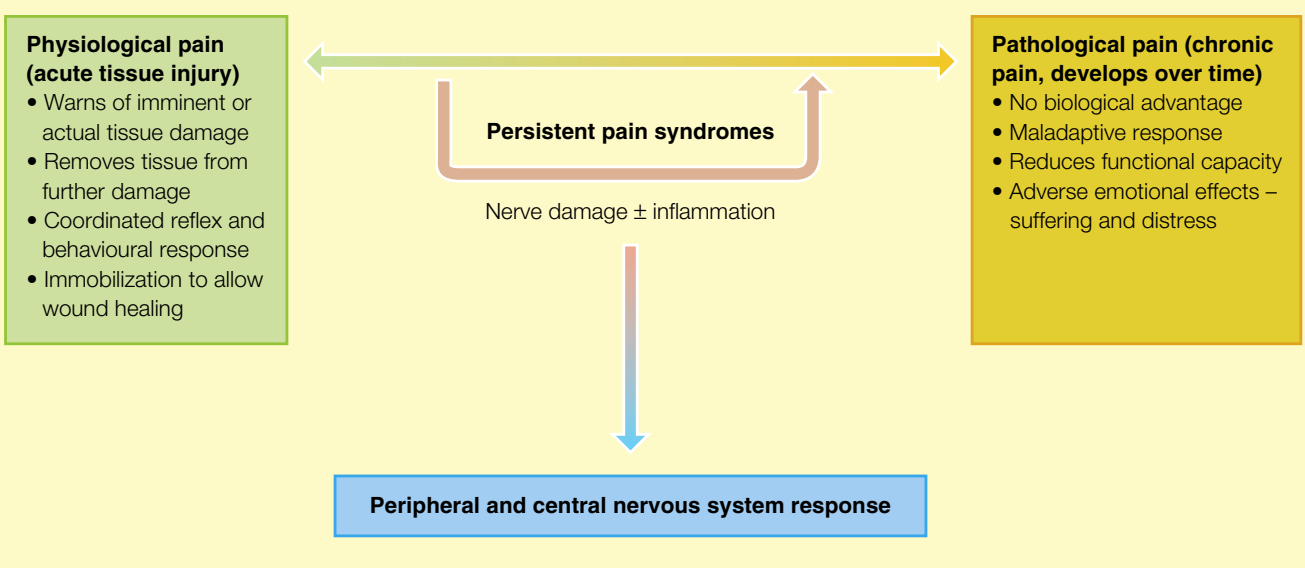
Lesley A Colvin is Consultant in Anaesthesia and Pain Medicine at the Western General Hospital, Edinburgh, and a Part-time Senior Lecturer at the University of Edinburgh, UK. Her main research interests include neuropathic and phantom pain.

This article focuses on the sensory systems involved in pain perception, but other aspects play a significant role in the experience of pain, particularly in chronic pain conditions. Woolf differentiated between acute, 'physiological' pain and chronic 'pathological' pain (Figure 1). The prevalence of chronic pain is about 30%. Persistent post-surgical pain may occur in 5–10% of patients, with certain procedures being particularly high risk. For example, post-amputation pain occurs in about 75% of patients, while about 30–40% of patients suffer from persistent pain problems after thoracotomy, mastectomy or cholecystectomy.

Many changes in the peripheral and central nervous system contribute to the development and maintenance of pain. The challenge to clinicians is whether improved understanding of neurobiology can be translated into prevention or more effective treatment of chronic pain.

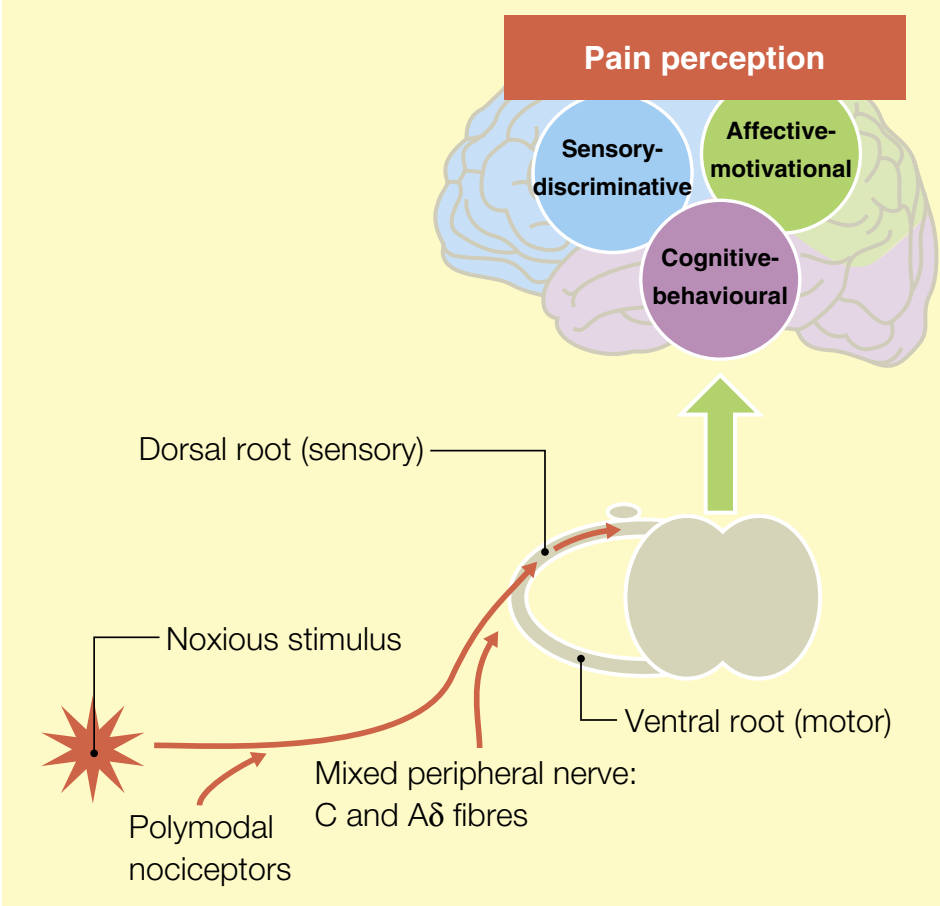
Figures 2 and 3 outline the pathways involved in pain processing. In chronic pain, particular and specific changes in the nervous system can be detected, depending on whether nerve damage or a continuing inflammatory response is the main component of the syndrome. In addition, recent studies indicate that cancer pain may also cause unique and characteristic alterations in the nervous system.

Differences between acute and chronic pain



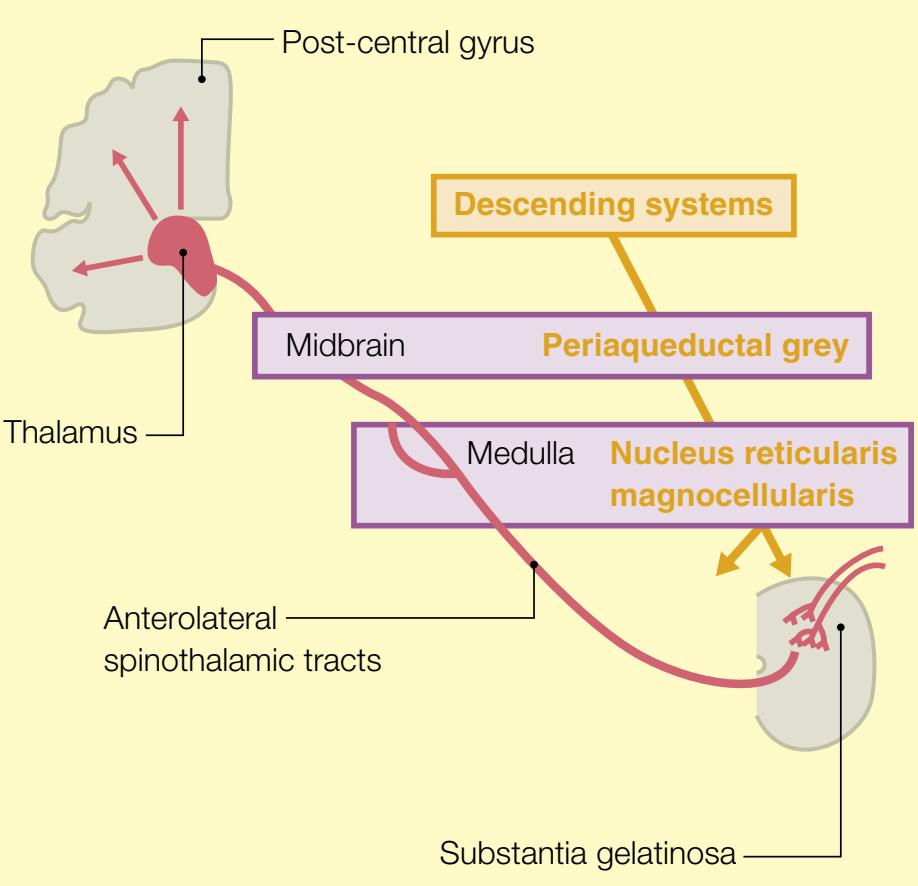
1

Pathways involved in pain processing



2

Central pain pathway



3

Peripheral alterations

Following nerve injury, two major changes may occur peripherally in primary sensory neurons: alterations in the electrical response properties and alterations in the chemical nature of the neurons.

Electrical properties

Spontaneous activity: normally, a particular high-threshold peripheral stimulus (e.g. pin prick) is required to activate peripheral nociceptors. Neuronal sodium channel permeability then increases, resulting in action potential generation and propagation. After nerve injury, action potentials arise spontaneously at sites distant from peripheral nociceptors, in the absence of any peripheral stimulation. These spontaneously arising action potentials, or 'ectopic discharges', can originate from the nerve injury site, and more proximally, at the cell bodies themselves, in the dorsal root ganglia. The type of sodium channel involved in the generation of these ectopic discharges (the $Na_v1.3$ tetrodotoxin-sensitive channel) is normally found only during development, but reappears after nerve injury. Animal models and clinical microneurographic work have shown that the rate of ectopic discharges may be related to the severity of spontaneous pain.

Evoked activity: normally a high-intensity peripheral stimulus initiates action potentials in nociceptors and these are propagated centrally along small myelinated Aδ fibres and unmyelinated C fibres. The initiation of action potentials stops when the stimulus has ceased and mechanical stimulation of the sensory axon distant from peripheral nociceptors does not generate action potentials. In contrast, after nerve injury, there may be continued action potential generation, termed 'after discharges'. There may also be a change in the pattern of action potential firing, with prolonged bursting discharges. Further impulses may be initiated at the nerve injury site, which may become mechanosensitive after injury.

In response to peripheral nerve injury, there is a clear trend towards increased and altered electrical input into the spinal cord, which has lost the close link to the stimulus-encoded input that is normally found. This increase in primary afferent drive is likely to contribute to the changes that occur in the spinal cord.

Chemical properties

Peripherally synthesized substances that are transported centrally by primary afferent fibres play an important role in neuronal homeostasis. Glial cells (e.g. Schwann cells) are also likely to be involved in this process. Damage to peripheral axons interferes with retrograde transport of peripherally derived chemicals. Substances such as neurotrophins seem to play a major part in maintaining the 'primary afferent phenotype', the characteristic pattern of neurotransmitters produced by primary afferent neurons. At least part of the stimulus for altering neurotransmitter synthesis by primary sensory cell bodies is the loss of tonically transported neurotrophins from the periphery, which act at specific receptor sites.

In addition to actions at the dorsal root ganglia, loss of retrogradely transported neurotrophins may have further effects downstream within the spinal cord. Within the dorsal root ganglia, sympathetic fibres begin to sprout and form basket-like structures around the cell bodies of primary afferent neurons. There appears to be some cross-talk between sympathetic and sensory neurons, with stimulation of sympathetic neurons generating impulses in sensory fibres.

Central alterations in the spinal cord

Extensive and persistent changes in the spinal cord after periph-eral nerve injury include anatomical changes in the 'hard-wiring' of the system, neurochemical changes and functional changes.

Anatomical changes

Large myelinated Aβ fibres, that normally terminate in laminae III/IV of the dorsal horn, begin to sprout into the superficial dorsal horn. They may make functional synaptic connections in the substantia gelatinosa (the area of the spinal cord involved in pain transmission). The formation of these new connections may be one of the mechanisms underlying allodynia, where light touch (normally transmitted by Aβ fibres) is perceived as painful.

Neurochemical changes

There are a huge number of changes in neurotransmitter production, release and receptor activation in response to peripheral injury. Some of the amino-acid and neuropeptide transmitters are considered here. The neurochemical transmitter changes affect intracellular second and third messenger systems, with substances such as nitric oxide being implicated in altering gene expression. Immediate early genes, such as *c-fos* and *c-jun* may also play a role in maintaining chronic pain via alterations in protein synthesis.

Amino acids – the balance between excitation and inhibition is altered by nerve injury. There is a tendency towards an amplification of sensory input within the spinal cord. These changes may persist after the original tissue damage has healed, with continuing alterations in central processing. Figure 4 shows the involvement of amino-acid neurotransmitters in the spinal cord.

- The main excitatory amino acid involved in pain processing is glutamate. Fast transmission of sensory information occurs via ionotropic (ion channel) receptors, such as the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor. After nerve injury, or a repeated high-intensity stimulus, the voltage-dependent magnesium block of the N-methyl-D-aspartate (NMDA) receptor is lifted and subsequent release of glutamate results in increased action potential generation, involving NMDA receptor activation. Metabotropic glutamate receptors may also be involved in nociceptive processing. These are not ion channels, but are coupled to G-proteins, with glutamate binding producing intracellular changes in enzyme activation and calcium levels.
- The two main inhibitory amino acids found in dorsal horn neurons are γ-aminobutyric acid (GABA) and glycine. After peripheral nerve injury, GABA levels in the dorsal horn are decreased bilaterally. Glycine-containing inhibitory neurons in the dorsal horn may also be more susceptible to the massive neuronal discharge occurring at the time of nerve injury, resulting in preferential inhibitory cell death.

Amino acids and receptors

Excitatory receptors
Glutamate receptors
Ionotropic
- α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)
- N-methyl-D-aspartate (NMDA)
- Kainate

Metabotropic

Inhibitory receptors
γ-aminobutyric acid (GABA) receptors
$GABA_A$ (mainly post-synaptic)
$GABA_B$ (mainly pre-synaptic)

Glycine receptors

4

Neuropeptides – many neuropeptides are involved in sensory processing, and their synthesis and release alters in response to peripheral injury. Figure 5 shows some of the changes that occur in the primary sensory neuron production of neuropeptides after nerve injury.

Changes that occur in the primary sensory neurons after nerve injury

Excitatory changes
Decreased synthesis
- Substance P
- Calcitonin gene-related peptide (CGRP)

Increased synthesis
- Vasoactive intestinal peptide (VIP)
- Pituitary adenylate cyclase activating polypeptide (PACAP)
- Cholecystokinin (CCK)

Inhibitory changes
Decreased synthesis
- Somatostatin

Increased synthesis
- Galanin
- Neuropeptide Y (NPY)

5

Functional changes
After nerve injury there is an increase in spontaneous neuronal activity within the spinal cord that seems to be partly independent of peripheral ectopic discharges. It may be related to a decrease in 'descending noxious inhibitory control'. The descending pathways involved originate in the brain stem, and normally exert tonic inhibition on intrinsic spinal neurons by the release of serotonin (5-HT) and norepinephrine.

There is also an increase in the functional response evoked within the spinal cord by a given peripheral stimulus, with an increase in receptive field size and prolonged neuronal activation.

Supraspinal changes

One of the limitations of animal studies is that they focus on the peripheral and spinal cord changes in sensory processing. By combining the information gained from these studies with clinical investigations using brain-imaging techniques to examine the wider aspects of pain perception, understanding of this dynamic system can be improved.

Recent studies using indirect measures of neuronal activation have demonstrated that there are rapid and persistent alterations in cortical responses after upper limb amputation. Additionally, it appears that the greater the changes in the somatosensory map on the cortex, the greater the severity of phantom pain. The underlying mechanism for this may vary between patients. Potential mechanisms include unmasking of silent synapses and neuronal sprouting from the thalamus and within the sensory cortex itself.

Neurosurgical Techniques in the Treatment of Chronic Pain

T R K Varma

T R K Varma is Consultant Neurosurgeon at the Walton Centre for Neurology and Neurosurgery, Liverpool, and The Liverpool Pain Institute. He qualified from Bangalore University and trained in Liverpool, Sheffield and Cardiff. He was formerly Consultant Neurosurgeon at Dundee. His clinical interests are in functional neurosurgery including neurosurgery for chronic pain.

Over several decades, many surgical procedures have been undertaken in an attempt to alleviate chronic pain and most have involved ablation or excision of neural tissue. However, present neurosurgical techniques based on current understanding of the pathophysiology of pain attempt to modify or modulate pain pathways.

It is sometimes possible to treat the cause of chronic pain and investigations must always be directed at this possibility. Only when treatable causes have been excluded should other treatment modalities for chronic pain be considered. Pain resulting from spinal root compression or instability pain caused by metastatic spinal disease might be treatable by direct surgical techniques.

Neuroablative procedures

Neuroablation or destruction of neural tissue has been the mainstay of surgical procedures for chronic pain but the recognition that nerve injury is often the cause of chronic pain syndromes has resulted in reluctance to induce further nerve damage. However, some neuroablative procedures remain useful in the treatment of chronic pain.

Cordotomy

Interruption of the spinothalamic tract in the anterolateral quadrant of the spinal cord abolishes nociceptive pain from the contralateral side of the body. However, this effect is not always long lasting and the procedure is mainly used in pain caused by malignant disease that proves resistant to drug treatment. There are several methods of performing a cordotomy but the most commonly used techniques are a percutaneous cervical cordotomy or an open thoracic cordotomy.

Percutaneous cervical cordotomy: under local anaesthesia, using radiological control, a lateral cervical puncture is carried out at the C1/2 level following which an electrode is placed in the anterolateral quadrant of the spinal cord. The optimal position of the electrode is verified by electrical stimulation that should produce sensory effects on the contralateral side. A thermal lesion is then created by applying a radiofrequency current to the tip of the electrode that should result in loss of pain sensation in the opposite side of the body. The percutaneous method has the advantage of being a relatively minor procedure but requires good patient cooperation and tolerance.

Open cordotomy is usually undertaken under general anaesthesia though techniques of waking the patient during the procedure to confirm satisfactory lesioning of the cord have been described. A small upper thoracic laminectomy is carried out and the anterolateral quadrant of the spinal cord is sectioned with specially designed blades.

Indications for cordotomy (Figure 1): because the analgesic effects reduce with time and there is a risk of delayed dysaesthetic pain syndromes, cordotomy is seldom carried out in patients with pain resulting from benign disease.

Indications for cordotomy

Cervical cordotomy

Indications

- Unilateral pain below C4/5

Contraindications

- Pain above C4/5
- Bilateral pain
- Axial pain
- Compromised respiratory function
- Dysaesthetic pain (?)

Open thoracic cordotomy

Indications

- Unilateral or bilateral lower limb pain due to malignant disease

Contraindications

- Axial pain
- Dysaesthetic pain
- Poor anaesthetic risk

(Loss of bladder function invariably ensues after bilateral cordotomy)

The distribution of nerve fibres in the spinothalamic tract makes it impossible to obtain pain control above C4/5. In cervical cordotomy the reticulospinal fibres responsible for spontaneous respiration are also destroyed and if carried out bilaterally there is a risk of respiratory failure. This is also the situation if there is significant lung disease on the side of the cordotomy and caution must be exercised in patients with pulmonary malignancy.

Dorsal root entry zone lesions

The superficial part of the grey matter in the dorsal horn of the spinal cord has a complex of neural networks that are thought to modulate pain pathways. Lesions have been made in the area where the dorsal root enters the spinal cord (dorsal root entry zone) in an attempt to control a variety of pain syndromes. The operation requires a laminectomy to expose the dorsal root entry zone followed by either a series of radiofrequency coagulations or an incision and diathermy of the area. Though it has been used in a variety of neuropathic pain conditions the best indication for this procedure is for pain resulting from brachial plexus avulsion.

Other neurosurgical ablative procedures

Other ablative procedures in the spinal cord that are sometimes performed include commissural myelotomy for lower limb cancer pain and cordectomy for spinal cord injury pain.

Today, few intracranial ablative procedures are carried out for chronic pain. Mesencephalic tractotomy may be an option in patients with head and neck cancer. Patients with malignant disease in whom cordotomy has failed may occasionally benefit from lesions placed in the thalamic and subthalamic sensory pathways.

Pituitary ablation, with either a percutaneous alcohol injection or a trans-sphenoidal hypophysectomy, has been undertaken for pain caused by disseminated breast and prostatic malignancy.

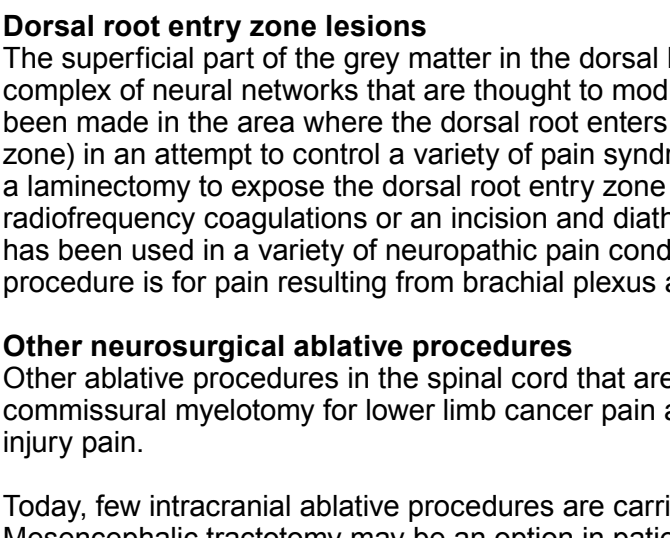
Neuromodulation procedures

The current trend in neurosurgery for chronic pain has been to replace ablative techniques with those that attempt to modulate the generation or transmission of pain impulses. The two methods that are widely used are neurostimulation and drug delivery systems.

Neurostimulation

Chronic electrical stimulation of the CNS as a method of controlling pain was introduced in the early 1970s but was handicapped by unreliable hardware. Improvements in stimulator technology have allowed this method of treatment to be widely used.

Spinal cord stimulation: previously called dorsal column stimulation, the technique was introduced in 1967 and was widely thought to be based on the gate control theory of pain proposed by Melzack and Wall. The exact mechanism of action is uncertain but the best indications for the procedure are now emerging. Refractory angina and advanced peripheral vascular disease are the best indications for spinal cord stimulation. Neuropathic pain, including the complex regional pain syndromes, is probably the most widely used indication (Figure 2). Its use in axial pain of spinal origin and in the so-called ‘failed back surgery syndrome’ is disputed, though some authors claim good results in this condition.



Reversal of autonomic changes in complex regional pain syndrome following spinal cord stimulation. Note the reduction of swelling in the left hand before (**a**) and after (**b**) spinal cord stimulation.

The outcome of spinal cord stimulation depends on rigorous assessment of patients and choice of indications. Most large series show that in carefully selected patients 60% derive 60–70% pain relief. This has to be balanced against the need for long-term supervision of the hardware along with re-operation for system failure.

Surgical methods of spinal cord stimulation – patients considered for spinal cord stimulation have to be subjected to a rigorous preoperative assessment to determine the potential benefits they may derive from the treatment. In certain patients, spinal cord stimulation could have a placebo effect and therefore assessment and evaluation by a multidisciplinary team is essential.

Before implantation of a permanent system it is usual to undertake a trial of stimulation with a percutaneously placed epidural electrode connected to an external pulse generator. The position of the electrode is adjusted so that electrical stimulation projects a sensation of paraesthesia into the painful area. A prolonged period of stimulation is then undertaken to allow careful assessment of the patient’s response to stimulation. Implantation of a permanent system should be considered only in patients who show a consistent reduction in pain levels (60–70% reduction in the visual analogue score (VAS)) in parallel with reduction in analgesic requirements and with normal activity.

A wide range of hardware is available for implantation and the choice is often based on the expertise and experience available locally. Percutaneously placed epidural electrodes have the advantage of converting a trial electrode into a permanent electrode but have the disadvantage of being prone to migration. Electrodes placed by laminotomy are less prone to migration and can give a wider area of stimulation but require a more invasive procedure.

The power source for stimulation could be a totally implantable pulse generator or a radiofrequency coupled receiver that has an external power source. The former, which is similar to a cardiac pacemaker, has several advantages but requires expensive replacements for battery depletion. Currently available systems have sophisticated electronic devices that allow the clinician and patient to alter the stimulation parameters.

Other neurostimulation techniques

- Stimulation of nerve roots or peripheral nerves is now seldom undertaken. There are a few studies on the use of electrical stimulation of the trigeminal nerve for facial pain.

- Deep brain stimulation of the periventricular grey matter or of the sensory pathways in the brain continues to be investigated as a potential target for chronic electrical stimulation for the treatment of chronic pain.

- In motor cortex stimulation a variety of methods are used to identify the motor cortex before an electrode placed extradurally over the motor cortex is connected to an implantable pulse generator. The mechanism of action remains unclear, but interest has been shown in the evaluation of motor cortex stimulation for the treatment of central pain syndromes, and particularly in central post-stroke pain.

Drug delivery systems

For a long time, anaesthetists have appreciated the use of intraspinally administered analgesia and external infusion devices have also been used in palliative care. The development of reliable implantable drug infusion devices has led to their increased use in the management of chronic pain syndromes. Electronically controlled systems allow for sophisticated external programming of infusion cycles and are being increasingly used for benign chronic pain syndromes. These systems are expensive and require careful long-term follow-up for dose adjustments and drug refills. While opioids are the most commonly used drugs a variety of other analgesics are being evaluated for intrathecal use.

Trigeminal neuralgia

Trigeminal neuralgia is probably the most common chronic pain syndrome requiring neurosurgical treatment. Surgical treatment must be considered if the pain proves refractory to drug treatment or if there is intolerance to drug treatment. The cognitive side-effects of drug treatment are often underestimated and this is particularly important in younger patients in whom a lifetime of anticonvulsant medication can be avoided by surgery.

Surgical treatment

Percutaneous neuroablative procedures: the trigeminal ganglion and rootlets can be accessed percutaneously by an entry lateral to the angle of the mouth and directed under radiological control to foramen ovale at the base of the skull. Percutaneous procedures have the advantage of being relatively minor and well-tolerated operations especially in medically compromised patients. The disadvantages are the short-lived effects with the need for frequently repeated procedures. The incidence of denervation pain syndromes (e.g. anaesthesia dolorosa) is high and they are effectively untreatable. However, these techniques are extremely useful in secondary trigeminal neuralgia (e.g. multiple sclerosis) and in physiologically compromised patients.

Radiofrequency thermocoagulation – with intermittent intravenous anaesthesia a radiofrequency electrode is inserted through the foramen ovale and the position verified by electrical stimulation. When the appropriate divisions of the nerve have been identified a radiofrequency thermal lesion is produced to damage the more sensitive pain fibres while preserving the touch fibres.

Chemical neurolysis – alcohol and phenol have now been largely replaced by glycerol for chemical neurolysis. The procedure can be undertaken under local anaesthesia and under ideal circumstances selective ablation of pain fibres can be achieved.

Balloon compression – a small arterial embolectomy catheter is placed in Meckel's cave and is repeatedly inflated to gently crush the trigeminal ganglion and lesion the pain fibres.

Other ablative procedures

Stereotactic radiosurgery – using stereotactic surgical techniques, a controlled dose of radiation is administered precisely to the trigeminal root entry zone in the brainstem. This is a relatively new procedure that is non-invasive but the long-term effects are uncertain.

Open selective rhizotomy – open section of the trigeminal nerve was previously undertaken in the middle cranial fossa but is now largely carried out in the posterior cranial fossa. Good long-term denervation can be achieved, though the risks of denervation pain syndromes are high.

Microvascular decompression: vascular compression of the trigeminal nerve at the root entry zone is now largely accepted as the main aetiological factor in trigeminal neuralgia and can be radiologically confirmed by MRI. Microvascular decompression treats the cause of the disease without inducing nerve damage. Following a retromastoid craniectomy a microsurgical exposure of the trigeminal nerve in the cerebellopontine angle is under-taken. The vascular compression is usually identified by the brainstem at the root entry zone and the offending vessel is mobilized away from the nerve. A synthetic sponge is then inserted between the vessel, the nerve and the root entry zone.

Microvascular decompression is a major neurosurgical operation with the attendant risks, but despite this it is well tolerated, even by elderly patients. Risks such as CSF leaks, infection, haemorrhage and unexpected neurological deficits remain, though the specific risks to the auditory and facial nerves can be reduced by meticulous microsurgical techniques and intraoperative neurophysiological monitoring. These risks are counterbalanced by the fact that the technique attempts to treat the cause of the condition and is associated with good long-term results. The avoidance of iatrogenic nerve damage and denervation pain syndromes is a significant advantage. ◆

Organization of Pain Management Services

Chris C Spanswick

Chris C Spanswick is Consultant in Pain Management and Anaesthesia at the Manchester and Salford Pain Centre, Hope Hospital, Salford. He qualified from Manchester University and trained in general anaesthesia in the armed services and at Manchester. He has worked in pain clinics since 1981 and was involved in developing the first Pain Management Programme specifically for patients with chronic low back pain.

Good administration is vital for any organization if it is to succeed in delivering the service it intends. A well-organized pain clinic will be able to deliver a high quality service efficiently. It will enable clinicians to focus on individual patients and their needs. Patients presenting with chronic pain represent a major clinical challenge because they commonly have complex clinical problems. They present with additional psychosocial problems, are demanding to treat and have often experienced significant problems during their previous encounters with the healthcare system. By creating an administrative system in which responsibilities and workload are clearly defined the staff will be able to perform more effectively and efficiently. This will engender good morale and help to attract and retain staff.

The report of the Clinical Standards Advisory Group indicated the complex nature of chronic pain and its impact on patients and their families. It outlined the lack of support and resources in many pain treatment facilities. It pointed out that psychologically based approaches could be effective but that few patients had access to such treatment. Purchasers did not seem to understand what services they were buying and were often uncertain about the potential outcome of treatment. Some regarded chronic pain as not being a high- profile problem.

Shape of the service

Pain clinics in the UK vary from single-mode treatment clinics (e.g. acupuncture clinics) to large multidisciplinary pain centres involving staff from differing specialties and professions. Most pain clinics are run by anaesthetists with support from other professions (e.g. nursing). The shape of the pain service largely depends on the case mix (Figure 1).

Typical pain clinic case mix

- Average pain history of 5 years
- Complex problems with concurrent disease
- Failure to respond to previous treatments
- High level of healthcare use (drugs, GP, accident and emergency department, specialists)
- High levels of psychological distress
- Low level of physical functioning
- Employment problems
- May be seeking compensation

1

The International Association for the Study of Pain (IASP) has published *Desirable Characteristics for Pain Treatment Facilities*. While these may be regarded as a counsel of perfection, there are a number of important points that should be applied to any pain service. The UK Pain Society endorsed these recommendations in their own document *Desirable Criteria for Pain Management Programmes*.

The skills of more than one profession are needed to help patients with such complex problems. Over the past 20 years there has been a move away from pain clinics being run entirely by anaesthetists to the development of multidisciplinary or interdisciplinary teams, usually involving nurses, physio-therapists, occupational therapists and clinical psychologists. Each profession is able to bring a different perspective to the assessment and management of patients with chronic pain problems. Thus, by assessing and treating not only the pain but also the many problems caused by the pain or concurrent to the pain, it is more likely that there will be an improvement in physical and psychosocial measures. The main aim is a reduction in pain and an improvement in the quality of life.

The treatment options available in a clinic depend on the resources, including the administrative personnel, individual clinical skills and interests, the available facilities (e.g. theatre sessions with radiography, gymnasium), links with other services (e.g. spinal services) and appropriate funding (Figure 2).

Types of service available

- Clinics (e.g. new patient, follow-up, clinical psychology, rapid referral, pre-pain management programme assessment)
- Clinic treatments (e.g. acupuncture, transcutaneous electrical nerve stimulation)
- Outpatient treatments (e.g. individual rehabilitation)
- Day case treatments (e.g. epidurals, facet joint blocks, sympathectomies)
- In-patient treatments (e.g. long-term epidurals, spinal cord stimulation)
- Pain management programme

2

Key players

It is important to identify the key players to ensure the success of a pain clinic. Apart from the patients, the key players are the referring agents (e.g. GPs, specialists), the managers of the trust or hospital unit and the purchasers of healthcare (Primary Care Groups, Health Authorities). Each of these needs to understand the nature of the service being offered to the patients, the expected outcome and the costs involved in running the service.

Regular clinical audit provides vital information for managers about case mix and outcome. It is important to explain to managers the complexity of the presenting clinical problems and the significant degree of psychological distress and disability (Figure 3). For example, most patients seen in pain clinics present with levels of distress seen in only 15% of patients attending routine orthopaedic clinics.

Data for key players

- Describe case mix in detail, including medical, psychological and physical function problems
- Argue the case for careful broad-based assessment
- Describe the (proposed) service in detail
- Highlight links with other services and departments (e.g. orthopaedic surgery, rehabilitation services)
- Outline resources needed and those currently available (personnel, time, space and facilities)
- Describe consequences (financial and clinical) of not setting up, or developing, the service

3

Without support from clinicians and local managers it is difficult to convince purchasers of the need for the service. Careful documentation with supporting evidence of benefit must be available. The links with other services should be emphasized, in particular how the pain clinic can help in the development of common clinical pathways. This should be done in collaboration with hospital and unit managers, who will often understand the current trends in purchasers' thinking and will assist in tailoring the arguments to be presented to the purchasers.

Resources

The shape of the service is often determined by the case mix. Many pain clinics develop without much planning. As a consequence they are often run on tight budgets and inadequate resources. Often there is a lack of secretarial and administrative back-up which can lead to poor delivery of service and undue stress on clinicians. Both the Pain Society and the IASP have published documents outlining resource requirements. All clinical staff must have experience in assessing and treating patients with chronic pain. Time must be made available for continuing professional development, audit and research. Figure 4 lists the essential resources required by any clinic wishing to offer a broad range of assessment and treatment options.

Potential resource needs

- Clinical personnel (physician, nurse, physiotherapist, psychologist)
- Time (each clinician should have enough time for dedicated clinical sessions, training, audit and research)
- Administrative support (business manager,audit co-ordinator, secretary, clerk)
- Premises (clinic room(s), treatment room(s), pain management programme room, office(s))

4

Organization

Good organization is achieved by making the best use of resources and playing to people's strengths. There should be a clear agreed shape of service with a clinician responsible for clinical matters. Each team member should be given a clear area of autonomy and responsibility. There must be a senior administrator to monitor workload, track patients, facilitate audit and maintain contact with purchasers. Regular meetings of the team to discuss clinical and administrative matters are essential for cohesion. Purchasers tend to pressurize clinics to see a greater number of patients more quickly, but quality of service should take precedence over quantity.

Clinical pathways: much of the treatment of chronic pain can be set out in a protocol that can be performed by non-medical staff, under the supervision of the physician. By outlining in detail both a generic patient pathway (e.g. assessment process) and syndrome-specific pathways (e.g. treatment of neuropathic pain) it is possible to ensure a high quality of service delivery and also monitor progress and outcome more successfully. Inclusion and exclusion criteria as well as a clear pathway for those patients thought to be suitable for the pain management programme should be published.

Administrative pathways are complex and need adequate investment to allow clinicians to function efficiently and effectively. Much information can be obtained by questionnaire before the clinic appointment or at the clinic. This can provide vital clinical information for triage, assessment and outcome measurement as well as providing data about case mix. Adequate resources must be allocated to record this data.

Links with other services are vital if the pain clinic is to provide a useful service. Common protocols and explicit referral criteria should be negotiated with other users of the service (e.g. orthopaedic surgery) to ensure appropriate referrals and improve the quality of service. ◆

Patient-Controlled Analgesia

Ann Taylor
Kate Davies

Ann Taylor is Senior Lecturer in Pain Education in the Department of Anaesthetics and Intensive Care Medicine at the University of Wales College of Medicine, Cardiff, UK. She qualified as a nurse in 1983 and specialized in intensive care. During this time she became interested in acute pain management. Her interests include pain management and interprofessional education.

Kate Davies is Lecturer in Pain Education at the University of Wales College of Medicine, Cardiff, UK. She qualified from University College Hospital London as a nurse and specialized in vascular surgery. She developed an interest in pain management and now works as part of a team that runs a distance learning MSc in pain management.

It is impossible for a practitioner to predict the amount of analgesia required to relieve each patient's pain effectively. Patient-controlled analgesia (PCA) allows individualized pain relief according to the patient's requirements. It allows patients to administer a predetermined dose of analgesia within the constraints of a lockout period using a programmed device (Figure 1). This concept acknowledges that the patient is a good judge of the magnitude of their pain. PCA is now widely used as an alternative to intramuscular analgesia in managing postoperative and acute episodic pain.

PCA can be administered by oral, inhaled, epidural or intravenous methods. For patients with acute pain, the most commonly used form is intravenous PCA, usually delivering an opioid. Although PCA (and nurse-controlled analgesia) is appropriate for use in a paediatric setting, there are specific requirements for children. Therefore, this article discusses intravenous PCA in adults.

1 Patient-controlled analgesia machine.

Rationale and history of PCA

PCA overcomes some of the problems of traditional therapies, including variable absorption with intramuscular therapy and frequent adjustments of infusion rates with continuous infusions. Although PCA allows the patient to 'control' the administration of the drug, it may be more accurate to call it patient-assisted analgesia because it is prescribed and limited by a doctor.

Intravenous PCA was developed to address the need for an improved mode of administering standard opioids. The first demonstration of a PCA machine was in 1976 at the Welsh National School of Medicine. This became the first commercially available PCA machine 'The Cardiff Palliator'. PCA allows on-demand repetitive dosing of small amounts of opioid by the patient, followed by a lockout period during which the machine will not allow any more doses of analgesic to be given. The drive for the patient to press the button is to reduce their pain to an acceptable level. This titrates the plasma concentration of opioids around the minimum effective analgesic concentration and avoids the peaks and troughs associated with traditional intramuscular regimens. Therefore, constant plasma levels of opioid and consistent analgesia are more easily attained with PCA than with intramuscular analgesia.

The usual drug of choice for use with PCA is morphine, but other opioids such as pethidine, fentanyl and tramadol have also been used successfully.

Patient suitability

PCA is suitable for use in adults following surgery where there is a likelihood of parenteral opioid analgesia being required for 24 hours or more, or for the management of acute episodic pain such as that associated with a sickle cell vaso-occlusive crisis. Correct selection of patients is important because they have to be mentally able to understand the concept of self-administration of analgesia and physically capable of pressing the button to deliver the analgesic dose. Specially adapted handsets are available for patients with conditions such as rheumatoid arthritis for whom use of the usual handset and button may prove difficult.

Relative contraindications for PCA use are:

- patients who are abusing illicit drugs
- patients who have marked metabolic disorders such as sepsis or severe fluid and electrolyte abnormalities
- patients with end-stage renal and hepatic disease
- patients who have severe chronic obstructive pulmonary disease
- patients who suffer from sleep apnoea.

For patients in whom PCA is contraindicated, careful assessment and reassessment of analgesic requirements needs to be undertaken to ensure adequate relief is achieved and the safety of the patient is maintained. Advice from experienced healthcare practitioners regarding specialized care should be sought.

Mode of action

The patient presses the button to deliver analgesia only when they have pain or discomfort. The safety of the device depends on a negative feedback loop of which the patient is a part. This works because if the minimum effective analgesic concentration is exceeded or if the patient is very sensitive to opioids, they will become sedated and therefore will not administer any further doses until the plasma concentration of opioid has decreased to a safer level and they become less sedated. As sedation is a precursor to respiratory depression, its occurrence is therefore reduced or avoided.

Parameters

Loading dose

The loading dose is the opioid dose initially required to achieve the minimum effective analgesic concentration. The actual dose required to achieve effective analgesia is impossible to predict and varies depending on the severity of the pain and the effectiveness of the analgesia for each patient. The loading dose can be administered by pre-setting the PCA pump and allowing automatic administration, but usually the anaesthetist or nurse titrates the loading dose to the desired effect in the recovery unit. If the loading dose is omitted, patients are unlikely to obtain good analgesia because even if the demand button is pressed as often as permitted by the programme, the minimum effective analgesic concentration may not be achieved. The resultant ineffective management of pain may reduce the patient's trust in PCA and increase their anxiety, contributing to their experience of pain.

Bolus dose

The bolus dose is the quantity of analgesia the patient receives after a successful self-administration demand. It is assumed that patients will demand doses of analgesia until pain has been relieved, but the size of the bolus dose influences the patient's perception of how effective the treatment has been. If the dose is too small, the patient fails to achieve adequate analgesia. If the dose is too large, the plasma concentration gradually increases with repeated doses until it reaches a level that may cause excessive sedation and possibly respiratory depression and other opioid-related side-effects such as nausea and vomiting.

The efficacy of PCA is dependent on the skill and expertise of the prescriber. The optimal bolus dose is that which provides consistent, satisfactory analgesia without producing excessive or dangerous side-effects. This has been quoted as morphine, 1 mg, and pethidine, 10 mg, in healthy adults. In elderly or frail patients, a smaller dose is often required.

Lockout interval

The lockout interval is the time during which the machine will not administer a further dose despite further demands from the patient. The ideal interval is related to the size of the bolus dose, and it should reflect the length of time necessary for the patient to appreciate the effects of the bolus dose. The lockout interval is also determined by the pharmacokinetics of the drug and the pharmacodynamics of that drug in the patient; in particular, the length of time for the drug to reach peak plasma concentrations after intravenous bolus injection. In general, a larger bolus dose requires a longer lockout interval. If the patient has impaired drug clearance (e.g. elderly patients) a longer lockout interval is required. For morphine, peak concentration after intravenous bolus is achieved after about 4 minutes. It would be inappropriate to set a lockout time shorter than the time to achieve peak plasma concentration. Subcutaneous or epidural PCA require a longer lockout interval because the time to peak effect is longer.

The 1 mg bolus dose of morphine is best combined with a 5-minute lockout interval unless the patient is elderly or frail. The initial combination of bolus dose and lockout interval should be reassessed continually and altered if necessary for each individual patient.

Background infusion

The basis of PCA means that the patient experiences pain before demanding relief. If a drug with a short half-life is used, analgesia is rapidly achieved but the patient is required to make frequent demands for analgesia. If the patient falls asleep, they may wake up in pain, which then requires several demands, depending on the length of the lockout interval, to attain analgesia. Pharmacokinetically it might be felt that a background infusion would improve analgesia, particularly at night, by reducing the frequency of demands required to maintain the plasma concentration at the desired level. In practice, this has not been found to be the case because it neither improves the effectiveness of analgesia by PCA nor reduces the number of demands but does result in higher opioid consumption. However, a background infusion may be useful to replace the maintenance requirements in patients in whom acute pain is superimposed on existing chronic pain that necessitates the use of opioid analgesia.

The addition of a background infusion removes patient control and they will receive analgesia even if they do not need it. This reduces the inherent safety of PCA by decreasing the negative feedback element and some studies have shown that respiratory depression can occur when a background infusion is used. It is essential that patients are carefully monitored and it may be appropriate for the patient to be nursed in a high dependency or intensive care setting where the nurse to patient ratio is high. There is also the potential to programme a 4- or 24-hour dose limit, which allows only a predetermined total amount of drug to be administered within a given time. This is particularly pertinent when pethidine is used, because with repeated or high doses there is an accumulation of its active metabolite (norpethidine) which acts as a CNS stimulant. While a dose limit improves the safety of PCA when used with a background infusion, it may cause ineffective relief from pain for those patients who require large doses of analgesia.

Expectations of effect

PCA is not the panacea for all pain, but it can be beneficial in the management of acute pain. To maximize the potential of PCA, it is necessary to select patients appropriately. This technique can safely achieve no or mild pain at rest, and mild-to-moderate pain on movement for patients following straightforward intermediate or major surgery, or acute episodic pain where the anticipated pain is likely to require parenteral opioids for 24–48 hours. For patients who have had complex major surgery where the anticipated pain is likely to be severe and prolonged, it is more appropriate to select a method such as epidural infusion, provided it is not contraindicated.

The beneficial effects of PCA can be enhanced by concurrently administering additional analgesics such as a non-steroidal anti-inflammatory drug (NSAID) and/or paracetamol. These combinations can produce an additive or synergistic effect because the drugs act by different mechanisms to achieve pain relief. The opioids act on specific opioid receptors in the CNS, while NSAIDs act mainly in the periphery to inhibit the initiation of pain. Combined drug regimens may also decrease the amount of each drug required to relieve pain and thus reduce the potential for drug-related side-effects. Some acute pain services have a policy to ensure that NSAIDs and/or paracetamol are prescribed for regular administration to accompany PCA provided there are no patient contraindications. This may also avoid the troughs in analgesia that occur during the night when the patient is asleep and cannot use PCA.

Complications of PCA

Figure 2 describes the procedure to follow if analgesia with PCA is inadequate.

Drug-related side-effects

Problems with PCA are related mainly to the drug used. The incidence of problems is comparable with other methods of parenteral opioid administration. Opioids are associated with a high incidence of nausea (up to 80%). This is probably because prophylactic anti-emetics tend not to be given routinely to patients receiving analgesia via PCA.

The respiratory depression associated with PCA is dose dependent, as with any other opioid administration. Increasing levels of sedation can alert the practitioner to impending respiratory depression. However, respiratory depression can occasionally occur in unsedated patients, therefore monitoring of all vital signs is essential to detect deleterious changes. The principle of patient control of bolus dose combined with the lockout period may protect against this complication to some extent. Other side-effects include pruritus, paralytic ileus and constipation. Figure 3 provides guidelines for medical and nursing staff to address common drug-related side-effects associated with PCA.

Procedure if analgesia with PCA is inadequate

2

Drug-related side-effects of PCA

Respiratory depression or excessive sedation

- If the respiratory rate drops to 10 remove PCA button from the patient, give oxygen 4 litres/minute by mask and reassess regularly
- If the SaO_2 is being recorded and falls below 94%, give oxygen at 4 litres/minute, if there is no improvement after 5 minutes seek advice from the Acute Pain Service or obstetric on-call anaesthetist
- If the respiratory rate drops below 8 and the sedation score is 2 (mostly sleeping) or 3 (difficult to waken), give oxygen at 4 litres/minute. Give naloxone, 50 μg (1 ml ampoule of naloxone contains 400 μg, dilute with normal saline to 4 ml and give in 0.5 ml (50 μg) increments until the respiratory rate increases to 12 and the patient is awake or dozing intermittently) and seek advice from the Acute Pain Service or obstetric on-call anaesthetist

Itching

Occasionally opioid drugs cause itching, particularly of the face – if this distresses the patient, treat as follows

- Change the opioid drug from morphine to pethidine or vice versa
- Naloxone, 50 μg, used with caution will reverse this side-effect without reversing analgesia – this should be reserved for very resistant, distressing pruritus
- Antihistamines: chlorphenamine (chlorpheniramine, Piriton), 4 mg, 4 hourly p.r.n. orally (max 24 mg in 24 hours), or if the patient cannot absorb tablets, 10–20 mg i.m. (max 40 mg in 24 hours)

Nausea or vomiting

- Do not stop or discourage use of PCA – pain can also cause nausea
- Give regular anti-emetic medication (see below), do not wait until the patient vomits
- If anti-emetic treatment fails, changing from morphine to pethidine or vice versa may reduce or eliminate nausea
- Give regular diclofenac plus regular paracetamol if not contraindicated. This may have an opioid sparing effect.

Anti-emetic treatment:
First choice: cyclizine, 50 mg i.v. 8 hourly p.r.n.
Second choice: prochlorperazine, 12.5 mg i.m. 6 hourly p.r.n.
Third choice: ondansetron, 8 mg i.v., one dose per 24 hours

Hallucinations may occur with morphine or pethidine – if the patient is distressed seek advice from the Acute Pain Service

Source: Acute Pain Service. University Hospital of Wales, Heath Park, Cardiff.

3

Mechanical problems

Mechanical problems such as 'syphoning', can be resolved by using anti-syphon valves. Syphoning occurs when all the contents of the syringe empty into the patient via the giving set, it is usually associated with damaged or cracked syringes and may result in overdose. Reverse flow of PCA solution into another intravenous infusion connected to the same cannula has also been reported and can lead to the patient receiving a bolus of opioid from the infusion fluid rather than from the PCA. One-way valves in the intravenous giving set can prevent this. Some pumps are susceptible to a build-up of static electricity that can reprogramme the system, and this has been reported as producing a non-fatal overdose.

User-related problems

Staff-related: misprogramming can be prevented by scrupulous protocols and ensuring the programming is checked by two nurses or doctors. Machine design could be improved to make available default settings, which could be pre-programmed; there would then be no need to programme the machine with each use, but merely to check it. Pre-filled syringes may also assist in avoiding errors in drug concentration, however, these need to be checked carefully. These changes may improve safety, but they do not allow for patients who require more individualized dosing regimens.

Patient-related: there are many reasons why patients do not use PCA to its full potential:

- they may not have been taught how to use it properly
- they have not retained the information on how to use it
- they may be confused postoperatively
- they are afraid of the side-effects associated with the drugs
- they fear addiction to the opioid drugs.

Problems can also occur if other patients, relatives or healthcare staff press the button, resulting in the administration of a dose of opioid. Also, the patient may press the PCA button thinking that it is the nurse call bell, resulting in an inadvertent opioid dose.

Requirements for PCA use

Patient education

For patients to use PCA to its maximum potential, they should be instructed in its use before surgery. It is advisable that they are given written information to support any verbal instruction. The type of information the patient may require includes:

- how to administer the analgesia
- when and how often to administer the analgesia
- what happens if the syringe runs out
- what to do if the analgesia does not work
- what the main side-effects are and how they are managed
- how safe PCA is and the risks associated with its use
- expectation of the pain after surgery and the effect that PCA should have.

Staff education

The setting up and programming of the PCA device is the responsibility of the anaesthetist or member of the Acute Pain Service initiating the treatment. However, the staff caring for the patient need to have written guidelines and protocols to standardize care and ensure safe practice. Staff will need to be educated regarding the following aspects:

- patient education
- standardized PCA regimens
- drug side-effects and their management
- changing syringes
- managing safety regarding the drugs and the PCA device
- monitoring of patients
- when to discontinue PCA.

Monitoring requirements

In the recovery area, staff will be required to assess the patient and titrate analgesia according to the patient's report of pain. PCA can be commenced once the patient is awake and able to use it. Hospitals have differing policies, but the following is recommended as safe practice. For the initial 2-hour period, pulse, blood pressure, respiratory rate, pain on movement and sedation levels should be assessed and recorded every half hour, then every 2 hours for 48 hours and 4-hourly thereafter if previous observations have been satisfactory. If observations are not satisfactory, the frequency of monitoring pain and vital signs will need to increase depending on the patient's condition. Patients who have had upper abdominal surgery or who have known pulmonary disease or who are receiving PCA with a background or concurrent infusion should have their oxygen saturation level monitored as well. If during the night, the patient is asleep and observations have been satisfactory it is acceptable to record the pulse and respiratory rate only. A recording should be entered on the sedation score chart to indicate that the patient was asleep at the time the observation was made. The amount of drug used should be recorded hourly on an appropriate chart and the infusion site checked for pain, swelling and leakage of fluid. A policy needs to be in place to advise ward staff who to contact should there be PCA-related problems.

When to stop PCA

The time for which patients require PCA following surgery is variable. On average, most patients require PCA for about 48 hours following surgery, but this differs between patients and the type of surgery. The following points should be considered before stopping PCA.

- If the patient has not reported any episodes of severe pain on movement in the previous 12 hours and the overall level of pain has reduced, the pain could be managed with weak opioid oral analgesics and/or NSAIDs if appropriate.
- If the patient is not using the device effectively, consider removing it and providing an alternative form of analgesia.
- When the patient is able to drink free fluids and has not experienced nausea and vomiting since commencing free fluids, oral analgesia can be commenced.
- If the patient is able to mobilize without being hindered by pain, PCA can be stopped.
- The amount of drug used in the previous 12 hours should be considered. The previous 12-hour PCA opioid dose must equate with or be less than the proposed maximum dose of oral analgesic substitute.
- If the patient does not want to use the PCA device to its maximum potential to effect pain relief, consider removing it and providing an alternative form of analgesia. However, discuss the patient's reasons and address any issues in order to improve compliance if possible. The patient may also be reluctant to have the PCA discontinued because they may fear the lack of control over their analgesia and the resultant increase in pain. This requires careful thought and discussion with the patient about assessment and management of their pain including the provision of appropriate alternative analgesia.

For patients using PCA to manage acute episodic pain, a careful assessment of their pain and condition should be made before stopping PCA and the following points should be considered:

- level of pain
- amount of drug used in the previous 12 hours
- patient's wishes.

Most patients require a less potent alternative form of analgesia once the PCA device has been discontinued. An initial alternative dose should be given and its effect monitored before PCA is discontinued.

Pharmacological Treatment of Chronic Pain

Mick Serpell

Mick Serpell is Consultant and Senior Lecturer in Anaesthesia at the Western Infirmary, Glasgow, UK. He qualified from Dundee University where he undertook most of his anaesthetic training. He specialized in regional anaesthesia and pain management at Orebro, Sweden, and Dartmouth-Hitchcock, NH, USA. These subjects continue to be his research interest.

Pain mechanisms involve numerous pathways, transmitters and receptors at numerous levels (peripheral, spinal and supra-spinal). Therefore there will never be a single 'magic bullet' antinociceptive agent, but a mixture of agents working together will be required to provide optimal analgesia.

Assessment of chronic pain
It is important to identify and manage any treatable aetiology of pain in the early stages because this will reduce the chances of it developing into a chronic problem. However, by the time most patients present at a pain clinic, they have been fully investigated and the cause is either identified and untreatable, unknown or of 'trivial' significance. This reaffirms that chronic pain is not just a symptom but an illness, with a major component occurring at the microbiological level. Our diagnostic tools are inadequate to detect these abnormalities and therefore clinicians and patients are often left without a satisfactory diagnosis.

The full assessment of a patient with pain requires evaluation of the biomedical and other components. The predominant issues should be identified and managed concurrently. The disability of pain is equal to the sum of the patient's physical, emotional, environmental, social and employment problems.

Pain is classified into nociceptive, neuropathic and psychogenic types, which can be acute or chronic (Figure 1).

Characteristics of clinical pain

Nociceptive (pain due to tissue damage)
Somatic
- Site – well localized, cutaneous or deep
- Radiation – dermatomal
- Character – sharp, aching, throbbing, gnawing
- Periodicity – often constant, also incident pain
- Associations – seldom

Visceral (sympathetically innervated organs)
- Site – vague distribution
- Radiation – diffuse, can be transferred to body surface
- Character – dull, vague (cramping, squeezing, dragging)
- Periodicity – often periodic, building up to peaks
- Associations – nausea, vomiting, sweaty, blood pressure and heart rate changes

Neuropathic (pain due to injury of nerve pathway)
Site of injury
- Central – central pain (thalamic infarct)
- Mixed – plexus avulsion, post-herpetic neuralgia
- Peripheral – neuroma,nerve compression, phantom, neuralgias, painful polyneuropathy, reflex sympathetic dystrophy, causalgia

Character
- Burning, tingling, pricking, numb, cold, pressing, squeezing, itching
- Constant often with intermittent shooting, lancinating, electric shock

Psychogenic (difficult to differentiate whether secondary to or actual cause of pain)
- Anxiety, depression (30% of depressives complain of pain on initial presentation)

1

Treatment
Goals: the main goals in the management of chronic pain are to reduce the pain as much as possible, to improve maximal function and where there is remaining pain, to improve the patient's ability to cope. In the early stages, the first objective is achievable to almost complete analgesia but when patients are in the intractable phase, the latter two goals are often the only ones possible.

Principles: the general principle of treatment comprises modulation of the pain pathways; destructive procedures are seldom performed. The treatment strategies are based on managing the nociceptive and neuropathic constituents of the condition. Chronic pain is often a combination of the two constituents, though often one plays the predominant role.

A logical and ordered approach is required, which must be initiated as rapidly as possible to avoid prolonging the patients' suffering. There is evidence that rapid control of pain symptoms can reduce the development of chronic pain. Pain symptoms are managed using pharmacological techniques, regional analgesia, physical therapy and psychological therapies. There is no strong evidence that one form of therapy is more effective than another. The exact order of implementation of therapies depends on local availability, side-effect profile and the patient's preference (most patients prefer to avoid medication). Optimal pharmacological treatment for chronic pain is that the medication should be taken 'round the clock' as opposed to 'as required'. It is easier to reduce severe pain by preventive measures rather than trying to manage it once it has become established.

This article deals only with pharmacological treatments and regional analgesia but the reader should be aware of the importance of physical and psychological modes of management.

Nociceptive pain

Nociceptive pain is the most common form of chronic pain. Low back pain and degenerative or inflammatory joint pains account for most of the referrals at pain clinics. There are also a large number of chronic visceral and postoperative pains. Although pain, such as that from rheumatoid arthritis, may begin as purely nociceptive, over time there is a neurological reaction which suggests that all pains eventually become neuropathic to a degree. Therefore, it makes sense to consider the use of neuropathic-type analgesics if pain control is still suboptimal. Pharmacological treatment of nociceptive pain can be classified into systemic and local modulation.

Systemic modulation
The World Health Organization (WHO) 3 step analgesic ladder was developed in the early 1980s as a tool to manage cancer pain. Analgesics, including paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs), codeine and the stronger opioid drugs (with or without adjuvants) have proved successful in controlling pain in over 80% of cancer patients. However, in non-cancer pain, step 3 is seldom used to its full potential because of the reluctance of these patients to use strong opioids.

Step 1: all non-opioid analgesics are derived from three types of compounds:
- aniline derivatives (e.g. paracetamol)
- aspirin and other acidic NSAIDs
- non-acidic pyrazole drugs (e.g. phenylbutazone, dipyrone).

Paracetamol is tolerated well by most patients and when taken regularly, seems to be as effective as the NSAIDs in managing the pain of rheumatoid arthritis. There is little effect on the liver when taken at normal recommended doses (maximum dose 4 g/day). It is indicated for mild-to-moderate pain, but reduces the requirements for more potent analgesics in severe acute pain. Although this has not been tested for chronic pain it should have the same effect and be worth adding to any regimen.

Over two dozen different NSAIDs are listed in the *British National Formulary.* Although they are a heterogeneous group of drugs with several types of chemical structure and subtle differences in bioproperties, they all inhibit the cyclo-oxygenase (COX)-mediated production of prostanoids (Figure 2). This mechanism is responsible for most of the analgesic effect and the side-effects (Figure 3). These drugs are useful for musculoskeletal pain and incident (movement-related) pain. There is no definitive algorithm of which drug to prescribe first but it is logical to try in sequence two or three different NSAIDs from different groups. Patients can obtain benefits or side-effects from one drug and not from another. It is appropriate to start with the drug that has the fewest side-effects, and then move to others. Consequently, most patients try ibuprofen first, followed by voltarol or mefenamic acid.

Classification of non-steroidal anti-inflammatory drugs

Group	Drug
Enolic acids	
• Oxicams	Piroxicam
• Pyrazoles	Phenylbutazone
Carboxylic acids	
• Salicylates	Aspirin Salsalate Diflunisal Benorilate (benorylate)
• Proprionic acids	Ibuprofen Naproxen Ketoprofen Fenbufen Fenoprofen Flurbiprofen Tiaprofenic acid
• Acetic acids	Indometacin (indomethacin) Diclofenac Ketorolac Sulindac
• Fenamates	Mefenamic acid Flufenamic acid

2

Side-effects of non-steroidal anti-inflammatory drugs

Gastrointestinal
- Nausea
- Dyspepsia
- Diarrhoea
- Peptic ulceration
- Perforation
- Bleeding

Renal
- Fluid retention
- Renal failure
- Papillary necrosis
- Interstitial fibrosis

Respiratory
- Bronchoconstriction
- Pulmonary eosinophilia
- Alveolitis

Coagulation
- Reduced platelet aggregation
- Increased bleeding time

Skin
- Stevens-Johnson syndrome
- Toxic epidermal necrolysis
- Angioedema

Visceral
- Congestive heart failure
- Hepatitis
- Pancreatitis
- Aseptic meningitis

3

With long-term use of NSAIDs the side-effect profile increases. Annually, 65,000 patients are admitted to UK hospitals for upper gastrointestinal perforation or haemorrhage; 20% (13,000) of these problems are directly caused by NSAIDs and 20% (2,500) of these patients will die. This problem has led to the development of a new generation of NSAIDs that reduce the incidence of side-effects – COX-2 inhibitors and dextro-isomers. COX-2 inhibitors (e.g. celecoxib, refecoxib) predominantly block the action of the COX-2 isoenzyme, therefore providing analgesia while permitting COX-1 to produce the beneficial prostanoids and so reduce side-effects. Dexketoprofen is the
S(+)-enantiomer of ketoprofen and is more potent, has a faster onset of action and fewer side-effects than the racemic mixture or the laevo form. Early evidence demonstrates that the COX-2 inhibitors are safer, but are not completely without NSAID-type side-effects. Similar evidence is emerging for dexketoprofen.

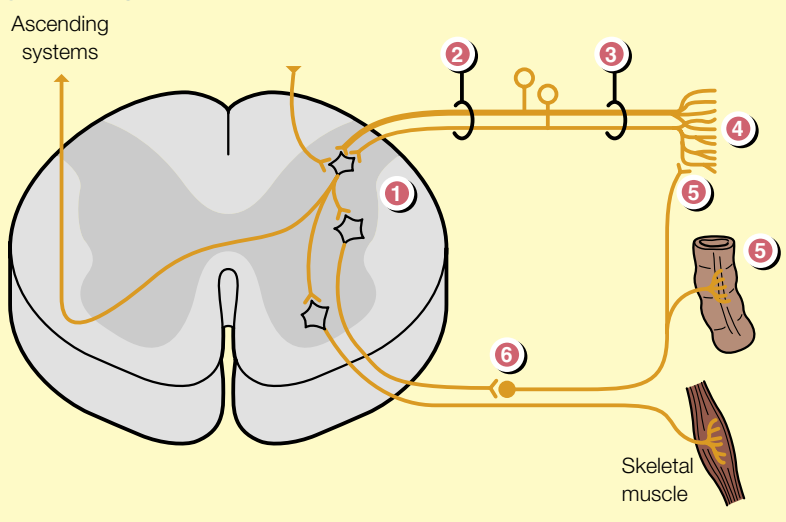
Aspirin is seldom used as an analgesic because it has a higher incidence of the side-effects listed in Figure 3. It causes irreversible inhibition of COX and therefore its effects do not subside with a reduction in plasma level but have to await production from new cellular growth, which may take several days. Phenylbutazone, the only pyrazole available in the UK, is restricted for resistant ankylosing spondylitis because of the incidence of aplastic anaemia and agranulocytosis.

Step 2: the less potent opioids (e.g. codeine, dihydrocodeine, dextropropoxyphene) are commonly used but inappropriately prescribed. Often, these drugs are not taken regularly and are usually combined with paracetamol. This limits the daily dose of opioid that can be taken because the patient is restricted to about eight tablets per day (maximum 4 g/day of paracetamol). The use of compound analgesics makes consumption simpler for the patient, but limits optimal opioid titration and is often more expensive. If the decision to use an opioid is made, then it should be titrated to an appropriately potent level to assess response. This philosophy and other aspects of step 3 of the WHO ladder are discussed elsewhere. The issue of adjuvant drugs is discussed below.

Local modulation
Local modulation uses the local application of treatments. These may be physical, such as transcutaneous electrical nerve stimulation (TENS) or acupuncture. They both have few side-effects and should be tried early. Alternatively, treatment may be pharmacological in the form of regional application of drugs.

Injection of drugs into tissue (e.g. into a myofascial 'trigger spot') or a nerve has the advantage of requiring only a small dose with a consequent low risk of side-effects. Regional analgesia can be applied to any nerve, from superficial peripheral nerves to more complex and deeper nerves that require X-ray facilities (Figure 4). They can be grouped into somatic (peripheral or cranial), sympathetic and central nerve blocks (epidural and spinal). The indications for performing a nerve block are that it can aid in the diagnosis, it sometimes gives a prognostic indicator as to how easy the pain will be to treat, it can be therapeutic and educational (to experience motor/sensory loss if a neurolytic procedure is contemplated). Nerves are injected at a peripheral site first, but if this is unsuccessful injection can be performed at progressively more central sites. While not a long-term cure, these blocks often have a beneficial response outlasting the pharmacological action of the local anaesthetic. They can provide benefit for days to weeks and can be useful in conjunction with other therapies.

Types of regional blockade performed for pain relief



1 **Pharmacological inhibition**
Using spinal or epidural block

Afferent blockade
2 Differential blockade
3 Peripheral nerve somatic or visceral

4 **Tissue/organ injection**
Periarticular
Cutaneous
Soft tissues
Viscera
Skeletal muscle

5 **Transmitter block**
Autonomic target organs

6 **Sympathetic block**

4

The drugs used include a mixture of pharmacological agents. Local anaesthetic drugs such as bupivacaine can be used as a dilute solution (0.1%) which often blocks the pain fibres but spares most of the sensory and motor fibres. This is called an analgesic versus an anaesthetic block. Various other drugs are often used to reduce pain fibre activity such as opioids, corticosteroids, α_2-agonists (e.g. clonidine) and N-methyl-D-aspartate (NMDA) antagonists (ketamine).

Some patients ask if they can have a neurolytic block to destroy the nerve permanently. Neurolytic blocks (using alcohol, phenol, cryotherapy or radiofrequency) do not have a permanent effect. The neural system usually regenerates and adapts after 3–6 months and the pain can return or be worse with sensory dysaesthesia and deafferentation pain and motor deficits. These procedures are usually reserved for terminally ill patients who will not survive long enough to experience these complications. However, there are some conditions for which this approach is appropriate, for example neurolytic sympathetic block for small vessel peripheral vascular disease.

Occasionally a patient has symptoms that are amenable to more invasive procedures. These include implanted drug delivery systems (epidurals and spinals) and dorsal column or intracranial stimulation. More invasive treatments should be performed only in appropriately selected patients by centres experienced in such procedures.

Neuropathic pain

Diagnosis
Neuropathic pain affects 2–4% of the population. This does not include the patients with chronic nociceptive pain, mentioned earlier, who may also have a significant component of neuropathic pain. Neuropathy activates certain excitatory and inhibitory mechanisms and it is the relative over-excitability of the neural balance that determines whether pain is produced. The primary aim of treatment is membrane stabilization of the abnormal nerves. The exact abnormality probably involves several mechanisms.

Patients often find neuropathic pain symptoms difficult to describe but some of the words commonly used include burning, tingling, numb, pressing, squeezing and itching (Figure 5). It may be present constantly or intermittent with electric shooting sensations. The signs of neuropathic damage are often subtle but are usually elicited with the aid of simple tools such as a pin, cotton wool and tuning fork. Occasionally more specialized equipment is used such as von Frey hairs, thermal thresholds for temperature and pain detection, electromyography or nerve conduction velocity studies.

Signs of neuropathic damage

Negative phenomena	Positive phenomena
Sensory	
Hypoaesthesia	Hyperaesthesia, dysaesthesia, paraesthesia
Hypoalgesia	Hyperalgesia, hyperpathia, allodynia
Autonomic	
Vasodilatation	Vasoconstriction
Hypohidrosis, anhidrosis	Hyperhidrosis
	Piloerection
Motor	
Paralysis	Fasciculations, dystonia

Modified from Table 1 in *Serra J. Acta Neurol Scand* 1999; **173**: 7–11. Printed with permission.

5

The site of injury and cause of the nerve damage vary and include several pathologies. It is important to identify any treatable aetiology of pain in order to prevent progression of the disease (i.e. good normoglycaemic control for diabetic neuropathies). However, this is not always possible and treatment of pain should commence as soon as it is experienced. Although neuropathic pain can be unrelenting and difficult to treat, several options are available.

Treatment
The conventional analgesics used for nociceptive pain are often ineffective for neuropathic pain. Most of these drugs are called 'adjuvant analgesics' because their primary indication is not for pain (i.e. antidepressants, anticonvulsants, antiarrhythmics). However, many of them are used more commonly for neuropathic pain than for their approved indication. They share a common action, are usually membrane stabilizers and can suppress the excessive neuronal activity that maintains this disease process.

Currently all neuropathic pains are treated the same regardless of cause or symptoms. In the future, diagnostic criteria may identify subpopulations of patients which respond to particular drugs based on pain mechanism characteristics and physical findings. There is no evidence to support the old dictum that burning pain is more responsive to tricyclic antidepressants and lancinating pain is more responsive to anticonvulsants. At present, the general mode of drug prescription is sequential drug trials. A patient undergoes a titration of a drug to a suitable dose and for a suitable duration until they obtain greater than 50% pain relief or experience intolerable side-effects. If there is no relief, the drug is usually omitted. If they obtain partial pain relief, a second drug is usually added to the regimen. If a patient obtains benefit they can continue the medication indefinitely, though they should be encouraged to wean off gradually every 6 months or so to ensure they still require the medication.

Antidepressants: the tricyclic antidepressants are the 'gold standard' of treatment because they are the most effective and best known. The tertiary amines have more side-effects than the secondary amines; the latter can be used as an alternative if side-effects are a problem (Figure 6). They inhibit the reuptake of the neural transmitters noradrenaline and serotonin and thus potentiate the dorsal inhibitory pathway that terminates in the dorsal horn of the spinal cord.

Side-effects of antidepressants

Secondary amines
- Predominantly blocks noradrenaline reuptake (i.e. nortriptyline, desipramine)
- Less sedation than tertiary amines
- Fewer anticholinergic effects than tertiary amines
- Weight gain
- Nortriptyline is less hypotensive than the tertiary amines

Tertiary amines
- Block noradrenaline and 5-HT reuptake (i.e. amitriptyline, imipramine, dothiepin)
- Antihistamine effect – sedation
- Anticholinergic effects (dry mouth, constipation, urinary retention)
- Weight gain
- Cardiac arrhythmias – tachycardia, hypotension

Selective serotonin reuptake inhibitors
(i.e. fluoxetine, sertraline, citalopram)
No evidence that they are better than placebo

Third-generation antidepressants
(i.e. venlafaxine inhibits noradrenaline and 5-HT reuptake)
Results in less sedation and fewer anticholinergic effects
In theory, should work but only weak evidence at present

6

Amitriptyline is started at 10 or 25 mg at night and gradually increased in 10 or 25 mg increments every few days to 50–100 mg at night. Analgesic benefit may occur after 2 weeks but often requires 8 weeks. Compliance is poor because patients often experience side-effects early on without any benefit and so discontinue the medication. Also, if they have not had an adequate explanation of the rationale for an antidepressant to be used, they may think that the doctor believes their pain to be psychological in origin and may feel that they have not been taken seriously. They must be told to persevere if possible and that they will become tolerant to most of the side-effects after a few days to weeks. One in three patients will get more than 50% pain relief, an excellent result for a chronic pain condition. If amitriptyline is too problematical then a less sedating alternative such as imipramine, nortriptyline or venlafaxime is worth trying. Not all antidepressants relieve pain; the serotonin selective reuptake inhibitors (SSRIs) are not regarded as useful and are seldom used.

Anticonvulsants have been used successfully for neuropathic pain. The older drugs such as carbamazepine and phenytoin are as effective as amitriptyline. However, they produce more central side-effects such as sedation, and induce liver enzymes, which can affect the metabolism of other drugs. This is particularly important in the elderly because they often have neuropathic pain and are taking several drugs.

Carbamazepine can cause allergy, and liver and bone marrow suppression. Again, the secret is to titrate low and slow, from 100 mg t.i.d. up to 300 mg t.i.d. over a few weeks. Before taking an anticonvulsant the patient's baseline haematology and biochemistry profile should be determined.

Gabapentin is the only anticonvulsant with a licence specifically for neuropathic pain. It is increasingly being used as first-line therapy because it appears to be as effective as the other anticonvulsants and with fewer side-effects. Other drugs worth trying are lamotrigine, clonazepam, valproate and more recently topiramate.

Antiarrhythmics: lidocaine (lignocaine), 5 mg/kg, can be given intravenously as an infusion over 1 hour with cardiovascular monitoring to assess the responsiveness of the patient's pain. If it results in an improvement for several weeks or months, it can be repeated as required. If it brings improvement for a few hours or days only, give the patient oral mexilitine to maintain the effect (oral lidocaine (lignocaine) is unsuitable because it undergoes extensive first-pass metabolism). Patients must have a baseline electrocardiogram to ensure they have no underlying contraindication to mexilitine. The dose is gradually increased from 100 mg t.i.d. towards 300 mg t.i.d. but most patients experience nausea at high doses.

Topical drugs have fewer side-effects because they are not taken systemically. Pain in a small and accessible cutaneous area is suitable for topical treatment.

Capsaicin is a nerve toxin that inactivates the small pain C fibres. It needs to be applied 3–4 times daily for up to 8 weeks before it can be appraised. Capsaicin comes in two strengths, 0.075% for neuropathic pain and 0.025% for arthritic pain. The former can cause an uncomfortable burning sensation, but this often recedes after 1 week or so. However, if it is a problem, it can be mixed with lidocaine (lignocaine) gel or glyceryl trinitrate ointment or titrated up gradually from the 0.025% strength.

Topical imipramine is licensed for itch but seems promising for neuropathic pain. Lidoderm patches (containing lidocaine (lignocaine)) and topical clonidine are available only in the USA. Few neuropathic pains have a sympathetic component and therefore clonidine has only a limited role. The lidoderm patch is often used as first-line treatment in the USA.

Opioids: it used to be said that neuropathic pain was resistant to opioids, but this is not always the case. They can help one of eight patients and are always worth a trial as a last resort. Morphine is the standard drug but it may be more appropriate to try other opioids if inefficacy or side-effects occur. The reason neuropathic pain is relatively resistant to opioids is that there is an increase of cholecystokinin (CCK) in the spinal cord which acts as an opioid antagonist. One way to address this problem is with CCK antagonists such as cholycade or devacade, and clinical trials are under way.

Tramadol has a dual mode of action, it is a moderately strong opioid (equipotent to pethidine) with two-thirds of its activity caused by a mechanism similar to amitriptyline. It is a multi-modal drug in keeping with the underlying principle of current pain management strategies.

Other drugs: ketamine can be useful given alone, or to potentiate the effects of an opioid. It can be given as an intravenous or subcutaneous infusion in a dose of 0.1–0.5 mg/kg/hour. It can also be taken orally and titrated from 20 mg b.d. to 50 mg q.i.d. if required. The oral dose is impossible to predict from the parenteral dose owing to the highly variable oral bioavailability.

There is evidence that oral tizanidine, 4–16 mg/day, is beneficial; it is an α_2-agonist like clonidine.

Pain management programme
When all medical management has failed it may be time to consider a pain management programme. It should be considered earlier on if the patient is coping poorly. It is a programme that uses primarily psychological and physiotherapy techniques to help patients improve their ability to cope and function. The aim is to empower the patient to adapt and achieve as optimal a quality of life as possible. ◆

Principles of Ethics in Pain Research

Hugh Neill
Nick Pace

Hugh Neill is Consultant Anaesthetist at Crosshouse Hospital, Kilmarnock, UK. He trained in Glasgow and has an interest in the management of acute and chronic pain.

Nick Pace is Consultant Anaesthetist at Western Infirmary, Glasgow, UK. He qualified from Glasgow University and trained at the Glasgow Western and Royal Infirmaries; University Hospital of South Wales and Parkland Memorial Hospital, Dallas, Texas, USA. His interests include airway management and anaesthesia for renal and adrenal diseases. He is currently completing a PhD in medical law.

Ethics are the rules and principles that govern proper conduct and as such may vary with time and place. Modern research ethics owe their origins to the atrocities conducted, in the name of scientific experimentation, in the concentration camps during World War II. The Nuremberg code of 1947 and more recently the World Medical Association Declaration of Helsinki (1964, revised 1975, 1983, 1989, 1996 and 2000) provide a framework of principles that guide biomedical research today.

A major theme is the conflict of interest that may develop between the rights of individual research subjects and the benefits of that research to present and future members of society. The Helsinki Declaration stipulates that 'considerations relating to the well-being of the human subject should take precedence over the interests of science and society' and that the doctor should 'obtain the subject's freely given informed consent'.

Pain research is governed by the same ethical principles that apply to all biomedical research. Patients with chronic pain may represent a vulnerable group that characteristically expresses a willingness to try new therapies, at the risk of side-effects, in order to achieve some benefit. Their relationship with the specialists caring for them may make them susceptible to pressure (not always intended) to participate in research studies and a placebo effect is well recognized. Research with the aim of expanding the scientific understanding of pain mechanisms requires careful ethical consideration if human subjects are involved. Central to the ethics of research is the free, autonomous choice to participate by the research subject. This is achieved by obtaining 'fully informed consent', guided by the principles in Figure 1.

Principles for informed consent in research

Competence
Research should be carried out only on legally competent persons unless the physical or mental condition that prevents obtaining informed consent is a necessary characteristic of the research population. In such instances consent may be given, subject to certain restrictions beyond the remit of this article, by others with legal authority over the research subject, as for example parents on behalf of their child

Disclosure of information
The Helsinki Declaration requires that every subject must be 'adequately informed of the aims, methods, sources of funding, any possible conflicts of interest, institutional affiliations of the researcher, the anticipated benefits and potential risks of the study and the discomfort it may entail'

Understanding
The information should be presented in a form and language that the research subject understands

Voluntary
Research subjects should be helped to feel comfortable about saying "No" if they feel this is the right choice for them. It may be necessary to have a named other person, who is not directly involved in the study, available to discuss any issues the research subject may wish to raise

Authorization
Having fulfilled the criteria listed above the research subject should sign the consent form and be allowed to keep a copy of the information sheet

Therapeutic, non-therapeutic research and innovative treatment

Although no longer distinguished in the revised Declaration of Helsinki, it can be useful to differentiate between therapeutic and non-therapeutic research. In therapeutic research the subject may derive therapeutic benefit from the trial. In non-therapeutic research the only intention is to extend knowledge of a particular condition and it will be of no benefit to the research subject. Phase 1 drug studies, which study the toxicity of drug schedules, are examples of non-therapeutic research. Both types of research require thorough ethical examination by Local (LRECs) or Multicentre Research Ethics Committees (MRECs).

New treatments or techniques are often introduced into clinical practice without prior formal ethical scrutiny and this leads to a number of anxieties. In general, techniques that diverge substantially from normal practice, or that warrant more than minimally greater risk, or those where the intention is to acquire new knowledge that is not solely for the benefit of the patient, should be subject to ethical committee review. In all examples of innovative or non-standard therapy, ethical doctrine dictates that patients should be fully informed and consent obtained.

Randomized controlled trials

The randomized clinical trial poses a particular ethical problem for researchers. Randomization is ethical only if there is significant doubt about the best treatment for a patient volunteering as a research subject. If one treatment is perceived by the doctor to be advantageous, or otherwise inappropriate, for an individual patient, then randomization would be unethical and should not proceed. This is known as 'therapeutic equipoise'. The clinician should be indifferent to the choice of treatment because there is no body of evidence to dictate which treatment may be better. The new proposed treatment may be better, equal or worse than the established treatment. The 'double blind' technique also aids in achieving therapeutic equipoise.

There is an argument that because subjects may exclude themselves from randomized trials, the final pre-selected group is not representative of the total population, invalidating any extrapolation of results. The effect of informed consent in reducing participation may be greater when one limb of a study is a placebo group because participants may consider (correctly) that they have a 50% chance of receiving an ineffective therapy (placebo) while there is a chance that the intervention under test is effective. This may be of greater importance in pain research.

The circumstances in which it is ethical to deprive a patient of treatment need to be strictly regulated. An extreme view is that placebos should be allowed only when there is no agreed alternative treatment of greater therapeutic value than placebo. This viewpoint is becoming more widely accepted.

Problems may also develop after the study if patients wish to continue a treatment that has proved beneficial but is not yet licensed for general use.

Despite this and other concerns, randomized clinical trials remain the accepted gold standard in clinical research. Although participation in trials may appear to constitute a potentially hazardous step for the individual patient, those who participate in trials do better, even when receiving placebo or a less effective treatment, than patients not involved in the research study. This probably reflects the greater degree of monitoring, compliance to protocol and generally higher quality of care in research projects.

It is imperative that patients are asked to take part only in well-designed, scientifically sound research projects. Poorly designed research is unethical because erroneous scientific data cannot contribute to new knowledge and calculation of risk versus benefit for a particular treatment is impossible. There is also an ethical duty to publish and make available results (negative or positive) of well-conducted scientifically validated trials.

Law and medical research

In many countries, human research is conducted within a legislative framework of principles. In Britain, research, apart from that on embryos, is not governed by legislation. There is no legal requirement for research ethics committees to be established in all health districts, though it is Department of Health policy that all research carried out in the National Health Service is subject to their scrutiny. At present, a combination of general medical law (laws of consent and confidentiality), general legal provisions and a pattern of established good practice exists.

British courts have not considered how much information a research subject should be given. However, the Canadian case of *Halushka* is indicative of the approach British courts might take.

This case concerned the trial of a new anaesthetic agent in which the subject suffered a cardiac arrest when a catheter was advanced into his heart. The basis for the lawsuit was insufficient disclosure of information to enable valid consent to be obtained. The judge stated that 'there could be no exceptions to the ordinary requirements of disclosure in the case of research as there may well be in ordinary practice'.

It would thus seem that the rights of the research subject are greater than the rights of a patient receiving normal routine therapy. The standard of information offered to research subjects requires 'full and frank' disclosure of the risks involved. This standard appears to be even greater for 'non-therapeutic research'. Thus, if research is designed to test a hypothesis and thus contribute to general knowledge, the law is more likely to set limits on the risk of harm that an individual may agree to.

Psychological Techniques in the Management of Pain

Herma F Caris

Herma F Caris is a Clinical Psychologist working in Pain Management at the Pain Clinic, Borders General Hospital, Melrose, UK. She qualified as a psychologist in the Netherlands and underwent further training in clinical psychology in Kent, UK. Her interests are in health psychology, especially its clinical application to chronic and acute pain management and chronic illness management.

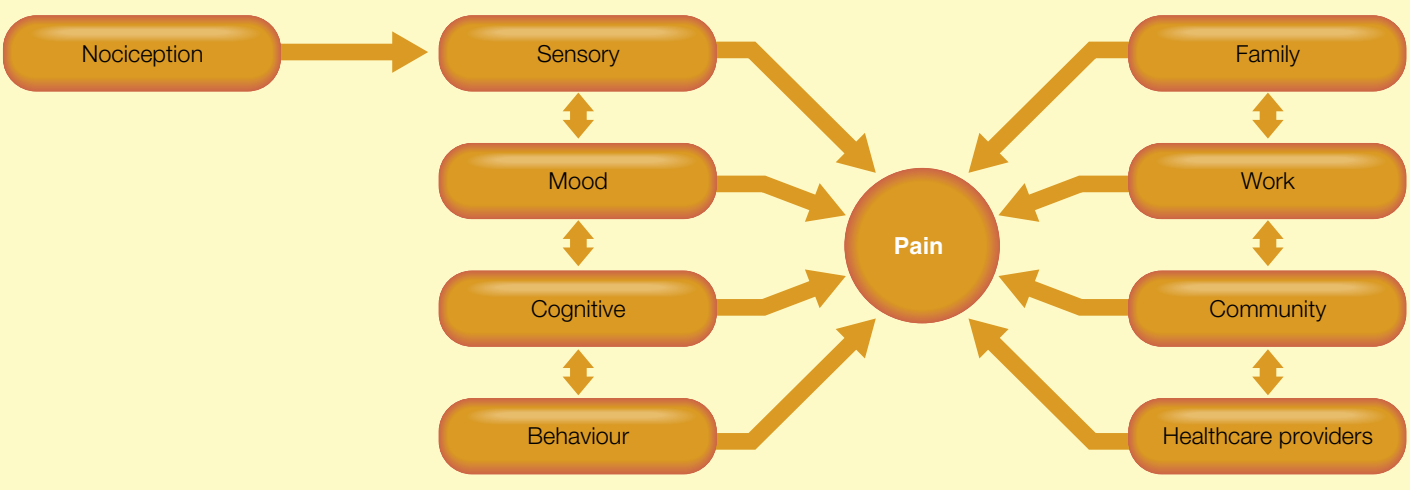
Everyone has experienced pain to some degree, but attempts to define it accurately have often been unsatisfactory. In the 1980s, the International Association for the Study of Pain defined pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage', and this definition is widely accepted. It stresses that pain can occur in the absence of a physical cause, and it emphasizes the psychological contribution to pain.

If the premise is that pain is a complex subjective phenomenon that is uniquely experienced by each individual, then psycho-logical issues such as knowledge about idiosyncratic beliefs, appraisal and coping repertoires are essential for optimal treatment planning and delivery and for evaluating treatment effectiveness.

Until the early 20th century, concepts such as the mind and the soul were thought to have no bearing on physical function and behaviour. At that time, influential writings began to appear that emphasized the importance of adopting a more integrated, holistic approach to health and illness. This culminated in the development of the gate control theory and the biopsychosocial model, which is widely applied to the study and treatment of pain.

Biopsychosocial model
The biopsychosocial model focuses on illness rather than disease. Illness is seen as a result of a complex interaction of biological, psychological and social variables. The main tenet of this model is that there is a continuing, dynamic and reciprocal interplay between these variables, which shapes the patient's perceptions and response to disease and pain. From this perspective, the diversity in illness expression is accounted for by the complex interrelationships among those variables (Figure 1).

Multidimensional model of pain



1

In the biopsychosocial model, the role of the psychologist in the treatment of pain is essential. Treatment from the biopsychosocial perspective aims to furnish patients with knowledge and techniques to improve their control over the effects of pain on their lives and to modify the sensory, affective, behavioural and cognitive facets of the pain. Ideally, pain management consists of an interdisciplinary structure (i.e. medical, physiotherapy, nursing, occupational therapy, psychology). The psychologist's initial role is to assess the patient's psychosocial functioning (current and pre-morbid), personality characteristics, motivational status, coping resources and social support. This aids interdisciplinary treatment planning. Subsequently the psychologist provides pain management treatment, when indicated, and monitors progress (Figure 2).

Role of the psychologist in an interdisciplinary pain management team

- Provides evidence-based psychological therapy to improve the patient's ability to cope with pain and the interpersonal stresses and problems arising as a result of pain
- Provides education to other team members about the psychological needs and problems of pain patients
- Assesses psychological parameters and social/ environmental factors that affect the patient's pain experience and treatment outcome
- Researches pain management
- Improves effective communication between patients and healthcare providers

2

One of the hallmarks of the biopsychosocial perspective is the concept of evolution; at different points during the evolution of the pain experience, the weighting of the biological, psychological and social variables changes. Therefore, there is a distinction between the acute phase of pain experience and the chronic state experience of pain. During the acute phase, biological factors generally predominate, but over time psychological and social factors may gradually assume a disproportionate role in accounting for symptoms and disability. Therefore the role of the psychologist is less central, yet not insignificant, in the management of acute pain than it is in chronic or persistent pain management.

Techniques for acute pain

Psychological techniques may be useful in acute pain management if standard medical techniques fail to provide the amount of pain relief desired, or if patients are intolerant of or opposed to interventional techniques.

Education
Increasing the patient's knowledge about pain and medical procedures can help to reduce the anticipation of threat or harm. Relieving anxiety often decreases reported pain. Providing education and information may act synergistically with pharmacological methods of pain relief.

Cognitive strategies
Sometimes the fears associated with pain and analgesic use are not alleviated by a simple, rational explanation of the facts. In these cases, a clinician trained in addressing the multidimensional aspects of pain (i.e. sensory, affective, cognitive, social, behavioural) will have to assist the patient. There may be some benefit in addressing some cognitive factors that can impede adequate pharmacological pain control. Maladaptive pain-specific beliefs and self-efficacy beliefs can negatively mediate pain perception and the use of coping strategies. Beliefs about the duration of pain are important. If patients can be helped to view pain in terms of discrete time duration, coping will be more adaptive and pain reduction more likely. It may also be important to address maladaptive beliefs that have sprung from past traumatic experiences involving pain or painful procedures. This process of attempting to look at pain-related issues from a different, more 'healthful' angle, can be classified as a low-level form of cognitive restructuring. Cognitive restructuring is the core of cognitive therapy, which is an essential component of chronic pain management described below.

Using positive affirmations (i.e. positive and encouraging self-statements) can also be helpful in acute pain management.

Distraction is another useful method in acute pain management. Distraction strategies can be simple, such as getting patients to focus on an interesting item in the room, a mathematical task or a story, or introducing counter-stimulation to some other part of the body. Sometimes distraction needs to be more complex. An example of the latter would be inviting the patient to imagine him/herself in an interesting, pleasant place or situation, which would verge on the strategy of formal relaxation.

Relaxation and biofeedback
Relaxation training is a systematic approach to teaching individuals to acquire awareness of their physiological responses and achieve a cognitive, an affective and a physiological sense of comfort and tranquillity.

Biofeedback is a procedure in which the therapist monitors, through a machine, the patient's bodily responses and then feeds this information back to the patient. This information enables patients to learn to exert some control over their bodily function and thus to enhance pain control.

Because relaxation therapy generally entails fewer sessions and does not require machinery, it is often chosen as the first intervention. There is a wide range of relaxation techniques; one form is not consistently superior to any other. The major forms used are progressive muscle relaxation therapy, guided imagery, autogenic training and meditation.

Hypnosis
There is usually some overlap between relaxation and hypnosis and these techniques are commonly blended as needed. Hypnosis is a state of highly focused attention during which alteration of sensations, awareness and perceptions can occur. An integral part of hypnosis is suggestion (this is not necessarily the case in relaxation). Suggestion is a way of conveying to a patient that something will be accomplished or experienced; this can be explicit or implied. In acute pain situations, where long-term coping with pain is unnecessary, hypnosis can be used to obtain relief by actively moving the patient's mind to comfort and pleasure unrelated to symptoms.

Techniques for chronic pain

Chronic pain is often demoralizing and incapacitating. Patients often develop significant symptoms of depression and anxiety if they are unable to obtain relief. Over time, a vicious cycle ensues between chronic physical pain and psychosocial dysfunction in which each condition exacerbates the other. Determining suitability for treatment is a crucial element of the psychological assessment interview. Pre-morbid psychological problems can contribute to or are aggravated by the chronic pain and may negatively interfere with a patient's ability to achieve progress. The presence of certain social or environmental factors, such as personal injury litigation or a disability claim, can potentially hamper therapeutic progress. Such factors may lead to the decision to postpone treatment or to commence treatment cautiously.

Treatment of chronic pain involves a comprehensive, holistic approach, using medication and functional rehabilitation. The objectives are for patients to learn to accept that pain is not always curable and therefore something they may have to live with, to get a better understanding of the pain, and to elevate the level of perceived control over the pain.

The following psychological techniques are essential in effective chronic pain management. All of the treatment approaches can be administered on an individual or on a group basis. Group treatment has the added value of peer support and vicarious learning. Individual therapy generally allows for greater depth.

Education
When pain is persistent or chronic, patients need to be informed of the nature and biopsychosocial background of their pain. This helps to modify any unrealistic assumptions and expectations, and enhances their motivation to engage in pain self-management. The basic building blocks of the 'psychology of pain', such as the gate control theory, learning processes and psychosocial aspects, should be explained to patients to furnish them with a sound foundation for understanding and applying self-management strategies.

Relaxation
Relaxation methods are core to the treatment of chronic pain. They are described above in the section on acute pain.

Cognitive therapy
Cognitive therapy is a structured, time-limited, problem-focused, goal-oriented and educative form of psychotherapy. It is present (rather than past) oriented, stresses a collaborative relationship between therapist and patient, and encourages active participation in the treatment by both therapist and patient. Cognitive therapy has been used in chronic pain management for 20 years. It is based on the idea that cognitions (thoughts) have a strong controlling influence on emotions, behaviour and pain experience. This approach places specifically irrational ideas about pain and suffering at the forefront and suggests that the modification of these maladaptive beliefs is the central ingredient for a more successful adaptation to a life with chronic pain. The aim is to promote cognitive restructuring, facilitating a basic change in a person's perspective, attitudes, beliefs, emotional reactions and behaviours related to the pain they are experiencing. This entails teaching patients skills for identifying, evaluating and modifying the inner dialogue they maintain with themselves, in order to change the nature of the pain experienced favourably. This requires a sound motivation to change.

Hypnosis
Long-term coping is necessary for chronic pain and so the technique of hypnosis differs from that used for acute pain. As a general rule, positive suggestions (i.e. the indication of what is felt), are more powerful than negative suggestions (e.g. the pain will disappear). The most commonly used suggestions for chronic pain relief include: creating an escape or distraction, replacing the pain with something else that is similar but hurts less or is of lesser intensity, or creating sensory transformation.

Operant conditioning
Operant conditioning is an empirically based behavioural model of learning. It finds its clinical application in behaviour therapy. In the 1960s and 1970s, Fordyce contributed greatly to the field of pain management, by introducing and highlighting the role of operant conditioning principles in the genesis and maintenance of pain behaviour problems. The theory of operant conditioning asserts that all overt behavioural responses are significantly influenced by both their consequences and the context in which they are emitted. The most fundamental paradigm within the model is that of reinforcement. Operant conditioning methods have become a fundamental part of successful pain rehabilitation, particularly in terms of increasing physical functioning. The mainstay of this approach is the targeting of behavioural excesses, as well as deficiencies, for intervention. Behavioural excesses are targeted for reduction or elimination, and for replacement by more adaptive behaviours. Behavioural deficits are targeted for remediation through shaping and positive reinforcement procedures. Operant conditioning methods are ideally used in concert with other psychological and medical treatments within an interdisciplinary team approach.

Psychodynamic psychotherapy
Most patients with chronic pain benefit significantly from the interventions described so far and they should be treatments of choice for all patients suffering from chronic pain. Occasionally, however, these treatments do not have the desired effect, or patients are assessed as unlikely to respond to such interventions. In those cases the psychodynamic approach might be a treatment option. The psychodynamic perspective (i.e. Freudian) highly values unconscious processes, especially those related to pain proneness. These processes have their origins in untoward early life experiences. These unconscious factors lie dormant until life events such as physical trauma or illness provide a theatre for expression in chronic suffering. Psychodynamic therapy is often long-term, and this may curtail its use within current healthcare systems. ◆

Radiofrequency Lesioning Techniques in the Management of Chronic Pain

Dil Kapur

Dil Kapur is Consultant in Pain Management at the Royal Victoria Infirmary, Newcastle upon Tyne, UK. He is a graduate of Birmingham University Medical School and trained in anaesthesia and pain management in Leeds and Newcastle. His clinical and research interests include interventional procedures in pain management and the clinical neuropharmacology of analgesic drugs.

The concept of destroying neural tissue by electrical current is not new. Direct current (DC) causes electrolysis of tissue fluids and effective destruction of nervous tissue (this is the manner in which the CNS is destroyed by the 'electric chair'). DC apparatus was used in the 1950s to perform limited neuroablative procedures, but such lesions were difficult to control and the DC was painful and hazardous to apply.

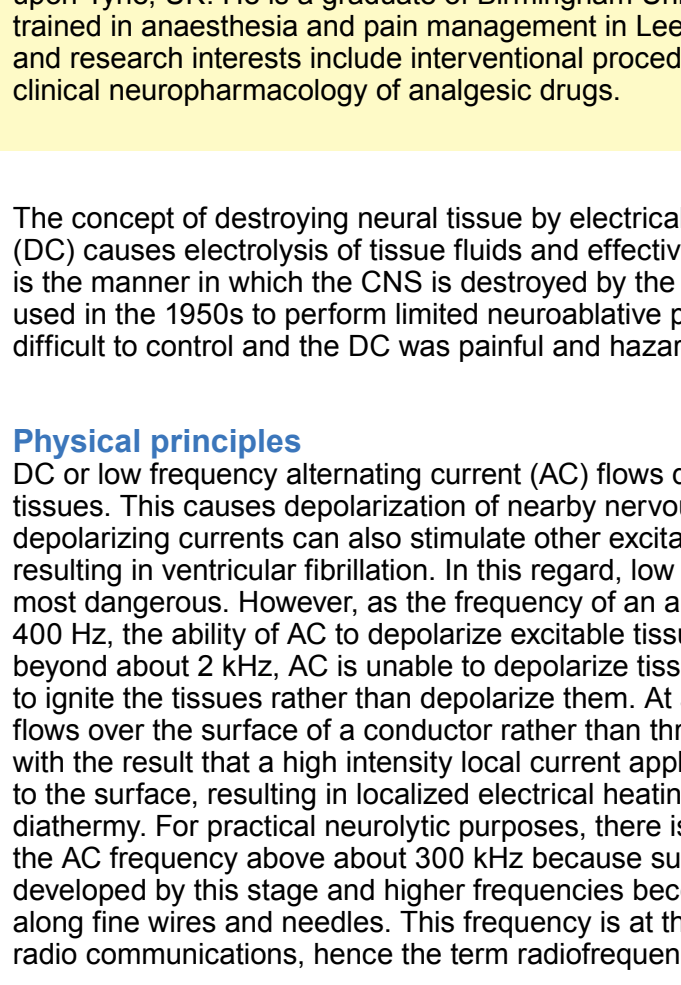
Physical principles

DC or low frequency alternating current (AC) flows directly through central bodily tissues. This causes depolarization of nearby nervous tissue and pain. Such depolarizing currents can also stimulate other excitable tissue, such as the heart, resulting in ventricular fibrillation. In this regard, low frequency AC of about 50 Hz is the most dangerous. However, as the frequency of an applied AC is increased above about 400 Hz, the ability of AC to depolarize excitable tissue decreases dramatically such that beyond about 2 kHz, AC is unable to depolarize tissues and the currents required tend to ignite the tissues rather than depolarize them. At a frequency above several kHz, AC flows over the surface of a conductor rather than through the substance of the material with the result that a high intensity local current applied to an area dissipates rapidly to the surface, resulting in localized electrical heating – this is the basis of surgical diathermy. For practical neurolytic purposes, there is little advantage in increasing the AC frequency above about 300 kHz because surface conduction effects are well developed by this stage and higher frequencies become increasingly difficult to transmit along fine wires and needles. This frequency is at the lower end of the range used for radio communications, hence the term radiofrequency (RF).

RF lesioning

Practical RF lesioning apparatus uses an RF source to apply a current to an insulated needle with an exposed tip. The needle can accommodate a close tolerance platinum thermocouple that measures the temperature generated around the uninsulated section of the needle. Control circuitry within the equipment regulates the current applied to maintain a preselected temperature, usually in the range 60–90°C. A timer regulates the duration of applied current. Modern equipment also includes devices for measuring impedance and applying low intensity stimulating currents to the needle in order to help locate nervous tissue.

An RF current applied to the needle causes a zone of heating around the uninsulated portion of the needle. It is important to remember that it is the tissue that is heated, not the needle. The heating occurs in an oblate spherical pattern and the area with minimal heating is the tip of the needle. For this reason, it is essential that the needle is placed adjacent and parallel to a nerve rather than perpendicular to it (Figure 1).



1

Heating nervous tissue above about 50°C denatures intra-cellular proteins and kills neurons. Temperatures above 65°C destroy myelin and kill axons. As a general rule, temperatures of 70–80°C are used, though lower temperatures are safer when lesioning areas of the CNS such as in spinal cordotomy.

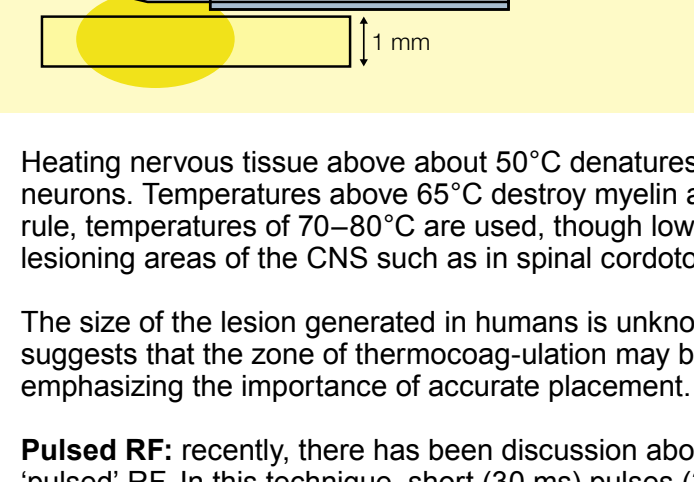
The size of the lesion generated in humans is unknown. However, *in vitro* work suggests that the zone of thermocoag-ulation may be as little as 4–6 mm in diameter, emphasizing the importance of accurate placement.

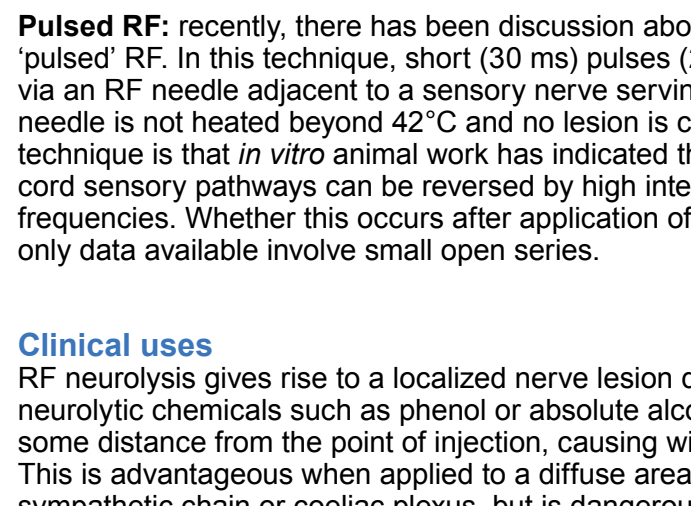
Pulsed RF: recently, there has been discussion about the technique of so-called 'pulsed' RF. In this technique, short (30 ms) pulses (2 Hz) of RF current are delivered via an RF needle adjacent to a sensory nerve serving a painful area. The tip of the needle is not heated beyond 42°C and no lesion is created. The rationale for using this technique is that *in vitro* animal work has indicated that long-term potentiation of spinal cord sensory pathways can be reversed by high intensity stimulation of Aδ fibres at low frequencies. Whether this occurs after application of pulsed RF is unknown and the only data available involve small open series.

Clinical uses

RF neurolysis gives rise to a localized nerve lesion different from that generated by neurolytic chemicals such as phenol or absolute alcohol. The latter substances spread some distance from the point of injection, causing widespread neural destruction. This is advantageous when applied to a diffuse area of neural tissue such as the sympathetic chain or coeliac plexus, but is dangerous where specific neurolysis is required and spread might cause serious morbidity. A good example of such a situation is spinal facet joint neurolysis. Figure 2 shows RF lesioning needles placed to destroy the medial branch of the dorsal ramus of the L4 spinal nerve. These nerves innervate the facet joints but lie close to the lateral foraminae carrying the main mixed spinal nerve. Application of a neurolytic chemical to this area would run a high risk of causing permanent injury to these nerves. RF lesioning on the other hand can provide a localized lesion. Moreover, the position of the lesion can be checked by electrical stimulation before lesioning. Similar considerations apply to RF lesioning procedures within the spinal cord such as cordotomy or dorsal root entry zone lesions.

Radiofrequency lesioning of the medial nerve branch at L4





The radiofrequency cannula is placed along the lateral margin of the articular pillar where it abuts the medial end of the transverse process. Note that the tip of the cannula is within 5–10 mm of the spinal nerve exiting the lateral foramen

2

Outcomes

Data from randomized controlled trials or large open series support the use of RF lesioning in the conditions listed in Figure 3. There is insufficient evidence to give recommendations about the use or safety of many of the other purported uses of RF lesioning. The greatest experience of RF lesioning is in the area of lumbar facet neurolysis. Patient selection is important because only 1–2% of patients presenting with chronic lower spinal pain have facet arthropathy. Nevertheless, within this group of patients, 70% can expect a clinically significant reduction in pain over the course of the first 6 months, though this has fallen to about 40% by 3 years. A more limited data set suggests that similar outcomes might be expected after cervical facet denervation.

Indications for radiofrequency neurolysis in chronic pain

Condition	Procedure	Evidence[1]
Lumbar facet arthropathy	Lumbar facet rhizolysis	RCT LOS
Cervical facet arthropathy	Cervical facet rhizolysis	RCT LOS
Trigeminal neuralgia	Trigeminal gangliolysis	LOS
Unilateral cancer pain (e.g. mesothelioma)	Cervical spinal cordotomy	LOS
Segmental cancer pain	Dorsal root entry zone lesion	Anecdotal
Discogenic low back pain	Pulsed radiofrequency	Anecdotal
Sympathetically maintained pain	Sympathectomy	Anecdotal

[1]RCT, randomized controlled trials
LOS, large open series (> 50 patients, more than one series)
Anecdotal, case reports, small open series (< 50 patients or only one series)

3

In many cases, RF trigeminal gangliolysis has been supplanted by brainstem microvascular decompression of the trigeminal root, but it remains an option in patients who are unfit for surgery or in whom a compressing vessel is not seen. Initial success has been reported to be as high as 90% but recurrence is common after 2–3 years and complications, while uncommon, are potentially debilitating.

Spinal cordotomy was the earliest operation performed on the CNS for the relief of pain. Percutaneous RF techniques were described in the 1960s and are now the technique of choice. Unilateral pain of a somatic origin responds best to this technique, and in conditions such as mesothelioma complete relief of pain is possible in over 70% of patients. Recurrence of pain is common beyond 1 year though some series report substantial and persisting pain relief in a minority of patients. Nevertheless, potential complications are serious and persistent, therefore this technique can be recommended only for patients with intractable cancer pain that has not responded to conventional techniques.

Complications

The safety of percutaneous RF lesioning compares favourably with many of the techniques it has supplanted and in most cases it is considerably safer. Nevertheless, it is an invasive and destructive technique and complications are well reported.

Unintentional nerve injury

Most lesioning procedures take place in close proximity to other nerve trunks or ganglia where nerve destruction could have serious effects. Both cervical and lumbar facet denervations take place close to major spinal nerves and destruction of, for example, the C6 nerve root could have serious consequences for the patient's functional status. For this reason, it is essential that the patient is awake and not heavily sedated while these procedures are performed; this allows the use of sensory and motor stimulation to confirm safe needle placement.

In procedures such as cordotomy or trigeminal gangliolysis, it is more difficult to avoid damage to adjacent neural structures. Trigeminal gangliolysis is associated with widespread loss of facial sensation in a small number of patients. Corneal anaesthesia can be particularly troublesome and potentially dangerous and occurs in about 5% of patients. Cordotomy can be associated with damage to the pyramidal tracts, even with accurate needle placement. This can result in extensive motor weakness of a hemiparetic nature. Despite this, such motor deficits often recover in a few hours; a persisting Babinski sign indicates that this is not always due to recovery of the pyramidal tracts but rather to other descending motor tracts being 'reprogrammed' to accommodate voluntary motor function.

Peripheral and central neuropathic pain

To the basic scientist, the concept of deliberately generating a nerve injury to relieve pain would seem fraught with hazard. Injured nerves have a high capacity to cause pain. All forms of nerve destruction caused by RF lesioning (or any other technique) may result in neuropathic pain, though it should be emphasized that such pain is not inevitable.

Neuropathic pain after facet joint denervation is uncommon though in some cases the pain that 'recurs' may represent neuropathic pain rather than pain from the facet joint. A number of patients may develop temporary cutaneous allodynia over dermatomes related to the facet joint sclerotome, probably representing sensory reorganization within the spinal cord, but this usually settles within 4–6 weeks.

Trigeminal neuralgia is a neuropathic pain condition and gangliolysis is associated with one of the most serious and intractable complications of neuroablative techniques, 'anaesthesia dolorosa' This is a condition in which intense pain is experienced in an area that is otherwise numb. The condition responds poorly to most pharmacological treatments and can cause great distress to sufferers. The syndrome occurs in about 5% of patients undergoing the procedure.

Cordotomy has its own spectrum of neuropathic pain states which differ from those described above. The most serious is the post-cordotomy dysaesthesia syndrome in which a large unilateral area of the patient's body develops sensations of severe pain. This complication is rare (about 1%) but other centrally generated dysaesthesias are reported after cordotomy. These usually take some time to develop, emphasizing that this technique is best reserved for patients with a short life expectancy.

Future directions

Improvements in imaging techniques have increased the scope for accurate placement of lesions using RF equipment. Two-dimensional fluoroscopy can now be of similar quality to standard radiographs. The most interesting development is the use of CT. CT-guided cordotomy is well described. Procedures such as dorsal root entry zone lesioning, commisural myelotomy and dorsal rhizotomy could all, theoretically, be performed using CT guidance but no large series exist to validate such techniques. ◆

Regional Techniques for Acute Pain

Fergus A Millar

Fergus A Millar is Consultant in Anaesthesia at Ninewells Hospital, Dundee, UK. He qualified from Glasgow University and trained in Anaesthesia and Intensive Care at Ninewells Hospital. He spent a year in the R Adams Cowley Shock Trauma Center, Baltimore, pursuing his interest in trauma. His other interests are perioperative care and acute pain.

The use of local anaesthetics for the treatment of acute pain can be traced to the days of the pharaohs. Hieroglyphics show that the ancient Egyptians used a topical substance to ease the pain of circumcision. Since the discovery of cocaine and the subsequent development of local anaesthetic agents, many techniques have been described for providing regional anaesthesia, some of which are suitable for providing prolonged analgesia.

Most acute pain therapy is directed at treating postoperative pain but there are a small number of acutely painful conditions in which regional anaesthetic techniques can be used to provide analgesia. Single shot local anaesthetic techniques can provide up to 18 hours of analgesia, depending on the site of injection and the length of surgery. To provide longer analgesia, a catheter must be placed to allow infusion or repeated boluses of local anaesthetic. The three main regional anaesthetic techniques discussed in this article are:

- central neural blockade (mainly epidural)
- nerve plexus blockade
- peripheral nerve blockade.

The advantages and disadvantages of regional techniques are listed in Figure 1.

Advantages and disadvantages of regional techniques

Advantages

- Potential to provide almost total analgesia at the operation site
- Avoidance of opioid side-effects
- Reduction of the stress response
- Active and passive movement is easier
- Sympathetic blockade with increased blood flow
- Reduced incidence of deep vein thrombosis and pulmonary embolism
- Reduced morbidity and mortality
- Potential reduction in hospital stay

Disadvantages

- Difficult to perform
- Central neural blockade can cause instability of the cardiovascular system
- Respiratory problems (particularly central neural opioids)
- Extra education for those providing postoperative care
- Potential neurological damage
- Morbidity and mortality from local anaesthetic toxicity
- Entry site for infection (particularly epidurals)

1

Epidural analgesia

The epidural is the most common catheter technique used for acute pain. Intrathecal catheters are available, but owing to some case reports of cauda equina syndrome and arachnoiditis, they are not widely used in the UK and are not discussed here. Epidural techniques offer the widest scope for the treatment of acute pain, from the thorax to the feet. Cervical epidurals can be used in head and neck surgery but this is not widely practised in the UK. The indications for epidural analgesia are:

- surgery (intra-operative and postoperative)
- trauma (especially fractured ribs or pelvis)
- labour pain
- acute ischaemic pain
- severe angina not controlled by conventional means (seldom used but some papers have shown a clear benefit).

Absolute contraindications are patient refusal, allergy to local anaesthesia, infection at the site of injection and lack of resuscitation equipment or skills. Relative contraindications require an assessment of the individual's risk and benefit and include, hypovolaemia, dehydration, bowel obstruction, co-existing neurological disease, coagulopathy and compartment syndrome.

The benefits of postoperative epidural analgesia are:

- effective analgesia
- reduced opioid requirement
- reduction in the stress response after surgery
- reduction in the incidence of deep vein thrombosis (DVT) and pulmonary embolism (PE)
- an earlier return to gastrointestinal function after abdominal surgery
- reduction in postoperative morbidity and mortality.

Epidural solution

The epidural has to be correctly sited, with the catheter inserted in the middle dermatome of the actual or anticipated site of pain. The combination of local anaesthetic and opioid is the optimal way to provide epidural analgesia. The opioid reduces the amount of local anaesthesia required thereby reducing the extent of motor and sympathetic block. As analgesia and not anaesthesia is required, a weaker solution of local anaesthetic (0.1–0.2% bupivacaine) can be used. The author's current practice is to use 0.1% bupivacaine with diamorphine, 25 μg/ml. Other opioids include fentanyl and morphine. Opioids act at the substantia gelatinosa in the dorsal horn. There are pharmacokinetic differences between the commonly used opioids that result in clinical differences. The more lipophilic the opioid, the quicker the drug penetrates the dura and crosses the CSF to its site of action. Lipophilic opioids also have a quicker termination of action because they are more rapidly absorbed into the blood stream. Fentanyl is more lipophilic than diamorphine and morphine is the least lipophilic. Morphine has a slow onset but can last for 24 hours because it is slow to clear from the CSF, and is usually the drug responsible for late-onset respiratory depression. Patient monitoring must be continued for at least 24 hours. Clonidine, midazolam and neostigmine have been used but there is no product licence for these drugs. Opioids are not licensed for use in epidurals, but their use is accepted, because there is a large body of supporting evidence.

Epidural regimens

Most postoperative epidural analgesia regimens consist of establishing an effective block and maintaining it with a continuous infusion. The infusion usually consists of a weak mixture of local anaesthetic and an opioid because this mixture is additive or possibly synergistic.

There is currently some interest in using patient-controlled epidural analgesia (PCEA), particularly in obstetric units (Figure 2). The advantage of PCEA is that it allows the patient some control over their pain relief. PCEA is useful for weaning patients from epidural to oral analgesia. It is potentially a valuable research tool, because it allows more accurate comparisons between drugs and regimens. The author uses a mixture of background infusion and a bolus facility after major surgery, thus giving the patient some control although the block does not completely regress if the patient falls asleep. The bolus facility in the PCEA may increase the effectiveness of the epidural, as some research has shown bolus doses of local anaesthetic to be more effective than background infusions.

The concurrent use of paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs) is recommended because they improve the quality of analgesia and are useful for weaning the patient off the epidural.

2 Patient-controlled epidural analgesia.

Management

The key to successful acute pain management with epidural catheters is to avoid complications (see below). The patient must be cared for in a safe environment where the staff are trained in the care and monitoring of patients with epidurals. Regular assessment of the patient is essential and the following observations are recommended: hourly measurement of blood pressure, heart rate, respiratory rate, sedation score, level of sensory block, degree of motor block, pump performance and, if appropriate, urine output and central venous pressure. This level of monitoring should be carried out for all major surgery, the only extra requirement for epidurals is sensory block height, motor block and pump performance.

Cardiovascular management: epidurals using local anaesthetics reduce preload and afterload and can cause bradycardia, resulting in reduced cardiac output and hypotension. This is complicated by the effects of major surgery and its associated fluid shifts. Prevention of these problems requires treatment of the bradycardia (block height may be too high), restoration of the preload and an increase in afterload. Fluid management for patients who have an epidural following major surgery can be difficult and therefore hourly urine volumes and central venous pressure monitoring can be helpful. Epidurals are often used to provide analgesia following major gastrointestinal surgery and this can have an impact on splanchnic blood flow. If the patient becomes hypovolaemic, splanchnic blood flow may be reduced thus compromising anastomotic blood flow. If normovolaemia is achieved, then epidural analgesia with local anaesthetic can increase splanchnic blood flow.

Respiratory management: respiratory complications of epidurals are uncommon but can be fatal. If the block extends upwards beyond C3/C4, respiratory arrest will occur. Even a high thoracic block can interfere with respiratory effort by paralysing the intercostal muscles. Epidural opioids can cause respiratory depression and arrest. The less lipophilic opioids take longer to reach the CSF, but once there, persist longer resulting in cephalad spread; if they reach the respiratory centre, respiratory depression can occur. Morphine is particularly associated with this because it is the least lipophilic of the opioids used in epidurals. Patient observation is the key to the prevention of respiratory complications: block height, sedation score and respiratory rate must be monitored. This is not foolproof and if respiratory complications occur prompt action is required: a clear airway, adequate ventilation and sufficient oxygen must be ensured. If local anaesthetic is the cause, supportive measures are required with fluids and vasopressors until the local anaesthetic action terminates. Naloxone, in small incremental doses, treats opioid-related respiratory depression.

Complications

Cardiovascular – when using local anaesthetic, there will be a sympathetic block that can result in vasodilatation, reducing preload and afterload. If the cardiac sympathetic fibres (T1–T4) are involved, this can cause bradycardia and reduced contractility. Hypotension and reduced cardiac output can then occur.

Respiratory – motor blockade of the intercostal muscles causes respiratory depression and even arrest. The innervation of the diaphragm is C3, C4 and C5. The use of opioids can cause respiratory depression. All opioids can do this, but morphine, being the least lipophilic, can cause late-onset respiratory depression (up to 24 hours following administration).

Itch, nausea and vomiting are opioid-related side-effects that can be distressing. Itch can be treated with small doses of naloxone, 20 μg i.v. Nausea and vomiting can be treated with anti-emetics.

Motor block can delay mobilization but use of weaker local anaesthetic solutions will minimize it.

Dural puncture can occur and, if not recognized, can result in extensive or total spinal block and may require cardiorespiratory support. Post-dural puncture headache can occur.

Subdural block is uncommon but can result in a total spinal.

Infection is uncommon but can result in meningitis. Strict aseptic techniques during epidural insertion are mandatory.

Epidural spinal haematoma is a rare and potentially devastating complication. It can occur spontaneously or be triggered by antiplatelet or anticoagulation therapy. It is difficult to determine the incidence following central neural blockade, but a rate of 1/150,000 for epidurals and 1/220,000 for spinals has been quoted. This risk increases if there is a haemostatic abnormality or there has been difficulty with needle insertion (87% of reported cases of spinal haematoma had one of these problems). In 75% of the reports, epidurals were used and 75% of those had a catheter inserted. In half of these the haematoma occurred following catheter removal. Tryba has published guidelines to help reduce the risk of DVT and PE (see Further Reading). The three main points are given below.

- Low dose heparin: 4 hours recommended between administration and performance of the block. A minimum of 1 hour following block before low dose heparin is given. This also applies to catheter removal.
- Low molecular weight heparins (LMWH): there is a difference between US and European doses for DVT and PE prophylaxis, and Tryba's guidelines advise the lower European doses. An interval of 10–12 hours is required after LMWH before performing epidural blockade. The recommended interval between epidural blockade and giving LMWH is 4 hours. This 4-hour interval also applies to catheter removal. It is imperative that the nursing and medical staff caring for the patient are aware of these recommendations.
- Aspirin and NSAIDs alone do not increase risk but in combination with low dose heparin or LMWH, the risk of spinal haematoma rises.

The signs and symptoms of spinal haematoma are:

- increasing motor block
- increasing sensory block
- back pain.

If spinal haematoma is suspected, an urgent CT or MRI scan and a neurosurgical opinion must be obtained. If a haematoma occurs, swift action is required to decompress the spinal cord and prevent or limit permanent neurological damage. A laminectomy is required. The person performing the block must document any difficulty with epidural placement. The patient must be cared for in an environment that allows early recognition, so education and training are vital. Epidural abscess may present in a similar fashion with the additional signs of fever and a raised white cell count. Investigation and management are similar to those for spinal haematoma.

Peripheral nerve/plexus catheters

Most local anaesthetic techniques described for the provision of anaesthesia are single injection methods. The effectiveness of the block in providing postoperative analgesia depends on the length of surgery, the type of local anaesthetic drug, the accuracy of the initial block, adjuvant drugs and the vascularity of the injection site. The placement of a catheter close to the nerve or plexus provides an opportunity to prolong the analgesia. A good understanding of nerve/plexus anaesthesia provides an excellent platform on which to develop the skills necessary for nerve/plexus catheters. The advantages and disadvantages of nerve/plexus catheters are listed in Figure 3.

Most catheter techniques are used for upper limb pain, because lower limb pain can be dealt with using epidural analgesia. However, techniques for lower limb catheters can provide significant analgesia with fewer cardiovascular complications. The indications for nerve/plexus catheters are given in Figure 4.

Advantages and disadvantages of nerve/plexus catheters

Advantages

- Extend the period of analgesia
- Localize sympathetic block
- Improve blood flow
- Reduce opioid requirement
- Fewer cardiovascular system complications

Disadvantages

- Difficult to place
- Easily dislodged
- Specialized equipment
- Source of infection
- Continuous motor block

3

Indications for nerve/plexus catheter

Indications

- Acute postoperative pain (e.g. elbow replacement)
- Trauma (beware compartment syndrome and discuss with surgeon before the block)
- Repeated painful procedures over 5–7 days (e.g. burns dressing changes)
- Re-implantation of digits, hand, foot (improved blood flow)
- Acute limb ischaemia (e.g. vasculitis, peripheral vascular disease)

Contraindications

- Infection at injection site
- Local anaesthetic allergy
- Severe coagulopathy
- Risk of compartment syndrome (discuss with surgeon)
- Inability to provide adequate care for the patient with a nerve/ plexus catheter

4

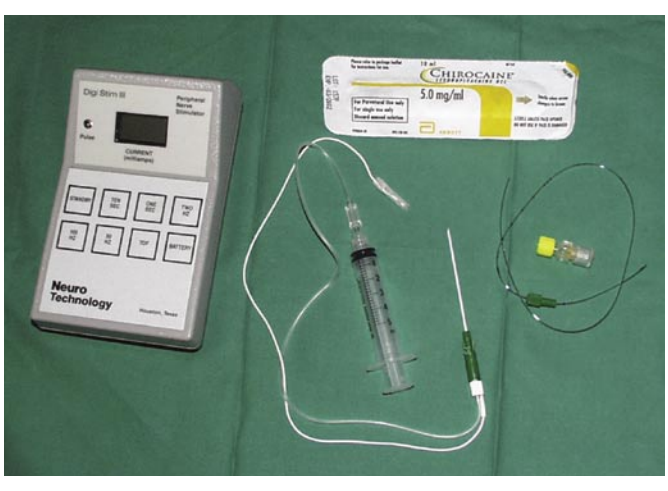
Techniques

The safety of the patient is paramount, therefore, everything required should be assembled before the procedure begins. The anaesthetist should have a dedicated knowledgeable assistant and have instant access to resuscitation drugs.

Equipment: most of the equipment required for placing a nerve/plexus catheter is readily available:

- peripheral nerve stimulator with low output (0–5 mA)
- dressing pack
- antiseptic solution
- catheter kit
- local anaesthetic agent
- syringes and needles.

Commercial kits (Figure 5) require the insertion of a cannula and then threading the catheter through the cannula. Tips to aid insertion of a nerve/plexus catheter are given in Figure 6.



5 Commercial catheter kit.

Tips to aid insertion of a nerve/plexus catheter

- Select the appropriate length of catheter kit
- Use a nerve stimulator
- Once the nerve/plexus is located, inject 2–3 ml of local anaesthetic to expand the ‘space’ around the nerve/plexus allowing easier cannula insertion
- There is a risk of exiting the nerve ‘sheath’ if the cannula is threaded too far, therefore advance it 2–3 mm at a time
- Inject 4–5 ml of local anaesthetic through the cannula (there should be no resistance)
- Thread the catheter, which should be easy, remove the cannula and inject the rest of the local anaesthetic via the catheter. Aim to thread the catheter about 2–5 cm along the nerve ‘sheath’
- Secure and dress with a sterile, transparent, occlusive dressing

6

Upper limb: the upper limb nerve supply comes from the brachial plexus C5–T1, making a cervical epidural impractical. However, it is relatively easy to perform plexus anaesthesia and insert catheters. Continuous brachial plexus block is useful for pain relief following major surgery (e.g. elbow replacement), re-implantation surgery and pain due to ischaemia (e.g. vasculitis).

Axillary brachial plexus block is the most widely used for catheter techniques. It is good for hand and forearm surgery and analgesia. Anyone who can perform a single-shot axillary block can also insert a catheter. The catheters can be dislodged despite adequate fixation.

Interscalene plexus block is good for shoulder surgery and analgesia. For successful cannulation, the angle of approach to the plexus should be more acute (the needle should point more caudad) to aid insertion of the catheter. Aim to thread 2–4 cm of catheter. Adequate fixation can be difficult.

Infraclavicular plexus block has been described with good results. The perpendicular approach to the plexus may make catheter placement difficult. Fixation of the catheter to the anterior chest wall reduces its displacement.

Lower limb: the lower limb is amenable to continuous epidural blockade and therefore the use of nerve/plexus catheters is less common. However, they do offer some advantages, particularly cardiovascular stability, preservation of motor function in the other leg and retention of urinary tract control.

Lumbar plexus – there are several descriptions of the anatomy and approach to the lumbar plexus, and they can all involve threading a catheter. The use of a nerve stimulator helps to locate the nerves. The lumbar plexus consists of lumbar roots L2–L4, but by approaching it from the L4 transverse process (as described by Alon Winnie), there may be some sciatic plexus blockade. This can be useful following hip and knee surgery.

Femoral nerve is relatively easy to block – to place a catheter, approach the nerve with the needle at 45° to the skin to aid its placement. There have been a number of studies showing significant analgesia and opioid dose reduction when femoral nerve catheters have been used following major knee surgery. By placing a catheter, there is a greater chance of blocking the lateral cutaneous nerve of thigh and obturator nerve, because the local anaesthetic is delivered further up the nerve sheath.

Sciatic nerve is more difficult to block than the femoral nerve because it is not as close to the skin. The needle must be off the perpendicular to aid catheter placement. This can be achieved using two approaches to the sciatic nerve (Labatt and Raj) to map the surface anatomy. This technique is particularly effective for analgesia after below-knee amputation and any acute pain in the foot.

Mansoor recently described an approach to the sciatic nerve that is also suitable for nerve catheters. The patient lies on their side with the leg to be blocked uppermost. A line is drawn between the ischial tuberosity and the greater trochanter, 4–5 cm from the ischial tuberosity along this line, the needle is inserted with a slight caudad angle. The nerve is encountered as it leaves the pelvis. The angled approach makes this block amenable to catheter placement.

Lower approaches to the sciatic nerve have been described and are also suitable for catheter techniques. The posterior approach via the apex of the popliteal fossa, with placement of a catheter has been described. The advantage of the lower approach is that the hamstring muscles have no motor block, so the patient can stabilize their knee and mobilize more easily. This technique is useful for foot surgery, trauma and below-knee amputations.

Common peroneal nerve and tibial nerve can be individually blocked and a catheter placed at the popliteal fossa. They are useful for foot surgery.

Drugs for nerve/plexus catheters: local anaesthetics are the main drugs used. Other drugs, especially opioids, have been used with mixed results and should be avoided. There is no generally accepted drug, concentration or delivery method for nerve/plexus catheters. Bupivacaine and ropivacaine have been used successfully. Suggested concentrations of bupivacaine range from 0.1% to 0.375% and ropivacaine 0.2%. Continuous infusions, patient-controlled top-ups and intermittent boluses have all been described. There seems to be little difference between them, with the intermittent bolus method perhaps being slightly more effective. The choice may be governed by what is practical in the particular institution. The only exception is femoral nerve catheters for total hip and knee surgery where a large intermittent bolus may be more effective. This is due perhaps to the mass of drug encouraging cephalad spread and thus achieving the Winnie 3-in-1 block. Continuous infusions are less labour intensive and usually employed. The concurrent use of NSAIDs, paracetamol and opioids is recommended because it improves the analgesic efficacy.

Role of Opioids in the Treatment of Chronic Non-Cancer Pain

Mick Serpell

Mick Serpell is Consultant and Senior Lecturer in Anaesthesia at the Western Infirmary, Glasgow, UK. He qualified from Dundee University where he undertook most of his anaesthetic training. He specialized in regional anaesthesia and pain management at Orebro, Sweden, and Dartmouth-Hitchcock, NH, USA. These subjects continue to be his research interest.

The estimated prevalence of chronic non-cancer pain in the community is about 30% and yet only 0.2% of the general population receive prescriptions for strong opioids. This compares with chronic cancer pain for which the adoption of potent step 3 analgesics in the WHO ladder is commonly used. There is no evidence that the pathophysiological mechanisms of cancer and non-cancer pain or the severity of pain and disability resulting from them are different, and yet the two groups are treated differently. The main reasons for this seemingly irrational pharmacological approach are that doctors and patients are concerned about waning efficacy, the potential for neuropsychological impairment and the development of drug addiction. Also, patients associate opioids with cancer and impending death.

Chronic pain is a complex entity and analgesics are only part of the treatment. The goals of treatment are to reduce pain and suffering and to improve function, with the aim of enabling patients to regain their social and occupational activity and become less reliant on healthcare services.

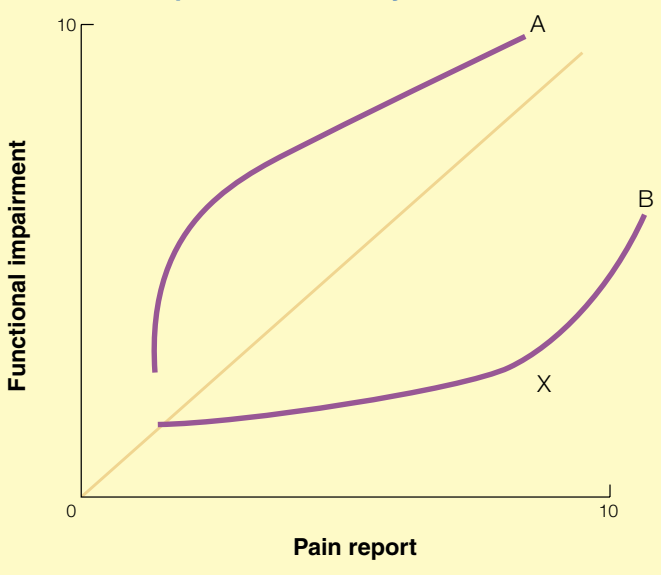
Before a treatment can be recommended, the following must be ascertained:
- is it effective – if so, how effective compared with other options?
- how safe is it?

Efficacy

The efficacy of opioids for cancer pain is widely accepted. They result in good control of pain for 80% of patients. Their use is based on empirical clinical practice and there are few randomized controlled trials.

In non-cancer pain, controlled clinical trials have demonstrated that opioids can reduce pain scores in both nociceptive and neuropathic pain types, though the former is more responsive. Only a few studies have examined psychological issues, such as functional status and quality of life, but these are the most important outcomes to measure. Patients with similar pain scores can demonstrate completely different levels of disability (Figure 1). The symptom of pain is subjective; pain is what the patient says it is. However, pain relief after an intervention is not just what the patient says it is, but what they can do. This measure allows the doctor to gauge any improvement objectively. Therefore, in an opioid trial, the level of disability from pain should be reduced as well as the severity of pain, before it can be deemed a success (Figure 2). This is the ultimate goal of pain management, and future research should address these issues.

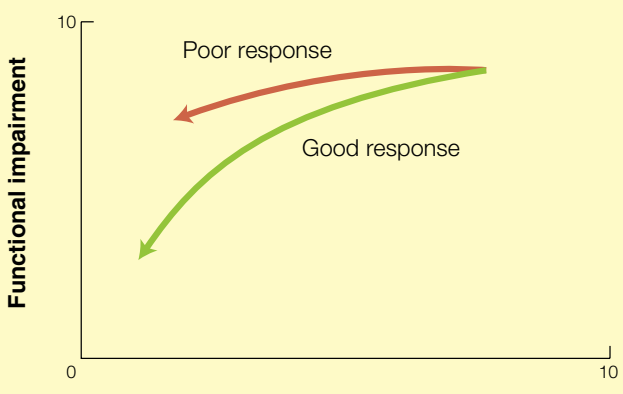
Link between pain and disability



Patient A is developing severe dysfunction (measured by Brief Pain Inventory) with a low pain score. Patient B maintains good function until severe pain is experienced at X.

1

Response to treatment of two patients with similar pain and dysfunction levels



Both patients have equal improvements in pain scores but the patient in the upper curve shows little improvement in function.

Printed with permission from Chapman C R, Dunbar P J. Measurement in Pain Therapy: is Pain Relief really the Endpoint? *Curr Opinion Anaesthesiol* 1998; **11:** 533–7.

2

In studies that assess psychological and quality-of-life issues, the success of opioids is variable. Also, only a few studies have evaluated the use of opioids for treatment periods longer than 1 or 2 months. However, some patients respond well and the task of future research must be to identify these people and determine how they can best be managed.

The efficacy of opioids compared with other drugs is harder to establish because there are no quality trials. Potent opioids are conventionally used only as a last resort, when everything else has been tried and failed. Therefore they are often first used in a relatively resistant subgroup of patients, which does not predispose to success.

Side-effects

Side-effects from opioids are the same as in cancer therapy, though most patients are outpatients and are less tolerant of treatments that impair their ability to perform at home and at work. Patients develop tolerance to many of these side-effects, though there is a significant drop-out rate (usually 30%), mainly due to CNS and gastrointestinal effects. Pain can impair cognitive function; it may also have an arousal effect and counteract the sedative effects of opioids. In patients who can tolerate opioids, there is no deterioration in cognitive function. Psychomotor performance is also maintained so the ability to drive is not diminished. Constipation is such a common problem that the prescription of regular laxatives is mandatory. Psychological addiction is often confused with drug tolerance and physical dependency, but is a separate issue.

Drug tolerance is the requirement for an escalating dose of drug to maintain the same effect. This is a form of neuroadaptation that occurs with the side-effects as well and is not a common problem because most patients who have genuinely opioid-responsive pain will establish themselves on a relatively stable daily dose. These patients often require supplementary opioids for breakthrough analgesia on some days, but they can return to, or get below, their baseline requirements on other days.

Physical dependence occurs as the body becomes accustomed to the drug. If the drug is suddenly discontinued, the body may go through withdrawal symptoms. This is a normal physiological response to chronic opioid exposure, it is not a sign of psychological dependence. It is avoided by gradual dose reduction if the opioid is to be discontinued.

Psychological dependence is drug-seeking behaviour to acquire the drug for non-medical purposes (i.e. euphoria rather than analgesia). It is characterized by a pattern of persistent dysfunctional opioid use that may consist of one or all of the following:
- adverse consequences associated with the use of opioids
- loss of control over the use of opioids
- preoccupation with obtaining opioids despite the presence of adequate analgesia.

There is only a small risk of psychological dependence in appropriately selected patients. One study looking at 10,000 patients found evidence of psychological dependence in only four patients. Prescribing guidelines have been developed to assist practitioners in selecting the appropriate patients and ensuring an acceptable risk:benefit ratio of long-term opioid therapy (Figure 3). The process of administration has to be agreed on by all parties concerned. It needs to be closely monitored and tightly controlled. In the current climate of increasing substance abuse in the general population, physicians need to be aware that the opioid drugs they prescribe may be diverted to improper uses. However, suitable patients should not be denied this option simply because of these general concerns.

Selection and management of patients for chronic opioid treatment

Selection criteria
- No previous history of drug or alcohol abuse (if so, require more careful management)
- No abnormal pain behaviour
- No impoverished social environment
- No psychotic problems
- Screening by psychologist

Management criteria
- Contract agreement between patient, GP and pain consultant
- Opioids will be discontinued if any suspicion of abuse determined by missing prescriptions or random blood sampling
- Adequate trial period of opioid, frequent reviews
- Patient must demonstrate improved function (reduced pain of secondary importance)
- Single source for opioids, once dose is established use long-acting opioids

3

Administration

The technique of opioid administration follows the same general principles as those for cancer pain. Injectable preparations should not be used for non-cancer pain because they reinforce dependency. In particular, pethidine should be avoided because it is too short acting and can accumulate as norpethidine, which is a CNS stimulant. ◆

Role of the Sympathetic Nervous System in Pain

Michael H Basler

Michael H Basler is a Consultant Anaesthetist at Glasgow Royal Infimary, Glasgow, UK. He undertook his training in pain medicine in Adelaide, Australia. His research interests include sympathetic, neuropathic and burn pain.

The sympathetic nervous system was described about 100 years ago but its relationship with pain is still being debated. It is most commonly perceived as a component of chronic pain syndromes and cancer pain, though recent interest has looked at its role in the pathogenesis of cardiac pain.

Historical aspects

Interest in the sympathetic nervous system and pain developed in the early 1900s and over the ensuing two World Wars many patients underwent interruption of their sympathetic nervous system in the hope of providing analgesia. However, there is still uncertainty about the role of the sympathetic nervous system in pain, and the clinical benefits and hazards of its interruption.

The clinical disorders in which the sympathetic nervous system is thought to play a central part and sympathectomy is indicated are:

- complex regional pain syndrome
- abdominal cancer pain
- pelvic cancer pain
- peripheral vascular disease
- herpes zoster
- intractable angina
- erythromelalgia.

Historical points

- Silas Weir Mitchell described a syndrome of pain, hyperalgesia and trophic changes in American Civil War veterans who had sustained nerve injuries. He termed this syndrome causalgia, which means ‘burning pain’
- In the early 1900s, Leriche, a French surgeon, described patients with severe painful peripheral nerve injuries that he concluded were related to ‘wounds of the sympathetic’

Complex regional pain syndrome (CRPS)

CRPS is a disorder of unknown aetiology that usually presents in a peripheral limb following an injury, which is often minor. It can also follow surgery and may be associated with medical disorders such as stroke, myocardial infarction and several neurological disorders (e.g. syringomyelia, polio). It is a syndrome of diffuse limb pain, often burning in nature, with variable sensory, motor, autonomic and trophic changes (Figure 1).

Changes of complex regional pain syndrome

Sensory
- Allodynia
- Hypoaesthesia
- Hyperaesthesia

Autonomic
- Vascular abnormalities
- Hyperhidrosis
- Oedema

Trophic
- Shiny skin
- Altered hair growth
- Brittle nails
- Osteopenia

Motor
- Weakness
- Stiffness

If untreated the clinical picture usually has three stages:
- pain and oedema (acute)
- muscle wasting and cyanosis (dystrophic)
- bone and skin changes (atrophic).

Aetiology

The main aetiological theories of CRPS can be separated into peripheral and central components though there may be a continuum of neural events occurring throughout the CNS.

Peripheral nervous system: after partial nerve injury, injured and uninjured axons begin to express α-adrenoceptors, which render them sensitive to circulating catecholamines and noradrenaline released from postganglionic sympathetic terminals. This occurs in C polymodal nociceptors in both the resting and active states. Noradrenaline has been shown to release prostaglandins from sympathetic postganglionic neurons, which may initiate nociceptor activity. There are decreased levels of circulating noradrenaline and its metabolites in the limbs of patients with CRPS. Denervation hypersensitivity has been proposed as a mechanism involved in the generation of some of the trophic changes. Recent research has concentrated on the inflammatory aspects of CRPS and it has been shown that there are increased levels of cytokines in neuropathic pain syndromes.

CNS: nerve injury also induces the sprouting of sympathetic axons into the dorsal root ganglion where they form baskets around the cell bodies of sensory neurons and may constitute a mechanism in which sympathetic activity initiates activity in sensory fibres.

Diagnosis

The formal diagnostic criteria of CRPS as defined by the International Association for the Study of Pain (IASP) are given in Figure 2.

Formal diagnostic criteria of CRPS as defined by the International Association for the Study of Pain

- The presence of an initiating noxious event or cause of immobilization
- Continuing pain, allodynia and hyperalgesia disproportionate to the inciting event
- Evidence, at some time, of abnormal skin blood flow, sudomotor activity or oedema
- The diagnosis being excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction

CRPS type 2 (causalgia) differs from CRPS type 1 (reflex sympathetic dystrophy) because a definitive nerve is involved. These diagnostic criteria have recently been re-examined and were thought to have inadequate sensitivity and specificity but no revision has yet taken place. Clinically cold allodynia is thought to be associated with sympathetically mediated pain.

The response to sympathetic blockade clinically confirms whether sympathetically maintained pain or sympathetically independent pain is present. The diagnosis of CRPS can be present even when sympathetically independent pain is present. The response to local anaesthetic sympathectomy is not a good predictor for benefit from a neurolytic procedure. Intravenous regional anaesthesia with guanethidine has been demonstrated to have no benefit over placebo. The phentolamine infusion test has been proposed as a predictor of response to sympathectomy though its validity has been questioned. Tests of autonomic function such as thermography and sweat output tests are used for research purposes.

Recently there has been interest in the use of laser Doppler as a measurement of cutaneous blood flow, reflecting sympathetic activity. Radionuclide bone scan imaging may show a diffuse uptake in affected extremities and X-rays may show periarticular osteoporosis.

Differential diagnosis: several pathologies can be confused with CRPS including local pathology (fracture, sprain), vasospasm, cellulitis, Raynaud’s disease, thrombosis and thromboangiitis obliterans.

Treatment

Early multidisciplinary treatment aimed at the initiating cause (if known) and maintaining function in the affected extremity is essential. In a critical review by Kingery most trials for the treatment of CRPS were shown to be of small size, were unlikely to be placebo controlled or double blinded or have valid statistical testing. The two treatment modalities are described below.

Local anaesthetic techniques: Hannington Kiff first described intravenous regional blockade with guanethidine in 1974. Since then, randomized controlled trials have shown it to be no better than placebo. The timing of intravenous regional blockade is contentious and some authorities believe early blockade in the acute phase of CRPS can be beneficial. The serotonin antagonist ketanserin, the anti-arrhythmic bretylium and the non-steroidal anti-inflammatory drug ketorolac have also been used for intravenous regional blockade, though their long-term efficacy is undetermined. Sympathetic blockade has never been evaluated in a placebo-controlled trial and surgical procedures have been presented only in small series. Epidural clonidine, intrathecal opiates and dorsal column stimulation have all been used as therapy for CRPS but their efficacy is undetermined.

Pharmacological therapy: a variety of medications have been reported to provide relief in CRPS and there is considerable overlap with agents used to treat neuropathic pain. The tricyclic antidepressants (amytriptyline) and anticonvulsants (carbamazepine, gabapentin, phenytoin) are effective. Intra-venous and topical lidocaine (lignocaine) and oral mexilitene are beneficial as is topical capsaicin. Most trials did not involve long-term follow-up. Corticosteroids were the only treatment with prolonged effectiveness, which is consistent with an inflammatory aetiology.

Abdominal cancer pain

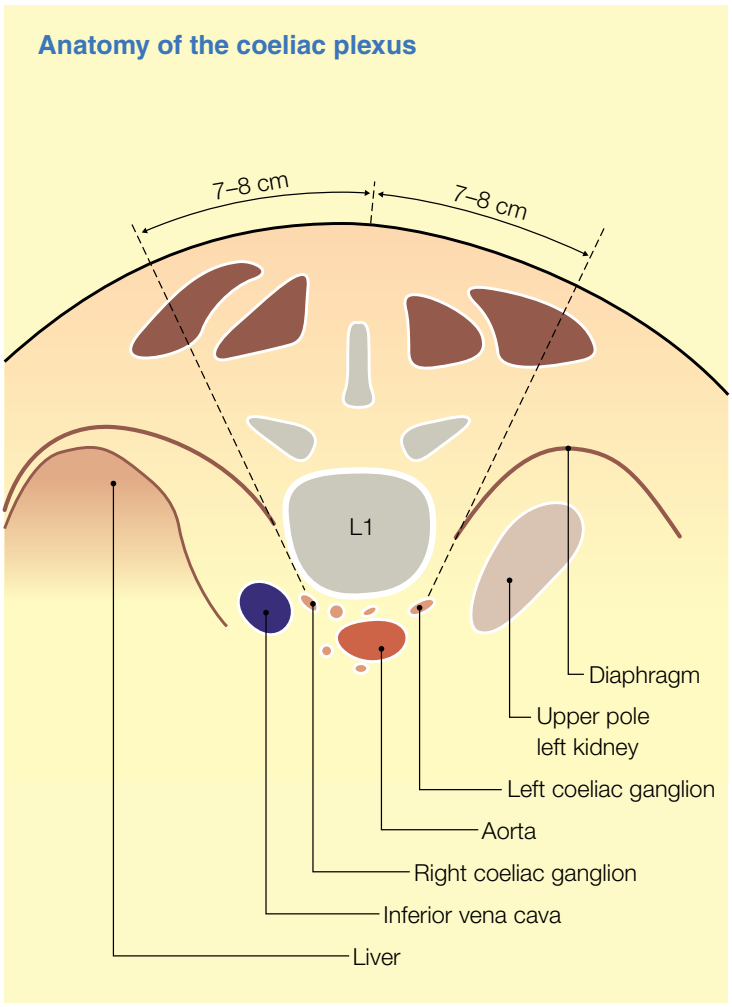
Over 50 trials have studied the benefits of coeliac plexus blockade (Figure 3) in abdominal cancer pain but only two are randomized controlled trials. Two meta-analyses have shown 70–90% relief for this treatment of pain in pancreatic cancer. It is widely used for the treatment of intractable pain in pancreatitis though the rare complication of paraplegia should be considered. More common complications include hypotension, diarrhoea, impotence (caused by decreased sympathetic function), pneumothorax and renal damage. Laparoscopic techniques have been proposed as a safer way to provide blockade without damaging the spinal arteries.

Pelvic cancer pain

Autonomic blockade in the form of a superior hypogastric block has been proposed as a form of analgesia for pelvic pain. This requires local anaesthesia or a neurolytic agent to be placed at the L5/S1 interspace. The lateral approach is similar to the technique for coeliac axis blockade, though the needle is directed 45° from a point 5–7 cm from the midline until the body of L5 is encountered. A medial approach has been described, which requires a needle to pass under the transverse process of L5, which can be impossible if sacralization of the lumbar vertebrae has occurred. Studies on this technique consist of case series used in the treatment of pelvic cancer pain.

Peripheral vascular disease

Lumbar sympathetic blockade and neurolysis has been shown to decrease pain in peripheral vascular disease. This is thought to result from a vasodilatory effect, though venous shunting has been shown to occur. It is useful in rest pain rather than for claudication. Technically the approach to blockade is similar to a coeliac plexus block, though at two levels lower. Some authorities propose a diagnostic block with local anaesthesia (10–15 ml of 2% lidocaine (lignocaine) or 0.5% bupivacaine) before embarking on a neurolytic procedure using 6% phenol, 3–5 ml. A common complication of this block is inner thigh pain, which is thought to be related to genitofemoral neuralgia.



3

Other conditions

Herpes zoster

There is limited evidence that when sympathetic block is performed within 2 months of the onset of acute herpes zoster, there is a decrease in the incidence of post-herpetic neuralgia. It is postulated that this is due to an increased blood flow to the drug root ganglion, which prevents further neural damage.

Intractable cardiac pain

There is renewed incidence in the value of sympathectomy in the management of intractable angina. Most protocols propose a left thoracic sympathectomy initially. If no improvement occurs there is still benefit in attempting a left stellate ganglion block. There are case reports of the use of stellate ganglion block in the treatment of long QT syndrome and the possibility of post-block arrhythmias should be considered.

Erythromelalgia

Erythromelalgia is a rare syndrome of unknown cause, characterized by burning pain, redness, oedema and increased skin temperature in the legs or arms, or both. Sympathetic blockade reduces these symptoms. ◆

Soft Tissue Pain and Physical Therapy

Denis J Martin
Shea Palmer

Denis J Martin is Assistant Director of the Scottish Network for Chronic Pain Research at Queen Margaret University College, Edinburgh, UK. His research interests include chronic pain management and pain assessment.

Shea Palmer is Lecturer in Physiotherapy at Queen Margaret University College, Edinburgh, UK. His research interests include soft tissue injury and neurophysiology.

Soft tissue pain is defined here as pain originating or appearing to originate from muscle, ligament or tendon. The phrase 'appearing to' is used because the pain may be referred from another tissue, usually in a proximal to distal direction.

Pathophysiology
Pain is a natural response to soft tissue injury and is one of the cardinal signs of inflammation. Acute pain is useful because it encourages protection of the damaged tissue, which gives it the best chance to heal. Prolonged pain can result in an established sensitization of the CNS from which pain will persist, independent of influences from the original soft tissue, resulting in chronic pain. The development of chronic pain is associated with psychosocial problems mediated at least partially by cortisol-based mechanisms. There will probably be some degree of neuroplastic changes towards chronicity related to central sensitization even in the sub-acute stage.

History
Acute soft tissue pain: the history invariably involves the application of a force to the tissue, excessive to its loading capacity, leading to structural damage. The force can be external (e.g. a physical blow) or it can come from within (e.g. by over-stretching). The patient can generally describe a specific incident with consequent pain.

A common form of soft tissue pain is exercise-induced muscle soreness that occurs gradually within 24 hours of unaccustomed, usually eccentric, exercise. It typically resolves after 72 hours with no associated damage.

Chronic pain, related, or perceived to be related to soft tissue, has a less obvious clinical history. There may or may not be a history of injury. It is obvious, however, that the pain has outlasted any useful process. The patient may have a psychosocial history of frequent healthcare use and many chronic pain sufferers have multiple somatic symptoms.

Differential diagnosis: structures giving rise to acute pain can be isolated by a history of injury, pain on palpation and pain on selective stretching or contraction of the tissue. Eliciting pain in the area of complaint by stressing distant tissues tests for referred pain. The determination of early neuroplastic changes which result in chronicity is a major diagnostic challenge and quantitative sensory testing methods are showing promise. Patients in the advanced stages of chronic pain typically have a long history of unsuccessful healthcare use from a variety of agencies. They often have signs of negative psychosocial traits such as depression and poor self-esteem. At this stage, attempts at differential diagnosis of a primary structure are meaningless, because the problem will have become dissociated from it.

Management
In an acute soft tissue injury, management of the underlying healing process ensures that pain at rest disappears with resolution of inflammation – usually within a week. There will be pain on movement and palpation for 3–6 weeks following injury. Pain after this time may be an early manifestation of neuroplastic changes towards chronicity. Inactivity because of pain rapidly leads to general and localized musculoskeletal and cardiovascular deconditioning. Therefore, a goal in acute pain management is prevention of chronicity. The cost of acute pain management is dwarfed by the severe human and socio-economic costs of chronic pain.

Acute pain
The aim of physical therapy for acute soft tissue pain is to restore the person to optimum function through early rehabilitation. There are long-standing anecdotal claims of its effectiveness. Heat, massage and exercise are the traditional methods of physical therapy for acute soft tissue pain.

- Cold is applied using sprays, contact packs and water baths to reduce bleeding, decrease inflammatory exudate and affect nerves to reduce pain. It is used as an immediate first-aid measure and a general pain-relieving modality, though it is less well tolerated than heat.
- Heat is applied to superficial tissues using contact heat packs, water baths or radiant infra-red lamps. Deeper structures can be heated using short-wave diathermy and ultrasound. Heating aims to improve tissue extensibility, increase blood flow and affect nerves to relieve pain. Heat should not be applied in the inflammatory or early healing stages of repair because it promotes bleeding and disrupts the newly forming circulatory system.
- Athermal electromagnetic energy is used to avoid the problems associated with heating tissue. It is applied with pulsed short waves, pulsed ultrasound and low-level light/laser to enhance the healing process and relieve pain.
- Electricity is used to stimulate nerves to reduce pain and there are also claims of optimizing the healing rate of tissue. Transcutaneous electrical nerve stimulation (TENS) devices are the most useful methods, though interferential current is also used.
- Acupuncture, sometimes combined with electricity, is now commonly used by physical therapists.
- Physical manipulation and mobilization of joints and soft tissue (e.g. massage, spinal manipulation) relieves pain by activation of nerves and/or by improved tissue extensibility.
- Exercise regimes are promoted and prescribed to improve the strength or extensibility of specific structures or to improve overall fitness and well-being.

Increased knowledge about the biological and biophysical effects of these methods and how they relate to mechanisms of pain has added weight to their claimed clinical effects. However, systematic reviews of clinical trials are almost unanimous in stating that there is insufficient scientific evidence of clinical effectiveness, with the low quality of trials proving a major barrier to such rigorous evaluation. (This criticism is not unique to physical therapies and harsh judgements should be reserved until the scientific evidence has matured.) Another barrier towards their evaluation is that the techniques tend to be used together in a wide number of permutations rather than on their own. There is further controversy in determining the optimum choice of dose and method of delivery of treatment.

Chronic pain
In chronic pain, a strictly biomedical approach aiming for cure is too limited to address the disabling effects of the pain. It is also potentially damaging because its lack of success can add to the patient's feelings of hopelessness, exacerbating the effects of chronic pain. Current thinking advocates a wider biopsychosocial approach to management, with clinicians and patients working together to maximize physical, functional and social activity while living with pain.

Biopsychosocial pain management is supported by scientific evidence and one of its cornerstones is physical therapy. A direct effect of chronic pain is that sufferers fear movement because they believe it will lead to tissue damage and more pain. Thus, they are inclined to do little for long periods, interspersed with relatively intensive bursts of activity when they feel more able. These intensive bursts of activity are liable to lead to flare-ups of pain, which promote further fear-mediated avoidance of activity and consequently further deconditioning.

Physical therapies such as ultrasound are likely to be counterproductive if used as putative agents of cure in a biomedical model of chronic pain. They may have a palliative role, but in biopsychosocial management of chronic pain the defining features of physical therapy are working with the patient to set activity-related goals and instilling habits of pacing of activity.

Physical therapy begins with educating the patient about living with chronic pain. The therapist explains the harmful effects of inactivity such as cardiovascular deconditioning and muscle wasting, which can have a marked effect. The therapist also helps patients to overcome their fear of movement, identifying the reasons for such fear and addressing misconceptions that lead to the belief that chronic pain is a sign of tissue damage. Gradual exposure to activity is a commonly used technique. Physical therapy encourages the patient to adopt an activity pattern of even pacing to smooth out the peaks and troughs of the activity–rest cycle. Education, goal setting and pacing are used to help the patient to cope with any flare-ups that occur. Physical therapy works best within a multidisciplinary team, and close liaison with the occupational therapy department, for example, benefits the rehabilitation of the chronic pain sufferer.

When acute injury occurs in someone with chronic pain, the difference between it and the concurrent chronic pain must be explained. The management of the acute pain should not compromise the continuing self-management of the chronic pain. Maintenance of general activity needs to be encouraged and successful resolution of the acute pain should not be allowed to raise false hopes of a similar reduction of the chronic pain.

Prognosis
The prognosis for acute soft tissue pain is good. Pain at rest should resolve of its own accord or under appropriate management within 1 week, and pain on movement and palpation should be gone within 3–6 weeks. A poor blood supply, however, will impair healing and leave the structure open to re-injury with recurrent pain. Another complicating factor is a history of excessive psychosocial stress, which has been shown to predispose an individual to chronic pain.

The prognosis of chronic pain is less certain. The pain is less likely to resolve and the associated negative effects of the pain on mood and psychological coping are likely to worsen without managed care. With managed care and continuing support, however, the chronic pain sufferer can be expected to attain a substantially high level of function and social participation. ◆

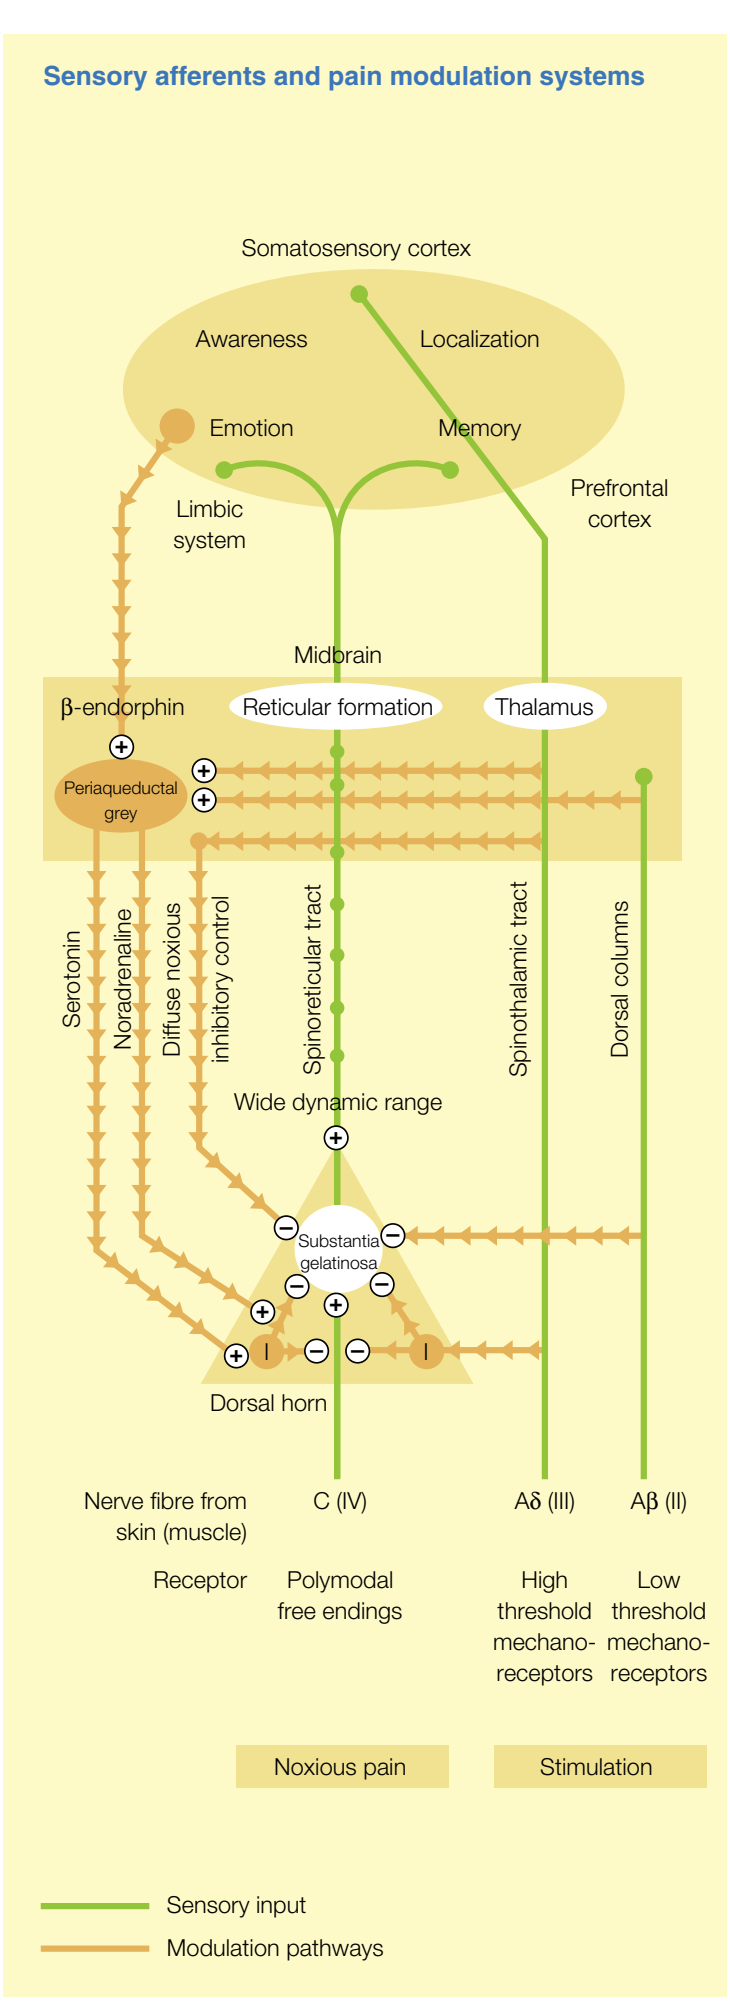
Stimulation-produced Analgesia: Acupuncture, TENS and Alternative Techniques

John H Brown

John H Brown is Consultant Anaesthetist at the Western Infirmary and Gartnavel General Hospital, Glasgow, UK. He qualified from Glasgow University and trained in Glasgow and Manchester. His interests are medical acupuncture and the management of chronic pain.

Stimulation techniques activate the body's intrinsic pain- modulation systems by the application of various forms of physical energy. Counter-irritation methods are not new. Acupuncture is described in *The Yellow Emperor's Book of Internal Medicine* in the 3rd century BC; the Egyptians used electric fish in 2500 BC and Hippocrates used them in 400 BC to treat headache and arthritis; the Romans understood the benefits of physical activity, hot baths and massage. We are now developing an understanding of the neurophysiological mechanisms underlying these techniques. Advances in basic science subsequent to the gate control theory of pain by Melzack and Wall in 1965 have provided a sound model around which research into this complex subject will revolve.

Noxious pain
Those suffering pain after tissue damage commonly describe it as aching, upsetting and poorly localized. Such sensory information originates in nonspecific peripheral polymodal nociceptors and travels via small, unmyelinated, slow C fibres to the first great relay centre in the substantia gelatinosa (between laminae 1 and 5) of the dorsal horn (Figure 1). Convergent wide dynamic range neurons act as gatekeepers to the slow, primitive, polysynaptic pathway to the reticular formation and onwards to complex integration in the great supraspinal centres. It is important to distinguish acute from chronic pain; the latter is associated with permanent excitability of the wide dynamic range cells (wind up) and formation of abnormal central neural connections (plasticity).



1

Modulation of noxious pain
Dorsal horn (laminae 1 to 5): incoming noxious pain activity is reduced by inhibitory interneurons, presynaptic and postsynaptic inhibition, and specific receptors controlling ionic flux through nerve membrane channels. Modulatory input arrives via descending pathways and lateral branches from myelinated afferent A fibres. Aβ fibres arise in low-threshold mechanoreceptors (e.g. activated by conventional 'tingly' transcutaneous electrical nerve stimulation (TENS)) and Aδ in high-threshold (e.g. responsive to low-frequency needle manipulation). Pain-inhibiting neurotransmitters include metenkephalin, dynorphins A and B, and γ-aminobutyric acid. Cholecystokinin (CCK-8), substance P and other peptides antagonize the effects of spinal opioids and promote wide dynamic range excitability.

Supraspinal centres: the most important pain inhibitory neurotransmitter is β-endorphin, which is present in fibres connecting the hypothalamus to the periaqueductal grey. MRI scans and positron emission tomography have illustrated the many brain structures above the midbrain and thalamus that are activated by painful stimuli. Interconnections between the prefrontal cortex, limbic system (hypothalamus, hippo-campus, amygdala, cingulate gyrus) and reticular formation are responsible for the cognitive and emotional influences on the behavioural response to pain. There is widespread somatotopic projection in pain pathways and relay centres, in similar fashion to the well-known homunculus (with expanded face, hands and feet) in the somatosensory cortex.

Descending pathways: serotonin (5-HT) as a transmitter starts in the periaqueductal grey and descends to the dorsal horns in the spinal cord via the dorsolateral funiculus. Noradrenaline as a transmitter originates in the pons and descends in the same pathway. Diffuse noxious inhibitory control is a powerful pain-suppressing system triggered by painful stimulation anywhere in the body. All three pathways project to all segments of the spinal cord and inhibit dorsal horn activity.

Heterosegmental analgesia
Pain originating in one part of the body can be reduced by strong counter-irritation in another area. The noxious counter-irritant (localized to one segment) excites a loop, via the Aδ fibres, midbrain and descending tracts, to all segments not concerned with the noxious stimulus. Many techniques such as cupping, cautery, skin irritants, painful massage or joint manipulation, resemble acupuncture and TENS with respect to this powerful generalized effect.

Traditional Chinese acupuncture
Traditional Chinese acupuncture is a holistic system that was developed by meticulous observation over millennia. It incorporates elaborate concepts and theories to explain disturbed body functioning: Qi (the vital life energy flowing along meridians); bodily imbalance in the cosmic regulators Yin and Yang; re-establishment of normal equilibrium by insertion of needles at special points to disperse 'evil air'. Careful examination of the radial pulse and the tongue are essential aids to diagnosis. Europeans had been aware of these ideas for several hundred years but it took the reopening of China to the West after President Nixon's visit in 1972 to create a significant upsurge in medical interest. Many doctors undertook basic training in China and absorbed the classical theories to the extent that they could treat many common problems. Some developed their knowledge to an advanced degree. Others, convinced that acupuncture was effective, tried to rationalize it within the framework of known physiology and anatomy, and the Western scientific approach to acupuncture was born. Many modern practitioners no longer believe that meridians or discrete acupuncture points exist, yet they respect the observational skills of the ancient Chinese physicians. They have retained the ancient nomenclature and terminology and continue to use many of the powerful needling areas. Chinese 'Ah Shi' tender points correspond well with common musculoskeletal trigger points. Many other traditional Chinese points lie over nerve tracts or areas where nerves penetrate the superficial fascia.

Acupuncture treatment of tender areas
Trigger point therapy: common causes of trigger points are trauma, repetitive overstrain, emotional upset and excessive cold or heat. They are found in muscles, tendons, ligaments, joint capsules, periosteum and subcutaneous tissues. They may be active (producing unpleasant symptoms) or latent (found in symptomless people). They are usually localized to one body region and produce muscle weakness, shortening, palpable taut bands and fibrositic nodules. Often there is referred pain to an area distant from the trigger point, with a pattern specific to each disordered muscle. Pain is vague, poorly localized and unpleasant; for example trigger points in the sternomastoid in the neck may cause pain over the eye with no supraorbital tenderness. Deactivation may be by dry needling (acupuncture) or by wet needling (injecting dilute local anaesthetic or saline). Superficial needling into overlying subcutaneous tissues may also be effective.

Periosteal acupuncture may have a more powerful effect than subcutaneous or muscle stimulation. Selected known bony tender
areas may be 'pecked' by needles and radiation of pain noted. For example, needling the cervical articular pillar may produce pain radiation in the back, head or arms, and may be used to treat problems in the upper half of the body. The sacroiliac joint area may be used for problems in the lower back or legs.

Segmental acupuncture
Segmental acupuncture has been developed in The Netherlands over the past 15 years and draws together strands of known neuroanatomy and physiology. It is typical of the Western analytical approach. The body is divided into segments that comprise a dermatome, myotome, sclerotome and viscerotome, all having the same level of innervation and sensory input into the dorsal horn. The autonomic nerve supply within these segments is important because referred pain from internal organs is localized to the segmental dermatomes and myotomes (Figure 2).

Formulation of a segmental diagnosis

Disordered structure
Surface scars, old fractures, pathology of internal organs

Disordered function
Muscle hypertonicity, trigger points, palpitations

Segmental symptoms
Referred pain (visceral and musculoskeletal), hyperalgesia, autonomic upset (poor circulation, disordered sweating, pilomotor dysfunction, swellings, oedema, bone resorption)

2

Treatment of pain and muscle dysfunction is by stimulating segmental Aβ and Aδ fibres. This can be done by pressure, massage, muscle stretching, TENS or acupuncture. Dry or wet needling may be used near tender areas and in segmental skin, muscle and periosteal points. Depth of insertion is important. For example, the bladder 23 point lateral to lumbar 2 spine is on the thoracic 11 dermatome, but overlies the cervical 6/7/8 myotomes (latissimus dorsi) and the lumbar 2 sclerotome.

Electroacupuncture analgesia and TENS
Electroacupuncture analgesia via needles is usually restricted to the clinical environment. Low-cost TENS machines with reusable electrodes are commonly used in the domestic environment. Electrical stimulation has superseded repetitive manual twirling because it allows stimulation intensity and frequency to be controlled precisely (Figure 3). The distinction between conventional TENS and electroacupuncture analgesia has become blurred by the efficiency of modern skin electrodes and the variety of stimulation modes on modern stimulators.

Frequency dependent analgesia

Via Aβ fibres
- Recruited at 50–200 Hz
- Low intensity stimulation
- Occurs immediately
- Lasts only as long as stimulation
- Increased dynorphins in dorsal horn
- κ receptor activated in dorsal horn

Via Aδ fibres
- Recruited at 2–4 Hz
- High intensity stimulation
- Occurs after 20–30 minutes
- Lasts hours to days after cessation
- Increased metenkephalin in dorsal horn
- μ receptor activated in dorsal horn

Low frequency stimulation should be restricted to 20 minutes, because periods in excess of this produce increased levels of the pain facilitatory, opioid antagonist, CCK-8, in the dorsal horn. When electroacupuncture analgesia is used as pre-emptive analgesia for minor operations, or as the analgesic component for balanced general anaesthesia, the benefits may be maximized and prolonged by stimulating at varying frequencies between 2 and 100 Hz. This will produce dynorphins and enkephalins in the dorsal horn, β-endorphin in the hypothalamus and periaqueductal grey, and will prevent production of CCK-8.

Both electroacupuncture analgesia and TENS have been used successfully for a variety of chronic pain conditions. At low frequencies, care must be taken that painful muscle contractions do not occur. Patients may become tolerant to conventional TENS after weeks to months of good relief. Efforts to avoid this include using complex waveforms, randomly distributed pulses, multiple electrodes, and ramped pulses of rising intensity. An interesting new device (transcutaneous spinal electroanalgesia) uses ultrashort bursts of high voltage stimulation via skin electrodes along the central dorsal spine, with effects similar to dorsal column stimulation.

Microsystems

Auriculotherapy was popularized by Nogier in France in the 1970s. He mapped correspondence points in the ear for the entire body. The body is represented in an upside down position with the head in the lobe facing forwards. The spine runs up along the cartilaginous ridge on the outer ear with the lower limbs near the apex. The face, hands and feet have a relatively large projection just as in the somatosensory cerebral cortex. Nogier noted that physical pathology may be diagnosed by pressure sensitivity and skin resistance changes at the appropriate ear point. Treatment via needles, press studs, adhesive metal beads or electrical stimulation at this point produces analgesia in the distant muscle or joint. Other microsystems have been described in the scalp, face, hands and feet. Reflexology involves massaging relevant parts of the body map on the soles of the feet to treat systemic conditions.

Related complementary methods

Many complementary methods have a segmental approach and produce selective stimulation of Aβ and Aδ fibres. Physiotherapists use many techniques that stimulate receptors in joint capsules, muscles and skin (manipulation, muscle stretching, massage, vibration, ultrasonics, and hot or cold applications). Patients may be trained to apply acupressure themselves (e.g. pressing directly over trigger points). German neuraltherapy (therapeutic local anaesthesia) uses segmental diagnosis and involves injections around nerves, muscle tender points and selected periosteal areas. Chiropractic techniques use sudden thrusts to correct disorders of spine and joints. Osteopathy has a more holistic approach to restore function and posture via gentle massage and joint manipulation. There are numerous massage styles (e.g. Shiatsu, Rolfing). Some are fairly painful and recruit heterosegmental mechanisms. The Finnish sauna with hot baths, beating with birch leaves, and sudden cold immersion, is another example. Laser devices are available (particularly for needle phobics and children) but there is no Aδ stimulation and benefits may be related to tissue-healing properties rather than to pain modulation.

Unanswered questions

Prolonged pain relief – it is common for patients with chronic musculoskeletal problems to achieve relief and functional improvement lasting weeks or months after a single 10 minute acupuncture session. Professor Han of Beijing has proposed that there may be a reverberating mesolimbic loop of analgesia involving midbrain structures and periaqueductal grey to maintain descending modulatory activity.

Convergence – somatotopic convergence within central CNS structures is assumed to be the anatomical explanation for the various microsystems; the exact mechanisms are unknown.

Facilitation – little is known about the central and descending pain facilitatory systems and their role in maintaining chronic pain. The effects of counter-irritation methods are unknown. ◆

Adverse Sequelae of Spinal Anaesthesia and Management of Postspinal Headache

E Anne Thornberry

E Anne Thornberry is Consultant Anaesthetist at the Gloucestershire Royal Hospital, Gloucester, UK. She qualified from King's College Hospital, London, and trained in anaesthesia in Chester, Bristol and Southampton. She has a special interest in obstetric anaesthesia and was formerly Co-ordinator of Obstetric Anaesthetic Services at Queen Alexandra Hospital, Portsmouth.

Adverse sequelae from spinal anaesthesia can occur early or late and be minor or major (Figure 1). An early complication occurs at the time the spinal anaesthetic is performed or during the course of the anaesthetic. Late complications present after the spinal anaesthesia has resolved. Minor adverse sequelae cause temporary discomfort or inconvenience to the patient while major sequelae are potentially life-threatening or result in prolonged or permanent signs or symptoms. There is some overlap between the groups. Early complications may be the origin of late sequelae and minor complications can become major if they are not managed appropriately. Late, major sequelae are uncommon. Serious complications, excluding postspinal headache, occur in about 1/22,000 spinal anaesthetics.

Adverse sequelae of spinal anaesthesia

Minor
Early complications
- Localized trauma
  - Localized pain
  - Root pain
- Bloody tap
- Failure of block
  - Dry tap
  - Inadequate spread
- Nausea and vomiting
- Pruritus

Late complications
- Neurapraxia
- Urinary retention
- Backache
  - Localized haematoma
  - Muscle spasm
  - Ligament strain

Major
Early complications
- Hypotension
- Bradycardia
- Respiratory depression
  - High block
  - Opiates
- Total spinal
- Local anaesthetic toxicity
  - Intravenous injection
  - Excessive dose
- Allergic reactions to local anaesthetic

Late complications
- Low CSF pressure symptoms
  - Headache
  - Neck stiffness
  - Tinnitus
  - Photophobia
  - Cranial nerve lesions
  - Subdural haematoma
- Meningitis
- Nerve root damage
  - Axonotmesis
  - Neurotmesis
- Spinal cord injuries
  - Trauma (e.g. needle damage, injection of local anaesthetic, injection of air)
  - Spinal cord ischaemia (e.g. compression, epidural abscess, epidural haematoma, anterior spinal artery syndrome)
  - Neurotoxic damage (e.g. arachnoiditis)
  - Cauda equina syndrome

1

Minor sequelae

Early complications
Pain: localized pain on insertion of spinal anaesthesia can be minimized by good technique. Root pain is more difficult to avoid. Both of these complications are generally of short duration, but if multiple attempts are made to perform the dural puncture, localized bruising can occur, prolonging the discomfort.

Bloody tap describes the puncture of an epidural vein. It makes identification of the subarachnoid space difficult because blood can occlude the spinal needle. A dry tap describes the failure to find the dural sac. Both of these complications cause discomfort as a result of repeated attempts to achieve spinal anaesthesia.

Emesis: hypotension is a common accompaniment of spinal anaesthesia and is the most common cause of nausea and vomiting. Intrathecal opiates can also trigger emesis and may cause significant pruritus. The use of vasopressors, anti-emetics and small doses of an opiate antagonist can minimize these adverse sequelae.

Late complications
Nerve damage: neurapraxia describes an injury in which the nerve and axonal sheath remain intact. Recovery is complete and can be rapid or take several weeks. Generally neurapraxia is caused by stretching or compression of a nerve rather than direct trauma.

Urinary dysfunction: the urge to micturate is blocked during spinal anaesthesia and may lead to urinary retention in the immediate postoperative period. Care must be taken to prevent over-distension of the bladder, which can cause ischaemia of the submucosal stretch receptors in the bladder wall, resulting in prolonged bladder dysfunction.

Backache is commonly the result of local bruising of the soft tissues or periosteum. Ligament strain can occur if joints are stretched beyond their normal range of movement and is more likely if this position is held for some time (e.g. in lithotomy). Muscle spasm can be triggered by localized trauma and can be severe. It generally responds to bed rest and anti-inflammatory analgesics.

Major sequelae

Early complications
Cardiovascular disturbances: hypotension and bradycardia are the result of the normal physiological response to blocking the autonomic nervous system. Hypotension is exacerbated by hypovolaemia and under these circumstances can be severe and life-threatening. Obstetric patients are also at increased risk because of aorto-caval compression in the supine position.

If the spinal blockade extends beyond the level of T1, the sympathetic output to the heart is disrupted, resulting in profound bradycardia requiring rapid administration of an anticholinergic agent (e.g. atropine). Sudden-onset hypotension and bradycardia associated with nausea and vomiting and sweating is likely to be caused by a vasovagal faint.

Respiratory depression may be the result of extensive spread of the spinal anaesthesia blocking all the intercostal muscles. Above C6 all the muscles of respiration are paralysed and artificial ventilation is required. If opiates have been given intrathecally their direct action on the respiratory centre can cause respiratory depression; this can be delayed and present as a late complication.

Total spinal block is a spinal anaesthetic that spreads to include all spinal segments and the brain. It occurs if an excessive dose of local anaesthetic is administered. The patient experiences loss of consciousness, profound hypotension, bradycardia and respiratory arrest and requires urgent resuscitation to prevent cardiac arrest.

Local anaesthetic toxicity is extremely unlikely with spinal anaesthesia alone because the normal therapeutic dose is well within the margins of safety. Allergic reactions to local anaesthetics are extremely uncommon but some have been reported.

Late complications
Low CSF pressure: postspinal headache is the headache associated with low CSF pressure after a spinal anaesthetic and is also known as a postdural puncture headache. It is a severe, fronto-occipital headache and is classically postural, becoming more severe in the upright position. Associated symptoms include neck stiffness, tinnitus and photophobia. The headache is caused by loss of support of the brain tissue owing to a leak of CSF from the dural puncture site. This results in traction on innervated tissues such as the venous sinuses. Compensatory cerebral vasodilatation may contribute to the symptoms. Traction on the VIth cranial nerve can cause diplopia. Prolonged low CSF pressure can cause subdural bleeding as a result of tearing of the dural blood vessels.

Meningitis: a postspinal headache must be differentiated from meningitis. Meningitis may also present with headache and neck stiffness, but it is unlikely to be postural. It is associated with a fever and a raised WBC count. Meningitis may be septic, secondary to bacterial infection, or aseptic, secondary to chemicals, blood, pyrogens or viral infection.

Traumatic damage to nerve roots and spinal cord: direct injury to the spinal nerve roots or the spinal cord by needle damage or injection of local anaesthetic or air into the tissues can cause axonotmesis and neurotmesis. Axonotmesis is a degeneration of the axon with the axon sheath remaining intact; recovery is complete but slow. Neurotmesis describes disruption of both the axon and sheath with little chance of complete recovery. Both these injuries are extremely painful when they occur, but this early warning sign is lost if the procedure is performed under general anaesthesia.

Other spinal cord injuries
Infarction of the spinal cord can occur if the capillary blood flow to the cord is reduced for a significant length of time. This can result from severe arterial hypotension, direct compression of the capillary bed, venous hypertension or a combination. The blood supply to the spinal cord is from one anterior artery and two posterior spinal arteries. There are no anastomoses between the anterior and posterior arteries. Anterior spinal artery syndrome is a description of the neurological deficit that occurs if the anterior blood supply is interrupted but the posterior supply remains intact.

Haematoma and abscess formation are two recognized causes of cord compression leading to ischaemic damage. Puncture of an epidural vein with a spinal needle is unlikely to induce a significant haematoma in a normal individual but could do so in the presence of a coagulopathy or anticoagulation. An epidural abscess can develop as a result of introducing organisms from the skin or haematogenous spread. Initially, both present with backache and marked localized tenderness over the spine. An abscess may also present with malaise, fever and headache. Severe backache, weakness or bladder and bowel symptoms are late signs and indicate that urgent spinal decompression is required within 6–12 hours.

Arachnoiditis is inflammation of the arachnoid and pial meninges. Lignocaine can be neurotoxic in high doses and has been implicated in cases associated with the use of spinal catheters. Preservatives have also been blamed, in particular sodium bisulphite in the original chloroprocaine formulation. A feature of arachnoiditis is that the onset of neurological symptoms can be delayed and progressive.

Cauda equina syndrome describes a combination of leg weakness, perineal sensory loss, and urinary and faecal incontinence. This may be the result of trauma, ischaemia or chemical toxicity.

Management of postspinal headache

The reported incidence of postspinal headache is variable; with 25–27 G atraumatic needles the incidence is less than 1%. Younger patients are more vulnerable than older patients, women more than men, and pregnant women are at the greatest risk. Pencil-point, atraumatic spinal needles (e.g. Whitacre, Sprott) are thought to cause fewer headaches because they part the fibres of the meninges. Bevelled needles (e.g. Quincke) are more likely to cut the fibres.

The severity of symptoms range from a mild, postural headache to a severe, debilitating headache. It is usually self-limiting, resolving within 6–8 days, but can persist for months. The differential diagnosis includes a nonspecific headache, migraine, meningitis, intradural, extradural and subdural haematoma, pneumoencephalus, sinusitis or a headache associated with hypertension.

Mild symptoms

Mild symptoms can be managed with conservative treatment (Figure 2). Simple analgesics should be prescribed regularly, for example paracetamol, 1 g 4-hourly with a maximum dose of 4 g in 24 hours, or non-steroidal anti-inflammatory drugs (e.g. diclofenac, 50 mg 8-hourly). The patient should be encouraged to drink sufficient fluids to prevent dehydration. There is no proven benefit to overhydrating the patient with intravenous therapy but if the patient is unable to take adequate oral fluids this may be necessary. Bed rest helps to relieve symptoms. Raising the intra-abdominal pressure using abdominal binders or by asking the patient to lie prone can also provide relief. This rise in pressure is transmitted to the epidural veins and indirectly raises CSF pressure.

Attempts to use drugs to increase the rate of production of CSF have not proved beneficial. The use of intravenous sodium caffeine benzoate, 500 mg diluted in 1 litre of normal saline, infused over 1 hour, can reverse the cerebral vasodilatation and produce temporary relief. It is used as a palliative measure to support a patient until more definitive treatment can be instigated.

Severe symptoms

Severe or persistent symptoms are treated using an epidural blood patch (Figure 2). The principle of this procedure is to inject the patient's own blood into the epidural space. This has two actions – it indirectly increases CSF pressure, providing instant relief, and it clots over the hole, preventing further CSF leak until the hole closes spontaneously. The efficacy of this procedure is high, though it is not uncommon to require a second blood patch. The technique has a good safety record but backache after the procedure is common and may last for 2–3 days. The success of the epidural blood patch is improved if at least 15 ml of autologous blood can be injected. The injection should be slow, over at least 2 minutes, but if pain or paraesthesia develop, the procedure should be discontinued. Strict asepsis must be used to avoid meningitis. After the procedure, the patient should lie supine for a minimum of 30 minutes followed by gentle mobilization.

Care of the Postoperative Unconscious Patient

Jenny Tuckey

Jenny Tuckey is Consultant Anaesthetist at the Royal United Hospital, Bath, UK. Her research interests include obstetric anaesthesia, use of the levering laryngoscope, feasibility of day-case laparoscopic cholecystectomy and the Bezold–Jarisch reflex.

In the period immediately after surgery, the patient should be closely monitored in the recovery room or postanaesthesia care unit. The anaesthetist will delegate further care of the patient to a specially trained nurse. A comprehensive handover should be given that includes the patient's age and premorbid state, details regarding surgery, vascular access, invasive monitoring, peroperative analgesia and blood loss where indicated. Provision should have been made for postoperative analgesia and fluids.

The most important areas for close attention are:

- **a**irway
- **b**reathing and gas exchange
- **c**irculation
- unconscious state
- pain management
- temperature
- wound.

Airway of the unconscious patient

All airway emergencies can lead to hypoxaemia, hypercapnia and ultimately death if not promptly recognized and treated. Airway emergencies include:

- soft tissue obstruction
- laryngeal spasm
- laryngeal oedema
- haemorrhage
- tracheomalacia after thyroid surgery
- tumour.

The most common emergencies are discussed below.

Soft tissue obstruction occurs when the pharynx is blocked and the passage of respiratory gases is prevented. The most common cause is the tongue. Clinical signs of airway obstruction include snoring or crowing, flaring of the nares, and tracheal tug. With total obstruction, there is asynchronous movement of the chest and abdomen, and an absence of breath sounds and air movement at the mouth.

Treatment − the presence of foreign bodies in the mouth must be excluded. Manoeuvres such as chin lift and jaw thrust usually displace the tongue and improve the airway. A well-lubricated oral or nasal airway may help. Oral airways may provoke gagging, coughing, vomiting or laryngeal spasm in a semiconscious patient. A nasopharyngeal airway is tolerated better in an awakening patient but may provoke epistaxis.

Laryngeal spasm is a common cause of airway obstruction in the immediate postoperative period. This reflex contraction of the vocal cords may cause partial or complete obstruction. It is more common in children, smokers, asthmatics and following upper airway surgery. It may be provoked by secretions, extubation of the trachea or insertion of an artificial airway in a semiconscious patient. Optimal positioning or the use of an artificial airway does not relieve the obstruction.

Treatment − the patient's airway should be suctioned gently; 100% oxygen should be administered. Continuous positive airway pressure (CPAP) or gentle intermittent positive pressure ventilation should be applied by face mask. Care should be taken to avoid over-vigorous ventilation because oxygen will enter the stomach and encourage reflux and splinting of the diaphragm. If hypoxaemia ensues, prophylactic atropine, 600 µg i.v., will prevent bradycardia. Suxamethonium, 0.1−0.2 mg/kg, relaxes the cords and enables oxygenation. If the patient is at risk of aspiration, they should be re-intubated.

Laryngeal oedema: problematic swelling of laryngeal tissues occurs most often in children because of the small calibre of their airways. It results in stridor, inspiratory retraction of soft tissues, and a croup-like cough. It may be caused by laryngeal mucosal ischaemia following the use of an excessively large tracheal tube, trauma during intubation, or allergy.

Treatment − humidified oxygen should be administered; nebulized adrenaline, 5 mg in saline, and dexamethasone may also be required. In awake patients, the erect posture is beneficial. Anaphylaxis requires treatment with incremental intravenous adrenaline. Re-intubation may be necessary.

Breathing and gas exchange in the immediate postoperative period

Respiratory complications are the primary cause of life-threatening morbidity in the recovery room.

Postoperative hypoxaemia: arterial hypoxaemia is defined as an arterial oxygen tension less than that predicted for the patient's age and the prevailing barometric pressure. The causes of postoperative hypoxaemia are discussed below.

Decreased inspired oxygen − in practice, this occurs as a result of diffusion hypoxia. Nitrous oxide is about 35 times more soluble in blood than nitrogen. Following nitrous oxide anaesthesia, nitrous oxide diffuses out of the blood and into the alveoli in larger volumes than nitrogen diffuses in the opposite direction. As a result, the alveolar concentration of oxygen falls and arterial hypoxaemia may occur if the patient breathes room air. Diffusion hypoxia may be avoided by administering supplemental oxygen for 10 minutes after nitrous oxide anaesthesia.

Alveolar hypoventilation results from either abnormal control of breathing or abnormal mechanics of breathing (Figure 1). The elderly or debilitated are at greater risk of respiratory depression.

• Abnormal control of breathing – treatment is with oxygen, with awareness of the risk of normal haemoblobin oxygen saturation with hypercarbia. Use of naloxone, doxapram and flumazenil should be considered. The patient may require postoperative ventilation.

• Abnormal mechanics of respiration – the underlying cause should be treated. Oxygen should be given and drug treatment reversed. Bronchodilators and ventilation with or without a tracheal tube should be considered.

Increased ventilation/perfusion mismatch − anaesthesia induces a gas exchange abnormality as a result of atelectasis in the dependent parts of the lung. This is caused by a reduction in the functional residual capacity (FRC). FRC is reduced because of diminished inspiratory muscle tone at the induction of anaesthesia, resulting in loss of outward elastic recoil of the chest wall.

Cranial displacement of the diaphragm is due to a reduction in its muscle tone, so that it is no longer able fully to oppose the hydrostatic pressure of the abdominal contents. Reduction in FRC occurs whether the patient is paralysed or breathing spontaneously.

Airway closure becomes important when FRC is less than the closing capacity. The resulting airway closure and gas trapping causes an increase in venous admixture and shunt. Airway closure increases with advanced age and obesity. Abdominal incisional pain causes reflex diaphragmatic dysfunction. Shunt occurs with pulmonary oedema of any aetiology, consolidation and pulmonary aspiration.

Initial treatment includes oxygen therapy and management of the underlying cause (e.g. analgesia for pain). Effective epidural analgesia and aggressive chest physiotherapy optimize postoperative lung function after major trunk surgery.

Causes of alveolar hypoventilation

Abnormal control of respiration

- Drugs – volatile agents, induction agents (except ketamine), opioids (parenteral, 'spinal')
- Recent hyperventilation
- Preoperative CNS – trauma, haemorrhage, tumour
- Peroperative CNS – haemorrhage, thrombosis, emboli
- Hypothyroidism
- Hypothermia
- Obstructive sleep apnoea

Abnormal mechanics of respiration

- Upper airway obstruction
- Muscle weakness – residual neuromuscular blockade, muscle disease, aminoglycosides, electrolyte disturbance
- Abdominal 'splinting' – obesity, abdominal distension, pain, tight dressings
- Bronchospasm – known asthmatic, presence of tracheal tube, anaphylaxis
- Chest wall abnormality – congenital, trauma
- Phrenic nerve dysfunction – idiopathic, brachial plexus block, 'total' spinal

1

Cardiovascular system

The cardiovascular system may be deranged immediately postoperatively. Commonly encountered problems are discussed below.

Postoperative hypotension can be caused by a reduction in preload, contractility or afterload.

Reduced preload is caused by loss of intravascular volume or diminished venous return. The most common causes of reduced preload are blood loss (e.g. on-going or inadequately replaced, exacerbated by coagulopathy), 'third space' losses and capillary leak. Reduced venous return can result from:

- postural changes (e.g. head-up tilt especially with regional block)
- supine hypotension syndrome (in late pregnancy)
- raised intrathoracic pressure (e.g. positive end-expiratory pressure, tension pneumothorax)
- massive pulmonary embolism (reduced return to the left atrium).
- residual effect of venodilating drugs (e.g. induction agents, volatile agents and glyceryl trinitrate).

Treatment involves enhancing venous return (e.g. by optimizing patient posture) and administering fluids. In difficult cases, a central venous line is a useful guide to fluid requirements.

Reduced myocardial contractility may be caused by the residual effect of anaesthetic drugs, pre-existing ventricular dysfunction or new myocardial ischaemia. It may be compounded by hypoxia, ischaemia, arrhythmias, hypothermia and acid–base or electrolyte disturbance.

Treatment aims to correct hypoxia, acid–base and electrolyte disturbance, and to optimize preload. Inotropes should be used if there is evidence of myocardial dysfunction. Ischaemia should be documented with an ECG and glyceryl trinitrate therapy considered.

Decreased afterload − postoperative causes of decreased afterload (reduced systemic vascular resistance) include diminished sympathetic tone secondary to regional block, vasodilators, septic shock and rewarming. Treatment involves optimizing preload, and use of vasopressors if there is clear evidence of reduced systemic vascular resistance.

Postoperative hypertension: the most common causes of postoperative hypertension are:

- pain (from wound, full bladder)
- pre-existing hypertension
- administered vasopressors
- hypoxia/hypercarbia.

The underlying cause should be treated (e.g. morphine for pain, catheterize bladder) and oxygen administered. Specific antihypertensive therapy may be required (e.g. hydralazine, β-blockers, nifedipine).

Myocardial ischaemia/infarction occurs most often in patients with a history of recent myocardial infarction, cardiac failure, arrhythmias, advanced age, aortic stenosis, or hypertension, or in those undergoing vascular or major trunk surgery. It occurs as a result of adverse myocardial oxygen supply/demand ratios (e.g. with hypoxia, hypotension, tachycardia or hypertension).

Extrinsic causes should be treated, and both oxygen and glyceryl trinitrate (sublingual or by infusion) administered. If there are no contraindications, low-dose aspirin should be given in case of infarction. Thrombolysis is contraindicated because of the recent surgery and the risk of haemorrhage.

Left ventricular failure implies reduced myocardial contractility and increased pulmonary capillary hydrostatic pressure resulting in pulmonary oedema. Reduced cardiac output results in impaired cognition, cool moist skin, oliguria and metabolic acidosis. Pulmonary oedema causes tachypnoea, hypoxia, cyanosis, fine-end inspiratory crepitations, and pink frothy sputum.

Treatment includes combinations of therapies to reduce preload and afterload, and increase cardiac contractility (e.g. oxygen, frusemide, inotropes, nitrates, incremental intravenous diamorphine and adoption of the sitting position).

Arrhythmias are usually benign but their effect on cardiac output should be ascertained. If new, a cause should be sought and treatment begun where possible.

The causes of arrhythmias include:

- residual anaesthetic drugs and gases; some inhalational agents (e.g. halothane) sensitize the myocardium to catecholamines
- pre-existing heart disease
- myocardial ischaemia
- hypoxaemia, hypercarbia, electrolyte and acid–base imbalance; hypokalaemia predisposes to arrhythmias and exacerbates digoxin toxicity
- increased sympathetic drive from pain
- increased vagal tone
- hypothermia.

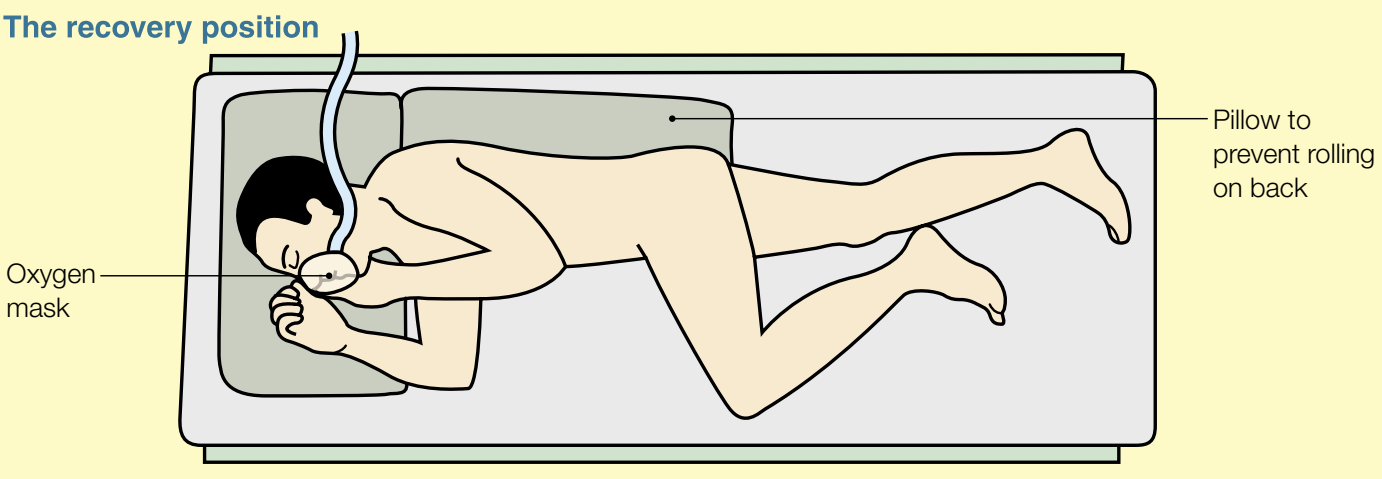
The common arrhythmias include sinus tachycardia, bradycardia, supraventricular tachycardias (SVT), ventricular tachycardias (VT) and conduction defects including complete heart block. Treatment should be individually tailored (e.g. analgesia for pain-induced sinus tachycardia, cardioversion for SVT and VT, and electrical pacing for complete heart block).

‘Neurological’ care of the unconscious postoperative patient

Patient posture: the position of choice for any unconscious patient is the ‘recovery’ position (Figure 2). This position displaces the tongue anteriorly, encouraging anterior displacement of secretions or vomitus. However, there are situations when the immediate postoperative position is determined by other factors (e.g. supine position if there is spinal instability or head-up tilt following neurosurgery).

When ‘recovering’ an unconscious patient, care must be taken to reduce skin damage in ‘pressure areas’. Padded cot-sides may be useful if the patient is restless. If recovery of consciousness is prolonged, the eyelids should be kept closed to prevent corneal drying and care should be taken to avoid corneal abrasions. Venous access ports must be accessible and secure, and catheters and drains should be positioned so as to be visible and facilitate drainage.

The recovery position



2

Prolonged loss of consciousness: the duration of the unconscious state depends on:

- drugs used − long-acting drugs or drugs with active metabolites may cause delayed awakening
- duration of surgery − there is a greater potential for accumulation of drugs with repeated doses
- patient’s age − drug metabolism may be impaired with increasing age
- any intercurrent disease − renal, hepatic and thyroid pathology and hypothermia may result in delayed metabolism and clearance of sedative drugs
- adverse intraoperative events − hypoglycaemia, hyperglycaemia, cerebral ischaemia/hypoxia, thrombosis, haemorrhage, hypercarbia, a total spinal and the transurethral resection of the prostate syndrome.

Care of the postoperative unconscious patient

Care should be directed towards managing pain, temperature and the surgical wound.

Pain: in order to minimize sympathetic activation and ensure a comfortable return to consciousness, adequate analgesia must be administered and prescribed (e.g. intravenous morphine, epidural topped up).

Temperature: postoperatively, the patient’s temperature may be normal, increased or decreased.

Pyrexia may be caused by pre-existing fever, secondary to febrile transfusion reaction or, rarely, by malignant hyperthermia.

The patient should be cooled by fanning, tepid sponging and paracetamol suppositories. The source or cause of the pyrexia should be treated (e.g. transfusion should be stopped). In the case of malignant hyperthermia, administration of the causative agent should cease, and 100% oxygen, fluids, dantrolene, 1−10 mg/kg, and mannitol should be given. Any acid–base and electrolyte imbalance must be treated urgently.

Hypothermia is common perioperatively and may be defined as a core temperature of less than 36°C. Hypothermia can occasionally be advantageous (e.g. cerebral preservation before cerebral insult such as hypoxia or ischaemia); generally, however, hypothermia has adverse physiological effects on the postoperative patient. These include increased incidence of myocardial ischaemia, coagulopathy and delayed wound healing.

General anaesthesia resets the thermal inter-threshold range so that heat generating/conserving mechanisms are not activated until the core temperature has fallen by about 2.5°C. General anaesthesia causes a reduction in the basal metabolic rate, inhibits shivering and reduces the patient’s ability to conserve heat by vasoconstriction. Unaided rewarming postoperatively may cause adverse physiological alterations. The muscular activity of shivering causes a significant increase in metabolic rate, and oxygen consumption may increase as much as fivefold. This coincides with the period of recovery when the patient is most likely to become hypoxaemic for other reasons.

The incidence of postoperative shivering is 5−65%. It is more common after longer procedures, in young men, during anaesthesia employing spontaneous ventilation and following volatile rather than total intravenous anaesthesia. Surprisingly, there is a poor correlation between body temperature and the incidence of shivering postoperatively.

Hypothermia may be compounded by the sympathetic block associated with regional blockade. This ablates the core–shell divide and increases heat loss.

Methods of rewarming postoperative patients include use of a forced-air warming device, warmed fluids and minimizing skin exposure. Irrigation of body cavities (bladder) with warmed fluids may be used in severe cases. A number of drug remedies have been shown to reduce shivering (e.g. intravenous pethidine, 0.3 mg/kg, via κ receptors, and doxapram, 1.5 mg/kg).

Surgical wound: the wound should be inspected for bleeding, swelling, cyanosis or ischaemia. The circulation distal to rigid orthopaedic plasters and devices should be monitored for signs of ischaemia.

When wound haemorrhage occurs, pressure should be applied to bleeding points. If limbs are at risk of swelling they should be elevated. The surgeon should always be informed in cases causing concern to the anaesthetist or recovery room staff.

Causes and Treatment of Postoperative Nausea and Vomiting

Shakil Abbas

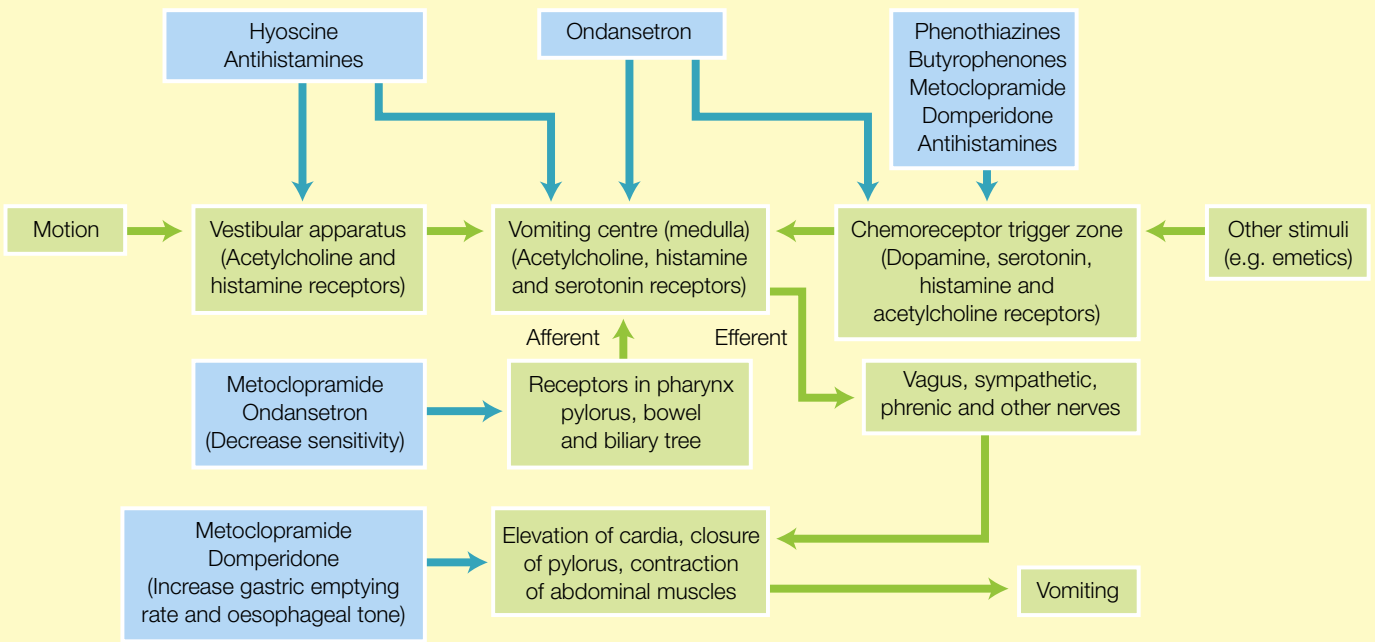
Shakil Abbas is Specialist Registrar in Anaesthetics at Salisbury District Hospital, UK. He qualified from Dow Medical College, Karachi, Pakistan. After commencing his anaesthetic career in Karachi, he underwent further training in different regions in the UK, including Glasgow and Southampton. His specialist interests are paediatric anaesthesia and adult intensive care.

Postoperative nausea and vomiting are the most common and distressing manifestations of anaesthesia-related morbidity and the most common indication for the unplanned overnight admission of a patient scheduled for day-case surgery. The incidence is 20−30% and has remained fairly constant for decades, though it is higher in some surgical populations.

Nausea and vomiting following surgery may result in dehydration, electrolyte imbalance, delayed discharge, tension on suture lines, venous hypertension, increased bleeding under skin flaps, increased intracranial and intra-ocular pressure, and increased blood pressure and heart rate. The risk of pulmonary aspiration of vomitus is increased if the airway reflexes are depressed by the residual effects of anaesthetic agents.

Pathophysiology: the vomiting centre is located in the reticular formation in the medulla. It coordinates, but does not initiate, vomiting (Figure 1). It receives input from the cerebral cortex (e.g. visual, emotional, olfactory), gastrointestinal tract (autonomic afferent fibres), chemoreceptor trigger zone and the vestibular system. The chemoreceptor trigger zone is located on the floor of the fourth ventricle in or above the area postrema, outside the blood−brain barrier. It contains histamine, dopamine, acetylcholine (muscarinic), serotonin (5-HT_3) and opioid receptors. The presence of these receptors may explain the mechanisms behind the anti-emetic actions of antagonists at the histamine, dopamine, acetylcholine and serotonin receptors, along with the emetic effects of opioids.

Pathophysiology of vomiting and the sites and mechanisms of actions of anti-emetic drugs



1

Causes

Causes of postoperative vomiting may be categorized into non-anaesthetic, anaesthetic-related and postoperative factors.

Non-anaesthetic factors

Patient-related factors

Age − incidence is higher in children. The peak incidence is at 11−14 years of age. Emesis decreases in old age.

Gender − women are more likely to vomit. This difference is not noted in pre-adolescents or in patients over 70 years old.

Obesity − increased body weight is associated with a greater incidence of postoperative vomiting. It may be related to increased residual anaesthetic agents in the adipose tissue, larger residual gastric volume and increased incidence of oesophageal reflux.

Anxiety − patients with high preoperative anxiety have a higher incidence of emesis. The possible reasons include an increased level of catecholamine release or an increase in gastric volume secondary to excessive air swallowing.

Previous postoperative nausea and vomiting − some individuals are susceptible to sickness. Those prone to motion sickness are more likely to vomit postoperatively.

Gastroparesis − patients with delayed gastric emptying may be at increased risk of vomiting after surgery. The condition may include gastrointestinal obstruction, cholecystitis, neuromuscular disorders and intrinsic neuropathies.

Surgical factors: patients undergoing long surgical procedures are more likely to vomit. Emesis is more likely after abdominal procedures, laparoscopy, dental extraction, dilatation of the cervix and ear operations. In children, there is a high incidence of emesis after strabismus surgery, orchidopexy, middle-ear surgery and adenotonsillectomy.

Anaesthetic-related factors

All the opioids possess marked emetic properties. Ether, cyclopropane and trichloroethylene are associated with a high incidence of postoperative vomiting, but there is little difference between the volatile anaesthetics currently used. Ketamine and etomidate have emetic effects; propofol has anti-emetic properties.

Vigorous positive pressure ventilation via a face mask may cause gastric distension with anaesthetic gases, leading to emesis postoperatively. Hypoxaemia at any stage and hypotension during regional anaesthesia induce vomiting.

Postoperative factors

Visceral or pelvic pain is a common cause of postoperative vomiting. Premature resumption of oral fluids, sudden changes in position and the sight and smell of offensive substances (e.g. vomitus, blood, faeces) can lead to vomiting.

Management

In patients with persistent nausea and vomiting, fluid and electrolyte replacement using intravenous infusions should be considered. Pain control should be optimized using non-opioid analgesics and/or local anaesthetic blocks. Patients with obtunded protective airway reflexes should be nursed in a lateral position.

Gentle handling of the patient is necessary. A nausea and vomiting scoring scale is used for monitoring.

Pharmacological management

No drug currently available will antagonize all the receptor sites involved in vomiting and therefore if one agent is ineffective, a second anti-emetic that acts on a different receptor should be administered. However, routine prophylactic use of an anti-emetic with every anaesthetic is not recommended.

Antidopaminergic agents

Prochlorperazine is one of the more commonly used anti-emetics in the phenothiazine group. It acts on the dopaminergic receptors in the chemoreceptor trigger zone, along with an α-adrenergic receptor-blocking property. Side-effects include sedation, hypotension, dysphoria and extrapyramidal effects (e.g. acute dystonia, akathesia, Parkinson-like rigidity).

Metoclopramide acts centrally by antagonizing the effects of dopamine. It also has a peripheral action on the gastrointestinal tract, which appears to be blockade of dopaminergic neurons that modulate acetylcholine release. It is structurally related to procainamide but has no local anaesthetic or anti-arrhythmic actions. It is a prokinetic, which increases lower oesophageal sphincter tone, speeds gastric emptying and increases the propulsive activity of gastrointestinal smooth muscle. The terminal half-life of metoclopramide is 4 hours. Side-effects include mild sedation, extrapyramidal reactions, restlessness, hunger, dizziness, anxiety and hyperprolactinaemia.

Droperidol is a potent neuroleptic with an anti-emetic effect, mediated via dopamine receptor antagonism. Anti-emetic effects may be achieved with doses that cause minimal sedation. The terminal elimination half-life is 2 hours, but the anti-emetic effect lasts longer. Droperidol may cause hypotension, secondary to an α-adrenergic receptor-blocking effect. Extrapyramidal reactions and sedation are other recognized problems.

Antihistamines: cyclizine antagonizes central histamine (H_1) receptors. It has a short duration of action of 4 hours. It can cause sedation and a dry mouth, but is not associated with extrapyramidal reactions. Other drugs in this group include promethazine, diphenhydramine and dimenhydrinate; they also possess anticholinergic properties.

Anticholinergics: hyoscine antagonizes muscarinic cholinergic receptors and thus has a central anti-emetic action. It is used to prevent motion sickness. The duration of action is short; elimination half-life is 1 hour. A transdermal preparation is available for a more sustained effect and fewer side-effects. Hyoscine can cause sedation, hallucination, dry mouth, tachycardia, mydriasis and cycloplegia. It is contraindicated in patients with narrow-angle glaucoma or urinary obstruction.

Serotonin antagonists: ondansetron was the first serotonin receptor antagonist used extensively in postoperative nausea and vomiting. Other drugs in this group include granisetron, tropisetron, itasetronan and dolasetron. Ondansetron binds at the serotonin receptor in the chemoreceptor trigger zone and at vagal afferents in the gastrointestinal tract. Clearance occurs primarily (95%) by hepatic metabolism, with an elimination half-life of about 4 hours. It is well tolerated and its other advantages are absence of sedation, extrapyramidal effects, adverse cardiovascular actions, dysphoria and dry mouth. It has minimal side-effects, which include dizziness, headache and impairment of liver function tests. The dose of ondansetron should be reduced in patients with hepatic insufficiency.

Corticosteroids: dexamethasone may be used as an adjunct to standard anti-emetic therapy in cases of persistent vomiting. Its proposed mechanism of action is decreased release of arachidonic acid, reduced turnover of serotonin and decreased permeability of the blood−brain barrier.

Non-pharmacological management

Stimulation of the acupuncture point PC6 (Nieguan) has been used for centuries in China to treat nausea and vomiting. Its use to prevent postoperative nausea and vomiting has met with varying degrees of success. However, there is the possibility of trauma to nerves and blood vessels or sepsis.

Diagnosis and Treatment in the Recovery Room

Anthony Beaumont

Anthony Beaumont is Consultant in Intensive Care and Anaesthesia at the Kent and Canterbury Hospital, UK. He qualified from Charing Cross Hospital, London, and trained in London and Adelaide, Australia. His research interest is equipment in the ICU. His clinical interests are non-invasive ventilation, postoperative pain control and perioperative patient management.

The recovery room provides the facility to monitor and treat potentially life-threatening disturbances caused by anaesthesia, surgery or both. Complications occurring during the recovery from anaesthesia can be categorized as:

- cardiovascular (e.g. hypotension, hypertension, dysrhythmias, myocardial infarction, cardiac failure)
- respiratory (e.g. hypoxaemia, ventilatory failure, airway obstruction)
- others (e.g. nausea and vomiting, hypothermia, CNS disturbances, pain).

Hypertension

The incidence of hypertension increases with age. With the increasing number of older patients presenting for surgery, postoperative hypertension is a major problem for the anaesthetist. The incidence of postoperative hypertension may be as high as 60% depending on the patient and the surgical procedure; vascular surgery has the highest incidence.

Causes: the normal physiological responses to surgery include activation of the sympathetic nervous system and, therefore, an increase in blood pressure. Identification and treatment of the underlying cause (Figure 1) usually allows the blood pressure to return to normal in a short time. If hypertension develops in the postoperative period, it usually begins within 30 minutes of the end of the operation and is resolved within 4 hours of surgery. For this reason, if treatment is required, short-acting drugs can be used.

Causes of postoperative hypertension

Common causes

- Known hypertensive patient
- Pain
- Hypothermia
- Anxiety
- Blood gas disturbances (hypoxaemia, hypercarbia)
- Acute withdrawal of antihypertensive medication
- Distended bladder or bowel
- Fluid overload

Uncommon causes

- Undiagnosed phaeochromocytoma
- Acute drug withdrawal (e.g. sedatives)

1

Decision to treat: the accepted American Heart Association definition of hypertension is a blood pressure greater than 140/90 mm Hg. However, most would not regard this as high enough to warrant treatment in the post-anaesthetic period. In this situation, the accepted treatment threshold is a systolic pressure over 180 mm Hg or a diastolic pressure over 100 mm Hg, though there are instances when more aggressive treatment is warranted. These may include the type of surgery or the patient's cardiac status. On the other hand, if the patient is known to be hypertensive normally, higher levels of blood pressure may be accepted before perioperative treatment is begun.

If treatment is required, first-line therapy is as follows.

- Treat the underlying cause and check that ventilation and oxygenation are adequate. Measuring an arterial blood gas may assist in the assessment.
- Treat pain with opiates to the point of drowsiness. This should also relieve anxiety. (The combination of opiates and sedatives is not recommended.)
- Check for bladder and bowel distension and relieve them if appropriate.
- Warm the patient. If the patient is cold, re-warming may cause vasodilatation and hypotension.
- If the patient does not respond to first-line therapy, consider giving an antihypertensive agent (Figure 2).

Antihypertensive medication

Drug	Action
• Esmolol	Short-acting β-blocker. May need to be given by infusion of 25–300 μg/kg/minute
• Labetalol	α- and β-blocker. Increments of 5 mg may be given at 5-minute intervals to control blood pressure. May cause bradycardia
• Glyceryl trinitrate	Cutaneous patches, intravenous or sublingual routes. Causes dilatation of the venous system initially, then the arterial system
• Nifedipine	Calcium channel blocker. May be given sublingually. Relaxes arteriolar smooth muscle. Is a negative inotrope
• Clonidine	α_2-blocker. Has a sedative and analgesic action in addition to its blood pressure-lowering effect. Dose 50–100 μg i.v.
• Hydralazine	Arteriolar smooth muscle relaxant. May be given as a bolus, 25–50 mg i.v. Is not a negative inotrope
• Sodium nitroprusside	Arteriolar smooth muscle relaxant. Needs to be given by infusion in a light-protected system. Invasive blood pressure measurement is recommended

2

Hypotension

Hypotension may be defined as a reduction in blood pressure of more than 20–30% below the preoperative baseline. However, patient anxiety may have altered the preoperative values and they may not reflect the patient's true resting blood pressure.

The potential end-result of hypotension is hypoperfusion. In general, clinical signs of hypoperfusion are more important than numerical values of blood pressure. These signs include pale, cool skin, slow capillary refill time (> 2 seconds), sweating, tachycardia, reduced conscious level, tachypnoea, nausea and vomiting. Plasma lactate may be elevated as a result of anaerobic metabolism. The classic signs of hypotension and tachycardia may not always be seen in hypovolaemic shock if β-blockade is present.

Clinical examination of the central venous pressure may not be easy, but should be attempted. Ultrasound examination of the size of the internal jugular vein helps to assess the intravascular volume. If in doubt, a central venous catheter should be inserted to permit direct measurement of the central venous pressure.

Oxygen should be administered to all patients who are hypotensive until its aetiology has been elucidated and treatment has been given.

Causes (Figure 3): fluid loss is the most common cause of hypoperfusion either as a result of underestimated blood loss in the operating theatre or continued blood loss in the recovery room. Surgical drains are unreliable in assessing postoperative blood loss. Blood may clot before coming out through a drain or the drain may be positioned in a site distant from the source of bleeding. The response to a bolus of colloid, 10 ml/kg, is usually sufficient to diagnose hypovolaemia. If further fluid replacement is necessary it is guided by response to treatment.

Causes of hypotension

Fluid loss

- Unrecognized intraoperative blood loss
- Continuing haemorrhage

Myocardial dysfunction

- Myocardial ischaemia or infarction
- Rhythm problems
- Negative inotropic agents (anaesthetic drugs)
- Uncommon problems (e.g. tamponade, pulmonary embolism)

Vascular dysfunction

- Spinal anaesthesia
- Sepsis
- Anaphylaxis
- Rewarming
- Drugs (e.g. intraoperative hypotensive agents)

3

Vascular dysfunction – a reduction in vascular resistance may be suspected in patients who have a spinal or epidural as part of their anaesthetic, or in patients with sepsis (e.g. peritonitis). Residual anaesthetic drugs may also be a cause of hypotension. Drugs that increase arteriolar tone (Figure 4) may be required to increase the blood pressure above a minimum mean value of 70 mm Hg.

Myocardial dysfunction should be considered as a possible cause of hypotension if the central venous pressure is normal or high and there is no response to simple fluid administration. These patients require careful evaluation. ECG monitoring and a formal 12-lead ECG should be obtained and compared with the preoperative ECG for signs of ischaemia or infarction. Cardiac enzyme analysis (e.g. troponin) also helps in diagnosis. Treatment should centre on the restoration of myocardial blood flow and contractility using nitrates and inotropes. Dysrhythmias may also cause hypotension; treatment depends on their nature.

Drugs that increase arteriolar vascular tone

Drug	Effects
• Ephedrine	Predominantly β in effect with some α effects. Causes an increase in blood pressure and cardiac output. Preferred in pregnant women
• Metaraminol	Predominantly α in effect, causes a marked increase in systemic vascular resistance and blood pressure
• Methoxamine	Predominantly α in effect, causes a marked increase in systemic vascular resistance and blood pressure
• Adrenaline	α and β effects; increases blood pressure and cardiac output
• Noradrenaline	Predominantly a in effect, causes a marked increase in systemic vascular resistance and blood pressure

4

Shivering

Postoperative shivering may develop in up to 60% of patients recovering from general anaesthesia. It is a potentially serious complication because it increases oxygen consumption by up to 100% from baseline. Postoperative pain usually increases because the muscle activity 'stretches' the wound. Other complications of hypothermia following surgery include coagulation abnormalities, increased risk of infection, delayed wound healing and increased time spent in the recovery room. Two distinct patterns of shivering are observed in the postoperative period.

- The tonic pattern resembles normal shivering with a 4–8 cycle/minute waxing and waning pattern. This pattern is seen in thermoregulatory-induced shivering.
- The clonic phasic is characterized by a 5–7 Hz bursting pattern resembling clonus. This is the pattern seen in non-thermoregulatory-induced shivering.

Causes: there are a number of aetiological factors. The thermoregulation causes are:
- cold induced (normal thermoregulatory response to a reduction in core and skin temperature)
- cytokine release (fever and shivering in response to pyrogenic mediators released following surgery).

The non-thermoregulation causes are:
- pain
- response to volatile anaesthetic agents.

Treatment is aimed at returning the core and peripheral temperature to the normal range. Skin surface warming reduces shivering, because the regulatory system tolerates greater core hypothermia when cutaneous temperature is raised. A variety of drugs reduce shivering, including pethidine, clonidine, ketanserin, and magnesium sulphate.

Cyanosis

Postoperative hypoxaemia is common and may be caused by many factors. Hypoxaemia is usually detected using a pulse oximeter, because clinical evaluation often fails to recognize saturations below 80%. The causes of postoperative hypoxaemia include:
- atelectasis
- second gas effect (diffusion hypoxia)
- hypoventilation
- bronchospasm
- aspiration
- pneumothorax
- pulmonary embolism
- pulmonary oedema.

Atelectasis is the most common cause of a right to left shunt. It may occur as a result of collapse of a whole lung or diffuse segments within the lungs. Secretions or blood in the airways are common causes. Reduction in functional residual capacity is an almost inevitable consequence of anaesthesia because tone in the chest wall and diaphragm is reduced. If the functional residual capacity falls below the closing capacity, intrapulmonary shunting occurs. Patients at particular risk include the elderly, the very young, and patients with previous lung disease, pulmonary oedema, infection or obesity. These patients are all at increased risk of segmental collapse and secondary infection. Treatment should include sitting the patient up, physiotherapy, deep breathing exercises, incentive spirometry, intermittent continuous positive airway pressure (CPAP) or, in extreme cases, ventilation in an ICU.

The second gas effect is a transient cause of hypoxia that is easily prevented by the administration of oxygen. As nitrous oxide diffuses out of the blood into the alveolus it dilutes the alveolar gas. If the patient is breathing room air, a low alveolar concentration of oxygen results. For this reason, all patients who have received an anaesthetic containing nitrous oxide should receive supplemental oxygen for 10 minutes following cessation of the anaesthetic.

Hypoventilation is defined as a raised partial pressure of carbon dioxide in arterial blood (Pa_{CO_2}) as a consequence of alveolar hypoventilation. There are a number of causes:
- reduced respiratory drive
- reduced respiratory muscle function
- chronic or acute lung disease
- obesity.

A reduction in respiratory drive may be the result of anaesthetic drugs, especially opiates, which flatten the carbon dioxide response curve and shift it to the right. Respiratory muscle function is also reduced following surgery; upper abdominal surgery can result in a reduction in vital capacity of up to 60%.

Failure of reversal of neuromuscular blocking drugs can result in inadequate muscle function. This may be the result of hypothermia, hypermagnesaemia, acidosis, or the potentiation of neuromuscular blockade by other drugs (e.g. gentamicin) or by renal failure. Monitoring of these patients should include train-of-four monitoring of neuromuscular blockade, sequential blood gas estimations and clinical examination.

Treatment should follow the steps given below.
- Ensure adequate reversal of neuromuscular blockade.
- Titrate opiates to the patient's pain without causing excessive rises in Pa_{CO_2}. Where opiate overdose is suspected, small doses of intravenous narcotic antagonists may be needed and may have to be repeated, because the half-life of naloxone is shorter than that of most opiates.
- Epidural analgesia can reduce the hypoventilation usually seen after abdominal surgery.
- Intravenous doxapram, 1 mg/kg, may be beneficial in patients who are suspected of having a reduced respiratory drive. Doxapram may be given by infusion, if the initial intravenous bolus is effective.
- CPAP may assist in reducing the work of breathing; occasionally bilevel positive airway pressure is beneficial in patients with chronic lung disease.

Bronchospasm may occur following anaesthesia as a result of aspiration, intubation, a previous history of asthma, chronic obstructive pulmonary disease or drug reactions. Smokers are at particular risk, especially if they have not smoked in the 2 weeks before surgery. This group has increased airway sensitivity and an increased volume of bronchial secretions compared with non-smokers and patients who smoke up to the day of operation.

Bronchospasm may occur with cardiac failure, therefore the cardiovascular system should be examined for a raised jugular venous pressure and a gallop rhythm; ECG changes may also be present. A chest radiograph also assists in the differential diagnosis and helps to tailor therapy. CPAP is of considerable benefit in acute pulmonary oedema, but may be of little help in acute bronchospasm.

Treatment – first-line drug treatment is to administer nebulized β_2-stimulants. Occasionally, cholinergics or corticosteroid therapy may be indicated. If aspiration is suspected, antibiotics need not be begun immediately. Stomach contents are usually sterile and do not cause infection, but the resulting inflammation may make the patient more susceptible to infection. Routine treatment of the patient who has aspirated should include oxygen therapy, β_2-stimulants and careful monitoring for infection (e.g. fever, raised WBC count, sputum cultures, chest radiography).

Pneumothorax is usually the result of direct lung injury during surgery or the result of central vein cannulation. Pneumothorax as a result of ventilation is uncommon, unless very high ventilatory pressures have been used. Treatment depends on the size of the pneumothorax and whether ventilation is to continue into the postoperative period (Figure 5).

Pulmonary embolism is an uncommon, but important, cause of arterial hypoxaemia in the immediate postoperative period. Patients at risk include the obese, the elderly, patients with malignancy, patients with a history of embolic problems and those who have been relatively immobile before surgery.

The typical EGC changes ($S_1Q_3T_3$) are seldom seen; however, signs of right heart strain with sudden hypoxaemia, hypotension and pleuritic chest pain should raise the index of suspicion of a pulmonary embolism. The definitive test is pulmonary angiography or a ventilation–perfusion scan. The latter may not be reliable, however, in patients with atelectasis or pre-existing lung disease.

Treatment involves anticoagulation with intravenous heparin. For the patient who has a high risk of bleeding, treatment with tinzaparin, 175 µg/kg, is a useful (though unlicensed) alternative. Subsequently, patients are converted to oral warfarin therapy. An accurate diagnosis is therefore essential, to ensure that the post-surgical patient is not needlessly exposed to anticoagulation therapy.

Treatment of pneumothorax

Pneumothorax type	Treatment
• Less than 20% and unsymptomatic	Do not treat, monitor with frequent chest radiographs
• Greater than 20% or symptomatic	Insert narrow-bore catheter to drain the air (large-bore catheters are unnecessary)
• Tension pneumothorax	14 G canula inserted into the second intercostal space followed by catheter insertion
• Any pneumothorax in a ventilated patient	Insert narrow-bore chest drain

Pulmonary oedema: most patients who develop pulmonary oedema do so within 60 minutes following the end of surgery. Of these patients, 50% have a history of heart disease; others may have associated postoperative hypertension. The diagnosis may be suspected in patients with wheezing, and a previous cardiac history, and confirmed by a chest radiograph. Patients who have prolonged laryngeal obstruction may develop pulmonary oedema as a result of the sustained high negative intrathoracic pressures. The diagnosis is usually evident in such patients. Pulmonary oedema may also occur as a result of increased permeability in conditions such as disseminated intravascular coagulation, trauma, shock and sepsis. This type of oedema is often called acute lung injury and requires treatment in a critical care setting.

Treatment is aimed at the cause of the oedema. Relief of obstruction and oxygen therapy (Figure 6) is often sufficient to correct post-obstruction oedema. Traditional treatment with oxygen, diuretics, vasodilators and fluid restriction is often sufficient for most other causes. Occasionally CPAP, bilevel positive airway pressure or intubation and ventilation may be required for a few hours.

Stridor

Stridor is the result of extrathoracic obstruction of the airway. It may be caused by laryngeal oedema or 'laryngeal spasm'.

Laryngeal oedema may occur at the level of the vocal cords, the subglottic area, or in other areas of the larynx and upper airway. A precise diagnosis, made by fibre-optic laryngoscopy, is generally unnecessary for treatment. Inspiratory wheezing is characteristic and may lead to hypoxia, hypercapnia and respiratory failure, if pronounced. Reduction in stridor may indicate total obstruction of the trachea and, therefore, observation of air movement must be repeatedly confirmed. Causes include a large tracheal tube, tube movement, recent upper airway infection, or excessive coughing or bucking.

Treatment includes administering warmed, humidified oxygen. In severe cases, intravenous dexamethasone and nebulized racemic adrenaline (or 5 ml of 1:1000 adrenaline) are useful; ECG monitoring must be used while the latter is in progress. Adrenaline can be repeated, though reactive hyperaemia is possible with return of the symptoms. Reintubation is occasionally required.

Oxygen therapy devices

Oxygen delivery device	Advantages and disadvantages
• Nasal cannula	Simple, easy to use and well tolerated. 2 litres/minute equates to about 28% oxygen but is dependent on the patient's respiratory pattern. May dry out the nasal membrane if used with higher flow rates
• Simple face mask	Simple and easy to use. Delivered oxygen percentage (35–50%) depends on the patient's respiratory pattern and oxygen flow rate. Carbon dioxide accumulation may occur if the flow rate is less than 5 litres/minute
• Venturi mask	Delivers precise concentrations of oxygen (24%, 28%, 31%, 35% and 60%). Simple, reliable, effective and independent of the patient's respiratory pattern
• Non-rebreathing masks	May be used to deliver 60–90% oxygen. The mask must be tight fitting and the flow rate should be adjusted to prevent collapse of the reservoir bag during inspiration

'Laryngeal spasm': stridor caused by laryngeal spasm is often the result of mistimed extubation, debris on the vocal cords, the presence of an airway or irritation of the vocal cords. It is more common in patients who have a history of airway irritability and in smokers.

Treatment should include simple measures to ensure a patent airway such as head tilt and chin lift. Oxygen will be needed. CPAP via a face mask is often valuable. If these measures are ineffective, a small dose of suxamethonium may be necessary. Assisted ventilation is then required.

Prophylaxis has been recommended. Lignocaine (either intravenously or topically on the vocal cords) and intravenous corticosteroids have been used, but the most effective method is meticulous airway management, suctioning before extubation and correct timing of extubation.

Managing Postoperative Pain Relief

Mansukh Popat

Mansukh Popat is Consultant Anaesthetist in Oxford. A college tutor for 5 years, he is now Deputy Regional Adviser. His clinical and research interests include obstetric anaesthesia, difficult airway management and postoperative pain relief.

Pain following surgery is acute and self-limiting, but failure to relieve it is morally and ethically unacceptable. Good postoperative pain control alleviates the patient's distress and may also prevent or modify the physiological and psychological responses to surgery. There is no evidence that relieving postoperative pain speeds recovery and results in early discharge from hospital, but adequate pain relief results in fewer pulmonary complications and may reduce the transition to chronic postoperative pain.

The need for analgesia is generally straightforward, and provided the equipment and staff are available, the appropriate methods should be offered. To provide a rational approach to adequate postoperative pain relief, it is important to assess the factors described below.

Anaesthetic technique: the analgesia used during surgery influences the choice of postoperative technique.

Surgery

Site of surgery – generally, upper abdominal operations are more painful than those of the lower abdomen, which are more painful than peripheral operations. Operations on the thorax cause severe pain; those in the head and neck are usually only moderately painful.

Extent of operation – if only the superficial layers are cut, surgery is less painful than if muscles have been split. A muscle-cutting incision results in more pain than a muscle-separating incision.

Ambulation after surgery – pain relief in a patient who needs to be ambulant following surgery should be directed at ensuring that the patient is fit to go home on the day of surgery.

Age of the patient

Babies and infants – pain is a subjective phenomenon and its treatment depends on subjective assessment, which is difficult to determine in babies and infants. Drug handling by their immature systems is also a problem.

Elderly patients may not be able to cope with normal drug doses and a reduction in dose may be required. Frail patients may not be able to use technology such as patient-controlled analgesia (PCA) machines. Elderly patients also have a high incidence of co-existing disease.

Co-existing disease

Respiratory disease – care should be taken to avoid respiratory depression with opioids and possibly exacerbating asthma with non-steroidal anti-inflammatory drugs (NSAIDs).

Renal failure – patients with renal failure require a reduced dose of opioid and care should be taken with NSAIDs.

Head injury and impaired consciousness – problems include pain assessment, risk of respiratory depression and dose requirements.

Psychological state of the patient: patients differ in how they perceive pain, as shown by the variations in opioid requirement for different patients using PCA. Patient anxiety is increased by many factors (e.g. hospitalization, surgical diagnosis, and ability to cope with pain and an unfamiliar environment). Patients who are most anxious before surgery are more likely to be distressed following surgery. However, anxiety specifically related to the surgical experience is more important in pain control, because postoperative pain intensity is related to context-based (state) anxiety rather than to personality-based (trait) anxiety.

Staff and equipment: techniques such as epidural analgesia and PCA require adequately trained ward staff, appropriate equipment and experienced anaesthetists.

Methods of pain relief

Methods of providing postoperative pain relief are listed in Figure 1. Adequate pain relief can be provided easily with simple, safe and effective methods when the response of the patient to these treatments is measured, treatment is tailored to their individual needs and they are allowed to control pain relief. It is important to choose the appropriate drug, route and mode of delivery. Although single techniques are effective, a multimodal approach may provide effective analgesia while reducing the side-effects of any one method used alone.

Methods of providing postoperative pain relief

Drug treatment
- Opioids
- Non-steroidal anti-inflammatory drugs
- Paracetamol and combinations (e.g. paracetamol, 500 mg, plus codeine, 8 mg)

Regional anaesthetic techniques
- Central neuraxial blocks: epidural and spinal
- Peripheral nerve blocks
- Local infiltration

Psychological methods
- Relaxation
- Hypnosis
- Psychoprophylaxis

1

Opioids

Opioids are the mainstay of treatment for severe postoperative pain. Many opioids are available, but it may be better for an institution or ward to use one opioid so that all staff are familiar with its dose, side-effects and methods of administration. Morphine is the best known and most studied opioid and can be administered in a variety of ways (Figure 2).

Routes of administration of analgesics

Parenteral administration
- Intramuscular bolus on demand[1]
- Intravenous bolus[1]
- Continuous infusion[1]
- Patient-controlled analgesia[1]

Non-parenteral administration
- Oral[1]
- Buccal/sublingual[1]
- Rectal[1]
- Spinal and epidural[1]
- Intra-articular
- Transdermal[1]
- Inhalation

[1]Opiates may be given by these routes

2

Intramuscular administration of a bolus injection of morphine as required is still popular in many hospitals. Unfortunately the doses administered are often inadequate because of traditions, misconceptions and fear. Doctors and nurses have a misconception that opioids cause addiction, but this is not the case if they are used for acute pain. Staff shortage, distractions on the ward and controlled drug regulations result in a delay between the onset of the need for pain relief and its eventual administration, leading to low plasma levels of the drug and inadequate pain relief. Surveys suggest that up to 60% of patients treated in this way may be dissatisfied. The situation is improved by optimizing intramuscular opioid administration with the help of algorithms. A predetermined dose of morphine or pethidine is given every hour if the patient has moderate to severe pain. The nurses monitor pain and sedation scores, blood pressure and respiratory rate to decide if the drug should be withheld.

Intravenous administration: a small dose of opioid is administered and the dose is titrated to relieve pain. This method is effective but requires trained staff and monitoring and is therefore appropriate for patients in recovery and high-dependency areas rather than those on the general ward.

Continuous intravenous infusion is effective, but the dose is determined by trial and error. It is suitable when respiratory depression is desired (e.g. in ICU to sedate and ventilate patients).

PCA is commonly associated with the use of a patient-controlled device for administration of opioids by the intravenous route.

PCA is a goal-directed therapy. The goal is patient satisfaction. The patient is in charge and provides feedback control to the machine. The machine is programmed to deliver a small intravenous dose of opioid (bolus dose) when the patient presses a button. A safety feature (lockout time) is the time interval during which the machine will not deliver the drug despite the patient pressing the button. Although possible, a continuous background infusion is generally not used. For morphine, a bolus dose of 0.5–3 mg with a lockout time of 5–15 minutes is commonly used.

Advantages and disadvantages – PCA has advantages over other routes because it provides rapid, prompt drug administration via easy-to-use pumps. There is little difference in outcome between efficient intermittent intravenous injection and PCA. However, with PCA the patient determines the rate of intravenous administration of the drug thereby providing feedback control. PCA has been shown to provide greater patient satisfaction and to improve ventilation when compared with conventional routes. There is no significant difference between PCA and conventional analgesia regarding length of hospital stay. PCA should be safe and efficacious because plasma levels fall within the therapeutic window, but this is not always the case. Side-effects are similar to opioid use by other routes. Attempts at adding anti-emetics to opioids in PCA have not produced any benefits.

Monitoring is required for the safe administration of PCA. It should include pulse, blood pressure and respiratory rate. The level of sedation and pain should be assessed using sedation and pain scales. Other information that should be recorded routinely includes nausea and vomiting, itching, amount of drug used and amount of drug left and how many tries were successful. There should be clear nursing guidelines regarding the actions to be taken in cases of inadequate analgesia and when side-effects occur. Good risk management with PCA should emphasize the same drug, protocols and equipment throughout the hospital.

Non-opioid drugs

NSAIDs, paracetamol and paracetamol combinations are appropriate when patients can take drugs orally and are able to go home on the day of surgery. Alone, they do not reduce severe pain, but their efficacy as a component of multimodal analgesia is confirmed by enhancement of opioid-based analgesia. If patients can swallow it is best to give these drugs orally. NSAIDs given rectally or by injection do not perform better or faster than the same drug given at the same dose by mouth.

The side-effects of NSAIDs are serious and contraindications must be respected. The risks and benefits must be assessed in patients with gastrointestinal disease, renal impairment, asthma, bleeding diathesis and previous hypersensitivity.

Regional anaesthetic techniques

Epidural analgesia forms a major part of pain relief after major surgery to the abdomen, thorax or lower limbs. It requires trained staff to operate it and to monitor pain, nausea and vomiting, sedation scores, blood pressure, respiratory rate and sensory levels every hour. The pump and catheter site are checked regularly. Guidelines should be in place to treat complications. Debate continues on whether patients with epidural infusions should be nursed on wards or in high-dependency areas. Epidural anaesthesia alone may be used for surgery and extended for postoperative use or it may be used as a combined technique of general and regional anaesthesia. Local anaesthetics, opioids or a combination of both are commonly used.

Epidural local anaesthetics – the first major application of thoracic segmental epidural anaesthesia used lignocaine 1.5% as bolus or continuous infusion. Lignocaine causes acute tachyphylaxis and is therefore considered unsatisfactory; bupivacaine is now the most common drug used. Intermittent doses of bupivacaine, 0.25–0.5%, can be used, but the duration is limited to 3–4 hours. Instead, an infusion of bupivacaine 0.25% at a rate of 3–7 ml started immediately following the peak effect of a single dose of bupivacaine, 0.5%, maintains satisfactory analgesia. It is important that the epidural catheter tip is placed at the spinal level representing the centre of the segmental distribution of desired analgesia; for lower abdominal (T10–L2) operations the catheter tip should be at T12, for upper abdominal operations (T6–T11) at T8 and for thoracic operations (T4–T8) at T6.

Ropivacaine is less toxic than bupivacaine after intravenous administration in human volunteers. It is less lipophilic and has a higher clearance rate than bupivacaine. The sensory block produced by ropivacaine is similar to that produced by equipotent doses of bupivacaine, though the motor block is less pronounced and shorter in duration. This, plus a more favourable toxicity profile, may allow ropivacaine to be used in higher concentrations than bupivacaine.

Epidural opioids – following the discovery of opioid receptors in the spinal cord, opioids have been used extensively for epidural administration. Morphine was the first to be utilized but almost all the available opioids have been used. The analgesic action of an epidural opioid is best explained by its lipophilicity. A drug with a low partition coefficient between water and fat (i.e. morphine) is hydrophilic; fentanyl is considered lipophilic.

- A hydrophilic opioid, injected in the epidural space, is not absorbed by fat or by blood vessels near the site of the injection but slowly penetrates the dura. A slow vascular uptake maintains high CSF concentrations with actions on opioid receptors at various levels of the spinal cord and the CSF. This explains analgesia in the spinal dermatomes distant to the site of the injection and the possibility of late-onset side-effects.
- A lipophilic opioid injected epidurally is avidly absorbed by fat and blood vessels and leaves only a small amount of drug to cross the dura. Once in the CSF, it is rapidly absorbed in the blood; leaving small amounts of the drug in the CSF to act on the receptors; hence, the lack of side-effects and the short duration of action.

For these reasons, lipophilic opioids are best administered at dermatomes near the site of the surgery, whereas hydrophilic opioids can be used where the injection site is large or distant from the surgical site.

Combination of local anaesthetics and opioids – local anaesthetics and opioids have a synergistic effect at spinal cord level. Subthreshold doses combine synergistically and result in spinal analgesia with few side-effects. Combinations of opioids and local anaesthetics are useful in relieving pain, both at rest and on movement. Opioids are good for visceral pain and local anaesthetic for segmental analgesia. Currently the most favoured technique uses drugs such as fentanyl and diamorphine combined with bupivacaine.

Side-effects of epidural analgesia include complications of the technique (e.g. accidental dural puncture and headache, infection, haematoma, nerve damage). Epidural local anaesthetic may cause hypotension, motor block, immobility or toxicity as a result of accidental intravascular and intrathecal injection. Opioids may cause respiratory depression, nausea and vomiting, itching, urinary retention and somnolence

Other drugs – clonidine is a selective α_2-adrenergic receptor agonist. There is good evidence of synergism between opioids and clonidine at the spinal cord level. Clonidine, 3–5 μg/kg, has demonstrated an opioid-sparing effect.

Spinal analgesia: many operations in the lower abdomen or the lower limbs can be performed with intrathecal blocks using bupivacaine; analgesia lasts for a few minutes to several hours. It has been shown that addition of intrathecal opioids reduces the incidence of visceral pain intraoperatively and, when longer-acting drugs such as morphine and diamorphine are used, provides a few hours of postoperative analgesia. This approach has been used following analgesia for caesarean section when it is common to inject diamorphine, 0.25 mg, or preservative-free morphine, 0.1–0.2 mg, intrathecally.

Peripheral nerve blocks include plexus blocks (brachial plexus) or nerve blocks (sciatic, femoral). They may be administered as the sole anaesthetic, providing postoperative pain relief of varying duration depending on the drug used. They may also be used as part of a combined regional and general anaesthetic technique. Single-shot or catheter techniques are used. Bupivacaine is the most common local anaesthetic used in concentrations of 0.1–0.25% at 8–10 ml/hour. There is a theoretical suggestion that these techniques reduce the amount of opioids and other analgesics used postoperatively, but studies are inconclusive. These blocks require expertise to administer and are associated with several complications, especially when performed with the patient anaesthetized.

Local anaesthetic can also be injected in the intrapleural space with a Touhy epidural needle as a single-bolus or catheter technique. Indications include unilateral surgery where thoracic dermatomes are involved (e.g. mastectomy, cholecystectomy). Analgesia for thoracotomy is unsatisfactory and toxic doses are required for bilateral surgery or midline incisions. The mechanism of this block is probably by spread to the intercostal nerves. The technique can result in serious complications (e.g. pneumothorax) and should be practised by experienced anaesthetists only.

Local infiltration of the wound by the surgeon is commonly used after body cavity and surface operations. Conclusive evidence of its usefulness has been shown in hernia operations only.

Psychological techniques

The value of psychological preparation for surgery in reducing pain and thus analgesics is being increasingly recognized. Techniques include relaxation training, procedural information, cognitive coping methods and behavioural instructions.

Acute pain service

It is now a condition for accreditation for training by the Royal College of Anaesthetists that an acute hospital has an acute pain team. The functions of this team include patient management, staff and patient education, drawing up guidelines and risk management.

Postoperative Fluid Therapy

John Knighton
Andrew Soppitt

John Knighton is Consultant in Intensive Care Medicine and Anaesthesia at the Queen Alexandra Hospital, Portsmouth, UK. After qualifying from Guy's Hospital, London, he trained in intensive care medicine and anaesthesia in the south of England.

Andrew Soppitt is Specialist Registrar in Intensive Care Medicine and Anaesthesia at Southampton General Hospital, UK. After qualifying from Birmingham University, he trained in intensive care medicine and anaesthesia in the south of England.

Postoperative fluid therapy should be a continuation of the intraoperative fluid replacement planned by the anaesthetist and continued on the hospital ward. The fluids prescribed must take into account normal maintenance requirements and losses, and be adjusted for the nature of the surgical operation and coexisting medical problems. A working knowledge of the body fluid compartments and the redistribution of intravenous fluids within them, as well as daily requirements for water and electrolytes are essential.

Body fluid compartments

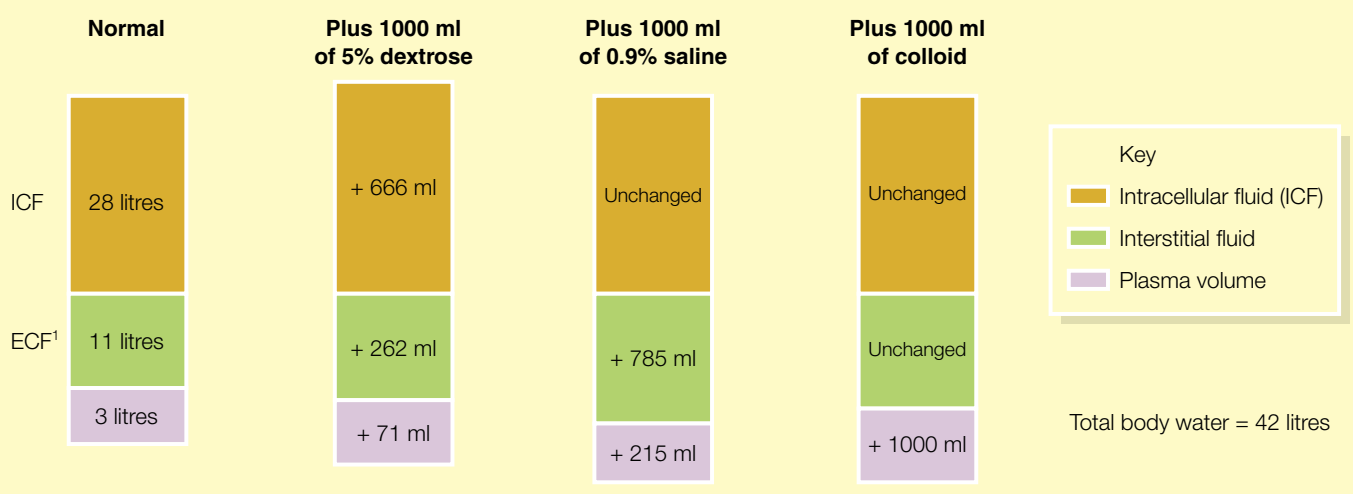
The body consists of two fluid compartments: the extracellular fluid (ECF) and the intracellular fluid (ICF). The ICF accounts for about two-thirds of the total body water. The ECF includes the blood plasma volume and the interstitial fluid volume (Figure 1).

Sodium is in diffusional equilibrium throughout the ECF but not the ICF, where potassium is the principal cation. The net result is that sodium-containing solutions are distributed throughout the body fluid compartments according to their sodium concentration relative to ECF. Therefore with infusions of 1000 ml the following occurs.

- Water (e.g. as 5% dextrose) is distributed throughout both body fluid compartments (ECF and ICF). Only a small proportion (about 3/42 or 71 ml) remains in the blood plasma volume after redistribution.
- Sodium is distributed throughout the ECF in proportion, but not in the ICF. Isotonic (0.9%) saline solutions remain in the ECF. A larger proportion (3/14 or 215 ml) remain in the blood plasma volume after redistribution.
- Solutions of large molecules, such as albumin and colloids, are distributed only within the plasma volume, assuming there is an intact capillary barrier.

True dehydration represents loss of water from all body compartments and ultimately requires water replacement. More commonly in the postoperative setting, there is predominant loss of ECF as both plasma and interstitial fluid, which requires replacement with sodium-containing solutions.

Body fluid compartments and their relative proportions in a 70 kg man



[1]Extracellular fluid (ECF) is composed of interstitial fluid and plasma volume.

1

Maintenance requirements

Simple and widely used formulae give an estimate of the basal requirements for water and electrolytes that must be provided in a postoperative fluid regimen. The return to enteral provision of fluid and nutrition should be achieved as soon as possible, and is often unnecessarily delayed.

The maintenance fluid requirements are about 35 ml/kg/ 24 hours of water or 4 ml/kg/hour for the first 10 kg body weight, plus 2 ml/kg/hour for each kg from 10 to 20 kg, plus 1 ml/kg/hour for each kg above 20 kg.

To maintain sodium balance, about 1–2 mmol/kg/day sodium is required and about 0.5–1 mmol/kg/day of potassium. These figures assume normal fluid losses (i.e. sweat, urine), and may need supplementing before or after surgery, depending on the patient's condition. For example, high-volume nasogastric aspirates result in large losses of potassium and hydrogen ions. The composition and volumes of some additional fluid losses are shown in Figure 2.

Suitable postoperative fluid regimens include maintenance requirements and additional supplementation of losses such as those described. There may also be the need for transfusion of blood products, which is not covered in this contribution.

Composition and daily fluid losses for a 70 kg man

Fluid	Volume (ml)	Na (mmol/litre)	K (mmol/litre)	Cl (mmol/litre)
Gastric	1500	10–140	5–40	50–150
Sweat	500	30–50	5	40–55
Ileal fluid[1]	3000	40–140	5–30	20–90
Diarrhoea	200–2000	20–160	10–40	30–120
Pulmonary losses	300			

[1]Including bile and pancreatic juice

2

Assessing the adequacy of fluid therapy

Maintenance requirements give a starting point for fluid prescription. Simple clinical findings such as skin turgor, dry tongue and thirst indicate more fluid is required. Examination of the cardiovascular system may reveal intravascular depletion. Persistent oliguria is a sign of inadequate fluid replacement, which precedes renal compromise; it is commonly untreated. If there is difficulty in assessing fluid losses and in high-risk cases, the use of indwelling urinary catheters with hourly urine output recordings and the use of central venous pressure monitoring are invaluable. Laboratory results such as low urine sodium (< 20 mmol/litre), high urine osmolarity (> 400 mOsm/kg) and increasing serum urea, serum lactate or a worsening metabolic acidosis may help to identify patients in whom postoperative oliguria is the result of inadequate fluid.

Specific problems

Third space fluid losses

In addition to blood loss and unavoidable losses of other fluids (e.g. gut fluids) there may be significant internal redistribution of body fluids, particularly within the ECF. These so-called 'third space' losses are caused by the sequestration of sodium-rich (isotonic with plasma) fluid from the interstitial space as a result of tissue trauma, inflammation or infection. The fluid lost in this way effectively represents an expansion of the ECF and may account for large fluid losses from the plasma, leading to circulatory hypovolaemia. Fluid sequestration may be extensive, but is difficult to quantify other than by its effect on depletion of the plasma volume.

Third space losses cannot be prevented by fluid restriction and require replacement if adequate circulating volume is to be maintained. In procedures where large losses of such fluid are anticipated (e.g. major bowel surgery, extensive pelvic dissection), the key to replacing such losses adequately lies in careful assessment of the circulating volume, clinically and using invasive monitoring such as central venous pressure measurement. Replacement of fluid sequestered in this way must be with isotonic fluids or colloids. The use of hypotonic solutions may promote hyponatraemia (see below).

The sequestered fluid usually returns to the circulation 2 or 3 days following surgery, often inducing a diuresis. Its return into the functioning ECF represents a reversal of the inflammatory response that promotes fluid sequestration.

Children

The postoperative fluid requirements for children may be calculated using the same formula described above for adults. Dextrose-containing solutions are often used because of concerns regarding possible hypoglycaemia in fasted children. In practice, this is a problem only in small infants and neonates, in whom the use of 10% dextrose is occasionally required. Neonates also have a limited ability to excrete a sodium load and weaker saline solutions may be more appropriate. In older children, dextrose/saline (e.g. 4% dextrose plus 0.18% normal saline) solutions are commonly used as maintenance fluids postoperatively. In most cases this is acceptable, but it must be remembered that such fluids are hypotonic and may lead to hyponatraemia in certain circumstances (see below).

Additional losses of fluids, such as high-volume nasogastric aspirates, must be replaced in addition to maintenance requirements. Third space losses, which can be significant in children, should be replaced with isotonic saline or colloid solutions directed at restoring and maintaining circulating plasma volume and preventing dilutional hyponatraemia.

The use of volumetric infusion pumps to control the delivery of fluid therapy in children is advisable both for safety and reliability.

Postoperative hyponatraemia

Several factors contribute to the development of postoperative hyponatraemia, but it is an avoidable iatrogenic complication with potentially disastrous consequences. Surgery, trauma, stress or infection may all cause the non-osmotic release of antidiuretic hormone, which tends to decrease renal free water clearance. This, combined with loss of sodium-rich fluids (e.g. to the third space or from an ileostomy), tends to generate an imbalance of sodium and water retention that may promote hyponatraemia. If this is unrecognized and fluid therapy is given as hypotonic saline (e.g. 4% dextrose plus 0.18% saline) or dextrose alone then hyponatraemia develops, sometimes rapidly, causing cerebral oedema and seizures. Hypotonic fluids should not be used to replace the loss of isotonic fluids.

Postoperative Pulmonary Atelectasis

Jonathan Cooper

Jonathan Cooper is Consultant Anaesthetist at St Peter's Hospital, Chertsey, UK. His interests include trauma and acute pain relief.

Atelectasis is an absence of gas in part of or in the entire lung. Common causes include hypoventilation, bronchial obstruction (e.g. by sputum, foreign body or vomit), endobronchial intubation, or air space compression (e.g. by oedematous lung tissue, pleural effusion or haemothorax). All involve airway obstruction with distal gas trapping. Since the partial pressure of trapped gas is higher than that of mixed venous blood, uptake of alveolar gas occurs and the lung becomes less aerated. Usually this takes several hours or days, because poorly soluble nitrogen in alveolar gas slows absorption. However, uptake is accelerated if the inspired gas contains high concentrations of oxygen. Atelectasis is common postoperatively; depending on the definition used, its incidence is 20–69%. It causes pulmonary shunt and hypoxaemia, reduces lung compliance, increases the work of breathing and predisposes to pneumonia.

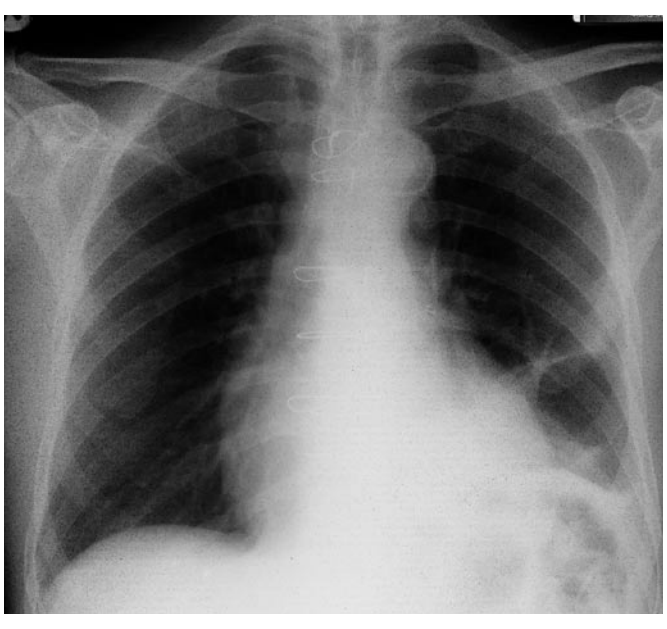
Diagnosis

The diagnosis of atelectasis can be made clinically, but is more often made radiologically.

Clinical diagnosis – atelectasis is suggested by reduced chest wall movement on the affected side, possibly with tracheal or mediastinal shift towards the lesion. Percussion note over the lesion is dull and breath sounds are usually reduced or absent over the affected area. Tachypnoea, tachycardia and hypoxaemia are common accompaniments.

Radiographic diagnosis (Figure 1) – depending on the degree of atelectasis, the chest radiograph may be normal or show signs of lung volume loss. Typical radiological signs include:

- pulmonary opacification distal to the occluded airway
- compensatory hyperexpansion of surrounding normal lung
- elevation of the diaphragm or ipsilateral hemidiaphragm
- shift of intrathoracic structures towards the collapsed segment of lung (e.g. interlobar fissure, trachea, heart, mediastinum or hilus)
- approximation of the ribs – unilateral atelectasis may cause the ipsilateral ribs to lie closer together.



1 Postoperative atelectasis. There is loss of left lung volume, elevation of the left hemidiaphragm with loss of definition of the medial aspect, and linear atelectasis of the left lower lobe (arrow).

Prevention

High-risk patients – physiotherapy reduces postoperative pulmonary complications only in high-risk patients; patients with the following high-risk factors should be identified:

- upper abdominal and thoracic incisions
- body mass index greater than 27
- history of smoking
- chronic obstructive pulmonary disease
- age over 60 years
- impaired preoperative cognitive function (reduced compliance with therapy).

Preoperative breathing exercises – physiotherapy is of most benefit when started preoperatively. Postoperative breathing techniques are easier to learn and practise in the preoperative period when there is no pain. Patients should be taught both deep and diaphragmatic breathing techniques. Effective deep breathing requires a maximal inspiration followed by a 3-second breath hold at full inspiration, before breathing out passively. As the chest expands, lung compliance increases, resistance to airflow decreases and lung re-expansion becomes easier. Diaphragmatic breathing may be facilitated if the patient places a hand over the upper abdomen while making a conscious effort to push outward on to the hand during inspiration.

Intraoperative management – postoperative atelectasis begins intraoperatively. Anaesthetic agents reduce respiratory muscle tone, causing a fall in functional residual capacity and collapse of small airways. The following interventions reduce the risk of atelectasis:

- ensuring adequate patient tidal volumes
- maintaining lung volumes, for example with continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP)
- avoiding accidental endobronchial intubation
- avoiding unnecessarily high F_iO_2
- humidifying inspired gases (e.g. use of a circle system) – without humidification, mucociliary transport becomes less efficient at clearing secretions; this predisposes to airway blockage and gas resorption
- use of a vital capacity manoeuvre – intraoperative lung inflation to an airway pressure of 40 cm H_2O for 7–8 seconds may expand all previously collapsed lung tissue.

Many of these prophylactic interventions are useful in managing postoperative, ventilated patients in the ICU.

Postoperative analgesia – thoracic epidural analgesia is preferable, but whatever the technique, patients are less likely to develop atelectasis if they are pain-free, can breathe deeply, cough well and cooperate with physiotherapy.

Treatment

If the cause of atelectasis is air space compression, the causal pathology (see above) should be treated. Otherwise, treatment of postoperative atelectasis depends on whether the patient is breathing spontaneously or receiving mechanical ventilation.

Spontaneously breathing patients

Humidified oxygen therapy prevents airway blockage and gas resorption.

Mobilization – in the standing position, the downward movement of the diaphragm is unimpeded by the weight of the abdominal contents. Walking increases cardiorespiratory effort, thus increasing diaphragmatic movement.

Positioning – in the awake patient, the dependent lung lies on the steep part of the compliance curve, whereas the non-dependent lung is on the flatter portion (Figure 2). The movement of the dependent hemidiaphragm is about twice as much as that of the non-dependent hemidiaphragm. Thus, a greater portion of the tidal volume goes to the lower lung. In spontaneously breathing patients, physiotherapy should be performed with the atelectatic side in the dependent position.

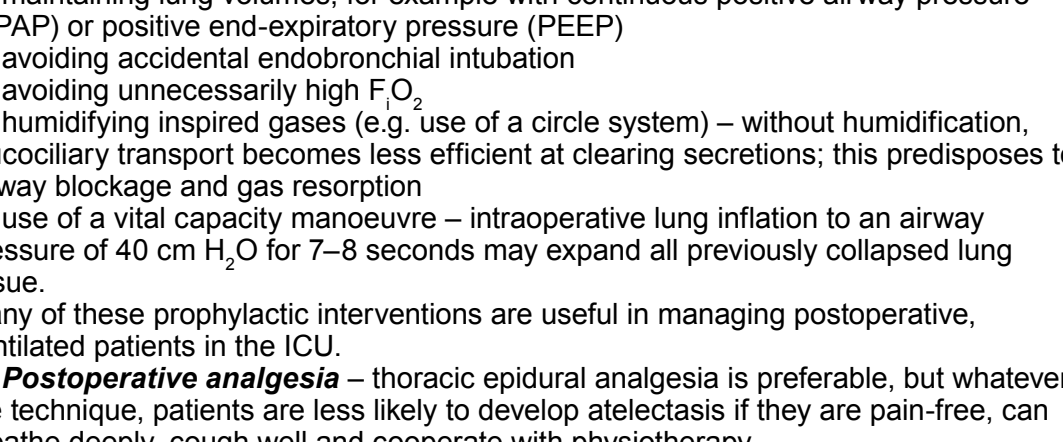
Breathing exercises – sequential diaphragmatic and deep breathing exercises (see page 11), with the addition of a forced expiration technique to help clear secretions, may re-expand a collapsed lung. To motivate patients, incentive spirometry may be used. This provides a visual clue (e.g. keeping ping-pong balls afloat within the device) or actual volume measurement that indicates how deeply the patient is breathing.

Intermittent positive pressure breathing (IPPB) is useful when atelectasis is persistent or the oxygen saturation in arterial blood is low. Following patient triggering, the IPPB device augments patient effort by applying a positive pressure throughout inspiration.

CPAP may reopen collapsed lung tissue.

Tracheal suction – the removal of tenacious sputum requires regular bronchial toilet; when regular orotracheal or nasotracheal suction is poorly tolerated, use of a minitracheostomy assists sputum removal.

Distribution of ventilation in the patient in the lateral decubitus position



Distribution of ventilation **a** when awake and **b** when anaesthetized. Induction of anaesthesia has caused a loss of lung volume in both lungs, with the non-dependent lung moving from a flat, non-compliant portion to a steep, compliant part of the pressure–volume curve. Thus, the anaesthetized patient in a lateral decubitus position has more of the tidal ventilation in the non-dependent lung (where there is the least perfusion) and less of the tidal ventilation in the dependent lung (where there is the most perfusion). V, alveolar volume; P, transpulmonary pressure. Reproduced with permission from Benumof J L, Alfrey D D. Anesthesia for Thoracic Surgery. In: Miller R D, ed. *Anesthesia.* 4th ed. Edinburgh: Churchill Livingstone, 1994: 1663.

2

Ventilated patients

Humidified oxygen therapy should be administered. Occasional instillation of saline into the tracheal tube also moistens secretions.

Positioning – in anaesthetized and ventilated patients, lung volume is reduced, moving the non-dependent lung down the pressure–volume (P–V) curve to the steep, compliant part (Figure 2). Consequently, keeping the atelectatic lung uppermost improves ventilation.

Manual hyperinflation – 'bagging' with a Waters' circuit is often used in intensive care. The generation of high inspiratory pressures overcomes the critical opening pressures of surfactant-deficient alveoli, thereby expanding collapsed lung. Caution is advised because hyperinflation may risk pulmonary barotrauma.

CPAP or PEEP reopen some, but not all, collapsed lung tissue; discontinuation results in the rapid return of atelectasis.

Open-lung concept – this ventilator strategy can be used to minimize the effects of over-distending relatively normal lung, while optimizing recruitment in atelectatic alveoli. A static P–V curve is constructed by inflating the lungs with a series of increasing tidal volumes and measuring the corresponding airway pressures. PEEP is then set at about 2 cm H_2O above the point at which the slope of the P–V curve increases (lower inflection point) and the upper limit of the inspiratory plateau pressure is set below the point at which the slope of the P–V curve begins to flatten (upper inflection point).

Kinetic therapy beds may prevent the development of compression atelectasis by providing mechanical percussion and continual rotation along the patient's longitudinal axis.

Bronchoscopy is useful when obstruction of a large bronchus is responsible for atelectasis.

Prevention of Deep Vein Thrombosis and Pulmonary Embolism

Paul Sadler

Paul Sadler is Consultant in Intensive Care Medicine at Queen Alexandra Hospital, Portsmouth, and Royal Hospital Haslar, Gosport, UK.

Thrombosis within the deep veins of the leg and/or pelvis can be classified into distal and proximal forms:
- distal deep vein thrombi occur in the deep veins of the calf
- proximal thrombi exist when the thrombus extends above the knee to the thigh or pelvis.

Deep vein thrombosis (DVT) carries a high incidence of pulmonary embolism (PE) – mechanical obstruction of a pulmonary artery or arteriole. The incidence of PE is much greater with proximal DVTs, occurring in up to 40% of cases. DVT and PE are collectively termed thomboembolic disease.

Incidence

The true incidence of DVT is not known. However, postoperative DVT is confirmed by venographic evidence in about 33% of patients if no prophylactic anticoagulant measures are taken. The incidence is higher with certain operations (e.g. total hip or knee arthroplasty; 40–70%).

Aetiology

The main risk factors for thromboembolic disease are:
- prolonged or major surgery
- malignancy
- pelvic, hip or leg fracture
- previous thromboembolic disease
- immobility (pre-existing or postoperative)
- age over 40 years
- hypercoagulable state
- obesity
- pregnancy
- oestrogen therapy (increased if ethinyl oestradiol dose > 50 µg/day)
- co-existing illness – heart failure, myocardial infarction, sepsis.

Pathophysiology

Three factors influence thrombus formation:
- abnormalities of blood flow (e.g. reduced lower limb flow occurs during postoperative immobility, dehydration, cardiac failure)
- injury to the vessel intima (e.g. following pelvic or lower limb trauma, local inflammation)
- changes to blood causing hypercoagulability (Figure 1).

Causes of blood hypercoagulability

Inherited
- Antithrombin III deficiency
- Protein S deficiency
- Protein C deficiency
- Mutation in factor V gene (causes resistance to activated protein C found in 60% of cases of idiopathic deep vein thrombosis)

Acquired

Physiological
- Pregnancy
- Obesity

Disease related
- Malignancy
- Congestive heart failure
- Nephrotic syndrome
- Lupus anticoagulant
- Thrombotic thrombocytopenic purpura

Drug induced
- Oestrogen therapy
- *Heparin-induced thrombocytopenia*

Perioperative management

Although it is often forgotten, the use of prophylaxis reduces the incidence of postoperative DVT from 30% to less than 5%. There are several techniques for the prevention of DVTs.

Preoperative – techniques include:
- heel cushions to prevent pressure on the calf veins
- elevation of the legs to promote venous drainage
- pharmacological methods – unfractionated heparin (UFH), low molecular weight heparin (LMWH), warfarin, dextrans, antiplatelet drugs (e.g. aspirin), hirulog (a direct-acting thrombin inhibitor given subcutaneously)
- caval filters.

Intraoperative prevention of DVTs involves the use of extradural and spinal anaesthesia.

Intraoperative and postoperative – techniques include:
- heel cushions to prevent pressure on the calf veins
- elevation of the legs to promote venous drainage
- graduated compression stockings
- intermittent pneumatic sequential compression devices
- electrical stimulation of the leg muscles
- pharmacological methods – UFH, LMWH, warfarin, dextrans, antiplatelet drugs, hirulog
- early postoperative mobilization.

Compression of the lower limbs increases blood flow through the deep veins and decreases stasis. Correctly sized and appropriately worn graduated compression stockings reduce the incidence of DVT by more than 50%. They are available in calf-length and thigh-length sizes. Thigh-length stockings can form constrictive bands if not worn correctly and are more likely to cause complications such as skin necrosis and arterial thrombosis. Importantly, no benefit has been demonstrated over calf-length stockings. Graduated compression stockings should be worn until the patient is fully mobilized.

The sequential inflation of bladders placed around the calf or foot assist in pumping blood through the deep veins. Sequential compression devices are most commonly applied in the operating theatre and removed at the end of a procedure. Calf devices appear to be more effective than foot devices. Prolonged postoperative use of sequential compression devices often fails because of poor patient compliance.

Pharmacological methods: UFH causes a confirmational change in antithrombin III (AT III), making it a rapid inhibitor of clotting co-enzymes IIa, IXa, Xa, XIa and XIIa. UFH inhibits thrombin by linking thrombin and AT III, thereby prolonging the activated partial thromboplastin time (APTT). It provides highly effective prophylaxis at a dose of 5000 IU s.c. 2–3 times a day. It is most effective when started at least 2 hours preoperatively and improved results have been obtained by titrating the dose to keep the APTT at the upper limit of the normal range. The requirement for blood tests makes this second method unpopular. The main side-effects are:
- bleeding
- thrombocytopenia
- osteoporosis
- paradoxical hypercoagulable state
- local bruising.

Thrombocytopenia and osteoporosis appear to be related to the large molecular size (molecular weight 12,000–15,000) of UFH; they are less common if LMWH (molecular weight 4000–6500) is used. LMWH is as effective as UFH in preventing the thromboembolic complications of surgery. It is also just as likely to produce unwanted bleeding, despite its smaller molecular size, making it less able to cross-link AT III and thrombin. However, less frequent injections are required with LMWH and it has fewer side-effects. After surgery, UFH and LMWH should be continued until full mobilization is achieved.

Intravenous low molecular weight dextrans are expensive, require intravenous administration and carry a significant risk of cardiac and anaphylactic complications. They are not as effective as heparin for thromboembolic disease prophylaxis. Hirulog is under investigation and is proving effective.

It is preferable for patient and clinician to avoid the need for injections. Oral heparin has low bioavailability, but the use of an adjunct to improve this is being studied. Warfarin, titrated to keep the international normalized ratio at 2.0, is as effective as subcutaneous UFH or LMWH at moderate-risk doses. Although bleeding problems appear to be no greater, there are concerns over warfarin's reversibility and the need for blood tests to monitor therapy. Aspirin prophylaxis has received new interest but has yet to prove as effective as UFH or LMWH.

Caval filters: in cases of recurrent PE secondary to DVT, a filter can be placed in the inferior vena cava to prevent onward passage of mobile clots. Although these devices reduce the incidence of PE, they may increase the incidence of recurrent DVT.

Anaesthetic management: spinal and epidural anaesthesia have the theoretical advantage of causing vasodilatation and increasing lower limb blood flow and may be associated with a decreased incidence of thromboembolic disease compared with general anaesthesia. It is most important to recognize 'at-risk' patients early and to provide appropriate thromboembolic disease prophylaxis. Perioperative prophylactic regimens vary between hospitals, but a suitable approach is described in Figure 2. Early mobilization can be encouraged by limiting the use of regional neuromuscular blockade (if possible), providing a rapid recovery from anaesthesia, ensuring good analgesia and facilitating the use of modern ambulatory devices if drug infusions are required. The oral contraceptive pill usually has a low oestrogen content and, though a risk factor for thromboembolic disease, a policy of withdrawing it before surgery is no longer justified.

Concerns exist regarding the use of regional anaesthesia in patients already receiving prophylactic anticoagulation, particularly in terms of the risk of epidural haematoma formation. Epidural or spinal techniques should not be performed within 6 hours of the injection of UFH or LMWH. Alternatively, the start of prophylaxis may be delayed until the regional block has been performed, but this may decrease its effectiveness.

Sample regimen for perioperative prophylaxis of thromboembolic disease

Low-risk patients (e.g. age < 40 years, minimal immobility – DVT risk < 2%)
- Early mobilization

Moderate-risk patients (e.g. age > 40 years, general surgery or leg fracture – DVT risk 10–20%)

Preoperative
- Calf-length graduated compression stockings (GCS)
- Enoxaparin, 20 mg o.d., or heparin, 5000 IU s.c. b.d. – if there is a high risk associated with bleeding (e.g. neurosurgery), a postoperative calf sequential compression device (SCD) can replace enoxaparin/heparin

Perioperative
- Calf SCD

Postoperative
- As preoperative until mobilized

High-risk patients (e.g. major hip/knee surgery or previous thromboembolism – DVT risk > 40%)

Preoperative
- Calf-length GCS
- Enoxaparin, 40 mg o.d., or heparin, 5000 IU s.c. t.d.s.

Perioperative
- Calf SCD

Postoperative
- As preoperative until mobilized

Effective prophylaxis: DVT and PE are significant causes of perioperative morbidity and mortality. Prophylaxis using a combination of compression techniques and anticoagulation is effective in reducing their incidence. Prophylaxis should begin preoperatively, compression devices must be applied properly and both continued until the patient is fully mobilized.

The Recovery Room

Andrew Yates

Andrew Yates qualified from St Thomas's Hospital, London, before joining the Royal Navy. As an Anaesthetist, he saw active service in the Falklands and in the Adriatic on HMS Ark Royal and was Principal Medical Officer to Royal Yacht Britannia. He is now a Consultant Anaesthetist in Portsmouth and Clinical Director of Theatres.

As the complexity of anaesthesia and surgery has increased, so has the ability to operate on a wider range of patients. Although the availability of an intensive care unit (ICU) is essential for some operations and a high dependency unit (HDU) is desirable for many others, most hospitals in the UK depend on the facilities available in the recovery room for early postoperative care. In many hospitals without an HDU, recovery facilities are available for the first 24 hours after surgery.

Design

Over the last 30 years, the recovery room in hospitals has evolved from a single holding area outside the theatre suite, to an environment where patients are stabilized and monitored, some for considerable periods of time, before return to the ward. This contribution does not directly address the design of the day case unit, but the same principles apply.

The design of a recovery area should benefit the patients and staff and should take account of the regulations and other factors described below.

Clinical considerations

The recovery room should be designed to suit the individual needs of each theatre suite. In some hospitals, this area may include an HDU or it may lead to an adjoining HDU and ICU. Other recovery rooms segregate children or those undergoing sedation or local anaesthetic procedures. The recovery room must be configured into the general layout of the theatre suite and should maximize the effective use of varying staff skill mixes. Ideally, recovery facilities should be centralized in the theatre suite.

Throughput: the main factor in designing an adequate recovery area is to know the throughput. A number of methods are used to predict the average occupancy of recovery areas. They all depend on a number of variables:

- number of theatres
- case mix
- number of patients per list
- envisaged change in workload over lifespan of theatre suite
- average length of patient recovery.

Patients should enter and exit through different doors. Anaesthetists, surgeons and theatre staff must have access to the recovery room from the theatre suites, but ward staff, porters and parents require access from outside. The increase of methicillin-resistant *Staphylococcus aureus* and other hospital-acquired infections impacts on these arrangements.

Size and shape: the correct size of the recovery room is crucial; if it is too small it will be the theatre bottleneck on which all activity throughout the theatres will depend. This may lead to pressure on staff to discharge patients sooner than they might otherwise. If the recovery room is too large, it will be wasteful of resources. It is recommended that there are a minimum of 1.5 beds per theatre with each bed space requiring a minimum of 9.3 m^2. It is important that the area is unobstructed. All patients should be observed easily with adequate space between each recovery bay and across the area for the passage of beds, radiographic equipment, staff and crash trolleys.

Building regulations and fire safety

From the start of planning, attention must be paid to regulations and guidance notices and the recovery planning team should be fully conversant with them. NHS Estates, an executive agency of the Department of Health, publishes a series of Health Bulletin Notices and other related guides, prepared in consultation with representatives and experts in their fields, which give information on all aspects of hospital design. Fire safety is a vital consideration and the design of the recovery room must allow the swift and safe removal of patients.

Health and safety

The Health and Safety at Work Act (1974) places a duty of care on every employer '… to ensure, so far as is reasonably practicable, the health, safety and welfare at work of all his employees…' (Section 2 (I)). A host of regulations and directives have been passed from the original Act, and all theatre staff should be aware of those applicable to their workplace. Likewise, the guidance of the 1989 Control of Substances Harmful to Health regulations must be adhered to and the Health and Safety Commission's Advisory Committee on Toxic Substances (ACTS) recommended in 1996 occupational exposure standards (OESs) for anaesthetic agents. Thought must be given, from an early stage in recovery room design, to all aspects of these Acts.

Environment

In the past, scant attention was paid to the working conditions of recovery staff even though they may be required to work for long hours. Regulations have improved the environment, but many existing recovery rooms fall below standard. When designing a recovery room, consideration must be given to the following factors:

- light (natural, artificial, direct, indirect)
- decor (floor, walls and ceiling)
- ventilation and climate (temperature, humidity, pollutant elimination and scavenging)
- preventing infection
- noise levels
- radiation screening
- communication.

Ideally, access to natural light improves the working environment, but the design of centralized recovery rooms often makes this impossible. It is important to have effective lighting for patient observation and for staff. The decor should be designed to make the surroundings pleasant. The creation of the correct environment is vital to the well-being of staff and patients. Department of Health requirements recommend 15 air changes per hour without recirculation. Particular attention must also be paid to the room temperature, which should be maintained at 19−22°C. The area should be free of draughts, the humidity should be maintained at 38–45%. There must be effective scavenging of exhaled anaesthetic gases. Noise levels should be minimized at all times and doors should be self-closing. Radiographs are often performed in the recovery room, therefore screening should be available. The recovery room should be considered as a clean site to minimize nosocomial infection.

Good communication systems are important. They should include intercom facilities to each theatre and rest area, emergency alarms and telephones. A rest area for staff should not be designed into the recovery room because it is essential that staff are able to leave the workplace and relax, if only for brief periods.

Equipment

Although recovery rooms vary, the basic items of equipment are universal.

General facilities

Clinical equipment

- There should be a fully equipped anaesthetic machine and ventilator; more than one in larger units.
- A full range of anaesthetic equipment and drugs should be to hand at all times, to deal with intubation, cardiac arrest, tracheotomy, anaphylactic reaction and malignant hyperpyrexia.
- There should be a defibrillator, ideally in the recovery room, or if not, close at hand.

Portable suction, oxygen supplies and battery-powered lighting should be available in case of electrical failure or if the room has to be evacuated.

- Patient-warming devices should be available.
- Large stocks of intravenous fluids should be present.

Cleanliness and tidiness: the following facilities are required to maintain cleanliness and tidiness in the recovery room:

- storage areas for linen, unused equipment and monitoring
- cupboards for drugs and separate secure unit for controlled drugs
- fridge-freezer for drugs and ice
- hand-washing facilities at suitable positions within the area
- separate clean and dirty areas, with enclosed sluice
- space for a desk with IT support and monitoring console
- individual suitable chair at each patient bay
- storage for bed oxygen cylinders
- portable screens.

Individual bay

The following items of equipment are essential in individual bays:

- bed or trolley that can tilt both ways, with protective sides available
- piped dedicated split oxygen supply and flowmeters with tubing to either an appropriate face mask, self-inflating resuscitation bag with anaesthetic mask or T-piece for laryngeal mask airway
- selection of oral and nasal airways
- piped vacuum suction
- sufficient electrical points (six 13 A sockets per bay)
- lighting (dependent on general levels in room)
- emergency alarm
- monitoring sufficient for individual requirement.

Monitoring differs depending on the patient, but, in the UK, it should follow the guidelines of the Association of Anaesthetists of Great Britain and Ireland. Monitors can be linked to a central console at the nursing station, but future developments may lead to 'cordless' continual monitoring of the patient from anaesthetic room to ward, for 24 hours or more after surgery.

Staffing

The recovery period is potentially dangerous, and it is estimated that 20% of patients develop one or more complications during this time; upper airway obstruction is the most common. Therefore, it is imperative that the recovery room has sufficient staff of the appropriate skill mix for the operative workload in the theatres. Each patient should be individually cared for until fully conscious, stable and maintaining their own airway.

With the decline in the number of nurses in theatre, there has been a steady change in the pattern of staffing in the recovery room. Currently, there is a mix of nurses and operating department assistants/practitioners. The recovery room is the only area in the theatre complex where basic and advanced nursing skills are needed side by side − and this responsible and rewarding role should be emphasized to the student nurse. All recovery staff must undergo structured training under close supervision before they are allowed to recover patients (ENB 182 and 183 or NVQ Level 3 in operating theatre practice). There is no other area in a hospital where non-medical staff routinely look after all aspects of patients emerging from the effects of all forms of anaesthesia after every type of surgery.

Notwithstanding the staffing constraints of hospitals in the UK, ward nurses would benefit from exposure to the recovery environment and recovery staff should have experience of the HDU and ICU. The trainee anaesthetist would also benefit from working in the recovery room and learning about the routine management of the postoperative patient. In some hospitals, a designated anaesthetist is available immediately to assist and advise the recovery staff. It is generally impractical to have a paediatric recovery nurse available at all times, but the team should be able to liaise with a member of the paediatric ward staff. All recovery staff must keep up to date with adult and paediatric resuscitation techniques.

Instructions to recovery staff

Whether a patient has been anaesthetized for 5 minutes or 5 hours, it is important that the anaesthetist hands over their care to the recovery staff in a correct and informed manner, giving all relevant information (Figure 1).

The anaesthetist should also provide instructions about the patient's recovery, with reference to analgesia, anti-emetics, fluid requirements, supplementary oxygen and rewarming. The anaesthetic record should be available together with the operation notes. The theatre practitioner who scrubbed for the surgeon should give a brief verbal résumé of the procedure. The anaesthetist should always remain until the recovery staff are confident the patient is stable. Patients are the responsibility of the anaesthetist until they are discharged to the ward.

Patient information required by recovery staff

- Name, age, American Society of Anesthesiologists (ASA) grade
- Operation and surgeon
- Type of anaesthetic (local or general)
- Any pre-existing condition of relevance (e.g. hypertension, diabetes, allergies)
- Method of airway maintenance during surgery
- Spontaneous or intermittent positive-pressure ventilation
- Opiate loading and other methods of pain control
- Whether reversal agents used
- If regional technique, method employed
- General condition during procedure (especially pulse and blood pressure)
- Fluid balance and blood loss during surgery
- Positioning of patient during surgery
- Any untoward events that occurred during surgery
- Dentition (crowns, bridges, loose teeth)

Discharge to the ward

Most patients are discharged to the general ward for continuing postoperative care. Each patient should fulfil the same criteria before discharge from the recovery room:

- patient conscious with a patent airway
- cardiovascular parameters stable
- respiratory pattern and depth adequate, with maintained oxygen saturation
- no excess bleeding from surgery
- patient comfortable (i.e. has adequate pain relief)
- patient adequately rewarmed
- urine output maintained (if monitored)
- prescription and epidural/patient-controlled analgesia charts written and legible
- fluid regimen and instructions to ward clearly stated
- surgical notes and instructions documented.

Adverse Drug Reactions

Norman Calvey

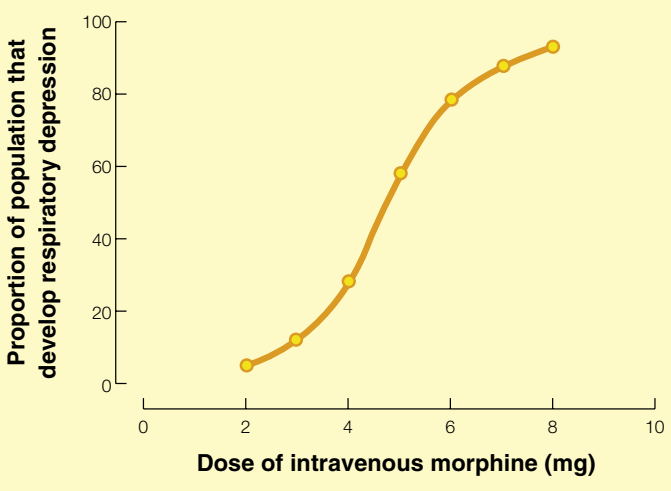
Norman Calvey is Honorary Senior Research Fellow in the University Department of Anaesthesia, Liverpool, UK. He qualified in science and medicine from Liverpool University and has worked in Departments of Pharmacology and Anaesthesia. His research interests include pharmacokinetics and drug isomerism.

Adverse reactions to drugs are relatively common and often cause iatrogenic disease. They present in different ways and vary in severity from mild skin rashes to the production of gross malignant and teratogenic changes. In the UK, adverse drug reactions are responsible for 3–5% of all hospital admissions, and occasionally cause death. In clinical practice, they are usually divided into Type A and Type B reactions.

Type A reactions are relatively common and are often related to the main pharmacological effects of drugs. They are usually well known and predictable and are sometimes referred to as 'mechanism-based reactions' or 'side-effects'. They are often dose related, and are usually more common when the drug dose is high. Many of the toxic effects of drugs on target organs are classified as Type A reactions (e.g. hepatic cirrhosis induced by paracetamol or isoniazid, or nephrotoxicity caused by angiotensin-converting-enzyme inhibitors). Most have a prevalence of more than 1/1000 (0.1%), and they are readily identified in preclinical and clinical trials. Patients vary in their susceptibility to Type A reactions, and they may be produced by a range of doses in different individuals. They are particularly likely to occur in the elderly or in patients with renal or hepatic impairment.

Many of the unwanted effects of morphine (e.g. sedation, respiratory depression, emesis, constipation, hypothermia) are typical Type A reactions; in some instances, individual variation in patient response corresponds to a characteristic S-shaped (sigmoid) curve (Figure 1). Consequently, they can be expected to occur in all patients who are given the drug at a sufficiently high dose. Similarly, the anticholinergic (antimuscarinic) effects produced by many agents (e.g. some H_1-histamine antagonists, β-adrenoceptor antagonists, antiarrhythmic drugs, anticonvulsants, phenothiazines) are classified as Type A reactions.

Inter-individual variation in response to morphine



1

Type B reactions are usually unrelated to the main pharmacological effects of the drug and are often dose independent, relatively uncommon and unpredictable. In general, their prevalence is less than 1/1000 (0.1%), and they may not be identified in preclinical or clinical trials. Although they are less common than Type A reactions, they are a significant cause of serious adverse responses to drugs. In some patients their aetiology is obscure, but in others they are related to genetic predisposition or drug hypersensitivity.

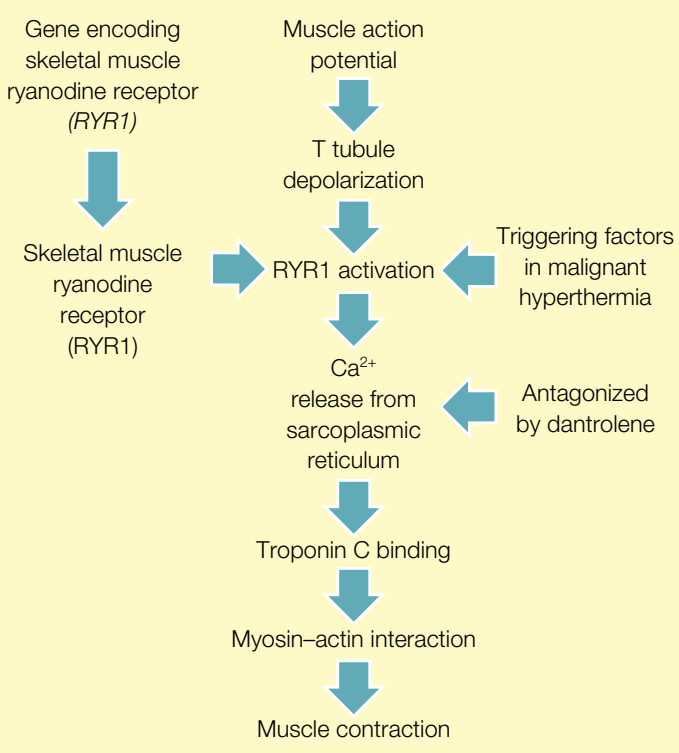
Reactions resulting from genetic predisposition (idiosyncratic reactions)

In anaesthesia, the three important drug reactions resulting from genetic predisposition are malignant hyperthermia, hepatic porphyria and prolonged apnoea induced by suxamethonium.

Malignant hyperthermia

Malignant hyperthermia (malignant hyperpyrexia) is an abnormality of skeletal muscle generally inherited by autosomal dominant transmission (see also page 222). In about 50% of patients, the condition is linked to an abnormality in the ryanodine gene (*RYR1*) on chromosome 19q (the long arm of chromosome 19). *RYR1* normally encodes the ryanodine receptor in the sarcoplasmic reticulum, which is activated in response to depolarization of the transverse tubules (T tubules) in the triads of skeletal muscle. Receptor activation results in Ca^{2+} release from the sarcoplasmic reticulum and initiates myosin–actin interaction and muscle contraction (Figure 2). In malignant hyperthermia, exposure to 'triggering agents' (i.e. suxamethonium or fluorinated anaesthetics) results in excessive Ca^{2+} release from the sarcoplasmic reticulum, producing muscle rigidity, metabolic and respiratory acidosis, tachycardia, hyperkalaemia and pyrexia. The mortality of malignant hyperthermia reactions used to be high (about 65%) but recently it has been reduced to 5–10%, mainly owing to greater aware-ness of the condition, the rapid instigation of methods to ensure cooling, and the use of dantrolene sodium (which uncouples T tubule depolarization from Ca^{2+} release).

Excitation–contraction coupling in skeletal muscle



2

Susceptibility to malignant hyperthermia is confirmed by muscle biopsy and exposure to halothane and caffeine in *in vitro* conditions; in these circumstances there is a greater increase in tension than in normal muscle. Similar effects are produced by ryanodine and chlorocresol. If the diagnosis is confirmed, genetic counselling of patients and their families is essential.

Hepatic porphyria

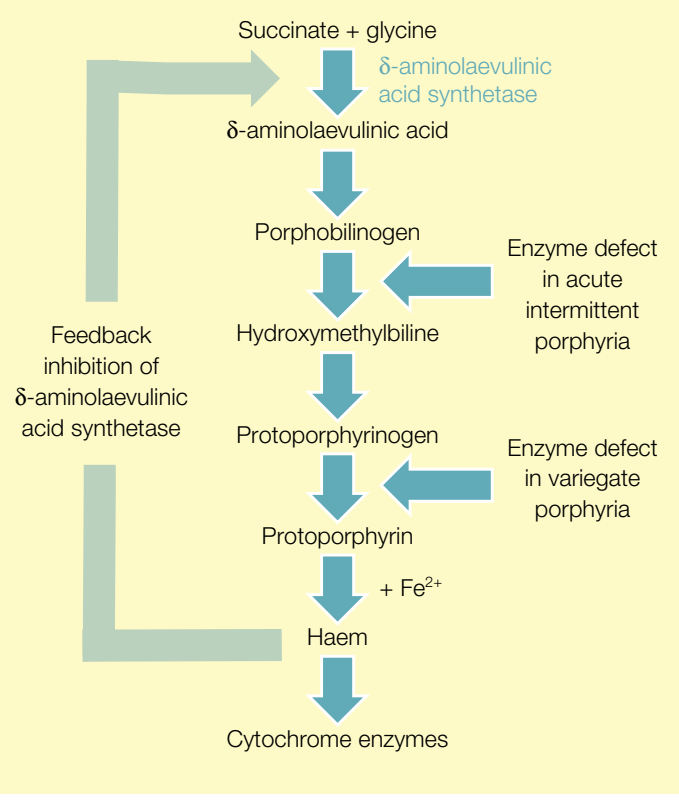
In certain hepatic porphyrias (particularly acute intermittent porphyria and variegate porphyria), attacks of the disease can be precipitated or exacerbated by certain drugs (particularly drugs that increase the synthesis of cytochrome P450).

In humans, haem has an essential role as the prosthetic group of various haemoproteins (e.g. haemoglobin, myoglobin, cytochrome oxidase, cytochrome P450). The synthesis of haem depends on the enzyme δ-aminolaevulinic acid synthetase (ALA synthetase) which catalyses the synthesis of δ-aminolaevulinic acid from succinate and glycine. Two molecules of δ-aminolaevulinic acid subsequently combine to form porphobilinogen, which is sequentially converted to hydroxymethylbiline, protoporphyrinogen and protoporphyrin. Finally, combination with divalent iron results in the formation of haem (Figure 3). In normal conditions, free haem exerts close feedback inhibitory control on the activity of ALA-synthetase; this is the main physiological factor controlling haem synthesis.

In the acute porphyrias (notably acute intermittent porphyria and variegate porphyria), there is a deficiency or reduced activity of one or more enzymes in this pathway (Figure 3); consequently, haem synthesis is decreased, causing activation of ALA-synthetase, and the accumulation of precursor porphyrins in tissues. Acute porphyrias are usually autosomal dominant conditions with a variable degree of penetrance and enzyme activity is typically about 50% of normal. Consequently, many patients remain asymptomatic for prolonged periods.

Exacerbations of acute intermittent porphyria are most commonly associated with neuromuscular weakness, neurological lesions, neuropsychiatric disturbances and abdominal pain; similar phenomena (as well as cutaneous manifestations) usually occur in variegate porphyria. Although attacks can be precipitated by physiological factors (e.g. menstruation, pregnancy), drugs that affect or induce cytochrome P450 (e.g. all barbiturates, phenytoin, carbamazepine, rifampicin) are more commonly involved, and should be avoided in patients with acute porphyria. These enzyme-inducing agents increase the incorporation of haem into cytochrome P450, decrease intracellular haem levels, and thus activate ('derepress') ALA synthetase (Figure 3). Consequently, porphyrin synthesis is increased and the disease may be exacerbated. Haem derivatives (e.g. haematin and haem arginate) suppress the enhanced activity of ALA synthetase and have an important role in the treatment of acute attacks of porphyria.

Hepatic synthesis of haem and cytochrome enzymes



3

Prolonged apnoea induced by suxamethonium

Suxamethonium is an ester of choline and succinic acid, and conventional doses of the drug (1 mg/kg) have a duration of action of 3–5 minutes, owing to their rapid hydrolysis by plasma cholinesterase. Inheritance of genetic variants of cholinesterase may reduce the rate of ester hydrolysis, increase the duration of action and cause prolonged apnoea. Delayed hydrolysis may also predispose to tachyphylaxis and dual block.

Genetic variants in plasma cholinesterase are determined by four allelomorphic genes that have been identified at a single locus on chromosome 3. These genes encode the normal or usual enzyme (E_1^u), the atypical enzyme (E_1^a), the fluoride-resistant enzyme (E_1^f) and the absent or silent enzyme (E_1^s). The atypical enzyme is the most common genetic variant. In homozygous individuals, the atypical enzyme can be distinguished from the normal (usual) enzyme by its resistance to inhibition by the local anaesthetic cinchocaine (dibucaine). The 'dibucaine number' is defined as the enzyme inhibition (%) produced by dibucaine (10^{-5} mol/litre), using benzoylcholine as the substrate. Normal homozygotes (E_1^u E_1^u) have dibucaine numbers of 80; hetero-zygotes for the atypical enzyme (E_1^u E_1^a) have dibucaine numbers of 60, while homozygotes for the atypical enzyme (E_1^a E_1^a) have dibucaine numbers of 20 (Figure 4). Since four allelomorphic genes are present, ten genotypes have been identified, three of which show a greatly prolonged response to a conventional dose of suxamethonium. Their prevalence in Caucasian populations is just over 1/1000 (0.1%).

Recently, at least six additional allelomorphic genes have been identified by DNA-cloning techniques. In addition, a second distinct chromosomal locus has been identified, which is associated with two further genetic variants ($E_{Cynthiana}$ and C_5); these are thought to be responsible for increased cholinesterase activity.

In theory, the duration of action of other anaesthetic drugs that are esters (e.g. atracurium, mivacurium, procaine, esmolol, remifentanil) may be prolonged by genetic variants in plasma cholinesterase. Although this may occur with mivacurium, particularly when homozygotes (E_1^a E_1^a) or heterozygotes (E_1^u E_1^a) for the atypical enzyme are involved, it does not appear to be of clinical significance with other drugs.

Genetic variants in plasma cholinesterase that commonly prolong the effects of suxamethonium

	Genotype	Approximate prevalence	Dibucaine number
Normal cholinesterase	$E_1^u E_1^u$	950/1000	80
Significant genetic variants	$E_1^a E_1^a$	1/1000	20
	$E_1^a E_1^s$	1/10,000	20
	$E_1^s E_1^s$	1/100,000	None

Other genetic variants are of minimal clinical significance

Other drug reactions
Other drug reactions related to genetic predisposition include:
- haemolytic anaemia (antimalarial drugs)
- resistance to oral anticoagulants (warfarin)
- toxic effects of drugs (isoniazid, hydralazine, phenelzine)
- hypotensive responses (debrisoquine)
- increased intraocular pressure (corticosteroids)
- increased alcohol-induced facial flushing (chlorpropamide)

Reactions resulting from drug hypersensitivity (allergic reactions)

Hypersensitivity or allergic responses to drugs are abnormal reactions to drugs that are dependent on immunological factors; they are usually divided into four main types, depending on the mechanism involved.

Type I hypersensitivity (immediate type hypersensitivity)
In Type I hypersensitivity, drugs or their metabolites combine covalently with plasma or tissue proteins. The resultant antigenic complex induces the formation of IgE antibodies, which become attached to mast cells in various tissues of the body (e.g. skin, bronchial and intestinal mucosa, blood vessels, basophil leucocytes). On subsequent exposure to the antigen, adjacent IgE molecules on the mast cell membrane are cross-linked, resulting in Ca^{2+} entry, mast cell degranulation, and the release of various pharmacological mediators (e.g. histamine, heparin, 5-HT, leukotrienes, platelet-activating factor).

Type I hypersensitivity responses are most commonly seen in atopic patients given penicillins or cephalosporins; these groups of antibiotics are structurally related, and may show cross-sensitivity reactions. In the case of penicillins, degradation products (e.g. penicillinoyl derivatives) are believed to be the main antigenic determinants. Hypersensitivity responses may also be produced by insect stings and the oral ingestion of certain foods (e.g. eggs, fish, cows' milk, peanuts) or the medical use of foreign proteins (e.g. streptokinase, asparaginase, heparin, vaccines, blood products). They are occasionally implicated in adverse reactions to anaesthetic agents, including thiopental (thiopentone), suxamethonium and non-depolarizing relaxants. Clinical manifestations of Type I hypersensitivity include anaphylactic shock, hypotension, bronchospasm, laryngeal oedema and urticaria.

Anaphylactic shock is rare; it is an acute medical emergency. Circulatory support, oxygen administration and intramuscular or intravenous adrenaline (epinephrine) are essential, and may be life-saving. Other drugs (e.g. parenteral corticosteroids, H_1-histamine antagonists) may also be used, but are of less immediate value. Anaphylactic shock is usually considered to result from the generalized release of all the pharmacological mediators referred to above.

Bronchospasm is a serious complication of Type I hypersensitivity, and is mainly a result of the local formation and release of leukotrienes C_4, D_4 and E_4 ('cysteinyl-leukotrienes') from mast cells in the bronchial mucosa. Tracheal intubation and positive-pressure ventilation with 100% oxygen may be required, and in severe cases adrenaline (epinephrine) is necessary. In other instances, administration of β_2-agonists (e.g. intravenous or nebulized salbutamol or terbutaline) or aminophylline should be considered. In bronchospasm, β_2-agonists and aminophylline can be used concurrently because they act on different receptor systems.

Laryngeal oedema (angio-oedema) may present as glottic or subglottic oedema, and require urgent intubation or tracheostomy. Adrenaline (epinephrine) and oxygen therapy are often required. Intravenous H_1-receptor antagonists (e.g. chlorphenamine) and corticosteroids are sometimes useful, though their onset of action may be delayed.

Anaphylactoid reactions – histamine and other factors may be directly released from mast cells and basophils by non-immunological mechanisms. These phenomena are often referred to as anaphylactoid reactions, because they may be difficult to distinguish clinically from the anaphylactic responses associated with Type I hypersensitivity. Many therapeutic agents can produce local or generalized histamine release from mast cells, including:
- basic drugs (morphine, pethidine, tubocurarine, atracurium, suxamethonium, trimetaphan, vancomycin)
- solubilizing agents (polyethoxylated castor oil)
- radiocontrast media
- colloidal plasma expanders (modified gelatin and dextrans)
- polypeptides (polymyxin B, bradykinin, substance P, anaphylatoxins).

Anaphylactoid reactions are not uncommon in anaesthetic practice (particularly when high concentrations of drugs are rapidly injected into small blood vessels). They may occur more often when several different drugs are administered through small infusion needles; in these conditions, physicochemical combination may result in the production of colloid aggregates, resulting in histamine release. Anaphylactoid reactions present clinically as localized vasodilatation, hypotension or skin reactions; occasionally circulatory collapse or bronchospasm occur.

It may be difficult to detect patients who are susceptible to anaphylactoid responses, though individuals with a history of atopy (asthma, hay fever or eczema), or with a previous or family history of adverse reactions are particularly vulnerable. Some drugs appear to be relatively safe (e.g. etomidate, vecuronium, fentanyl, local anaesthetics). Preoperative prophylaxis with H_1- and H_2-receptor antagonists may confer some degree of protection in susceptible patients.

At least two intravenous anaesthetics (propanidid and althesin) have been withdrawn because of their association with severe anaphylactoid reactions.

Type II hypersensitivity (cytolytic reactions)
In Type II hypersensitivity, drugs combine with macromolecules or proteins in the cell membrane, forming an antigenic complex which induces the synthesis of IgG or IgM antibodies. These immunoglobulins then cross-react with the antigenic complex in the presence of complement, causing cell lysis or agglutination; alternatively, target cells are attacked by killer lymphocytes.

Type II hypersensitivity reactions usually involve the combination of drugs with proteins in erythrocyte, granulocyte or platelet membranes, resulting in haemolytic anaemia, leucopenia, agranulocytosis or thrombocytopenia.

Haemolytic anaemia is occasionally induced by methyldopa. Antibodies directed against rhesus antigens occur in 10–15% of patients, though clinically overt anaemia is less common.

Leucopenia is sometimes produced by phenothiazines, phenyl-butazone, carbimazole or clozapine. Although this complication is rare, antileucocyte antibodies or leucocyte lysis can often be detected in affected individuals. The condition may progress to agranulocytosis; its onset is usually delayed (3–12 weeks) but may occur with dramatic rapidity in susceptible patients.

Thrombocytopenia may be induced by heparin or thiazide diuretics; in some instances this is due to Type II hypersensitivity, and antiplatelet antibodies can be demonstrated.

Pancytopenia or aplastic anaemia is occasionally induced by drugs, though if it is caused by drug hypersensitivity is unclear.

Halothane hepatitis is also related to a Type II hypersensitivity reaction. One of the oxidative metabolites of halothane (trifluoroacetyl chloride) is thought to bind covalently with proteins in the hepatic cell membrane. In susceptible patients, antibodies to this complex are synthesized and cross-react with the antigenic protein adduct, causing cellular lysis and acute hepatic necrosis. In many patients with halothane hepatitis, the presence of cross-reacting antibodies can be demonstrated.

Type III hypersensitivity (immune-complex-mediated responses)
Type III reactions do not require previous exposure to drugs or toxins. They are usually caused by the formation of precipitin complexes (and complement fixation) by the reaction of circulating antibodies (IgG) with soluble antigens (e.g. bacterial toxins). Normally, precipitins are removed by the reticulo-endothelial system, but when excess antigen is present, immune complexes are deposited in the vascular endothelium. Type III hypersensitivity reactions are responsible for serum sickness, a systemic response to certain drugs (e.g. sulphonamides, penicillins, certain anticonvulsants) which usually occurs 7–14 days after exposure. Type III hypersensitivity may also be responsible for pathological changes in acute glomerulonephritis, polyarteritis nodosa and rheumatoid arthritis.

Type IV hypersensitivity (delayed, cell-mediated responses)
In delayed hypersensitivity, antibody formation is not involved, and the reaction results solely from the combination of antigen with T cell (killer) lymphocytes. The antigen or hapten is introduced by contact or injection and combines covalently with receptors on the lymphocyte membrane. This results in lymphocyte mitosis and the local release of lymphokines (e.g. lymph node permeability factor) that affect vascular permeability. A local inflammatory reaction usually occurs within 24–48 hours, resulting in erythema, induration, blistering and exfoliation, as a result of the accumulation of macrophages and lymphocytes at the site of injection.

Delayed hypersensitivity is responsible for the positive response to the Mantoux reaction and occurs in most forms of contact dermatitis, whether produced by metals or drugs. It is also a factor in many drug rashes, erythema multiforme (the Stevens–Johnson syndrome), and in the morbilliform rashes that are sometimes induced by ampicillin and amoxicillin (amoxycillin) in patients with glandular fever or chronic lymphatic leukaemia.

Adverse reactions to drugs during fetal life

Drugs administered during pregnancy may cross the placental barrier and adversely affect the fetus. The placenta consists of a vascular syncytial membrane, with the functional properties of a typical lipid barrier. Lipid-soluble, low molecular weight drugs are readily transferred across the placental membrane and their rate of removal from maternal blood is predominantly affected by:
- placental blood flow
- diffusional area
- concentration gradient.

In practice, all lipid-soluble drugs that cross the blood–brain barrier also cross the placenta and their elimination by fetal tissues may be prolonged. In contrast, polar (ionized) or large molecular weight compounds do not readily cross the placenta.

Inhalational anaesthetics, intravenous barbiturates and most opioid analgesics can diffuse from maternal plasma to the fetus, and when used in labour may produce respiratory depression in the newborn. Similar effects may be produced by some sedative and hypnotic drugs. Lipid-soluble β-adrenoceptor antagonists (e.g. propranolol, oxprenolol, metoprolol) can cross the placenta and may cause fetal bradycardia. In addition, fetal hypoglycaemia may be induced by insulin, oral hypoglycaemic agents or some β-adrenoceptor antagonists. When diazepam is used in late pregnancy (e.g. in the management of pre-eclampsia and eclampsia), it readily crosses the placenta, but is only slowly metabolized by the fetus. Its active metabolites (i.e. desmethyldiazepam, oxazepam) accumulate in fetal tissues, and can cause neonatal hypotonia and hypothermia.

Commonly used drugs with teratogenic effects

Drug	Effect on fetus
Methotrexate	Hydrocephalus, neural tube defects
Tretinoin	Hydrocephalus
Phenytoin	Cleft lip/palate, cardiac defects
Sodium valproate	Neural tube defects
Oestrogens	Vaginal adenosis, testicular atrophy
Aminoglycosides	Cochlear and vestibular damage
Tetracyclines	Dental pigmentation, enamel hypoplasia
Carbimazole	Goitre, hypothyroidism
Propylthiouracil	Goitre, hypothyroidism
Warfarin	Nasal hypoplasia, epiphysial calcification

More serious effects are produced by drugs taken during pregnancy that produce fetal damage or malformation (teratogenic changes). In early pregnancy (0–18 days) drugs that affect cell division (e.g. cytotoxic agents, folate antagonists) may affect formation of the blastocyst and cause fetal death. Nevertheless, fetal abnormalities are more commonly produced by drugs that are administered during organogenesis (2–8 weeks).

These drugs include methotrexate, tretinoin, phenytoin, sodium valproate, oestrogens, progestogens, aminoglycoside antibiotics, tetracyclines, antithyroid drugs and warfarin (Figure 5). In some instances, the effects of drugs may be delayed for many years. When stilboestrol was used in late pregnancy, alteration in the maternal hormonal environment produced vaginal dysplasia and malignancy in female offspring after a latent period of 10–20 years. ◆

Anticoagulants and the Management of Coagulopathy

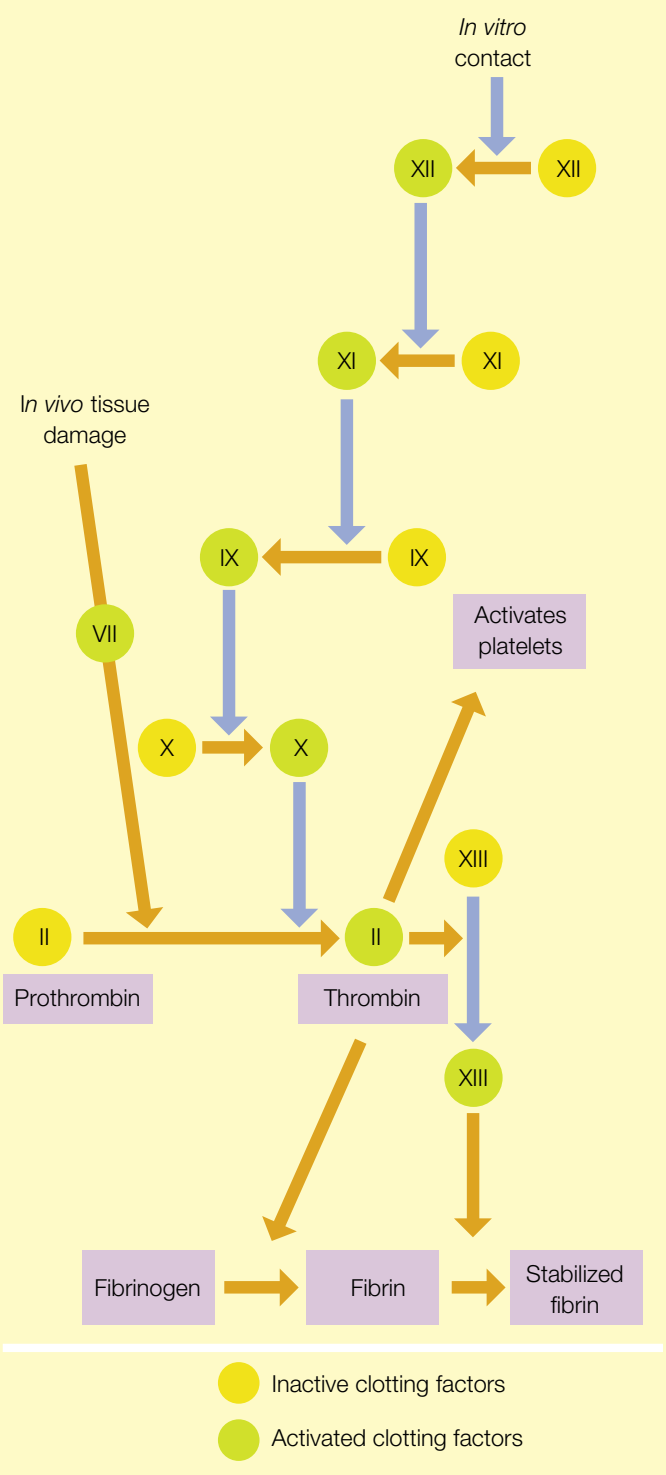
Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

The prevention of blood loss from a damaged blood vessel is an essential feature of life. Injury to the skin and underlying structures leads to vasoconstriction, adhesion and activation of platelets to form a plug, or thrombus, that stops the bleeding, and fibrin formation, which reinforces the plug. A white thrombus forms initially in high-pressure arteries when platelets adhere to the damaged endothelium. The growing thrombus reduces arterial flow and the local stasis causes fibrin to be deposited, trapping erythrocytes so that a red thrombus is formed around the initial white thrombus. This may cause local ischaemia by blocking the artery. In low-pressure veins, red thrombi can develop without a central white thrombus and they often have a long tail of fibrin and trapped red cells, which can break free and form an embolus remote from the initial area of damage.

The blood coagulation cascade is shown in Figure 1. Modification of this cascade by drugs is clinically useful when there is a disorder of coagulation (coagulopathy).

Blood coagulation cascade



1

Role of vitamin K

Vitamin K is a cofactor for the action of carboxylase enzymes that are important in the production of coagulation or clotting factors II, VII, IX and X. In addition, there are several other vitamin K-dependent proteins including osteocalcin in bone. Vitamin K is a fat-soluble vitamin derived from two sources. Vitamin K_1 (phytomenadione) occurs in plants. Bacteria in the gut synthesize vitamin K_2 (menaquinone), which is a series of compounds with side chains of different length. Both vitamins require bile salts for absorption, and deficiencies can arise due to obstructive jaundice when bile secretions are inadequate or absent. Such malabsorption syndromes may be treated with menadiol sodium phosphate, a water-soluble preparation. However, this is ineffective for haemorrhagic disease of the newborn or relative overdoses of coumarin-like anticoagulant drugs (see later) in which phytomenadione is the treatment of choice.

Anticoagulants affecting coagulation proteins

Warfarin and the coumarin anticoagulants

A haemorrhagic disease of cattle was found to be caused by a deficiency in plasma prothrombin caused by bishydroxycoumarin, a toxin found in spoiled sweet clover silage. This was synthesized as dicoumarol and subsequently its derivatives, particularly warfarin, have been widely used commercially as rodenticides and clinically as antithrombotic agents in humans. Warfarin is the most commonly used drug in the group and others, such as acenocoumarol and phenindione, are used only in patients who show idiosyncratic adverse reactions to warfarin. Vitamins K_1 and K_2 are activated in the body by reduction of the epoxide, generated by the carboxylation of prothrombin, to the hydroquinone form. This step is sensitive to the coumarins, which act effectively as vitamin K antagonists. The synthesis of all the vitamin K-dependent clotting factors is partially inhibited so the onset of the anticoagulant effect of coumarins is dependent on the degradation rate of the clotting factors in the plasma. The onset of action usually takes about 12 hours and maximum effects occur several days after the commencement of treatment. This long delay poses several problems in achieving a balance between giving enough to prevent excessive coagulation and giving too much, resulting in unwanted haemorrhage. Measuring the prothrombin time monitors treatment. Warfarin crosses the placenta readily. It is teratogenic in early pregnancy and may cause intracranial haemorrhage in the neonate during birth. It is thus avoided during pregnancy. Warfarin is also excreted in breast milk. This could pose a problem for suckling infants because they are inherently deficient in vitamin K owing to their lack of gut flora. However, phytomenadione treatment of the neonate is now routine and treatment of the mother with warfarin is not contraindicated. There are many drug interactions with coumarin anticoagulants of which the most important appears to be the risk of haemorrhage with the concurrent use of antibiotics such as co-trimoxazole and co-amoxiclav.

Heparin

Heparin is present in mast cells and is extracted from animal tissue such as beef lung or porcine intestinal mucosa. It is a family of sulphated glycosaminoglycans with a range of molecular weights and, because its constitution is variable, it is bioassayed against an international standard and is measured in units of activity rather than mass. Heparin is a rapidly acting anti-coagulant given intravenously or subcutaneously, with a short duration of action. It may be referred to as standard or unfractionated heparin to distinguish it from the low-molecular-weight heparins (e.g. dalteparin sodium, enoxaparin) which have a longer duration of action and are administered subcutaneously. Heparin is used in the treatment of deep vein thrombosis and pulmonary embolism and low doses may be used in anaesthesia to prevent the development of these two conditions in high-risk patients undergoing general surgery. The low-molecular-weight heparins are being increasingly used for this purpose. Heparin is used to maintain the extracorporeal circuits in cardiopulmonary bypass surgery and haemodialysis.

Heparin is an effective anticoagulant *in vivo* and *in vitro*. It activates a protease inhibitor, antithrombin III, which inhibits many of the active forms of the coagulation factors (Figure 1). Thrombin is particularly sensitive to standard heparin, which provides a catalytic template to which antithrombin III and thrombin bind. The low-molecular-weight heparins are not long enough to bind to both antithrombin and thrombin and have their main anticoagulant action via inhibition of activated factor X (Figure 1). They have minimal effects on clotting *in vitro*.

Heparin exhibits saturation kinetics with the apparent half-life increasing with dose. In contrast, the low-molecular-weight heparins have longer half-lives than standard heparin and because they follow first-order kinetics the half-life is not dependent on dose. This simplifies dose regimens.

The main unwanted effect of heparin is haemorrhage, which can be controlled by stopping drug administration or, if more active treatment is required, by administering the antagonist, protamine sulphate. It is a strongly basic protein that forms an inactive complex with the acidic heparin molecule. It is important that patients are not overdosed with this heparin antagonist because it can prolong bleeding time. Like most strong bases, protamine can release histamine and rapid intravenous injections can result in hypotension. It also activates the immune system and IgG- and IgE-mediated allergic responses have been described, particularly in patients with a history of fish allergy (protamine is derived from fish) or neutral protamine Hagedorn (NPH) insulin-dependent diabetes. Catastrophic pulmonary vasoconstriction is a rare, but often fatal, consequence of the use of protamine to neutralize heparin. A recent paper suggests that inhaled nitric oxide, a potent pulmonary vasodilator, is an effective treatment for this condition. Thrombocytopenia can occur with standard heparin, but is unlikely to be a serious problem in anaesthetic use unless therapy is prolonged.

Danaparoid sodium

Danaparoid sodium contains heparan sulphate (84%), dematan sulphate (12%) and chondroitin sulphate (4%). Its main effect is to inhibit factors Xa and IIa at a ratio greater than heparin with minimal effects on platelet function. In the USA, it is approved for the prophylaxis of deep vein thrombosis in patients undergoing elective hip replacement. It exhibits low cross reactivity with heparin antibodies and may be the treatment of choice for heparin-induced thrombocytopenia. It has recently been approved in the UK. Dematan sulphate is a glycosaminoglycan related to heparin and inhibits thrombin selectively. Its potential use as a sole agent in place of heparin is under investigation.

Antiplatelet drugs

Antiplatelet drugs are particularly effective in reducing thrombus formation in the arterial circulation where the anticoagulants mentioned above have little effect. Aspirin is the most important drug in this group because it alters the balance between thromboxane A_2, which promotes aggregation, and prostacyclin, which inhibits it (see *Anaesthesia and Intensive Care Medicine* **3:6:** 225). Prostacyclin can be used to prevent platelet aggregation but it is too short lived to have widespread application. It must be given by infusion and causes vasodilatation, resulting in flushing and headache.

Thrombin activates platelets (Figure 1) by inducing the expression of glycoprotein IIb and IIIa receptors which bind fibrinogen thus linking adjacent platelets. Inhibitors of this receptor have been recommended by the National Institute for Clinical Excellence (NICE) for high-risk patients with un-stable angina or non-Q-wave myocardial infarction and patients undergoing percutaneous coronary intervention. Abciximab is a monoclonal antibody that binds to the receptor, but should be used only once for the last group of patients. Eptifibatide and tirofiban are licensed for high-risk patients with unstable angina or non-Q-wave myocardial infarction.

Platelet activation is also induced by adenosine diphosphate (ADP) released from degranulating platelets. Clopidogrel and toclopidine inhibit the binding of ADP to its platelet receptor. They are licensed for the prevention of ischaemia, stroke or myocardial infarction in at-risk patients.

Fibrinolytic and antifibrinolytic drugs

Fibrin and fibrinogen are broken down by the protease plasmin, which is produced by the conversion of inactive plasminogen. Drugs that activate plasmin break up thrombi and are used in the treatment of life-threatening venous thrombosis and pulmonary embolism. Streptokinase, extracted from β-haemolytic streptococci, binds to the plasminogen exposing its active site and thus inducing plasmin-like activity. Antibodies to strepto-kinase appear after about 4 days and the drug should not be used again for at least 1 year. Alteplase, reteplase and tenecteplase are recombinant tissue plasminogen activators. Alteplase is unmodified human tissue plasminogen activator while the others have some amino acid sequences deleted to increase the elimination half-life to allow bolus administration. They are more selective for fibrin-bound plasminogen than for free plasminogen and are thus promoted as being clot selective.

Inhibition of plasminogen activation can be achieved with drugs such as tranexamic acid, which are used in conditions where there is a risk of haemorrhage such as prostatectomy and dental extraction for patients with haemophilia. Aprotinin inhibits proteolytic enzymes and is used for patients at risk of significant blood loss during surgery. ◆

Antidepressants, Antipsychotics and Anticonvulsants

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Antidepressant drugs

Antidepressant drugs are used to treat clinical depression, the symptoms of which are shown in Figure 1. Characteristically, affective disorders are associated with changes in mood such as depression or mania. In some patients, the mood swings are always towards depression and this is known as unipolar depression. The remainder exhibit bipolar disease in which depression and mania alternate.

While the biochemical basis of depression is uncertain, many of the useful drugs acutely preserve noradrenaline (norepinephrine) and/or 5-HT (serotonin) at the synapse. However, in general, they require several weeks to take effect, which suggests that changes downstream from the acute effects are responsible for their beneficial effects in affective disorders. Downregulation of neurotransmitter receptors (e.g. a_2- and b-adrenoceptors) and 5-HT_2 receptors have been observed after long-term antidepressant therapy and may be relevant to their antidepressant activity. The mechanism of action of antidepressant drugs is summarized in Figure 2.

Symptoms of clinical depression and mania

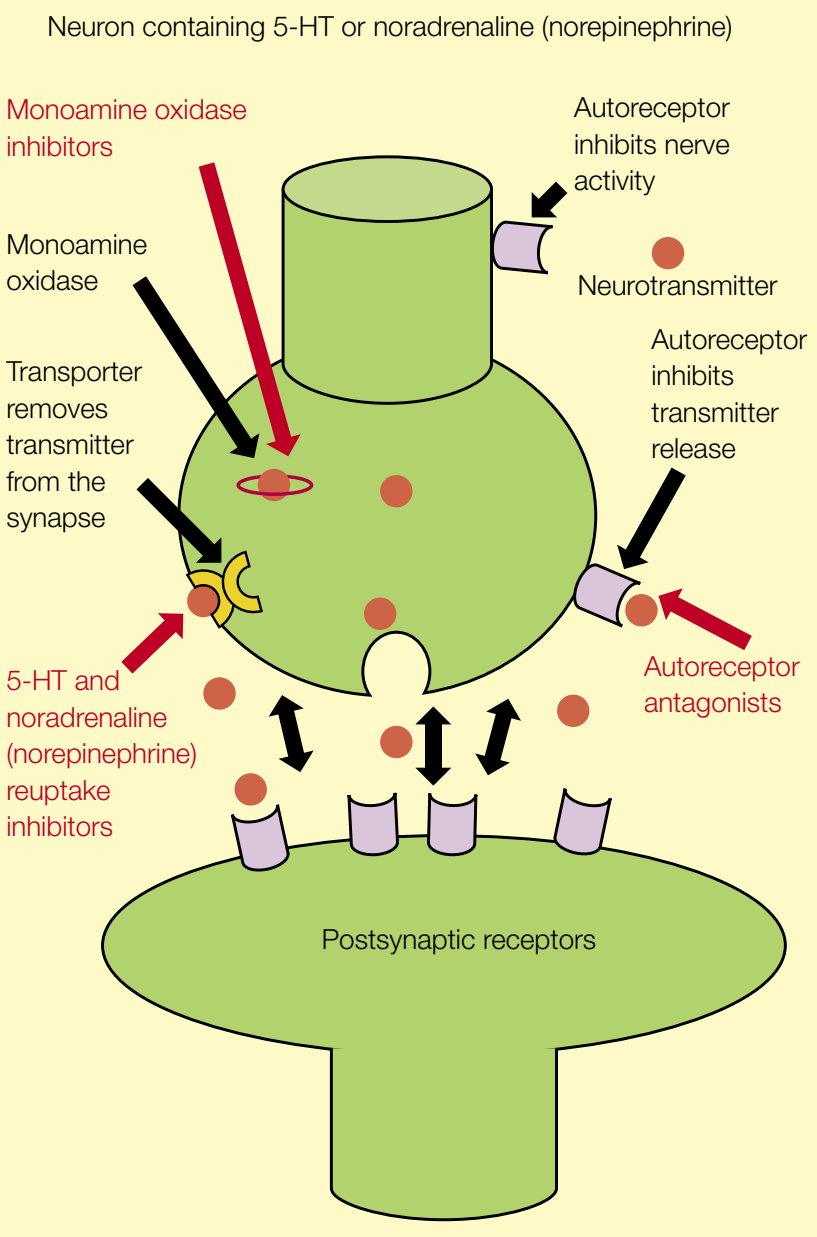
Clinical depression
- Depressed mood
- Loss of motivation
- Apathy
- Pessimism
- Low self-esteem
- Sleep disturbance
- Retardation of thought

Mania
- Excessive self-confidence
- Exuberance

Often combined with:
- Irritability
- Aggression
- Delusions

1

Sites of action of antidepressants



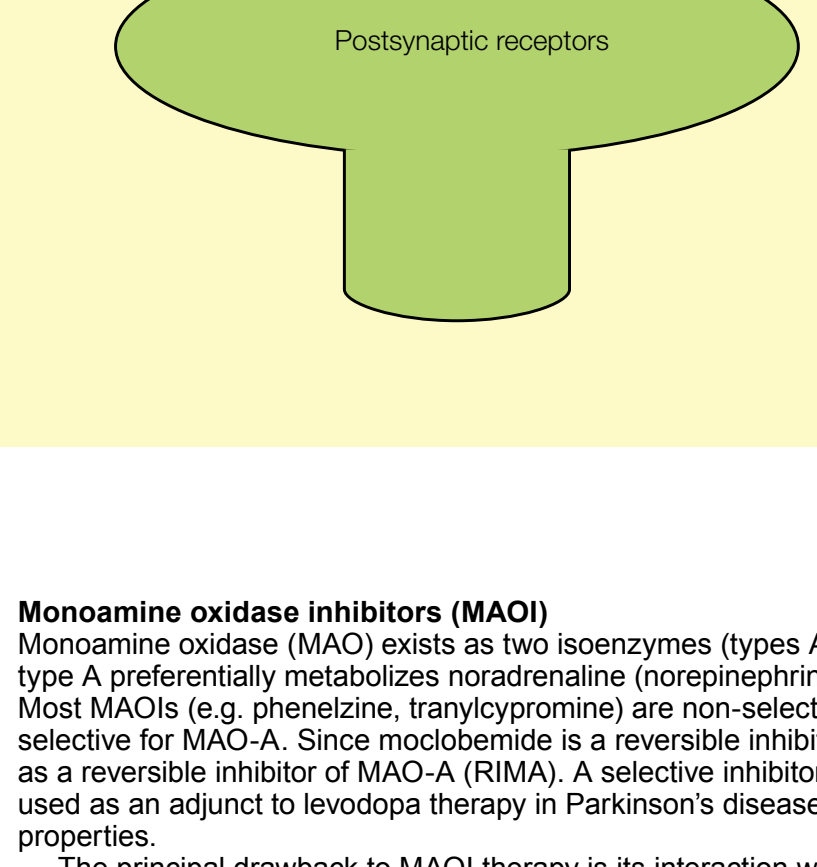
2

Monoamine oxidase inhibitors (MAOI)
Monoamine oxidase (MAO) exists as two isoenzymes (types A and B) of which type A preferentially metabolizes noradrenaline (norepinephrine) and 5-HT (Figure 3). Most MAOIs (e.g. phenelzine, tranylcypromine) are non-selective but moclobemide is selective for MAO-A. Since moclobemide is a reversible inhibitor it is sometimes listed as a reversible inhibitor of MAO-A (RIMA). A selective inhibitor of MAO-B, selegiline, is used as an adjunct to levodopa therapy in Parkinson's disease. It has no antidepressant properties.

The principal drawback to MAOI therapy is its interaction with drugs and certain types of food. Tyramine is an amine produced during fermentation and it is an indirectly acting sympathomimetic (i.e. it releases noradrenaline (norepinephrine) from vesicles within the nerve terminal cytoplasm). Once released into the cytoplasm it may leak out or be metabolized by MAO. Once ingested, tyramine is normally metabolized by MAO in the liver and gut wall so that little enters the systemic circulation. However, when MAO is inhibited, large quantities can reach the circulation and the noradrenaline (norepinephrine) released can cause a hypertensive crisis. Tyramine is found in ripe cheese (hence the 'cheese reaction'), concentrated yeast extracts (*Marmite*), vintage Chianti and broad bean pods.

MAOIs also interact with sympathomimetic agents found in cold cures, other antidepressants and the opioid analgesic pethidine.

Effects of monoamine oxidase inhibitors (Type A)



Abbreviation: MAO, monoamine oxidase

3

Inhibitors of noradrenaline (norepinephrine) and/or 5-HT transporters (reuptake inhibitors)
Once released from the presynaptic neuron, the activities of noradrenaline (norepinephrine) and 5-HT on the postsynaptic receptors are limited by an active reuptake process into the presynaptic terminal. Drugs that compete with the two amines for the carrier protein or transporter can inhibit this process. The tricyclic antidepressants (e.g. amitriptyline, imipramine) have similar activity on both the noradrenaline (norepinephrine) and 5-HT transporters while others have some selectivity for either noradrenaline (norepinephrine) or 5-HT (Figure 4).

Tricyclic antidepressants may cause hypotension, probably through an effect on the medullary vasomotor centre. They also have muscarinic acetylcholine receptor antagonist properties and thus cause dry mouth and blurred vision. Seizure threshold is reduced and, in overdose, convulsions may accompany excitement and delirium. Cardiac dysrhythmias are also common in overdose, and death can occur due to ventricular fibrillation. The serotonin selective reuptake inhibitors (SSRIs), such as fluoxetine, produce fewer side-effects, the most common being insomnia and nausea.

The uptake inhibitors do not precipitate the cheese reaction, but they are prone to other drug interactions. In particular, SSRIs in combination with MAOIs can cause hyperthermia and cardiovascular collapse, known as the 'serotonin syndrome'.

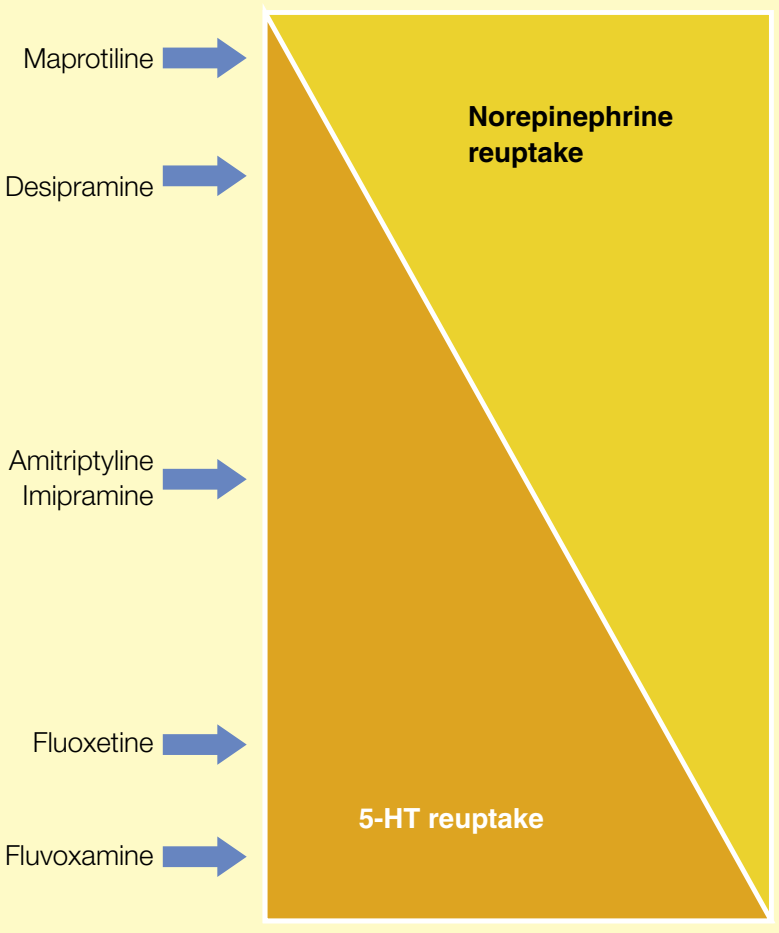
Atypical antidepressants
Some agents have no obvious action on either uptake or metab-olism of 5-HT or noradrenaline (norepinephrine). Mianserin may promote release of noradrenaline (norepinephrine) and 5-HT by acting as an antagonist on α_2- and 5-HT_2-autoreceptors.

Mood stabilizers
Lithium prevents the mood swings associated with unipolar depression and bipolar manic depression. However, during an acute attack, lithium is useful only in reversing the mania because it has no effect on depression. Lithium is limited to the prophylactic control of bipolar disease because of its toxicity. Antipsychotic drugs (see later) are equally effective in reversing mania and are less toxic than lithium.

The therapeutic actions of lithium are thought to involve the blockade of the phosphatidyl inositol pathways such that membrane phosphatidyl inositol is depleted and receptor-mediated effects linked to this second messenger system are inactivated. Toxicity appears to be related to the ability of Li^+ to replace Na^+ in excitable tissue. Although it enters the cell in place of sodium, it is not pumped out by Na^+/K^+-ATPase and its accumulation leads to partial depolarization of the cell. Toxicity is enhanced by Na^+ depletion and can be reduced with Na^+ replacement.

Some anticonvulsants such as carbamazepine and valproate (see later) have also been used to treat bipolar disorders.

Relative inhibition of noradrenaline (norepinephrine) or 5-HT transporters



4

Antipsychotic drugs

Antipsychotic drugs may be used to treat schizophrenia, manic depression and psychosis caused by chemical or traumatic head injury. Typical symptoms of schizophrenia are shown in Figure 5. Schizophrenia occurs in about 1% of the population and has a tendency to run in families but other non-genetic influences are also important.

All antipsychotic drugs (also termed neuroleptic drugs or major tranquillizers) are dopamine antagonists. Neurolepsis is a state of altered consciousness characterized by quiescence, reduced motor activity and indifference to the surroundings. Anaesthetists have used these drugs in combination with potent opioid analgesics in techniques like neurolept analgesia and anaesthesia and as preanaesthetic medication.

Symptoms seen in schizophrenia

Positive symptoms
- Delusions
- Hallucinations
- Thought disorder

Negative symptoms
- Withdrawal from society
- Few emotional responses

5

The main neuronal pathways in the brain that use dopamine are shown in Figure 6. The mesolimbic and mesocortical pathways are important in the beneficial effects of dopamine antagonists in psychosis, but blockade of the nigrostriatal pathway leads to side-effects such as extrapyramidal disorders resembling Parkinson's disease. Blockade of the tubero-hypophyseal pathway increases prolactin release resulting in breast swelling, pain and lactation in men and women. Dopamine is also the neurotransmitter involved in vomiting induction at the chemoreceptor trigger zone thus many antipsychotics are used as anti-emetics.

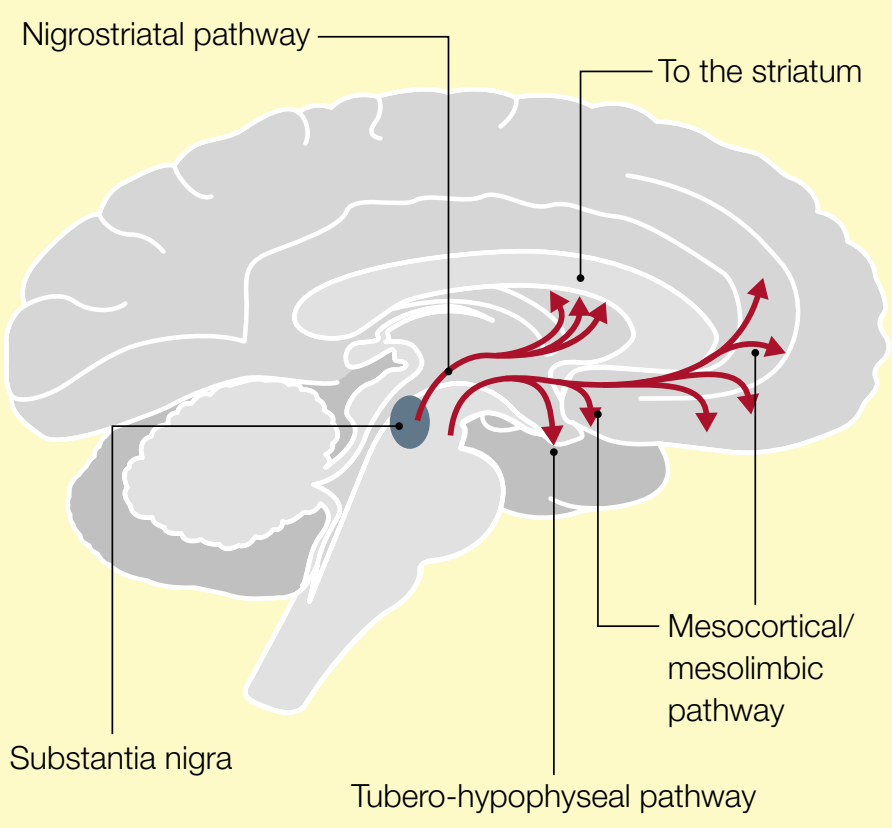
The two main groups of G-protein-linked dopamine receptors are D_1, the family that stimulate adenylyl cyclase and the D_2 family that inhibit or have no effect on adenylyl cyclase. Subgroups of these families are D_1 and D_5 in the D_1 family and D_2, D_3 and D_4 in the D_2 family. In general, the known actions of dopamine agonists and antagonists occur mainly via receptors of the D_2 family.

Since the distribution of these receptor subtypes differs in the CNS, there has been interest in developing selective compounds that might possess fewer side-effects. For example, the receptors in the basal ganglia, that mediate the extrapyramidal side-effects of dopamine antagonists are mainly of the D_2 subtype, thus drugs selective for D_3 or D_4 receptors may not possess this side-effect. Clozapine and other newer atypical antipsychotics have some selectivity for D_4 receptors and have a much better side-effect profile when used as antipsychotic agents than the traditional dopamine antagonists. However, they are also antagonists at several other non-dopaminergic receptors such as 5-HT_2, which may explain this phenomenon. The atypical antipsychotics are effective against positive and negative symptoms of schizophrenia, while the classical drugs are useful only for positive symptoms.

A rare complication of antipsychotic drug administration is the neuroleptic malignant syndrome characterized by rigidity, tremor, autonomic dysfunction and fever coupled with an increase in serum creatinine phosphokinase and white blood cell count. It is more likely to occur when high parenteral doses are used and there is appreciable mortality (over 10%). Treatment involves removal of the drug and supportive therapy. Unlike malignant hyperthermia induced by general anaesthetics, the use of drugs such as dantrolene does not appear to be helpful and a disorder of calcium metabolism in skeletal muscle is probably not the cause. However, there has been a report of both syndromes occurring in the same patient. Recovery occurs in about 14 days without any cognitive impairment unless high fever, hypoxia or other complications have induced these changes.

Individual antipsychotic drugs are compared in Figure 7.

Main dopaminergic pathways in the brain



6

Comparison of individual antipsychotic drugs

Drug	Dopamine receptor selectivity	Other receptors antagonized	Comments
Classical			
• Chlorpromazine	D_2, D_3>>D_1, D_4, D_5	Many	Extrapyramidal effects Sedative Gynaecomastia Obstructive jaundice
• Haloperidol	D_2=D_3=D_4 >> D_1,D_5	Some effect on α-adrenergic and 5-HT_2	More extrapyramidal effects than above Little sedation
• Flupentixol (flupenthixol)	Little	Some effect on α-adrenergic and 5-HT_2	Available as a depot preparation Extrapyramidal effects Gynaecomastia
Atypical			
• Clozapine	Some selectivity for D_4	5-HT_2	No extrapyramidal effects Agranulocytosis May be effective in treatment-resistant patients Effective against negative symptoms
• Olanzapine	Some selectivity for D_4	5-HT_2	No extrapyramidal effects May be effective in treatment-resistant patients Effective against negative symptoms

7

Anticonvulsants

Anticonvulsant drugs are used to treat epilepsy, which affects about 1% of the population. Epilepsy is characterized by abnormal electrical activity over part or all of the brain detected as sharp waves and/or spikes on an electroencephalograph (EEG) recording. The EEG is obtained from electrodes distributed over the surface of the scalp. The clinical classification of epilepsy is shown in Figure 8.

In general, partial seizures are more difficult to treat than generalized seizures and 20–30% of patients do not have their seizures adequately controlled by current therapy.

Some of the currently available anticonvulsant drugs enhance inhibitory γ-aminobutyric acid (GABA) transmission either by inhibiting GABA metabolism (Figure 9) or by enhancing GABA transmission at the $GABA_A$ receptor via an action on a modulatory site such as the benzodiazepine receptor. Other drugs, such as phenytoin and carbamazepine, prevent excessive neuronal discharge by blocking voltage-dependent sodium channels. However, some (e.g. ethosuximide) block T-type calcium channels. Drugs that block excitatory neurotransmission are, in general, not clinically available, though some reports suggest that lamotrigine may have this effect. The commonly used anticonvulsants are compared in Figure 10.

Phenytoin is unusual in that it exhibits zero-order kinetics in the therapeutic dose range. The enzymes that metabolize phenytoin become saturated such that the rate of metabolism does not increase with increasing plasma concentration. Thus, small changes in dose can have a large effect on plasma concentration resulting in the need to control the plasma concentration carefully to maintain seizure control with minimal adverse effects.

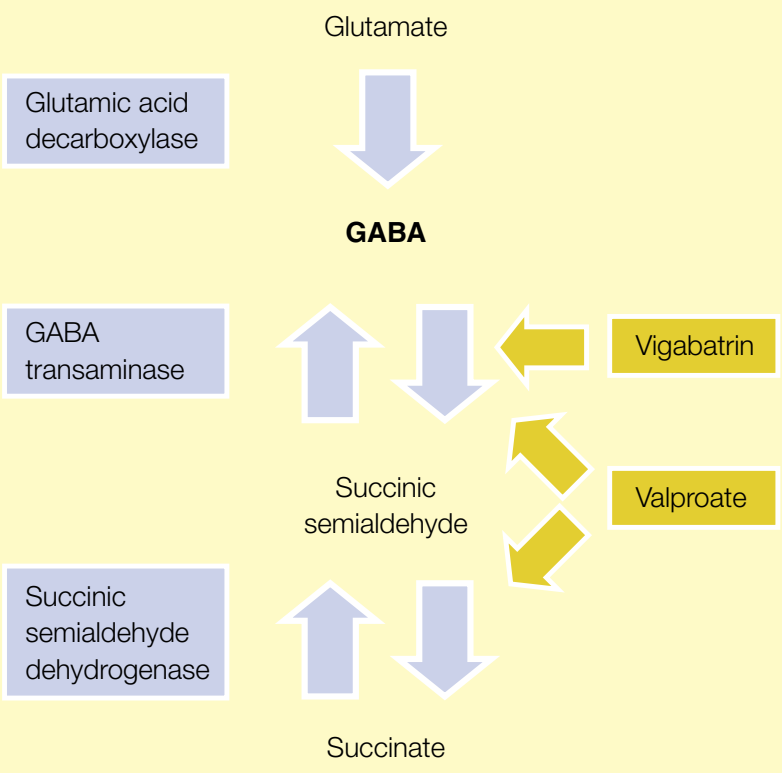
Classification of epilepsies

Generalized seizures
Abnormal electrical activity involving the whole brain
- Grand mal – tonic-clonic seizure involving synchronous muscle jerking and unconsciousness often including incontinence. Full recovery may take a few hours
- Petit mal – absence seizure when the patient, usually a child, ceases all activity but there is no excessive muscle jerking. The patient is unaware and recovers quickly

Partial (focal) seizures
Abnormal electrical activity occurs in a localized area of the brain and may be limited to that area or spread to a secondary generalized seizure
- Simple partial seizures – dependent on the site of the focus the seizure may be motor (jerking of a muscle group), sensory (e.g. unexplained smells) or autonomic (e.g. sudden pallor). There is no unconsciousness unless the seizure becomes generalized
- Complex partial seizures – apparently purposeful movements without conscious awareness. The movements may be stereotyped and can involve an emotional component

8

Anticonvulsants that inhibit γ-aminobutyric acid (GABA) metabolism



9

Comparison of anticonvulsant drugs

Drug	Mechanism	Clinical use	Adverse effects	Other comments
• Benzodiazepines	Enhance γ-aminobutyric acid (GABA) transmission by modulation of the $GABA_A$ receptor	Mainly for emergency treatment of status epilepticus	Sedation and tolerance	Tolerance occurs too quickly for chronic use in most cases
• Carbamazepine	Use dependent on blocking sodium channels	Most seizure types but ineffective in petit mal	Ataxia, blurred or double vision	Induction of microsomal liver enzymes
• Ethosuximide	Inhibits T-type calcium channels	Useful only for petit mal and may make other types of seizure worse	Nausea, headache and anorexia	Use declining
• Lamotrigine	Use dependent on blocking sodium channels. May reduce glutamate release	Broad range of seizures including petit mal	Nausea, ataxia, hypersensitivity reactions	
• Phenobarbitone	Enhance GABA transmission by modulation of the $GABA_A$ receptor	Most seizure types but ineffective in petit mal	Sedation, low therapeutic index	Induction of liver microsomal enzymes Inexpensive – mainly used in the Third World
• Phenytoin	Use dependent on blocking sodium channels	Most seizure types but ineffective in petit mal	Ataxia, gingival hypertrophy, fetal abnormalities (cleft palate)	Induction of liver microsomal enzymes Metabolized by zero-order kinetics (see text)
• Valproate	Inhibits enzymes metabolizing GABA (see text). Also blocks sodium channels	Most seizure types including petit mal	Fewer than most others Gastrointestinal pain and nausea Fetal abnormalities (spina bifida) Rare hepatoxicity	
• Vigabatrin	Inhibits enzymes metabolizing GABA (see text)	All seizure types	Sedation and behavioural changes	Induction of liver microsomal enzymes

Anxiolytics and Hypnotics

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology for postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

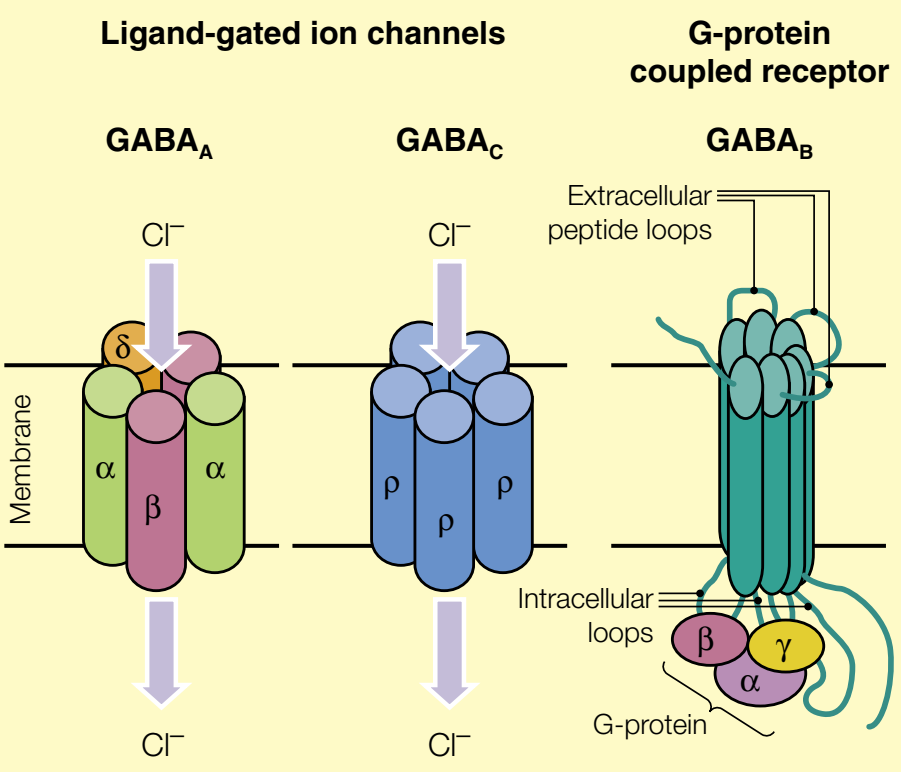
Until recently the pharmacology of drugs used to treat anxiety (anxiolytics) and insomnia (hypnotics) were identical because the same drugs were used for both purposes. While the anxiolytic action of hypnotics was probably an advantage, the hypnotic action of anxiolytics was a major drawback. Daytime drowsiness severely limited their usefulness in treating long-term anxiety states. More recently, drugs that lack marked hypnotic activity, acting on tryptaminergic receptors, have been introduced. These drugs (e.g. buspirone) have obvious advantages in psychiatry but they generally take several days or even weeks to produce their effects and are of limited use in anaesthesia.

γ-aminobutyric acid (GABA)

The traditional hypnotics and anxiolytic drugs, such as barbiturates and benzodiazepines, enhance GABA transmission via the $GABA_A$ receptor. GABA is the main inhibitory neurotransmitter in the brain and it is known to interact with three receptor types, $GABA_A$ and $GABA_C$, which are ligand-gated ion channels, and $GABA_B$, which is a G-protein-coupled receptor (Figure 1). The $GABA_C$ receptor is a simple form of the $GABA_A$ receptor in that all five subunits are of the same type, in this case the ρ subunit. The characteristics of these three receptors are listed in Figure 2.

The $GABA_A$ receptor is probably the most complicated. Five subunits are arranged in a rosette and the central area, where they meet, forms a channel through which chloride ions can pass. In normal circumstances, opening of the chloride channel causes the negative chloride ions to flow into the cell, causing hyperpolarization and thus inhibition of cellular activity. There are four types of subunit (α, β, γ and δ) which can make up the receptor, though the first three are the most common. The α and β subunits provide the binding site for the GABA molecule while α and γ subunits are necessary for benzodiazepine binding. Thus, benzodiazepines bind to a separate site from GABA and this 'benzodiazepine receptor' is just one of at least 11 modulatory sites on the $GABA_A$ ion channel. The barbiturates, neurosteroids and many general anaesthetic agents bind to other modulatory sites. (The neurosteroids are related to the steroid hormones but do not act on the conventional intracellular steroid receptors. Their function in the body is uncertain, but synthetic analogues include the steroidal anaesthetics such as alphaxalone, which was withdrawn from human use some years ago.)

Receptors for γ-aminobutyric acid (GABA)



1

Characteristics of γ-aminobutyric acid (GABA) receptors

	$GABA_A$	$GABA_B$	$GABA_C$
Selective agonist	Muscimol	Baclofen	?
Selective antagonist	Bicuculline	Phaclofen or saclofen	?
Effector mechanism	Ligand-gated chloride channel	G-protein coupled	Ligand-gated chloride channel
Subunits	Pentamer with three different subunits	Not applicable	Pentamer with all identical subunits
Location	Widespread in CNS	Widespread in CNS	Retina of the eye

2

Benzodiazepines

Benzodiazepines enhance responses to GABA by increasing the affinity of the receptor to GABA. This is manifest as an increase in the frequency of the ion channel opening in response to GABA. Benzodiazepines have no effect on the gating mechanism of the channel and they are active only when there is continuing GABA transmission. Flumazenil is a benzodiazepine antagonist; it binds to benzodiazepine receptors but does not modulate the response to GABA. Thus, flumazenil will antagonize the actions of benzodiazepines but not the action of modulators binding to other sites or indeed GABA itself.

Benzodiazepines have five characteristic pharmacological actions (Figure 3) and thus it was surprising that the first candidate endogenous ligand to be found for the benzodiazepine receptor, ethyl-β-carboline, had diametrically opposite pharmacology. In animals (and the odd courageous human), β-carboline derivatives produced anxiety, even panic, convulsions and restlessness. Even more surprising was the observation that these effects, like those of the benzodiazepines, were antagonized by flumazenil, the benzodiazepine antagonist. A suggested explanation of this phenomenon (known as inverse agonism) is illustrated in Figure 4.

The $GABA_A$ receptor exists in two conformational states one of which binds GABA and opens the chloride channel and the other does not. In the absence of a modulator, these two states are in equilibrium and there is moderate, but not maximal, sensitivity to GABA. Benzodiazepines bind preferentially to the GABA-sensitive conformation and upset the equilibrium in favour of GABA responsiveness because the receptor cannot convert to the inactive form. In contrast, β-carboline derivatives prefer to bind to the inactive state and the equilibrium moves towards decreased GABA responsiveness. Flumazenil can bind to the receptor in either the active or inactive state, thus antagonizing the action of both the agonist and inverse agonist. Subsequent to the discovery of the β-carbolines, inverse agonists have been described at other non-benzodiazepine receptors.

Characteristic properties of benzodiazepines

Anxiolytic Anxiety is reduced but most drugs of this class are not antidepressant (exception alprazolam). Some short-acting drugs may produce aggression that has been described as a symptom of withdrawal

Hypnotic Slow wave sleep is reduced (useful for the treatment of night terrors that occur in this stage of sleep). All hypnotics reduce REM sleep and withdrawal is associated with a rebound increase in REM sleep and consequently excess dreaming which subjectively reduces the quality of sleep. Benzodiazepines cause less reduction in this part of the sleep cycle than other hypnotics

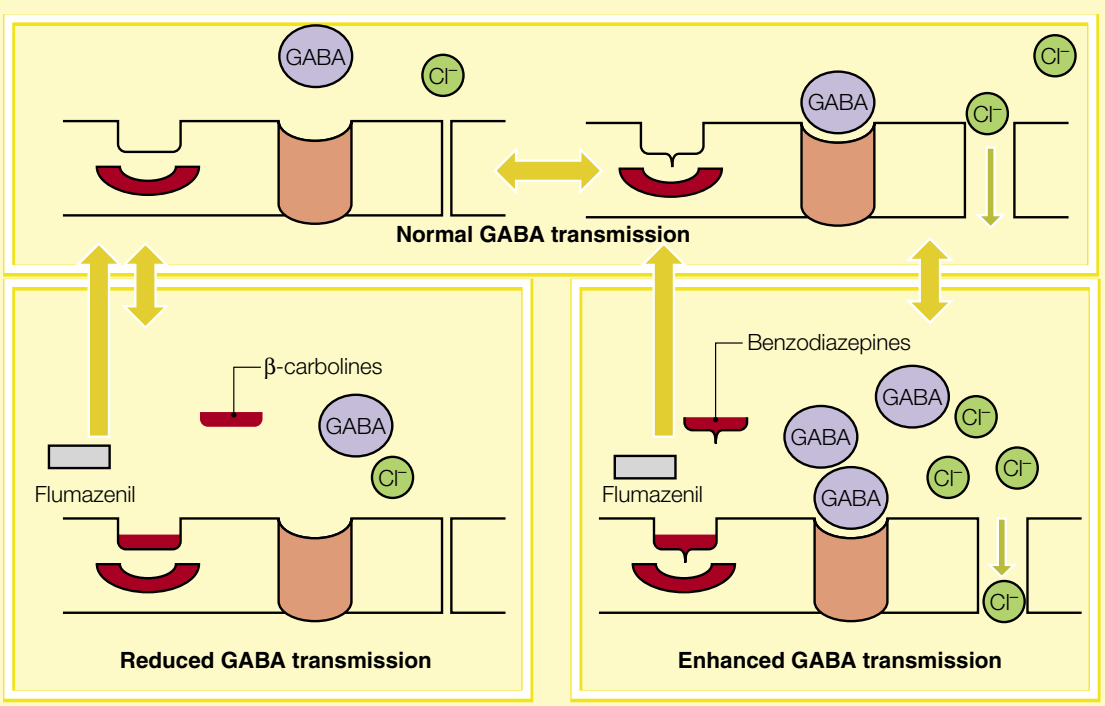
Muscle relaxant Muscle tone is reduced by a central action separate from sedation. Heightened muscle tone is seen in anxiety and is responsible for the headache and muscle pains associated with the condition. Benzodiazepines reduce this symptom

Anticonvulsant Tolerance to the anticonvulsant effects of benzodiazepines occurs rapidly so they are usually reserved for emergency use in status epilepticus rather than for chronic treatment of epilepsy. Clonazepam, a partial agonist at benzodiazepine receptors, has some selectivity for anticonvulsant actions

Amnesic Most produce some anterograde amnesia (lorazepam is particularly active in this respect). This property can be useful clinically when a patient has to undergo repetitive awake procedures that are undignified and embarrassing

3

Inverse agonism



4

Variety of benzodiazepine receptors: molecular biology indicates that each of the subunits making up the $GABA_A$ receptor has several variants to its amino acid make-up. These variations in structure can affect the binding characteristics of the subunits and thus the way that the receptor as a whole can be modulated. Some variants of the α and γ subunits do not bind benzodiazepines, thus making the $GABA_A$ receptors with this make-up insensitive to benzodiazepines. Tolerance to benzo-diazepines occurs owing to the induction of benzodiazepine insensitive subunits to make up the $GABA_A$ receptor. Other variants can bind benzodiazepine or similar molecules with slightly different structures, thus allowing selective modulation of a proportion of benzodiazepine receptors.

Selective benzodiazepine ligands: zolpidem has been classified as selective for type one of the two benzodiazepine receptors that have been described in association with the $GABA_A$ receptor. The nomenclature of these receptors is confused because some texts use BZ receptors, others BDZ receptors, and yet others BDZ receptors, since it was argued the receptors also bind molecules that are not strictly benzodiazepine structures. (Beware of advertisements for non-benzodiazepine anxiolytics: they may have different chemical structures but they still bind to benzodiazepine receptors; e.g. zopiclone.) The author uses the BDZ terminology. Zolpidem has selectivity for BDZ_1 receptors and has marked hypnotic activity with little anticonvulsant or muscle-relaxant activity. Some sources also question the presence of anxiolytic activity in this molecule. At present it is impossible to tie the main pharmacological actions of the benzodiazepines and related structure to activation of individual BDZ receptors. Some drugs selective for the various BDZ receptors are shown in Figure 5. Alpidem, which is also supposed to have some selectivity for BDZ_1 receptors, is anxiolytic but has negligible hypnotic activity.

The BDZ_3 receptors are sometimes called the peripheral benzodiazepine-binding site because they are not necessarily associated with $GABA_A$ receptors and are found in mitochondria within peripheral cells. They are probably involved in intra-cellular signalling. The natural ligands for BDZ_3 receptors are peptides, including the endozepines and Diazepam Binding Inhibitor (DBI). These peptides are inverse agonists at classical BDZ receptors. There are reports that BDZ_3 receptors may have a role in the CNS, which is activated by high doses of benzodiazepines and possibly carbamazepine.

Subtypes of benzodiazepine receptors

Receptor	Selective agonists	Selective antagonists
BDZ_1 (also ω or BZ)	Zolpidem Alpidem	Flumazenil Clonazepam
BDZ_2	Clonazepam	Flumazenil
BDZ_3	Alpidem	PK11195

5

Barbiturates

The barbiturates were once the mainstay of anxiolytic and hypnotic drug treatment, but only phenobarbital (phenobarbitone) used as an anticonvulsant, and thiopental (thiopentone) used as an intravenous anaesthetic, still have widespread clinical use. The clinical demise of these compounds resulted from their low therapeutic index. Increased dosage leads to respiratory and cardiovascular depression followed by death. Until the introduction of the benzodiazepines, when barbiturate use was widespread, they were the drugs of choice for suicides and poisoners. Indeed the amnesic action of the drugs meant that unintended overdoses were common in self-medicating patients.

Although barbiturates also enhance GABA transmission and, in low doses, have similar pharmacological properties to the benzodiazepines, they do so by altering the gating mechanisms of the chloride channel so that it stays open longer in response to GABA. This action occurs at a diversity of $GABA_A$ receptors, including those that are insensitive to benzodiazepines. In addition, at high doses of barbiturate, the chloride channel may be open for such long periods of time that the neuron becomes incapable of depolarization and thus inactive. Both these factors contribute to the increased toxicity of barbiturates over benzodiazepines.

5-hydroxytryptamine (serotonin)

A number of drugs active as either agonist or antagonist at 5-HT receptors have shown anxiolytic activity in animals. There are at least seven subtypes of 5-HT receptor with further subdivisions of some of them. Those with clinically useful agonists and or antagonists are listed in Figure 6. Some of them, such as ondansetron, a $5\text{-}HT_3$ receptor antagonist, failed to be effective anxiolytics in humans but others, such as buspirone, an agonist at $5\text{-}HT_{1A}$ receptors, has proved to be useful. Buspirone has some actions at dopamine receptors, but more selective agonists at $5\text{-}HT_{1A}$ receptors (e.g. gepirone, isapirone) also have anxiolytic activity in humans, suggesting that tryptaminergic actions are the important mechanism with respect to anxiolytic activity. Although the exact role of 5-HT in anxiety states is unknown, some recent evidence has suggested a link between the loss of $5\text{-}HT_{1A}$ receptors and loss of benzodiazepine sensitivity.

Therapeutically important 5-HT receptors

Receptor	Effector mechanism	Agonist	Clinical use	Antagonist	Clinical use
$5\text{-}HT_{1A}$	G-protein coupled	Buspirone	Anxiolytic		
$5\text{-}HT_{1D}$	G-protein coupled	Sumatriptan	Anti-migraine		
$5\text{-}HT_{2A}$	G-protein coupled			Ketanserin	Vasodilator
$5\text{-}HT_3$	Ligand-gated ion channel			Ondansetron	Anti-emetic
$5\text{-}HT_4$	G-protein coupled	Metoclopramide	Prokinetic		
		Cisapride (withdrawn)			

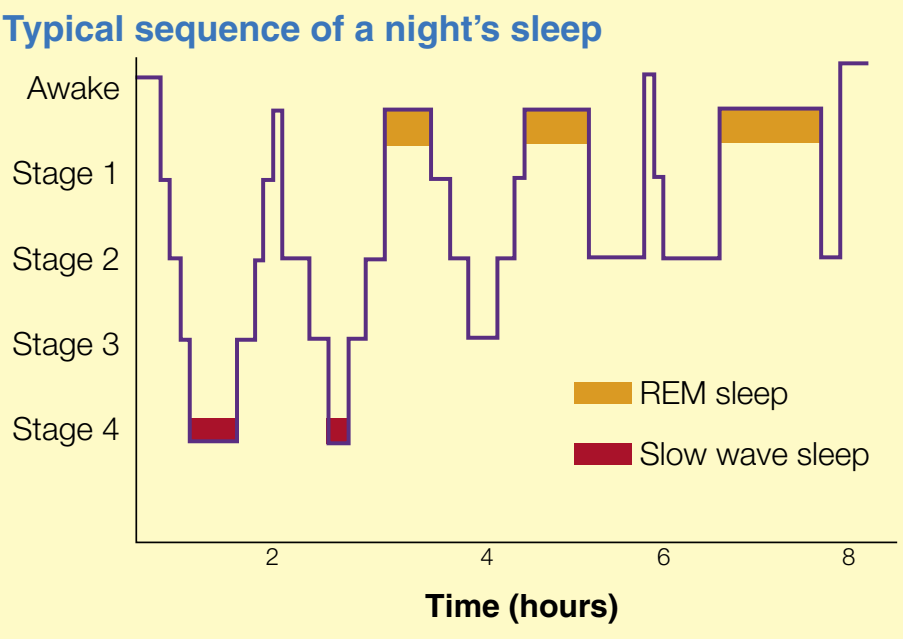
Histamine

Antagonists at histamine H_1-receptors produce mild hypnosis, but they are useful for this purpose only in sensitive individuals. Children are more likely to respond to antihistamines in this way and promethazine syrup is regularly used for sedation and hypnosis in children.

Hypnotic drugs

When a hypnotic drug is used to treat insomnia, the aim is to restore physiological sleep patterns to the patient. The stages of sleep may be recognized by characteristic electroencephalography (EEG) changes in brain activity. The deepest sleep (stage 4) is also known as slow wave sleep and is associated with a low metabolic rate and level of adrenal corticosteroid secretion. In contrast, the secretion of growth hormone is high. Another important stage of sleep is REM (rapid eye movement) sleep in which dreaming occurs. Diminution of this stage of sleep leads to irritability and anxiety. A typical sequence of a night's sleep is shown in Figure 7.

Typical sequence of a night's sleep



All hypnotic drugs reduce REM sleep though the barbiturates are worse than the benzodiazepines and there is some evidence that zolpidem (the BDZ_1 agonist) causes less disruption than the others. Withdrawal of hypnotics leads to a rebound increase in REM sleep with a consequent lack of deeper stages of sleep. This contributes to habituation because the patient does not feel rested. It follows that a drug that produces the closest to physiological sleep patterns is least likely to cause these withdrawal effects. Trials are under way to determine whether zolpidem may be closer to this ideal. Benzodiazepines also reduce stage 4 sleep but not the associated increase in growth hormone. This may be the base for their use in night terrors that occur during stage 4 sleep.

Some other agents (Figure 8) are still prescribed by some, usually elderly, practitioners, but in general they are not recommended. Most of these agents appear to potentiate GABA, but because of their antiquity this has not been studied rigorously. The exception is ethanol, which can potentiate GABA by several different mechanisms, dependent on the dose. The low-dose effects may occur only with a particular splice variant of the γ subunit. However, ethanol appears to have some actions at most ligand-gated ion channels. No hypnotic drug is recommended for long-term use.

Drugs used as hypnotics

Group	Examples	Comment
Barbiturates	• Pentobarbital (pentobarbitone)	Seldom used because of dangers of overdose and many drug interactions due to induction of liver enzymes
	• Amobarbital (amylobarbitone)	
	• Butobarbital (butobarbitone)	
Benzodiazepines	• Diazepam	Long-acting so more useful for patients with early wakening. Active metabolite.
	• Nitrazepam	
	• Temazepam	Short-acting so more useful for patients with long sleep latencies. Active metabolite but it is unimportant in overall activity of the drug
	• Zolpidem	Not a benzodiazepine structure. Selective hypnotic? Short duration of action. May produce more physiological sleep patterns
Antihistamines	• Promethazine	Also possess muscarinic antagonist properties so may cause dry mouth. Not effective in all patients. Used in children, but not recommended
	• Diphenhydramine	
Others	• Chloral hydrate	Irritant action may cause gastrointestinal tract disturbances
	• Meprobamate	Less effective than benzodiazepines and more toxic in overdose
	• Clomethiazole	Mainly used in the elderly because of reduced hang-over effects Dependence occurs
	• Ethanol	Self-medication

Anxiolytic drugs

While all of the drugs mentioned above as hypnotics can be used as anxiolytics, only benzodiazepines are used clinically for this purpose. The relative merits of drugs acting as agonists at $5\text{-}HT_{1A}$ receptors and those acting on benzodiazepine receptors are shown in Figure 9.

Drugs used as anxiolytics

Mechanism	Example	Comments
GABA enhancement	Diazepam	Sedation and dependence Fast onset of action Recommended only for short-term treatment
$5\text{-}HT_{1A}$ agonist	Buspirone	Delayed onset Little sedation and no dependence Not useful for panic attacks

Body Compartments and Drug Distribution

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Once absorbed into the body a drug is distributed to various compartments that can be defined in a variety of ways.

Compartmental analyses

The compartments used in compartmental analyses to describe drug distribution and elimination bear no relationship to real body compartments. They are discussed in *Anaesthesia and Intensive Care Medicine* **2:6:** 237 and are based on mathematical modelling related to actual measurements of plasma concentration of drugs. In these models, the volume of distribution of the drug is the volume that would contain the administered dose assuming that the concentration was the same as that in the plasma. The practical use of compartmental and physiological pharmacokinetic models in anaesthetic practice is described elsewhere.

Body fluid compartments

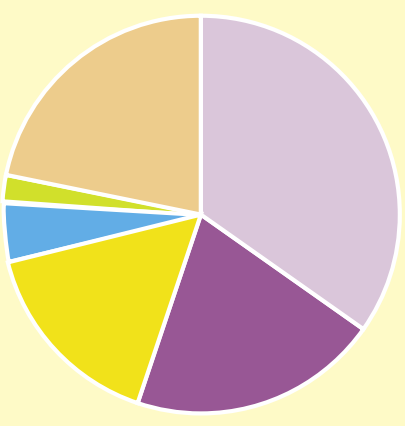
Most drugs are distributed in body fluids, therefore an alternative method of determining distribution is to consider body fluid compartments that have a finite volume. Figure 1 shows the percentage of water found in some types of tissue and it is interesting to note that the water content of blood is no greater than that of some solid tissues. Total body water is about 60% of body weight in a young adult man. In young women, the total body water averages about 50% of body weight because they have less muscle mass and more subcutaneous fat. Fat has a lower water content than most other tissues. Increasing age decreases the percentage of body weight that is water because water-rich muscle tends to be replaced with fat. The total body water can be divided into several parts (Figure 2).

Approximate water content of body tissues

	Percentage
Blood	80
Bone	30
Connective tissue	60
Fat	20
Kidney	80
Brain grey matter	85
Brain white matter	70
Skeletal muscle	75

1

Main body compartments as a percentage of body weight



2

Extracellular fluid constitutes about 20% of body weight and includes blood plasma (4–5%), interstitial fluid (15–16%), lymph (about 1%) and a small amount of fluid in the pleural and abdominal cavities and in the pericardial sac. The latter small volumes together with CSF, digestive secretions and intraocular fluid are sometimes called transcellular water. These fluids are separated from the plasma by endothelium as well as an epithelial layer. The epithelial layer modifies the chemical composition of the transcellular fluid so that it is not a simple ultrafiltrate of plasma as is the interstitial fluid.

The remaining body water consists of intracellular fluid including fat (20%). Drugs may be bound or free in each of these fluid compartments but only free drug can pass between compartments.

Some small lipid-soluble drugs such as phenytoin, caffeine and ethanol are distributed in a volume that approximates to total body water. In women, total body water relative to weight is less than in men, therefore a given dose of alcohol per kg body weight produces a higher ethanol concentration. Some drugs are so large (e.g. heparin) that they cannot cross the capillary wall and are retained in the plasma compartment. In general, when drugs are confined to the plasma compartment it is because of their extensive binding to plasma proteins. The plasma volume is measured experimentally using Evans' blue dye, which binds strongly to plasma albumin. When drugs that are extensively plasma protein bound are given repeatedly their distribution gradually increases as unbound free drug escapes to other compartments and is no longer confined to a physiological fluid compartment. Very polar molecules cannot penetrate cells and their distribution is limited to extracellular fluids. Examples include quaternary ammonium compounds such as neostigmine and many neuromuscular blocking agents, the amino sugar antibiotics and mannitol.

With these exceptions, most drugs have volumes of distribution (i.e. the total quantity of drug in the body divided by the concentration in the plasma) that do not identify closely with any real anatomical compartment. If the drug is strongly protein bound outside the plasma then the volumes of distribution may be many times greater than body size. For example, the volume of distribution of some tricyclic antidepressants is more than 10 litre/kg body weight.

Interpretation of drug distribution in terms of organ or tissue spaces is complex and is discussed elsewhere.

Special compartments

Brain and CSF

The vascular endothelium enclosing the brain differs from most endothelial cells in that it lacks intracellular pores and pinocytotic vesicles, resulting in tight junctions between the cells, thus restricting the passage of aqueous bulk flow. The glial cells surrounding the capillaries also secrete chemicals that maintain the permeability characteristics of the endothelial cells. Transport across the blood–brain and blood–CSF barriers is selective and directional even for small ions such as potassium and chloride. Thus the composition of the blood and CSF is different (Figure 3).

Components of CSF and serum

Component	CSF	Serum
Protein	35 mg/dl (0.35 g/litre)	7000 mg/dl (70 g/litre)
Glucose	60 mg/dl (3.3 mmol/litre)	90 mg/dl (5 mmol/litre)
K^+	2.8 mEq/litre (2.8 mmol/litre)	4.5 mEq/litre (4.5 mmol/litre)
Ca^{2+}	2.1 mEq/litre (1.1 mmol/litre)	4.8 mEq/litre (2.4 mmol/litre)
Cl^-	119 mEq/litre (119 mmol/litre)	102 mEq/litre (102 mmol/litre)
pH	7.35	7.41

3

Circulating neurotransmitters, such as 5-HT, norepinephrine and dopamine pass across the blood–brain barrier only in trace amounts to avoid overstimulation of central neurons. Glucose is essential for neuronal function and is actively transported into the brain even when circulating concentrations are low.

Only drugs with high lipid solubility can penetrate the blood–brain barrier, which is found in most regions central to the arachnoid membrane. Exceptions include the area postrema on the floor of the fourth ventricle and the floor of the hypothalamus. The lack of a blood–brain barrier in these areas allows a number of blood-borne hormones (e.g. angiotensin II) to modulate the activity of the autonomic nervous system. The capillaries of the posterior pituitary and pineal gland are also permeable to allow the release of hormones into the systemic circulation.

Highly lipid-soluble drugs rapidly permeate the brain, the only limitation being cerebral blood flow, examples are anaesthetic drugs, the uptake and distribution of which are discussed in *Anaesthesia and Intensive Care Medicine* **2:6:** 241 and **2:7:** 277.

Strongly ionized drugs are excluded from the brain and organic ions are actively extruded from the CSF and brain. For example, the penicillins use the organic acid transport system, which is similar to the transport processes in the renal tubule.

Penetration of the brain by weak acids and bases is pH dependent and follows the rules described in *Anaesthesia and Intensive Care Medicine* **3:3:** 105.

Drugs administered into the epidural or subarachnoid space

When drugs are injected into the epidural space they reach spinal nerves by several different routes. The drugs diffuse rapidly into the CSF at the dural cuff and into the dural spinal nerve roots. Later the drug seeps through the intervertebral foramina where a local anaesthetic may produce paravertebral nerve block. The rate of penetration into the spinal cord depends on lipid solubility. Morphine, which is relatively poorly lipid soluble, penetrates the spinal cord slowly and thus the onset of analgesia is slow. However, the duration of analgesia is long because of slow egress from the cord. More lipid-soluble opioids (e.g. fentanyl, pethidine) have a faster onset of action but a shorter duration. The transfer of several local anaesthetic drugs from the epidural space to the systemic circulation exhibits biphasic absorption characteristics. The first, rapid phase is probably a result of the high concentration gradient between the drug in the epidural space and the blood. The slower phase results from distribution of the local anaesthetic into tissue and subsequent partitioning between the tissue and the blood. Much slower absorption into the systemic circulation occurs after subarachnoid administration of drugs due to the dilution into the CSF and the poor vascular perfusion of the subarachnoid space. Although the onset of action of most drugs acting on the spinal cord is faster with subarachnoid rather than with epidural administration, the characteristics related to lipid solubility still apply. However, the volume of the subarachnoid space is small and there is the potential for nerve damage. Distribution of drug within the CSF and into the brain can be slow and there is large inter-patient variability.

Fetus

The fetus acts as if it were a transcellular compartment because drugs need to cross cell membranes in order to penetrate the tissue. Like the blood–brain barrier the placental barrier consists of an epithelial layer with tight junctions between cells so that no molecular filter is present and penetration depends on lipid solubility rather than molecular size. However, the placental barrier does not protect the fetus from the unwanted effects of maternal drugs. Every drug given to the mother passes to the fetus to some degree.

Lipid-soluble drugs cross the placenta by simple diffusion. The rate of diffusion increases with increasing lipid solubility, decreasing molecular size and decreasing degree of ionization. Most drugs used in anaesthesia are highly lipid soluble and have low molecular weight and thus equilibrate with the fetal compartment in a single circuit. Transfer of drugs of this type is said to be flow-dependent.

Drugs such as the neuromuscular blocking agents are fully ionized in solution, they cross the placenta slowly and their transfer is said to be permeability dependent. The degree of ionization of a drug also affects its rate of passage across the placenta. The fetus has a pH about 0.1 lower than the mother therefore there is a tendency for basic drugs (e.g. some opioid analgesics) to be trapped on the fetal side of the placenta (see *Anaesthesia and Intensive Care Medicine* **2:5:** 171). Normally protein binding masks this effect, but it can cause problems if the fetus is acidotic.

The amount of drug transferred to the fetus also depends on the plasma concentration of free drug in the mother and the duration of exposure. The maternal plasma concentration of drug increases with dose and is greatest when the intravenous route is used. Protein binding is also important because there is equilibrium between bound and free drug and only the free drug can cross the placenta. High doses of drug may saturate the binding sites causing an increase in free drug and greater availability for placental transfer. Protein binding also provides a reservoir of drug in the maternal circulation that can prolong fetal transfer. In general, the fetal compartment equilibrates slowly with the maternal circulation and single therapeutic doses of a drug seldom cause significant problems in the fetus. For example, an induction dose of an intravenous anaesthetic to the mother is unlikely to anaesthetize the fetus because only a small fraction of the dose reaches the fetal brain. Prolonged exposure to maternal concentrations of a freely diffusible drug results in similar drug exposure to mother and fetus.

For flow-dependent drugs, significant falls in drug transfer can occur if blood flow to the placenta is reduced. This occurs during uterine contraction and techniques have been used to reduce fetal drug exposure by injecting a bolus of drug at the appropriate time.

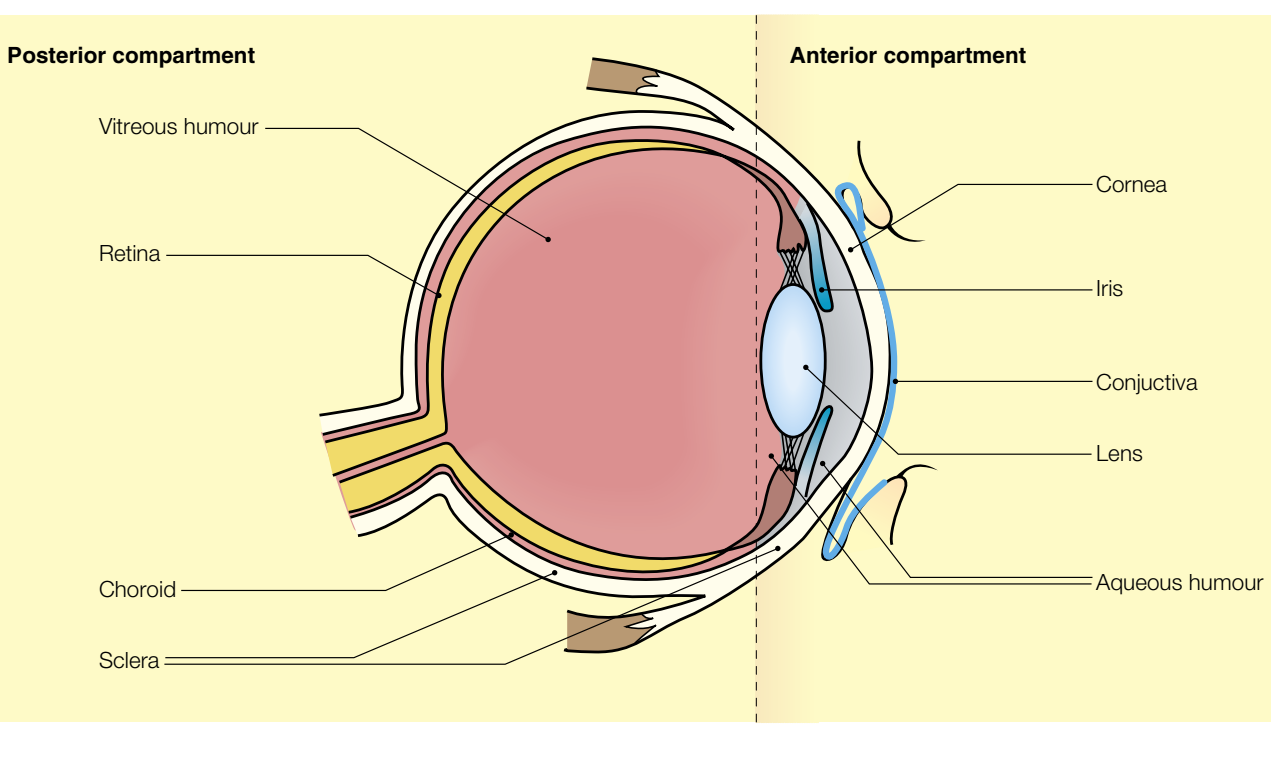
The placental transfer of some drugs used in anaesthesia is summarized in Figure 4.

Consequences of placental transfer of some drugs used in anaesthesia

Drug group	Effect on fetus	Comment
Opioids	Low Apgar scores at birth Respiratory depression in mother leading to fetal hypoxia	Cross placenta readily although different members of group differ in lipid solubility Morphine crosses the placenta least readily
General anaesthetic agents	Fetal depression Respiratory depression	More likely with prolonged induction to delivery time or high concentrations of drug
Neuromuscular blocking agents	Neonatal paralysis or slow commencement of respiration	Placenta crossed very slowly so seldom problems with normal doses
Local anaesthetic agents	Reduced motor tone	Probably does not occur Drugs are usually given via the epidural or intrathecal route and only small quantities reach the fetus

Although the fetus can metabolize many drugs, the enzyme systems are immature and the drug half-life may be increased. Examples include pethidine and lidocaine (lignocaine), which also have toxic metabolites with a long duration of action.

Eye
The sclera, conjunctiva, iris, retina, ciliary muscle and choroid have a moderately good blood supply but the cornea, lens and vitreous humour are avascular (Figure 5). Drugs can penetrate the structures and aqueous humour in the anterior compartment from the conjunctival sac. However, the volume of drug that can be administered by this route is limited. There is little perfusion each side of the conjunctival membrane, therefore the rate of drug movement from the tear film is proportional to lipid solubility and the degree of ionization of the drug. The cornea has a high water content and therefore water-soluble drugs (e.g. pilocarpine) can also penetrate into the aqueous humour. Many anti-infective agents can cross into the aqueous humour, but penicillins are actively extruded in the same way as they are from the CNS. Some drugs are bound to melanin which accounts for the slower onset of the mydriatic action of α-adrenergic agonists in patients with darkly pigmented irises. Drugs cannot reach the posterior compartment of the eye by diffusion from the conjunctival sac because the distance is too great. However, drugs can reach these structures through the systemic circulation. Melanin is also found in the retinal pigmental layer and chloroquine accumulates here causing retinal lesions that decrease visual acuity.



Skin and nails
Skin and nails are avascular, therefore penetration is relatively slow. Some drugs (e.g. the antifungal griseofulvin) have a high affinity for keratin and are concentrated in skin and nails. When treating microorganism infections of skin and hair it is important to consider the kinetics of turnover of these tissues. In the skin, microorganisms dwell in the stratum corneum, which is replaced every 2–3 weeks. Most drugs prevent the infection of new cells, therefore treatment for at least 4 weeks is required to eradicate the infection. Similar infection of the hair begins at the root, which is about 4 mm below the surface of the skin. Hair grows at 1 mm per week, therefore treatment must be continued for at least 6 weeks to be certain of cure.

Drug reservoirs

Protein binding: many drugs are bound to plasma proteins (see *Anaesthesia and Intensive Care Medicine* **2:8:** 314). Protein binding is usually reversible, though covalent binding of highly reactive drugs such as the alkylating agents can occur.

Fat is a large, non-polar compartment constituting on average 15–20% of body weight. Non-polar drugs can dissolve in fat where they exert no pharmacological action but form a large reservoir of drug in contact with the plasma. Blood supply to fat is relatively low, therefore partition occurs slowly and equilibrium between plasma and fat takes a long time to achieve. It is important to consider the amount of body fat when giving acute doses of highly lipid-soluble compounds such as the general anaesthetics and for chronic dosing with fairly fat-soluble drugs such as the benzodiazepines.

Fat also accumulates some food contaminants that are little metabolized, such as DDT, an insecticide widely used between 1940 and 1970. The content of DDT in human fat reached a peak in the 1970s. Since then its use has been banned and the concentrations in humans have gradually declined.

Bone: divalent metal ion chelating agents (e.g. tetracyclines) accumulate in bones and teeth where they may cause staining. This may be unsightly but is not dangerous. Toxic heavy metals (e.g. lead, radium) may also adsorb onto the bone surface and may become incorporated into the bone matrix. From there they may be released slowly into the blood causing toxic effects long after exposure has ceased. This accumulation of heavy metals by bone can be used therapeutically in the administration of strontium-89 in the treatment of bone metastases. Otherwise, drug access to bone is governed by the local blood flow.

Liver: prolonged treatment with the antimalarial quinacrine can result in liver concentration many thousand times that in the plasma. Amiodarone, a class III antidysrhythmic drug, accumulates in high concentration in the liver, lung and fat. It remains pharmacologically active for 6 weeks or more after administration has ceased.

Skin: when drugs are administered transdermally the skin may act as a reservoir continuing to supply the drug even after the skin patch has been removed. This has been reported for fentanyl patches (see *Anaesthesia and Intensive Care Medicine* **3:2:** 105). ◆

Bonding, Binding and Isomerism

Norman Calvey

Norman Calvey is Honorary Senior Research Fellow in the University Department of Anaesthesia, Liverpool, UK. He qualified in science and medicine from Liverpool University and has worked in departments of pharmacology and anaesthesia. His research interests include pharmacokinetics and drug isomerism.

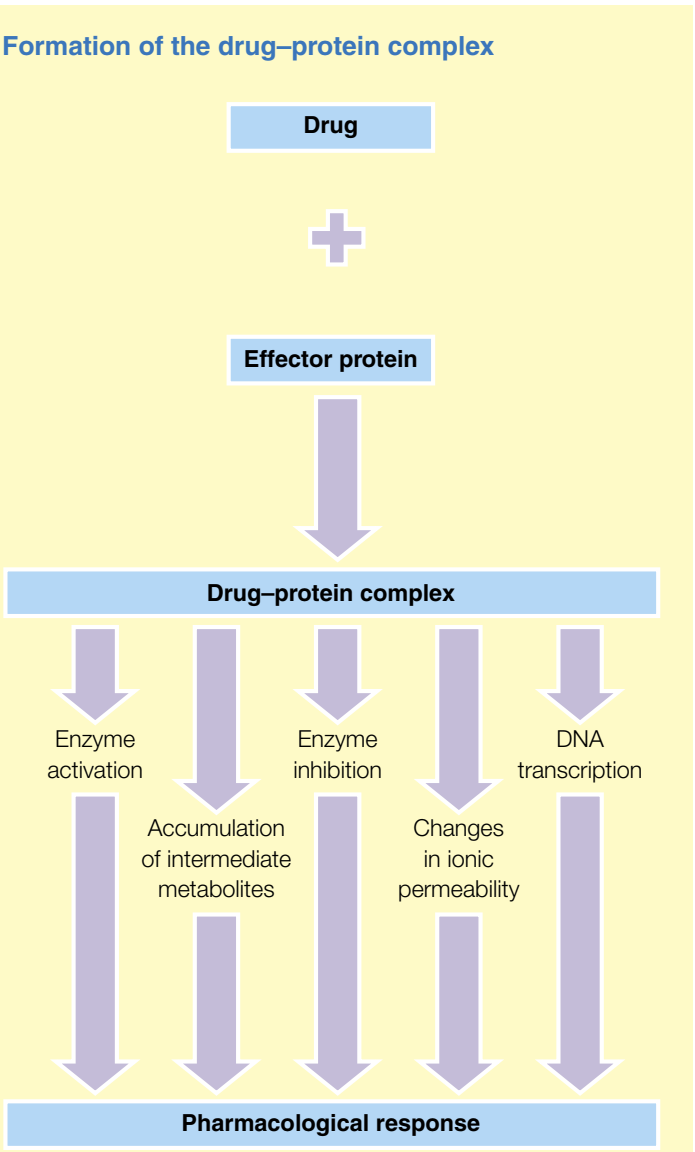
Some drugs are extremely potent agents, for example as little as several billion molecules of α-bungarotoxin, angiotensin II, or tetrodotoxin may produce effects on neuromuscular transmission, peripheral resistance, or nerve conduction. The body contains many trillions of molecules, therefore the effects of these drugs cannot depend on their random distribution, but must be governed by their selective binding to target cells or tissues. These principles were recognized by the German physician and scientist Paul Ehrlich more than 100 years ago, as summarized in his well-known dictum: *Corpora non agunt nisi fixata* (drugs will not act unless they are bound).

Although there are exceptions to this rule, it is applicable to almost all the drugs used in humans. The action of most drugs is dependent on their reversible binding to regulatory proteins in cells, which subsequently mediate their effects; binding to other cellular constituents is usually nonspecific and of lesser importance.

Binding of drugs to regulatory proteins

Regulatory proteins that mediate the actions of drugs are usually classified as enzymes, receptors, ion channels or other proteins (e.g. carrier proteins). A few drugs are bound by structural proteins (e.g. tubulin, immunophilin). Some drugs are bound by DNA (e.g. cytotoxic agents).

The combination of drug and effector protein usually results in the formation of a transient drug–protein complex, which produces secondary effects on protein function (Figure 1). The protein binding of drugs is also essential for their elimination from the body by metabolic enzymes or transport proteins.



1

Drug binding and drug design

Recently, the molecular binding sites on many enzymes and receptors have been defined and characterized. In some instances, the effects of drugs have been related to their molecular structure, and paradigms of their binding sites on target proteins have been obtained. In other instances, it has been possible to determine the structure of receptors and drug–receptor complexes by X-ray crystallography or nuclear magnetic resonance spectroscopy. These techniques often allow the conformation of drugs at their binding sites to be established, as well as the structure and configuration of their target regulatory proteins.

As a consequence of these studies, three-dimensional models of drug–protein complexes may lead to the design and synthesis of chemical analogues that bind to target proteins with enhanced selectivity or affinity. Alternatively, large chemical libraries can be searched by computer programs for compounds with specific three-dimensional structures that will combine with the target receptor or enzyme protein.

Plasma protein binding

The binding of drugs by plasma proteins plays an important part in their distribution after oral or intravenous administration, and facilitates access to their site of action. Most drugs are relatively lipid soluble, with a low solubility in plasma water, therefore protein binding is essential for their transport and rapid distribution.

Drugs are usually reversibly bound to plasma proteins, according to the reaction:

unbound drug + protein ↔ drug–protein complex

During tissue perfusion, the concentration of unbound drug in plasma falls, and the protein-bound drug rapidly dissociates. Consequently, a continuous concentration gradient is present for the diffusion of drugs from plasma to tissues.

Quantitative aspects

Plasma protein binding of drugs may range from zero to almost 100% (Figure 2). There are considerable differences in the degree of protein binding, even among closely related drugs. Thus, the binding of local anaesthetics to α_1-acid glycoprotein ranges from 6% (procaine), 55% (prilocaine), 65% (lidocaine (lignocaine)) to 94–95% (ropivacaine and bupivacaine); these values are reflected by the binding of their bases to ion channels, which are responsible for differences in their duration of action and toxicity.

In general, only the unbound fraction of drugs in plasma is available for diffusion into tissues, and is therefore responsible for their pharmacological effects. For some drugs (e.g. diazepam, phenytoin, warfarin), unbound concentrations in plasma are only 1–2% of total plasma levels. They can be determined by *in vitro* techniques (such as equilibrium dialysis, ultracentrifugation or ultrafiltration). Salivary secretions and CSF samples may also reflect the concentration of the unbound drug in plasma.

Drugs and endogenous agents are bound by albumin, globulins or a combination of the two.

Plasma protein binding of some common drugs (at conventional plasma concentration)

Drug	Plasma protein binding (%)	Binding protein
Procaine	6	
Prilocaine	55	
Lidocaine (lignocaine)	65	
Tetracaine (amethocaine)	75	
Ropivacaine	94	
Bupivacaine	95	
Morphine	30	α_1-acid glycoprotein
Pethidine	64	
Fentanyl	80	
Alfentanil	90	
Pindolol	50	
Propranolol	80	
Atenolol	0	
Atracurium	< 20	
Vecuronium	< 20	
Pancuronium	30	α_1-acid glycoprotein
Tubocurarine	50	and albumin
Methohexital (methohexitone)	80	
Thiopental (thiopentone)	80	
Phenytoin	95	Albumin
Diazepam	97	
Warfarin	99	

2

Binding to albumin: albumin plays the predominant role in the binding of drugs by plasma proteins. Each albumin molecule has at least two binding sites with a variable affinity for drugs, and mainly binds acidic or neutral compounds (e.g. salicylates, non-steroidal anti-inflammatory drugs, tolbutamide, sulphonamides, oral anticoagulants). Some basic drugs and physiological substrates (e.g. bilirubin, tryptophan) are also bound by albumin.

Binding to globulins: plasma globulins mainly bind basic drugs (e.g. phenothiazines, local anaesthetics, opioid analgesics). Drugs are usually bound by β-globulins, or by an acute-phase protein (α_1-acid glycoprotein). Many vitamins and endogenous hormones are also bound by plasma globulins. Hydrocortisone (cortisol) is mainly bound with high affinity by a specific protein (transcortin). Similarly, thyroxine, oestrogens and progestogens are bound by specific globulins.

Binding to albumin and globulins: some muscle relaxants (e.g. tubocurarine, pancuronium) are bound to both albumin and globulins. The resistance to their action that is sometimes seen in liver disease may be related to increased plasma protein binding.

Plasma protein binding and pathological conditions

In pathological conditions associated with hypoalbuminaemia (e.g. hepatic cirrhosis, nephrosis, trauma, burns), drug binding to plasma proteins is modified. The plasma concentrations of unbound drugs may be increased, and can cause toxic effects, for example with prednisolone and phenytoin. These changes are most likely when drugs are given in large doses or intravenously. In these conditions, the binding of drugs by albumin may be saturated, causing an increase in their unbound concentrations. Well-perfused tissues and organs (e.g. heart, liver, kidneys, brain) may receive a higher proportion of the dose, resulting in toxic effects. A similar phenomenon may occur in those with renal impairment and in the elderly, possibly because of the altered affinity of drugs for albumin.

Plasma concentrations of the acute-phase globulin α_1-acid glycoprotein are often increased after surgery and in certain conditions (e.g. myocardial infarction, rheumatoid arthritis, ulcerative colitis, Crohn's disease, renal failure, malignant disease). In these conditions, the binding of basic drugs (e.g. propranolol, local anaesthetics, opioid analgesics) may be modified, resulting in a decrease in the concentration of unbound drug.

Plasma protein binding and drug elimination

Plasma protein binding may restrict the hepatic clearance of extensively bound drugs (> 70% bound) with a low intrinsic hepatic clearance (e.g. diazepam, phenytoin, warfarin). In these conditions, plasma protein binding may limit the access of drugs to hepatic enzyme systems, decreasing their clearance and prolonging their terminal half-lives. In other circumstances, plasma protein binding does not restrict the hepatic or renal elimination of drugs or drug metabolites. Some extensively protein-bound substances (e.g. para-amino-hippurate, diodrast and benzylpenicillin) are almost completely eliminated in a single passage through the renal circulation.

Plasma protein binding and drug interactions
Drugs that are extensively bound may be displaced from their binding sites on plasma proteins by other agents, thus producing drug interactions. In practice, most drugs are extremely potent, and their plasma concentrations after therapeutic doses are less than the millimolar levels required to saturate their binding sites. In these conditions, displacement reactions are unlikely; any displacement may transiently raise the unbound concentration, but this will usually be compensated for by increased renal and hepatic clearance.

For these reasons, it is now thought that plasma protein displacement reactions alone are not an important cause of drug interactions. When they occur, they are most likely to involve drugs or endogenous substances that are predominantly confined to plasma, and those that have a narrow therapeutic index.

Chemical nature of drug binding

The binding of drugs by regulatory or plasma proteins may involve at the least the four different types of chemical bonding described below.

Ionic (electrostatic) attraction: ionized compounds may be attracted to anionic or cationic sites on proteins, forming readily reversible bonds. Some tertiary and quaternary amines (e.g. acetylcholine, neostigmine, glycopyrrolate) are attracted by an anionic glutamate group (glutamate 202) in acetylcholinesterase, facilitating their reaction with the enzyme. Similarly, in the anticoagulant heparin an anionic pentasaccharide sequence is attracted to basic arginine residues in antithrombin III, forming a stable complex. This enhances inhibition of thrombin and other activated coagulation factors.

Dipole–dipole interactions: molecules with partially positive and partially negative charges can attract or repel each other in solution; opposite charges are attracted while similar charges are repelled. Nonpolar molecules can be attracted to each other by induced dipole–dipole interactions known as London forces. Both attractive and repulsive dipole–dipole interactions are usually collectively known as van der Waals forces, and are dependent on intermolecular distance. The critical distance at which intermolecular attraction is greatest is known as the van der Waals radius.

Hydrogen bonding is a powerful type of dipole–dipole interaction. It takes place between partially positive hydrogen atoms in secondary amine (-NH) or hydroxyl (-OH) groups and adjacent electronegative atoms with unshared electrons (e.g. oxygen, nitrogen or fluorine atoms). Hydrogen bonds are rapidly reversible bonds, the dissociation energy of which is higher than in other dipole–dipole interactions.

Covalent bonds are stable chemical bonds (owing to the sharing of a pair of electrons by two atoms). They have a relatively high dissociation energy (8–10 times that of hydrogen bonds) and typically occur between carbon and its compounds. Drugs that are bound to receptors and enzymes by covalent bonds (e.g. phenoxybenzamine, most monoamine oxidase inhibitors) usually have a long duration of action (days or weeks).

Isomerism

Isomers are chemical entities with identical numbers of different atoms. Although they have the same chemical composition and molecular formula, their physical and chemical properties may be different (depending on the type of isomerism involved). The two main types of isomerism are structural isomerism and stereoisomerism.

Structural isomerism
Structural isomers have an identical molecular formula but different chemical structures, because their individual atoms are not arranged in the same manner. Individual structural isomers are usually identified as entirely different drugs with distinctive names (e.g. isoflurane, enflurane).

Tautomerism (dynamic isomerism) is a type of structural isomerism. In tautomerism, two unstable structural isomers in equilibrium can be converted to each other (usually by pH changes). Tautomerism is partly responsible for the increased lipid solubility of thiopental (thiopentone) and methohexital (methohexitone) after intravenous use.

Stereoisomerism
Stereoisomers have the same molecular formula and chemical structure but a different configuration (i.e. the spatial arrangement of their substituent groups differs). They are usually classified as enantiomers or diastereomers.

Enantiomers are pairs of stereoisomers that are non-super-imposable mirror-images of each other. This type of stereoisomerism depends on the presence of a chiral centre in their molecular structure, which is usually a single carbon atom with four different substituents. Drugs with this type of structure (chiral drugs) have a mirror-image that cannot be superimposed on their original configuration, and therefore exist in two enantiomeric forms (R and S isomers). Both enantiomers are optically active; one of them rotates polarized light to the right (the (+) or (d) form), while the other rotates polarized light to the left (the (–) or (l) form). Consequently, individual stereoisomers are designated as R(+), R(–), S(+) or S(–). Equal mixtures of the two enantiomers (racemic mixtures) have no optical activity. In recent decades, progress in chemical technology has simplified the synthesis and preparation of individual R and S enantiomers (e.g. by asymmetric chemical syntheses, or by the chiral inversion of one enantiomer).

Diastereomers are pairs of stereoisomers that are not enantiomers (i.e. not mirror-images), and usually have different physical and chemical properties. Although some of the stereoisomers of methohexital (methohexitone), tramodol, atracurium and mivacurium are enantiomers, others are diastereomers.

Racemic mixtures: about 60% of commonly used anaesthetic agents are chiral drugs. Most of them are administered as racemic mixtures of R and S isomers, including most inhalational anaesthetics, some intravenous agents and local anaesthetics, and many autonomic drugs (Figure 3). Although both enantiomers have the same structure, they have a different configuration, and their substituent groups occupy different positions in space. Consequently, they may form different three-dimensional relationships in the asymmetric environment of receptors and enzymes, which mainly consist of L-amino acids with stereoselective properties. In these conditions, there may be differences between the pharmacodynamic activity and pharmacokinetic properties of individual enantiomers, since their relationship with specific receptor sites and hepatic enzyme systems may not be identical.

Some chiral drugs used in anaesthetic practice

Single isomers	Two isomers (racemic mixtures)	More than two isomers
• Etomidate	• Methohexital (methohexitone)	• Atracurium
• Levobupivacaine	• Thiopental (thiopentone)	• Mivacurium
• Ropivacaine	• Ketamine	
• Cisatracurium	• Halothane	
• Vecuronium	• Enflurane	
• Pancuronium	• Isoflurane	
• Rocuronium	• Desflurane	
• Hyoscine	• Prilocaine	
• Morphine	• Bupivacaine	
	• Adrenaline (epinephrine)	
	• Noradrenaline (norepinephrine)	
	• Dobutamine	
	• Atropine	
	• Glycopyrrolate	

Differences in pharmacodynamic activity: there are often differences in the potency of individual enantiomers (suggesting that drug action is related to interaction with proteins). Isoflurane is an example of this phenomenon; in most experimental conditions the S(+)-stereoisomer is about 20% more potent than its enantiomer. Greater differences in potency are not uncommon; thus, S(+)-ketamine is 3–4 times more potent than R(–)-ketamine, while l-atropine, l-noradrenaline, and l-adrenaline are 50–100 times more potent than their d-enantiomers. These differences in potency can be expressed by the eudismic ratio (stereospecific index), which represents the activity of the more active isomer (the eutomer) in relation to its antipode (the distomer). Eudismic ratios greater than unity may be due to differences in the affinity or intrinsic activity of the enantiomers.

In other instances, there are qualitative differences in pharmacological activity. Occasionally the enantiomers have complementary actions, and both contribute to the overall activity of drugs (e.g. tramadol, dobutamine). In other cases, one isomer is an agonist, while its enantiomer is a partial agonist or competitive antagonist.

Differences in pharmacokinetic properties: in some instances, one isomer is more rapidly metabolized than its enantiomer. Thus, R(+)-propranolol, R(–)-prilocaine and S(+)-ketamine are more rapidly metabolized than their enantiomers, and have a higher hepatic clearance. Alternatively, one enantiomer may inhibit the metabolism of its antipode (e.g. R(–)-ketamine). Similar metabolic interactions are known to occur with other chiral drugs (e.g. levomethorphan).

Some inactive enantiomers undergo unidirectional metabolic conversion (‘inversion’) to their antipodes. Both R(–)-ibuprofen and R(–)-fenoprofen are converted to their more active S(+)-enantiomers after oral absorption, thus enhancing the potency of the racemic mixture.

Differences in the metabolism and distribution of enantiomers can affect the pharmacokinetics of chiral mixtures, and the isomers may have different half-lives, clearances, and volumes of distribution.

Single enantiomers: a number of chiral anaesthetic agents (e.g. etomidate, ropivacaine, levobupivacaine) have been synthesized and used as single isomer preparations, which may have certain advantages. For example, levobupivacaine may be less cardiotoxic and have a longer duration of action than racemic bupivacaine; ropivacaine has similar properties. Cisatracurium is also a single isomer preparation, which is more potent and causes less histamine release than atracurium.

Some drugs derived from plants or organisms are also single stereoisomers (e.g. l-hyoscine), because naturally occurring enzymes are stereoselective and synthesize drugs in a distinct and specific configuration.

Complex stereoisomeric mixtures: some anaesthetic agents are administered as mixtures of more than two stereoisomers (Figure 3). Atracurium contains ten different stereoisomers, while mivacurium is a mixture of three isomers. Methohexital (methohexitone) was originally synthesized and used as two pairs of enantiomers (i.e. four isomers); the drug is now used as a chiral mixture of the two less excitatory forms.

Current perspective: in many countries, drug regulatory authorities have encouraged the development and use of new drugs as single stereoisomers. Since 1990, most new drugs have been used as specific enantiomers, and it seems likely that this trend will continue.

His interests include the pharmacology of substances used for medical or recreational purposes to modify brain activity.

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. Her research interests include pain, analgesia and anticonvulsant drugs.

CNS stimulants increase the activity of the brain and/or spinal cord. They have a long history beginning with the use of plants (e.g. *Camellia sinensis* contains caffeine, *Erythroxylum coca* cocaine) to produce psychostimulation, reduce appetite, fatigue and the tendency to sleep, and increase alertness and vigilance. CNS stimulants now include synthetic chemicals (e.g. amfetamines (amphetamines)) which are used widely for non-medical recreational or social purposes. Some have therapeutic uses in peripheral tissues, which may cause CNS stimulation as an adverse effect.

Classification of CNS stimulants as psychomotor stimulants acting on the cerebral cortex, analeptics stimulating medullary respiratory centres, or spinal cord stimulants enhancing reflexes can be misleading because stimulation is dose dependent and may spread to other CNS areas with high doses. Despite their long-established use, knowledge of the neurochemical effects of CNS stimulants in humans is incomplete. Nevertheless, their preferred grouping reflects the pharmacological mechanisms perceived to be responsible for their stimulant activity (i.e. sympathomimetics, methylxanthines or convulsants).

Sympathomimetics

Mechanism of action

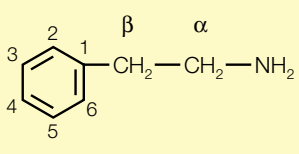
Numerous β-phenylethylamine derivatives structurally similar to the sympathetic nervous system neurotransmitter, noradren-aline (norepinephrine) exist as natural products, in foods (e.g. tyramine) or plants (e.g. ephedrine), and in synthetic drugs (e.g. amfetamine (amphetamine)) (Figure 1). They produce effects characteristic of increased sympathetic nervous system activity, hence the term sympathomimetics. Receptors for noradrenaline (norepinephrine) and two other important catecholamine messengers, adrenaline (epinephrine) and dopamine, are located in peripheral tissues and the CNS. Phenylethylamines, binding as agonists to postsynaptic receptors (e.g. phenylephrine (Figure 1f)) at α_1-adrenoceptors, elicit direct responses from postsynaptic neurons or effector cells. Some β-phenylethylamine derivatives lack the necessary molecular attributes to bind directly to catecholamine receptors (e.g. tyramine (Figure 1c)). This type of compound indirectly enhances the activity of endogenous monoamines (catecholamines and possibly the indolealkylamine, serotonin) by inhibiting monoamine:

- metabolism, by monoamine oxidases
- reuptake, into cells by transporters
- storage, in vesicles and extravesicular pools.

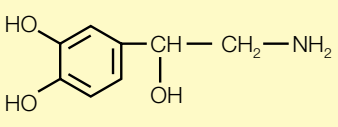
The extent to which a sympathomimetic acts directly and/or indirectly on receptors is not easily identified from its molecular structure, but can be determined experimentally. Most sympathomimetics have some affinity for catecholamine receptors. The type(s) of monoamine receptor (α-adrenoceptors, β-adrenoceptors, dopamine receptors, serotonin receptors) for which a sympathomimetic shows affinity is determined by its molecular structure, and may be different from the receptors acted on by endogenous biogenic amines. Thus, the pharmacological profile of a sympathomimetic may not be consistent with simple enhancement of physiological activity mediated by endogenous monoamine activity.

The biological effects of many catecholamines, including the major neurohumoral transmitters, are short lasting because of in-activation by enzymes, mainly monoamine oxidases (MAO), and/or reuptake into cells. Inhibition of MAO and/or uptake potentiates endogenous monoamines and directly acting sympathomimetics, therefore interactions between antidepressants working by these mechanisms and sympathomimetics cause, for example, hypertensive crisis. Substitution for H on the α-carbon in β-phenylethylamine blocks oxidation by MAO, consequently compounds such as amfetamine (amphetamine) and ephedrine with CH_3 on the α-carbon act for hours, not minutes (Figure 1). Cocaine and structurally related drugs potentiate endogenous monoamines and directly acting sympathomimetics, mainly by preventing transporters carrying monoamines into axon terminals or glial cells.

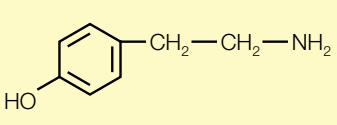
Some β-phenylethylamines with sympathomimetic, CNS stimulant and/or hallucinogenic activity



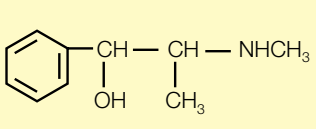
a β-phenylethylamine



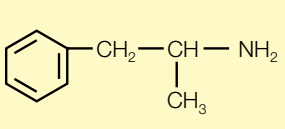
b Noradrenaline (norepinephrine)



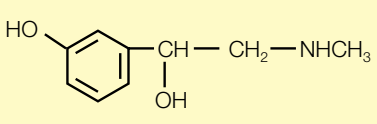
c Tyramine



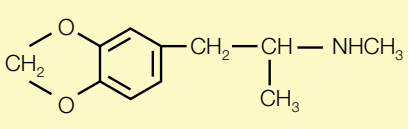
d Ephedrine



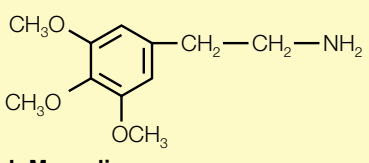
e Amfetamine (amphetamine)



f Phenylephrine



g 3,4-methylenedioxymethamfetamine (MDMA, Ecstasy)



h Mescaline

1

The increased monoamine–receptor interactions produced directly or indirectly by sympathomimetics produce peripheral and central effects. Sympathomimetics are used clinically for their peripheral actions as mydriatics (phenylephrine) and nasal decongestants (ephedrine, phenylephrine). Although their decongestant effect is limited by rebound vasodilatation and congestion on withdrawal, sympathomimetics have widespread use in self-medication products on public sale. Even after local application to the eye or nose, systemic absorption of these agents can occur, producing adverse effects peripherally (e.g. arrhythmias, tachycardia, hypertension) and centrally (e.g. dizziness, insomnia).

Lipophilicity is one prerequisite for CNS drug activity, thus β-phenylethylamine derivatives with few polar groups tend to have greater CNS stimulant activity. This is illustrated by am-fetamine (amphetamine) (Figure 1e) and its active isomer, dexamfetamine (dexamphetamine), which lack OH on the β-carbon, as possessed by ephedrine, and are more potent CNS stimulants. Sympathomimetics producing CNS stimulation have limited, regulated therapeutic use: dexamfetamine sulphate and methyl-phenidate in the management of attention deficit/hyperactivity disorder and narcolepsy. CNS stimulants have no approved application in the treatment of depression, obesity, senility or the relief of fatigue, because of their toxicity and abuse potential.

Abuse

CNS stimulation – psychostimulation produced by amfet-amines (amphetamines) and cocaine appeals to some people for non-medical recreational purposes. Legislation controlling the manufacture, supply and possession of abused drugs has promoted the production and use of unregulated derivatives presumed, sometimes erroneously, to have a similar pharmacology to the parent compound. These so-called 'designer drugs' are not designed to improve the safety of established drugs, but to evade legal restrictions. In the case of CNS stimulants, the designer drugs in current use are structurally related to amfetamine (amphetamine). Many amfetamine (amphetamine) derivatives are manufactured for illegal recreational use, the most familiar being 3,4-methylenedioxymethamfetamine (Ecstasy; Figure 1g).

Hallucinogens – amfetamine-related compounds possess CNS activity, variously described as hallucinogenic or pyschoto-genic. Substitutions for OH on the β-phenylethylamine ring can produce compounds with marked hallucinogenic activity (e.g. methylenedioxy derivatives such as Ecstasy are more potent hallucinogenic agents than amfetamine). Dimethoxy derivatives of β-phenylethylamine (e.g. 2,5-dimethoxy-4-methamfetamine (street name, STP)) are structurally similar to the naturally occurring hallucinogen mescaline, extracted from *Lophophora williamsi* (Figure 1h). Although similar in structure to hallucinogenic β-phenylethylamines, mescaline does not have a significant effect on adrenergic mechanisms. Mescaline and other hallucinogenic β-phenylethylamines depress serotonergic neuron activity in the brain, a property shared with hallucinogens with an indolealkylamine structure (e.g. bufotenine, lysergide (lysergic acid diethylamide), psilocybin). Both chemical classes of hallucinogens produce qualitatively similar autonomic, sensory and perceptual effects. In addition, there is cross-tolerance between mescaline and lysergide. Indications are that these hallucinogens share a common site of action, possibly serotonin receptors.

Adverse effects – CNS stimulation and hallucinations appear to be separate actions of sympathomimetic amines. These parallel pharmacological effects of Ecstasy-like drugs attract abuse by numerous people seeking relief from fatigue and/or heightened sensory perception, particularly of audio and visual stimuli, with the further prospect of experiencing synaesthesia, elation and euphoria. These drugs can cause severe adverse effects consistent with their sympathomimetic, CNS stimulant and hallucinogenic properties, including agitation, convulsions, delirium, hyperreflexia, hyperthermia and ventricular arrhythmias. Adverse effects may occur with acute doses previously tolerated. Chronic use leads to tolerance, dependence and personality changes, including psychosis possibly secondary to organic brain damage. Failure by hospital staff in England to recognize and treat the adverse effects of Ecstasy has recently resulted in damages being awarded to a recreational drug abuser.

Anaesthesia

Patients with a history of acute or chronic amfetamine (amphet-amine) abuse or taking amfetamine-like drugs for medical reasons may present for surgery and general anaesthesia. Acutely these drugs release endogenous monoamines from neuronal stores, but chronic use may lead to depletion of these stores. This may result in a patient being unable to respond to stimuli normally modulating blood pressure, and possibly unexpected hypotension. Patients should therefore be withdrawn from amfetamine-like drugs before elective general anaesthesia. However, a recent paper reports successful anaesthesia in a patient with narcolepsy treated with a combination of amfetamine and dexamfetamine for more than 40 years (see Further Reading). Nevertheless, there are reports of severe hypotension in such patients if amfetamine-like substances are not withdrawn. Most authorities recommend intensive cardiovascular monitoring and the availability of a directly acting sympathomimetic (e.g. phenylephrine) if withdrawal is impossible before general anaesthesia.

Methylxanthines

Caffeine (1,3,7-trimethylxanthine) is the most potent CNS stimulant of the three major naturally occurring methylxanthines, the others being theophylline (1,3-dimethylxanthine) and theobromine (3,7-dimethylxanthine) (Figure 2). Although a weak CNS stimulant in comparison with sympathomimetics, caffeine occurs in coffee, tea, chocolate, cola and guarana drinks and has become established as the most widely consumed socially acceptable (i.e. legal) CNS stimulant in the world. In addition to its importance as an ingredient in beverages used for cultural and recreational purposes, caffeine can produce physical and psychic dependence, which contributes further to its frequent and sometimes excessive use. Caffeine is formulated into numerous compound analgesic preparations available to the public for the claimed purpose of enhancing the analgesic action, possibly by increasing gastrointestinal absorption of the analgesic. Solid dose forms of caffeine for CNS stimulation are also on public sale.

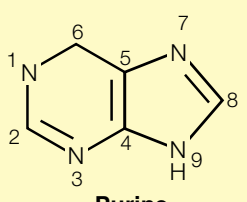
Mechanism of action – methylxanthines influence cell activity by three major mechanisms:

- antagonism at adenosine receptors
- inhibition of cyclic nucleotide phosphodiesterases
- translocation of intracellular Ca^{2+}.

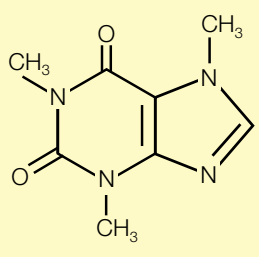
Endogenous adenosine (Figure 2) modulates the physiological activity of numerous cell types by binding to at least four types of specific G protein-linked receptors. Adenosine, interacting with receptors in the CNS, causes decreased release of excitatory neurotransmitters producing anticonvulsant, antipsychotic and sedative effects. Caffeine at concentrations producing CNS stimulation competitively antagonizes adenosine binding to its receptors; phosphodiesterase inhibition and Ca^{2+} mobilization occur at higher concentrations and contribute to its toxicity.

Clinical pharmacology – caffeine is used widely to relieve mental fatigue, produce wakefulness and shorten reaction times. Methylxanthines also have peripheral effects including bronchodilatation exploited clinically with theophylline and its more soluble derivative, aminophylline when CNS stimulation and insomnia can occur as adverse effects. Excessive amounts produce symptoms of anxiety, insomnia, restlessness, muscle tremor, tachycardia and extrasystoles. Large doses of caffeine may cause convulsive movements as stimulation spreads from higher centres to motor areas, medulla and spinal cord. The stimulant action of caffeine on the medullary vasomotor centre is usually offset by its peripheral vasodilator effect on arterioles; blood pressure is unchanged. The lethal dose of caffeine in humans is high, but death has been attributed to overdose with caffeine tablets.

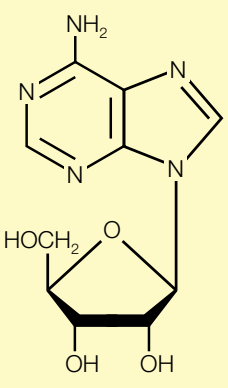
Methylxanthines: structural relationship to the purinergic neurotransmitter, adenosine



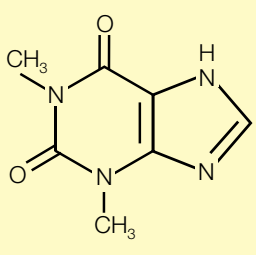
Purine



Caffeine
(1,3,7-trimethylxanthine)



Adenosine



Theophylline
(1,3-dimethylxanthine)

Theobromine
(3,7-dimethylxanthine)

Convulsants

Convulsions can be produced by agents acting in various ways at different sites. Many convulsants act by disinhibition (i.e. preventing the tone exerted by inhibitory neurotransmitters). This covers methylxanthines acting as adenosine receptor antagonists, but their social acceptance and low toxicity arbitrarily excludes them from this group, which includes convulsants such as the glycine receptor antagonist, strychnine. The group includes respiratory stimulants or analeptics, which were once widely used to treat ventilatory failure. In excessive dose, respiratory stimulants including nikethamide can cause convulsions, therefore physical methods of ventilatory support (e.g. nasal intermittent positive-pressure ventilation) are now first-line treatment.

Doxapram is the only drug in this group that is still generally available, owing to its wider margin of safety than other analeptics (e.g. nikethamide, ethamivan). In healthy individuals, doxapram increases tidal volume and respiratory rate and consequently produces a fall in the partial pressure of carbon dioxide in arter-ial blood ($PaCO_2$) and a rise in that of oxygen (PaO_2). The exact mechanism is unknown, but it is thought to involve stimulation of peripheral chemoreceptors in the carotid body. Single doses have a short duration of effect (less than 1 hour) owing to redistribution rather than metabolism; even so the drug has a short half-life (about 3 hours) and is usually administered intravenously as a continuous infusion. Doxapram is metabolized in the liver. The main metabolite, keto-doxapram, has some pharmacological activity and accumulates after prolonged infusions. The indication for doxapram treatment is limited to the management of patients with hypercapnic respiratory failure who are unsuitable for intubation and ventilation. It is contraindicated in respiratory failure secondary to asthma, pneumothorax, pulmonary embolism or oedema. Some recent studies investigated the usefulness of low doses of doxapram in the management of apnoea of prematurity (see Further Reading) and concluded doxapram may be a useful second-line drug when other therapies, including methylxanthines as first-line drug therapy, have failed. ◆

Drug Targets

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Most drugs bind to a particular cellular component in order to produce their effects; exceptions are the osmotic diuretics and antacids. Some antitumour and antimicrobial drugs directly target DNA, but targeting proteins is the most common method of drug action.

General anaesthetics were thought to interact with membrane lipids (see page 329) but this has been questioned as more is revealed about how general anaesthetics modulate ligand-gated ion channels.

Typical protein drug targets

Carrier molecules

Ions and polar organic molecules require a carrier protein to transport them across the lipid cell membrane. Examples of therapeutic importance are the 5-hydroxytryptamine (5-HT) and noradrenaline transporters, which are inhibited by the tricyclic and related antidepressant drugs, the Na^+-K^+-$2Cl^-$ co-transporter, which is inhibited by loop diuretics and the proton pump, which is inhibited by omeprazole. Research in many pharmaceutical companies is targeting other carrier molecules such as glutamate and γ-aminobutyric acid (GABA) transporters, which may be the basis for new classes of drugs.

Enzymes

Most biochemical reactions occur through the actions of catalytic proteins called enzymes. They may be inhibited reversibly, such as the inhibition of cyclo-oxygenase by ibuprofen, or irreversibly, such as the inhibition of cyclo-oxygenase by aspirin. It is now known that many enzymes exist as multiple isoforms and some recently developed drugs have selectivity for one or more of these variants. Cyclo-oxygenase has two isoforms; COX-1 and COX-2. COX-2 is induced in activated inflammatory cells and produces the prostaglandin mediators of inflammation. COX-1 is expressed in most tissues and mediates many of the protective effects of prostaglandins. Drugs selective for the COX-2 enzyme (e.g. celecoxib, rofecoxib) are anti-inflammatory but do not cause the gastric irritation commonly seen with non-selective non-steroidal anti-inflammatory drugs in patients without gastrointestinal pathology.

Enzymes may also convert pro-drugs into an active form such as the conversion of heroin and codeine to morphine or zidovudine to zidovudine triphosphate. Toxic metabolites may also be produced by enzyme activity, for example trifluoroacetic acid from halothane and N-acetyl-p-benzoquinoneimine from paracetamol.

Drugs may also be a false substrate for an enzyme, thus blocking the normal function of the enzyme, for example the replacement of uracil by fluorouracil in DNA synthesis.

Voltage-gated ion channels

Some membrane-spanning proteins can change shape depending on the membrane potential. This allows ions access across the membrane through a central channel, which opens within the protein. The shape and size of the channel determines which ions pass through and the speed of passage depends on the transmembrane concentration gradient for that particular ion. Drugs can modulate the activity of voltage-gated ion channels by opening, closing or blocking them. In addition, a drug may act indirectly via G-protein modulation of channel opening.

An example of drug-induced channel blockade, which has been in routine clinical use for many years, is the action of local anaesthetics on sodium channels. Local anaesthetics simply block the sodium channel. In contrast, L-type calcium-channel blockers (e.g. verapamil, nifedipine) affect the gating process of the channel rather than blocking ion passage. Blockade of T-type calcium channels may be important in the anticonvulsant action of several drugs, such as ethosuximide and flunarizine.

Many biotoxins are selective for specific ion channels. For example, tetrodotoxin, from the Japanese puffer fish, blocks most sodium channels and scorpion α-toxin opens them. Ziconotide, a derivative of ω-conotoxin from sea snails, is an N-type calcium-channel-blocking drug and is being studied as a potential treatment for chronic pain. Potassium channel pharmacology is rapidly expanding and the basis of the vasodilator action of minoxidil and diazoxide has been revealed as the opening of ATP-sensitive potassium channels. In addition, the antidiabetic drug glibenclamide closes this channel. Non-selective voltage-sensitive potassium-channel-blocking agents include tetraethylammonium and 4-aminopyridine, but their clinical use is limited by convulsions and nausea. More selective drugs acting on the voltage-sensitive potassium channels are being sought.

Receptors

Receptors are defined pharmacologically as proteins that regulate a particular physiological role in response to recognition of a particular molecular shape. A typical example is noradrenaline (norepinephrine) activating the α-adrenoceptor and causing the contraction of vascular smooth muscle. Receptors are the targets of most drugs presently in use.

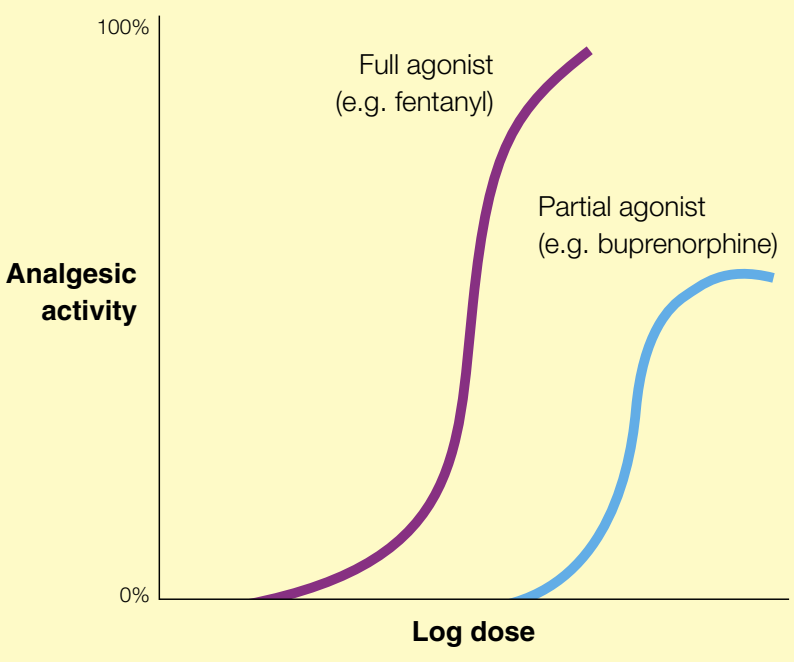
Agonists and antagonists

An agonist can be defined as a molecule that binds to a receptor, causing activation and a resultant cellular change. An antagonist may bind to the same receptor but cannot initiate a response, thus blocking that receptor to an agonist. Antagonists are sometimes defined as drugs that can prevent the action of an agonist, but this definition must apply equally to physiological or functional antagonism, where a drug exerts an opposite effect, thus antagonizing the action of an agonist. An example of such an interaction would be the antagonism of histamine-induced vasodilatation by adrenaline (epinephrine).

A full agonist can produce the largest response that the effector organ is capable of giving. The term efficacy has been used to describe the way that agonists can vary in the response that they produce even when occupying the same number of receptors. A high-efficacy agonist produces a maximum response even when occupying a small proportion of the available receptors.

A partial agonist cannot fully activate the receptor irrespective of the concentration available. In contrast to a full agonist, a partial agonist cannot exert a maximal response. Buprenorphine is a partial agonist at opioid μ receptors. Partial agonists have lower efficacy and cannot produce a maximal response even when occupying all the receptors (Figure 1).

Receptor agonists

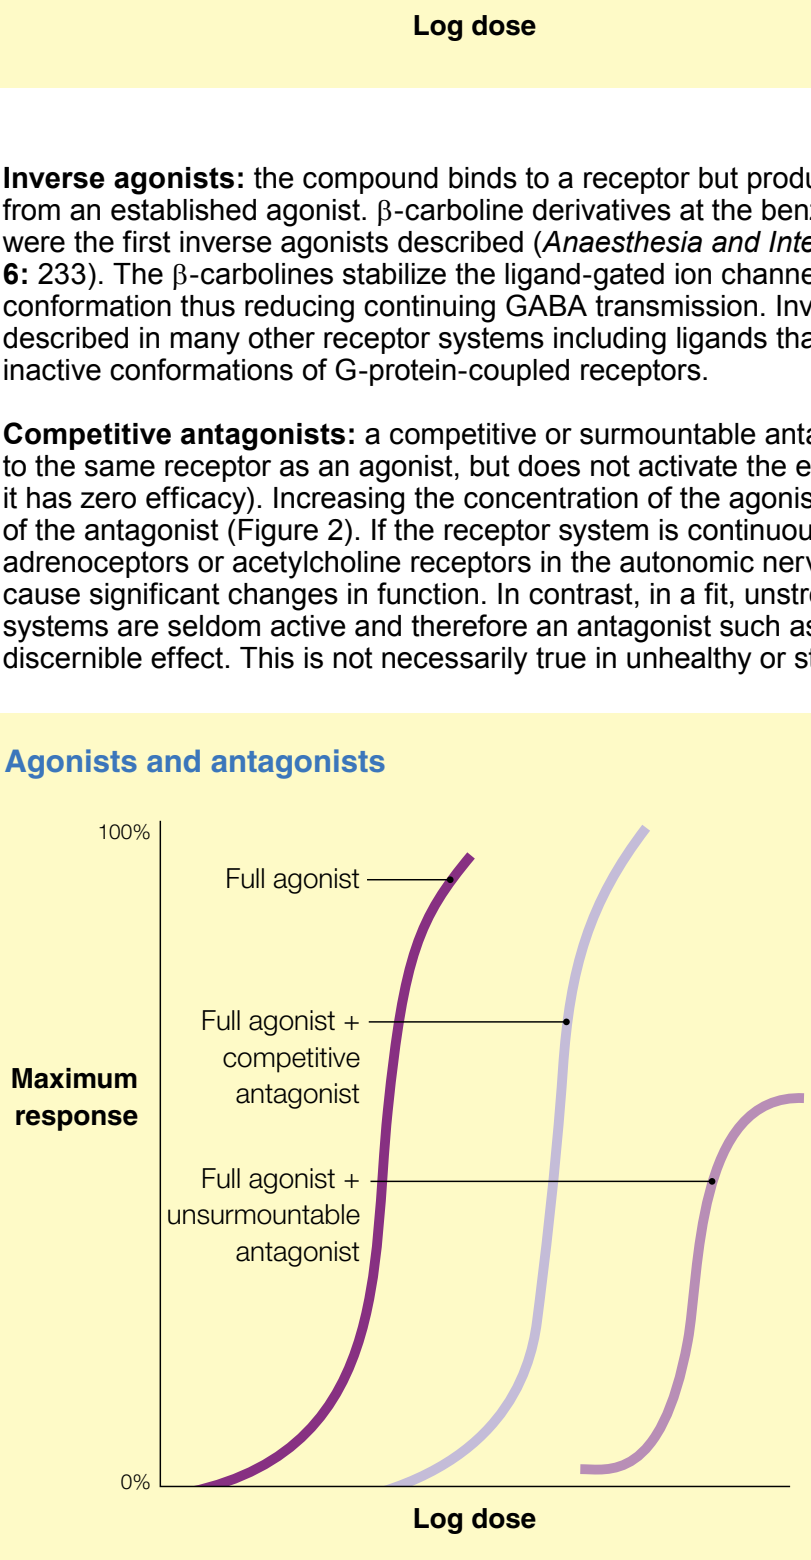


1

Inverse agonists: the compound binds to a receptor but produces the opposite effect from an established agonist. β-carboline derivatives at the benzodiazepine receptor were the first inverse agonists described (*Anaesthesia and Intensive Care Medicine* **2: 6:** 233). The β-carbolines stabilize the ligand-gated ion channel $GABA_A$ in its inactive conformation thus reducing continuing GABA transmission. Inverse agonists have been described in many other receptor systems including ligands that preferentially stabilize inactive conformations of G-protein-coupled receptors.

Competitive antagonists: a competitive or surmountable antagonist binds reversibly to the same receptor as an agonist, but does not activate the effector mechanism (i.e. it has zero efficacy). Increasing the concentration of the agonist can reverse binding of the antagonist (Figure 2). If the receptor system is continuously active, as are adrenoceptors or acetylcholine receptors in the autonomic nervous system, antagonists cause significant changes in function. In contrast, in a fit, unstressed person, opioid systems are seldom active and therefore an antagonist such as naloxone has no discernible effect. This is not necessarily true in unhealthy or stressed individuals.

Agonists and antagonists



2

Non-surmountable antagonists: when receptor antagonism is established no amount of agonist will completely reverse it. Phenoxybenzamine is a non-surmountable antagonist and covalently binds to the norepinephrine-binding site on the α-adrenoceptors. Antagonists that bind to other sites on the receptor causing a change in the conformation of the agonist-binding site (allosteric antagonism) are also non-surmountable.

Receptor classification

Until recently, receptors were classified on the basis of their agonist and antagonist profiles. Molecular biology has demonstrated that receptors can also be classified according to their amino-acid sequences. Many of the receptors so detected have no known function.

Families of receptors

Four main families of receptors have been revealed by cloning and structural studies.

Ligand-gated ion channels: fast synaptic transmission is initiated by a neurotransmitter binding to a receptor that directly causes the opening of an ion channel. They are multi-subunit receptors in which all subunits traverse the membrane. Those most studied appear to be made up of five subunits, which may be of the same type, surrounding a channel. Some ligand-gated ion channels are compared in Figure 3. As with the voltage-gated ion channels, modulation of channel gating by the binding of ligands to a variety of sites on the receptor complex, can significantly affect function; the benzodiazepine modulation of the actions of the $GABA_A$ receptor is an important example.

Examples of ligand-gated ion channels

Name	Ion gated	Agonist	Antagonist	Modulator
• Nicotinic acetylcholine	Na^+	Suxamethonium	Vecuronium	
• $GABA_A$	Cl^-	Muscimol	Bicuculline	Benzodiazepines and general anaesthetics
• NMDA (glutamate)	Ca^{2+} Na^+	N-methyl-D-aspartate	Ketamine (channel blockade)	Glycine
• $5\text{-}HT_3$	Ca^{2+}		Ondansetron	

G-protein-coupled receptors: receptors linked to G-proteins or guanine nucleotide-binding regulatory proteins comprise most membrane-bound receptors. The receptor is composed of seven α-helices that traverse the membrane forming a bundle. Three extracellular and three intracellular loops connect the helices. The long third cytoplasmic loop provides the coupling with the G-proteins. The binding sites for agonists are often buried in pockets within the bundle of α-helices. The G-protein is a go-between connecting the receptor to a number of G-protein effectors including second messenger systems and ion channels. Some examples of G-protein linked receptors and their effectors or second messengers are shown in Figure 4.

Examples of G-protein-linked receptors

Receptor	Effector	Agonist	Antagonist
Muscarinic acetylcholine	Activation of phospholipase C (IP_3 and DAG)[1] Inhibition of adenylyl cyclase Activation of K^+ channels Inhibition of Ca^{2+} channels	Pilocarpine	Atropine
β_1-adrenoceptor	Activation of adenylyl cyclase	Dobutamine	Atenolol
μ opioid receptors	Inhibition of adenylyl cyclase Activation of K^+ channels Inhibition of Ca^{2+} channels	Morphine	Naloxone
D_2-dopamine receptors	Inhibition of adenylyl cyclase Activation of phospholipase C (IP_3 and DAG)	Bromocriptine	Spiperone

[1] IP_3, inositol triphosphate; DAG, diacylglycerol.

Direct enzyme-linked receptors possess large intracellular and extracellular domains joined by a single membrane-spanning helix. The extracellular domain provides the binding site for peptide agonists, usually growth hormones such as insulin. The intracellular domain is usually a protein kinase that phosphorylates amino-acid residues, often tyrosine, and the group has been called the tyrosine-kinase-linked receptor.

Intracellular receptors affecting gene transcription: these non-membrane-bound receptors may either be nuclear (e.g. thyroid hormone receptor) or cytosolic (e.g. glucocorticoid receptor). In the latter, the presence of a ligand leads to the movement of the receptor–ligand complex into the nucleus. Ligands for these receptors are lipid soluble and pass into the cell. The binding of the ligand to the receptor results in an uncurling of the receptor protein to reveal the DNA binding domain. An increase in RNA polymerase activity and the production of a specific mRNA occurs and protein production is enhanced. Alternatively, the receptor complex may switch off the synthesis of some proteins.

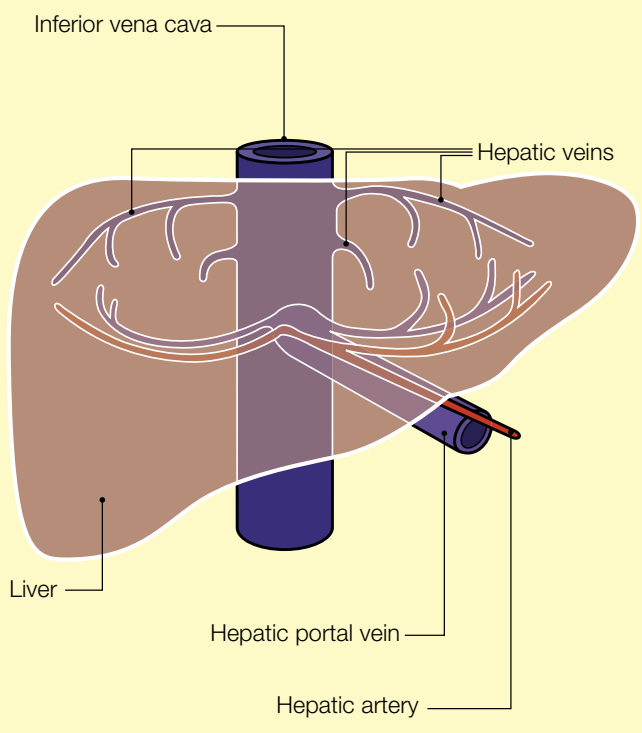
Drugs and the Liver

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

The multiple functions of the liver include the production of proteins (e.g. enzymes and clotting factors), storage of iron and glycogen, and the metabolism of fats, proteins, bile acids and bilirubin. Most important, from a pharmacological point of view, is that the liver controls much of the metabolism and excretion of drugs and toxins. These functions are carried out by the hepatocytes that make up 90% of the organ. Sinusoids, lined with Kupffer cells, lie between the hepatocytes and make up the biliary tree that comes together as the common bile duct before emptying into the duodenum. The blood supply of the liver is illustrated in Figure 1.

Blood supply of the liver



1

Interactions between drugs and the liver can be divided into two main areas:

- how the liver and its diseases affect drug metabolism
- how drugs can affect the functions of the liver.

Drug metabolism in the liver and the effects of enzyme induction and inhibition on drug activity are discussed in *Anaesthesia and Intensive Care Medicine* **3:3** and **3:7**. Some of the drugs whose metabolism is severely affected in patients with liver failure are listed in Figure 2. They have high hepatic clearance. Any drugs used in anaesthesia (e.g. benzodiazepine, propofol) that are metabolized by the liver may show a prolongation of action is patients with liver disease. The remainder of this article concentrates on how drugs affect the biliary system and/or liver function.

Drugs to be used with caution in liver failure because of severely reduced metabolism

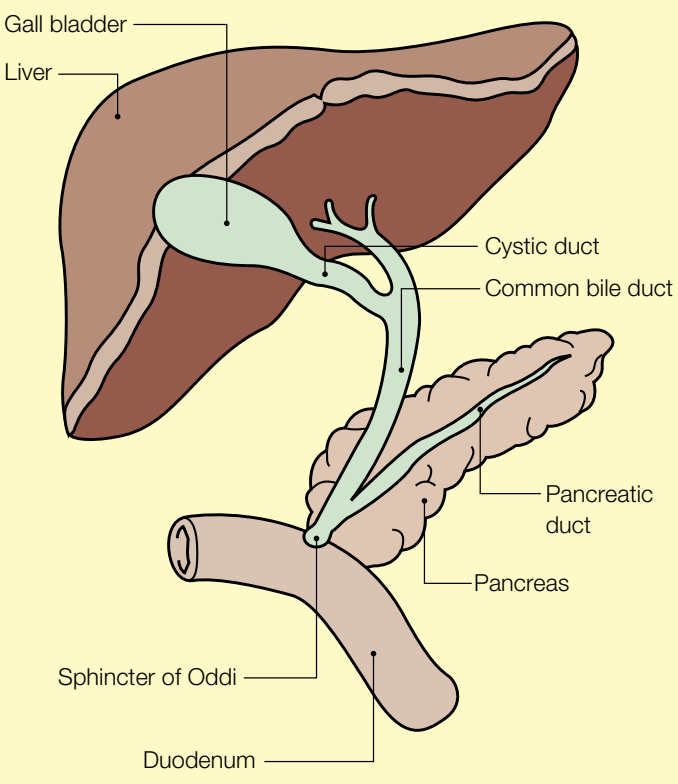
- Alprenolol
- Desipramine
- Isoprenaline
- Lidocaine (lignocaine)
- Morphine
- Nitroglycerine
- Pentazocine
- Pethidine
- Propoxyphene
- Propranolol

2

Drugs affecting the biliary system

The function of bile salts, which are present in bile, is to emulsify fats in the intestine so that pancreatic lipase, which is insoluble in lipids, can more readily attack the droplets. Bile salts are reabsorbed from the intestine via the hepatic portal vein and are recycled by the liver. Liver cells produce about 1 litre of bile per day, which is stored in the gall bladder (Figure 3) and released only through the hepatopancreatic sphincter (sphincter of Oddi) when chyme enters the duodenum. The formation of cholesterol gallstones (cholelithiasis) is the most common pathological condition of the biliary tract. Passage of gallstones down the bile duct can cause intense pain. Opioid drugs can reduce the pain, but some (e.g. morphine) can cause a spasm of the sphincter of Oddi and raise pressure in the bile duct. Co-administration of a muscarinic acetylcholine receptor antagonist or using a partial opioid agonist (e.g. buprenorphine) can reduce this. Pethidine has some intrinsic antimuscarinic activity and it may be less likely to produce sphincter of Oddi constriction. The smooth muscle relaxation produced by the release of nitric oxide from nitrates may also relieve biliary spasm.

Gall bladder



3

If gallstones are non-calcified they can be dissolved by chenodeoxycholic acid and ursodeoxycholic acid. The former is identical to one of the natural bile acids in humans while the latter is found mainly in the bear. These two bile acids can be given orally and they decrease hepatic synthesis and secretion of cholesterol. They are treated like endogenous bile acids in the body. However, in most patients with gallstones, surgery or shattering the stone with lithotripsy is the treatment of choice.

Anaesthetic drugs and liver function

Many drugs, including those used in anaesthesia, are likely to affect liver function but in general these effects are transitory, small and without long-term consequences. However, in patients with existing hepatic dysfunction and multisystem organ failure even minor changes to hepatic function can be important.

Inhalational, intravenous and local anaesthetic agents can reduce liver blood flow. Because of its association with postoperative hepatic dysfunction (see later) halothane has received most attention in this regard. There is a dose-dependent decrease in portal liver blood flow that parallels the fall in cardiac output produced by halothane. There may be a compensatory, but limited, increase in hepatic artery blood flow. The overall reduction in liver blood flow caused by halothane decreases with time and is usually less than that induced by surgery alone. However, in patients whose liver function is severely compromised, the reduced blood flow and consequent hypoxia may be significant. Among the inhalational agents, isoflurane appears to have the least overall effect on hepatic oxygen supply and demand and may be the agent of choice for patients with liver disease. Intravenous anaesthetic agents appear to have little direct effect on liver blood flow but may have secondary effects owing to reduced cardiac output and sympathetic stimulation if ventilation is depressed. Ketamine has increased liver blood flow in some studies. The reduced liver blood flow induced by spinal or epidural administration of local anaesthetics mirrors the fall in mean arterial pressure.

Postoperative liver dysfunction

Almost all inhalational anaesthetic agents have been associated with postoperative liver dysfunction, but most attention has been focused on halothane. Halothane-associated hepatitis (see *Anaesthesia and Intensive Care Medicine* **2:1:** 7) has been attributed to a direct effect of halothane or a metabolite on liver cells, while fulminating hepatic failure has been attributed to an immune reaction following repeat halothane exposure. The classification of hypersensitivity reactions is shown in Figure 4. Some patients with the fulminating disease have highly reactive trifluoroacetyl proteins in their serum presumably derived from a halothane metabolite combined with a protein to form an immunogen. In animal studies an antigen to this protein can be expressed on the surface of liver cells and destruction of the cell occurs by type II hypersensitivity reactions involving killer T cells. The release of antibody-antigen complexes from the damaged cells can then cause type III reactions. Fulminating hepatic failure carries a high mortality but is rare (1/35,000 anaesthetics). Cross-sensitivity may occur with other halogenated anaesthetic agents that can produce trifluoroacetyl proteins (e.g. enflurane). However, because halothane is metabolized to a greater extent than most volatile anaesthetics it has the greatest propensity for the production of this protein.

Classification of hypersensitivity reactions

Type I	Immediate or anaphylactic (e.g. hay fever)
Type II	Antibody-dependent cytotoxic (e.g. autoimmune thyroiditis)
Type III	Complex-mediated via activated complement (e.g. farmer's lung)
Type IV	Cell-mediated (e.g. rheumatoid arthritis)

4

Halothane-associated hepatitis is characterized by an elevation of liver transaminase with transient jaundice but low morbidity. It may occur after a single administration of halothane and the incidence has been reported to be as high as 20%. However, there are many potential causes of postoperative liver dysfunction including hypoxia and hypotension and the diagnosis of halothane-associated hepatitis is by exclusion of other potential causes.

Other drugs and liver function

Ethanol causes dose-dependent liver damage and is the most common cause of cirrhosis. Many patients are asymptomatic but may present in hospital with gastrointestinal haemorrhage owing to portal hypertension secondary to the cirrhosis. The bleeding is most often from oesophageal varices. These may be treated by endoscopic injection of a sclerosant (an irritant that causes thrombus formation) such as sodium tetradecyl sulphate, ethanolamine oleate, sodium morrhuate, polidocanol. or even absolute alcohol. Other treatments involve surgical procedures.

Aspirin has been associated with Reye's syndrome in children, which involves fatty degeneration of the viscera and liver failure. The condition is associated with viral infections such as influenza, and in some countries is common when the fever has been treated with aspirin. Aspirin is no longer recommended for children under 12 years of age and the incidence of Reye's syndrome has reduced. However, not all reports have supported an association of aspirin with the syndrome. The hepatic toxicity of paracetamol is described in *Anaesthesia and Intensive Care Medicine* **2:11:** 457. Other compounds that can cause liver damage are listed in Figure 5. ◆

Additional drugs associated with hepatotoxicity

Androgens
Reversible obstructive jaundice

Chlorpromazine
Reversible obstructive jaundice

Isoniazid
Effects may be more profound in slow acetylators

Ketoconazole
Rare but often fatal liver toxicity can occur after cessation of drug Similar reports for fluconazole

Phenytoin
Effects may be more profound in slow acetylators

Solvents
Examples include toluene (glue sniffing), carbon tetrachloride and trichloroethylene (dry cleaning fluids)

Valproate
An increase in serum glutamic oxaloacetic transaminase is common, but hepatitis is rare

Drugs for Muscle and Joint Disease

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Joint disease

Drugs used to treat joint diseases such as osteoarthritis and rheumatoid arthritis are described elsewhere.

Osteoarthritis

Paracetamol is first-line pain therapy for osteoarthritis because only a minor inflammatory component is involved. Non-steroidal anti-inflammatory drugs (NSAIDs) can also be prescribed but gastrointestinal side-effects limit the usefulness of most agents that show little selectivity for the cyclo-oxygenase (COX)-2 enzyme. Recently introduced, selective COX-2 inhibiting drugs such as celecoxib and rofecoxib may be beneficial, but await detailed study. Neither paracetamol nor NSAIDs treat the disease, only the pain associated with it.

The main process involved in disease progression is cartilage destruction and some chondroprotective drugs (e.g. chondroitin, glucosamine, hyaluronic acid) have been used to try to halt or reverse the disease; long-term trials are awaited.

Rheumatoid arthritis

Rheumatoid arthritis is an inflammatory, autoimmune disease in which the immune system invades and destroys cartilage in the joint. NSAIDs and the anti-inflammatory glucocorticosteroids were formerly the mainstay of therapy, though gastrointestinal side-effects limited their use. Both groups of drugs inhibit the production of prostanoids. NSAIDs cause the inhibition of the COX enzyme responsible for converting arachidonic acid into the cyclic endoperoxides. Alternatively, glucocorticosteroids increase the cellular production of lipocortin, an inhibitor of phospholipase A_2 causing a decreased release of arachidonic acid and thus decreased prostanoid formation. In addition, glucocorticosteroids decrease COX-2 synthesis.

Disease-modifying anti-rheumatic drugs (DMARDs) have been recommended at an early stage in the development of the disease, despite their inherent toxicity. Used early in the disease process, DMARDs can maintain joint function at near normal, while later use causes only a mild improvement in an already disabled joint. Many DMARDs are classical immunosuppressants (e.g. methotrexate, ciclosporin (cyclosporin), azathioprine, cyclophosphamide). Gold and penicillamine are older treatments, the use of which is declining. In the UK, sulphasalazine is first-line therapy but its mechanism of action is unknown.

A decrease in the activity of tumour necrosis factor (TNF) in rheumatoid arthritis has a beneficial effect. Two approaches have been used to achieve this outcome. Infliximab is a preparation of anti-TNF-α antibodies and etanercept contains soluble TNF receptors fused to the Fc portion of human IgG.

Gout

Gout is a familial disease associated with an overproduction of purines. It is characterized by recurrent attacks of arthritis caused by the deposition of sodium urate in joints and cartilage; the base of the big toe is the joint most commonly affected. Acute attacks of gout result from the shedding of urate crystals from the slow build-up of urate on cartilaginous surfaces. The engulfing of crystals by phagocytosis causes the release of inflammatory mediators such as interleukin-1 (IL-1) and the lipoxygenase product LTB4. There is also activation of the kinin complement and plasmin systems.

Acute attacks of gout may be treated with NSAIDs (e.g. indomethacin, ketoprofen, naproxen, piroxicam, diclofenac). These drugs inhibit prostaglandin synthesis and urate crystal phagocytosis. Salicylates reduce urate excretion and therefore should not be used in gout. An alternative for the treatment of an acute attack is cholchicine, which inhibits leucocyte migration and phagocytosis. It prevents the polymerization of tubulin into microtubules thus reducing cell motility. The most common side-effect is gastrointestinal disturbances. The long-term treatment of gout involves inhibiting uric acid synthesis with allopurinol (a xanthine oxidase inhibitor), or increasing uric acid secretion using probenecid or sulphinpyrazone. Neither treatment is effective for acute attacks and may precipitate them (particularly allopurinol) or make them worse. Several diuretic agents are also uricosuric agents (e.g. probenecid) and may enhance the predisposition to urate renal stones.

Skeletal muscle relaxants

Skeletal muscle relaxants used to treat muscle spasticity or chronic spasm may act centrally (baclofen, benzodiazepines, tizanidine) or peripherally (dantrolene, botulinum toxin). Older centrally acting muscle relaxants include mephenesin, carisoprodol, methocarbamol and meprobamate. They are less effective than the drugs described below and are more toxic in overdose. Their use is not recommended as first-line treatment.

Baclofen is used to treat chronic spasticity resulting from conditions such as multiple sclerosis or traumatic partial section of the spinal cord. It is ineffective in cerebral spasticity caused by birth injury or stroke. Baclofen is an analogue of γ-aminobutyric acid (GABA) which penetrates the blood–brain barrier. It is not antagonized by bicuculline and is a selective agonist for the $GABA_B$ receptor. Unlike the $GABA_A$ receptor, which is a ligand-gated ion channel, the $GABA_B$ receptor is G-protein coupled and mediates inhibition of adenylyl cyclase. Baclofen inhibits monosynaptic and polysynaptic activation of motor neurons in the spinal cord. Baclofen is the only drug acting on the $GABA_B$ receptor that has significant clinical use, though antagonists appear to have anticonvulsant actions, which are being investigated. The most common side-effect is drowsiness and sedation, but nausea and muscle hypotonia may also occur. Some patients also report mood disturbances such as depression and anxiety.

Benzodiazepines reduce muscle tone by a central action and can be used for muscle spasm due to many causes including tetanus. Muscle relaxation probably contributes to their use as anxiolytics. Benzodiazepines enhance the response to GABA, acting at the $GABA_A$ receptor.

Tizanidine, like baclofen, is mainly used to treat spasticity caused by multiple sclerosis or spinal cord damage. It is an α_2-adrenoceptor agonist and acts by increasing presynaptic inhibition of motor neurons in the spinal cord. Its side-effects are similar to those of other α_2-adrenoceptor agonists (i.e. sed-ation, dry mouth).

Dantrolene has been used for severe chronic spasticity of skeletal muscle, neuroleptic malignant syndrome and malignant hyperpyrexia. Dantrolene blocks Ca^{2+} release from the sarcoplasmic reticulum by limiting the capacity of Ca^{2+} and calmodulin to activate the ryanodine (RYR-1) receptor, this reduces muscle contraction. This action is peripheral, therefore dantrolene lacks the CNS side-effects seen with other skeletal muscle relaxants and is probably the treatment of choice for muscle spasm. However, the dose should be increased slowly and liver toxicity has been reported. Dantrolene is used for the treatment of muscle spasm associated with amyotrophic lateral sclerosis. It may cause excessive muscle weakness.

Botulinum toxin injected directly into the affected muscle has been used to treat strabismus, blepharospasm and other spastic conditions such as spasmodic torticollis and foot deformities caused by spasticity in children with cerebral palsy. Careful placing of the injections is essential because a misplaced injection results in paralysis of a non-affected muscle. Botulinum toxin contains several components (A–G), of which A and B are used clinically. Each component is a peptidase that cleaves a protein, such as a synaptobrevin or a synaptotaxin, involved in transmitter release. Botulinum toxin is highly specific for acetylcholine release and inhibits skeletal muscle and parasympathetic function. Treatment lasts for 3–4 months and recovery is due to nerve sprouting. Immunoresistance may occur with repeated use. Under the trade names Botox® or Dysport®, botulinum A toxin-haemagglutinin complex has been used cosmetically to reduce facial lines.

Drugs for myasthenia gravis

Myasthenia gravis is a defect of neuromuscular transmission, which causes skeletal muscle weakness that fluctuates and can be exacerbated by exercise of the muscle. Thus, sustained contraction of muscle is impossible and typical symptoms are dropping of the eyelid. In over 90% of patients, antibodies are present to the nicotinic acetylcholine receptor on the motor end-plate. However, the severity of the disease does not correlate well with the antibody titre. The thymus may be responsible for the initial pathogenesis, but it is not required for perpetuation of the disease. At least 70% of patients also have thymic hyperplasia and thymectomy may be helpful in some cases, particularly in young women, and is mandatory if a thymoma is present (15% of cases). A few patients have a mutation of the acetylcholine receptor. These congenital cases do not respond to treatment with anticholinesterase agents.

Anticholinesterase agents prevent the breakdown of acetylcholine by acetylcholinesterase in the synaptic cleft and allow more time for the transmitter molecule to find a functioning receptor. The effect in most patients is dramatic and the use of a short-acting anticholinesterase agent, edrophonium, is used as a diagnostic test for the disease. However if the disease is severe, there are insufficient nicotinic receptors to initiate an action potential and anticholinesterase agents become ineffective. Anticholinesterase agents also potentiate acetylcholine at the parasympathetic effector junction but tolerance to this effect occurs and it is not necessary to add a muscarinic receptor antagonist routinely to the regimen. The anticholinesterase agents used to treat myasthenia gravis are listed in Figure 1; they are all reversible anticholinesterase agents. Irreversible anticholinesterase agents (e.g. ecothiopate iodide) are no longer on the market in the UK, but are still available on a named-patient basis for use under expert supervision.

Anticholinesterase agents used in myasthenia gravis

Drug	Duration of beneficial effect	Comments
Neostigmine	Up to 4 hours	A muscarinic acetylcholine receptor antagonist may be required in the early stages
Distigmine	Up to 24 hours (longest duration of action)	Danger of cholinergic crisis is greater than with the shorter acting drugs
Edrophonium	Up to 5 minutes	Used only for diagnosis and for assessing the need for dose adjustment
Pyridostigmine	More than 4 hours	Slower onset than neostigmine, but smoother action

1

The antibodies in the plasma can be removed by plasma exchange, which is effective in the short term. Longer term reduction in antibody titre can be achieved with immunosuppressive compounds such as glucocorticosteroids, azathioprine and ciclosporin (cyclosporin). ◆

Enzyme Inducers and Inhibitors: Addition, Subtraction and Synergism

Norman Calvey

Norman Calvey is Honorary Senior Research Fellow in the University Department of Anaesthesia, Liverpool, UK. He qualified in science and medicine from Liverpool University and has worked in Departments of Pharmacology and Anaesthesia. His research interests include pharmacokinetics and drug isomerism.

Enzyme inducers and inhibitors

Enzymes are biological catalysts that play a crucial role in metabolism. Under normal conditions, their concentration and activity in individual subjects are mainly dependent on genetic and physiological regulation. Most enzyme systems are subject to inhibitory feedback control (i.e. their activity is inhibited by their metabolic products); similarly, increased utilization of their metabolites increases their activity. In certain enzyme systems, synthesis and activity can also be induced or inhibited by other agents. Enzyme induction and inhibition is particularly important in the hepatic mixed function oxidase system (cytochrome P450), which plays a central role in drug metabolism.

Cytochrome P450

Cytochrome P450 is present in the smooth endoplasmic reticulum (the microsomes), and consists of many different forms of a superfamily of haemoproteins. This enzyme system is responsible for most hepatic drug oxidation and reduction, as well as some hydrolytic reactions. More than 70% of hepatic cytochrome P450 is encoded by three gene families (*CYP 1*, *CYP 2* and *CYP 3*); drug metabolism in humans is mainly dependent on seven isoforms (CYP 1A2, CYP 2C8, CYP 2C9, CYP 2C19, CYP 2D6, CYP 2E1 and CYP 3A4). The predominant and most important isoform in humans is CYP 3A4, which is often involved in drug interactions.

Induction of cytochrome P450: several drugs selectively increase the synthesis and activity of certain isoforms of cytochrome P450. Enzyme induction usually occurs within 3–5 days, and is associated with an increase in the endoplasmic reticulum, biliary secretion and liver weight. In humans, the main clinically significant enzyme-inducing agents are the barbiturates, phenytoin, carbamazepine, griseofulvin and rifampicin (Figure 1). Chronic alcohol consumption and some polycyclic aromatic hydrocarbons (e.g. 3-methylcholanthrene and benzpyrene) also induce certain isoforms; some of these compounds are present in tobacco smoke and grilled meats.

Inducers and inhibitors of cytochrome P450

Inducers
- Barbiturates
- Phenytoin
- Carbamazepine
- Rifampicin
- Griseofulvin
- Alcohol (chronic consumption) (tobacco smoke, grilled meat)
- Polycyclic hydrocarbons

Inhibitors
- Imidazoles (ketoconazole, itraconazole, omeprazole, cimetidine, etomidate)
- Macrolide antibiotics (erythromycin, clarithromycin)
- Antidepressants (most)
- Human immunodeficiency virus protease inhibitors (indinavir, nelfinavir, ritonavir)
- Cyclosporin
- Amiodarone
- Gestodene
- Grapefruit juice

1

Enzyme-inducing agents commonly affect one or more specific enzyme isoforms. Thus, polycyclic hydrocarbons mainly induce CYP 1A1 and CYP 1A2, while barbiturates and phenytoin affect CYP 1A2 and CYP 3A4. Rifampicin is a potent inducer of CYP 2D6 and CYP 3A4, while ethyl alcohol affects CYP 2E1, which is responsible for the defluorination of many inhalational agents. Enzyme induction of cytochrome P450 often increases glucuronyl transferase activity, and thus enhances glucuronide conjugation; it commonly reduces effective plasma concentrations of other drugs, and may cause certain agents to increase their own metabolism (autoinduction).

Induction of cytochrome P450 may have secondary effects on other enzyme systems. Hepatic enzyme induction decreases intracellular haem, and thus reduces its negative inhibitory effects on amino-laevulinic acid and porphyrin synthesis; this may be important in patients with acute porphyria.

Inhibition of cytochrome P450: certain isoforms are competitively inhibited by other drugs (e.g. CYP 2D6 is inhibited by quinidine). Imidazole derivatives (e.g. ketoconazole, itraconazole, omeprazole, cimetidine, etomidate) combine with haem and non-competitively inhibit CYP 3A4 and certain other isoforms (e.g. CYP 1A2, CYP 2C8 and CYP 2D6). In addition, cyclosporin, amiodarone, many macrolide antibiotics, some antidepressant drugs, most anti-HIV protease inhibitors and grapefruit juice inhibit cytochrome P450 (particularly CYP 3A4) (Figure 1). Certain synthetic progestogens (e.g. gestodene) are oxidized by CYP 3A4 and combine with it covalently (suicide inhibition). Enzyme inhibition may increase the plasma concentrations of other concurrently used drugs, and interactions are not uncommon.

Induction and inhibition in other enzyme systems

Enzyme activity in other systems can also be modified by drugs. Certain bacterial enzymes (e.g. β-lactamases) are readily induced by many penicillins; similarly, enzyme induction may play an important part in acquired resistance to cytotoxic agents. In addition, many enzyme systems are inhibited by drugs, and enzyme inhibition may be the main mechanism of drug action (see *Anaesthesia and Intensive Care Medicine* **2:8:** 322).

Addition, subtraction and synergism

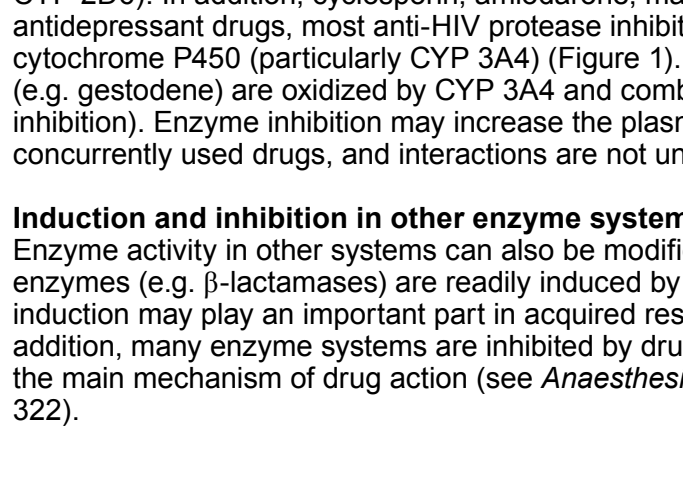
When two or more drugs are used concurrently, one drug may affect the action of the other. The terms addition, subtraction, and synergism are sometimes used to describe the effects observed when drugs are used in combination.

Addition

Addition or summation represents the additive effects of two or more similar drugs when used in combination; it is not a true interaction, and merely represents the sum of the effects of each agent when given alone. It is probably the most common effect observed when two drugs with similar actions are used simultaneously.

When two or more inhalational anaesthetics are used together, their potencies are additive. The potency of inhalational anaesthetics is expressed as the minimum alveolar concentration (MAC) value, which is defined as the minimum steady-state concentration that produces no reaction to a surgical stimulus (skin incision) in 50% of subjects at atmospheric pressure. When two different agents are administered simultaneously, their activities (when expressed as MAC values) are additive. Thus 0.5 MAC of nitrous oxide (52% v/v) and 0.5 MAC of halothane (0.37% v/v) have an equal effect to 1.0 MAC of either agent, or 1.0 MAC of any other inhalational anaesthetic. These relationships are traditionally expressed in the form of an isobole (a graph showing equi-effective combinations of drugs; Figure 2).

Isobole showing equi-effective concentrations of halothane and nitrous oxide



The two axes represent alveolar concentrations of halothane (abscissa) and nitrous oxide (ordinate). Points on the line correspond to equi-effective combinations of the two agents (with the same effect as the minimum alveolar concentration (MAC) of halothane; 0.75%, v/v). The linear relationship between the variables indicates that their potencies are additive. The line can be extrapolated to the ordinate, which it intercepts at the putative MAC of nitrous oxide

2

The additive potencies of combinations of inhalational agents have been used to determine the MAC of nitrous oxide (104% v/v), and have been used to support the unitary concept of anaesthetic action. In practice, combinations of anaesthetics may show slight deviations from exact additivity (e.g. nitrous oxide and isoflurane), which are usually considered to reflect patient variability.

Subtraction

Subtraction is more commonly referred to as drug antagonism, and occurs when the effects of one drug are reduced or abolished in the presence of another. The following are the three main groups of drug antagonists.

Reversible competitive antagonists (e.g. atropine, atracurium, esmolol, naloxone, flumazenil) combine reversibly with receptors but do not produce biological responses. They progressively reduce the pharmacological effects produced by agonists. Reversible competitive antagonists cause the parallel displacement of the logarithmic dose–response curve to the right, but do not affect the slope or the maximum response.

Irreversible competitive antagonists (e.g. phenoxybenz-amine) form stable chemical bonds with receptors and dissociate slowly from receptor sites. They characteristically result in non-parallel displacement of the logarithmic dose–response curve to the right, decreasing the slope and the maximum response.

Non-competitive antagonists interfere with the action of other drugs by:
- chemical antagonism
- physiological (functional) antagonism
- pharmacokinetic antagonism.

Synergy

Synergy occurs when the combination of two drugs with similar properties produces supra-additive effects (i.e. greater than those expected by simple summation). When benzodiazepines and intravenous anaesthetics are used concurrently, synergic effects on hypnosis may be observed. Synergic reactions between drugs are sometimes described or interpreted by isoboles.

Potentiation

Potentiation refers to the enhancement of the effects of one drug by another, but is usually used when the two drugs have dissimilar actions (e.g. cocaine potentiates the effects of noradrenaline (norepinephrine) on blood pressure). ◆

Enzymes

Norman Calvey

Norman Calvey is Honorary Senior Research Fellow in the University Department of Anaesthesia, Liverpool, UK. He qualified in science and medicine from Liverpool University and has worked in departments of pharmacology and anaesthesia. His research interests include pharmacokinetics and drug isomerism.

Enzymes are catalytic proteins that mediate almost all biochem-ical reactions in humans. The term enzyme means 'in leaven', and enzymes in yeasts and moulds have been used in the preparation of bread and cheese and the fermentation of wine for several millennia.

Enzymes (E) combine with substrates (S) forming an enzyme–substrate complex. The binding of the substrate is often stereoselective, and its structure is strained by high-energy intermolecular forces. Consequently, its bonds are easily broken, resulting in the formation of an enzyme–product complex and reaction products (P):

$$E + S \leftrightarrow E - S \rightarrow E - P \rightarrow E + P$$

Enzyme activity may depend on non-protein factors (co-enzymes); these may be ions or simple organic compounds. Many water-soluble vitamins are co-enzymes in biochemical reactions.

Enzymes and drug action

Receptor activation
When drugs combine with receptors, they often indirectly affect the activity of intracellular enzymes, including:
- adenylyl cyclase
- guanylyl cyclase
- phospholipase C
- protein kinase A.

Many receptors that control cellular growth and differentiation are inherent protein kinases and phosphorylate membrane proteins.

Enzyme inhibition
Drugs may also directly affect enzymes and modify their activity; they are often chemical analogues of endogenous substrates. Enzyme inhibition may be the main mechanism of drug action (Figure 1). Drugs may inhibit enzymes by reversible inhibition, irreversible inhibition or lethal synthesis.

Reversible inhibition is usually competitive. Drugs compete with natural substrates for enzymes, resulting in the formation of a reversible enzyme–inhibitor complex (both *in vitro* and *in vivo*). Edrophonium is a reversible inhibitor of acetylcholinesterase; its quaternary group forms an ionic bond with the enzyme, which readily dissociates when the plasma concentration falls. Consequently, its effects are usually transient.

Drugs that act by enzyme inhibition

Drug	Inhibited enzyme
• Allopurinol	Xanthine oxidase
• Aminophylline	Phosphodiesterase
• Aspirin	Cyclo-oxygenase
• Captopril	Angiotensin-converting enzyme
• Disulfiram	Aldehyde dehydrogenase
• Methotrexate	Dihydrofolate reductase
• Neostigmine	Acetylcholinesterase
• Phenelzine	Monoamine oxidase
• Warfarin	Epoxide reductase

1

Irreversible inhibition usually involves the formation of a stable chemical bond between an inhibitor and the enzyme. Regeneration of the inhibited enzyme is impossible; a latent period is required for enzyme resynthesis before normal function is restored. Irreversible enzyme inhibitors (e.g. methotrexate, most monoamine oxidase inhibitors) have a prolonged duration of action.

Inhibition by lethal synthesis: drugs are sometimes converted to metabolites that interfere with normal biochemical pathways. Fluorouracil is metabolized to a nucleotide that cannot be converted to thymidylate; consequently, DNA synthesis is inhibited.

Drug activation
Inactive drugs (pro-drugs) may have to be metabolized to active derivatives (e.g. enalapril). Some drugs (e.g. paracetamol) may be converted to toxic metabolites.

Enzymes and drug elimination

Most drugs are relatively lipid soluble, and are metabolized to less active, water-soluble derivatives before they are eliminated. Hepatic enzyme systems play the predominant role in drug metabolism, though some drugs are partly or completely degraded at other sites:
- plasma (e.g. suxamethonium, remifentanil)
- intestine (e.g. morphine, salbutamol)
- kidney (e.g. midazolam, dopamine)
- lung (e.g. angiotensin I).

Hepatic metabolism
The reactions mediated by hepatic enzymes are divided into:
- phase I reactions (functionalization reactions)
- phase II reactions (conjugation reactions).

Phase I reactions usually result in drug oxidation, reduction, or hydrolysis. Phase II reactions involve the conjugation of phase I metabolites or unchanged drugs with other chemical groups (e.g. glucuronides). Some drugs (e.g. oxazepam) are entirely metabolized by phase II reactions. Both phase I and phase II reactions generally increase the water solubility of drugs and facilitate their renal elimination.

Phase I reactions
Phase I reactions are carried out by the smooth endoplasmic reticulum or 'microsomes'. A non-specific enzyme system (cytochrome P450) is responsible for most drug oxidation and reduction and some hydrolytic reactions. Cytochrome P450 consists of many different forms of a superfamily of genetically related haemoproteins. During drug oxidation, the oxidized (Fe^{3+}) form of cytochrome P450 combines with the target drug. The resultant complex is then reduced by cytochrome P450 reductase and reacts with molecular oxygen. Finally, the oxidized drug is released and cytochrome P450 is regenerated. The enzyme system may also mediate reductive metabolism in hypoxic conditions (e.g. halothane), and the hydrolysis of some esters and amides (e.g. pethidine).

Cytochrome P450 isoforms: there are many genetically distinct forms of cytochrome P450 in human tissues. Three gene families (*CYP 1, CYP 2* and *CYP 3*) contain numerous enzyme isoforms and encode more than 70% of hepatic cytochrome P450. Seven distinct isoforms are mainly responsible for drug metabolism in humans (Figure 2). Individual hepatic isoforms have different but overlapping substrate specificities, and metabolize drugs at different rates; they are variably expressed in other tissues and differ in their susceptibility to enzyme induction and inhibition. Some enzyme isoforms (CYP 2C18 and CYP 2D6) are subject to genetic polymorphism. The different isoforms of cytochrome P450 are partly responsible for inter-individual differences in drug metabolism, and are an important cause of variability in drug response.

The main isoforms of cytochrome P450 involved in drug metabolism

Enzyme isoform	Typical substrate	Inducing agents
• CYP 1A1	Theophylline	Polycyclic hydrocarbons
• CYP 1A2	Erythromycin	Phenobarbital (phenobarbitone) Phenytoin
• CYP 2C9	Phenytoin	Rifampicin; carbamazepine
• CYP 2C19	Diazepam	Phenobarbital (phenobarbitone)
• CYP 2D6	Codeine	?
• CYP 2E1	Fluorinated anaesthetics	Phenobarbital (phenobarbitone) Ethanol
• CYP 3A4	Midazolam	Phenobarbital (phenobarbitone) Glucocorticoids

2

Induction of cytochrome P450: the synthesis and activity of some isoforms of cytochrome P450 can be selectively increased by other drugs (Figure 2); enzyme induction commonly occurs within several days. Activity of CYP 1A2 is induced by barbiturates, phenytoin, and polycyclic hydrocarbons in meat and tobacco smoke; enzyme induction may also increase liver weight and biliary secretion. CYP 2E1, responsible for the defluorination of many inhalational agents, is induced by ethanol and phenobarbital (phenobarbitone) as well as by fasting, obesity and diabetes. CYP 3A4 is induced by many agents, including glucocorticoids, some antibiotics and phenobarbital (phenobarbitone). Many drugs that induce cytochrome P450 also enhance glucuronyl transferase activity.

Induction and inhibition of cytochrome P450 in humans is often responsible for clinically significant drug interactions.

Inhibition of cytochrome P450: some isoforms of cytochrome P450 are competitively inhibited by other drugs (e.g. CYP 2D6 by quinidine). Certain imidazole derivatives (e.g. ketoconazole, omeprazole, cimetidine, etomidate) non-competitively inhibit certain isoforms (e.g. CYP 3A4) by combining with haem. In addition, some synthetic corticosteroids (e.g. gestodene) are oxidized by CYP 3A4 and combine with it covalently (suicide inhibition). Furafylline affects CYP 1A2 in a similar manner.

Other phase I reactions are independent of cytochrome P450. Dopamine and tyramine are metabolized by mitochondrial monoamine oxidase. Ethyl alcohol is oxidized and chloral hydrate is reduced by alcohol dehydrogenase in the cytoplasm.

Phase II reactions
Phase II reactions (conjugation reactions) usually involve the addition of glucuronide, sulphate, acetyl, or methyl groups to phase I metabolites or unchanged drugs.

Glucuronide conjugation is the most important of these reactions. Glucuronyl transferase catalyses the transfer of glucuronide groups (from uridine diphosphate-glucuronide) to unconjugated compounds. Several endogenous compounds (e.g. bilirubin, thyroxine) as well as many drugs (e.g. chloramphenicol, morphine) are conjugated to glucuronide metabolites, which have a low pK_a and are extremely water soluble.

Sulphate conjugation may occur in the gut wall or the cytoplasm of the liver cell. It is involved in the metabolism of chloramphenicol and isoprenaline.

Drug acetylation takes place in several tissues (e.g. spleen, lung, liver); its rate and extent is affected by genetic polymorphism. Isoniazid, hydralazine and phenelzine are acetylated by hepatic enzymes.

Methylation plays an important part in the metabolism of catecholamines by catechol-o-methyltransferase.

Factors Affecting Drug Absorption and Distribution

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

The bulk transfer of drugs in the blood stream is little influenced by the chemical nature of the drug. However, most drugs have to cross membranes to exert their pharmacological effect and this occurs by diffusional transfer, the nature of which differs widely depending on the chemical nature of the drug.

The membranes surrounding cells are lipid bilayers containing proteins (e.g. receptors and carrier molecules) and are intrinsically lipophilic. Drugs can cross the lipid membrane by passive diffusion or carrier-mediated transport, which often involves the expenditure of energy. However, there are aqueous channels through which small water-soluble molecules, such as ethanol, can pass. The ordered nature of the lipid bilayer makes it impossible for these aqueous channels to be wide enough to admit drug molecules larger than about 0.4 nm. A few large molecules, such as insulin, transfer across the membrane by a process known as pinocytosis in which the cell membrane invaginates to make a vesicle round the extracellular molecule and transports it into the cell or out of the other side.

In order for a drug to pass from the extracellular to the intracellular space it has to cross one cell membrane. However, for a drug to pass from the lumen of the gut into the systemic circulation it has to cross the epithelial barrier of the intestinal mucosa, a tightly connected layer of cells, which means that two cell membranes have to be crossed. Vascular epith-elium, which drugs have to cross to reach the internal organs of the body, is more complex and is discussed later in this article.

Diffusion through lipids

If the electronic charge is evenly distributed over the whole molecule the compound is non-polar and diffuses freely into lipids and crosses membranes easily. Thus, lipid solubility, or the partition coefficient between the aqueous environment and the lipid phase of the membrane, is one of the most important predictors of how well a drug is absorbed orally and how well it penetrates the various body tissues.

Anaesthetics are highly lipid soluble and are rapidly absorbed if given orally, though they are seldom given by this route. However, the author remembers a study in which she was given 10 times the anaesthetic dose orally of *Althesin*, a steroidal anaesthetic combination now withdrawn from human use. It tasted like paint stripper and luckily was metabolized rapidly by the liver before it entered the circulation. The point of the experiment was to study the extent of first-pass metabolism of the drug. The lipid solubility of intravenous anaesthetics ensures that their distribution from blood to brain is rapid and that they are extensively metabolized by the liver.

Large, very polar molecules such as the aminoglycoside antibiotics, which carry a basic charge, are effectively excluded from crossing membranes. They are not absorbed orally and, if injected, remain in the extracellular fluid.

Significant proportions of drugs are weak acids or bases and thus the ratio of the lipid-soluble non-ionized molecule to the ionized molecule depends on the pH of the environment. The pH of some body fluids is shown in Figure 1.

Normal pH range of some body fluids

Cerebrospinal fluid	7.3
Gastric juice	1.0–3.0
Large and small intestine (ileum)	8.0
Plasma	7.4
Small intestine (duodenum)	5.0–6.0
Urine	4.0–8.0

1

The proportion of a drug that is non-ionized and thus easily passes through membranes, can be calculated from the Henderson–Hasselbalch equation:

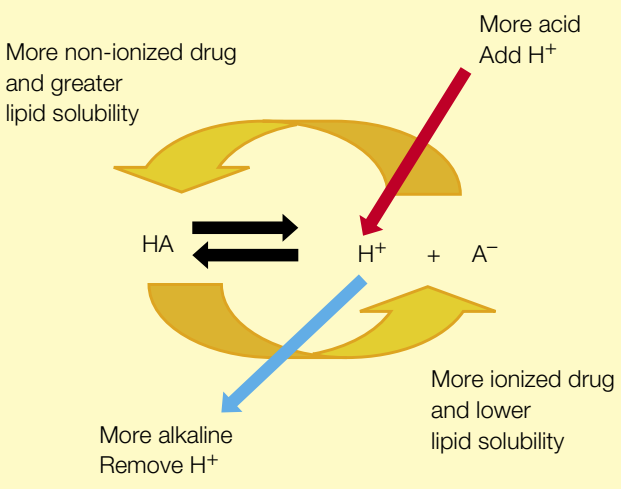
$pH = pKa + \log [A^-]/HA$ (acid form)

$pH = pKa + \log [B]/[BH^+]$ (base form)

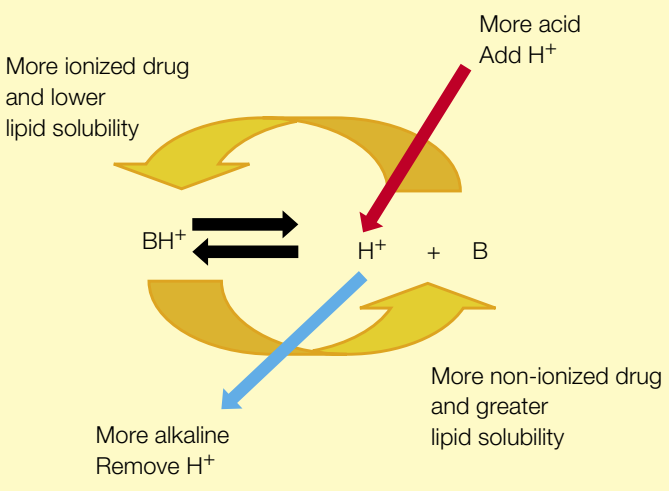
pKa is the negative logarithm of the dissociation constant in the same way that pH is the negative logarithm of the hydrogen ion concentration. From the above equation, pKa is equal to the pH where 50% of the drug is ionized. That is log $[A^-]/HA$ and log $[B]/[BH^+]$ are both log [50%]/[50%] which equals log 1 which antilogs to 0. A simple method of predicting whether a drug will be ionized is shown in Figure 2.

Method of predicting whether a drug will be ionized

Weak acid (e.g. aspirin)



Weak base (e.g. amphetamine)



2

For a weak acid, an acid environment such as is found in the stomach or in acid urine, favours the passage of drug across membranes. Therefore a weak acid is absorbed more rapidly in the stomach than in the intestine. However, the increased absorptive area of the small intestine means that the largest total quantity of a weak acid is absorbed from the intestine rather than from the stomach. Similarly, a weak acid is more readily reabsorbed from acid urine than from alkaline urine. Thus, acid urine promotes the retention of a weak acid in the body and alkaline urine promotes its excretion in the urine. The opposite applies to a weak base, a fact known to amphetamine addicts who take sodium bicarbonate to alkalinize the urine in order to retain the drug for longer in the body.

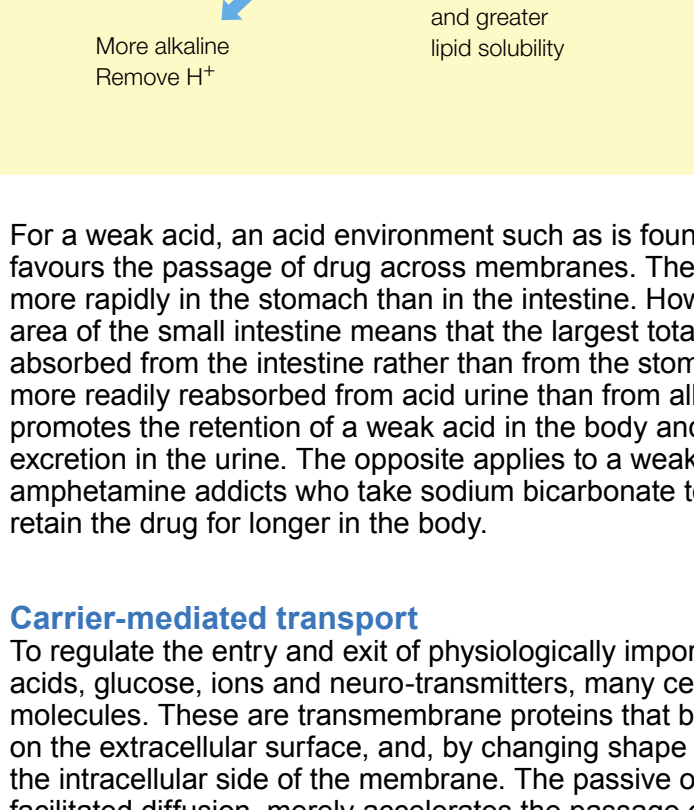
Carrier-mediated transport

To regulate the entry and exit of physiologically important molecules such as amino acids, glucose, ions and neuro-transmitters, many cell membranes contain carrier molecules. These are transmembrane proteins that bind to the desired molecule on the extracellular surface, and, by changing shape can deposit the molecule on the intracellular side of the membrane. The passive operation of such a system, facilitated diffusion, merely accelerates the passage of the molecule in the direction of its electrochemical gradient, and does not involve the expenditure of energy. Active transport using an energy source such as the hydrolysis of adenosine triphos-phate (ATP) can move a molecule against its electrochemical or concentration gradient. If a drug structurally resembles a substrate for a carrier protein it can cross a membrane using this mechanism; examples are methyldopa, levodopa and thyroxine.

Bioavailability

Bioavailability is the fraction of the ingested dose of a drug that reaches the systemic circulation. A drug injected into the blood stream is considered to have a bioavailability of 100% and the bioavailability of a drug by any other route is usually compared with this value. Practically, the area under the plasma concentration time curve for the drug is measured when the drug is given intravenously and via an alternative route such as orally (Figure 3). The two values are compared and the oral plasma concentration time curve is expressed as a percentage of the intravenous plasma concentration time curve. Reasons for low oral bioavailability are suggested in Figure 4. The concept of bioavailability does not consider the peak concentration of the drug or the time taken to reach that peak and is thus of limited value when comparing formulations of a single drug (see below). Thus the term bioequivalence, where there is evidence that similar pharmacological responses are obtained, is more useful.

Determining the percentage oral bioavailability



3

Binding of drugs to plasma proteins

Many drugs bind to plasma proteins so that only a fraction of the drug is free in the plasma and capable of producing pharmacological effects. Most commonly, drugs bind to albumin but some, such as quinine, bind to β-globulin and acid glycoproteins. Acidic drugs such as warfarin and non-steroidal anti-inflammatory drugs (NSAIDs) have a high affinity for the binding sites of plasma albumin, but some basic drugs such as the antidepressants are also bound.

Most drugs are pharmacologically active at concentrations that do not saturate plasma protein binding sites and thus the fraction of drug bound is independent of the drug concentration. However, the binding sites of a few drugs, such as tolbutamide and some of the sulphonamides, are almost saturated at therapeutic concentrations and thus the addition of more drug increases the concentration of free drug by a much greater amount than might have been expected.

Possible reasons for low oral bioavailability

- Drug has low lipid solubility (highly ionized) (e.g. vecuronium, streptomycin)
- Drug is broken down by the acid medium of the stomach (e.g. benzylpenicillin)
- Drug is metabolized by enzymes in the gut wall (e.g. tyramine in food)
- Drug is metabolized in the liver before entering the systemic circulation (e.g. lidocaine (lignocaine), morphine)

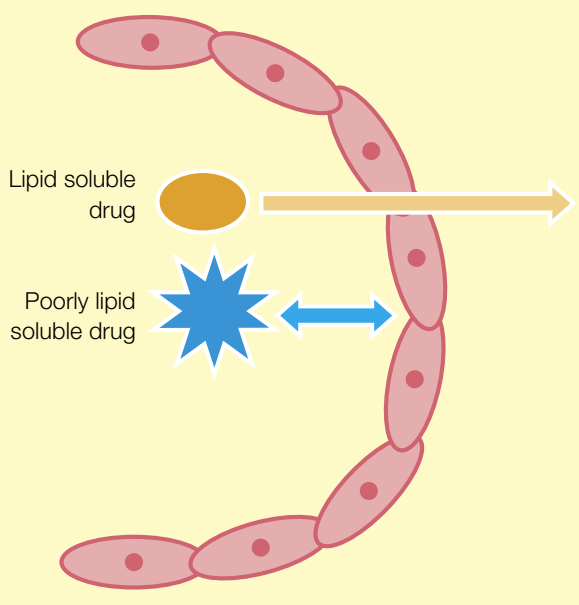
4

Because many drugs have affinity for albumin binding sites, competition between them was thought to be an important site of drug interaction. However, it is now considered to be a minor problem in most cases.

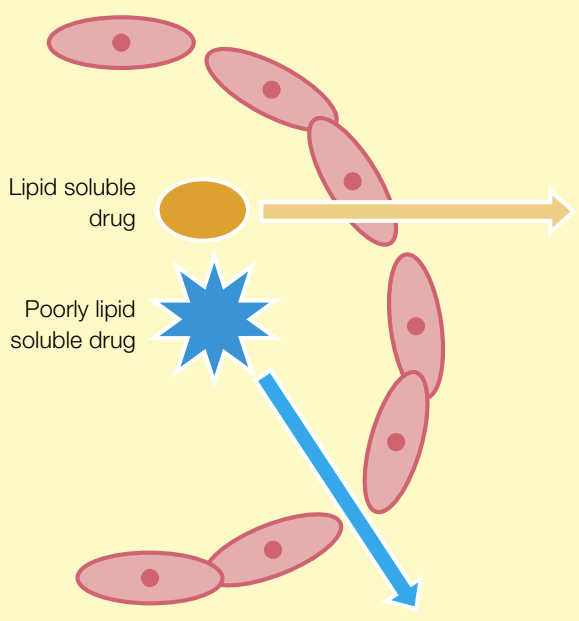
Blood–brain barrier
In most areas of the body, there are gaps or fenestrations between the cells of the vascular endothelium which are packed with a mass of proteins that act as a filter to the passage of molecules. Large molecules are retained while small molecules pass through readily. However, in the brain (and the placenta) there are tight junctions between the cells that allow the passage only of molecules that can pass through the cells. Thus, drugs with low lipid solubility are effectively excluded from the brain (Figure 5). This includes some antibiotics and anti-cancer drugs.

Passage of drugs through capillaries

Most brain capillaries



Non-brain capillaries and those near the chemosensitive trigger zone



5

The blood–brain barrier can be used to exclude a drug action from the brain for therapeutic benefit. For example, levodopa is used to treat Parkinson's disease, a deficiency of dopamine in the basal ganglia, but it is metabolized to dopamine in the periphery as well as in the CNS where it exerts unwanted cardiovascular and emetic action. When it is combined with a dopa decarboxylase inhibitor that cannot cross the blood–brain barrier (e.g. benserazide or carbidopa) a lower dose of levodopa can be used and the incidence of adverse effects reduced. Emesis induced by dopamine occurs at the chemosensitive trigger zone (CTZ) which, although within the brain, is surrounded by a leaky area of the blood–brain barrier. This enables the CTZ to respond to blood-borne emetic substances. During inflammation the blood–brain barrier can be disrupted and this accounts for the successful use of systemic penicillin for the treatment of meningitis.

Volume of distribution
The volume of distribution is calculated from the total quantity of drug in the body, divided by the concentration in the plasma. Thus, it is the volume occupied by the drug if the concentration throughout the body was the same as in the plasma. It does not identify closely with any real anatomical compartment. Some drugs, such as heparin, are so large that they cannot cross the capillary wall and are retained in the plasma compartment (0.05 litre/kg). Others, such as the neuromuscular blocking agents are polar and cannot penetrate cells. Their distribution is limited to extracellular fluids and their volume of distribution is in the region of extracellular fluid volume (0.2 litre/kg). Similarly, they are unlikely to cross the blood–brain or the placental barriers. Drugs such as ethanol are distributed in the total body water (0.55 litre/kg) because they penetrate readily into cells. However, if a drug binds outside the plasma compartment (e.g. digoxin) or partitions into fat (e.g. the anaesthetics) then distribution volumes are much greater than total body water.

Drug delivery systems

Absorption and transport of a drug to its receptor site in the body is part of optimal drug therapy. While the ease of oral administration makes it the best route in many cases, some patients require alternative routes because of bowel obstruction or emesis. Traditional oral or even parenteral administration may not achieve the maintenance of adequate concentrations of drug at the receptor for as long as it is needed and rapid removal of the drug when its effect is no longer required. The oral route is complicated by metabolism of the drug in the gut or liver, resulting in low systemic bioavailability.

Modern biopharmaceutical technology has also produced some delivery systems that allow precise control of drug input into the body by more unorthodox routes.

Topical and transdermal systems
Transdermal drug delivery refers to the delivery of a drug into the systemic circulation across intact healthy skin and a number of novel systems have been described. These can be distinguished from classical topical application formulations in that the latter are generally applied to broken, diseased or damaged skin. Even morphine has been used topically as an infused gel dressing in the treatment of painful skin ulcers. However, the topical application requires an occlusive dressing to prevent the drug being lost by leakage or absorption on to clothes or dressings.

One drug group that is an exception to the rule that topical applications are useful only if the skin is damaged is the NSAIDs. These preparations are widely advertised for acute and chronic painful conditions. Although there has been some scepticism whether topical NSAIDs have any action other than as rubefacients, a detailed analysis of randomized controlled trials of topical NSAIDs found that the preparations were more effective than placebo and that in general the side-effects were less than when bioequivalent doses were given orally.

The advantages of transdermal delivery of drugs are that gastrointestinal absorption and first-pass metabolism in the liver are avoided, thus increasing bioavailability. It is convenient and painless and provides sustained serum concentrations without peaks and troughs. In healthy skin the outermost layer, stratum corneum, is thick, avascular, lipophilic and keratinized and serves as a barrier to the intrusion of most chemicals. Below this are the more aqueous epidermis and dermis, which are the main sites of uptake of drugs that have penetrated the skin into the systemic circulation. In view of this, in order to be suitable for transdermal delivery, the drug must possess high lipid solubility, a typical example is glyceryl trinitrate.

Blood flow through the skin varies with temperature and skin permeability varies at different sites. Thus, delivery systems contain a rate-controlling membrane that limits drug release to the skin surface. Transdermal fentanyl, for example, consists of a four-layer patch. The upper layer is impermeable, preventing loss of drug and the entry of foreign substance. The drug reservoir contains fentanyl and alcohol (to enhance absorption) in a gel. Below this is the rate-controlling ethylene vinyl-acetate copolymer and finally a silicone adhesive impregnated with fentanyl enabling rapid absorption of the opioid on patch application. The rate of fentanyl delivered is directly proportional to the size of the patch. However, even with the drug-saturated adhesive layer, the absorption of drug into the systemic circulation is slow during the first 4 hours and steady state is not reliably reached by 24 hours. After removal of the patch there is continuing absorption from a subcutaneous depot, resulting in a very slow fall off in biological activity. These observations, together with doubts concerning the incidence of respiratory depression in unmonitored patients, have curtailed the use of fentanyl for postoperative pain. However, transdermal fentanyl has some advantages when used to treat chronic pain.

Nicotine is also well absorbed through the intact skin and nicotine patches are widely used to treat withdrawal symptoms that accompany cessation of smoking tobacco. The limitations of passive transdermal delivery have prompted studies of other means of enhancing transdermal drug delivery. Iontophoresis, in which ions of soluble salts are introduced across the skin or a mucosal surface by an electric current, provides a rapid rise in the systemic concentration of drug. Although the cost and size of the iontophoretic device may limit its usefulness, an iontophoretic 'on-demand' pain management system for fentanyl (E-TRANS) is undergoing trials.

Oral transmucosal administration
A greater range of drugs can be administered using the transmucosal route while retaining many of the advantages of transdermal applications. Drugs are usually supplied as a tablet, lozenge or lollipop and allowed to dissolve in the saliva either under the tongue (sublingual) or in the cheek (buccal). Unlike skin application, depots of drug do not form by this route and the drug can be removed from the mouth to terminate activity.

Fentanyl and buprenorphine, being lipid soluble, are particularly well absorbed by the sublingual route, while morphine is poorly absorbed and this contributes to the inconsistent efficacy of morphine give sublingually or buccally. Fentanyl lollipops, a sweetened lozenge on a stick, are currently marketed for premedication in children and for breakthrough pain in patients with chronic pain. Sublingual glyceryl trinitrate is used to treat angina thus avoiding first-pass metabolism in the liver.

Inhalational administration
Gaseous and volatile agents such as the inhalational anaesthetics are administered and eliminated from the body through the lungs. The lungs have a large surface area and a high blood flow such that rapid changes in drug concentration can be achieved. The speed at which equilibrium is reached between alveolar air and the blood is fastest if the gas or vapour is relatively insoluble in blood or tissue. Thus, nitrous oxide has a fast onset and offset of effects while diethyl ether is relatively slow. Some drugs intended to act locally in the lungs are also given by inhalation: for example β_2-adrenoceptor agonists (e.g. salbutamol) for the treatment of asthma. This limits the adverse systemic effects of the drug. However, some systemic side-effects still occur because some drug is absorbed into the systemic circulation.

Extradural administration
Drugs, particularly local anaesthetics and opioids, may be administered into the area between the dura mater of the spinal cord and the periosteum lining the vertebral canal. This epidural space is filled with blood vessels, lymphatics and adipose tissue, and drugs can penetrate rapidly into the dural root sleeves close to the dorsal root ganglia. Arachnoid villi may penetrate through gaps in the dura into the extradural space aiding penetration of drugs into the nerve root across the thin arachnoid membrane. The extent and duration of the effects of drug administered by this route depend on the concentration of the drug and the volume injected. Some uptake of drug into the spinal cord also occurs.

Pregnant women may be more susceptible to extradural administered drugs because the peridural venous plexus is extended owing to compression of the vena cava by the uterus and baby. This can reduce the potential epidural space, requiring a reduction of dose. ◆

Gastric Disorders

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Peptic ulceration (duodenal and gastric) affects 10% of the population at some time and most people have suffered from indigestion, dyspepsia or heartburn, many times. The causes include overindulgence, poor cooking, anxiety and the side-effects of non-steroidal anti-inflammatory drugs (NSAIDs). *Helicobacter pylori* also has an important role in ulcer formation.

Control of gastric acidity

The function of the stomach is to store ingested food and present it to the small intestine as a premixed, predigested chyme (juice). To achieve this, the stomach contains three layers of muscle for efficient mixing of food and secretes 2–3 litres/day of gastric juice from the gastric glands. The composition of gastric gland secretions is shown in Figure 1.

Secretions of the gastric glands

Secretion	Function	Originating cells	Site
Gastric lipase	Digests fat in infants	Chief cells	Near base of gastric glands
Gastrin	Stimulates HCl and enzyme secretion and stimulates gastric motility. Acts on a gastrin (cholecystokinin-B) receptor	Enteroendocrine cells	At the base of the pyloric glands Reaches site of action in the blood
Histamine	Stimulates HCl secretion Acts on histamine H_2-receptors	Enteroendocrine cells (mast cell like)	Close to parietal cells in gastric gland Diffuses to site of action
Hydrochloric (HCl)	Destroys pathogens, activates pepsin and lipase, reduces iron to useable Fe^{2+}	Parietal cells	Top half of acid gastric glands and some in the pyloric glands
Intrinsic factor	Enables absorption of vitamin B_{12}	Parietal cells	Top half of gastric glands and some in the pyloric glands
Mucus	Protects mucosa from HCl and enzymes	Mucosal cells	Surface of the mucosa and in the neck of the gastric glands
Pepsinogen	Converted to pepsin which digests proteins	Chief cells	Near base of gastric glands
Renin	Coagulates milk protein in the infant	Chief cells	Near base of gastric glands
Serotonin	Stimulates gastric motility	Enteroendocrine cells	At the base of the gastric gland
Somatostatin	Inhibits gastric, bile and pancreatic secretion and inhibits gastric motility	Enteroendocrine cells	At the base of the gastric gland

1

Peptic ulceration and gastro-oesophageal reflux disease are common pathological conditions associated with high gastric acid concentrations and reflux of stomach acid into the oesophagus, respectively. Drugs that reduce gastric acidity are effective treatment for these conditions. In women undergoing caesarean section, significant morbidity and mortality is associated with the aspiration of gastric contents and it is recommended that they receive antacid prophylaxis before surgery.

Antacids

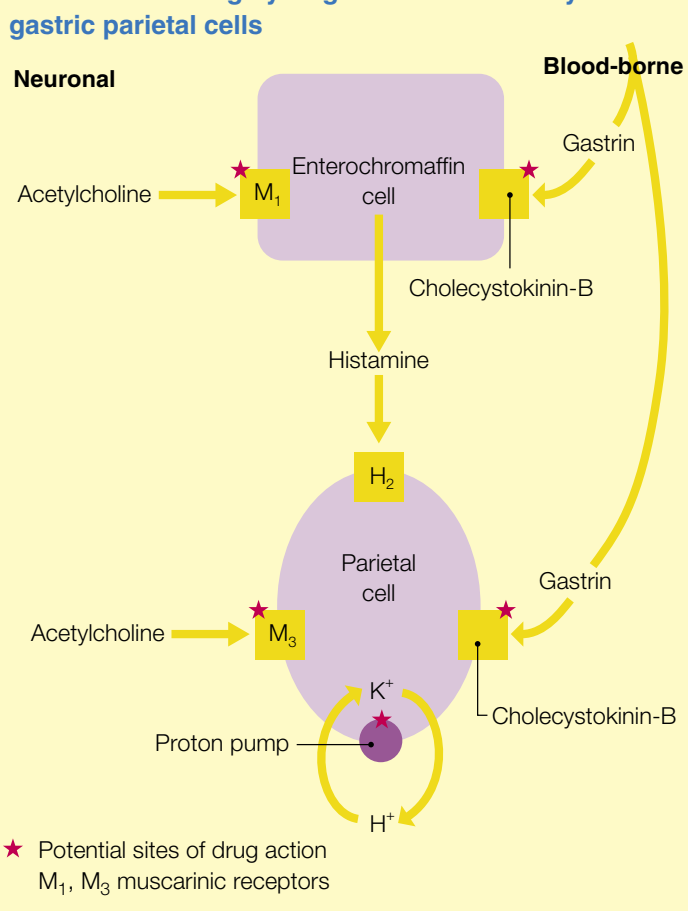
The easiest way of decreasing gastric acidity is to neutralize it with a weak base because most peptic activity ceases above a pH of 4–5. Many over-the-counter indigestion treatments contain aluminium hydroxide, magnesium hydroxide or magnesium trisilicate. In general, liquid preparations are more effective than tablets. Although magnesium- or aluminium-based preparations may enhance duodenal ulcer healing they are less effective than the other acid-reducing strategies described below. It has been suggested that antacids also increase the production of protective prostaglandins and combine with noxious substances in the stomach. The role of these additional properties is unclear. Aluminium-containing preparations are associated with constipation while magnesium-based preparations may induce diarrhoea. Both sodium bicarbonate and calcium salts may be effective for a short time, but both induce a rebound increase in acid secretion that has caused them both to fall out of favour. For antacid prophylaxis before caesarean section, a non-particulate antacid is desirable and sodium citrate is used routinely. Antacids may be combined with each other (to no obvious clinical benefit) or with an antifoaming agent (e.g. simethicone) which may be of particular use in the treatment of hiccup. Alginates may also be added, which produce a raft on top of the gastric contents and may help to protect the oesophagus in heartburn.

Drugs reducing the release of gastric acid

Factors facilitating proton release from the parietal cells are summarized in Figure 2. Vagal stimulation causes the release of acetylcholine which acts on muscarinic (M_1) receptors on the enterochromaffin-like cells to cause a release of histamine and directly on muscarinic (M_3) receptors on the parietal cell. Some textbooks suggest that M_2-receptors instead of M_3-receptors may be involved. Histamine may also be released from the entero-chromaffin-like cells by gastrin acting on the gastrin or cholecystokinin-B (CCK-B) receptor. It may also act directly on the parietal cell, presumably on another CCK-B receptor, because proglumide, a CCK-B receptor antagonist, prevents its action. Histamine, acting on H_2-receptors on the parietal cell, causes the release of hydrogen ions via H^+/K^+-ATPase (the proton pump). This is associated with the extrusion of chloride ions by a potassium/chloride symporter that is not shown in Figure 2.

Thus, drugs with inhibitory effects at four sites have the potential for reducing gastric acid secretion (Figure 2). Muscarinic antagonist drugs are seldom used to reduce gastric acid secretion mainly because of the extensive side-effects caused by blockade of other muscarinic receptors leading to blurred vision and dry mouth. Pirenzapine, a selective M_1-receptor antagonist, causes fewer side-effects than non-selective muscarinic antagonists, and can reduce gastric acid secretion by over 40%. The exact site of this action is uncertain but M_1-receptors are believed to be present in parasympathetic ganglia and their antagonism prevents post-synaptic vagal stimulation of the parietal cell. However, it is less effective than the other treatments mentioned below and is of only historical interest.

Factors facilitating hydrogen ion secretion by gastric parietal cells



2

Histamine H_2-antagonists (e.g. cimetidine, ranitidine) are available over the counter and are used in the treatment of peptic ulcers and reflux oesophagitis. They are capable of reducing basal and food-stimulated gastric acid by 90%. They have also been used to reduce gastric acidity before caesarean section.

Proton-pump inhibitors (Figure 3) are prodrugs that are stable at neutral pH, lipid soluble and devoid of pharmacological activity. They are weak bases that accumulate in the acidic secretory canaliculi of the parietal cells, where they are activated by a proton-catalysed process to produce thiophilic silfenamide and sulfenic acid. They bind covalently with the sulfhydryl groups of the cysteines situated on the extracellular domain of H^+/K^+-ATPase. Binding to cysteine 813 is essential for irreversible inhibition of the proton pump. Proton-pump inhibitors are not acid stable therefore they have to be enteric coated so that they are dispersed and absorbed at alkaline pH. Although their plasma elimination half-life is relatively short (1–2 hours), the irreversible nature of their action means that once daily administration is adequate. Proton-pump inhibitors promote the healing of peptic ulcers to a greater extent than H_2-receptor antagonists and they are also suitable for reducing gastric acidity before caesarean section. Proton-pump inhibitors in combination with an antibiotic such as amoxicillin (amoxycillin), clarithromycin or metronid-azole are recommended for the eradication of *H. pylori*. The drugs used clinically to reduce gastric secretion are listed in Figure 3.

Drugs used clinically to reduce gastric acid secretion

Drug group	Comment
H_2-receptor antagonists	
Cimetidine	Inhibits drug metabolism and has some affinity for androgen receptors where it is an antagonist
Famotidine Nizatidine Ranitidine	These agents have less effect on drug-metabolizing enzymes and androgen receptors
Proton-pump inhibitors	
Omeprazole	Also used for Zollinger–Ellison syndrome
Esomeprazole Lansoprazole	Also used for Zollinger–Ellison syndrome
Pantoprazole	More acid stable than others
Rabeprazole	

3

Negative influences on the release of gastric acid include somatostatin acting on the ST_2-receptor and prostaglandin E_2 acting on the EP-receptor. There have been some preliminary trials of octreotide, a long-acting somatostatin analogue in Zollinger–Ellison syndrome, a pancreatic tumour that secretes gastrin. However, the drug must be given parenterally, so it is of limited use in its present form. Misoprostol is a stable analogue of prostaglandin E_1 that has been used to reduce the gastric damage caused by chronic NSAID administration. Side-effects include diarrhoea, abdominal cramps and uterine contraction.

Mucosal protective agents

Once acid-induced gastric damage has occurred, pepsin can cause the hydrolysis of mucosal proteins, which contributes to mucosal erosion and ulceration. This process can be inhibited by sulfated polysaccharides such as sucralfate, which is an octasulfate of sucrose complexed with aluminium hydroxide. In the presence of acid, sucralfate crosslinks and polymerizes to produce a viscous sticky gel that adheres to epithelial cells, particularly ulcer craters. This protects the surface from further damage by acid, pepsin or bile salts. Sucralfate also binds to bile salts and stimulates the production of prostaglandins and epidermal growth factor. Both of these properties may contribute to ulcer healing. Sucralfate is also used in the prophylaxis of stress ulcers in ICUs. The main side-effect of sucralfate is constipation and it may inhibit the absorption of other drugs such as cimetidine and phenytoin.

Other compounds thought to provide a protective coat over ulcer craters are the colloidal bismuth compounds, bismuth subcitrate and tripotassium dicitratobismuthate. Bismuth compounds are also thought to inhibit pepsin activity and increase prostaglandin and mucus production. There is some evidence that they have a toxic effect on *H. pylori*, but they are usually used in combination with antibiotics. Ranitidine bismuth citrate is a recommended alternative to proton-pump inhibitors for the eradication of *H. pyl*ori.

Carbenoxolone is mainly of historical interest. It is a derivative of glycyrrhizic acid (found in liquorice root) and is thought to increase the quantity and viscosity of mucus in the stomach, thus enhancing the mucosal barrier. However, it has significant mineralocorticoid activity, which limits its usefulness. In addition, its ulcer-healing properties are no better than those of the H_2-receptor antagonists discussed above.

Controlling gastrointestinal motility

Prokinetic drugs

Gastrointestinal motility is stimulated by activation of the parasympathetic nervous system that releases acetylcholine onto muscarinic receptors. Thus, muscarinic agonists (e.g. bethanicol) and anticholinesterase agents (e.g. pyridostigmine, neostigmine, distigmine) can increase intestinal activity and have been used to treat paralytic ileus. However, parasympathetic effects such as bradycardia and sweating limit their usefulness.

More selective pro-kinetic drugs include metoclopramide and cisapride, both of which are agonist at 5-HT_4-receptors. Cisapride is the more selective of the two and can be used for treating reflux oesophagitis, usually in combination with a H_2-receptor antagonist. The actions of cisapride are to increase the lower oesophageal sphincter pressure, increase gastric emptying and possibly improve oesophageal peristalsis. However, a recent report of serious cardiac arrhythmias occurring in patients given this drug have caused a re-evaluation. Metoclopramide has several mechanisms of action that contribute to its prokinetic effects. As a 5-HT_4-agonist it stimulates excitatory neurons, suppression of inhibitory neuron activity is brought about by 5-hydroxy-tryptamine (5-HT_3)-receptor antagonism (which occurs only at high doses) and peripheral dopamine (D_2)-receptor blockade reduces the inhibitory action of dopamine on cholinergic neur-ons in the gastrointestinal tract. Metoclopramide has additional anti-emetic activity owing to central D_2-receptor antagonism and 5-HT_3-antagonist activity. Both domperidone and ondansetron also possess some moderate prokinetic activity because of their peripheral D_2- and 5-HT_3-antagonist activity, respectively.

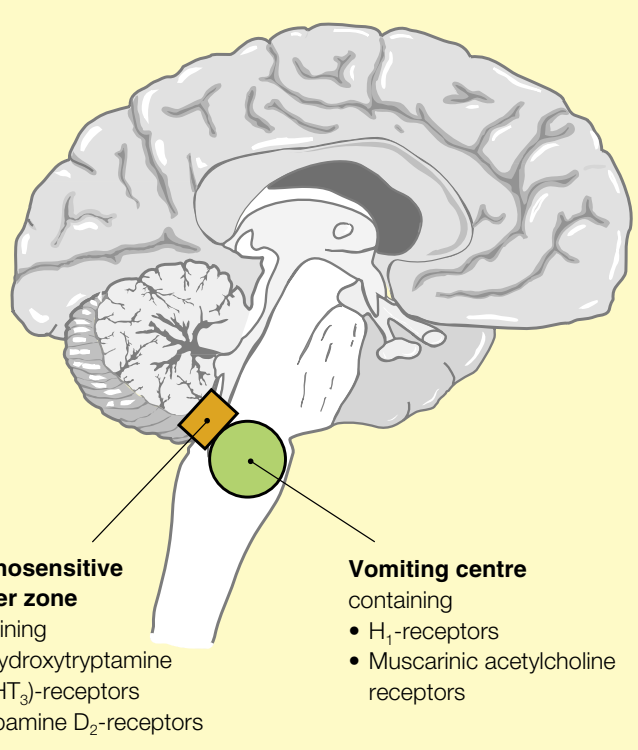
Erythromycin also has some prokinetic properties because it increases lower oesophageal sphincter pressure and increases gastric and small bowel, but not colonic, activity. It is thought to act on the motilin receptor. Motilin is a gastrointestinal tract hormone that participates in the initiation of motor responses that propel food through the stomach and the intestine.

Controlling vomiting

Emetic and anti-emetic drugs

The anatomy and physiology of vomiting and anti-emetic drugs is discussed elsewhere. Briefly, the two main parts of the brain involved in vomiting are the chemoreceptor trigger zone in the area postrema on the floor of the fourth ventricle and the vomiting centre in the medulla (Figure 4). Activation of D_2-receptors and/or 5-HT_3-receptors are responsible for activating vomiting at the chemoreceptor trigger zone and histamine H_1-receptors and muscarinic receptors for acetylcholine activate the vomiting centre. The principal anti-emetic drugs are antagonists at these receptors (Figure 5). Anti-emetic drugs may be used to treat postoperative nausea and vomiting (PONV), chemotherapy-induced vomiting, vomiting due to vestibular disturbance, including motion sickness and vomiting in pregnancy. However, therapy is not advised during the first trimester and subsequent use should be limited to severe vomiting.

Vomiting centre in the medulla



4

Anti-emetic drugs

Pharmacological action	Comments
Dopamine antagonists	
Chlorpromazine Perphenazine Prochloperazine Trifluoperazine	All may cause dystonic reactions due to dopamine receptor antagonism in the nigrostriatal tract May also block H_1 and ACh M receptors. Chlorpromazine is more sedative than the rest
Metoclopramide	Similar profile to above, but it is also prokinetic and in high doses is a 5-HT_3 antagonist
Domperidone	Penetrates the CNS poorly so is less likely to produce dystonic reactions. Only useful for moderately emetogenic chemotherapy
5-HT_3 antagonists	
Granisetron Ondanseton Tropisetron	They have both peripheral and central actions. Used for chemotherapy induced emesis and postoperative nausea and vomiting
Antihistamines (Histamine H_1-receptor antagonists)	
Cinnarizine Cyclizine Meclozine Promethazine	Mainly used for vestibular disorders. They are effective in emesis from other causes but are not usually the drug of choice. Drowsiness is the most significant side-effect together with antimuscarinic actions like dry mouth
Muscarinic acetylcholine receptor antagonists (ACh M)	
Hyoscine	Typical antimuscarinic action (e.g. blurred vision, dry mouth)

5

Opioid receptors are also present on the chemoreceptor trigger zone and are responsible for the emetic actions of opioid analgesics. It has been suggested that endogenous opioid peptides have a role in vomiting via δ receptors at the chemoreceptor trigger zone and μ receptors at the vomiting centre. Nitrous oxide is believed to release endogenous opioids. Some recent studies have suggested that when nitrous oxide is used as part of an anaesthetic regimen there is a significantly higher incidence of PONV and a higher need for anti-emetic drugs than in nitrous oxide free regimens.

In addition, prevention of enkephalin breakdown may be a mechanism by which cytotoxic drugs cause emesis. Stimuli from the pharynx and stomach also induce vomiting, probably via activation of 5-HT_3-receptors on the visceral afferent nerves. Vomiting can be induced by ipecacuanha, which acts as an irritant in the stomach via the action of two constituent alkaloids, cephaeline and emetine. This may be used to stimulate vomiting after oral ingestion of a toxin, provided that it is not corrosive and the patient is fully conscious. Lower doses of ipecacuanha act as an expectorant. Thus, 5-HT_3 antagonists act peripherally and centrally as anti-emetics.

Non-pharmacological techniques used to prevent PONV include acupuncture, electroacupuncture, transcutaneous electric nerve stimulation and acupressure. They are more effective than placebo in adults but not in children. Electrical stimulation of the vestibular system, using a nuchal-positive electrode placed over both mastoid processes also reduces the need for anti-emetic drugs in PONV. ◆

Histamine and Antihistamines

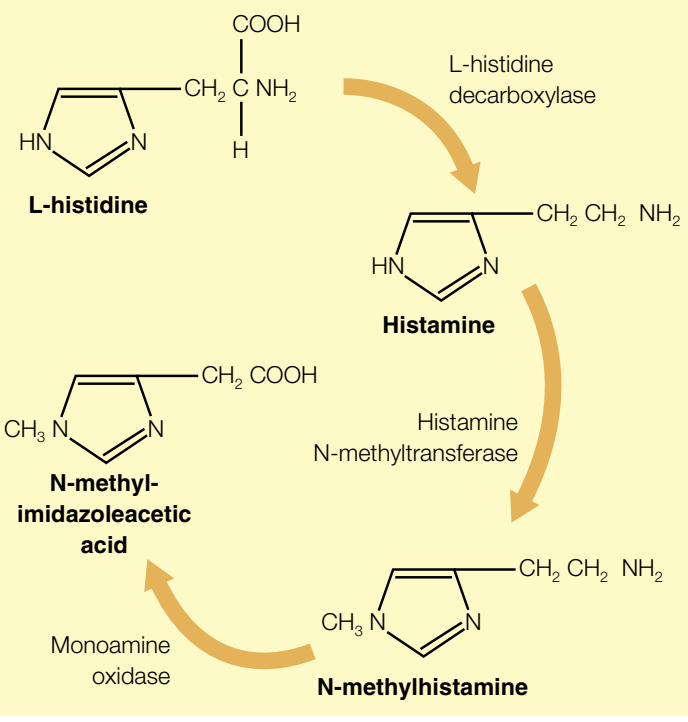
Roger Small

Roger Small is Reader in Pharmacology at the University of Manchester, UK. He graduated in pharmacy from Manchester University and studied pharmacology at postgraduate level. His research interests include the electrophysiology of airways smooth muscle and the actions of established and novel anti-asthma drugs.

Histamine

Histamine is found in all mammalian tissues. It is formed from histidine by the action of L-histidine decarboxylase. Histamine is metabolized mainly by the actions of histamine-N-methyltransferase and monoamine oxidase (Figure 1).

Biosynthesis and major metabolic pathway for histamine



1

Mast cells are the main storage site for histamine. There are high numbers of mast cells in the lung, skin and gastrointestinal mucosa and therefore these tissues contain the highest concentrations of histamine. In the blood, histamine is stored in basophils. Within the mast cells and basophils, histamine is stored as a granular complex with a heparin of high molecular weight and an acidic protein. Other histamine-containing cells include the histaminocytes of the stomach and the histaminergic neurons of the hypothalamus. The axons of the histaminergic neurons run in the medial forebrain bundle to supply large areas of the cortex and midbrain.

Histamine is released from mast cells and basophils during allergic or inflammatory reactions. The interaction of antigen with IgE antibodies anchored to the cell surface triggers a rise in the cytosolic concentration of free calcium ions. This causes exocytosis of the histamine storage granule followed by the release of histamine from the granule by the process of cation exchange. Many agents that are stronger organic bases than hist-amine (e.g. suxamethonium, morphine, radiocontrast media, carbohydrate plasma expanders) can enter mast cells and basophils and directly displace histamine from the storage granules. The actions of histamine are mediated by histamine receptors of the H_1, H_2 and H_3 subtypes. Figure 2 lists the properties of these receptor subtypes and the effects that they mediate.

Histamine receptors and the effects they mediate

Receptor subtype	Selective agonist	Selective antagonist	Location	Effect mediated	Signal transduction process
H_1		Mepyramine Chlorpheniramine Cetirizine Terfenadine	Smooth muscle of gastrointestinal tract and airways	Contraction	G_s modulation of phospholipase C with IP_3 production and Ca^{2+} release from endoplasmic reticulum
			Vascular endothelium Endothelial cells of postcapillary venules	Vasodilatation via NO release Contraction and increased vascular permeability	
H_2	Dimaprit	Cimetidine Ranitidine	Cardiac atria and ventricles	Increased rate and force of contraction	G_s modulation of adenylyl cyclase, with cAMP production, activation of PKA and increase (cardiac and parietal cell stimulation) or decrease (vasodilatation) in $[Ca^{2+}]$
			Vascular smooth muscle	Delayed vasodilatation	
			Gastric parietal cells	HCl secretion	
H_3	(R) α-methyl -histamine	Thioperamide	Histaminergic neurons in hypothalamus	Presynaptic inhibition of transmitter release	G protein mediated inhibition of Ca^{2+} influx

2

Antihistamines

Competitive antagonists at histamine H_1-receptors

Antagonists at H_1-receptors are stable, lipid-soluble amines that have the ethylamine side-chain of histamine. They reversibly inhibit the peripheral effects of histamine, such as contraction of gastrointestinal and airway smooth muscle, stimulation of sensory neuron terminals (itching) and oedema resulting from increased permeability of post-capillary venules. They also reversibly inhibit the more rapid of the two vasodilatory responses to histamine. Competitive antagonists at H_1-receptors are divided into sedating (first-generation) and non-sedating (second-generation) agents (Figure 3). First-generation anti-histamines have effects unrelated to their blockade of H_1-receptors (e.g. sedative, anti-emetic and anticholinergic).

Antagonists at H_1- and H_2-receptors

First-generation (sedating) H_1-antagonists

- Alimemazine (trimeprazine)
- Azatadine
- Brompheniramine
- Chlorphenamine (chlorpheniramine)
- Clemastine
- Cyproheptadine
- Diphenhydramine
- Hydroxyzine
- Triprolidine

- Cinnarizine
- Cyclizine
- Meclozine
- Promethazine

Have antagonist activity at muscarinic acetylcholine receptors. Useful in the control of nausea and vomiting associated with motion, Meniére's disease or gastric irritation

Second-generation (non-sedating) H_1-antagonists

- Acrivastine
- Cetirizine
- Fexofenadine
- Loratidine

- Mizolastine
- Terfenadine

Block cardiac delayed rectifier K^+-channels and may induce hazardous ventricular tachydysrhythmias

H_2-antagonists

- Famotidine
- Nizatidine
- Ranitidine

- Cimetidine

Binds to hepatic cytochrome P450. Beware interference with the metabolism of benzodiazepines, warfarin, phenytoin and theophylline

3

Most drugs from both groups are absorbed rapidly after oral administration. The sedative effects of the first-generation antihistamines depend on their ability to cross the blood–brain barrier. Second generation antihistamines do not cross the blood–brain barrier to any appreciable extent. Most of the sedating and non-sedating antihistamines are metabolized by hepatic mixed-function oxidase enzymes.

Sedating antagonists at H_1-receptors are useful in the treatment of allergic reactions such as seasonal allergic rhinitis and conjunctivitis (hay fever). Protection against the effects of allergen exposure is usually incomplete. In hay fever, antihistamines may reduce rhinorrhoea and sneezing, but are less effective against nasal congestion. Antihistamines have limited effectiveness in controlling allergic reactions because allergen exposure triggers the release of several other potent mediators as well as histamine. Several proprietary formulations of chlorpheniramine are sold to the public for the relief of hay fever.

Sedating antihistamines are also useful in controlling allergic reactions to drugs, the itching associated with urticarial skin rashes and insect bites and stings. Chlorpheniramine or promethazine may be administered by slow intravenous injection as an adjunct to adrenaline (epinephrine) in the emergency treatment of anaphylaxis.

All first-generation antihistamines have sedative activity, but promethazine may be prescribed for the short-term treatment of insomnia. Several proprietary formulations of promethazine and diphenhydramine may be sold to the public for the control of insomnia. Promethazine is commonly used as a sedative/hypnotic pre-anaesthetic in children. H_1-antagonists (cinnarizine, cyclizine, meclozine, promethazine) that also block muscarinic acetylcholine receptors are useful in the control of certain types of nausea and vomiting. These H_1-antagonists are ineffective against agents that induce vomiting by a direct action on the chemosensitive trigger zone. However, they can suppress the nausea and emesis associated with motion sickness or Meniére's disease. They can also suppress emesis induced by agents that act locally to irritate the stomach. The anti-emetic activity of these H_1-antagonists depends, at least in part, on their ability to block muscarinic acetylcholine receptors located at the level of the vestibular nuclei, the nucleus solitarius and the medullary vomiting centre. They are most effective if given before the onset of nausea. Meclozine may be sold to the public for the prophylaxis of motion sickness. The H_1-antagonists that also cause muscarinic blockade should be used with caution in prostatic hypertrophy, urinary retention, narrow angle glaucoma and pyloroduodenal obstruction.

Unwanted effects of first-generation antihistamines are common but tend to be mild. They all cause drowsiness. The sedative effects of H_1-antagonists may extend into the following day, may impair performance at skilled tasks and are enhanced by ethanol. Drugs with significant muscarinic blocking activity cause dry mouth, blurred vision, gastrointestinal disturbances and urinary retention. Other side-effects include hypotension, hypersensitivity reactions, tremor, convulsions, blood dyscrasias and hepatic dysfunction.

Non-sedating antagonists at histamine H_1-receptors are used for the symptomatic relief of allergic disorders such as hay fever and urticaria. They may also be used to alleviate the effects of insect bites and stings. Acrivastine, cetirizine and loratidine can be sold to the public for hay fever relief in adults and children over 12 years of age. Unwanted effects (e.g. headaches, dizziness) of second-generation antihistamines are usually mild and uncommon. However, mizolastine and terfenadine have the propensity to block myocardial potassium channels of the delayed rectifier type. For this reason they may prolong the QT interval of the ECG and carry a low risk (0.25 reactions per million doses) of precipitating hazardous ventricular arrhythmias such as torsade de pointes. It is therefore recommended that mizolastine and terfenadine are avoided if there is significant hepatic impairment, hypokalaemia or known or suspected prolonged QT interval. They should also be avoided if the patient is receiving other drugs known to prolong the QT interval or to delay their metabolism. Fexofenadine is an active metabolite of terfenadine that does not block cardiac potassium channels.

Competitive antagonists at histamine H_2-receptors
Antagonists at H_2-receptors inhibit the cardiac stimulation, gastric acid secretion and delayed vasodilatation induced by histamine (Figure 3). Inhibition of gastric acid secretion is the only effect of these drugs that is exploited therapeutically. They inhibit HCl secretion induced by histamine or gastrin and reduce the HCl secretion induced by acetylcholine released from postganglionic parasympathetic (vagal) nerve terminals. The antagonists at histamine H_2-receptors are used to promote the healing of gastric and duodenal ulcers. They are also beneficial in the treatment of ulcers induced by non-steroidal anti-inflammatory drugs and in the relief of gastro-oesophageal reflux disease. Cimetidine, famotidine, nizatidine and ranitidine can be sold to the public for the short-term relief of heartburn, dyspepsia and hyperacidity in those over 16 years of age.

Unwanted effects of antagonists at histamine H_2-receptors include diarrhoea and other gastrointestinal disturbances, headaches, rashes, tiredness and, occasionally, mental confusion. Most of the antagonists at histamine H_2-receptors also act as antagonists at androgen receptors and can cause gynaecomastia. They should be used with caution in patients with hepatic or renal impairment because their tendency to cause confusion may become more pronounced unless the dose is reduced. The antagonists at histamine H_2-receptors are, to a variable extent, excreted in milk and should be avoided in patients who are breast-feeding. Manufacturers advise avoiding these agents during pregnancy. Cimetidine binds to hepatic microsomal cytochrome P450 and therefore inhibits the metabolism of agents such as benzodiazepines, warfarin, phenytoin and theophylline and should be avoided in patients stabilized on them.

Antagonists at histamine H_3-receptors
No antagonists at H_3-receptors are in clinical use.◆

Inhalational Anaesthetics

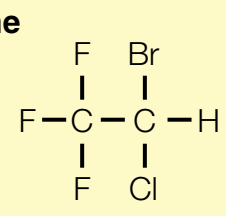
Nigel Harper

Nigel Harper is Consultant in Anaesthesia and Intensive Care at Manchester Royal Infirmary. He trained in Birmingham and Manchester. His research interests include neuromuscular pharm-acology, regional anaesthetic techniques and the pharmacology of inhalational agents. He is a founder member and Vice President of the Association of Low Flow Anaesthesia, an international forum that promotes research and development in this field.

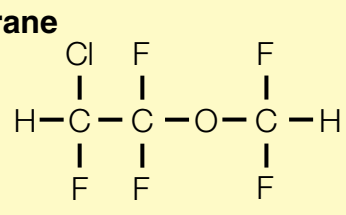
The volatile anaesthetic agents are halogenated hydrocarbons. They are more dense than water and when a vaporizer is used in a circuit, water vapour can condense on the surface of the volatile agent, reducing its vaporization. Isoflurane and enflurane are structural isomers (not stereoisomers because there is no chiral centre) (Figure 1). In general, increasing the halogenation of the molecule confers increasing potency. The addition of fluoride atoms confers greater stability and, in general, a lower boiling point and a higher saturated vapour pressure (SVP). Thus, the substitution of the choride atom in isoflurane (SVP 32 kPa) by a fluoride atom results in desflurane, which is hardly metabolized at all, boils at room temperature and has an SVP of 88.3 kPa (Figure 2). Greater solubility in blood or oil is associated with higher potency and a corresponding low minimum alveolar concentration (MAC). The molecular weights of the volatile anaesthetics in current use are similar (168–200 Da) and it follows that 1 ml of liquid produces a similar volume of saturated vapour (about 200 ml). This calculation becomes important when designing the new generation of administration devices that use direct injection of liquid agent into the circuit.

Chemical formulae of the commonly used volatile anaesthetic agents

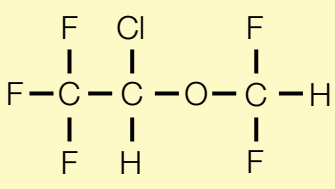
Halothane



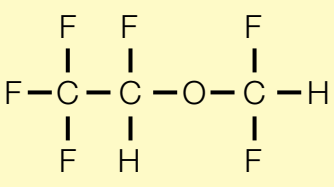
Enflurane



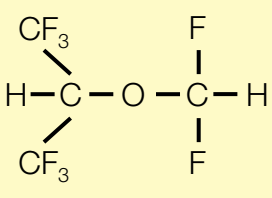
Isoflurane



Desflurane



Sevoflurane



1

Physicochemical properties of the inhalational agents

	Formula	Boiling point (°C)	Saturated vapour pressure at 20°C	Blood gas partition coefficient	Oil gas partition coefficient (kPa)
Halothane	$C_2HBrClF_3$	50.2	32.4	2.3	224
Enflurane	$C_3H_2ClF_5O$	56.5	22.9	1.9	96
Isoflurane	$C_3H_2ClF_5O$	48.5	31.9	1.4	91
Sevoflurane	$C_4H_3F_7O$	58.5	21.3	0.6	53
Desflurane	$C_3H_2F_6O$	23.5	88.3	0.42	19

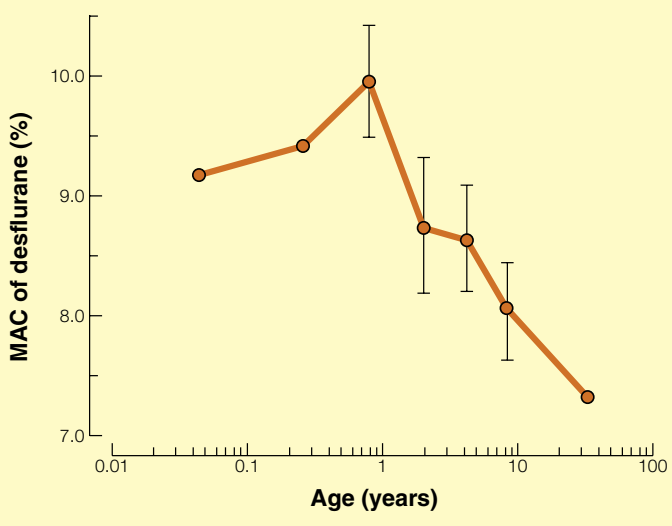
2

MAC

The MAC is the concentration (volumes %) of an agent in oxygen that prevents movement in response to a standard surgical incision in 50% of the population. MAC changes if anaesthetic adjuncts (e.g. nitrous oxide, opioids or benzodiazepines) are co-administered. Although it has been stated that an inspired concentration of 1.2–1.3 × MAC prevents awareness, it must be appreciated that MAC is calculated on the basis of movement and not on the basis of awareness. MAC varies with age; it is maximum at about 1 year and rapidly declines in adulthood (Figure 3). Compared with MAC at 20 years, the MAC is reduced by 20% at 40 years of age and by 40% at the age of 80 years.

The MAC of the volatile agents is reduced by the co-administration of nitrous oxide; 60% nitrous oxide reduces the MAC of isoflurane by about 40%, sevoflurane by 24% and desflurane by 20%. There is some evidence that the MAC of isoflurane decreases with duration of anaesthesia. MAC_{awake} refers to the concentration of agent at which consciousness is regained. There is less variation in MAC_{awake} than in MAC (Figure 4).

Variation of minimum alveolar concentration (MAC) with age



3

Minimum alveolar concentration (MAC) for skin incision and regaining consciousness for the volatile agents

	$MAC_{skin\ incision}$	MAC_{awake}
Halothane	0.74	0.38
Enflurane	1.7	0.5
Isoflurane	1.2	0.36
Sevoflurane	2.0	0.36
Desflurane	6.0	2.6

4

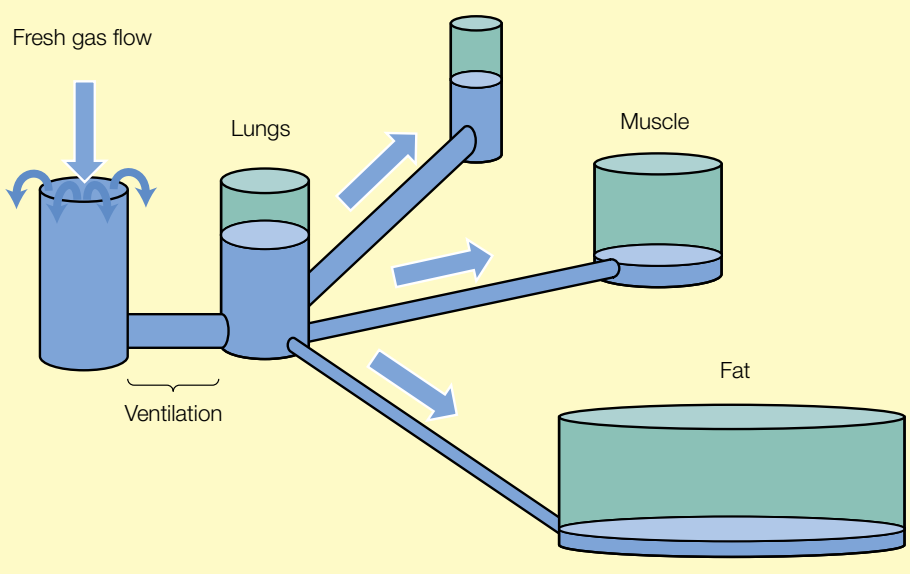
Uptake and distribution of volatile agents

There is increasing evidence that much of the action of volatile agents is at spinal level but, for the purposes of this discussion, the site of action will be assumed to be in the brain. The depth of anaesthesia depends on the partial pressure or tension of the agent at the site of action. Because volatile agents are present in their dissolved state in the body, their tension, or the avidness with which the molecules attempt to leave the dissolved state, is the important determinant of their effect in the CNS. An agent that has a low blood gas solubility coefficient (i.e. is poorly soluble in blood, such as sevoflurane) achieves a given tension faster than a more soluble agent (e.g. halothane) because fewer molecules need to be delivered to the pulmonary capillary blood from the alveoli per unit time. This phenomenon more than outweighs the higher MAC of the less soluble agents. Partial pressure is related to concentration in a gas mixture (partial pressure = concentration x barometric pressure) but the concentration (or number of molecules per unit volume) of a gas in a liquid depends on its partition or solubility coefficient. The inspired concentration of the agent is by far the most important determinant of how rapidly its tension builds up in blood and 'overpressure' is used in everyday practice to accelerate induction of anaesthesia. The end-tidal (alveolar) partial pressure of inhalational agent approximates to the brain tension only at near-equilibrium.

The partial pressure of volatile agent in any particular tissue depends on the delivery of agent via the blood, the partial pressure gradients between the tissue in question and the surrounding tissues, the affinity of tissues for the agent (tissue/gas partition coefficient) and the diffusibility of agent between one tissue and another. Changes in partial pressure with time are both perfusion and diffusion limited. At equilibrium, the partial pressure will be the same in all tissues, but this situation may take many hours to achieve. Diffusion between tissues probably becomes important only after the initial rapid uptake phase and is probably more important during recovery from anaesthesia. This may explain why the MAC_{awake} for different agents is less varied than the $MAC_{skin\ incision}$.

Uptake of an inhalational agent from the breathing system comprises the rapid 'wash-in' of agent into the functional residual capacity followed by distribution to the tissues. The rate of uptake into the tissues depends on blood flow, the solubility of the agent in the tissue and the total capacity of the tissue for the agent. The classical water analogue model was described by Mapleson (Figure 5). This model explains why a reduced cardiac output is associated with a shorter induction time. The reduced cardiac output is represented by a reduction in the diameter of the pipes to all the cylinders with the exception of that representing the brain. Cerebral blood flow is preserved as a result of autoregulation and, because the flow to the other cylinders is diminished and the inflow of agent into the lungs is unchanged, the transport of agent to the brain per unit time is increased and the desired brain partial pressure is attained more rapidly. The Mapleson model can also explain the effects of changes in ventilation.

Water analogue model



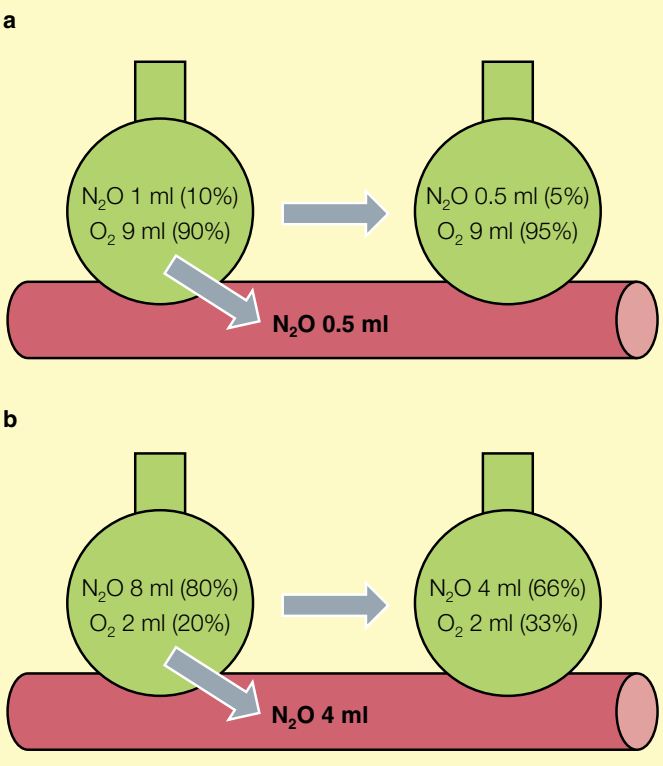
The tissues are represented by cylinders containing water; the volume representing the total storage capacity of that tissue. The head of water pressure represents the partial pressure of inhalational agent. The diameter of the interconnecting pipes represents transport of the inhalational agent in blood and is therefore proportional to the blood flow multiplied by the blood gas partition coefficient of the agent. The largest diameter pipe connects the lungs with the brain and viscera, the second largest to the muscle, and the smallest to the fat group consuming 75%, 23% and 2% of the cardiac output, respectively. The fat has the poorest perfusion but the largest capacity for inhalational agents. The partial pressure gradient between the alveoli and any particular tissue is represented by the difference in water level between the cylinder representing the lungs and the cylinder representing the various tissue compartments. Because the pipe leading to the cylinder representing the brain and viscera has the largest diameter, the partial pressure in the brain follows the alveolar partial pressure more closely than in other tissues.

5

The concentration effect

The concentration effect explains the observation that the higher the inspired concentration of inhalational agent, the faster the rise in alveolar concentration. During induction of anaesthesia the uptake of the inhalational agent from the alveoli per unit time is much greater than the uptake of the less soluble oxygen and nitrogen. Taking the latter part of inspiration and expiration together, the greater uptake of the inhalational agent in comparison with oxygen and nitrogen tends to reduce the concentration of the agent in the alveoli and, consequently, its partial pressure falls progressively until a new breath replenishes the supply of agent to the alveoli. This effect is more marked if the inspired concentration of agent is small because, although the absolute quantity of agent taken up is less, its partial pressure is reduced to a proportionally greater extent before the next inspiration begins (Figure 6).

The concentration effect



The uptake of nitrous oxide from the alveoli into the pulmonary capillaries. Each imaginary alveolus has an initial volume of 10 ml. **a** In the upper, left alveolus there is a low initial concentration of nitrous oxide. Of the 1 ml initially present at the end of inspiration, half is taken up into the pulmonary capillary before the alveoli are replenished during the next inspiration. As a result the volume of nitrous oxide in the alveolus has fallen to 0.5 ml. This represents a fall of 50% in the concentration, and therefore partial pressure, of nitrous oxide during one respiratory cycle. In **b** there is a higher initial concentration of nitrous oxide (80%, lower left). Again, half is taken up (4 ml) but the resulting fall in alveolar concentration is less: from 80% to 60% (lower right). This effect explains why a high inspired concentration of inhalational agent is associated with a rapid increase in alveolar concentration.

The second gas effect

Nitrous oxide (the first gas) is taken up from the alveoli in large quantities because its high concentration more than offsets its relative insolubility. The nitrous oxide that is taken up is replaced from the inspired gas, thus effectively increasing alveolar ventilation. The increase in alveolar ventilation also increases the supply of the second 'gas', for example isoflurane, to the alveoli. The alveolar concentration of isoflurane is thereby increased and its brain tension rises more rapidly than if nitrous oxide were not present. The second gas effect is more marked for more soluble second 'gases', such as halothane than for less soluble second 'gases', such as sevoflurane.

Metabolism and toxicity

Sevoflurane is less chemically stable than the other agents in current use. It undergoes significant biodegradation in the body and is also degraded by contact with carbon dioxide absorbents. About 3% of sevoflurane is biotransformed by the 2E1 isoform of cytochrome P450 to hexafluoroisopropanol and inorganic fluoride. Although 7 MAC hours of sevoflurane is associated with plasma fluoride concentrations of up to 40 μM, no convincing evidence of renal dysfunction in normal individuals has been published. The reaction with soda lime results in the formation of Compound A, a vinyl ether that results in renal tubular necrosis when administered in large concentrations to rats. It is thought that Compound A is conjugated with cysteine following which a toxic metabolite is released by the action of the enzyme β-lyase in the kidney. The concentration of β-lyase in the kidney in man is much less than in the rat. Compound A formation is favoured in the presence of dry soda lime at high temperatures.

Effects on the CNS

All the volatile agents impair the normal autoregulation of cerebral blood flow; it is increased four-fold by 1.6 MAC halothane and doubled by 1.6 MAC enflurane. The effect of isoflurane, sevoflurane and desflurane is less. The increase in cerebral blood flow can be attenuated by deliberate prior hyperventilation. All the agents, except halothane, cause a dose-related reduction in cerebral oxygen consumption. EEG activity is reduced in a dose-related fashion. Enflurane produces characteristic excitatory spikes at concentrations above 1.5 MAC, particularly in association with hypocapnia and it is prudent to avoid this agent in epileptic patients. Sevoflurane anaesthesia is associated with persistent EEG activity at 10–14 Hz at deeper planes of anaesthesia than the other agents, but is not epileptogenic.

Cardiovascular effects

All inhalational agents adversely affect the cardiovascular system to some extent (Figure 7). Several mechanisms are involved:

- direct depression of the vasomotor centre
- depression of baroreceptor reflexes
- depression of cardiac contractility
- dilatation of peripheral vessels causing a fall in systemic vascular resistance
- autonomic effects
- sensitization of the myocardium to catecholamines.

The combined effect is a dose-related fall in mean arterial pressure. Sevoflurane has the best cardiovascular profile and halothane the worst. Desflurane is associated with a sympathetically mediated sinus tachycardia when the concentration is increased rapidly above 1 MAC. This effect is attenuated by the addition of nitrous oxide.

In contrast, halothane may be associated with a dose-related bradycardia, slowing of atrioventricular conduction and ventricular arrhythmias. Halothane and enflurane decrease calcium ion release from the sarcoplasmic reticulum and marked hypotension may occur in patients taking calcium antagonists. Halothane has the greatest catecholamine-sensitizing effect and enflurane the least.

Coronary artery steal has been attributed to isoflurane, which dilates epicardial resistance vessels, but there is no evidence of an increase in perioperative cardiac events in clinical studies.

Sevoflurane appears to preserve the balance of epicardial to endocardial blood flow better than isoflurane and is associated with less reduction in mean arterial pressure.

Relative effects of the inhalational agents on the cardiovascular system

	Cardiac index	Heart rate	Systemic vascular resistance	Sensitization to catecholamines
Halothane	Large reduction	No change or small reduction	Reduction	++++
Enflurane	Reduction	No change	Reduction	–
Isoflurane	Reduction	No change or small increase	Reduction	+
Sevoflurane	No change	No change or small increase	No change or small reduction	+
Desflurane	No change	Large increase	No change or small reduction	–

Effects on respiration

All of the volatile agents depress the ventilatory response to hypercarbia and, to a greater extent, hypoxia in a dose-related fashion. Enflurane appears to have the greatest respiratory depressant effect and halothane the least. Isoflurane at 1 MAC depresses the ventilatory response to hypercarbia by 50% and the response to hypoxia is abolished. Airways irritation is most marked with desflurane and least with sevoflurane.

Renal effects

The fall in systemic arterial pressure induced by inhalational agents is associated with a fall in renal blood flow, glomerular filtration rate and urine output. Release of fluoride from these agents as a result of metabolism may impair renal function. A plasma concentration greater than 50 μM/litre has been considered to be renotoxic, but this threshold is probably spurious because the tissue concentration in the kidney is more important. Significant plasma concentrations of fluoride ions have been described after enflurane and sevoflurane anaesthesia, but the clinical significance is unclear. Nevertheless, it is prudent to avoid enflurane and sevoflurane in patients with pre-existing renal impairment.

Hepatic effects

The extremely rare fulminant hepatitis following halothane was originally thought to be the effect of a toxic metabolite produced by a reductive pathway. The current theory is that oxidative metabolism of halothane produces a trifluoroacetyl (TFA) halide. This compound changes the structure of cytochrome P450 and other proteins converting them into haptens, resulting in a dramatic inflammatory response in the liver in susceptible individuals. The presence in the plasma of anti-TFA antibodies is common in patients with halothane hepatitis but not other forms of hepatitis. Minor hepatic dysfunction associated with a transient rise in transaminases is more common and may be associated with a direct hepatotoxic effect of reductive metabolites.

Hepatic portal blood flow is reduced concomitantly with cardiac output and the portal venous oxygen saturation is reduced markedly. As a result, the liver depends on hepatic arterial flow to a greater extent. Autoregulation of the hepatic arterial bed is severely impaired by halothane, to a lesser extent by enflurane and sevoflurane, and least by isoflurane.

Neuromuscular effects

All inhalational agents potentiate the effects of neuromuscular blocking agents by reducing the release of acetylcholine at the neuromuscular junction and via a direct effect on contractility. Halothane has the least effect, enflurane, isoflurane and des-flurane are intermediate, and sevoflurane has the greatest effect.

Effects on the immune system

The volatile agents tend to produce an increase in the numbers of neutrophils but their function may be impaired. There is no evidence that the incidence of postoperative infection is influenced by the choice of anaesthetic agent.

Xenon

Xenon has an extremely low blood gas solubility (0.2) and a MAC of 63–71%. It is a dense gas with a high viscosity and its concentration is measured using a mass spectrometer or by its effect on the speed of sound. It is separated from air by fractional distillation. Xenon appears to produce anaesthesia by inhibiting NMDA channel opening. It has no smell, is not irritant, and produces rapid onset and offset of anaesthesia. Metabolism is almost nonexistent. Cardiovascular and respiratory stability is excellent though cerebral blood flow is increased. It may be associated with nausea. In common with nitrous oxide, it accumulates in air-filled body cavities. Although expensive, it has been used inclosed breathing systems; 60–70% can be scavenged and recycled.

The effects of barometric pressure on inhalational anaesthesia

Depth of anaesthesia is dependent on partial pressure and not concentration. Plenum vaporizers mix a definable ratio of carrier gas and gas that has been saturated with vapour. The vapour pressure of volatile agents depends on temperature only and not on atmospheric pressure. At high altitude it is unnecessary to alter the vaporizer setting to obtain the same clinical effect as at a lower altitude. The delivered concentration of volatile agent is reduced but the partial pressure remains unchanged. The desflurane vaporizer is an exception; it mixes pure desflurane vapour to the desired volume percent. The delivered partial pressure is reduced if the barometric pressure is reduced. At a barometric pressure of 80 kPa, a desflurane vaporizer set to 6% delivers the agent at a partial pressure of only 4.8 kPa. It is worth noting that infrared analysers measure the partial pressure of agent, not the concentration. The partial pressure of agent required to produce a clinical effect is unchanged at high altitude, but the concentration is increased. The concept of MAC is therefore unhelpful at high altitude.

Occupational exposure

There is continuing debate concerning the possible deleterious effects of occupational exposure of operating theatre personnel to inhalational agents. In the UK, the Health and Safety Commission's Advisory Committee on Toxic Substances has recommended the following Occupational Exposure Standards which came into force in 1996. Each is a maximum exposure over an 8-hour time-weighted, average, reference period: nitrous oxide 100 ppm; enflurane 50 ppm; isoflurane 50 ppm; halothane 10 ppm. This is a fifth of the exposure level at which no effects were seen in experimental animal studies.

Intravenous Induction Agents

J Max Fryer

J Max Fryer is Consultant in Anaesthesia and Pain Management at the Royal Preston Hospital, Preston, UK. He qualified from Manchester University and trained in the north-west of England. He has been involved in training as a tutor for the Royal College of Anaesthetists and as Chairman of the North West Specialty Training Committees. He is presently Deputy Regional Adviser for the north-west of England.

The first successful intravenous anaesthetic agents (IAAs) were produced in 1932 when sulphur was substituted for oxygen in the barbiturate ring to produce the thiobarbiturates. Waters and Lundy in the USA used thiopental (thiopentone) clinically in 1934. At that time, anaesthesia was usually induced by the inhalation of irritant anaesthetic vapours such as diethyl ether. Ether is irritant to the airways and induction slow, often with a prolonged excitement phase. IAAs produce a rapid smooth induction of general anaesthesia that is more pleasant for patient and anaesthetist. Thiopental (thiopentone), despite its imperfections, remains the gold standard for comparative purposes. Other IAAs in clinical use include methohexitone, etomidate, propofol and ketamine. The properties of the ideal IAA are given in Figure 1.

Properties of the ideal intravenous anaesthetic agent

Presentation and storage
- Water soluble
- Stable in solution at room temperature and on exposure to light
- Long shelf life

Rapid onset in one arm–brain circulation time
- Rapid penetration of the blood–brain barrier
- Highly lipid soluble (a large percentage non-ionized at body pH) and sufficient agent free to transfer (not highly protein bound)

Low side-effect profile
- No pain on injection
- Absence of excitatory effects on induction (coughing, hiccup or involuntary movement)
- Smooth emergence without confusion, restlessness or vivid dreams
- No emetic effects

Rapid recovery and lack of cumulation on repeat dosage
- Rapid redistribution to vessel-rich tissue
- Rapid clearance and metabolism to water-soluble non-active and non-toxic metabolites preferably in the liver, blood or other organs of the vessel-rich group
- Minimal disturbance of psychomotor skills and memory in the immediate recovery period

High degree of safety
- High therapeutic ratio
- Minimal cardiovascular and respiratory effects
- No release of histamine and no hypersensitivity reactions
- Safe if inadvertently injected into an artery, subcutaneously or into the nervous system (accidental epidural injection of thiopental (thiopentone) has been reported with no long-term sequelae)
- No venous sequelae (thrombophlebitis)

Little or no effect on other drugs and disease states
- No interaction with neuromuscular blocking drugs
- Can be used in patients with muscular dystrophy or porphyria

Other considerations
- Analgesic in subanaesthetic concentration

1

Mode of action

The site of action of IAAs is uncertain. There is no structural similarity between different agents and no reversing agent has been discovered. IAAs have effects on many other cells including phagocytes, the vascular endothelium and platelets, suggesting a number of modes of action. Isomerism is important in some cases suggesting a possible receptor-binding site. Meyer and Overton noted that volatile anaesthetic potency was related to lipid solubility and distortion of the lipid bilayer was considered a possible but nonspecific, site of anaesthetic action. Research has been directed towards the cell membrane proteins that regulate the functions of the neuron.

There is evidence that IAAs may act, in part, through the ligand-gated ion channels by enhancing the effects of inhibitory neurotransmitters especially γ-aminobutyric acid (GABA). Agonists at the postsynaptic $GABA_A$ receptor open the chloride ion channel. The influx of chloride ions into the neuron results in hyperpolarization. Thiopental (thiopentone) binds to the β subunits of the GABA receptor, increasing the time that the chloride channel is open. Benzodiazepines increase the frequency of opening of the chloride channel and bind to the α subunit. Thiopental (thiopentone) has an effect on the voltage-gated sodium and potassium channels. Propofol is thought to exert its main action by reducing the opening time of the sodium channels. In mice, the ED_{50} for propofol is decreased in the presence of the $GABA_A$ receptor agonist muscimol and increased in the presence of the antagonist bicuculline suggesting an action at the $GABA_A$ receptor. Propofol is known to reduce N-methyl-D-aspartate (NMDA)-activated currents. The main action of ketamine is inhibition at the NMDA receptor, but naloxone partially reverses ketamine analgesia suggesting additional action at the opiate receptors.

Pharmacokinetics

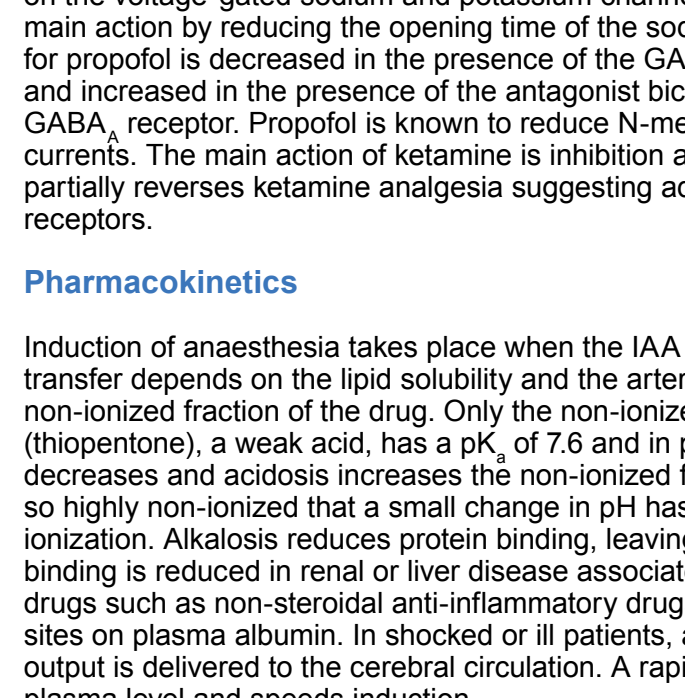
Induction of anaesthesia takes place when the IAA diffuses into the brain. The rate of transfer depends on the lipid solubility and the arterial concentration of the unbound, non-ionized fraction of the drug. Only the non-ionized fraction is lipid soluble. Thiopental (thiopentone), a weak acid, has a pK_a of 7.6 and in plasma 61% is non-ionized. Alkalosis decreases and acidosis increases the non-ionized fraction. Propofol and etomidate are so highly non-ionized that a small change in pH has little effect on the degree of ionization. Alkalosis reduces protein binding, leaving more IAA free for transfer. Protein binding is reduced in renal or liver disease associated with low plasma albumin and by drugs such as non-steroidal anti-inflammatory drugs (NSAIDs) that bind to the same sites on plasma albumin. In shocked or ill patients, a greater proportion of the cardiac output is delivered to the cerebral circulation. A rapid injection gives a higher peak plasma level and speeds induction.

The distribution and elimination of an IAA follows a three-compartment model. After injection, there is a high plasma level of the drug followed by a redistribution phase and elimination.

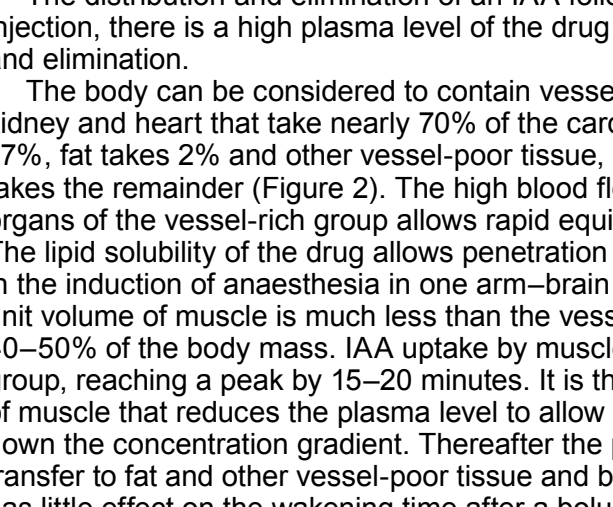
The body can be considered to contain vessel-rich organs such as the brain, liver, kidney and heart that take nearly 70% of the cardiac output at rest. Muscle takes 17%, fat takes 2% and other vessel-poor tissue, such as bone and connective tissue, takes the remainder (Figure 2). The high blood flow in proportion to the size of the organs of the vessel-rich group allows rapid equilibration of IAA within the tissues. The lipid solubility of the drug allows penetration of the blood–brain barrier resulting in the induction of anaesthesia in one arm–brain circulation time. The blood flow per unit volume of muscle is much less than the vessel-rich group, but muscle makes up 40–50% of the body mass. IAA uptake by muscle lags behind that of the vessel-rich group, reaching a peak by 15–20 minutes. It is the uptake of IAA by the large volume of muscle that reduces the plasma level to allow the IAA to leave the brain by diffusion down the concentration gradient. Thereafter the plasma level falls by the relatively slow transfer to fat and other vessel-poor tissue and by metabolic clearance. Blood flow to fat has little effect on the wakening time after a bolus of IAA, but fat may store significant quantities of IAA after repeat boluses or infusions especially in the obese. Agents with a higher rate of metabolism have increased clearance and a shorter terminal half-life, which improves the recovery profile and allows the use of infusions.

Distribution and elimination of intravenous anaesthetic agents

Perfusion and tissue mass



Redistribution of thiopental (thiopentone)



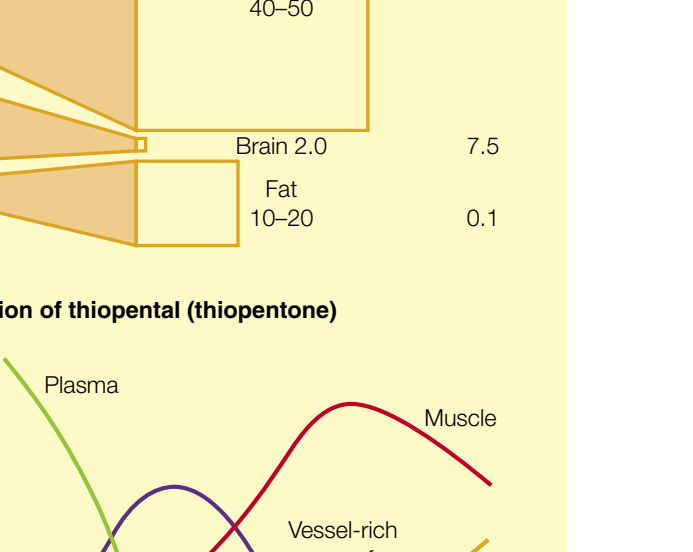
2

Barbiturates

The barbiturate ring is shown in Figure 3. There are four groups of barbiturates.
- The oxybarbiturates have hydrogen at position 1 and oxygen at position 2. They are of little clinical use because of delayed onset and prolonged action.
- The thiobarbiturates have hydrogen at position 1 and sulphur at position 2. Substitution of sulphur into pentobarbitone produces thiopental (thiopentone).
- Methyl barbiturates have a methyl group at position 1 and oxygen at position 2. Methohexitone is used commercially.
- Methyl-thio barbiturates have a methyl group at position 1 and sulphur substituted for oxygen. They are very potent but have marked excitatory effects and cannot be used clinically.

The potency of the barbiturate is increased as more carbon atoms are added to the side chains at position 5. An aromatic nucleus in the side chains at position 5 gives convulsant properties whereas a phenyl group produces an anticonvulsant. Some features of IAAs are compared in Figure 4.

The barbiturate ring



3

Comparison of some features of the intravenous anaesthetic agents

	Thiopental (thiopentone)	Methohexitone	Propofol	Etomidate	Ketamine
pH	10.5	11.1	7.4	8.1	3.5–5.5
pK_a	7.6	8.0	11.0	4.24	7.5
Protein bound (%)	80.0	80.0	98.0	75.0	12.0
Free non-ionized (%)	61.3	80	99.97	99.1	44.3
Terminal half-life (hours)	11.6	3.9	1.5–4.4	5.4	3
Hypersensitivity reaction	1:18,000	1:5,000	1:100,000	1:450,000	Very rare
Induction blood pressure change (%)	–8	–8	–17	–2	+28
Induction pulse change (%)	+14	+15	+7	+8	+33
Induction pain (%)	0	30–50	10–30	40–60	0
Induction movement (%)	0	5	5–10	30	Very little
Induction hiccups (%)	0	30	5	20	Very little
Induction apnoea (%)	6	20	40	20	Rare
Recovery restlessness (%)	10	5	5	35	Common
Recovery nausea (%)	7.5	7.5	5	20	Common
Recovery vomiting (%)	7.5	5	5	20	Common

Thiopental (thiopentone) (5-ethyl-5-(1-methylbutyl)-2-thio-barbiturate)
Thiopental (thiopentone) is presented as a pale yellow powder in an ampoule containing 6% anhydrous sodium carbonate in an inert atmosphere of nitrogen. It is poorly soluble in water but dissolves in the alkaline solution produced by the sodium carbonate. The 2.5% solution has a pH of 10.5. The inert nitrogen prevents degradation by oxygen and carbon dioxide. The aqueous solution is stable for 2 weeks. There is no added preservative but the alkaline solution is bacteriostatic and safe to keep for 48 hours. The induction dose is 4–5 mg/kg. Injection of thiopental (thiopentone) is painless even in small veins. Induction is smooth with unconsciousness in one arm–brain circulation time. The alkaline thiopental (thiopentone) is less soluble when injected into the blood at pH 7.4 allowing microcrystals to form. Injection into an artery is painful probably because of the microcrystals occluding small arterioles causing thrombosis. Extravasation to subcutaneous tissues may lead to necrosis. Thiopental (thiopentone) is antanalgesic in subanaesthetic concentrations. Rectal thiopental (thiopentone) has been used in children at a dose of 44 mg/kg, but absorption is unpredictable and careful nursing observation is required.

Initial recovery results from redistribution; it is smooth with a low incidence of restlessness or nausea and vomiting. Metabolism in the liver is slow and repeat or large doses lead to cumulation and delayed recovery. Only 10–15% of the remaining thiopental (thiopentone) is metabolized per hour. The sulphur is replaced with oxygen to produce pentobarbitone and the side chains at position 5 are oxidized. Renal excretion of thiopental (thiopentone) is 0.3%.

Methohexitone (α-dl-1-methyl-5-allyl-5-(1-methyl-2-pentynyl) barbiturate
Methohexitone was withdrawn in 1999 for an initial period of 12 months owing to production difficulties. The manufacturers hope to restart supply by mid-2001. Methohexitone is similar to thiopental (thiopentone) and is used as a 1% solution. There are four isomers of methohexitone but only the α d and l forms have anaesthetic properties. Induction of anaesthesia with 1–1.5 mg/kg is rapid, but pain on injection is common especially if the small veins on the hand are used. Excitatory movements, coughing and hiccups occur frequently. Methohexitone causes pain if injected into an artery, but thrombosis with the 1% solution is unusual. Epileptiform activity has been recorded by EEG but clinical fits are rare. Recovery from methohexitone is more rapid than from thiopental (thiopentone), because metabolism is significantly faster. Its use in day case anaesthesia had been superseded by propofol, but methohexitone is favoured for chair dental work and ECT.

Sterically hindered alkyl phenol

Propofol (2,6-di-isopropylphenol)
Propofol is a colourless to pale straw-coloured liquid that is slightly soluble in water. It was first released in 1977 in cremophor oil. Following reports of hypersensitivity reactions to the solvent, propofol was reformulated in a 1% aqueous emulsion containing soya-bean oil and egg phosphatide (*Intralipid*). Propofol has a neutral pH and a pK_a of 11.0 making it 99.97% non-ionized and highly fat soluble. It is 98% bound to protein.

Induction of anaesthesia with 2–2.5 mg/kg is smooth and pleasant with a low incidence of excitatory movements. Epileptiform fits during recovery have been recorded. Closing of the eyes is delayed compared with thiopental (thiopentone) and can lead to a relative overdose. A better endpoint is the loss of verbal contact.

Pain on injection through small veins is common and reduces the use of propofol in children. Injection of 1% lidocaine (ligno-caine) before the injection or mixing 20 mg of lidocaine (ligno-caine) with an ampoule of propofol reduces the incidence of pain. Lidocaine (lignocaine) can destabilize the soya-bean emulsion.

Propofol does not contain preservative and the aqueous emulsion is a good bacterial medium. Propofol should not be drawn up until immediately before injection. Propofol does not cause any ill effects if injected perivascularly or into an artery. Hypertriglyceridaemia can occur after prolonged infusions. Metabolism is mainly in the liver, but occurs during the anhepatic phase of liver transplant. Up to 10% may be metabolized in the gastrointestinal tract. The main metabolites are the glucuronide and quinol. The quinol metabolite explains the green-coloured urine that is sometimes seen after an infusion. Only 0.3% is excreted unchanged in the urine.

Carboxylated imidazole

Etomidate (D-ethyl-1-(α-methyl-benzyl)imidazole-5carboxylate)
Etomidate is presented as a clear solution of 20 mg in 10 ml of water and 35% propylene glycol. Etomidate is unstable dissolved in pure water. The pH is 8.1 and the pK_a 4.2. Etomidate is a base and 99% of the drug is non-ionized in the blood. Protein binding is 75%. The induction dose is 0.3 mg/kg.

Pain on injection is common and there is a high rate of thrombophlebitis in the postoperative period (30% by the third postoperative day) especially if the small veins on the hand are used. Recent work suggests that the solvent, propylene glycol, is the cause of thrombophlebitis.

Etomidate causes the least cardiovascular depression of the IAAs. Excitatory side-effects are common (involuntary movement 40% and cough or hiccups 10%) but are reduced by prior administration of an opiate. Recovery is less pleasant for the patient with increased restlessness, nausea and vomiting. Etomidate is a powerful antisteroid drug. Etomidate infusions were used in intensive care, but the mortality rate was higher than expected. Investigations showed that etomidate suppresses adrenocortical secretion by inhibiting mitochondrial, cytochrome P450-dependent, 11 β hydroxylase. This can be measured after an
induction dose, but the effect is not clinically significant unless an infusion is given. Metabolism is in the liver and plasma byesterase hydrolysis with 2% excreted unchanged in the urine.

Phencyclidine derivative

Ketamine (2-o-chlorophenyl-2-methylaminocyclohexanone hydrochloride)
Ketamine is a racemic mixture of two enantiomers; the S(+) enantiomer is 3.4 times more potent than the R(–) enantiomer. It is soluble in water and presented as a 1%, 5% and 10% solution. The pH is 3.5–5.5 and the pK_a 7.5. It is highly lipid soluble with 12% protein bound and 44% non-ionized. Ketamine produces dissociative anaesthesia. A dose of 2 mg/kg produces unconsciousness in 1–2 minutes. The endpoint can be difficult to judge with the patients often staring into the distance for a short while. Unlike most induction agents, ketamine increases the pulse rate, blood pressure and intracranial pressure. Salivation is increased and a muscarinic drug such as glycopyrrolate is usually given. The airway is well maintained but cannot be guaranteed. Induction is smooth but restlessness, dreams and hallucinations often complicate recovery. Benzodiazepine premedication reduces emergence delirium. Recovery is by redistribution, then metabolism, mainly in the liver by demethylation and hydroxylation by cytochrome P450. One metabolite, nor-ketamine, has one-third to one-fifth the activity of ketamine. Most of the ketamine is excreted in the urine as the glucuronide with 2.5% unchanged. Ketamine is analgesic. Up to 0.5 mg/kg produces intense analgesia without unconsciousness or delirium, allowing patients to undergo painful procedures such as physiotherapy for fractured ribs. An oral dose of 20–50 mg has been advocated for treatment of resistant chronic neuralgic pain.

Pharmacodynamics

CNS
Thiopental (thiopentone) and ketamine are anticonvulsant. Epileptiform activity has been recorded with methohexitone, etomidate and propofol, but all are anticonvulsant at higher doses. Propofol has been shown to reduce the degree of fits produced by ECT. All the IAAs, except ketamine, reduce the cerebral metabolic rate leading to a reduction in brain blood flow and a reduction in intracranial and intraocular pressure. Ketamine produces a dose-dependent increase in intracranial pressure.

Cardiovascular system
The barbiturates reduce myocardial contractility and promote venous pooling. The cardiac output and blood pressure fall with a small rise in the pulse rate. Methohexitone causes less myocardial depression than thiopental (thiopentone). In healthy patients, etomidate has little effect on contractility and there is only a small reduction in blood pressure. Etomidate is often used in the ill and elderly, but the cardiovascular stability in such patients is often poor and etomidate must be given with caution. Propofol produces the most marked fall in blood pressure. There is little reduction in contractility, considerable vasodilatation and a small increase in heart rate. In the elderly, the blood pressure and cardiac output can fall by more than 50% with delayed redistribution and recovery. The effect is dose dependent and minimized by a slow injection. In contrast, ketamine increases the heart rate and blood pressure by 20–40%. Noradrenaline production is increased. Ketamine can be used under difficult circumstances such as in the battlefield or for on-site procedures following major accidents.

Respiration
With the exception of ketamine, the IAAs depress respiratory drive. The barbiturates produce respiratory depression by a direct effect on the respiratory centre. The partial pressure of carbon dioxide in arterial blood increases and pH falls. Etomidate is the least respiratory depressant but the ventilatory response to carbon dioxide is reduced. Propofol has the most profound effect. Apnoea after induction is common and more prolonged than with other agents. The carotid body is sensitive to hypoxia and most anaesthetic agents increase that sensitivity during the induction of anaesthesia resulting in a sigh or deep breath. Propofol inhibits the response to hypoxia. Without the sigh or deep breath the oxygen saturation may fall during induction. Pre-oxygenation or asking the patient to take two big breaths of room air during induction reduces the incidence of desaturation at induction. Thiopental (thiopentone) increases laryngeal reflexes to the extent that coughing and laryngeal spasm can occur if there is stimulation from saliva, blood or the insertion of an airway or laryngeal mask. Propofol reduces the laryngeal reflexes and the short period of apnoea following induction aids the early insertion of a laryngeal mask airway. Ketamine has little effect on the respiratory centre and the ventilatory response to carbon dioxide is unaltered. The airway is usually well maintained but cannot be guaranteed, especially at higher doses when laryngeal reflexes may become obtunded.

Hepato-renal system
Any reduction in blood pressure following the induction of anaesthesia reduces both hepatic and renal blood flow, but there is little evidence that this is clinically significant. The barbiturates suppress the inhibitory pathways running from the hypothalamic nuclei to the posterior lobe of the pituitary, resulting in an increased production of antidiuretic hormone (ADH). Urine production is reduced to 10% of normal. Propofol, etomidate and ketamine have no effect on ADH secretion. The barbiturates induce liver enzymes.

Uterus and fetus
Thiopental (thiopentone) remains the induction agent of choice for caesarean section. It readily crosses the placenta, but fetal plasma levels are lower than maternal. Redistribution allows the plasma levels to fall by delivery so that the fetus is relatively unaffected. Propofol has been linked with reduced Apgar scores at 1 minute and is not recommended for obstetric anaesthesia, although recent work questions this view. There is limited information on the placental transfer of etomidate, but it has been used successfully in obstetrics. None of the IAAs have a significant effect on uterine muscle tone.

Muscles
Skeletal muscle tone is reduced only at a high dose. Muscle movement in response to pain is common with all IAAs unless anaesthesia is supplemented with opiates or with a volatile agent.

Concomitant disease
The barbiturates and etomidate may precipitate porphyria in susceptible patients. Propofol and ketamine are thought to be safe. The respiratory depressant effects of the IAAs are exaggerated in patients with muscular dystrophy. If general anaesthesia cannot be avoided, propofol with its high clearance allows more rapid recovery. Patients with myxoedema are very sensitive to IAAs especially the barbiturates. Myxoedema should be treated before induction of anaesthesia.

Safety
Hypersensitivity reactions to IAAs are uncommon but can be serious. Etomidate has the lowest incidence of reactions. The therapeutic ratio (ED_{50}:LD_{50}) in mice is low (3–4) for the barbiturates and propofol; etomidate is a little higher. The corticosteroid-based IAA *Althesin* (withdrawn in 1984) had a therapeutic ratio of 32, a property shared by other corticosteroid-based IAAs. Unfortunately the newer corticosteroid IAAs have produced marked excitatory movement in human volunteer studies and none have progressed to commercial use.

Contraindications to the use of IAAs include airway obstruction, known allergy, and for the barbiturates and etomidate, porphyria. IAAs should be used with caution in patients with ischaemic heart disease, constrictive pericarditis, asthma or epilepsy.

Ion Channels

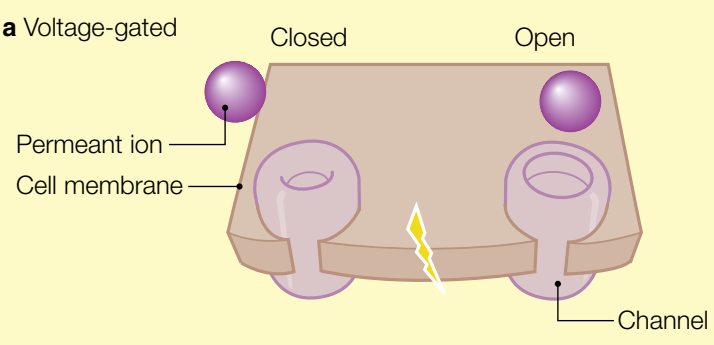
Richard J Prince

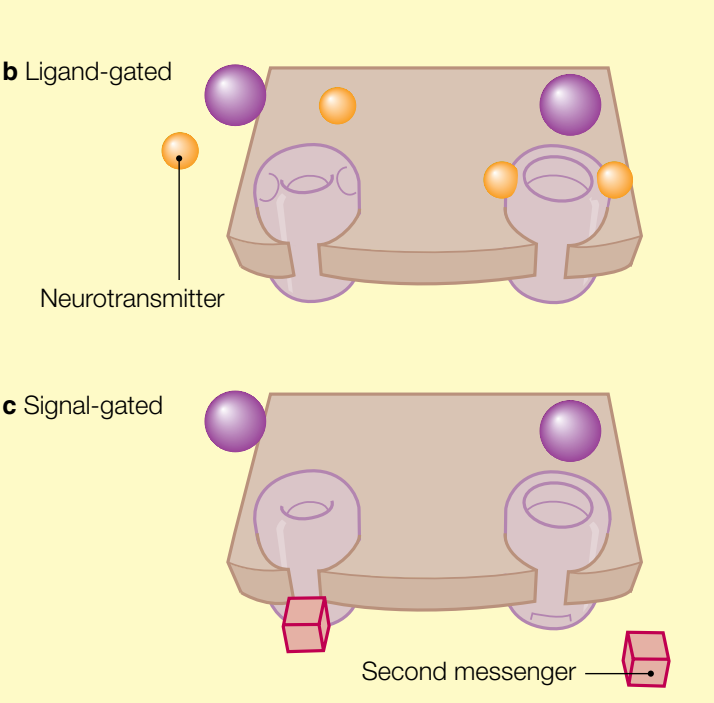
Richard J Prince is Lecturer in Pharmacology at the School of Biological Sciences, University of Manchester. He completed his PhD in pharmacology at the School of Pharmacy, University of London, and received postdoctoral training at Duke University, Durham, NC, USA, and the Mayo Clinic, Rochester, MN, USA. His research interests centre around the structure and function of ligand-gated ion channels.

The rapid movement of ions across cell membranes depends on a group of proteins known collectively as ion channels. Although they are all water-filled transmembrane pores, ion channels are structurally and functionally extremely diverse.

Typically, cells contain many different channels but only a few (leak channels) are constantly open. The opening and closing, or 'gating', of the remaining channels is tightly controlled using a variety of mechanisms (Figure 1). For example, voltage-gated channels, respond to changes in membrane potential, and ligand-gated channels open when a neurotransmitter binds to their extracellular domains.

Mechanisms for controlling channel gating





a Voltage-gated channels open in response to changes in the membrane potential. **b** Ligand-gated channels open when neurotransmitters bind to sites in their extracellular domains. **c** Signal-gated channels respond to the binding of intracellular second messengers to their intracellular domains. Some signal-gated channels, such as the ATP-sensitive K^+ channel, close when the second messenger binds as illustrated here, others such as Ca^{2+} sensitive K^+ channels are activated by second messenger binding.

1

Ion selectivity

Ion channels are usually selective for particular ions. Most are selective for Na^+, K^+, Ca^{2+}, Na^+/K^+ or Cl^-. Selectivity arises because ions do not simply fall through the channel pore but interact with a series of mechanical and charge barriers. The ion must conform to charge (cation or anion) and size (maximum and minimum diameter) criteria dictated by the channel structure.

The precise effects of activating a particular class of channel depend on the ion selectivity of the channel and on the particular ionic and electrical gradients across the cell membrane. Despite this complexity, the generalizations shown in Figure 2 hold for many cell types.

Distribution of organic ions across the cell membrane

Intracellular environment	Cell membrane	Extracellular environment	Change in membrane potential
Na^+ 12 mM	←	Na^+ 145 mM	Depolarization
K^+ 140 mM	→	K^+ 4 mM	Hyperpolarization
Na^+/K^+ selective	↔	Na^+ in, K^+ out	Depolarization
Cl^- 4 mM	←	Cl^- 120 mM	Hyperpolarization
Ca^{2+} 0.1 mM (free)	←	Ca^{2+} 2.5 mM	Diverse

The major inorganic ions are asymmetrically distributed across the membrane of a typical excitable cell and move down their electrochemical gradient (arrows) when permeable channels are opened. The movement of Na^+, K^+ and Cl^- ions produces characteristic changes in membrane potential: either depolarization (becomes more positive) or hyperpolarization (becomes more negative), but influx of Ca^{2+} has complex effects because Ca^{2+} functions as an intracellular second messenger and can activate other types of ion channel

2

Voltage-gated channels

Three families of voltage-gated channels have been identified on the basis of ion selectivity: Ca^{2+}, K^+ and Na^+ channels. They are thought to have evolved from a common ancestor and share many structural features. Within each family there are several channel subtypes that differ in their voltage sensitivity, tissue distribution and pharmacology. Voltage-gated Ca^{2+} channels, for example are subdivided into L-, N-, P- and T-types.

With a few exceptions (e.g. inward rectifier K^+ channels) most voltage-gated channels respond to changes in membrane potential in the same way: they open when the membrane depolarizes. After opening, some channels spontaneously enter a closed or inactivated state. Inactivation occurs rapidly in many Na^+ and Ca^{2+} channels but is slow or absent in certain K^+ channels.

Voltage-gated Na^+ and K^+ channels: the generation of action potentials depends on the interplay of voltage-gated Na^+ and K^+ channels. Action potentials occur in excitable cells when the membrane is depolarized beyond about –50 mV (threshold potential). This produces a transient increase in Na^+ permeability and a depolarization to about +30 mV owing to the rapid activation and inactivation of voltage-gated Na^+ channels. Simultaneously, a slow, sustained increase in K^+ permeability develops as voltage-gated K^+ channels open. This repolarizes the membrane to the resting potential of about –65 mV.

Voltage-gated Ca^{2+} channels: compared with action potentials, voltage-gated Ca^{2+} channel activation generates only small currents. However, because Ca^{2+} functions as an intracellular messenger, voltage-gated Ca^{2+} channels link electrical activity to changes in cell function. Important examples include the stimulation of vesicle fusion and neurotransmitter release at presynaptic nerve terminals and stimulation of contraction in cardiac and smooth muscle.

Drugs acting at voltage-gated channels

Local anaesthetics (e.g. lidocaine (lignocaine)) block voltage-gated Na^+ channels in nociceptive neurons and prevent the generation and propagation of action potentials, thereby producing anaesthesia. Similarly, block of cardiac voltage-gated Na^+ channels mediates the actions of class I antiarrhythmic drugs (e.g. lidocaine (lignocaine), flecainide).

Calcium antagonists typified by verapamil, diltiazem and the dihydropyridines (e.g. nifedipine) are useful antihypertensive and anti-anginal drugs because they specifically block L-type Ca^{2+} channels present in vascular smooth muscle and so cause vasodilatation. Verapamil and diltiazem also have antiarrhythmic properties (class IV antiarrhythmic drugs) because they block L-type Ca^{2+} channels in the atrioventricular and sinoatrial nodes of the heart.

Ligand-gated channels

Ligand-gated channels are divided into two main families, the nicotinoid channels and the ionotropic glutamate receptors. These protein families are not evolutionarily related but have similar functional properties. In both cases the ion channel is opened by the binding of a neurotransmitter to a specific receptor site located in the extracellular portion of channel complex. Four subfamilies of nicotinoid channel have been identified, of which two are cation selective (nicotinic acetylcholine receptors and 5-HT_3 receptors), and two Cl^- selective (γ-aminobutyric acid type A ($GABA_A$) receptors and inhibitory glycine receptors). All nicotinoid channels are pentameric proteins composed of homologous subunits. Within each subfamily, a range of subunits has been identified, which cells can assemble in different combinations to yield functionally distinct channel subtypes. Ligand-gated channel subtypes differ in their tissue distribution and pharmacology.

The most important function of ligand-gated ion channels is fast synaptic transmission. Excitatory transmission at the neuromuscular junction, for example, is mediated by nicotinic acetylcholine receptors located on the postsynaptic muscle membrane, while in the CNS a similar function is performed by ionotropic glutamate receptors. Conversely, $GABA_A$ and glycine receptors are responsible for fast synaptic inhibition.

Drugs acting at ligand-gated channels

Hypnotics, anxiolytics and anaesthetics: $GABA_A$ receptors are the targets of a wide range of sedative drugs including the benzodiazepines (e.g. diazepam), the barbiturates (e.g. thiopental (thiopentone)) and the general anaesthetics etomidate and propofol. These drugs all bind to allosteric sites on $GABA_A$ receptors and enhance inhibitory neurotransmission by potentiating the actions of GABA. Other sedative/psychoactive drugs inhibit excitatory neurotransmission. Examples include the dissociative anaesthetic ketamine and the hallucinogen phencyclidine, which block CNS ionotropic glutamate receptors.

Neuromuscular blocking agents: at the motor endplate, two classes of drug block neuromuscular transmission by binding to muscle-type nicotinic acetylcholine receptors. Non-depolarizing blockers (e.g. atracurium) are competitive antagonists, which occupy the acetylcholine binding sites of the receptor but do not open the channel. By contrast, the depolarizing blockers (e.g. succinylcholine) are high-affinity agonists that produce prolonged activation of the receptor. This causes sustained depolarization of the muscle membrane and thus prevents further electrical activity.

Local Anaesthetic Agents

Malachy O Columb

Malachy O Columb is Director of Intensive Care and Consultant in Anaesthesia at South Manchester University Hospital, UK. He graduated from University College, Dublin, Eire, trained in anaesthesia in Leeds and was a Member of Faculty at the University of Michigan, Ann Arbor, USA. His research interests include the clinical pharmacodynamics of local anaesthetic agents.

Since topical cocaine was first used for eye surgery by Koller in 1884, drugs that have 'membrane stabilizing activity' have been in widespread clinical use. In addition to local anaesthesia, related uses include the treatments of arrhythmias, epilepsy and neuropathic pain syndromes. Other significant milestones in the development of this class of drugs were procaine (1898), lidocaine (lignocaine) (1943) and bupivacaine (1957). Despite the numerous advances in the last 40 years in virtually all other aspects of anaesthetic pharmacology there has been no significant advance since bupivacaine. There have, however, been improvements in our understanding of dosing, particularly in combinations with other analgesics such as opioids and more recently with the appreciation of stereochemistry.

Chemistry

Local anaesthetics consist of three components: an aromatic ring, a link and an amine (Figure 1). Most anaesthetics are tertiary amines. They can be classified into two groups based on the nature of the link to amino amides [-NH-CO-] and amino esters [-O-CO-]. Being weak bases, they are solubilized for injection as strong, conjugate, acidic, hydrochloride salts (pH 3–6).

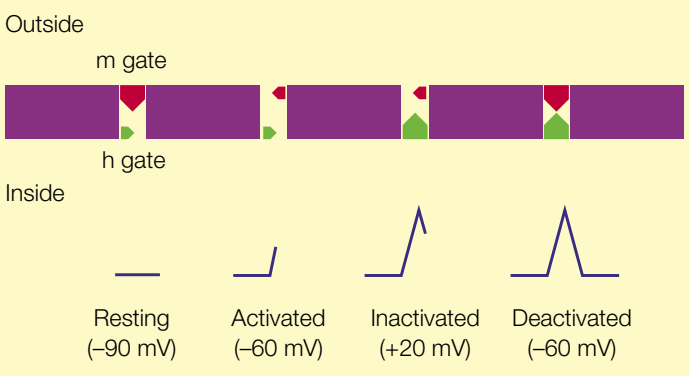
1

Mechanism of action

Local anaesthetics act by blocking the inward sodium current at the sodium ionophore during depolarization, thus preventing propagation of the axonal action potential. When delivered by injection, the local anaesthetic is predominantly in the acidic, ionized form (pH 3–6). This dissociates in the relatively alkaline perineural tissues (pH 7.4) to lipid-soluble, free base. This crosses the axolemma and re-ionizes in the acidic axoplasm to the active moiety, which blocks the sodium ionophore from within the cell or from the membrane lipid bilayer. It is therefore the non-ionized form that promotes delivery into the axon, and the ammonium or ionized state that provides activity. The ionophore exists in four states: resting, activated, inactivated and deactivated (Figure 2). Block is more readily achieved when the ionophore is activated than inactivated, and least readily achieved when deactivated and resting. During activation, the outer m gate opens at threshold potential (–60 mV) and ionized drug may gain direct access to the ionophore from outside. In the inactivated state, the inner h gate, which is voltage sensitive (+20 mV), closes after depolarization and prevents backward propagation of current. During the deactivated state (–60 mV), both m and h gates are closed so that the local anaesthetic can gain access only from within the membrane. During the resting phase (–90 mV), the inner h gate opens to prime the m gate for voltage-sensitive opening, so that ionized drug can gain access from the axoplasm.

The speed of onset of block is related to the concentration of molecules of local anaesthetic that are in the free base or non-ionized state. This depends on the initial dose, the dissociation constant (pK_a) and the pH of the tissues. By convention, dissociation constants are applied to the acidic forms and this sometimes causes confusion as inversions of the Henderson–Hasselbach equation (1) are often used depending on whether an acid or base is involved.

The four states of the sodium ionophore with axonal action potentials



2

$$pH = pK_a + \log([base] / [acid]) \quad (1)$$

$$\text{For an acid: } pH = pK_a + \log([ionized] / \{non\text{-}ionized\}) \quad (2)$$

$$\text{For a base: } pH = pK_a + \log([non\text{-}ionized] / [ionized]) \quad (3)$$

It is perhaps simpler to use equation 1 or a modification for all substances and consider only the acidic version:

$$pH = pK_a + \log([dissociated] / [associated]) \quad (4)$$

It is then helpful when looking at the pK_a for 'bases' to consider them in the acidic ionized form (Figure 3). Equations 1 and 4 can be further modified to:

$$pK_a - pH = \log([acid] / [base]) \quad (5)$$

$$pK_a - pH = \log([associated] / [dissociated]) \quad (6)$$

Using either equation and given that pH = 7.4, it can be seen that more molecules of bupivacaine (86%) will remain in the associated (ionized) form compared with lidocaine (lignocaine) (72%), and therefore the onset of action will be slower.

$$0.8 = \log([BH^+] / [B] \quad \text{versus} \quad 0.4 = \log([LH^+] / [L])$$

Typical pK_a, octanol partition coefficient and plasma protein binding values

Drug	pK_a	Partition coefficient	Protein binding (%)
Lidocaine-H^+ (LH^+)	7.8	43	64
Prilocaine-H^+	7.9	25	55
Bupivacaine-H^+ (BH^+)	8.2	346	93–95
Ropivacaine-H^+	8.2	115	94
Procaine-H^+	8.9		
Chloroprocaine-H^+	9.1		

3

The speed of onset of local anaesthesia can be accelerated by alkalinization or carbonation of the injectate. The addition of bicarbonate causes the strong conjugate acidic ammonium ions to dissociate and increase free base concentrations. The ingress of carbon dioxide into the axoplasm renders the interior even more acidic and this encourages re-ionization in a process referred to as diffusion trapping. Similarly, the acidic environment of an abscess will decrease the proportion in the free base state and this may explain the resistance to conduction block in such situations.

It is, however, useful to put the role of pK_a and pH into perspective. Chloroprocaine (used in the USA) has a very high pK_a (Figure 3) consistent with a very slow onset of block, but it is used when a fast onset is required for epidural anaesthesia (e.g. for emergency caesarean section). As a 3% w/v solution, larger doses can be given because of its low potential for systemic toxicity owing to ester hydrolysis. Thus, dosing is more important than pK_a.

The potencies of local anaesthetic agents are related to lipid solubility and are quantified as octanol partition coefficients (Figure 3). In addition, for agents that are enantiomers (enantiomorphs, optical isomers), it has been suggested that S-enantiomers are more potent than R-enantiomers. However, these apparent differences in potency are inconsistent and may be simply related to differences in vasoconstrictive and pharmacokinetic properties.

Local anaesthetic agents cross the membrane lipid bilayer as free base, however, the ionized form may enter from outside if the ionophore is repeatedly activated or opened. This gives rise to the phenomenon of frequency-dependent (or phasic) block. The onset of block with agents that have more ionized molecules outside the membrane can therefore be accelerated by stimulation. Thus, frequency-dependent block is better demonstrated for bupivacaine than for lidocaine (lignocaine).

Pharmacokinetics

Local anaesthetic agents are weak bases and, as such, become bound in the plasma to α_1-acid glycoproteins. Amino esters undergo rapid ester hydrolysis by plasma pseudocholinesterases and therefore have a lower potential for systemic toxicity. Amino amides undergo phase I and II hepatic cytochrome P450 metabolism. Phase I includes hydroxylation, N-dealkylation and methylation. Phase II includes conjugation with amino acids, such as glycine.

Toxicity

Since Albright reported six cases of cardiovascular collapse in 1979, following presumed accidental intravenous administration, attention has been focused on developing safer drugs, using lower doses and safer administration. Toxicity is usually manifested initially by subjective neurological disturbances, such as dizziness, circumoral tingling, metallic taste, diplopia and tinnitus. Objective signs include inappropriate agitation or sedation, tremor, myoclonic activity and epilepsy. The CNS signs usually precede the onset of hypotension with ventricular tachycardia or fibrillation. In animal studies, the ratio of CNS signs to cardiovascular collapse has been described for the various local anaesthetics to quantify a potential safety margin.

The likelihood of toxicity depends on the drug, dose, rate and site of injection, systemic absorption, acidaemia and clearance. Because of the multifactorial nature of toxicity, it has not been possible to establish absolute recommendations for maximum safe doses. Some information is, however, useful and the data in Figure 4 are provided for guidance only.

Cardiac arrest due to local anaesthetic toxicity with the pipecoloxylidine derivatives (e.g. bupivacaine), is more resistant to treatment. Ventricular tachycardia and fibrillation may induce a form of frequency-dependent entry of ionized drug into the myocardial cell, enhancing further toxicity. At the higher plasma concentrations associated with cardiovascular collapse it is likely that some cerebral protection may be provided due to direct anaesthetic effects. Therefore resuscitation attempts should be maintained as long as practical. Avoidance and treatment of acidaemia, hypercarbia and hypoxia will be useful. Atropine and adrenaline (epinephrine) may be required, the latter in addition to offset systemic vasodilatation. Bretylium may be useful as an antiarrhythmic agent in this setting for resistant ventricular arrhythmias.

Suggested maximum doses in a period of 4 hours

Local anaesthetic	Without adrenaline (epinephrine) (mg/kg)	With adrenaline (epinephrine) (mg/kg)
Cocaine	1.5	
Chloroprocaine	10	12
Lidocaine (lignocaine)	3	7
Prilocaine	4	8
Bupivacaine	2	4
Levobupivacaine	2	4
Ropivacaine	2.5	5

Specific local anaesthetic agents

Cocaine is a benzoic acid ester, which is used for topical anaesthesia of the mucosa of the upper airway because of its vasoconstrictor activity. Other local anaesthetics exhibit a biphasic effect on vasomotor tone – vasoconstriction at lower and vasodilatation at higher concentrations. The use of adrenaline (epinephrine) as a vasoconstrictor is unnecessary, particularly as cardiotoxicity may occur due to cocaine having indirect sympathomimetic activity. Cocaine blocks the presynaptic reuptake of noradrenaline (norepinephrine). Toxicity is enhanced because it is also resistant to metabolism by plasma pseudocholinesterases. Ester hydrolysis results in the release of ecgonine, a cerebral stimulant.

Lidocaine (lignocaine): the dimethylbenzene moiety is termed xylene. The amide link confers the term xylidine or xylidide. The major metabolite of N-dealkylation of one of the C_2H_5 groups is monoethylglycine xylidide (MEGX). Hepatic amidases result in various xylidine metabolites. Drugs that decrease hepatic blood flow, such as propranolol, will decrease metabolism and clearance. Lidocaine (lignocaine) is also used as a class 1_bantiarrhythmic agent.

Prilocaine is an exception in that it is a secondary amine. The monomethylbenzene moiety is termed toluene. The amide link confers the term toluidine. The o-toluidine metabolite of prilocaine can oxidize haemoglobin to methaemoglobin. Methylene blue can be used to reduce this ferric form back to the usual ferrous state. Prilocaine undergoes extensive pulmonary uptake, which results in lower systemic plasma levels and lower likelihood of toxicity. As a result, it remains the drug of choice for intravenous regional anaesthesia (Bier's block).

Bupivacaine is the butyl (C_4H_9) derivative of N-alkyl pipecoloxylidine and is therefore part of the same homologous series as mepivacaine (methyl: CH_3) and ropivacaine (propyl: C_3H_7). All pipecoloxylidine derivatives have an asymmetric carbon atom which confers chirality or enantiomerism. The usual preparation of bupivacaine is as a racemate. Following N-dealkylation, the pipecoloxylidine metabolite still has some activity.

Ropivacaine (or propivacaine) is the S-enantiomer of the propyl (C_3H_7) derivative of N-alkyl pipecoloxylidine. Metabolites include 3-hydroxyropivacaine (40%) and pipecoloxylidine (5%). The octanol partition coefficient for ropivacaine (115) suggests lower potency when compared with bupivacaine (346), but ropivacaine may exert more vasoconstrictor activity to offset this.

Levobupivacaine is the S-enantiomer of racemic bupivacaine. The plasma-bound fraction of levobupivacaine is greater at 95% compared with the racemate at 93%. *Chirocaine* is bound by Directive 91/507 of the European Economic Community (EEC), which states that the % w/v should be expressed in terms of the agent (free base) alone and not the hydrochloride salt. So levobupivacaine, by virtue of being expressed as free base, has 11% more molecules than the equivalent % w/v of the racemate bupivacaine (*Marcain*), which predates the directive. This difference in expressed formulation should be considered when comparing it with other local anaesthetics.

Stereochemistry

The pipecoloxylidines can exist as two enantiomers, R(+) and S(–). The prefixes R (rectus) and S (sinister) refer, respectively, to the clockwise or anticlockwise arrangement of atoms or molecules around the asymmetric carbon atom based on an arbitrary hierarchical series of sequence rules. They are not consistently related to rotations of planes of polarized light, and are therefore independent of other prefixes or terminologies, such as *d, l,* D, L, (+), (–), dextro or laevo.

Evidence from animal and human models has suggested that, among certain chiral local anaesthetics, the S-enantiomer was less toxic than the R-enantiomer and thus less toxic than the racemate. S-propivacaine (ropivacaine, *Naropin*) was developed for clinical use. Two clinical toxicology studies in human volunteers showed that 12–25% more ropivacaine could be tolerated before the onset of CNS toxicity. This perceived advantage for ropivacaine was based on the assumption of equipotency with bupivacaine. Two recently published studies using the minimum local analgesic concentration (MLAC) model found that ropivacaine was 40% less potent than bupivacaine. The human toxicology and MLAC efficacy studies have been formally compared to derive therapeutic indexes and the relative therapeutic ratio in humans for both local anaesthetics. The relative therapeutic ratio (ropivacaine:bupivacaine) for clinical CNS toxicity of 0.75 was found to be significantly in favour of bupivacaine. The perceived benefits for ropivacaine in relation to toxicity, motor-block sparing and differential sensory blockade may have to be re-evaluated, and may simply be explained by potency issues.

The most recent development has been that of S-bupivacaine (levobupivacaine). A human toxicology study has demonstrated that human subjects tolerated a median dose of levobupivacaine for the onset of CNS symptoms that was 5% greater than the racemate. In addition, levobupivacaine caused a significantly lower reduction in cardiovascular performance as assessed by stroke index, acceleration index and ejection fraction. Some of these effects may represent less vasodilatation and reductions in preload due to the significant augmentation of diastolic pressure with the racemate. An efficacy MLAC study showed that the potency of levobupivacaine was 98% that of the racemate on a % w/v basis (87% in molar terms). Again comparing therapeutic indexes, the relative therapeutic ratio (levobupivacaine:racemic bupivacaine) for CNS toxicity is 1.03 and therefore marginally in favour of levobupivacaine.

Emla

The development of *Emla* (eutectic mixture of local anaesthetics) for topical use has been welcomed, particularly in paediatric practice. This 50:50 solid solution of lidocaine (lignocaine) and prilocaine as lipid-soluble free bases has the lowest melting point of any combination. This defines the eutectic point and thus the eutectic mixture. Methaemoglobinaemia caused by extensive application and systemic absorption of prilocaine in infants has been reported. Amethocaine is now also available for topical application.

The future

Greater understanding of the role of chirality in local anaesthetic pharmacology is still required to justify clinical use further. Local anaesthetic-sparing combinations with other analgesics continue to be studied to develop synergistic regimens. Research is continuing into alternative approaches such as selective binding and inhibition of the sodium ionophore with dilutions of naturally occurring toxins, such as tetrodotoxin. It has become clear from errors in the development of enantiomers for clinical application that determining the relative potencies of drugs is of prime importance in evaluating claims for perceived advantages in toxicity and blocking characteristics.

Major Trauma and Exsanguination

Pramod K Luthra
Asha Luthra

Pramod K Luthra is Consultant in Hand and Reconstructive Surgery and Emergency Medicine at the Royal Oldham Hospital, Oldham, UK, and Associate Postgraduate Dean in the Department of Postgraduate Medicine and Dentistry, Manchester University, Manchester, UK. He trained in centres in the UK. His interests are in resuscitation, management of hand injuries and reconstruction of soft tissue deficits.

Asha Luthra is Consultant Anaesthetist at South Manchester University Hospital, and Honorary Clinical Lecturer, Manchester University, Manchester, UK. She qualified from Bangalore, India, and trained in anaesthetics in Manchester. Her interests include paediatric anaesthesia for plastic surgery and anaesthesia for major post-cancer reconstructive surgery.

Major trauma causes life-threatening injuries to single or multiple body systems and organs. Most patients with major trauma die at the incident site and only a small proportion with injuries and haemorrhage present for treatment. Their outcome depends on early corrective management and is influenced by their age, the mechanism of injury and any pre-existing disease process. Exsanguination is blood loss from the vascular compartment (loss at site of injury; e.g. fractured shaft of femur) and fluid shift to the extravascular space (obligatory oedema in tissues).

Blood loss

In an adult weighing 70 kg the normal blood volume is about 5 litres. Any significant loss can lead to hypovolaemia resulting in reduced preload and cardiac output. Blood loss is classified on the volume or the percentage loss in a healthy young adult (see Figure 2, page 289). Haemorrhagic shock following depletion of circulatory volume (exsanguination) leads to poor tissue perfusion, cell hypoxia or anoxia and finally cellular and tissue death. Haemorrhagic shock progresses through four stages if untreated and correlates to the volume of blood loss.

Initial stage (Class I)
Reduced cardiac output with lowered oxygen delivery leads to anaerobic metabolism at the cellular level.

Compensatory stage (Class II)
Neurological (sympathetic), endocrine and chemical responses ensure adequate tissue perfusion and delivery of oxygen to vital organs with progressive vasoconstriction in skin, viscera, muscle and kidneys. A fall in blood pressure is detected by baroreceptors, and this activates the sympathetic system via the vasomotor centre. Sympathetic stimulation triggers the fight, flight and fright response (e.g. cold and clammy skin, tachycardia, tachypnoea). The renin–angiotensin–aldosterone system is activated leading to fluid retention, reduced urinary output and vasoconstriction to help maintain blood pressure. Raised levels of cortisol and other stress hormones contribute to hyperglycaemia, shifting fluid into the vascular compartment, thus increasing circulatory volume. Antidiuretic hormone and aldosterone production is also stimulated leading to fluid and sodium retention and potassium excretion by the kidneys. The usual sign of this stage is tachycardia, but in severe and rapid blood loss, stimulation of ventricular distortion receptors can lead to vagally mediated bradycardia.

Progressive stage (Class III)
Reduced circulation and oxygen supply to the vital organs results in organ failure. Increased capillary permeability and loss of autoregulation reduces coronary blood flow leading to myocardial depression. Serum creatinine in the kidney is raised as are amylase and lipase in the pancreas, and alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in the liver. Ischaemic cells in the gut allow entry of bacteria and endotoxins.

Refractory stage (Class IV)
This is the irreversible terminal stage in which multiple organ failure occurs.

Cell damage
Anaerobic respiration and metabolism in the cell produce lactic acid contributing to metabolic acidosis. If adequate perfusion is not restored, cells swell causing cellular damage and death. Leakage of potassium and lysosomal enzymes from ischaemic cells combined with other toxic metabolites leads to precapillary vasodilatation and increased capillary permeability. This accounts for increased capillary filling and transudation of fluid to the interstitial compartment and a further fall in the intravascular volume.

Resuscitation may also have adverse effects, known as reperfusion injury (e.g. restoring oxygen delivery to tissues may trigger further cell damage). Experimental studies show that allopurinol may have a protective effect at cellular level.

Management

The A (airway), B (breathing) and C (circulation) approach ensures appropriate prioritization and management of life-threatening states. It is important to correct the physiological status and detect the specific cause of haemorrhage. Treatment involves:

- adequate oxygen delivery and consumption
- rapid and adequate fluid replacement in the intravascular compartment and prevention of further loss
- use of pharmacological agents.

Oxygenation
Rapid correction of pulmonary gas exchange is essential. High flow oxygen is essential and should be given by simple or advanced airway techniques and assisted mechanical ventilation. The aim is to increase arterial blood oxygen by augmenting the fraction of oxygen in inspired air (FiO_2), improving oxygen delivery and reducing unnecessary oxygen consumption.

Oxygen delivery can be optimized by improving microvascular circulation, the pulmonary ventilation-to-perfusion ratio and individual organ perfusion. Oxygen consumption and demand can be reduced by relieving pain and stress using analgesics and sedatives, assisting the work of breathing by using mechanical ventilation and avoiding hyperthermia because it increases the metabolic rate.

In a severely shocked patient, mechanical ventilatory assistance is required if the partial pressure of oxygen in arterial blood (PaO_2) stays below 8.7 kPa despite high flow oxygen, and if the respiratory work required to maintain adequate ventilation is excessive.

Fluid
Rapid and adequate volume replacement is paramount. A bolus of fluid, 20 ml/kg, should be administered rapidly as a fluid challenge and repeated as required to maintain correction. Failure to respond to the fluid is an indication that the amount transfused is inadequate or that there are continuing or unrecognized fluid losses. Whether to use crystalloids or colloids is debated, however, either can be used initially because it is rapid replacement that is important. Crystalloid solutions help to replace the intravascular volume rapidly but the effect is short lived. Colloid solutions help to augment the intravascular volume and the effect lasts longer. A combination of the two can help to attain an optimum result, a 2:1 ratio of crystalloid:colloid works well, but must be closely monitored to ensure adequate volume replacement. A small volume of hypertonic saline or *Dextran* given over a short period may help to improve cardiovascular function and may protect against reperfusion injury.

Haemodilution is beneficial, a fall of haematocrit to 30% improves microcirculation and allows optimal oxygen delivery to tissues. A fall below 25% or blood loss over 1.5 litres requires replacement of erythrocytes. Cross-matched blood is ideal, but if there is severe and rapid blood loss, matched blood or if necessary O negative uncrossed blood should be given. Use of SAG-M blood (plasma-poor red cells in **S**aline, **A**denine maintains 2,3-DPG activity in stored blood, **G**lucose and **M**annitol) allows better uncoupling of oxygen in cells. Further blood loss can be prevented by splintage, elevation of limbs, direct pressure and operative intervention.

Pharmacological assistance
Pharmacological agents should be considered when adequate fluid replacement and corrective gas exchange have failed to achieve cardiovascular stability. They are needed to improve the microvascular circulation and in doing so improve tissue oxygen delivery, reduce afterload and improve cardiorespiratory function.

Inotropic agents increase myocardial contractility but risk being slightly arrhythmogenic. They are classified as β_1-sympatho-mimetics (dobutamine, dopamine) or phosphodiesterase inhibitors (amrinone). In addition to improving contractility, dobutamine causes mild vasodilatation and improves oxygen consumption. Dopamine at low dose (1–5 μg/kg/minute) vasodilates and improves renal perfusion and at high dose (> 10 μg/kg/minute) affects vasoconstriction. Amrinone has a mild vasodilatory effect.

Adrenaline (epinephrine) stimulates contractility at low dose (0.01–0.2 μg/kg/minute) and is a vasoconstrictor at high dose.

Vasodilators reduce the filling pressure (preload) and the resistance against which the heart pumps (afterload) with a reduction in pulmonary congestion. Coronary artery dilatation improves myocardial oxygenation. Nitroglycerin affects venous dilatation at low dose and arterial dilatation at high dose. Nitroprusside and morphine affect venous and arterial dilatation and morphine also acts as an analgesic. Furosemide (frusemide) is a venous dilator and a loop diuretic.

Vasopressors: adrenaline (epinephrine), noradrenaline (nor-epinephrine), and phenylephrine, cause peripheral vasocon-striction to maintain circulation to the vital organs.

Acid–base balance can be corrected by adequate ventilation and improved cardiac output. Sodium bicarbonate is occasionally used in patients with pre-existing hyperkalaemia (e.g. those taking spironolactone) and may be exacerbated by massive blood loss. Diuretics (e.g. furosemide (frusemide)) are used in the later stages to reduce pulmonary congestion.

Late stages of shock
'Supranormal' levels of cardiorespiratory function, micro-circulation and individual organ flow may need to be attained in severe or late stages of shock to ensure good recovery, correct the oxygen debt that may follow tissue hypoperfusion and prevent reperfusion injury.

In the late stages of shock, prostacyclin may help the microcirculation by selectively reducing postcapillary resistance and reducing capillary leak.

Organ susceptibility to microcirculation disturbance in shock may vary. Prostacyclin improves splanchnic blood flow, preventing gut mucosal ischaemia and may help renal perfusion. Mannitol improves osmotic diuresis and may reduce the risk of reperfusion injury. Furosemide (frusemide) helps to increase renal prostaglandin production and thus improve renal circulation. Prostacyclin and prostaglandin E may help pulmonary parenchymal blood flow. ◆

Malignant Hyperthermia

F Richard Ellis
P J Halsall

F Richard Ellis is Emeritus Professor of Anaesthesia and Director of the Malignant Hyperthermia Unit, University of Leeds, UK. He is a Consultant Anaesthetist to the Leeds Teaching Hospitals NHS Trust. He gained his MB ChB from Manchester and his PhD from Leeds. In 1971 he established Europe's first Malignany Hyperthermia Investigation Unit.

P J Halsall is an Associate Specialist in Anaesthesia at St James's University Hospital, Leeds, UK. She graduated from Manchester University. She is involved in developing a DNA diagnostic service as an integral part of malignant hyperthermia screening.

Malignant hyperthermia (MH) was first defined as a clinical entity in 1960, when Jim Collier, a consultant anaesthetist in Melbourne, Australia, reported a strange reaction a young man had developed with halothane anaesthesia. Collier identified the hyperthermic response to anaesthetic vapours and the familial nature of predisposition to MH (several ether anaesthetic-related deaths had occurred in the patient's family).

Clinical features

The clinical features of MH comprise two groups that are causally but not clinically related (Figure 1).

Clinical features of malignant hyperthermia

Metabolic
- Hypercapnia
- Tachycardia
- Hyperthermia
- Acidosis
- Cyanosis

Muscle
- Spasm, rigidity, contracture
- Hyperkalaemia
- Myoglobinaemia/uria
- Raised creatine kinase
- Renal failure
- Disseminated intravascular coagulopathy

The first sign may be muscle spasm after suxamethonium (succinylcholine), though in the absence of this drug, muscle spasm usually develops later in response to administration of anaesthetic vapours. Probably as a response to this muscle spasm, skeletal muscle fibres become damaged (probably as a result of ischaemia), and potassium, myoglobin and creatine kinase are released into the circulation. Serum potassium can rapidly reach high levels (up to 15 mmol) that can be lethally cardiotoxic. Myoglobin can be deposited in the renal tubules, which can result in tubular obstruction and renal failure. The cumulative effect of the release of intracellular muscle contents into the circulation can be a disseminated coagulopathy.

Hypercapnia may be the first sign of metabolic stimulation. It is associated with an increased oxygen demand, which is achieved by an increase in cardiac output following an increase in heart rate. However, tachycardia is limited to 200 beats/minute and so when the heart rate reaches the maximum, the increasing demand for oxygen results in arterial desaturation and cyanosis. With developing hypoxaemia, lactic acidosis occurs and the combined effects of raised bicarbonate (hypercapnia) and raised lactate can reduce the pH to about 6.7 (a potentially lethal acidosis). Throughout the whole episode, the metabolic stimulation causes hyperthermia which may reach 43°C within the first hour. Above this temperature, proteins begin to denature and irreversible cerebral damage occurs.

The speed of the reaction may be so fast that a dangerous metabolic/muscle imbalance occurs within 30 minutes, and death may occur within 1 hour.

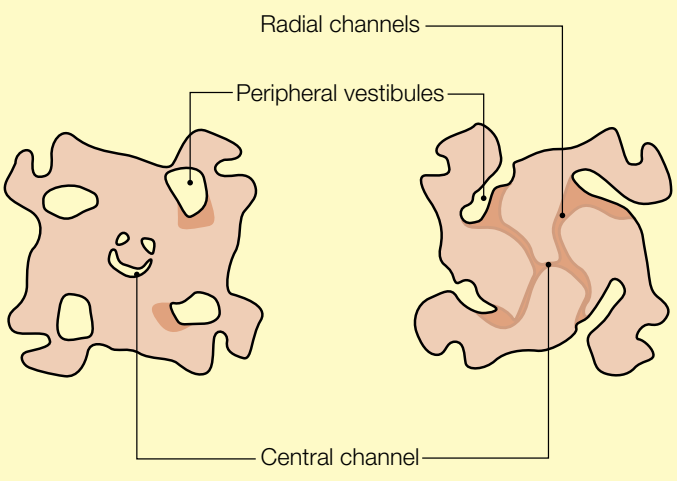
The incidence of MH may be as high as 1/6000 anaesthetics (Japan) or as low as 1/200,000 (UK). It depends on the use of the trigger drugs (suxamethonium and inhalational volatile vapours) and exposure to them. Thus, certain types of surgery (e.g. trauma and ear, nose and throat) are more likely to be associated with MH because of the selection of anaesthetic technique.

Pathophysiology

The acute episode is associated with a rise in intracellular ionic calcium. Recently, however, the demonstration of causative mutations in the *RYR1* gene on chromosome 19 has identified the abnormality predisposing to MH in the ryanodine calcium gate.

The ryanodine receptor (Figure 2) is a tetramer attached to the dihydropyridine voltage sensor in the T tubule in skeletal muscle (Figure 3). A mutation in a gene encoding for protein in this complex gene is intellectually satisfying especially as 15 gene mutations in the *RYR1* gene have 'causative' properties.

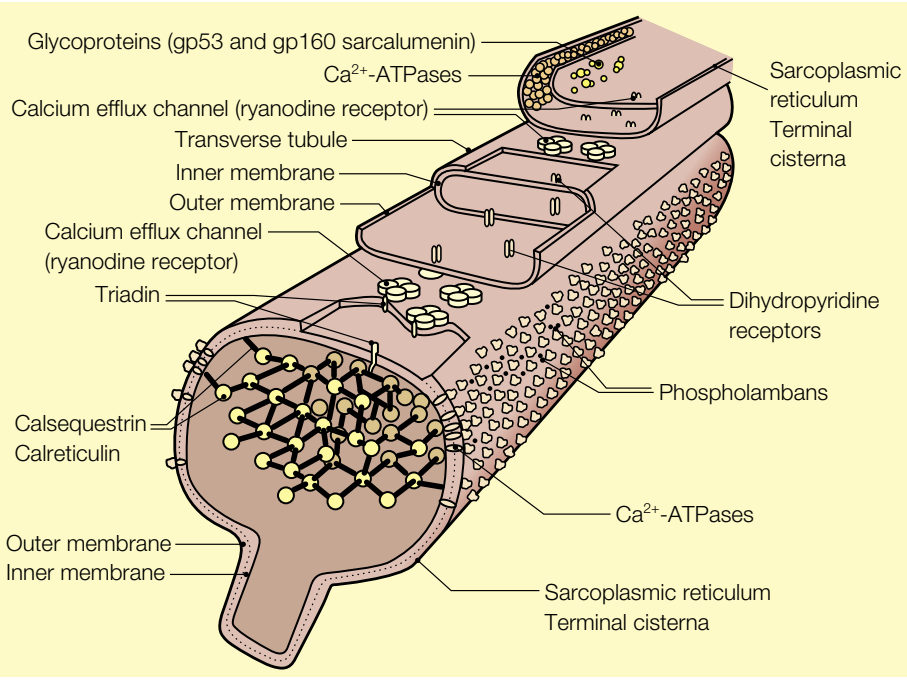
Ryanodine receptor



Cross-section of a computer-generated, three-dimensional reconstruction of the foot structure (calcium efflux channel) of skeletal muscle (ryanodine receptor). The reconstruction of the molecular interior shows that a single central channel leads outward through four radial channels to four peripheral vestibules which open to the sarcoplasm. This structural organization may allow the release of Ca^{2+} in the sarcoplasm at right angles to the central channel along the plane of the junctional gap

Triad

The relative positions of T tubule tetrads (dihydropyridine receptors), sarcoplasmic reticulum foot proteins (Ca^{2+} efflux channels or ryanodine receptors) and triadin are shown. Also shown are the proteins of the sarcoplasmic reticulum lumen, calsequestrin and calreticulin, and the glycoproteins gp53 and gp160 (sarcalumenin). The calcium ATPases and phospholamban pentamers are depicted on the outer surface of the sarcoplasmic reticulum. The ryanodine receptors occupy the junctional gap between the T tubule and sarcoplasmic reticulum. Triadin molecules co-localize with the ryanodine receptors in the junctional sarcoplasmic reticulum and serve to anchor calsequestrin adjacent to the sites of Ca^{2+} efflux from the sarcoplasmic reticulum. Dihydropyridine receptors are located in the T tubule junctional membrane opposite alternate ryanodine receptors. The T tubule tethers are not depicted



One of the problems in the genetics of MH is the apparent heterogeneity. Only 60% of families have an *RYR1* mutation. In one family the causative and defined gene mutation is on chromosome 1, and other genes on chromosomes 3, 5, 7 and 11 have been shown to co-segregate. It is perhaps surprising that there are so many causative mutations for MH in humans, whereas only one porcine mutation has been identified. It is found in three breeds of pig (Landrace, Pietrain, Poland China) as well as in some humans.

Pathopharmacology

MH is caused by two different types of chemicals (suxameth-onium and volatile inhalational vapours). Most of the work on inducing MH has been performed on susceptible pigs which are probably homozygous for MH due to inbreeding whereas most humans are heterozygous for the *RYR1* mutation.

If the *RYR1* mutation is the causative gene, and the evidence is good, it is difficult to understand how suxamethonium, which is a charged ionic compound, can penetrate the T tubule membrane and find a receptor on a membrane protein. Suxa-methonium causes increased masseteric muscle tone in 85% of normal subjects and it may be that people susceptible to MH are in the group that shows the most marked reaction to suxameth-onium owing to calcium lability within the sarcosplasm.

Other drugs that have been implicated in the induction of MH include phenothiazines, lidocaine (lignocaine), nitrous oxide, tricyclic antidepressants and ketamine, but the evidence has not been substantiated.

Management

Guidelines for the management of an MH crisis are given in Figure 4.

Guidelines for the management of a malignant hyperthermia crisis

- Presentation of malignant hyperthermia (MH) varies and the order of treatment may have to be modified. The steps below are intended as an aide memoire
- Know where dantrolene is stored in your theatre

Diagnosis: consider MH if
- Masseter muscle spasm occurs after suxamethonium
- Unexplained, unexpected tachycardia occurs with unexplained, unexpected increase in end-tidal CO_2

Early management
- Withdraw all trigger agents (i.e. all anaesthetic vapours)
- Install clean anaesthetic breathing system and hyperventilate
- Abandon surgery if feasible
- Give dantrolene, 1 mg/kg i.v. initially, and repeat as required up to 10 mg/kg
- Measure arterial blood gases, potassium and creatine kinase
- Measure core temperature
- Begin surface cooling avoiding vasoconstriction

Intermediate management
- Control serious arrhythmias with β-blockers
- Control hyperkalaemia and metabolic acidosis

Later management
- Clotting screen to detect disseminated coagulopathy
- Take first voided urine sample for myoglobin estimation
- Observe urine output for developing renal failure
- Promote diuresis with fluids/mannitol (20 mg dantrolene contains 3 mg mannitol)
- Repeat creatine kinase at 24 hours

Late management
- Consider other diagnoses and carry out appropriate investigations (e.g. vanillylmandelic acid (VMA), thyroid function tests, white cell count, chest radiography)
- Consider possibility of myopathy, neurological opinion, EMG
- Consider possibility of recreational drug ingestion (Ecstasy)
- Consider possibility of neuroleptic malignant syndrome
- Counsel patient and/or their family regarding implications of MH
- Refer patient to MH unit

Acute crisis

MH can occur rapidly during anaesthesia and many deaths have been reported within 1 hour of induction. The marked reduction in mortality since the 1960s, from 70% to 1%, is due to anaesthetists' greater awareness and knowledge of the condition and the better monitoring of all anaesthetized patients by oximetry, capnography, electrocardiography and pulse rate recording.

Early diagnosis may be sufficient to abort a crisis merely by withdrawing the causative drugs and installing a clean anaesthetic breathing system. Hypercapnia can be controlled by mechanically hyperventilating the lungs, and the developing hypoxaemia can be countered by increasing the inspired oxygen fraction.

The only specific drug to control MH is dantrolene, 1 mg/kg i.v. initially. It may have to be repeated up to 10 mg/kg to establish full control of the excessive calcium release from the sarcoplasmic reticulum (the calcium store in the muscle cell). Procainamide and glucocorticoids have also been used to control calcium release, but they are general membrane stabilizers and do not have any specific action on the sarcoplasmic reticular membrane.

The metabolic status of the patient must be monitored by measuring the arterial blood gases and plasma potassium repeatedly until the crisis is controlled. Blood should be kept for a later measurement of creatine kinase (CK), which indicates the degree of muscle breakdown. CK measurement should be repeated 12 hourly.

The earliest descriptions of MH recorded high body core temperatures as a consequence of prolonged metabolic stimulation. Today, owing to early diagnosis, the body core temperature seldom rises more than 1–2°C. Core temperature can help to monitor the progress of the acute crisis and should be recorded. In small children, who can develop rapid hyperthermia, body surface cooling could be considered using lukewarm water (cold water induces vasoconstriciton and heat retention).

Mainly as a consequence of the developing hyperkalaemia, the heart rhythm may become irregular. This can be controlled using β-adrenergic blockers. Hyperkalaemia should be controlled by dantrolene and the other measures mentioned above. Rising potassium can usually be controlled by dextrose/insulin, but in the worst case haemofiltration should be considered.

When MH is controlled, the pH stabilizes and begins to return to normal levels. If the pH remains low, an infusion of bicarbonate should be contemplated.

Late management
When muscle breakdown has been intense or prolonged, there is a danger of developing a disseminated intravascular coagulopathy (DIC). Any suggestion of oozing from cut surfaces or bruising should be investigated using a coagulation screen. Advice should be sought from a haematologist if a DIC develops.

The first voided specimen of urine should be tested for myoglobin using spectroscopy. Intense myoglobin-uria could herald the onset of renal tubular obstruction and renal failure, therefore all patients should be given a forced diuresis using a crystalloid load combined with an osmotic diuretic (e.g. mannitol).

A severe MH crisis can continue intermittently for several days with metabolic and body temperature instability. In these circumstances dantrolene, 25 mg q.d.s. may be given orally. Continuing renal failure may require haemodialysis before recovery.

Aftercare
There is often doubt about the diagnosis of MH, and the authors recommend that the patient is referred to an MH unit to consider whether a muscle biopsy using *in vitro* contracture testing (IVCT) is indicated. If the clinical diagnosis is confirmed by IVCT, family screening can be organized.

In 25% of families, the diagnosis of MH susceptibility can be made using DNA detection of one of the 15 known causative mutations in the *RYR1* gene on chromosome 19. In conjunction with other members of the European MH Group, the authors have published guidelines for DNA screening (see Further reading).

If MH is not confirmed, other causes of MH-like reactions should be sought including toxaemia, myopathy, thyroid disease, phaeochromocytoma, hypersensitivity to a drug or drug combination and neuroleptic malignant syndrome.

Management of anaesthesia
In the UK, 2500 MH-susceptible individuals have been identified. When they require surgery, they must inform the anaesthetist of their susceptibility (they are encouraged to wear an identification necklace). Anaesthesia can be conducted most easily using a local anaesthetic technique, though general anaesthesia can be conducted safely by avoiding known inducing agents. Prophylactic dantrolene is unnecessary. Modern anaesthetic techniques include the use of total intravenous administration and inhalational vapours can easily be avoided. Non-depolarizing relaxants act quickly enough for rapid intubation without the need for suxamethonium. ◆

ACKNOWLEDGEMENTS
The authors thank Dave Iles for permission to reproduce Figures 2 and 3 from Malignant Hyperthermia: A Molecular Genetic Study. CIP-Gegevens, Koninklijke Biblotheek, Den Haag, 1994.

The Association of Anaesthetists of Great Britain and Ireland are thanked for the Guidelines for the Management of a Malignant Hyperthermia Crisis, which they produced as a poster for the authors.

Mechanisms of Drug Action not Involving Protein Binding

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Most drugs act by binding to proteins, but a few exert their effects by osmosis, bulk formation, interacting directly with nucleic acids or by altering the pH of a physiological fluid such as stomach contents or urine. The latter mechanism is also discussed under drug absorption and drug interactions elsewhere.

Drugs utilizing osmosis

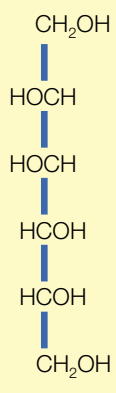
Osmosis is the physiological process by which water moves across a semipermeable membrane from one solution towards another that contains a higher solute concentration. Drugs that use this process are the osmotic diuretics (e.g. mannitol) and the osmotic laxatives (e.g. lactulose and the saline purgatives).

Osmotic diuretics

Mannitol (Figure 1) is a highly water-soluble compound that is not absorbed readily across membranes. It is given intravenously in relatively large doses so that it makes up an appreciable part of plasma osmolarity. Mannitol is unable to cross the blood–brain barrier or cross into the eye, therefore it can extract water from these compartments. It is used to treat cerebral oedema and glaucoma (raised intraocular pressure). Mannitol is filtered in the glomerulus of the kidney and very little is reabsorbed, thus increasing the osmotic pressure of the urine. Water is drawn into the renal tubules where they are most permeable to water (i.e. the proximal tubule, the descending limb of the loop of Henle and the collecting ducts). The increased osmotic pressure within the ducts reduces the passive reabsorption of water. The increased volume of urine reduces the dilution of sodium and thus the electrochemical gradient for its reabsorption, therefore sodium reabsorption is also reduced. Mannitol has been used to prevent acute renal failure because it can maintain a flow of urine even when the glomerular filtration rate is compromised. However, if the patient is unable to make urine, mannitol can cause cardiac failure or pulmonary oedema. Other osmotic diuretics include glycerol, isosorbide and urea, but mannitol is the most commonly used.

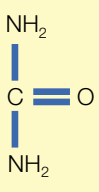
Osmotic diuretics

Mannitol

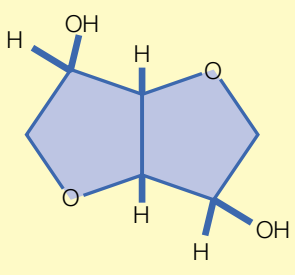


Glycerol

Urea



Isosorbide



1

Osmotic laxatives

Osmotic laxatives increase the volume of fluid in the lumen of the gastrointestinal tract and accelerate the transference of the contents through the intestine to the colon. The excessive bulk of fluid in the colon causes evacuation about 1 hour later. Magnesium sulphate (Epsom salts) and magnesium hydroxide are virtually insoluble and remain in the intestine to exert an osmotic effect. Very little is absorbed in a healthy patient, but small children or patients with poor renal function can absorb enough to cause problems such as CNS depression, heart block or neuromuscular blockade. Lactulose is a disaccharide of fructose and galactose and is administered as an oral solution. Bacteria in the intestine split lactulose into the two component sugars, which are poorly absorbed. These are fermented to form lactic and acetic acids, which cause the osmotic effects required; this process takes several days. All osmotic laxatives can cause abdominal cramps.

Bulk laxatives

Bulk laxatives are polysaccharide polymers that are not broken down in the gut, but retain water, thus inducing peristalsis; examples include bran, agar and methylcellulose.

Faecal softeners and antifoaming agents

The addition of a surfactant to the gastrointestinal tract promotes evacuation by softening the faeces. An example is docusate sodium, which also has some mild stimulant activity on intestinal motility.

Several antifoaming agents are included in many commercial antacid mixtures to break up gas bubbles in the stomach. It is believed that small air bubbles trapped during swallowing can lead to gastric bloating and flatulence. Simethicone (dimeticone) is an effective antifoaming agent but there is no evidence that it is useful in treating gaseous intestinal distension.

Gel-forming substances

Compounds such as kaolin, pectin and attapulgite form semisolid gels within the intestine, cause resistance to flow and increased firmness of the stool. They are commonly used to treat diarrhoea, but they do not reduce the volume of liquid excreted and thus have little benefit other than the formation of a firmer stool. It has been suggested that they absorb bacterial toxins but there is no firm evidence to support this view.

Drugs affecting nucleic acids

The nucleic acids found in cells are deoxyribonucleic acid (DNA), which makes up the genetic codes, and the three ribonucleic acids (RNA), which co-operate to make specific proteins using the information provided by DNA. The three types of RNA are messenger (mRNA), transfer (tRNA) and ribosomal (rRNA). The nucleic acids are formed from a string of nucleosides: each nucleoside consisting of a nitrogen-containing base connected to a pentose sugar and a phosphate group. RNA and DNA are compared in Figure 2.

Comparison of DNA and RNA

	RNA	DNA
Pentose sugar	Ribose	Deoxyribose
Nitrogen-containing bases	Adenine Cytosine Guanine Uracil	Adenine Cytosine Guanine Thymine
Function	Perform protein synthesis directed by DNA	Stores genetic code controlling protein synthesis
Size and shape	100–50,000 base pairs Shape varies with degree of hydrogen bonding along strand Three types: mRNA, tRNA, rRNA	More than 45 million base pairs Paired strands coiled into a double helix

2

Many drugs used in the treatment of cancers target DNA. The anti-cancer antibiotic, bleomycin, causes fragmentation of the DNA strand following free radical formation. This prevents mammalian cell division.

Alkylating agents (Figure 3) covalently attach alkyl groups to other molecules by the formation of positively charged carbonium ions. The carbonium ions interact with electron-rich sites such as those found on DNA. Most clinically useful drugs have two alkylating groups so that they can form covalent cross-links between adjacent strands of nucleic acids. This cross-link hinders subsequent separation of the two strands and is more difficult to repair than a single alkyl bond.

Examples of alkylating agents

Alkylating agents	Comment
Cyclophosphamide	Alkylate N7 bond of the guanine base
Nitrosoureas (e.g. lomustine)	Lipid soluble, crosses the blood–brain barrier therefore useful for tumours of the brain and meninges
Busulfan (busulphan)	Selective effect on bone marrow Used in chronic granulocytic leukaemia
Cisplatin	Causes intrastrand cross-linking between the N7 and O6 atoms of adjacent guanine bases. Particularly useful for solid tumours of the testis

3

Acriflavine and other acridine topical disinfectants intercalate into the DNA causing increasing distance between base pairs leading to frame-shift mutations.

Some antibiotics inhibit bacterial protein synthesis by interfering with the function of RNA. For example tetracycline competes with tRNA by binding to the complementary base on mRNA preventing the production of essential proteins.

Agents changing the pH of compartments

Urine can be made more alkaline by sodium bicarbonate, sodium citrate or potassium citrate. The salts are metabolized and the cations are excreted with bicarbonate. The use of these for the treatment of weak acid overdose is discussed elsewhere, as is the use of ammonium chloride to acidify the urine for the treatment of weak base overdose.

Alkalization of the urine also decreases inflammation in the urinary tract and may have some antibacterial effects.

Antacids are used to neutralize gastric acid and increase gastric pH. They are present in many over-the-counter indigestion mixtures and include magnesium hydroxide, magnesium trisilicate and aluminium hydroxide gel. Sodium bicarbonate is also effective in the short term, but the carbon dioxide produced can cause belching and the stimulation of a secondary rise in gastric acidity. ◆

Mechanisms of Drug Interactions

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Any physician administering more than one drug to a patient must be aware of potential interactions. While many are trivial and unimportant some are life threatening. If in doubt, 'look it up'. The response of a patient to a drug can be modified by individual variation (e.g. age, obesity) and by interactions with other drugs, foods or chemicals ingested at the same time. There are several types of drug interaction (Figure 1), but many are theoretical or clinically trivial. Drug interactions are usually described as pharmacokinetic (one drug affects the absorption, distribution or excretion of another) or pharmacodynamic (changes in drug action occur in the area of the target tissue). The later includes the actions of agonists and antagonists at the same or different receptors.

An additional mechanism of drug interaction is when two drugs are mixed and one complexes with the other; this is really a pharmaceutical incompatibility. An example is the formation of a complex when thiopental (thiopentone) and suxamethonium are mixed in the same syringe. This is simple chemistry and no pharmacological principle is involved. However, pharmaceutical incompatibilities can occur in the body and may be manipulated for the patient's benefit. An example is the termination of the anticoagulant activity of the strongly acidic heparin by the strongly basic protamine sulphate. In addition, heavy metals can be chelated by chemicals and removed from the circulation or the gastrointestinal tract. A chelate is a complex formed between a metal and a compound that contains two or more potential ligands. The stability of the chelate varies with the metal and the ligand. Calcium has a higher affinity for oxygen ligands than for sulphur and nitrogen ligands, while mercury and lead have the opposite affinity. This allows drugs to be designed that will chelate only with a specific metal. Some chelating agents used in medicine are listed in Figure 2.

Classification of drug interactions

Pharmaceutical incompatibility

Pharmacodynamic interactions
- Interaction at or near the site of action

Pharmacokinetic interaction
- Interaction at the site of entry
- Interaction at or near storage sites
- Interaction at or near the site of metabolism
- Interaction at or near the site of excretion

1

Chelating agents

Chelating drug	Therapeutic use	Comments
Desferrioxamine	Iron poisoning	Has low affinity for iron in haemoglobin and cytochrome enzymes but high affinity for iron stored as ferritin and haemosiderin
Dicobalt edetate	Cyanide poisoning. May be used after large doses of sodium nitroprusside	Toxic
Penicillamine	Heavy metal poisoning Wilson's disease in which copper is deposited in the body	Also used in rheumatoid arthritis, but mechanism does not involve chelation
Sodium calcium edetate	Lead poisoning	Calcium in the molecule prevents hypocalcaemia
Tetracycline	Antibiotic	May chelate with ions in the intestine (e.g. calcium or iron) reducing absorption of the drug because the chelate is highly insoluble

2

Pharmacodynamic interactions

Pharmacodynamic interactions occur because of the presence of another drug at the site of drug action.

Additive or synergistic interactions

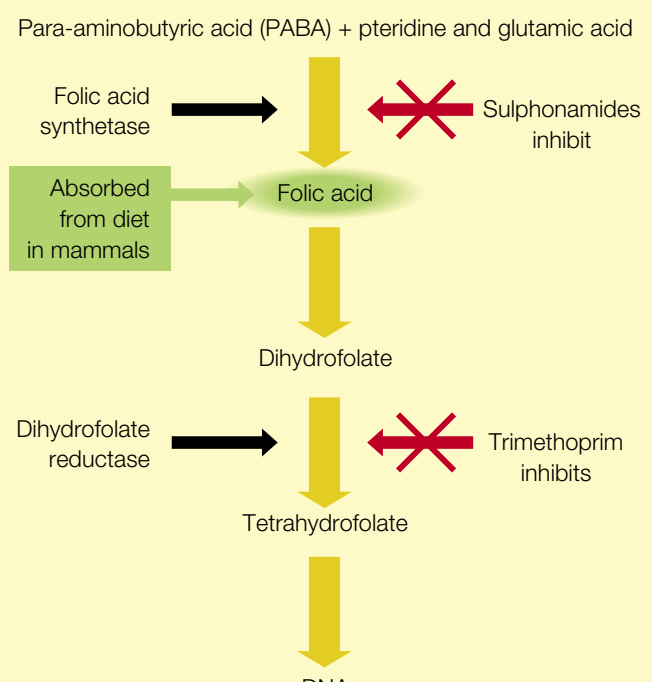
Additive or synergistic interactions occur when two drugs with similar pharmacological properties are given together. A commonly encountered example is ethanol combined with other sedative drugs such as benzodiazepine anxiolytics or histamine H_1-receptor antagonists used for travel sickness. Benzodiazepines alone have a high therapeutic index and while overdose may cause prolonged sedation they are seldom fatal. In contrast, a combination of benzodiazepine overdose with ethanol is often fatal.

Drugs with different therapeutic indications may have a common pharmacological action that is responsible for side-effects. Both the tricyclic antidepressants (e.g. amitriptyline), and antipsychotic drugs (e.g. thioridazine), possess muscarinic receptor antagonist properties. When combined or used with other antagonists at muscarinic acetylcholine receptors the enhancement of anticholinergic effects can result in heat stroke in hot, humid climates, or psychoses, in addition to dry mouth and blurred vision.

Aminoglycoside antibiotics (e.g. streptomycin) impair the influx of calcium ions into the neuron by chelating them, thus inhibiting acetylcholine release. This causes an enhancement of competitive neuromuscular blockade.

Synergy or potentiation is seen when sulphonamide antibiotics are combined with trimethoprim. Both drugs are bacteriostatic when given alone, but the combination is bactericidal (Figure 3).

Bacterial DNA pathway: site of action of antibiotics



Inhibition of a single enzyme by either sulphonamides or trimethoprim results in a bacteriostatic effect but inhibition of both enzymes is bactericidal

3

Drugs with similar adverse effects may also be additive, particularly with respect to ototoxicity (e.g. ethacrynic acid and streptomycin) or nephrotoxicity (tobramycin and cephalothin). However, not all combinations of similar drugs cause clinical problems. For example furosemide (frusemide) and streptomycin combinations do not result in enhanced ototoxicity.

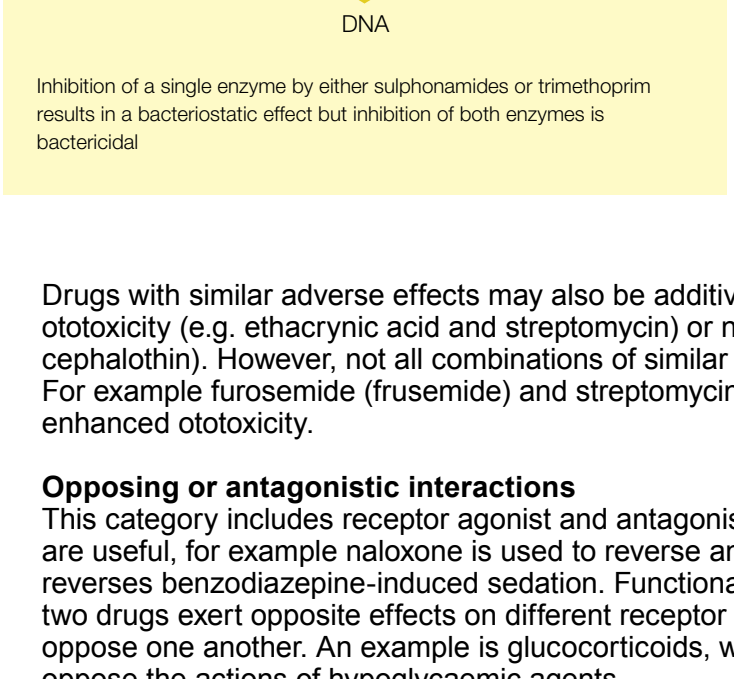
Opposing or antagonistic interactions

This category includes receptor agonist and antagonist inter-actions. Many of these are useful, for example naloxone is used to reverse an opioid overdose and flumazenil reverses benzodiazepine-induced sedation. Functional antagonisms also occur when two drugs exert opposite effects on different receptor systems and thus physiologically oppose one another. An example is glucocorticoids, which cause hyperglycaemia and oppose the actions of hypoglycaemic agents.

Alteration in drug transport mechanisms

Many drugs compete with each other for uptake at the site of action. The noradrenergic neuron is a prime site for this type of action (Figure 4). Indirectly acting sympathomimetic drugs such as amfetamine (amphetamine) derivatives need to be taken up into the neuron in order to release noradrenaline. Adrenergic neuron-blocking agents (e.g. guanethidine) that were formerly used as antihypertensive drugs, required uptake into the neuron to produce their effects. All these drugs use the noradrenaline reuptake mechanism. The tricyclic antidepressants inhibit this reuptake process and diminish the action of drugs requiring it. However, neither guanethidine nor amphetamine is widely used in modern therapeutics.

The noradrenergic neuron



4

Changes in fluid and electrolyte balance

Digitalis glycosides are the prime example of drugs that exhibit this type of interaction. Increased cardiac contractility is brought about by the inhibition of Na^+/K^+-ATPase causing a build up of Na^+ in the cardiac cell. This results in an increase in Na^+/Ca^{2+} exchange and a build-up of intracellular calcium and enhancement of contraction. In high doses this can lead to disturbances of cardiac rhythm. Plasma K^+ normally competes with digitalis for the binding site on Na^+/K^+-ATPase and thus the sensitivity of the enzyme to digitalis is increased if plasma K^+ is low. Digitalis may be used to treat heart failure and the oedema associated with the disease is often treated with diuretics. Both the loop diuretics and, to a lesser extent, the thiazide diuretics lower plasma K^+ and may thus increase digitalis toxicity. Lithium can take the place of sodium in a number of cellular processes, thus lithium toxicity is enhanced by low dietary salt.

Pharmacokinetic interactions

Absorption, distribution, metabolism and excretion of drugs can be modified by interaction with other drugs. There are many examples of these interactions in the literature and only some of the more important ones are mentioned here.

Absorption
Most interactions occur due to changes, usually reduction, in the absorption of orally administered drugs. If a drug is given acutely for a single-dose effect (e.g. analgesics, anxiolytics, hypnotics) then changes in the rate of absorption may alter the peak plasma concentration and the maximum therapeutic effect obtained. In contrast, when drugs are given chronically, it is usually the total amount of drug absorbed that is important rather than the rate of absorption.

The largest absorptive site in the gastrointestinal tract is the small intestine and thus drugs that enhance gastric emptying (e.g. the prokinetic agent metoclopramide) hasten drug absorption while drugs that inhibit gastric emptying (e.g. muscarinic acetylcholine receptor antagonists) slow absorption. This interaction has been exploited in anaesthesia when metoclopramide is used to increase the rate of onset of oral morphine administered as MST Continus tablets. The combined administration of paracetamol and metoclopramide has also been used to enhance the rate of drug absorption in the treatment of migraine.

The formation of insoluble chelates between tetracycline and a variety of divalent and trivalent ions has already been described (Figure 2). Fluoroquinolone antibiotics (e.g. ciprofloxacin, norfloxacin), which inhibit DNA topoisomerase II and prevent the supercoiling of DNA, also form poorly soluble chelates with these ions.

The effect of pH changes on drug absorption is discussed elsewhere. A rise in gastric pH due to H_2-receptor antagonists and antacids can markedly reduce the absorption of the anti-fungal agent ketoconazole but, in general, the effects of these drugs on absorption is small and variable because most drugs are absorbed in the small intestine rather than in the stomach.

The simultaneous presence of two anaesthetic gases in the lung may cause the 'second gas effect' in which the rapid absorption of one gas causes more gas to be delivered to the alveoli, enhancing absorption of the second anaesthetic. This phenomenon has been seen with 75% nitrous oxide and 1% enflurane when the plasma concentration of enflurane rises much faster in the presence of nitrous oxide.

Distribution
There are many theoretical drug interactions involving competition for plasma protein and tissue protein binding sites. While displacement of a drug from its binding site causes a transient increase in free (active) drug concentration, this is followed by increased elimination until a new steady state is reached. Few of these cause clinical problems, but there are a few well-documented exceptions. Both aspirin and the sulphonamides are given in large enough doses to cause displacement of other substances bound to albumin including bilirubin. This can be catastrophic in a jaundiced newborn baby in whom unbound bilirubin can penetrate the brain, causing basal ganglia disorders. Aspirin and sulphonamides can also change the ratio of free to bound phenytoin in the plasma, making dose adjustment more difficult and narrowing the therapeutic window.

Metabolism
The pharmacological actions of many drugs are terminated by metabolism that produces more water-soluble compounds that can be more readily excreted by the kidney. Most drug metabolism occurs in the liver (see Anaesthesia and Intensive Care Medicine 2:8: 322). Oxidation, reduction or hydrolysis of drugs (phase 1 reactions) occur in the endoplasmic reticulum often utilizing cyctochrome P450, a nonspecific enzyme system. A number of drugs and environmental pollutants can induce the P450 system making drug metabolism faster though the effect may take several days or even weeks to develop. Enzyme induction has been responsible for failure of oral contraception and ineffectiveness of corticosteroid or anticoagulant therapy. Each of the enzyme-inducing agents can also increase the metabolism of any other.

Some drugs have some selectivity for different isoforms of cytochrome P450 and they are responsible for more selective drug interactions. Grapefruit juice inhibits the activity of the CYP 3A3/4 isoform of cytochrome P450 that is responsible for the metabolism of a number of calcium channel blockers including felodipine, nifedipine, nimodipine and nitrendipine. Over two-fold increase in plasma concentrations of these drugs has been reported in patients drinking grapefruit juice, with a consequent decrease in blood pressure and an increase in side-effects, at least with felodipine.

Other drugs such as chloramphenicol inhibit cytochrome P450 enzymes, causing reduced metabolism and prolongation of drug activity. This may lead to toxicity if the drug has a low therapeutic index (e.g. phenytoin). Ketoconazole selectively inhibits the P450IIIA4 isoenzyme, which also metabolizes cyclosporin. This interaction is well known and transplant patients may need less than 25% of the dose of cyclosporin if ketoconazole is co-prescribed. Ketoconazole also appears to stop the metabolism of ketoconazole by the gut wall. Some other drugs inhibiting cytochrome P450 enzymes are listed in Figure 5.

Enzyme inhibitors involved in drug interactions

Drug	Enzyme inhibited	Comment
Allopurinol	Xanthine oxidase	Increases mercaptopurine toxicity
Ecothiopate and organophosphorus pesticides	Cholinesterase	Prolongation of suxamethonium neuromuscular blockade
Disulphiram and metronidazole[1]	Aldehyde dehydrogenase	Increase in blood aldehyde concentrations after alcohol ('antabuse reaction')
Erythromycin	Cytochrome P450IIIA	Inhibition of benzodiazepine metabolism
Phenelzine and tranylcypromine	Monoamine oxidase	Reduced destruction of tyramine from dietary sources causing hypertensive crisis

[1] Metronidazole also inhibits the enzyme responsible for the oxidation of the S(-) isomer of warfarin leaving the more potent anticoagulant within the body with a prolongation of bleeding time

Not all drugs are metabolized by the cytochrome P450 enzymes. Concurrent drug therapy can inhibit other drug- metabolizing enzymes and result in toxicity. Some examples of enzyme inhibitors that have caused problems are listed in Figure 5. Monoamine oxidase inhibitors can cause a number of interactions at the noradrenergic nerve terminal (Figure 4). They prevent the breakdown of noradrenaline (norepinephrine) that is taken up into the nerve so that more is accumulated in the store. Indirectly acting sympathomimetic drugs, of which tyramine is only one, cause enhanced release of noradrenaline (norepinephrine), over-stimulation of the α_1-adrenoceptors and a potential hypertensive crisis.

Excretion
Inhalational anaesthetics are excreted in the expired air and this can be increased by the addition of carbon dioxide to the inhaled gas to stimulate ventilation. Most other drugs are excreted in the bile or urine. Renal excretion can be altered by changes in protein binding (discussed above), inhibition of tubular secretion, alteration in kidney blood flow or urinary pH.

Probenecid is the classic example of a drug that was designed to compete with the active transport mechanism that secretes acids such as the penicillins into the renal tubule. Prolongation of the action of penicillin was essential in the early days when availability of the antibiotic was low and the price high. However, a number of other acidic drugs (e.g. aspirin, indomethacin, sulphonamides) share this property. Each can cause increases in the plasma concentrations of any other. Prostaglandins cause renal capillary vasodilatation, and prostaglandin production is inhibited by non-steroidal anti-inflammatory drugs, causing a reduction in renal blood flow. This is an important interaction for renally excreted drugs with a low therapeutic index, such as lithium. Changes in urinary pH affect the elimination of weak acids and weak bases. While this is not an important interaction for most drugs it can be used to enhance excretion of overdoses of susceptible drugs (Figure 6). ◆

Renal excretion of weak acids and bases

Renal excretion of a weak acid (e.g. aspirin)

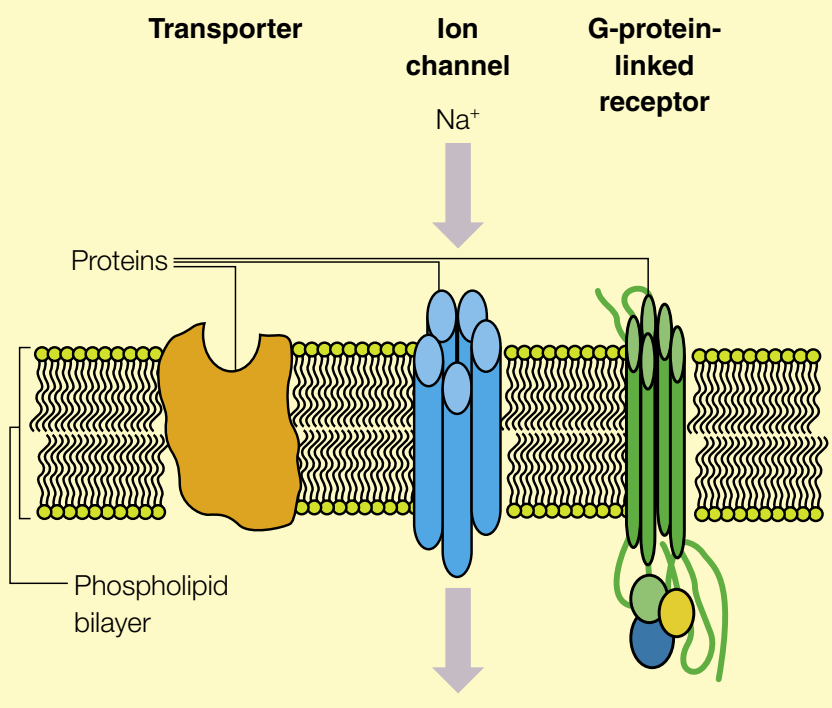
Membranes: Action of Gases and Vapours

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

A plasma membrane surrounds all cells and separates the intracellular from the extracellular environment. The two environments have different compositions and the membrane's function is to maintain the intracellular environment while allowing movement of substances, such as respiratory gases, ions and glucose, into and out of the cell. The membrane is also required to regulate the cell's response to intracellular signalling via hormones and neurotransmitters. The membrane consists of a phospholipid bilayer with proteins embedded in it (Figure 1). Phospholipids are glycerides in which a group containing phosphoric acid and a base replaces one of the three organic residues. The base may be cholamine (in kephalin) or choline (in lecithin) and, with the phosphoric acid, results in a highly polar 'head' to the molecule. The rest of the organic residues are fatty acyl chains, such as arachidonic or linoleic acids, which are non-polar. The phospholipid molecules arrange themselves so that the polar heads face the internal and external aqueous media and the non-polar tails form the middle of the membrane sandwich. The proteins associated with the membrane may be associated with the internal or external surface of the membrane or embedded within the membrane. Like the phospholipid bilayer, embedded proteins have polar regions in contact with the aqueous media. There are five main classes of membrane proteins (Figure 2). Both membrane proteins and phospholipids may be targets for gases and vapours, several of which can cause anaesthesia (Figure 3).

Cell plasma membrane



1

The five main classes of membrane proteins

1. Extrinsic protein bound by ionic forces to the internal or external surface of the lipid bilayer (e.g. cytoskeletal and extracellular matrix proteins)
2. Proteins anchored into the bilayer by a non-polar peptide (e.g. G-protein subunits)
3. Proteins with a single transmembrane span (e.g. synaptobrevin)
4. Proteins with several membrane spans (e.g. ion channels and G-protein-linked receptors)
5. Proteins linked to a glycolipid (e.g. acetylcholinesterase)

2

Some anaesthetic gases and vapours

	Minimum alveolar concentration	Formula
Inert gases		
• Xenon	71%	Xe
Non-organic gases		
• Nitrous oxide	1.02 atmospheres	N_2O
• Nitrogen	5 atmospheres	N_2
Hydrocarbons		
• Cyclopropane	9.3%	Halogenated hydrocarbons		
• Halothane	0.75%	CF_3-CHBrCl
Ethers		
• Diethyl ether	1.9%	C_2H_5-O-C_2H_5
• Isoflurane	1.2%	CF_3-CHCl-O-CHF_2
• Desflurane	7%	CHF_2-O-CF_3
• Sevoflurane	2%	CH_2F-O-$CH(CF_3)_2$

3

Interactions with the membrane lipid bilayer

The cell membrane is permeable to water (probably via specialized water channels), lipid-soluble molecules (e.g. corticosteroid hormones), and gases (e.g. oxygen, carbon dioxide). Other polar molecules, such as glucose and amino acids, utilize specific transporter proteins (Figure 1).

The correlation of oil/gas partition coefficient with anaesthetic potency has been repeatedly confirmed for a range of compounds. Both the lipid bilayer and the integral proteins contain hydrophobic sites that could be the target of anaesthetic action.

Closely packed phospholipid heads, with their tails extended, exist in a gel-like state that is highly ordered and in which there is little movement. Transition from this state to a more fluid, liquid-like, state can be brought about by a small increase in temperature or by the insertion of small molecules, such as anaesthetic gases and vapours, into the bilayer. There is a positive correlation between the fluidization of the phospholipid head and anaesthetic potency. It is logical to assume that fluidization would be reversed by increases in pressure. Thus, the well-established pressure reversal of anaesthesia would be consistent with fluidization of the lipid bilayer being relevant to anaesthetic action. While changes in fluidity could cause a change in membrane function that equates with anaesthesia, most scientists have discarded this hypothesis. At anaesthetic concentrations the fluidization produced by anaesthetic agents is equivalent to that produced by a 1°C increase in temperature. Minor elevations of temperature do not cause anaesthesia, indeed cooling rather than heating increases anaesthetic potency. In addition, some alcohols that cause anaesthesia, do not appear to fluidize lipid bilayers and there is some structural dependency of some molecules with anaesthetic action, which is incompatible with a simple fluidization hypothesis.

Critical volume hypothesis

An observation that anaesthetics occupy space in membranes dependent on molar concentration and volume led to the hypothesis that anaesthesia occurred when the molecules of an anaesthetic agent occupied a critical volume within the membrane. At anaesthetic concentrations, membranes expand by a consistent 0.4% though their own volume is only 0.02%. It was proposed that such an expansion could disrupt the ion channels necessary for cell functioning. The observation that anaesthesia could be reversed by increasing the ambient pressure (so that the membrane could revert to its normal size) seemed to support the premise that membrane expansion was the key to anaesthesia. However Halsey's group demonstrated that pressure reversal was not the same for all anaesthetics. While the greatest difference in pressure reversal was seen with the intravenous agents, the anaesthetic vapours and gases did not show a common pattern. The differences were explained in terms of a multisite expansion hypothesis, which suggested that anaesthetic agents could expand in more than one site and that the physical properties of these sites varied. In addition, pressure and the anaesthetic might act on different sites (i.e. a physiological or functional antagonism). This hypothesis received much criticism on methodological and interpretative grounds but it introduced the idea of possible multiple sites of anaesthetic action.

Interactions with membrane proteins

Early experiments with the enzyme luciferase demonstrated that anaesthetic gases and vapours could inhibit the protein in parallel with anaesthetic potency. Subsequently, interactions with many types of protein have been demonstrated but have not been proven to be the definitive site of anaesthetic action.

Ion channels are particularly sensitive to anaesthetic action. General anaesthetics, like local anaesthetics, can block voltage-gated sodium channels but a diminution in axonal conduction occurs only in concentrations greater than that necessary to produce general anaesthesia. Similarly, inhalational anaesthetics can be shown to inhibit voltage-gated calcium channels and activate potassium channels. The type of channel affected varies from agent to agent and much of this work has been done *in vitro* or in the snail and therefore its relevance to anaesthesia in mammals is uncertain.

Ligand-gated ion channels (Figure 4) are probably the most popular candidates for the site of anaesthetic action. In general, the anaesthetics inhibit or block excitatory ligand-gated ion channels and enhance the sensitivity of inhibitory ion channels such as γ-aminobutyric acid receptor A ($GABA_A$). Blockade of the ion channel in the N-methyl-D-aspartate (NMDA) type of glutamate receptor by ketamine caused great excitement. However, ketamine is an atypical dissociative anaesthetic that most pharmacologists could accept to be acting by a mechanism not mirrored by other anaesthetics. Isoflurane also decreases the probability of the NMDA channel opening, and ethanol and diethyl ether have been shown to have some preferential depressant effects on NMDA receptors. Many anaesthetics including the inhalational gases and vapours can enhance GABA transmission via the $GABA_A$ receptor. Studies in molecular biology have shown that the presence of a particular domain, or binding site, is necessary for these potentiating effects of a given anaesthetic agent. Interestingly, the domain is not the same for all anaesthetics, indicating multiple modulatory sites on the $GABA_A$ receptor. Inhibition and/or block of excitatory neurotransmission within the CNS is a tempting explanation for anaesthesia, but until the biochemical basis of consciousness is elucidated nothing can be certain.

Ligand-gated ion channels sensitive to anaesthetic gases and vapours

- Nicotinic acetylcholine
- γ-aminobutyric acid receptor A ($GABA_A$)
- Glycine
- Glutamate receptors
  - N-methyl-D-aspartate (NMDA)
  - α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)
  - Kainate
- $5\text{-}HT_3$

Interactions with the membrane lipid bilayer

The cell membrane is permeable to water (probably via specialized water channels), lipid-soluble molecules (e.g. corticosteroid hormones), and gases (e.g. oxygen, carbon dioxide). Other polar molecules, such as glucose and amino acids, utilize specific transporter proteins (Figure 1).

The correlation of oil/gas partition coefficient with anaesthetic potency has been repeatedly confirmed for a range of compounds. Both the lipid bilayer and the integral proteins contain hydrophobic sites that could be the target of anaesthetic action.

Closely packed phospholipid heads, with their tails extended, exist in a gel-like state that is highly ordered and in which there is little movement. Transition from this state to a more fluid, liquid-like, state can be brought about by a small increase in temperature or by the insertion of small molecules, such as anaesthetic gases and vapours, into the bilayer. There is a positive correlation between the fluidization of the phospholipid head and anaesthetic potency. It is logical to assume that fluidization would be reversed by increases in pressure. Thus, the well-established pressure reversal of anaesthesia would be consistent with fluidization of the lipid bilayer being relevant to anaesthetic action. While changes in fluidity could cause a change in membrane function that equates with anaesthesia, most scientists have discarded this hypothesis. At anaesthetic concentrations the fluidization produced by anaesthetic agents is equivalent to that produced by a 1°C increase in temperature. Minor elevations of temperature do not cause anaesthesia, indeed cooling rather than heating increases anaesthetic potency. In addition, some alcohols that cause anaesthesia, do not appear to fluidize lipid bilayers and there is some structural dependency of some molecules with anaesthetic action, which is incompatible with a simple fluidization hypothesis.

Critical volume hypothesis

An observation that anaesthetics occupy space in membranes dependent on molar concentration and volume led to the hypothesis that anaesthesia occurred when the molecules of an anaesthetic agent occupied a critical volume within the membrane. At anaesthetic concentrations, membranes expand by a consistent 0.4% though their own volume is only 0.02%. It was proposed that such an expansion could disrupt the ion channels necessary for cell functioning. The observation that anaesthesia could be reversed by increasing the ambient pressure (so that the membrane could revert to its normal size) seemed to support the premise that membrane expansion was the key to anaesthesia. However Halsey's group demonstrated that pressure reversal was not the same for all anaesthetics. While the greatest difference in pressure reversal was seen with the intravenous agents, the anaesthetic vapours and gases did not show a common pattern. The differences were explained in terms of a multisite expansion hypothesis, which suggested that anaesthetic agents could expand in more than one site and that the physical properties of these sites varied. In addition, pressure and the anaesthetic might act on different sites (i.e. a physiological or functional antagonism). This hypothesis received much criticism on methodological and interpretative grounds but it introduced the idea of possible multiple sites of anaesthetic action.

Interactions with membrane proteins

Early experiments with the enzyme luciferase demonstrated that anaesthetic gases and vapours could inhibit the protein in parallel with anaesthetic potency. Subsequently, interactions with many types of protein have been demonstrated but have not been proven to be the definitive site of anaesthetic action.

Ion channels are particularly sensitive to anaesthetic action. General anaesthetics, like local anaesthetics, can block voltage-gated sodium channels but a diminution in axonal conduction occurs only in concentrations greater than that necessary to produce general anaesthesia. Similarly, inhalational anaesthetics can be shown to inhibit voltage-gated calcium channels and activate potassium channels. The type of channel affected varies from agent to agent and much of this work has been done *in vitro* or in the snail and therefore its relevance to anaesthesia in mammals is uncertain.

Ligand-gated ion channels (Figure 4) are probably the most popular candidates for the site of anaesthetic action. In general, the anaesthetics inhibit or block excitatory ligand-gated ion channels and enhance the sensitivity of inhibitory ion channels such as γ-aminobutyric acid receptor A ($GABA_A$). Blockade of the ion channel in the N-methyl-D-aspartate (NMDA) type of glutamate receptor by ketamine caused great excitement. However, ketamine is an atypical dissociative anaesthetic that most pharmacologists could accept to be acting by a mechanism not mirrored by other anaesthetics. Isoflurane also decreases the probability of the NMDA channel opening, and ethanol and diethyl ether have been shown to have some preferential depressant effects on NMDA receptors. Many anaesthetics including the inhalational gases and vapours can enhance GABA transmission via the $GABA_A$ receptor. Studies in molecular biology have shown that the presence of a particular domain, or binding site, is necessary for these potentiating effects of a given anaesthetic agent. Interestingly, the domain is not the same for all anaesthetics, indicating multiple modulatory sites on the $GABA_A$ receptor. Inhibition and/or block of excitatory neurotransmission within the CNS is a tempting explanation for anaesthesia, but until the biochemical basis of consciousness is elucidated nothing can be certain.

Ligand-gated ion channels sensitive to anaesthetic gases and vapours

- Nicotinic acetylcholine
- γ-aminobutyric acid receptor A ($GABA_A$)
- Glycine
- Glutamate receptors
  - N-methyl-D-aspartate (NMDA)
  - α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)
  - Kainate
- $5\text{-}HT_3$

Methodology of Clinical Trials

Paul Coulthard

Paul Coulthard is Senior Lecturer and Honorary Consultant at the Central Manchester and Manchester Children's University Hospitals, which incorporates the Dental Hospital. He is Head of Oral and Maxillofacial Surgery and has a research interest in acute pain management.

Healthcare interventions should have a scientific basis provided by basic medical science and clinical research. This research evidence, together with clinical expertise integrated with an understanding of patient values, comprises evidence-based medicine. Clinical trials are scientific experiments that evaluate the effectiveness and safety of therapeutic interventions and are invaluable in guiding decisions about healthcare. The general term, clinical trial, encompasses controlled clinical trials and randomized controlled trials.

Study designs

Clinical research takes many forms.

Case studies or series observational studies are common, in which an intervention and outcome are described in one or more individuals. These may be useful in alerting clinicians to the feasibility or potential of a new treatment, but they lack a control group with which to compare the findings.

Retrospective studies look at patients who have already received a treatment. Outcomes may be compared with a control group but because randomization has not been used, matching or other statistical adjustments must be used to ensure that comparison groups are as similar as possible.

Prospective studies – in these studies, a defined group of patients receive a treatment and are followed over a period of time and the study may contain a control group.

Controlled clinical trial is a study that compares one or more intervention groups with one or more comparison (control) groups.

Randomized controlled trial or randomized clinical trial is an experiment in which investigators randomly allocate eligible people into intervention groups to receive or not to receive one or more interventions that are being compared. The results are assessed by comparing outcomes in the treatment and control groups. There is universal agreement that well-conducted randomized controlled trials constitute the best scientific evidence for treatment effectiveness.

Efficacy and effectiveness trials

Efficacy refers to whether an intervention works under ideal conditions in those who receive it. Comparing different surgical techniques is an example of an efficacy trial, where the investigators control the intervention, and therefore participant compliance is complete.

Effectiveness refers to whether an intervention works in practice. The intervention, such as novel analgesic or standard analgesic, may be accepted or rejected by the participant. An intention-to-treat analysis is one in which all the participants are analysed according to the intervention to which they were allocated, whether they received it or not. These analyses are favoured in assessments of effectiveness because they mirror the non-compliance and treatment changes that are likely to occur when the intervention is used in practice.

Phase I, II, III and IV trials

New drugs are evaluated in a series of clinical studies.

- A phase I trial is usually undertaken, following animal investigation, in healthy human volunteers to investigate the effect and metabolism of the novel compound. There is no control group.
- Phase II trials investigate the efficacy of a range of doses and are usually not randomized. If they are ineffective, further trials are not undertaken.
- A phase III trial is carried out if phase II trials show the new drug to be effective and safe. Typically they compare the effectiveness with placebo or an existing drug. These trials are usually randomized controlled trials.
- Phase IV trials are large studies to monitor the adverse effects of a new drug after its approval.

Parallel and cross-over design randomized controlled trials

In a parallel design, each group of participants is exposed to only one of the study interventions, for example, the new drug or placebo. This is the most common type of randomized controlled trial.

In a cross-over design, each participant is given each study intervention in successive periods. The order in which the participants receive each intervention is randomized. As each participant acts as his or her own control, fewer participants are required than for a parallel design.

Conducting a trial

Trial protocol: the research question should contribute something useful to existing knowledge and be developed following a thorough search of the existing sources of evidence, especially systematic reviews, to avoid duplication of work. The protocol also contains details of the background, scientific design and practical organization of the trial, including patient eligibility, treatments and outcome measures.

Ethics: the purpose of a research ethics committee in reviewing a proposed study is to contribute to safeguarding the dignity, rights, safety and well-being of the study participants. Informed consent is at the heart of ethical research and all studies must have appropriate arrangements for obtaining consent. Attention must also be given to systems to ensure confidentiality of personal information. When reviewing a research proposal, the research ethics committee also takes into consideration the principle of justice. This requires that the benefits and burdens of research be distributed fairly among all groups and classes in society, taking into account age, gender, economic status, culture and ethnic considerations. The principal investigator is the person designated as taking overall responsibility within the team of researchers for the design, conduct and reporting of the study, but research funders, the sponsor and the employing organization also have responsibilities.

Random allocation: the term random does not mean haphazard but rather that all participants have the same chance of being assigned to each of the study groups and allocation is not determined by the investigators, clinicians or study participants. Random number tables or computer-generated number sequences are the best way of doing this. By allocating the participants randomly, the characteristics of the participants are likely to be similar across groups at the start, and the investigators will be more able to quantify the impact of the intervention, with minimal effects from other factors, known and unknown.

Allocation concealment is the process used to prevent foreknowledge of group assignment in a randomized controlled trial. The allocation method should be impervious to any influence from the individual making the allocation by having the randomization process administered by someone who is not responsible for recruiting participants. Methods such as date of birth or case record numbers are open to manipulation because the treatment group is known when a patient is considered for entry into a trial and this knowledge may influence the decision to recruit that patient. Adequate methods include centralized randomization schemes and sealed envelopes each containing the name of the next treatment.

Blinding (masking) refers to keeping the investigators or participants ignorant of the group assignment. It is used to protect against the possibility that knowledge of assignment may affect patient response to treatment. A trial that is not blind is called an open randomized controlled trial, for example when surgery is compared with medication. In a single-blind randomized controlled trial, one group does not know the identity of the intervention that is given to each participant. In a double-blind randomized controlled trial, neither the investigator nor the participants know the identity of the intervention. To be successful, interventions must be indistinguishable to participant and investigators, therefore a placebo tablet must look, weigh and taste the same as the active medication. In a triple-blind randomized controlled trial, those evaluating the outcomes (data analysts and statisticians) do not know the identity of the intervention.

Bias is any factor or process that tends to deviate the results or conclusions of a trial away from the truth. Bias can be introduced into a trial voluntarily, but usually it is involuntary. Selection bias occurs when the outcomes of a trial are affected by systematic differences in the way in which individuals are accepted or rejected for a trial. With true randomization, all the study participants are given the same opportunity to be allocated or assigned to each of the study groups and this is the main appeal of the randomized controlled trial. However, other forms of bias can occur at any stage of the research process, for example, publication bias when editors accept manuscripts more favourably when the trial results are positive.

Sample size should be pre-specified. Patient variability means large numbers are needed in a trial. However, sample sizes are often not calculated and therefore small and important therapeutic effects may be missed. Reporting often lacks justification of sample size.

Trial quality

Good clinical practice: if trials are to benefit patients, they must be properly designed, conducted and appropriately analysed. Bodies such as the Association of the British Pharmaceutical Industry (ABPI) have played a key role in improving research quality. The ABPI has produced many useful guidelines including: *Good Clinical (Research) Practice, Good Clinical Trial Practice*, and the *ABPI Guidance Note: Patient Information and Consent for Clinical Trials*.

Research governance: clinical governance aims to improve the overall standards of clinical care in the UK National Health Service. A comparable strategy is in place to improve the quality of research practice in health and social care. The standards described in the *Research Governance Framework* offer a model for use by NHS staff using NHS resources, and research undertaken by industry, the charities, the research councils and UK universities.

The national research register is a database of continuing and recently completed UK research, funded by or of interest to the NHS. Over 76,000 research projects are included. This database is useful for identifying unpublished research, particularly important to those undertaking systematic reviews, and identifying and bringing together researchers between and across related areas of research.

Reporting trials: the reporting of randomized controlled trials and research in general is often incomplete. Ideally, the report of a trial should convey the relevant information to permit informed judgements to be made regarding the internal and external validity of the trial. The Consolidated Standards of Reporting Trials (CONSORT) statements checklist proposed in 1995 offers guidance in report presentation. Internal validity of the trial is the degree to which the trial design, conduct, analysis and presentation have minimized or avoided biased comparisons of the interventions under evaluation. External validity is the precision and extent to which it is possible to generalize the results of the trial to other settings. Several tools exist to evaluate the quality of trial reporting. ◆

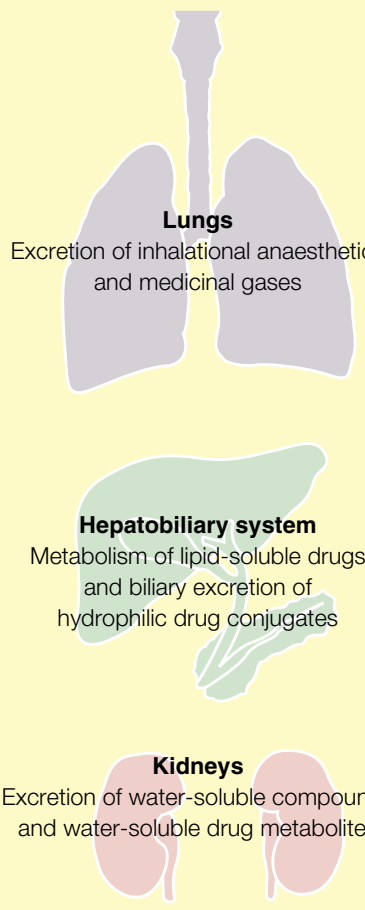
Modes of Drug Elimination

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Drug elimination is the removal of a drug from the body by metabolism and/or excretion. The main routes for drug excretion (Figure 1) are the kidneys, hepatobiliary system and the lungs, the latter being important for inhalational anaesthetics and medicinal gases. The kidneys excrete polar compounds unchanged in the urine. In contrast, lipid-soluble compounds have to be metabolized to polar compounds before excretion in the urine. Most metabolism occurs in the liver, which can also be involved in elimination through biliary excretion. Removal of a drug from the blood or plasma is expressed as clearance. Total body clearance is calculated by dividing the amount that enters the systemic circulation by the area under its blood or plasma concentration–time curve. For most drugs the total body clearance is the sum of hepatic and renal clearance, but for some drugs clearance by the lungs is important (see below).

Organs of drug excretion



1

Drug metabolism

The liver is the organ with the greatest metabolic capacity, but the kidney, lungs and blood-borne enzymes may also contribute. The enzyme systems involved in drug elimination can be classified as phase 1 or phase 2. Phase 1 includes oxidation, reduction and hydrolysis, some examples of which are given in Figure 2. In the liver, many of these reactions are catalysed by the mixed function oxidase system, of which the most important group is the cytochrome P450 system. This is described in greater detail in *Anaesthesia and Intensive Care Medicine* **2:8:** 322. Drugs that are cleared or removed efficiently by the liver (e.g. morphine, lidocaine (lignocaine), imipramine) are restricted in their rate of elimination solely by liver blood flow. The elimination of these drugs is little affected by enzyme induction, hepatic disease, and changes in protein binding or competitive binding interactions. In contrast, drugs whose elimination depends on intrahepatic processes (e.g. phenytoin, warfarin) may be seriously affected by the above changes, but will be little affected by changes in liver blood flow.

Examples of phase 1 metabolic pathways

Oxidation

• Phenytoin	*p*-hydroxyphenytoin
• Ethanol	Ethanoic acid
• Midazolam	α-hydroxymidazolam

Reduction

• Halothane	Trifluoroethane
• Cortisone	Hydrocortisone

Hydrolysis

• Pethidine	Norpethidine
• Aspirin	Salicylic acid

2

Enzyme systems other than those included in the cytochrome P450 system are involved in phase 1 reactions, examples are cholinesterase in the hydrolysis of suxamethonium and alcohol dehydrogenase in the oxidation of ethanol. Phase 1 reactions do not necessarily result in the inactivation of the drug and there are numerous examples of pro-drugs and toxic metabolites of drugs (see *Anaesthesia and Intensive Care Medicine* **3:3:** 114). Phase 2 reactions occur when a drug or phase 1 metabolite has a group (e.g. amino, hydroxyl, thiol) that makes it susceptible to conjugation. The most common conjugate is glucuronide but conjugates with sulphate, glutamate, acetate and methyl groups also occur. Commonly, phase 2 products are pharmacologically inactive and are excreted via the biliary route or via the kidney in the urine. However, there are some important active phase 2 products such as morphine-6-glucuronide, which has significant opioid activity.

Glucuronide formation can occur in the gastrointestinal tract as mentioned above and in the kidney, placenta and skin. The blood and many tissues contain esterases that are important in the metabolism of drugs such as remifentanil (tissue esterase) and suxamethonium (cholinesterase). Extrahepatic metabolism accounts for 50% of the conjugation of propofol with glucuronide and sulphate.

First-pass effects

In contrast to the situation for phase 1 metabolism, the enzymes responsible for phase 2 metabolism are found in the liver and the gut in similar quantities. Therefore, when given orally, a drug that is metabolized principally by phase 2 reactions (e.g. morphine) may be extensively metabolized before reaching the systemic circulation. This is known as first-pass gut metabolism. Other orally administered drugs may undergo significant first-pass hepatic metabolism. Once absorbed from the intestine, the drug enters the portal circulation to the liver. If the drug has a high hepatic clearance (see *Anaesthesia and Intensive Care Medicine* **2:6:** 237), then little unchanged drug will reach the systemic circulation. The local anaesthetics and the β-adrenoceptor antagonist, propranolol, are examples of this type of drug.

First-pass effects can also apply to drugs given intravenously. When a drug is given by a fast intravenous bolus it reaches the pulmonary capillary bed in high concentration before it enters the systemic circulation. Highly ionized drugs remain in the blood stream, but lipid-soluble drugs may diffuse into lung tissue. If the drug is not extensively bound to proteins in the lung, this has little effect on distribution because the drug rapidly diffuses out again as plasma concentrations fall. Some drugs, particularly lipid-soluble basic drugs such as local anaesthetics, propranolol and fentanyl, bind to lung protein and significant quantities are removed from the blood in the first circulatory pass. However, the contribution of the lung to the metabolism of these drugs is probably small.

Biliary excretion and enterohepatic recycling

Although the liver is the main organ for drug metabolism it may also excrete unchanged drug in the bile. Like the kidney, the liver has a number of acid and base handling systems that transport drugs from the plasma to the bile. Hepatocytes can transport uncharged molecules into the bile and a number of drug conjugates are concentrated in the bile. When these compounds are returned to the intestine, lipid-soluble drugs may be reabsorbed, conjugated drugs may be hydrolysed and the original drug reabsorbed. This is known as enterohepatic recycling and it may occur repeatedly leading to a reservoir of drug. Figure 3 gives examples of drugs that undergo significant recycling by this route. Enterohepatic recycling is particularly important to maintain the effects of ethinyloestradiol. Oral dosing with broad-spectrum antibiotics can cause diarrhoea thus preventing recycling of ethinyloestradiol and consequent oral contraceptive failure. Polar drugs that are excreted in the bile (e.g. neuromuscular blocking agents) are not reabsorbed from the intestine and so, for these drugs, biliary excretion is a true method of drug elimination.

Drugs that undergo enterohepatic recycling

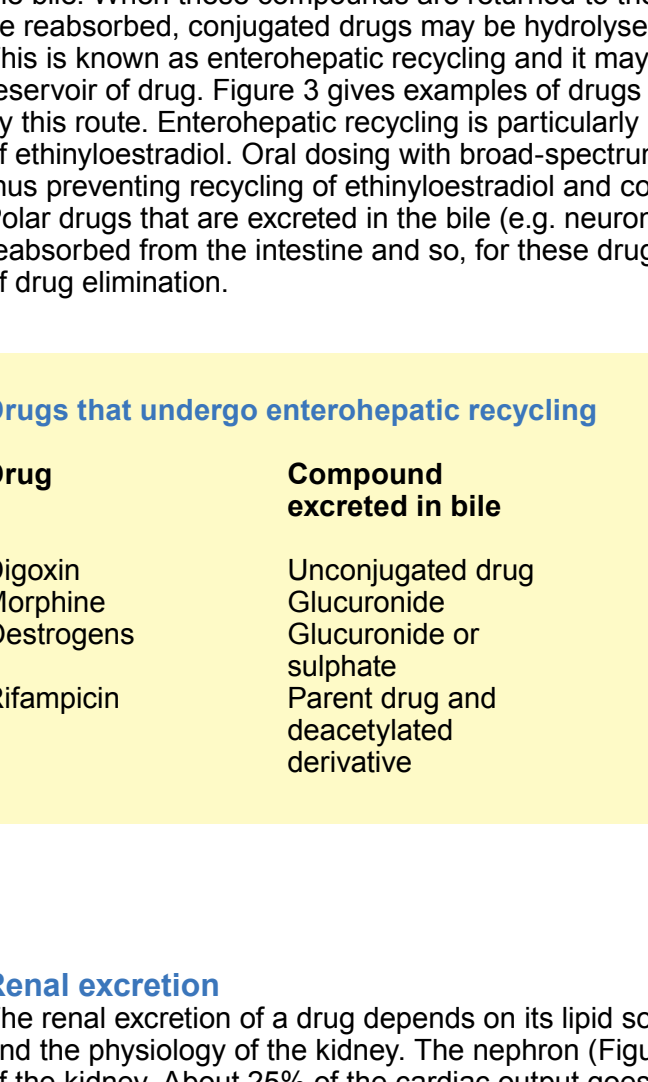
Drug	Compound excreted in bile	Fate in intestine
Digoxin	Unconjugated drug	Reabsorbed
Morphine	Glucuronide	Hydrolysed and reabsorbed
Oestrogens	Glucuronide or sulphate	Hydrolysed and reabsorbed
Rifampicin	Parent drug and deacetylated derivative	Parent drug reabsorbed and derivative excreted in the faeces

3

Renal excretion

The renal excretion of a drug depends on its lipid solubility, binding to plasma proteins and the physiology of the kidney. The nephron (Figure 4) is the basic anatomical unit of the kidney. About 25% of the cardiac output goes to the kidney and about 10% is filtered at the kidney. Drugs bound to proteins or cells are unable to pass across the glomerular membranes therefore only plasma water is filtered; the normal rate is about 125 ml/minute. This is measured by determining the clearance of creatinine, a catabolic product of amino-acid metabolism derived from muscle. Creatinine clearance is equal to the glomerular filtration rate. The drug concentration in the filtrate at this initial stage is the same as that in the plasma water. From the renal corpuscle the filtrate passes down the renal tubules. Meanwhile the blood from the glomerulus passes into the peritubular capillaries, which surround the proximal and distal tubules and the vasa recta that supplies the loop of Henle. In its passage down the tubules drug may be reabsorbed into the capillaries or drug may be added to the filtrate by active secretion.

Structure of a nephron



4

Active secretion
If the rate of excretion of a drug exceeds the rate of filtration of plasma water then active secretion of the drug is inferred. Active secretion occurs via a carrier mechanism and binding to plasma proteins does not inhibit it. Penicillin for example is 80% protein bound and thus only a small amount is filtered at the glomerulus. However, it is almost completely removed from the blood by secretion from the blood into the proximal tubule. Some drugs that are secreted into the proximal renal tubule are listed in Figure 5.

Some drugs actively secreted into the proximal renal tubule

Uric acid transport systems secrete organic acid drugs and metabolites
- Penicillins
- Glucuronide metabolites
- Probenecid
- Sulphate conjugates
- Salicylic acid
- Thiazide diuretics

Choline and histamine transport systems secrete organic bases
- Quaternary ammonium compounds (e.g. neuromuscular blocking agents)
- Morphine
- Pethidine

5

Passive diffusion across the renal tubule
Water is progressively reabsorbed as the filtrate passes down the nephron so that only 1% of the original filtrate emerges as urine. The amount of drug that is reabsorbed during its passage depends on its ability to permeate the tubule. Thus, highly lipid-soluble, non-polar drugs such as thiopental (thiopentone), phenytoin and inhalational anaesthetic agents pass through freely and little is lost in the urine. In contrast, polar drugs, provided they are too large to penetrate the water pores of the cells will be unable to be reabsorbed and will be voided in the urine. For these drugs, renal clearance approaches glomerular filtration rate. Examples include many neuromuscular blocking agents, polar metabolites and conjugates. The reabsorption of weak acid and bases depends on urinary pH, weak acids are more readily reabsorbed if the pH is acid and weak bases are more readily reabsorbed in alkaline urine. The adjustment of urinary pH to influence the excretion of certain drugs is discussed in *Anaesthesia and Intensive Care Medicine* **3:3:** 99.

Active reabsorption across the renal tubule
Drugs that resemble essential metabolites (e.g. levodopa, α-methyldopa, thyroxine) are actively reabsorbed. Uric acid is also actively reabsorbed and this can be inhibited by probenecid, which competes with uric acid for the active transport system. This is the basis of the use of probenecid for the treatment of gout.

Elimination via the lungs
The elimination of inhaled drugs by the lungs depends on alveolar ventilation, cardiac output and the degree of biotransformation of the agent. In general, the higher the alveolar ventilation the greater the rate of elimination of gases and volatile agents via the lungs. The administration of carbon dioxide to stimulate ventilation may decrease the time to recovery from inhalational anaesthetics.

An increase in cardiac output increases the concentration gradient between the vessel-rich compartment and the alveolar air, thus facilitating transfer of gases to the alveolar air and hastening elimination. Some inhalational anaesthetics (e.g. isoflurane, desflurane, nitrous oxide) are little metabolized and exhalation is the most important route of elimination. In contrast, halothane may be up to 20% metabolized and though recovery is due to exhalation, significant quantities of metabolite remain in the body. Some other agents can be smelt on the breath (e.g. ethanol, paraldehyde, thiols) but the quantity excreted by the lungs is insignificant.

Excretion by other routes
Non-ionized, lipid-soluble compounds can diffuse through the epithelial cells of glands and appear in sweat, saliva or tears. Saliva is usually swallowed, therefore it is not an effective mechanism for drug elimination. However, for some drugs, the concentration in saliva parallels concentrations in plasma so it can be used as an alternative fluid to measure drug concentrations when blood sampling is undesirable. Drugs may also be excreted in breast milk and some (e.g. ethanol) reach the same concentrations as in plasma. Since milk is a little more acidic than plasma there may be a tendency for some small concentrations of basic compound in breast milk. Quantitatively these routes of elimination are unimportant.

Some heavy metals such as arsenic and mercury are concentrated in hair or skin and this has been used by forensic scientists to detect cases of poisoning many years after the death of the subject. ◆

Neuromuscular Blocking Agents

Brian J Pollard

Brian J Pollard is Professor of Anaesthesia and Honorary Consultant Anaesthetist at Manchester Royal Infirmary, UK. He trained first in pharmacy and then in medicine, subsequently specializing in anaesthesia. His research interests include pharmacology related to anaesthesia, neuromuscular physiology and pharmacology, measurement of the depth of anaesthesia and management of the critically ill patient.

Motor nerves that supply striated muscle have their cell body in the CNS and a single long axon. This axon divides repeatedly as it approaches the muscle and may supply few or many muscle fibres depending on the function of the muscle. The nerve does not make direct contact with the muscle fibre at the neuromuscular junction, the prejunctional nerve ending being separated from the postjunctional muscle endplate region by a narrow gap, the junctional cleft.

The nerve terminal is concerned with the synthesis, storage, mobilization, release and recycling of the neurotransmitter. Acetylcholine (ACh) is synthesized in a process involving the acetylation of choline, which itself enters the nerve terminal by an active transport system. The reaction is catalysed by the enzyme choline-acetyltransferase and is an energy-dependent process involving coenzyme A. The synaptic cleft is filled with a mucopolysaccharide basement membrane material in which acetylcholinesterase is distributed, though it is particularly concentrated in the folds of the postjunctional membrane. The postjunctional endplate region contains the recognition and binding sites for ACh and the mechanism to translate this event into an electrical impulse that can activate the contractile mechanism of the muscle.

The process of neuromuscular transmission follows the arrival of an action potential at the nerve ending. ACh is released from vesicles in the immediately available store and this is rapidly replenished from the reserve stores (transmitter mobilization). ACh crosses the junctional cleft and combines with the postjunctional receptors. It is necessary for two molecules of ACh to combine with each receptor system to initiate opening of the channel and the binding of the first ACh molecule facilitates the binding of the second. Once the channel is open, sodium travels down its concentration gradient leading to local depolarization of the muscle membrane.

There are about 10,000 receptors per μm^2 located on the shoulders of the junctional folds. Each receptor unit has five glycoprotein subunits with a central cation channel passing through the postjunctional membrane. In each receptor, two of the glycoprotein subunits, the α subunits, are identical and each carries one ACh recognition site. The others are the β, α and either α in the adult or γ in the fetus (and in various other species). The α subunit also binds other agonists, toxins and reversible antagonists. Although the two α subunits have an identical amino-acid sequence, they are functionally different by virtue of their different positions in the receptor unit.

Receptors also exist on the prejunctional nerve endings, which subserve a feedback or modulating function controlled by ACh or other physiological mediators.

A number of potential sites of action exist for agents to modify neuromuscular transmission:

- inhibition of ACh release (e.g. botulinum toxin, gentamicin)
- prevention of ACh combination with postjunctional receptors (e.g. pancuronium)
- inhibition of choline uptake (e.g. hemicholinium)
- inhibition of ACh synthesis (e.g. triethylcholine)
- action at prejunctional receptors (e.g. tubocurarine)
- inhibition of acetylcholinesterase (e.g. neostigmine).

Not all of these mechanisms are clinically relevant, though drugs that affect neuromuscular transmission probably act at more than one site. Several mechanisms take place and result in potential inhibition of neuromuscular transmission as follows.

Receptor occlusion – any chemical substance that binds to either one or both ACh recognition sites can produce neuromuscular block by physically preventing ACh from binding and therefore the channel from opening. It is currently believed that the major component of the action of the clinical neuromuscular blocking agents (NMBAs) takes place through this mechanism.

Closed channel block – any bulky molecule binding near the channel opening may act like a lid, physically obstruct the mouth of the channel and impede the passage of cations. This binding will take place irrespective of whether the channel is open or closed.

Open channel block – any positively charged molecule may enter the channel once it has been opened. The presence of another molecule within the channel lumen will reduce current flow by physically obstructing the flow of ions through the channel. It is unlikely that channel block is of major importance in the clinical situation.

Prejunctional receptors – the existence of prejunctional receptors for ACh (nicotinic and muscarinic), noradrenaline (α- and β-adrenergic), and a number of other humoral mediators at the neuromuscular junction has been known for over 40 years. The physiological function of most of these receptors is unclear though it seems likely that the NMBAs may also modify neuromuscular transmission by their action on prejunctional receptors.

Membrane effects – the normal functioning of the channel depends on the integrity of the phospholipid cell membrane. A substance that dissolves in the lipid bilayer membrane, or which binds elsewhere in the vicinity of the receptor complex, may disturb the fluidity of the membrane and thereby influence the function of the channel.

Neuromuscular blocking agents

There are two ways to prevent the normal action of ACh at the neuromuscular junction. In the first, the binding site is occupied by an agent (an antagonist) that does not itself produce depolarization but prevents the access of ACh. In the second, the binding site is occupied by an agent that produces depolarization (an agonist) but the depolarization is prolonged and the receptor mechanism is thus rendered insensitive for a longer period of time.

Depolarizing neuromuscular blocking agents

Succinyldicholine (suxamethonium) is the only depolarizing agent in current clinical use. Normally the endplate is depolarized by ACh for only a very short period of time before it becomes repolarized. The persistent depolarization from succinyldicholine inactivates the voltage-gated sodium channels in the muscle membrane immediately adjacent to the motor endplate, resulting in a temporary insulating zone of electrical inexcitability around the endplates through which impulses cannot pass.

Succinyldicholine is the NMBA with the most rapid onset and the shortest duration of action. It has many unwanted side-effects, however. The most important are raised intracranial, intra-abdominal and intraocular pressures, hyperkalaemia, postoperative myalgia, bradycardia and the potential to trigger an episode of malignant hyperthermia. It has an active metabolite, succinylmonocholine, which is an NMBA with a potency about 20% of that of succinyldicholine. Being metabolized by plasma cholinesterase, its action is prolonged in patients who have a deficiency of that enzyme. All of these problems have stimulated the search for a non-depolarizing agent devoid of such side-effects and with a similar rapidity of onset and brevity of action.

Non-depolarizing neuromuscular blocking agents

Antagonists comprise the non-depolarizing NMBAs. These bind in a reversible manner to the ACh recognition sites on the α subunits, prevent ACh binding and activation of the receptor. In the presence of a non-depolarizing agent, a dynamic equilibrium exists that favours either the agonist (ACh) or the antagonist depending on their relative concentrations within the junction. The non-depolarizing agents are all large, bulky molecules with nitrogen with one, two or three positive charges. It was originally believed that there had to be two quaternary nitrogen moieties separated by a distance of about 1 nm and the early molecules conformed to this ideal. Some of the more recent molecular structures, however, are monoquaternary with more variable inter-onium distances. Although many of the NMBAs have been discovered and developed in a largely empirical manner, the more recent ones have evolved into precise pharmacological agents, with more precise receptor selectivity and minimal side-effects. Although not yet obtained, the development of an ultra-short-acting non-depolarizing agent with a very rapid onset to replace suxamethonium is on the horizon.

Since the introduction of these agents into clinical practice in 1942, many non-depolarizing relaxants have been synthesized, only a small number of which have found their way into regular clinical practice. A summary of their basic pharmacodynamic data is given in Figure 1.

Pharmacodynamic properties of the non-depolarizing neuromuscular blocking agents

	ED_{95} (mg/kg)	Onset time (minutes)	Duration (minutes)	Elimination half-life (minutes)
Alcuronium	0.25	5–6	60	200
Atracurium	0.23	3–5	25–35	20
Cisatracurium	0.05	4–6	30–35	
Doxacurium	0.03	7–10	60–80	130
Gallamine	2.4	4–7	45–60	135
Metocurine	0.28	5–6	60–80	220
Mivacurium	0.08	3–5	18–22	17
Pancuronium	0.06	3–4	50–60	130
Pipecuronium	0.05	4–6	40–60	138
Rapacuronium	1.1	1–2	18–22	
Rocuronium	0.3	2–3	30–40	120
Tubocurarine	0.5	4–7	50–70	200
Vecuronium	0.04	3–5	20–30	60

1

Long-acting agents

Tubocurarine was the first NMBA to enter clinical practice. It is extracted from *Chondodendron tomentosum*. Its use has declined and it is no longer available in the UK. Tubocurarine undergoes minimal metabolism and is excreted unchanged in both bile and urine. The possession of two separate routes of elimination led to it being used safely for patients with either impaired liver function or impaired renal function though its clearance is reduced in these situations. Tubocurarine is a potent antagonist at autonomic ganglia, and hypotension commonly follows its administration, with a reduction in both cardiac output and systemic vascular resistance. Tubocurarine may also release histamine at clinical doses and this may exaggerate the hypotension caused by block of autonomic ganglia. Skin flushing is common and bronchospasm may be seen in susceptible patients.

Metocurine, a relaxant produced by the methylation of the hydroxyl groups of tubocurarine, has enjoyed some popularity particularly in North America. It is about twice as potent as tubocurarine though its rate of onset and duration of action are similar. Side-effects are fewer than with the parent compound, though at higher doses autonomic block appears, resulting in hypotension. The potential for histamine release is much less than that of tubocurarine

Alcuronium is a bisquaternary compound synthesized from the naturally occurring alkaloid, toxiferine. It entered clinical practice in 1961. From the mid-1980s, its popularity began to decline and it was withdrawn from clinical use in the UK in 1999. Alcuronium is almost entirely renally excreted as the unchanged molecule and the clearance is therefore considerably prolonged in patients with renal impairment. A weak antagonist at autonomic ganglia, it may produce hypotension though this is not as marked as that with tubocurarine. The heart rate can be expected to rise by 5–10% owing to its weak vagolytic action.

Gallamine was the first synthetic, and the only trisquaternary, NMBA. It was popular during the 1950s and 1960s, but its use has declined. Gallamine is not metabolized but excreted unchanged in the urine. It is therefore an unwise choice in patients with impaired renal function. The most notable side-effect is a dose-related tachycardia caused by its potent vagolytic action. It does not often cause histamine release.

Pancuronium was the first steroid-based NMBA in clinical use. It is metabolized in the liver to the 3-OH, 17-OH, and 3,17-diOH derivatives though only the 3-OH compound has been detected in man. This metabolite possesses neuromuscular blocking activity with a potency of about 40% that of the parent compound. Pancuronium and its metabolites are excreted by the kidneys. In patients with impaired renal or hepatic function, the duration of action of pancuronium may be prolonged. Onset time is about 3–4 minutes and increasing the dose to 0.1 mg/kg reduces the onset time to about 2 minutes. Higher doses last proportionately longer, and accumulation can be observed following repeated doses. The blood pressure is well maintained and tachycardia, hypertension and an increased cardiac output may occasionally be seen resulting from block of cardiac vagal receptors and increased release of noradrenaline together with its decreased re-uptake from sympathetic nerve fibres. Pancuronium appears to be devoid of any propensity to release histamine.

Doxacurium is a bisquaternary benzylisoquinolinium substance with a chemical structure similar to atracurium. Its ED_{95} of 0.03 mg/kg makes it the most potent NMBA available. Its onset of action is slow (up to 10 minutes) with a duration of about 60 minutes. The onset can be shortened to about 3–4 minutes by increasing the intubating dose to 0.08 mg/kg, but the administration of such a high dose produces a block that may last up to 150 minutes. Doxacurium is excreted principally by the kidneys and its duration of action is therefore prolonged in patients with impaired renal function. Doxacurium has no effects on heart rate, blood pressure or cardiac output and it does not release histamine.

Pipecuronium belongs to the steroid family and was developed in Hungary in 1980. Its onset of action is about 4–6 minutes and this can be shortened to about 2–3 minutes by the administration of a larger bolus dose. Pipecuronium undergoes very little metabolism and most of the administered dose is recovered from the urine. Its action is extended in renal failure. Pipecuronium is almost devoid of cardiovascular side-effects and histamine release does not appear to be a problem.

Intermediate-acting agents

Atracurium is an ester with two positively charged nitrogen atoms and four asymmetric centres, giving a total of 16 possible stereoisomers. It was developed to exploit a novel method of metabolism – the Hofmann elimination reaction. Atracurium is metabolized by esterases in the plasma (< 1%) and the liver (about 60%), the remainder by the Hofmann reaction. Atracurium is unstable at body temperature and pH, and is stored in ampoules at 4°C at a pH of 3. Breakdown products of atracurium include laudanosine and acrylates. Laudanosine produces convulsions in certain laboratory animals and the acrylates are highly reactive, potentially hepatotoxic substances. No problems of toxicity have been reported in man, however. The duration is about 25–40 minutes and is little changed by renal or hepatic dysfunction. This reliable and predictable action has made it the drug of choice for many short-to-intermediate procedures. One of the key features of atracurium is its lack of cardiovascular effects though bradycardia has been reported, which is particularly noticeable when using a high-dose narcotic technique. Histamine release may be a problem when using doses in excess of about 0.5–0.6 mg/kg.

Cisatracurium is a single isomer preparation of the main active ingredient in atracurium. It is about three times more potent than atracurium though it has a slightly slower onset. Cisatracurium has been shown to possess greater cardiovascular stability than atracurium and, like atracurium, it is unaffected by renal or hepatic disease. Accumulation following repeated doses or a continuous infusion does not occur. Biotransformation of cisatracurium produces laudanosine and acrylates, as does atracurium, but because of its increased potency, there is less potential for accumulation of the metabolites.

Vecuronium is a synthetic steroid-based agent and, like pancuronium, it breaks down to 3-OH, 17-OH and 3,17-diOH compounds. The 3-OH derivative is also an NMBA with a potency of about 50–70% that of vecuronium. Vecuronium is eliminated through the kidneys both as the parent compound and as its breakdown products. Accumulation has been reported following larger doses, especially in the presence of renal failure. The duration of action of vecuronium may also be prolonged in liver failure. The onset of action of vecuronium is about 3–5 minutes and this can be reduced to about 2 minutes by increasing the intubating dose. An intermediate-acting agent, its duration of action is about 20–30 minutes and spontaneous recovery is reliable. Vecuronium is almost devoid of cardiovascular side-effects and this has made it a popular relaxant, particularly in those with compromised cardiovascular systems. Like atracurium, its lack of vagal action may unmask a bradycardia from surgical stimulation. There is very little histamine release at normal clinical doses.

Rocuronium is another steroid-based NMBA. Its important feature is its rapid onset with increased doses (Figure 2). The pattern of onset of rocuronium differs slightly from the other agents in that there is a faster initial phase. Intubation is thus possible after only 60 seconds with doses greater than 0.45 mg/kg. Accumulation has not been reported following repeated doses or with use by infusion. Rapid and satisfactory reversal can be accomplished by the use of routine clinical doses of neostigmine. Most of a dose of rocuronium is taken up by the liver and secreted into the bile though a significant amount is excreted in the urine. It is mainly eliminated unchanged. Rocuronium is almost devoid of cardiovascular side-effects and histamine release, has negligible ganglion-blocking actions and minimal effect on the vagus.

Onset characteristics of rocuronium

Dose (mg/kg)	Time to intubation (seconds)
0.3	120–150
0.45	90
0.60	60
0.90	45

2

Short-acting agents

Mivacurium belongs to the benzylisoquinolinium (atracurium) family and is the only non-depolarizing NMBA to be metabolized by plasma cholinesterase. Under circumstances in which the activity or quantity of plasma cholinesterase is reduced, the duration of action of a dose of mivacurium is prolonged. This includes patients with impaired renal function. The onset can be accelerated by increasing the intubating dose such that 0.25 mg/kg has an onset time of about 2.5 minutes. Recovery, once it has begun, is rapid and complete and unlike the other non-depolarizing agents, the duration of action is little affected by increasing the dose. It is often unnecessary to use an anticholinesterase agent to antagonize a mivacurium block, but if clinically indicated, reversal is rapidly secured with a routine dose of neostigmine. A transient fall in blood pressure and flushing in the arm used for venepuncture may sometimes be seen, particularly with larger doses, due to the release of histamine. Administering the mivacurium bolus more slowly over about 15–30 seconds can reduce these phenomena.

Rapacuronium is the newest of the NMBAs. It has not (at January 2001) been released for general use in the UK and so experience is limited. It has the most rapid onset of the non-depolarizing agents, a dose of 1.5 mg/kg producing good intubating conditions almost, but not quite, as rapidly as succinylcholine, 1 mg/kg. It seems likely that it will prove to be an acceptable alternative to succinylcholine for rapid-sequence induction. Its recovery profile is similar to that of mivacurium with a recovery index of about 6 minutes and spontaneous recovery to 90% in about 18–20 minutes. Onset and recovery at the larynx is more rapid than at the thumb. Although spontaneous recovery is considerably slower than with succinyl-choline, adequate reversal from a rapacuronium block has been reported using a routine dose of neostigmine after about 2–3 minutes. Recent reports have appeared of bronchospasm following rapacuronium administration which have led to its withdrawal in the USA. Some patients exhibit a tachycardia amounting to a rise in the heart rate of about 10–12%.

Non-opioid Analgesics

Barbara J Pleuvry

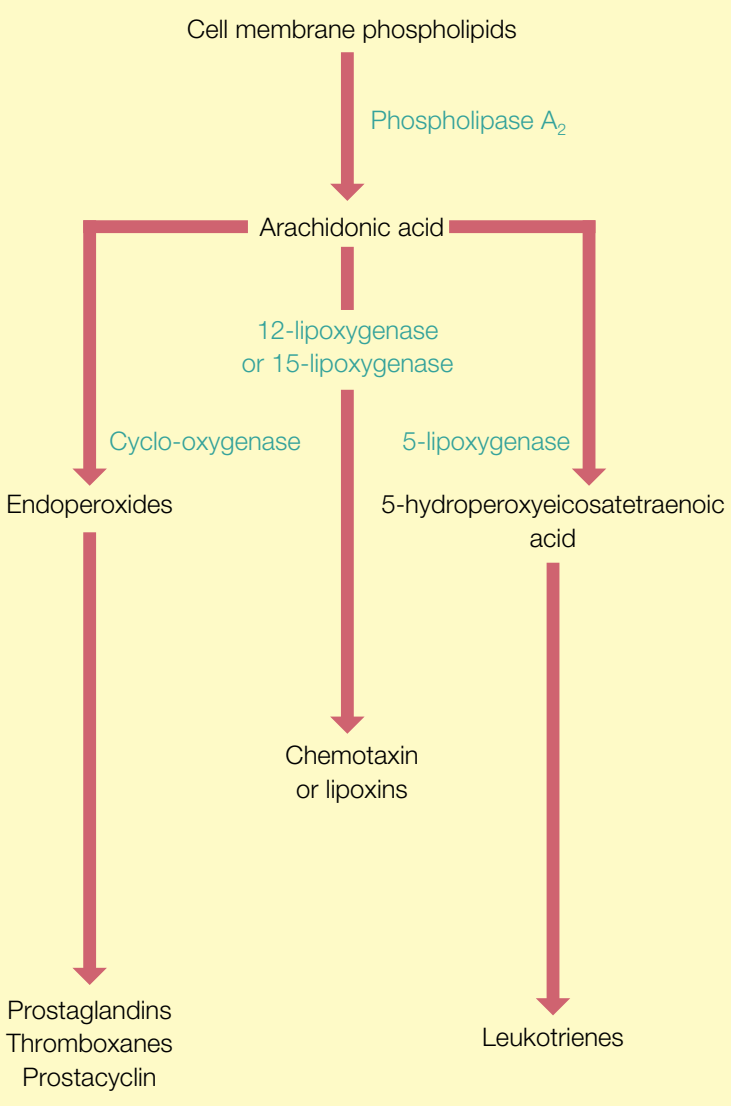
Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Non-steroidal anti-inflammatory drugs (NSAIDs)

Sodium salicylate, a chemical manipulation of the glycoside salicin obtained from extracts of willow bark, was introduced in 1875 to treat rheumatic fever. Acetylsalicylic acid (aspirin) was introduced about 25 years later and since then many anti-inflammatory analgesics have been marketed. Although paracetamol was first used clinically at the end of the 19th century, it was only when it was recognized as the active metabolite of both acetanilide and phenacetin (two compounds now withdrawn because of unacceptable toxicity), that it achieved popularity. Paracetamol possesses analgesic and antipyretic activities comparable with aspirin but is anti-inflammatory only in high doses therefore it should not be included as a NSAIDs.

The first convincing hypothesis to explain the anti-inflammatory, antipyretic and analgesic activity of NSAIDs was proposed in the early 1970s by Vane and colleagues. It was observed that NSAIDs inhibit the production and release of prostaglandins in all cell types tested. Prostaglandins together with the thromboxanes and leukotrienes are part of a group of arachidonic acid metabolites called the eicosanoids. Arachidonic acid is a twenty-carbon atom fatty acid containing four double bonds, and it is usually found esterified in the phospholipids in cell membranes. A number of stimuli, such as antigen/antibody reactions and general cell damage, can cause activation of phospholipase (A_2 and/or C) and liberate arachidonic acid. Once liberated, arachidonic acid is rapidly metabolized by a number of enzyme systems including cyclo-oxygenase (COX) and several lipoxygenases (Figure 1).

Metabolism of arachidonic acid



1

Prostaglandins and pain

Of all products of COX activity, the prostaglandins of the E series (PGEs) and prostacyclin (PGI_2) are most likely to have a role in inflammatory pain. They sensitize nociceptors to other noxious stimuli such as bradykinin and 5-hydroxytryptamine (5-HT) and they can produce pain. NSAIDs are inhibitors of COX. A second isoform of COX (cyclo-oxygenase 2 or COX-2) is induced by inflammation. This enzyme is susceptible to NSAIDs and it is likely that the anti-inflammatory action of these agents is due to COX-2 inhibition. It has been suggested that COX-1 inhibition is responsible for many of the side-effects of NSAIDs when used for their anti-inflammatory properties. Aspirin, and to some extent indomethacin and sulindac, are relatively selective for COX-1, while ibuprofen and piroxicam are less selective. Ibuprofen is preferred to aspirin for the treatment of inflammatory diseases because of its relative lack of side-effects. Although paracetamol inhibits COX-1 and COX-2 within the CNS, its lack of useful anti-inflammatory effects has been attributed to the weakness of its COX inhibition in the presence of high concentrations of peroxides that are found in inflammatory states. Alternatively, co-factors necessary for the inhibition of COX by paracetamol are not present in the inflamed tissues.

Pain that has no obvious inflammatory component is also sensitive to NSAIDs. It is unlikely that peripheral inhibition of COX has a role in this type of analgesic activity and there is debate as to whether inhibition of COX at any site is relevant. However, there may be a role for prostanoids in pain transmission in the spinal cord.

Non-selective COX inhibitors

There are at least 50 different NSAIDs or related drugs marketed for their analgesic, antipyretic and anti-inflammatory activity, all have significant adverse effects (Figure 2).

Adverse effects of non-steroidal anti-inflammatory drugs (NSAIDs)

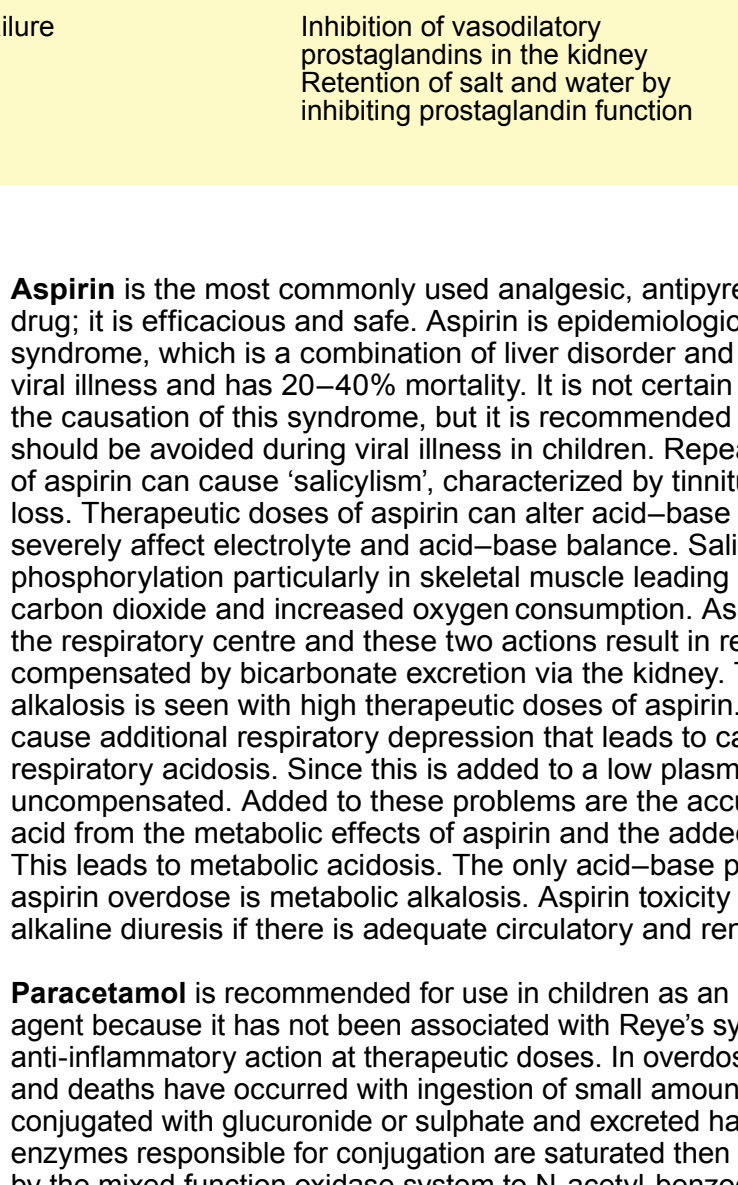
Adverse effects	Proposed mechanism	Comments
Gastrointestinal intolerance and ulceration	Inhibition of cytoprotective PGI_2 and PGE_2 in the gastric mucosa	Less of a problem with p-aminophenol derivatives (e.g. paracetamol)
Hypersensitivity reactions	Diversion of arachidonic acid synthesis down the leukotriene pathway	Relatively rare; more common with acetylated salicylates
Reduced platelet aggregation	Blockade of thromboxane formation	Particular problem with aspirin, a non-reversible inhibitor of COX Can be useful in thromboembolic disorders
Inhibition of uterine motility (delayed parturition)	Inhibition of PGE and F series which stimulate the uterus before birth	May be useful for inhibition of preterm labour
Renal failure	Inhibition of vasodilatory prostaglandins in the kidney Retention of salt and water by inhibiting prostaglandin function	Mainly a problem in patients with congestive heart failure, hepatic sclerosis or chronic renal disease Analgesic nephropathy with chronic NSAID consumption

2

Aspirin is the most commonly used analgesic, antipyretic and anti-inflammatory drug; it is efficacious and safe. Aspirin is epidemiologically linked to Reye's syndrome, which is a combination of liver disorder and encephalopathy following a viral illness and has 20–40% mortality. It is not certain that aspirin is implicated in the causation of this syndrome, but it is recommended that aspirin administration should be avoided during viral illness in children. Repeat ingestion of high doses of aspirin can cause 'salicylism', characterized by tinnitus, vertigo and hearing loss. Therapeutic doses of aspirin can alter acid–base balance, and toxic doses severely affect electrolyte and acid–base balance. Salicylates uncouple oxidative phosphorylation particularly in skeletal muscle leading to an increased production of carbon dioxide and increased oxygen consumption. Aspirin also directly stimulates the respiratory centre and these two actions result in respiratory alkalosis that is compensated by bicarbonate excretion via the kidney. This compensated respiratory alkalosis is seen with high therapeutic doses of aspirin. Toxic doses of aspirin cause additional respiratory depression that leads to carbon dioxide retention and respiratory acidosis. Since this is added to a low plasma bicarbonate it will be uncompensated. Added to these problems are the accumulation of pyruvic and lactic acid from the metabolic effects of aspirin and the added acid from the drug itself. This leads to metabolic acidosis. The only acid–base problem not associated with aspirin overdose is metabolic alkalosis. Aspirin toxicity can be treated with forced alkaline diuresis if there is adequate circulatory and renal function.

Paracetamol is recommended for use in children as an analgesic and antipyretic agent because it has not been associated with Reye's syndrome although it has little anti-inflammatory action at therapeutic doses. In overdose, paracetamol is hepatotoxic and deaths have occurred with ingestion of small amounts. Normally paracetamol is conjugated with glucuronide or sulphate and excreted harmlessly (Figure 3). If the enzymes responsible for conjugation are saturated then paracetamol is metabolized by the mixed function oxidase system to N-acetyl-benzoquinoneimine. This toxic metabolite is conjugated with glutathione. If glutathione is depleted then the toxic metabolite accumulates and binds with cell macromolecules to cause cell death. Liver and kidney cells are the usual targets for this effect and signs of liver or renal toxicity occur 24–48 hours after ingestion of the drug. Early treatment of paracetamol overdose with N-acetylcysteine (within 12 hours) to complex with the reactive metabolite of paracetamol can save life. Both paracetamol and aspirin are commonly available as combination analgesics with weak opioid agonists.

Metabolism of paracetamol



3

Ibuprofen and naproxen are both propionic acid derivatives. Naproxen has greater efficacy and, consequently, more adverse effects than ibuprofen, but its longer half-life makes twice daily administration feasible.

Other NSAIDs are listed in Figure 4 with their clinically relevant differences. Phenylbutazone can cause agranulocytosis and is seldom used. Indomethacin is still used for inflammatory conditions, especially ankylosing spondylitis and osteoarthritis, although gastrointestinal disturbances and CNS effects (e.g. confusion, headache) reduce its usefulness.

Characteristics of the most important non-steroidal anti-inflammatory drugs (NSAIDs)

Drug	Elimination half-life (hours)	Comments
Aspirin (acetylsalicylic acid)	Varies with dose (4 hours with low doses) Saturation kinetics above 4 g/day	Relatively selective for COX-1 (> 100-fold). Inhibits platelet aggregation in low doses
Diclofenac	1–2	Gastrointestinal bleeding and ulceration. Elevation of hepatic aminotransferases. Equally effective on both COX enzymes
Etodolac	7	May have some COX-2 selectivity. Fewer gastrointestinal problems
Ibuprofen	2	Reversible inhibitor of COX. Selectivity for COX-1 (15-fold)
Ketorolac	4–6	Somnolence and headache. Superior to aspirin for chronic pain states. Topically useful for eye inflammation
Mefenamic acid	2–4	Gastrointestinal discomfort, inflammation of the bowel. Haemolytic anaemia. No advantages over other NSAIDs
Meloxicam	Variable (about 50 hours)	May have some COX-2 selectivity. Fewer gastrointestinal problems
Nabumetone	3	Some gastrointestinal irritation. Useful for patients with allergic hypersensitivity to NSAIDs. Equally effective on both COX enzymes
Naproxen	14	More efficacious than ibuprofen, but more adverse gastrointestinal effects. Equally effective on both COX enzymes
Oxaprozin	40–60	Similar to ibuprofen. Long half-life allowing once daily dosage
Paracetamol	2–4	Not anti-inflammatory at therapeutic doses. Hepatotoxicity can occur with single doses of 10–15 g. COX-1 selectivity 7.5-fold
Piroxicam	Variable (about 50 hours)	Gastrointestinal disturbances. Reduces renal clearance of lithium. More than 100-fold selective for COX-1

Selective COX inhibitors

Two premises have led to the development of COX-2 selective drugs. Firstly, that inhibition of COX-1 is responsible for the undesirable actions of NSAIDs such as gastric irritation and renal injury. Secondly, that COX-2 inhibitors retain the anti-inflammatory, analgesic and antipyretic actions of the NSAIDs. Some existing NSAIDs (e.g. meloxicam, etodolac, nimesulide) have selectivity for COX-2. Meloxicam has fewer gastrointestinal side-effects than comparator NSAIDs but the equivalence of dose has been questioned. These compounds lose their selectivity for COX-2 at higher doses. Epidemiological studies of ulcer complications indicate that nimesulide offers no advantages with respect to the non-selective COX inhibitors.

Two highly selective COX-2 inhibitors (celecoxib, rofecoxib) have recently been introduced. Both caused significantly less gastric mucosal injury than non-selective NSAIDs in patients without gastrointestinal pathology. However, some caution has been expressed over these findings. Chronic treatment with selective COX-2 inhibitors in patients with pre-existing gastrointestinal injury or inflammation may show a significant increase in damage. COX-2 appears to have an important role in promoting the healing of ulcers.

Celecoxib and rofecoxib are analgesic, antipyretic and anti-inflammatory, but whether they will be as effective as non-selective agents in all inflammatory condition awaits the outcome of long-term clinical trials. The elimination half-life of celecoxib is 8–10 hours (longer for rofecoxib) such that once a day dosage is recommended. Celecoxib is an inhibitor of the P450 (CYP2D6) isoenzyme, therefore plasma concentrations of other drugs (antidepressants, antipsychotic, antiarrhythmic drugs) that are a substrate for this enzyme may be increased. Celecoxib is teratogenic in several animals and is therefore contraindicated in pregnancy. In one trial of postoperative dental pain, rofecoxib, in the dose used, was found to be superior to celecoxib and equivalent to ibuprofen.

Drugs used to treat arthritis

Osteoarthritis

Pain that worsens on movement, is the most common presenting feature of osteoarthritis. In uncomplicated disease, paracetamol is acceptable as first-line pain therapy because osteoarthritis has only a minor inflammatory component. NSAIDs are also prescribed for osteoarthritis, but gastrointestinal side-effects limit their usefulness. New developments concerned with COX-2 selective NSAIDs may be beneficial (see above), but await further study.

Cartilage destruction is one of the major processes of osteoarthritis progression. NSAIDs and other drugs have different effects on cartilage metabolism. Paracetamol and the NSAIDs treat the symptom of pain and not the disease itself. Indeed NSAIDs have been implicated in the more rapid progression of osteoarthritis. Simplistically relieving pain may lead to increased usage and further damage, but there are complex links between prostanoids and metaloprotinases that cause cartilage breakdown. Some specific chondroprotective agents (e.g. chondroitin, glucosamine, hyaluronic acid) have been examined in the hope of delaying or reversing the progress of the disease. Adequate long-term trials are required before their place in therapy can be defined.

Rheumatoid arthritis

Rheumatoid arthritis is an autoimmune disease in which the immune system invades the synovial cells and destroys cartilage in the joint. The pain of rheumatoid arthritis tends to be worse when rested. It is an inflammatory disease therefore NSAIDs used to be the mainstay of therapy, but they did not retard the development of the disease and, because high doses are needed to obtain an anti-inflammatory effect, patients suffered from gastrointestinal side-effects. Recently, the use of disease-modifying anti-rheumatic drugs (DMARDs) has been recommended at an early stage of the disease. If given early, DMARDs can stabilize the joint function at a near-normal stage rather than when it has become disabled. None of the drugs included in this group (Figure 5) are analgesic in any classical sense.

Tumour necrosis factor (TNF) has a central role in the pathological inflammatory response associated with rheumatoid arthritis and two approaches have been tried to decrease TNF activity. Etanercept contains soluble TNF receptors and has been shown to have beneficial effects, including pain reduction, in patients with rheumatoid arthritis, both as monotherapy and as an adjuvant to methotrexate. Similar studies with infliximab, a preparation of anti-TNF-α antibodies, have been reported.

Disease-modifying anti-rheumatic drugs (DMARDs) and their use in rheumatoid arthritis

	Mechanism	Unwanted effects	Comment
Azathioprine	Immunosuppressant Interferes with purine synthesis and inhibits lymphocyte proliferation	Bone marrow suppression Nausea, vomiting and diarrhoea are common. Skin eruptions	Reserved for patients with disease that is refractory to other DMARDs
Chloroquine and hydroxychloroquine	Suppresses lysosomal enzymes and inhibits interleukin-1 release but many reports are contradictory	Irreversible retinopathy with high doses. Gastrointestinal intolerance	Less effective than other DMARDs. Used only for mild disease or when other DMARDs are too risky
Cyclophosphamide	Immunosuppressant Decreases T and B lymphocytes	Bone marrow depression. Infertility. Infection risk	Only used (unlicensed) for patients with life-threatening complications of rheumatoid arthritis
Cyclosporin	Immunosuppressant Suppresses the synthesis and release of interleukin-1 and interleukin-2	Dose-related hypertension and nephrotoxicity	Used when other treatments have failed
Gold	Unknown. May affect B and T lymphocyte function	Wide-ranging toxicity Eczema and mouth ulcers common. Diarrhoea with auranofin	Oral gold (auranofin) is less toxic than parenteral gold but probably less efficacious
Leflunomide	Pro-drug. Inhibits pyrimidine pathway. Reduced B and T cell proliferation	Teratogenic. Abdominal pain	New class of drug, still under development
Methotrexate	Immunosuppressant Changes the balance between pro-inflammatory and anti-inflammatory cytokines	Nausea and stomatitis common Haematological toxicity rare with low doses (which are used in rheumatoid arthritis)	Most effective DMARD currently available. Relatively fast onset of action (1 month)
Penicillamine	Not certain; chelates divalent cations. Impairs antigen presentation	Nausea, rashes, leucopenia and thrombocytopenia. Bone marrow aplasia	Clinical use is declining due to toxicity
Sulfasalazine (sulphasalazine)	Unknown; combines an anti-inflammatory with antibacterial molecules	Low rate of serious adverse effects (leucopenia and thrombocytopenia) Gastrointestinal intolerance common	Better tolerated than gold. Formerly the first-line therapy in the UK. Onset between 6 and 12 weeks

Anti-migraine drugs

Migraine is a common, notoriously under-treated, neurological condition characterized by intense unilateral headache, nausea and vomiting. The diagnostic criteria for migraine adapted from the International Headache Society are given in Figure 6.

The pathological changes associated with migraine are uncertain. The suggestion that the aura is caused by vasoconstriction and the headache by vasodilatation is too simplistic. The headache appears to involve the activation of the trigemino-vascular system resulting in a neurogenic inflammatory response characterized by dural vasodilatation and plasma extravasation, resulting in pain. Migraine is thought to occur when inappropriate antidromic activation of the trigeminal nerve releases neuropeptide transmitters such as substance P and calcitonin gene-related peptide into the blood vessel wall. These peptides cause vasodilatation and oedema leading to sensitization of the trigeminal nerve causing pain and reflex activation of the facial nerve, which leads to extracranial vasodilatation and release of vasoactive intestinal peptide, all of which contribute to the migraine syndrome.

Diagnostic criteria for migraine

One or more focal neurological dysfunction signs make up the aura that may last up to 1 hour; the signs may be visual, motor or autonomic

- Some migraine attacks do not proceed beyond the aura and not all migraine attacks are preceded by an aura
- Untreated attacks last 4–72 hours

The headache has two of the four characteristics

- unilateral
- pulsating
- severe enough to disturb activities
- aggravated by movement

Associated symptoms (at least one present)

- nausea or vomiting
- intolerance of light
- intolerance of noise

Until the early 1990s, NSAIDs, paracetamol (discussed above), or ergot alkaloids supplemented with anti-emetics (e.g. metoclopramide) were used to treat migraine. Metoclopramide enhances the absorption of the analgesic by stimulating gastric motility. Combination analgesics were used in more severe cases. Ergot alkaloids were found to be effective anti-migraine drugs in the 1920s. The vasoconstrictor agent ergotamine was most commonly used. However, the ergot alkaloids are very non-selective pharmacological agents interacting with most of the receptors so far described for 5-HT, noradrenaline and dopamine. Following the hypothesis that 5-HT was crucially involved in migraine, more selective drugs were synthesized, resulting in sumatriptan, which had selectivity as an agonist at the 5-HT_1 family of receptors, and a particular affinity for the 5-$HT_{1B/1D}$ receptor. Sumatriptan is effective for the acute treatment of migraine and tends to reduce the nausea and vomiting as well as the headache. However, its oral bioavailability is low and the drug has a short half-life of 2 hours. The drug may cause constriction of the coronary blood vessels and is contraindicated in patients with pre-existing coronary artery disease.

Recently introduced triptans include zolmitriptan, naratriptan and rizatriptan, which have better oral bioavailability and longer half-lives. Although sumatriptan is often considered to be a selective 5-$HT_{1B/1D}$ receptor agonist, it and many other drugs in this group have affinity for 5-HT_{1F} receptors. Agonist drugs selective for 5-HT_{1F} receptors, such as LY-334370, prevent the dural plasma protein extravasation that is seen in migraine. This compound lacks the vasoconstrictor action of 5-$HT_{1B/1D}$ receptor agonists, and thus should be free of this adverse effect if current clinical trials show it to be effective in migraine.

Prophylactic treatment for migraine is recommended for patients who have three or more severe attacks per month. Figure 7 summarizes the drugs that have been found to be effective, though only 60–70% of patients benefit. The exact mechanism of the anti-migraine effects of these drugs is unknown and may be independent of their main therapeutic or pharmacological classification.

Prophylactic treatment for migraine

Drug group	Action in migraine prophylaxis	Efficacy	Unwanted effects
α_2-adrenoceptor agonists (e.g. clonidine)	?	Doubtful	Sedation
β-adrenergic antagonists (e.g. atenolol, propranolol, timolol)	Not related to β-adrenoceptor antagonism. Some β-blockers are inactive	50–70% patients obtain more than 50% reduction in attacks	Contraindicated in asthma
5-HT receptor antagonists (e.g. methysergide, cyproheptadine, pizotifen)	Could be 5-HT antagonism, but many other receptors affected	60–80% patients obtain more than 50% reduction in attacks. Useful for cluster headaches	Nausea, vomiting. Retroperitoneal fibrosis with methysergide on long-term therapy
Monoamine oxidase inhibitors (e.g. phenelzine, isocarboxazide)	Ability to increase endogenous 5-HT?		Orthostatic hypotension, insomnia and nausea
Tricyclic antidepressants (e.g. amitriptyline, nortriptyline)	Not correlated with antidepressant activity. Blockade of 5-HT transporter?	Particularly useful for mixed (migraine plus tension) headaches	Cardiac arrhythmias
Calcium channel blockers (e.g. flunarizine, diltiazem)	?	Effectiveness questioned by recent studies	Frequent constipation, orthostatic hypotension

Non Steroidal Anti-Inflammatory Drugs

Michael J Dascombe

Michael J Dascombe is Senior Lecturer in Pharmacology at the University of Manchester. He qualified in pharmacy at London University, then conducted research in pharmacology at London University and Aberdeen University for MRC PhD and Postdoctoral Scholarships. His research interests include the pharmacology of the brain and immune system during responses to infectious and inflammatory diseases.

Living tissues respond to noxious insults with a cascade of energy-consuming reactions evolved to limit damage. Inflammatory disease results from the inappropriate manifestation of this defence reaction; major symptoms are vasodilatation, erythema, raised temperature, pain, oedema and loss of normal function.

The characteristics of the inflammatory response that indicate involvement of endogenous chemical mediators are: similar syndrome, latency to onset, reversible nature and suppression by chemical antagonists.

Major classes of endogenous chemicals mediating acute inflammation include:
- fatty acid oxidation products (e.g. prostaglandins (PGs))
- kinins (e.g. bradykinin)
- lysosomal enzymes (e.g. neutral proteases)
- oxygen-derived products (e.g. superoxide radicals)
- pro-inflammatory cytokines (e.g. interleukin 1)
- vasoactive amines (e.g. histamine).

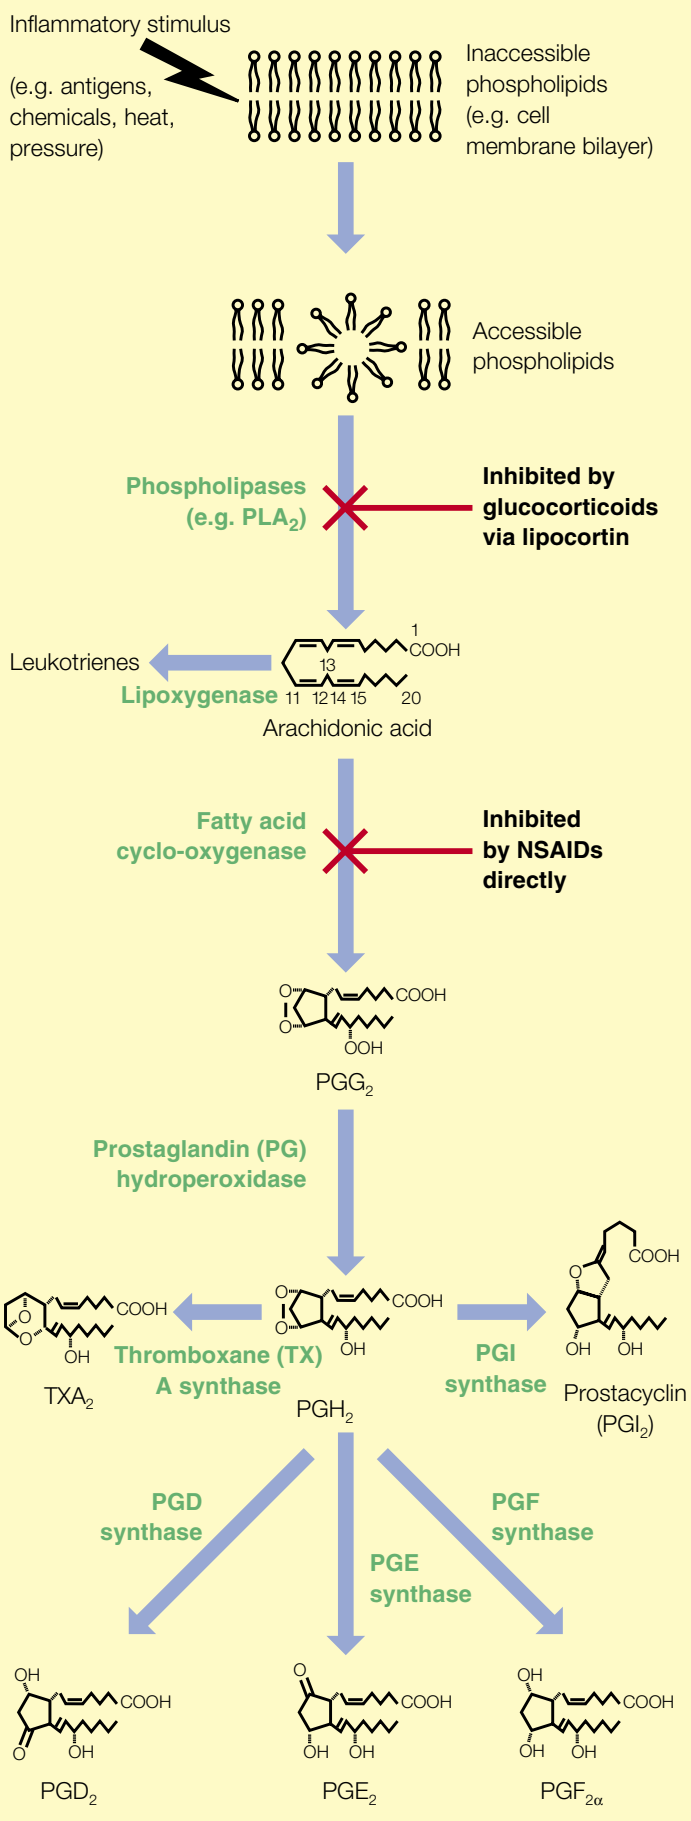
Drugs inhibiting the biological activities of these mediators alleviate the symptoms of inflammation; therefore there are several different pharmacological groups of anti-inflammatory drugs. This article describes the non-steroidal anti-inflammatory drugs (NSAIDs), the group most widely used.

Nature of NSAIDs
Numerous NSAIDs are available from several chemical classes. Many are weak organic acids, which partly determines their absorption, distribution, excretion and toxicity. Their pharmacological effects and mechanisms of action are also similar. Despite these similarities, the anti-inflammatory and adverse effects of selected NSAIDs vary between patients; choice should be determined by individual patient tolerance.

Aspirin (acetylsalicylic acid), a prodrug producing salicylic acid on hydrolysis, is used as a typical or 'type' compound to describe the pharmacology of salicylic acid derivatives (salicylates) in particular and NSAIDs, including non-salicylates (e.g. ibuprofen, naproxen, meloxicam) in general. This practice is based on the extensive knowledge acquired from the long and widespread use of salicylates, initially as plant extracts (e.g. *Salix*, *Spirea*) and since 1899 as the synthetic drug aspirin, though there are differences between aspirin as 'type' compound and other NSAIDs (see below).

Over the last 10 years, the role in which aspirin serves as a reference for other NSAIDs has altered from one of typical drug to one of comparison. This change followed the discovery of two isoforms of cyclo-oxygenase (COX), the enzyme activity inhibited by NSAIDs (Figure 1), and the development of drugs more selective for COX-2 than for COX-1.

Formation of biologically active oxygenated products of arachidonic acid via cyclo-oxygenase



1

Mechanism of action
Microsomal enzymes metabolize free (unesterified) 20-carbon, unsaturated (eicosanoic) fatty acids to a range of oxygenated products, eicosanoids (Figure 1). The rate-limiting step in this pathway is the availability of free fatty acids. During inflammation, phospholipase activity is enhanced and the release of free fatty acids increased from previously unavailable phospholipid stores. COX activity forms hydroperoxidated (15-OOH) fatty acid endoperoxides (e.g. PGG_2 from arachidonic acid, the most abundant fatty acid in man). The 15-OOH endoperoxides are chemically unstable and are converted, under the influence of hydroperoxidase then synthase activity, to progressively more stable products, which include prosta-glandins mediating inflammation, hyperalgesia and pyrexia. The established therapeutic uses of NSAIDs are attributable to their ability to inhibit COX activity, thereby reducing endogenous concentrations of biologically active eicosanoids (e.g. PGE_2, thromboxane A_2 (TXA_2)).

The enzyme prostaglandin endoperoxide synthase possesses both COX and hydroperoxidase activities. Two isoforms have been identified as different gene products with distinct cellular locations and COX activities:
- COX-1 constitutively expressed in a wide variety of cells
- COX-2 induced by inflammatory stimuli and growth factors.

The isoforms are similar in structure and enzymatic activity: both are homodimeric, glycosylated membrane proteins with a highly conserved catalytic domain with the NSAID binding site in a narrow hydrophobic channel. Classical NSAIDs (aspirin, ibuprofen, naproxen) are not selective and inhibit both COX-1 and COX-2 activities. NSAIDs bind reversibly, with the exception of aspirin, which covalently acetylates serine in position 530. NSAIDs inhibit COX activity by preventing abstraction of hydrogen from arachidonic acid carbon atom 13, thereby blocking peroxidation at carbon atoms 11 and 15. Hydroperoxidase activity appears unaffected.

Substitution of valine in COX-1 by isoleucine in COX-2 at positions 434 and 523 increases the size and changes the shape of the NSAID binding site channel in COX-2. These differences have been exploited in the development of highly selective COX-2 inhibitors (e.g. celecoxib, rofecoxib).

Therapeutic effects
The commonly sought therapeutic effects of NSAIDs are:
- symptomatic relief from inflammation in musculoskeletal disorders
- analgesia, particularly when associated with inflammation
- antipyresis.

All can be attributed to inhibition of prostaglandin production. Prostaglandins of the E family (PGEs) are important mediators of inflammation, hyperalgesia and pyrexia. Lowering concentrations of prostaglandins with NSAIDs results in reduced:
- vasodilatation, vascular permeability, chemotaxis and oedema (giving relief from inflammation)
- sensitization of nociceptors and hyperalgesia (analgesia)
- disruption to central neurons regulating core temperature (antipyresis).

In addition to the typical actions of NSAIDs listed above, aspirin also inhibits thrombus formation and helps prevent cardiothrombotic disease (e.g. ischaemic stroke, myocardial infarction). Although aspirin is hydrolysed rapidly in the body to salicylic acid, it does appear briefly in the presystemic circulation and irreversibly inhibits COX-1 in platelets. The major platelet product lost is TXA_2, a potent platelet aggregator and vasoconstrictor. Platelets are not nucleated and are unable to express new enzyme. The balance of COX products regulating cardiovascular events shifts towards the major prostaglandin from nucleated vascular endothelial cells, prostacyclin (PGI_2) an anti-aggregation agent and vasodilator.

Other applications for NSAIDs are being researched, including prevention of diabetic cataracts and treatment of multi-infarct dementia, Alzheimer's disease and gastrointestinal cancers. At present, these are unlicensed indications.

Adverse effects
Some of the adverse effects of NSAID therapy are shown in Figure 2; the list is not exhaustive and does not include therapeutic overdose toxicity. Preparations containing aspirin should not be given to children because of an association with Reye's syndrome. Loss of prostaglandins acting as autacoids (e.g. maintaining local blood flow) is often a contributory factor to the adverse effects of NSAIDs, but the overall causes are usually complex. Reduced metabolism of free fatty acids by COX may result in increased formation of inflammatory, bronchoconstrictor leukotrienes via the lipoxygenase pathway (Figure 1). Physiochemical properties of acidic NSAIDs can contribute directly to cell damage.

Some adverse effects of NSAID therapy

System	Adverse effect	Putative mechanisms
Gastrointestinal	Discomfort	Chemical irritancy
	Nausea	Back diffusion of gastric acid
	Diarrhoea	Loss of homeostatic prostaglandins
	Ulceration	Ischaemia
	Bleeding	Gastric barrier breakdown
Renal	Fluid retention	Loss of homeostatic prostaglandins
	Sodium retention	
	Renal failure	
Cardiovascular	Exacerbation of hypertension	Secondary to renal disturbances
	Exacerbation of congestive heart failure	
Pulmonary	Exacerbation of asthma	Loss of homeostatic prostaglandins Increase in leukotriene production
Blood	Haemorrhage	Decreased prothrombin Decreased thromboxane A_2

Early appreciation that the adverse effects of aspirin can be attributed to loss of prostaglandins with autacoid or homeostatic function has led to a search for NSAIDs selectively inhibiting inflammatory prostaglandins. Discovery of isoforms of COX has resulted in the development of highly selective COX-2 (*versus* COX-1) inhibitors as NSAIDs with a lower risk of gastrointestinal damage (e.g. celecoxib, rofecoxib). This advantage is reduced if patients take low-dose aspirin as a relatively selective COX-1 inhibitor for the prevention of cardiothrombotic disease; celecoxib and rofecoxib do not protect against ischaemic cardiovascular events.

Therapeutic use of highly selective COX-2 inhibitors is associated with changes in renal function (e.g. sodium retention, oedema and increases in blood pressure) indicating that renal COX-2 is constitutive and its products physiologically desirable. In the stomach, COX-2 products are implicated in adaptive cytoprotection and ulcer repair. Consequently, drugs like rofecoxib can exacerbate severe congestive heart failure and impair gastric ulcer healing. ◆

Opioid Mechanisms and Opioid Drugs

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

The analgesic property of opium was described 6,000 years ago by the Sumerians who lived in the south of Mesopotamia. However, it was only in the 1950s that an understanding of how it might work began to emerge. Observations of structure–activity relations between morphine and the natural or synthetic compounds that shared its analgesic action suggested the existence of opioid receptors. Morphine, one of the active compounds extracted from opium, is an agonist at opioid receptors and the discovery of the opioid antagonist naloxone gave scientists an important tool to uncover the natural role of opioid receptors in the body. Morphine and related opioid analgesics possess a number of properties other than analgesia (Figure 1) and morphine analogues are available that have selectivity for a few of these properties (e.g. dextromethorphan is a selective cough suppressant). This suggested to researchers that there might be more than one opioid receptor.

It has now been established by cloning and protein sequencing that there are three separate opioid receptors μ, δ and κ. All three receptors are members of the G-protein-coupled superfamily of receptors. In 1997, the International Union of Pharmacology (IUPHAR) reclassified opioid receptors as OP_1 (δ), OP_2 (κ) and OP_3 (μ) corresponding to the cloned receptors. Each receptor has a different distribution throughout the CNS. Some regions, such as the dorsal horn of the spinal cord, express μ, δ and κ receptors while others, such as the thalamic nuclei, express the μ receptor only. Three families of endogenous ligands for these receptors have been described, the enkephalins, the dynorphins and the endorphins. The characteristics of the opioid peptides are summarized in Figure 2. The enkephalins are pentapeptides (Figure 3) while the dynorphins and the endorphins contain a longer sequence of amino acids. Each family of opioid peptides is derived from its own precursor though dynorphins all have a leu-enkephalin sequence and endorphins have a met-enkephalin sequence at the proximal end of the molecule.

While only three opioid receptors have been cloned at the time of writing, this is not proof that subtypes of these receptors do not exist. There is evidence of subtypes of all three receptors, which may represent alternative splicing of the opioid receptor clones.

Earlier studies suggested an σ opioid receptor that mediated the psychotomimetic effects of some opioid analgesics (e.g. pentazocine). Cloning studies have confirmed the existence of this receptor but it is not now considered to be opioid in nature, because naloxone is an inconsistent antagonist. Nevertheless, some opioid drugs bind to σ receptors as does phencyclidine and its analogue ketamine.

Some pharmacological actions of opioid drugs

Analgesia
- Main use although less effective in neuropathic pain syndromes
- May be useful to prevent breathing attempts in ventilated patients

Constipation
- Site of action both CNS and peripheral. A troublesome side-effect when analgesic activity is required, however, useful for the treatment of diarrhoea
- Poorly absorbed opioids (diphenoxylate and loperamide) exert a local effect preventing fluid accumulation in the intestine; loperamide is so little absorbed that it can be sold over the counter

Emesis
- Undesirable in all instances
- Site of action chemosensitive trigger zone in the area postrema on the floor of the fourth ventricle
- Not separable from analgesic activity with current drugs
- N.B. Opioids also depress the vomiting centre

Euphoria
- Abuse potential
- Mediated by μ receptors

Tolerance and dependence
- Can be detected within 12–24 hours
- Tolerance occurs most readily to analgesia, respiratory depression, emesis and euphoria and less readily to constipation

Cough suppression
- Heroin, codeine and pholcodine are used as cough suppressants
- Dextromethorphan has selectivity for this action

Miosis
- Little tolerance to this effect so may be seen in addicts; caused by stimulation of the oculomotor nerve nucleus

Antidiuretic effect
- N.B. κ agonists have a diuretic action

Sedation
- Usefulness depends on the circumstances

3

Opioid mechanisms in pain pathways

Figure 4 shows the areas of the pain pathway where the endogenous opioid receptors are found. Opioid receptors are found at the level of the nociceptors. Opioid drugs acting at peripheral opioid receptors on sensory nerves can relieve inflammatory pain. μ, κ and δ receptors all appear to be present at this site.

Acting through an inhibitory G-protein, μ receptor activation inhibits adenylyl cyclase activity, thus preventing nociceptor sensitization by inflammatory mediators such as prostaglandin E_2 that involves the activation of adenylyl cyclase. Agonists at κ and δ receptors do not share this mechanism of activity, instead they are able to prevent bradykinin-induced release of noxious mediators from sympathetic nerves. These findings have led to the use of peripheral application of opioid drugs to treat inflammatory pain.

Most of the opioid receptors in the dorsal horn of the spinal cord are μ receptors though δ and κ receptors are present. At this site, both μ and δ agonists inhibit pain transmission though the role of κ receptor activation in pain control is more controversial. At the neuronal level, μ and δ opioid receptor activation causes a decrease in adenylyl cyclase activity, which in turn opens potassium channels (hyperpolarization) and closes calcium channels. Both these actions result in decreased release of a pain neurotransmitter, probably glutamate and/or substance P.

High concentrations of opioid receptors are found in the periaqueductal grey, nucleus raphe magnus and nucleus reticularis gigantocellularis and systemic morphine induces analgesia at these sites. The limbic system also contains opioid receptors and drugs acting at this point are believed to reduce the affective component of pain.

Opioid receptors are found at other sites (e.g. thalamus, cortex), which may be relevant to nociceptive control. However, concentration in other areas such as the tractus solitarius is more likely to be related to respiratory effects.

The opioid antagonist naloxone does not affect pain threshold or produce any other effects in a normal individual, indicating that opioid systems are not tonically active. However, it does prevent stress-induced analgesia and can make an existing pain condition worse. Naloxone has been useful to treat thalamic pain syndromes, but this is thought to be due to an effect on local blood flow rather than an analgesic action.

Site of endogenous opioid receptors

4

Analgesic opioid drugs

Agonists at m opioid receptors

Most of the analgesia produced by clinically useful analgesics is mediated via the μ opioid receptor as are most of the side-effects. Thus, the development of drugs having greater μ selectivity than morphine (e.g. sufentanil) has not resulted in large reductions in adverse effects. Nevertheless, the μ opioid analgesics now available have useful differences in pharmacokinetic properties that have had a significant beneficial effect on patient comfort and safety. Some of the more important μ opioid agonist analgesics are compared in Figure 5.

μ agonist analgesics

	Elimination half-life (hours)	Metabolites	Comments
Alfentanil	1.5–3.5	None active	Short duration of action of single doses but multicompartment distribution means this advantage is lost when given as an infusion
Fentanyl	1.5–5.5	None active	High potency and lipid solubility allow for transdermal administration. Also possesses local anaesthetic activity which may contribute to analgesia when used via the intrathecal or epidural route
Methadone	9–87	Active metabolite, but not clinically important	Firmly bound to proteins in tissues. Slow release results in mild but protracted withdrawal syndrome
Morphine	2–3	Morphine-6-glucuronide contributes significantly to analgesia in chronic use	Morphine-6-glucuronide contributes significantly to analgesia in chronic use. Poorly absorbed orally. Incidence of vomiting probably greater than other opioids
Oxycodone	2–3	None active	Can be given orally alone or in combination with non-steroidal anti-inflammatory drugs (NSAIDs). May be given as pectinate to provide sustained release (suppository)
Pethidine (meperidine)	3–5	Norpethidine (stimulatory effects)	Anticholinergic effects. Local anaesthetic activity Excitement or convulsions more common Interaction with monoamine oxidase inhibitors
Remifentanil	0.16–0.35	None active	Rapid metabolism allows intravenous infusions for total intravenous anaesthesia, but analgesia ceases on termination of infusion
Sufentanil	2.5–3.5	Not reported in humans	High potency and lipid solubility allow for transdermal administration

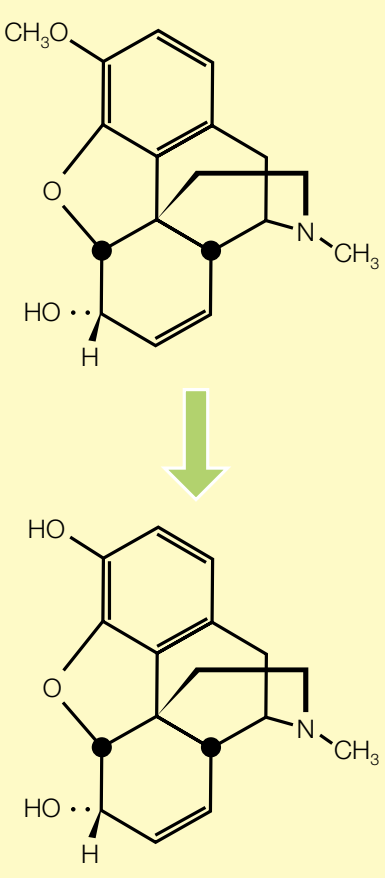
5

Weak and partial agonists at m opioid receptors

Codeine, dihydrocodeine and dextropropoxyphene have a maximum analgesic action below that of morphine. They are often called weak agonists, because there are no data indicating whether or not they are true partial agonists at μ opioid receptors. They cause less tolerance and dependence than the drugs in Figure 1. Codeine (Figure 6) and possibly dihydrocodeine are pro-drugs that are metabolized to morphine, which accounts for most of their pharmacological effects. Dextropropoxyphene is metabolized to norpropoxyphene, which may contribute to toxicity with repeated doses. It has been suggested that combinations of either codeine or dextropropoxyphene with aspirin produce a higher degree of analgesia than either drug given alone.

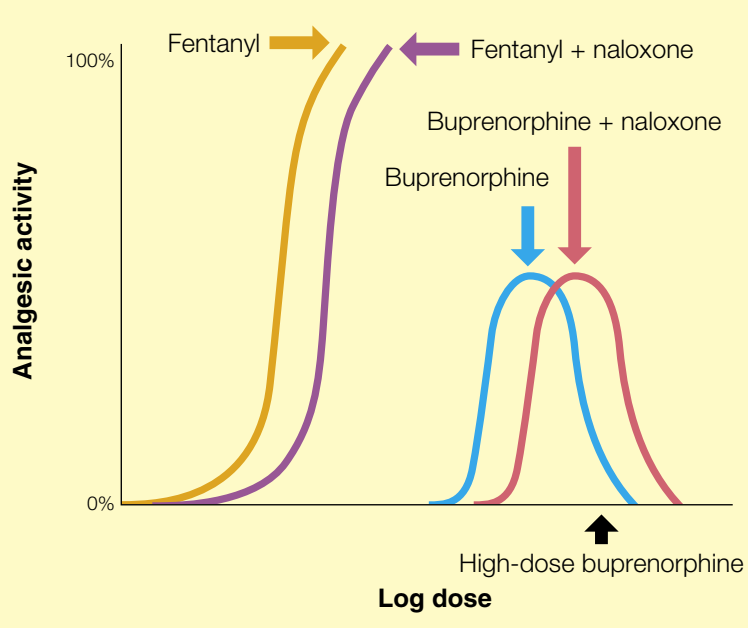
Buprenorphine is a true partial agonist at μ opioid receptors. Its oral bioavailability is poor and it is usually administered sublingually or by intramuscular injection. Buprenorphine has significant respiratory depressant activity. Once administered, reversal by naloxone is uncertain because of the slow dissociation of the drug from the opioid receptor. It has been suggested that naloxone may increase the agonist activity of a high dose of buprenorphine. The mechanism of this effect has been ascribed to the bell-shaped dose–response relationship proposed for the analgesic action of buprenorphine (Figure 7).

Codeine metabolized to morphine



6

Effect of naloxone on the log dose-response relationships to fentanyl and buprenorphine



7

Drugs acting at both k and μ opioid receptors

Pentazocine, nalbuphine and butorphanol were originally thought to be κ opioid receptor agonists and μ opioid receptor antagonists. However, they all produce respiratory depression, a property not associated with full κ agonists at least in experimental animals. It is now believed that they are probably partial agonists at both receptor types though the degree of agonist activity varies from drug to drug. Which receptor is involved in their analgesic activity is unclear. All three drugs have elimination half-times of about 3 hours. Pentazocine, like its predecessor nalorphine, produces more intense dysphoria and psychotomimetic effects than nalbuphine and butorphanol. Only the l-isomer of the racemate pentazocine combines with opioid receptors, the d-isomer having particular affinity for the σ, non-opioid, receptor. In addition, nalbuphine and butorphanol are not associated with cardiovascular stimulation. Nalbuphine is a more effective μ receptor antagonist than pentazocine and exhibits a well-documented ceiling effect on respiratory depression. Butorphanol has marked sedative actions. The abuse liability of these drugs is significantly less than that of morphine.

Meptazinol and tramadol

Meptazinol (elimination half-life about 2 hours) combines partial agonist activity at μ opioid receptors with activation of muscarinic cholinoceptors. In animals its analgesic action is sensitive to both naloxone and muscarinic antagonists. Meptazinol is rapidly metabolized in the neonate and was recommended for used in labour. Meptazinol is dysphoric in high doses and induces vomiting in a high proportion of patients, which is not surprising in view of its cholinomimetic properties. Both these effects have resulted in a marked decline in its use. It was originally claimed that meptazinol had selectivity for the μ_1 subgroup of receptors and this resulted in a lack of respiratory depressant activity (assuming this to be the property of μ_2 receptors). However, not all experts believe in this receptor subdivision and the cholinomimetic actions of the drug tend to reduce any opioid-induced respiratory depression.

Tramadol is a weak μ agonist with even weaker activity at κ and δ subtypes of opioid receptor. It inhibits the neuronal reuptake and promotes the release of both noradrenaline and 5-hydroxytryptamine. It has been used for over 20 years in Germany, but has been available in the UK only since 1994 and in the USA since 1995. It appears to produce minimal tolerance and dependence and relatively little respiratory depression. Tramadol is not useful in severe pain and the chief adverse effects are nausea and dizziness. Like other monoamine reuptake inhibitors, tramadol may lower seizure threshold. Its elimination half-life is about 6 hours.

Analgesic usefulness of selective opioid receptor agonists

A number of selective κ agonists have been tested as potential analgesics. Enadoline is a selective κ-opioid agonist that produces analgesia but lacks typical opioid side-effects such as constipation, respiratory depression, vomiting and dependence. Enadoline has been used for postsurgical pain in clinical studies but has given conflicting results. Enadoline, 25 mg, had no useful effect after dental surgery, but was equivalent to morphine, 10 mg, after abdominal or pelvic surgery. The reasons for these differences in effectiveness are unknown. Trials of enadoline that demonstrated a significant analgesic effect were terminated because of dose-limiting neuropsychiatric effects; a problem that appears to recur in compounds with opioid κ receptor activity.

These typical adverse effects of κ agonists can be reduced by the use of compounds that have limited access to the brain. Asimadoline is a peripherally acting κ opioid that has been shown to be antinociceptive in visceral models of pain. In the periphery, agonists at κ receptors are able to prevent bradykinin-induced hyperalgesia. Asimadoline is an effective anti-arthritic drug, attenuating both the joint damage and pain associated with adjuvant-induced arthritis in the rat and it is now on clinical trial for the treatment of osteoarthritis. Fedotozine is another κ agonist that has been used clinically, with some success, in irritable bowel syndrome and functional dyspepsia. However, these beneficial effects may not always be mediated via the κ receptor. Fedotozine does not appear to have the diuretic action seen with other κ agonists.

The original ligands for the δ receptor were the enkephalins and highly selective ligands were developed based on the enkephalin peptide structure, but no commercially useful drug appeared. Non-peptide δ agonists have been synthesized and show promise in animal studies but await trials in humans. TAN-67 has been reported to mediate both spinal and supraspinal antinociceptive activity via the δ_1 subgroup of opioid receptors. As with the κ opioid agonists mentioned above, δ agonists may have clinical applications not associated with classical analgesic activity. TAN-67 reduces infarct size and is cardioprotective in a rat model of coronary artery occlusion and re-perfusion.

In summary, while selective agonists at non-μ subtypes of opioid receptors exert analgesic properties, their clinical use may be limited to specific pathologies where pain relief is just one component of their beneficial action.

Pain and opioid sensitivity

The standard method of postsurgical pain control is the parenteral administration of opioids. Patient-controlled analgesia (PCA) is widely used to tailor opioid administration to an individual patient by titrating to an effective drug concentration and maintaining analgesia at that level. However, the ideal opioid for PCA, that has a fast onset of action, high efficacy, moderate duration of action and few side-effects does not exist. Morphine is the standard opioid against which others are judged and there is often little credible evidence that other drugs have significant advantages. In severe pain, partial agonists may be ineffective if the ceiling to their effect occurs at low doses. In many instances, postoperative pain is poorly controlled. The main reasons are poor routine evaluation of pain severity, the use of lower than recommended doses of analgesics and discrepancies in pain assessment between the patient and the medical or nursing staff. It has been suggested that education rather than new drugs or better delivery would cause the greatest improvements in the management of acute pain.

The parenteral use of opioids is a popular method of providing analgesia in obstetrics though it is associated with various adverse effects on the fetus, including low Apgar scores and neurobehavioural deficits. Avoiding additional opioids after the first stage of labour can reduce these effects, but this may lead to inadequate pain relief. Spinal opioids are ineffective in labour. In chronic pain syndromes, neuropathic pain is often opioid insensitive.

The routes used to administer opioid drugs are listed in Figure 8.

Routes of administration for opioid drugs

Route	Advantages	Disadvantages
Oral immediate release	• Convenient • Can be administered by patient or family • Low bioavailability, unpredictable absorption	• Side-effects may limit analgesic doses • Patient must be able to swallow
Oral modified release	• Convenient • Can have once-daily dosage • Can be administered by patient or family	• Some preparations have a slow onset • Dose titration is necessary initially • Unsuitable for acute pain
Topical	• May be effective for skin lesions when systemic opioids have failed	• Only effective if broken or inflamed skin • Occlusive dressings are required
Transdermal patches	• Does not require the patient to swallow • Can have a long duration of analgesic effect • Avoids first-pass metabolism	• Slow onset of analgesia • Only suitable for very lipid-soluble opioids (e.g. fentanyl) • Difficult to adjust dose rapidly • Action is not terminated by patch removal • Expensive
Transdermal iontophoresis	• Faster onset of analgesia than patches • Dose can be adjusted by current control	• Hardware (possibly bulky) needed for administration • Expensive
Oral transmucosal	• Avoids inactivation in the gut (especially buprenorphine) • Action can be terminated by removal of the drug (no depot formation)	• Absorption may be erratic • Drug can be swallowed accidentally
Rectal	• Relatively easy to use if oral route is unavailable • Inexpensive	• Not widely acceptable to patient and family • Absorption can be slow
Intranasal and inhalational	• Avoids injections	• Advantages for only a limited number of patients
Subcutaneous infusion	• Can be used without intravenous access • Can be used for patient-controlled analgesia (PCA)	• Limited volume can be administered • Requires nursing and pharmacy care • Local irritation can occur • Expensive apparatus
Intravenous infusions	• Rapid pain relief • Easy to titrate dose • Suitable for PCA	• Requires intravenous access • Possibility of infection • Requires nursing input • Apparatus expensive
Spinal (intrathecal or epidural)	• May be effective when other routes are not	• Pruritus, urinary retention and infection at catheter site • Expensive • Requires expert attention

Other Targets for Analgesic Drugs

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

The basic science behind conventional analgesics is discussed in *Anaesthesia and Intensive Care Medicine* **2:11:** 450 and 455. However, other transmitters and modulators appear to influence pain perception and many potential analgesics are being investigated. Many of these substances are peptides (e.g. enkephalins) and some basic differences between peptide neuro-transmission and transmission by traditional neurotransmitters such as noradrenaline (norepinephrine) and γ-aminobutyric acid are shown in Figure 1.

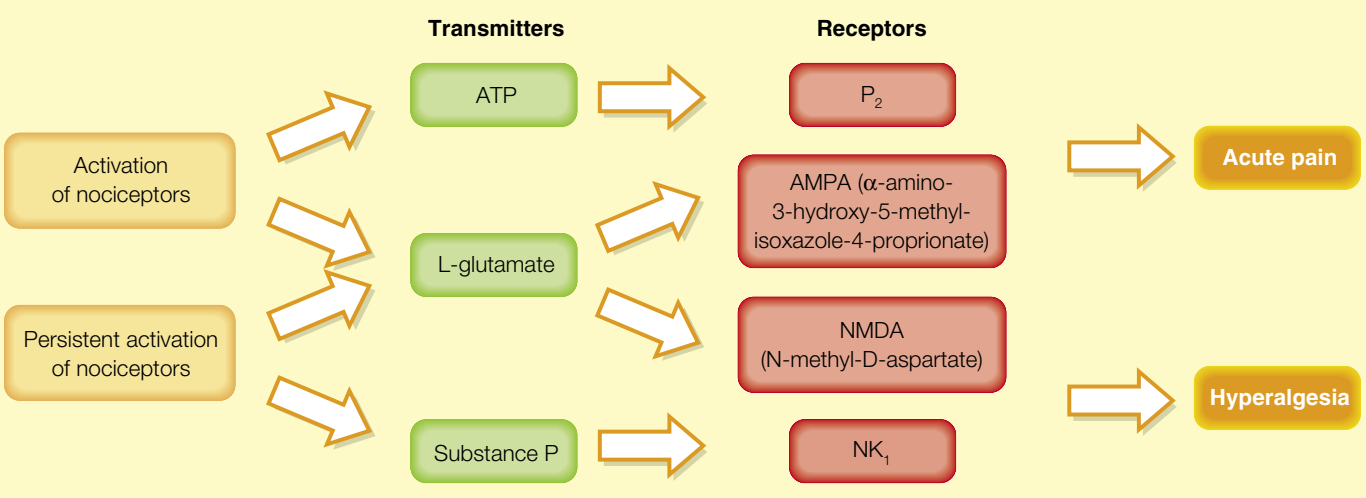
Comparison of peptide and non-peptide (traditional) neurotransmitters

Peptide	Non-peptide
• High molecular weight > 200 daltons (e.g. endorphins)	• Low molecular weight < 200 daltons (e.g. noradrenaline (norepinephrine))
• Synthesized by the genetic material of the neuron No necessity to take up specific precursors	• Precursor taken up into the neuron
• Many products possible from precursor gene by selective DNA splicing, selective cleavage of pro-hormone or post-translational modification (e.g. pro-opiomelantocortinyields both ACTH and endorphins)	• Only one product obtained from the precursor in an individual neuron
• Once released, enzymes are required for termination of activity	• May be metabolized by enzymes or taken up into neurons or glia

1

Individual modulators will be discussed, but Figure 2 illustrates the relationship between these compounds at one site in the pain pathway.

Pain transmission in the spinal cord



2

Acetylcholine

Cholinomimetic drugs (e.g. oxotremorine) and anticholinesterase agents that prevent the breakdown of acetylcholine have long been known to have analgesic activity. Neostigmine given intrathecally had significant analgesic activity in man, but adverse effects, such as prolonged motor block and nausea and vomiting, reduced its usefulness. If intrathecal neostigmine is combined with another analgesic, such as morphine, lower doses of each drug can be used to achieve the same analgesic effect, with a consequent reduction in the adverse effects of the individual agents. Epidural neostigmine combined with lidocaine (lignocaine) significantly increased the duration of pain relief compared with lidocaine alone, without increasing the incidence of adverse effects. The adverse effects of neostigmine can also be reduced, while maintaining the analgesic effect, by injecting the compound locally (intra-articularly) in patients undergoing knee arthroscopy. In the periphery, neostigmine appears to activate muscarinic receptors to acetylcholine to produce analgesia and the effect has been reversed experimentally by atropine.

Nicotinic receptors are also involved in cholinergic analgesia because nicotine is an effective analgesic acting within the CNS. In the dorsal horn of the spinal cord, nicotinic receptors have an important role in the modulation of persistent pain and neurogenic inflammation. Although nicotine has unacceptable adverse effects, continued interest in the therapeutic potential of cholinergic analgesia has been stimulated by the isolation of epibatidine from the skin of the Ecuadorian poison arrow frog. Epibatidine is significantly more potent than nicotine as an analgesic and rapidly enters the brain after intravenous administration. However, it also showed unacceptable adverse effects, in particular, disruption of motor activity. Neuronal nicotinic acetylcholine receptors are pentameric ligand-gated ion channels that exist in several different subunit combinations, which exert different physiological functions. One of these subunit combinations (α4,β2 subtype) is responsible for analgesic activity and a selective agonist (R)-5-(2-azetidinylmethoxy)-2-chloropyridine (ABT-594) has been developed that has a greater separation between analgesic and motor effects than nicotine and epibatidine. Safety trials of the compound in humans are planned.

Adrenaline (epinephrine) and noradrenaline (norepinephrine)

In some patients, the sympathetic nervous system is responsible for continuing pain and persistent hyperalgesia and pain can be abolished by local anaesthesia of sympathetic ganglia or by depletion of noradrenaline (norepinephrine) by substances such as guanethidine. Antagonists at α_1-adrenoceptors, but not at β-adrenoceptors can also provide relief. No simple test is available to predict the success of sympathetic interventions.

Both α_1- and α_2-adrenoceptor binding sites are found in the parts of the brainstem controlling pain modulation. While α_1-receptor activation increases responses, α_2-receptor activation decreases responses to pain by preventing the release of substance P in the spinal cord. Intrathecal and epidural administration of α_2-agonists (e.g. dexmedetomidine, clonidine) have been receiving attention as potential treatments for pain in humans. The chief drawbacks to α_2-agonists as analgesics are the concurrent sedative and hypothermic properties. There is clearly summation, if not synergy, between opioids and α_2-agonists; a reduction in adverse effects might therefore, result from combinations of the two classes of drug.

5-hydroxytryptamine (5-HT)

5-HT is released from mast cells and blood platelets during tissue damage. In high concentrations it elicits pain directly and it is involved in inflammatory hyperalgesia. However, whether 5-HT causes pain or analgesia depends on the location and the receptors involved (Figure 3) and thus applications of agonist or antagonists as analgesics will rely on localization of effects.

5-HT receptors and pain

Receptor	Location	Analgesic activity
5-HT_1	Peripheral nociceptors	Antagonists
	Brainstem	Agonists
5-HT_2	Peripheral nociceptors	Antagonists
	Brainstem	Agonists
5-HT_3	Nociceptors	Antagonists
	Dorsal horn	Agonists
5-HT_4	Nociceptors (visceral?)	Antagonists

3

A particularly important site of pain control is a descending inhibitory control, which constitutes one of the gating mechanisms that control pain transmission in the dorsal horn, and carries tryptaminergic fibres from the brainstem. Direct application of 5-HT to the spinal cord is analgesic and 5-HT uptake inhibitors have analgesic properties. Some patients with chronic pain obtain relief with antidepressant drugs that prevent the reuptake of 5-HT, suggesting that underactivity of tryptaminergic systems may contribute to their problem. Prevention of 5-HT reuptake contributes to the analgesic activity of the weak opioid drug tramadol, and ritanserin, a 5-HT_2-receptor-blocking drug, antagonizes the antinociceptive activity of tramadol suggesting that this subtype of 5-HT receptor may be important with respect to 5-HT actions on pain pathways. Agonists at $5\text{-HT}_{1B/1D}$-receptors prevent the sensitization of caudal trigeminal neurons in response to dural vasodilatation. This action is relevant to the successful use of triptans (see *Anaesthesia and Intensive Care Medicine* **2:11:** 460) to treat a migraine attack.

γ-aminobutyric acid (GABA)

GABA, the major inhibitory neurotransmitter in the brain, has a widespread distribution. In most areas of the brain, such as the periaqueductal grey, GABA agonists at either GABA_A or GABA_B receptors appear to be analgesic. However, when applied to the nucleus reticularis gigantocellularis, in contrast to other brain areas, agonists at GABA_A receptors facilitate pain while antagonists are analgesic. Whether identifying the vast number of subtypes of the GABA_A receptor will allow separation of the two opposing activities of GABA_A agonists on pain transmission remains to be seen. Nevertheless the overall effect of systemic administration of GABA_A agonists in man is analgesia.

In neuropathic pain there is an up-regulation of GABA_B receptors as a consequence of loss of inhibitory neurons caused by the excitotoxicity of excessive glutamate release. In these conditions, the GABA_B agonist baclofen is analgesic, though tolerance to this action develops quickly. For this reason, baclofen is not an effective analgesic in man except in the treatment of trigeminal neuralgia. A more potent GABA_B agonist has been developed (CGP 44532), which is a more effective analgesic than baclofen and appears to retain this activity after chronic administration. This may be a more promising candidate for analgesic activity in humans.

Gabapentin

Gabapentin was synthesized as a structural analogue of GABA but does not bind to any known GABA receptor. It appears to have a specific interaction with the α2δ subunit of the voltage-dependent calcium channel. The analgesic actions of gabapentin are of value in hyperalgesic states and the drug has been used successfully to treat neuropathic pain. A significant part of gabapentin's activity is spinal, though supraspinal activity cannot be ruled out. Gabapentin and its analogues may have some advantages over drugs such as morphine and amitriptyline in the treatment of mechanical allodynia because they block both static and dynamic components of the pain.

Excitatory amino acids

L-glutamate is released in areas of the spinal cord containing primary afferent terminals. There are a number of receptors for glutamate that can be subdivided into the inotropic receptors, NMDA (N-methyl-D-aspartate), AMPA (α-amino-3-hydroxy-5-methyl-isoxazole-4-proprionate) and kainate, L-AP4 (L-2-amino-4-phosphonobutyrate) and metabotropic receptors, of which eight have been cloned. It is likely that AMPA receptors are involved in primary pain transmission (Figure 2). Thus, acute pain control strategies should focus on the AMPA receptor in the spinal cord.

The ion channel associated with the NMDA receptors is blocked by magnesium ions at normal resting potentials. When the neuronal membrane is depolarized by a primary pain transmitter the magnesium ion block of the NMDA receptors is removed. This results in the synaptic potential being prolonged by NMDA receptor activation, resulting in a hyperalgesic or allodynic state. Both direct NMDA receptor antagonists and NMDA channel blockers such as dizocilpine (MK 801) can reduce hyperalgesia in animal models of neuropathic pain. However, preventative treatment is necessary with the NMDA receptor antagonists to achieve this effect. In contrast to the analgesic actions of excitatory amino-acid antagonists in the spinal cord, supraspinally they reduce analgesia.

What is important, however, is whether modulation of excitatory amino-acid transmission can provide analgesia in humans. Flupirtine, a non-opioid centrally acting analgesic has been shown to function as a weak NMDA antagonist. Ketamine is a dissociative anaesthetic first described as an analgesic in 1965. Subsequently it was shown to block the channel gated by NMDA and, in view of the experimental evidence suggesting that an NMDA receptor might be involved in hyperalgesia and wind-up pain, there have been a number of trials assessing the efficacy of ketamine in the treatment of chronic pain conditions. While some patients benefited from ketamine treatment, the drug does not seem to be effective in all types of chronic pain. When used alone as an analgesic, the psychotomimetic effects of ketamine are common and probably preclude its use as a sole agent. A reduction in dose, and thus side-effects, can be obtained by combining NMDA antagonists with opioids for the treatment of chronic pain states. Low-dose ketamine has been used as an adjuvant to other pain control procedures in postoperative pain.

NMDA antagonists also prevent the induction of tolerance to the analgesic action of morphine, though both preventative treatment and a single dose of the channel blocker, dizocilpine, can reverse morphine tolerance. Dextromethorphan was introduced over 40 years ago as an alternative to morphine, but preliminary studies demonstrated that, although it had little analgesic activity, it was an effective antitussive. Subsequently, dextromethorphan was shown to have some NMDA-receptor-blocking action and has analgesic actions in animal models of neuropathic pain. In human trials, dextromethorphan alone was shown to have little useful analgesic activity in neuropathic pain but, when combined with morphine, it has a potential for preventing the development of tolerance. A combination tablet for moderate-to-severe cancer pain containing dextromethorphan and morphine has been submitted to the US Food and Drug Administration for approval.

Since magnesium ion normally blocks the NMDA-receptor-operated channel, it follows that magnesium should exert some analgesic activity. Indeed, an inverse relationship between pain experienced and serum magnesium concentration has been observed in women in labour, and in patients with myocardial infarction, pancreatitis and burns. Studies have demonstrated that magnesium sulphate reduces analgesic requirements in the perioperative period.

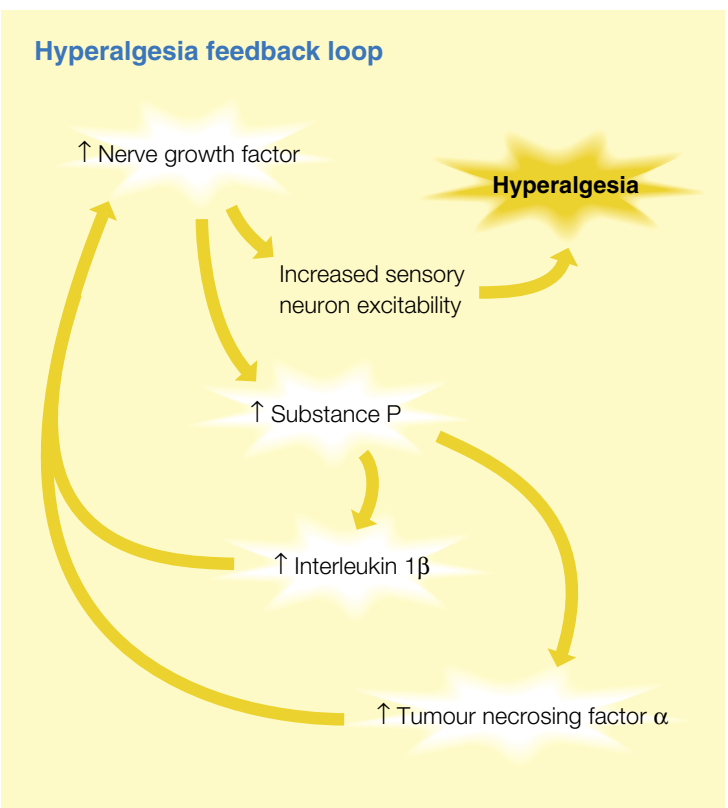
Bradykinin
Bradykinin is proteolytically cleaved from plasma and tissue kininogen at the site tissue of injury and is the most potent pain-producing substance so far described. It interacts with at least two receptors known as B_1 and B_2. B_2 is the most abundant and appears to be responsible for nociceptor excitation. While selective B_2-antagonists, presently available, are too short-lived to be clinically useful, a non-selective bradykinin receptor antagonist D-Arg [4-hydroxy-Pro^3-D-Phe^7] bradykinin has produced encouraging results in clinical trials for the treatment of pain from burns. The fact that this antagonist is non-selective may be advantageous, because it is now apparent that B_1-receptors are expressed during chronic inflammation and contribute to hyperalgesia. A selective B_1-antagonist has been developed des-Arg^9[Leu^8] bradykinin, which inhibits hyperalgesia in animals. Both these receptors are potential targets for analgesic therapy.

Tachykinins
The tachykinins, substance P, neurokinin A and neurokinin B, all play a role in pain transmission, and antagonists at all three receptors, NK_1, NK_2 and NK_3, are under investigation as potential analgesics. Substance P is released in the area of the nociceptor during pain initiation but it is associated with the flare response rather than nociceptor stimulation. Substance P and neurokinin A are released within the dorsal horn of the spinal cord in response to noxious stimulation of the primary afferent nerves. Neurokinin A, which stimulates NK_2 receptors, is a likely candidate as a primary pain transmitter because NK_2-receptor antagonists are more effective in inhibiting C-fibre evoked activity than substance P antagonists (NK_1 antagonists). Substance P plays a role in wind-up pain and selective NK_1-receptor antagonists attenuate wind-up pain and the increase in spinal neuron excitability induced by repetitive C-fibre activity and peripheral inflammation. Nevertheless the NK_1-receptor antagonist CP-99,994 has been shown to provide significant analgesia after dental surgery though ibuprofen provided a better and longer-lasting effect. Neurokinin B acts on NK_3-receptors that also appear to be involved in hyperalgesic states, though they have selectivity for hyperalgesic states initiated by thermal rather than mechanical stimuli.

Cholecystokinin
Within the CNS, the cholecystokinin (CCK) group of peptides has been found predominantly in dorsal horn neurons and has been suggested as an endogenous antagonist of opioid (i.e. morphine)-induced analgesia. Inflammatory pain exhibits an enhanced sensitivity to morphine and is associated with a decrease in CCK in the spinal cord. Nerve section induces CCK and the pain produced is relatively insensitive to morphine. While there are other explanations for this observation, CCK antagonists can restore morphine sensitivity in neuropathic pain. CCK and opioid peptides have parallel distributions in many brain areas associated with pain perception and it may be that the two systems reciprocally modulate CCK-enkephalin release. There appears to be a critical balance between opioid and CCK systems in the control of pain, and their interrelationship depends not only on the tone of both systems, but also on the exact nature of the pain-inducing stimulus. It is likely that manipulation of the balance between them using antagonists at either CCK-A or CCK-B receptors may benefit an individual patient, but will not provide an all-embracing analgesic without side-effects. Nevertheless, preliminary studies combining the CCK antagonist proglumide with opioids for the treatment of cancer pain have shown promise. It has also been shown that proglumide enhances the analgesic action of morphine in chronic pain and may prevent the development of tolerance to opioids.

Somatostatin
Somatostatin, which has been localized in interneurons in the superficial layers of the dorsal horn, produces analgesia by a mechanism distinct from that shown by opioids. Although there is some controversy about the anti-nociceptive activity of somatostatin in the experimental animal, intrathecal infusions of somatostatin itself or the stable analogue, octreotide, have been used successfully to treat cancer pain in humans that was refractory to opioids.

Nerve growth factor (NGF)
During inflammation there is increased synthesis of NGF and the subsequent increase in sensory neuron excitability and promotion of axon sprouting contribute to hyperalgesia. NGF increases the content of mediators such as calcitonin gene-related peptide and substance P in sensory nerves making greater quantities available for release. Substance P in turn up- regulates the production of tumour necrosing factor α (TNFα) and the interleukin, IL-1β, which completes the feedback loop by increasing the synthesis of NGF. The development of drugs that break this loop (Figure 4) could be a route to novel analgesic and anti-inflammatory compounds. There is some early evidence that anti-NGF antibodies may be potential analgesics in the treatment of neuropathic pain because some studies have indicated that anti-NGF did not prevent nerve regeneration.



4

Nociceptin (orphanin FQ)
Nucleic acid probes based on the δ opioid receptor resulted, not only in the cloning of the μ and κ opioid receptor, but also in a new sequence of a novel G-protein-linked receptor that failed to bind classical opioid ligands. The distribution of this orphan (opioid-receptor-like: ORL) suggested that it might have a role in somatosensory processing. The endogenous ligand of this receptor was isolated by two separate groups and was named nociceptin or orphinan FQ. In the spinal cord, nociceptin consistently produces analgesic effects, but supraspinally it appears to exert an anti-opioid effect.

Leukotrienes
The D4 and B4 variant leukotrienes, which are products of arachidonic acid metabolism via the lipoxygenase pathway, appear to have a role in nociceptor sensitization. The evidence suggests that their actions are indirect via the release of other noxious mediators (e.g. prostanoids, substance P). These two leukotrienes have relative selectivity for the BLT and CysLT1 receptors, respectively. The CysLT1 receptor antagonists, zafirlukast and pranlucast, are used in the treatment of asthma, but analgesic uses in humans have not been reported.

Adenosine and adenosine triphosphate (ATP)
Although adenosine and ATP are primarily involved in energy metabolism, they have a wide range of other unrelated pharmacological effects including modulation of nociceptive transmission. Receptors for adenosine were originally designated as P_1-purinoceptors for adenosine and P_2-purinoceptors for ATP. Subsequently, the P_1-receptors have been subdivided and renamed A_1, A_{2a}, A_{2b} and A_3: all are G-protein-linked receptors. Analgesia occurs in neuropathic pain with low doses of adenosine and it appears to involve mainly the A_1-receptor. However, a highly selective adenosine A_1-receptor agonist (WAG 994) was shown to be poorly analgesic in postoperative dental pain when used in doses that did not produce adverse effects. In contrast, enhanced pain perception seen with high concentrations of adenosine is mediated largely through the A_2-receptor.

Large quantities of ATP can be released by tissue damage and produce sharp transient pain. This action is thought to be due to a direct action on ion channels via the ATP-sensitive purine (P_2) receptor and can be blocked by specific P_2-antagonists such as suramin. A subgroup of P_2-receptors, P_{2X}, is selectively expressed in small-diameter sensory neurons. Selective antagonists at this receptor may be potential analgesic drugs. ATP can be selectively released from the dorsal horn of the spinal cord and can cause fast depolarization of dorsal horn neurons (Figure 2).

Cannabinoids
Cannabis extracts have been available for centuries and their analgesic properties are well known. However, the absence of well-controlled clinical trials has meant that no useful clinical analgesics have emerged from them. The most abundant cannabinoid found in extracts is Δ^1 tetrahydrocannabinol (sometimes referred to as Δ^9 because of an alternative numbering system) which mediates an analgesic effect via the CB_1 cannabinoid receptor. An endogenous ligand for the cannabinoid receptor has been isolated and is an arachidonic acid derivative known as anadamide. The cannabinoid system appears to be tonically active because cannabinoid antagonists cause hyperalgesic responses.

In addition, cannabinoid agonists reduce hyperalgesia and inflammation by a peripheral action on CB_1-receptors though CB_2-receptors may also be involved at this site. Nabilone, a cannabinoid analogue, has shown analgesic activity in patients with intractable pain caused by multiple sclerosis.

Vanilloids
Capsaicin, responsible for the pungent taste of red peppers, binds to receptors found in polymodal nociceptors causing initial stimulation and subsequent inhibition. The inhibitory effect of capsaicin on pain perception is believed to involve the depletion of a number of peptides such as substance P and CCK. The initial stimulation of nociceptors causes an intense burning sensation that has limited its usefulness as an analgesic. This problem has been avoided by administering a local anaesthetic before topical capsaicin in the treatment of complex regional pain syndromes and neuropathic pain. Nine out of 10 patients obtained relief lasting 1–18 weeks. In lower doses, capsaicin cream has been used to treat residual limb pain in traumatic amputees.

Voltage-operated sodium channels
Several use-dependent sodium channel blockers, including carbamazepine and mexiletine, can relieve neuropathic pain. Sodium channels accumulate in large-diameter peripheral nerves at the site of nerve injury and it has been suggested that abnormal sodium channel activity may be associated with nerve damage and related pain. System administration of local anaesthetic drugs such as lidocaine (lignocaine) and mexiletine appear to be effective only in pain due to nerve damage, and there is little evidence that they should be used in other types of pain such as cancer pain.

Not all sodium channel blockers have the same effect on pain transmission. For example, bupivacaine reduces the dorsal horn neuronal responses to repetitive C-fibre stimulation while lamotrigine appears to increase wind-up in these neurons. Whether these differences between sodium channel blocking drugs result from selectivity for subtypes of sodium channel or other unrelated properties awaits investigation. The sodium channels expressed by sensory neurons are highly resistant to tetrodotoxin block. This opens the way to the rational design of selective sodium channel blockers. There is strong evidence for a role for the tetrodotoxin-resistant sodium channel (PN3/SNS), which is predominantly localized in the dorsal route ganglia, in hyperalgesia and allodynia.

Voltage-operated calcium channels
Verapamil, the L-type voltage-operated calcium channel blocker, has been shown to enhance the postoperative analgesia-sparing effects of epidural bupivacaine in patients undergoing abdominal surgery. Flunarizine, which produces a non-selective block of calcium channels, has also been reported to have antinociceptive properties. Certain types of sea snails contain ω conotoxins, which are blockers of N, P and Q-type calcium channels. Ziconotide (SNX 111), a synthetic derivative of ω conotoxin MVIIA, produces analgesia in animal models of acute persistent and neuropathic pain The compound is now on clinical trial and has been successful in the treatment of a patient with intractable brachial plexus avulsion. Although dose-dependent adverse effects were seen, such as dizziness, blurred vision and lateral gaze nystagmus, these could be resolved with dose reduction without the return of pain. The pharmacokinetics of ziconotide mean that relatively expensive drug-delivery systems are necessary and that may limit its use in the treatment of chronic pain.◆

Overview of Hormone Therapy

Alex Pleuvry

Alex Pleuvry is an Independent Pharmaceutical Consultant. He qualified in pharmacy from the University of London, and spent most of his career in the pharmaceutical industry. His particular area of interest is the chemotherapy and hormone therapy of cancer.

A hormone is a substance, produced in a ductless organ, which is secreted directly into the blood and thence conveyed to a second organ, where it exerts its biological effect. Some neurotransmitters and 'local hormones' may be encompassed by this definition, but are beyond the scope of this article.

The range of natural hormones is demonstrated in Figure 1. Most natural hormones are peptides or steroids. Those produced by the hypothalamus, anterior and posterior pituitary, pancreas and parathyroid are peptides. The thyroid produces iodo-amino acids (T3 and T4) and the peptide calcitonin. Hormones produced by the adrenal cortex, placenta and gonads are steroids.

Natural hormones

Source	Hormone	Target
Hypothalamus	Growth hormone-releasing factor (GHRF)	Anterior pituitary, GH
	Somatostatin	Anterior pituitary, GH
	Thyrotrophin-releasing hormone (TRH)	Anterior pituitary, thyrotrophin
	Corticotrophin-releasing factor (CRF)	Anterior pituitary, ACTH
	Gonadotrophin-releasing hormone (GnRH) or luteinizing hormone-releasing hormone (LHRH)	Anterior pituitary/follicle-stimulating hormone (FSH) and LH
	Prolactin-releasing factor (PRF)	Anterior pituitary/Prolactin
Anterior pituitary	Growth hormone (GH)	Regulates growth
	Thyrotrophin	Thyroid/T3 and T4
	Adrenocorticotrophin (ACTH)	Adrenal cortex, corticoids
	FSH	Ovary, oestrogen, progestogen
	LH	Ovary, oestrogen and progestogen or testis, testosterone
	Prolactin	Mammary gland, milk production
Posterior pituitary	Antidiuretic hormone (ADH)	Kidney tubules
	Oxytocin	Mammary gland, milk expression Uterus, post-partum contraction
Thyroid	Thyroxine (T4)	Regulation of metabolism, growth and development
	Tri-iodothyronine (T3)	Regulation of metabolism, growth and development
	Calcitonin	Control of plasma calcium
Parathyroid	Parathyroid hormone	Control of plasma calcium
Pancreas	Insulin	Reduction in blood sugar
	Glucagon	Liver: stimulation of glucose breakdown but inhibition of glycogen synthesis and glucose oxidation
	Somatostatin	Local control of insulin and glucagon release
Adrenal cortex	Mineralocorticoids (e.g. aldosterone)	Control of water and electrolyte balance
	Glucocorticoids (e.g. hydrocortisone, corticosterone)	Control of carbohydrate and protein metabolism
Ovary	Oestrogens	Promotes proliferative phase of endometrial regeneration Promotes formation of progesterone receptors in target tissue
	Progesterone	Promotes secretory phase of endometrial regeneration Maintenance of pregnancy
Placenta	Gonadotrophins, oestrogens, progesterone	Maintenance of pregnancy
Testis	Testosterone	Maturation of male sexual organs and development of secondary sexual characteristics Maintenance of spermatogenesis Anabolic effects

1

Hormones combine with receptors that belong to several different superfamilies of receptors. For example, insulin binds with tyrosine kinase-linked receptors and the steroid and thyroid hormones link with receptors that regulate gene transcription. Somatostatin receptors show significant homology with opioid receptors, which may explain the analgesic action of somatostatin analogues such as octreotide. Several hormones also have a functional role as neurotransmitters (e.g. somatostatin, calcitonin).

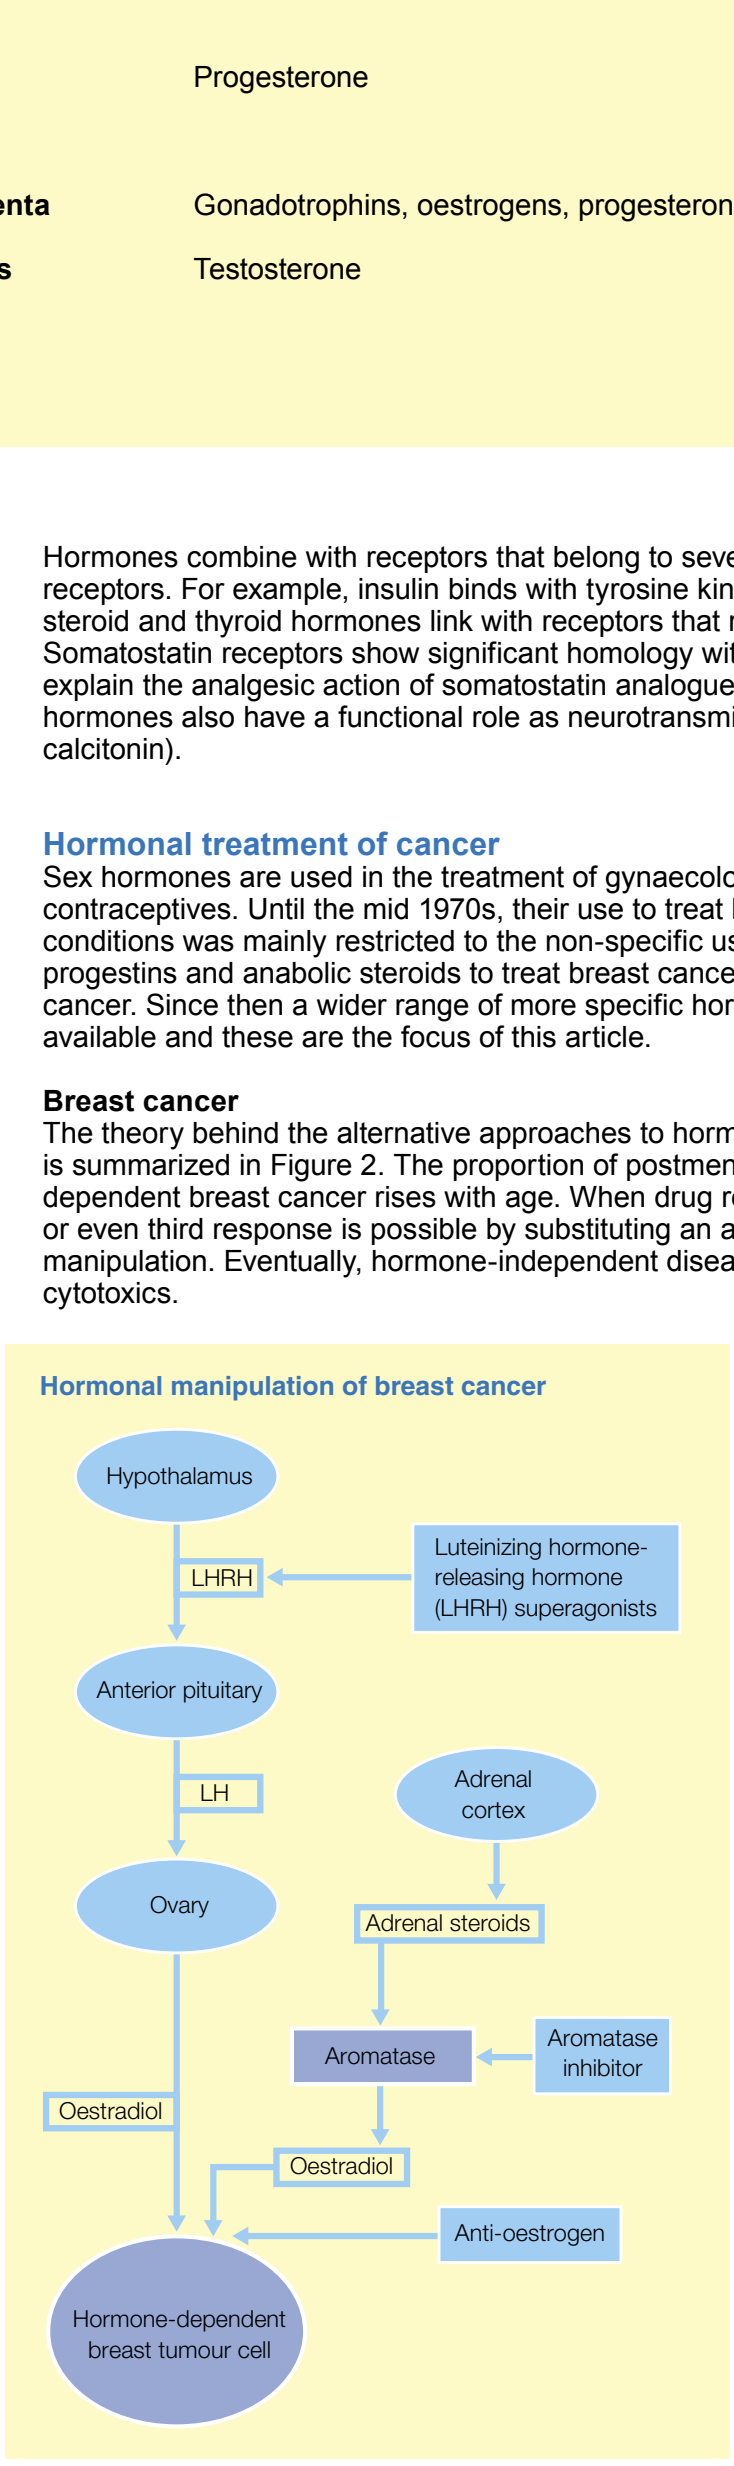
Hormonal treatment of cancer

Sex hormones are used in the treatment of gynaecological disorders and as oral contraceptives. Until the mid 1970s, their use to treat hormone-dependent malignant conditions was mainly restricted to the non-specific use of androgens, oestrogens, progestins and anabolic steroids to treat breast cancer and stilboestrol for prostate cancer. Since then a wider range of more specific hormonal agents has become available and these are the focus of this article.

Breast cancer

The theory behind the alternative approaches to hormonal treatment of breast cancer is summarized in Figure 2. The proportion of postmenopausal patients with hormone-dependent breast cancer rises with age. When drug resistance occurs, a second or even third response is possible by substituting an alternative type of hormonal manipulation. Eventually, hormone-independent disease develops, which requires cytotoxics.

Hormonal manipulation of breast cancer



2

Anti-oestrogens: the nuclei of hormone-sensitive breast cancer cells contain receptor proteins (ER) that specifically bind oestradiol. This activates the interaction of the hormone-receptor complex with specific regions of DNA resulting, eventually, in tumour cell growth. The binding of oestradiol to the receptor is competitively inhibited by anti-oestrogens (e.g. tamoxifen) which thus inhibit tumour cell proliferation. Tamoxifen is also associated with increased levels of growth inhibitory factor (TGF-β), decreased levels of TGF-α and increased levels of sex hormone-binding globulin (SHBG), which reduces free oestradiol concentrations. Tamoxifen also has some partial agonist effects, which may cause endometrial or ovarian changes, resulting in a higher than expected incidence of endometrial cancer following long-term treatment.

Tamoxifen is not only the most widely used anti-oestrogen but also the most widely used hormonal agent in the treatment of breast cancer. Several simple tamoxifen analogues were developed, mainly involving halogen substitutions, but the development of most of these simple analogues for breast cancer has ceased, though raloxifene is used in the treatment of osteoporosis. Today, the main use of tamoxifen is in the adjuvant treatment of early breast cancer, typically for 5 years, to reduce the recurrence rate. More recently, it has been approved by the FDA for the prevention of breast cancer in women at high risk.

Fulvestrant is the first of a new class of oestrogen receptor down-regulator that targets and degrades oestrogen receptors. Phase III trials of fulvestrant (ICI 182780) have demonstrated a broader range of activity, including effectiveness in tamoxifen-resistant patients, and a longer duration of effect than current endocrine agents. It was approved by the FDA in April 2002.

Aromatase inhibitors: in postmenopausal women with hormone-dependent breast cancer, the principal source of oestrogen is through aromatization of adrenal steroids. The enzyme aromatase, a member of the cytochrome P450 group found in peripheral tissues and breast tumours, converts androstenedione into oestrone and testosterone into oestradiol. The early inhibitors (e.g. aminoglutethimide) were non-specific, inhibiting other cytochrome P450 enzymes resulting in reductions in cortisol and aldosterone synthesis. The more recently introduced new generation of specific aromatase inhibitors (e.g. anastrozole) show a higher degree of selectivity, are well tolerated and can be administered orally. They are used clinically in the treatment of postmenopausal women with advanced breast cancer but are unsuitable for premenopausal women. Trials are in progress to test their efficacy in earlier disease.

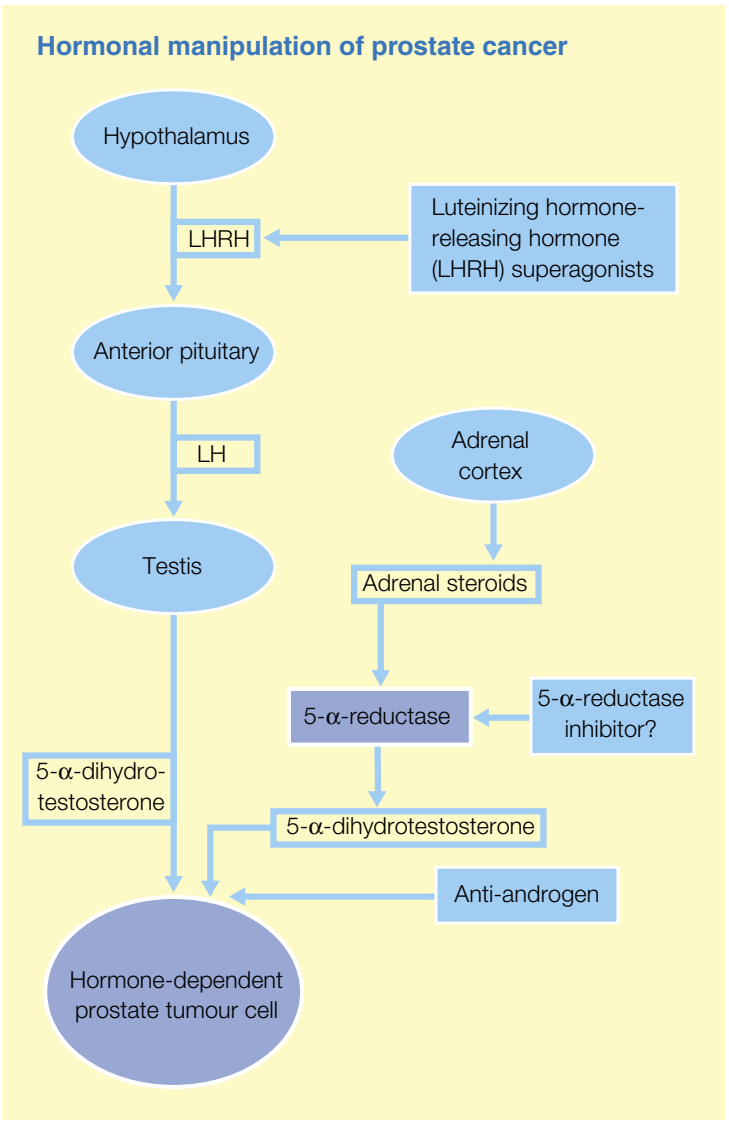
Luteinizing hormone-releasing hormone (LHRH) agonists: physiologically, LHRH is released in a pulsatile manner by the hypothalamus and binds to the LHRH receptors on the anterior pituitary gland causing release of follicle-stimulating hormone (FSH) and LH. The latter acts on the ovary to secrete oestrogen. The potent analogues of LHRH, the most widely used being goserelin and leuprorelin, occupy the LHRH receptors and down-regulate them. New receptors are synthesized but the constant presence of the analogue causes them to be occupied immediately and disappear. The result is that oestrogen levels fall to castrate levels. These LHRH analogues are used in the treatment of women with functioning ovaries but are unsuitable for postmenopausal women.

Progestins and anti-progestins: progestins have long been used as second- or third-line non-specific therapy in breast cancer. The discovery of the progestin receptor suggested a role for an anti-progestin (e.g. mifepristone) in breast cancer, but clinical results have been disappointing.

Prolactin inhibition: observation that the dimethyl-benzanthracene (DMBA) rat tumour model of breast cancer was strongly prolactin dependent led to the development of bromocriptine. However, clinical results were disappointing because oestrogen dependence is significantly more relevant in human breast cancer than prolactin dependence.

Prostate cancer

The theory behind the alternative approaches to hormonal treatment of prostate cancer is summarized in Figure 3. At diagnosis, most patients have hormone-dependent disease, but hormonal treatments fail eventually with the appearance of hormone-refractory disease. The traditional treatments for metastatic prostate cancer were an oestrogen (e.g. stilboestrol) which was found to have cardiovascular consequences, or bilateral orchidectomy. Use of both has declined since the appearance of the LHRH analogues and anti-androgens.



3

Anti-androgens: the Leydig cells of the testis, under the influence of LH secreted by the pituitary, produce 95% of total androgen as testosterone. Most of the testosterone is serum bound to SHBG or albumin but the remaining 2–3% free form is the functionally active substance that passes into the prostate gland where it is converted by 5-α-reductase to the more potent androgen dihydrotestosterone (DHT). DHT binds to androgen receptors in the cell nucleus, activating prostatic cell functions. The anti-androgens inhibit the binding of DHT to the androgen receptor thus inhibiting prostatic cell growth. The early inhibitors, notably cyproterone, were also steroidal progestins and were therefore non-specific, resulting in side-effects. Flutamide is a more specific non-steroidal anti-androgen but the more recently introduced bicalutamide is better tolerated. The controversy over the merits of combination use of anti-androgen with LHRH analogue (maximal androgen blockade (MAB); also known as combined androgen blockade (CAB)) in advanced prostate cancer continues but the trend is for bicalutamide to be increasingly used in the treatment of earlier stages of the disease.

LHRH agonists and antagonists: in prostate cancer, the action of LHRH analogues is analogous to that in breast cancer (discussed above) except that, because the pituitary is prevented from producing LH, testosterone production from the testis falls to castrate levels.

It could be argued that an LHRH antagonist might be more efficient because it would block LHRH receptors directly. There would be no release of testosterone at the start of treatment, thus avoiding the testosterone flare associated with the super-agonists, and perhaps the efficacy would be equivalent to that of a combination of a superagonist and an anti-androgen. The early antagonists suffered considerable toxicity problems but abarelix proceeded to phase III trials in prostate cancer. However, it was rejected by the Food and Drug Administration because of concerns about the reliability of duration of efficacy.

5-α-reductase inhibitors: the adrenal glands are secondary sources of androgens accounting for 5% of total testosterone and this encouraged the development of 5-α-reductase inhibitors, notably finasteride, which has proved effective in treating benign prostatic hypertrophy but not prostate cancer.

Neuroendocrine tumours
The somatostatin analogues, octreotide and lanreotide, are used in treating the symptoms of carcinoid tumours and VIPomas.

Corticosteroids
The main use of the glucocorticoids in cancer is as supportive therapy in conjunction with cytotoxic chemotherapy but they are also used to reduce intracranial pressure in the treatment of brain cancer (primaries and metastases) as well as to inhibit lymphocyte proliferation in the treatment of lymphomas and leukaemias.

Drug interactions relevant to anaesthesia

The hormonal anticancer agents are remarkably free from drug interaction problems, in contrast with the cytotoxic anticancer agents. In some, but not all, patients the anticoagulant effects of warfarin are markedly enhanced in the presence of tamoxifen. This may require dose reduction of the anticoagulant. The opposite occurs when anticoagulants are administered with the first-generation aromatase inhibitor aminoglutethimide, therefore the dose of the anticoagulant may need increasing.

Challenges for the formulator

The LHRH analogues and somatostatin analogues are peptides that if given orally would be destroyed in the gastrointestinal tract. Initially these analogues were administered by daily subcutaneous injection, which was inconvenient for patients with consequent compliance problems. Nasal sprays have been used but the major advance was the development of 1-month depot subcutaneous injections using lactide-glycolide co-polymer technology. 3-month (and longer) injectable depots have also been marketed. Recently a surgically implantable depot containing a LHRH analogue has been developed to last for 12 months. An injectable gel formulation has also been developed. ◆

Overview of Pharmacokinetics

Norman Calvey

Norman Calvey was formerly Senior Research Fellow in the University Department of Anaesthesia, Liverpool, UK. He qualified in science and medicine from Liverpool University and has worked in Departments of Pharmacology and Anaesthesia. His research interests include pharmacokinetics and drug isomerism.

The term pharmacokinetics is derived from the Greek words *pharmakon* (drug) and *kinesis* (movement), and is commonly used with reference to two related concepts. It can be used to refer to the disposition of drugs by absorption, distribution, metabolism and excretion. It is also used to describe a mathematical approach to the behaviour of drugs; various constants or parameters are derived from the analysis of plasma concentrations [C] at various times after drug administration. This review is mainly concerned with the latter aspect of pharmacokinetics.

Pharmacokinetic parameters

The parameters that best describe the behaviour of drugs in the body are volume of distribution (V) and clearance (CL). V represents the apparent volume available for drug disposition; CL reflects the ability of the body to eliminate drugs. The half-life ($t_{½}$) can be derived from values for V and CL.

Volume of distribution

V is the apparent volume into which a drug is distributed at equilibrium; it represents the volume that would contain the drug if its concentration throughout the body was the same as in plasma. It is partly determined by physical properties (e.g. lipid solubility, plasma/tissue binding), as well as physiological factors (regional blood flow, plasma protein concentration).

In healthy adults, V for different agents ranges from 5 litres to more than 1000 litres. Drugs can be divided into three main groups. Compounds with a V of 5–50 litres are extensively bound to plasma proteins (e.g. warfarin) or localized in extracellular fluid (e.g. muscle relaxants). Drugs with a V of 50–500 litres are widely distributed in most tissues (e.g. local anaesthetics, opioid analgesics). When V is greater than 500 litres, there is extensive tissue localization and binding (e.g. digoxin). V is increased in the newborn and in pregnancy, and may be affected by renal and cardiac failure.

Clearance

CL was originally defined as the volume of plasma from which a drug must be entirely eliminated within a set time in order to account for its removal from the body. It also represents the rate of drug elimination (mg/minute) per unit of [C] (mg/ml). The rate of drug elimination is normally proportional to [C], therefore CL is usually constant. Several sites (e.g. liver, lung, kidney, plasma) may be involved in the elimination of a single drug; CL is the sum of these individual clearances.

Renal clearance: in many instances, both CL and renal clearance (CL_R) can be directly measured. When CL_R is greater than 70% CL, drug accumulation may occur in patients with renal insufficiency (or during renal transplantation).

Hepatic clearance: most drugs are cleared from the body by the liver (by metabolism and/or biliary excretion). In steady-state conditions, hepatic clearance (CL_H) is dependent on blood flow (Q) and the extraction ratio (ER); thus, $CL_H = Q \times ER$. The ER (which has a value between 0 and 1) reflects the ability of the liver to remove drugs from the circulation.

Alternatively, CL_H can be considered in terms of Q and $CL_{intrinsic}$ (defined as the ability of the liver to irreversibly eliminate drugs) as 'capacity-limited' or 'flow-limited' clearance.

- In capacity-limited elimination, $CL_{intrinsic}$ is relatively low compared with Q, and $CL_H \approx CL_{intrinsic} \times f$, where f is the fraction of unbound drug. In these conditions, $CL_{intrinsic}$ is rate-limiting; CL_H is relatively low and is not altered by changes in Q, but is modified by changes in $CL_{intrinsic}$ (due to enzyme induction, inhibition, age, malnutrition or disease), as well as protein binding. This type of elimination occurs with many common drugs (e.g. diazepam, warfarin, phenytoin).
- In flow-limited elimination, $CL_{intrinsic}$ is relatively large compared with Q, and $CL_H \approx Q$. In these conditions, Q is rate-limiting; CL_H is dependent on and determined by Q (21 ml/kg/minute in adults), but is relatively insensitive to changes in hepatic enzyme activity or plasma protein binding. This type of elimination is involved in the clearance of most β-adrenoceptor antagonists, opioid analgesics and local anaesthetics.

Clearance by other routes: some drugs are predominantly eliminated from the body by non-renal and non-hepatic routes. For example, some anaesthetic drugs are esters (e.g. remifentanil, suxamethonium, mivacurium and esmolol) and are predominantly eliminated from the body by hydrolysis; in these instances, values for CL may be greater than hepatic and or renal blood flow.

Half-life

Half-life ($t_{½}$) is the time required for [C] to decrease by 50% during the terminal phase of decline. It is approximately related to V and CL by the expression:

$$t_{½} = k \times \frac{V}{CL}$$

where k is a constant (ln (natural logarithm) 2; 0.693). Consequently $t_{½}$ is a hybrid pharmacokinetic parameter, and depends on the primary parameters V and CL. Alterations in $t_{½}$ may reflect changes in V and or CL, and differences between the $t_{½}$ of drugs do not necessarily reflect changes in drug elimination.

When drugs are administered in identical oral doses at intervals that are equal to their $t_{½}$, steady-state concentrations are reached after about 4–5 $t_{½}$s. This delay can be avoided by an initial loading dose. Drugs are often given orally at intervals that are about equal to their $t_{½}$s; this usually provides an acceptable compromise between the decline in drug concentrations after each dose, and the maintenance of an acceptable [C]. Nevertheless, $t_{½}$s may be a poor indication of the duration of drug action.

Context-sensitive half-times: when drugs are given by intra-venous infusion, computer-derived values for their context-sensitive half-time (CSHT) are a better indication of their disposition and activity than $t_{½}$s. The CSHT can be defined as the time required for the plasma concentration to decrease by 50% at the end of a specified period of infusion.

For some drugs (e.g. remifentanil), the CSHT (3–5 minutes) is independent of the duration of infusion; its effects are rapidly reversible, even after prolonged infusions. In other instances (e.g. alfentanil, midazolam, propofol) the CSHT is initially relatively constant, but increases 2–3 times after infusions of 6–8 hours. By contrast, in these conditions the CSHT of fentanyl increases 10–12 times, and its effects may persist for several hours after the termination of prolonged infusions.

CSHTs are a useful indication of the disappearance of drug activity after infusions of different durations, and may therefore be of considerable value in total intravenous anaesthesia.

Compartmental analysis

In compartmental analysis, a suitable pharmacokinetic model is used to describe drug disposition and elimination; values for V, CL, and other constants are then derived from the parameters of the model. The pharmacokinetics of many drugs were originally interpreted by a simple, one-compartment open model, which has limitations. Two- and three-compartment open models are now used to describe the behaviour of drugs after intravenous administration.

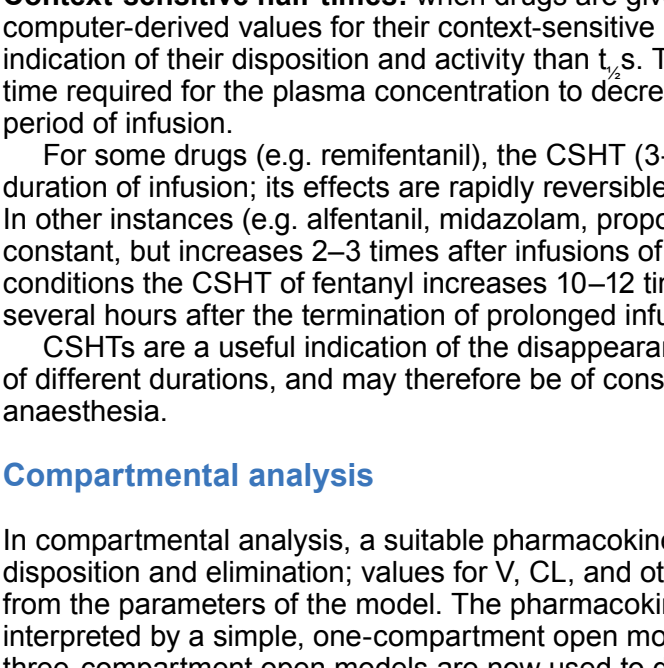
Two-compartment models

After intravenous injection of most drugs, there is an initial rapid decrease in [C] (distribution phase) followed by a slower decline (elimination phase). When ln [C] is plotted against time, the decrease in [C] can be resolved into two exponential components by extrapolation (Figure 1). The terminal decline in [C] is extended to the ordinate, which it intersects at point B. Subtraction of the extrapolated values from the initial data points gives a series of residual points, reflecting the initial phase of exponential decline (defined by the line that intercepts the ordinate at A). Both the distribution and elimination phases have characteristic slopes (α and β) and half-lives ($t_{½\alpha}$ and $t_{½\alpha}$); their intercepts (A and B) represent the amount that each half-life contributes to the decrease in [C].

The decline in [C] can be interpreted in terms of a two- compartment open pharmacokinetic model (Figure 2). The compartments have no physiological meaning; their parameters and constants are determined solely by the behaviour of the drug in the body. The model is a theoretical concept that accounts for the observed decline in [C].

Values for A, α, B and β are used to derive the parameters of the model (e.g. CL, V, k_{12}, k_{21}, k_{10}). V is represented by two different expressions (V_{area} and V_{ss}); V_{area} overestimates V when CL is high. V_{ss} (i.e. V at steady state) is preferable, because it is independent of CL.

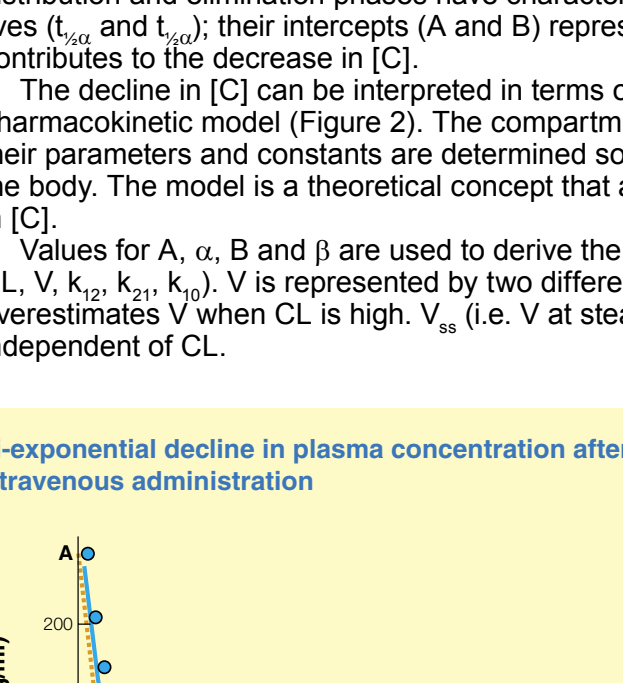
Bi-exponential decline in plasma concentration after intravenous administration



Data points correspond to plasma concentration at different times after drug administration. The terminal decline in concentration is extrapolated to the ordinate which it intersects at point B. The extrapolated values are subtracted from the data points to give a series of residual values, representing the initial phase of exponential decline which intersects the ordinate at point A. α and β represent the slopes of the distribution and elimination phases of exponential decline.

1

Two-compartment open pharmacokinetic model



k_{10} is the elimination rate constant; k_{12} and k_{21} are the rate constants controlling drug transfer between the central and peripheral compartments

2

Three-compartment models

In many instances, three-compartment models provide a better interpretation of the data (e.g. with opioids, muscle relaxants, intravenous anaesthetics). The decline in [C] is resolved into three exponential components; values for the intercepts (A, B and C) and the slopes (α, β and γ) of the components are obtained and interpreted by a three-compartment open model, with administration into and elimination from the central compartment.

Other models

Pharmacokinetic–pharmacodynamic models

When drugs act reversibly, there is often a close correlation between their [C] and pharmacological effects. Nevertheless, after intravenous administration there is usually a short delay between the rise in [C] and the onset of their action; during recovery, the fall in [C] commonly precedes their offset. This phenomenon of hysteresis or temporal disequilibrium can be rationalized by the addition of a minute, distinct, effect or 'biophase' compartment, with individual rate constants, to the central compartment of a pharmacokinetic model. The rate constant (k_e or k_{eo}) characterizes the disequilibrium between the central compartment and the biophase during the onset and offset of drug action. In these conditions, there is a hysteresis-free relationship between their biophase concentration and pharmacological effects.

Pharmacokinetic–pharmacodynamic models of this type have been developed for muscle relaxants, opioids, and intravenous anaesthetic agents, and may have a role in the development of closed-loop control systems.

Physiological models

Physiological models are more complex than pharmacokinetic models; they depend on the interpretation of drug distribution in terms of organ or tissue spaces with defined volumes, perfusion characteristics and partition coefficients. Individual compartments may have 'flow-limited' or 'membrane-limited' characteristics (depending on whether blood flow or transmembrane transport is the limiting factor governing drug transfer).

These complex models are based on the detailed analysis of anatomical and physiological data, and depend on numerous assumptions; consequently, their resolution may be extremely difficult. Nevertheless, they have a number of distinct advantages. They can be used to predict changes in drug concentration in different tissues in relation to [C]; in addition, they can take account of physiological changes produced by drugs or occurring during anaesthesia (e.g. alterations in cardiac output, blood volume, regional blood flow and renal function).

The disposition of several drugs, including thiopental (thiopentone), lidocaine (lignocaine), and some inhalational anaesthetics, has been described in terms of physiological perfusion models.

Non-compartmental methods

Non-compartmental methods do not depend on the assumptions inherent in compartmental models, though they can be used to derive values for CL and V_{ss}. CL is derived from the relationship:

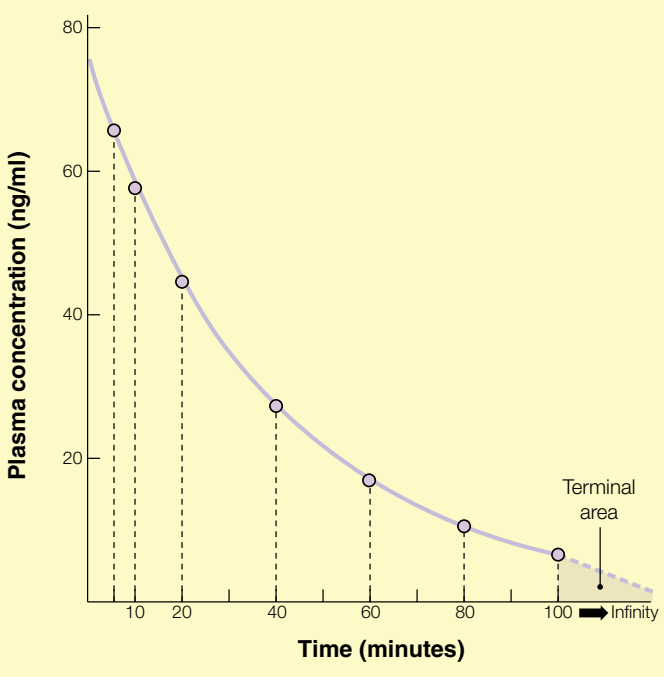
$$CL = \frac{Dose}{AUC}$$

where AUC is the area under the plasma concentration–time curve between time zero and infinity. The AUC can be estimated by the 'trapezoidal rule', which depends on the measurement and summation of the area of each trapezoid between successive sampling times and the corresponding values for [C] (Figure 3). The terminal area between the final [C] versus time, and time infinity is estimated from the expression:

$$\text{terminal area} = (\text{final [C]} \times t_{1/2}) \div 0.693$$

V_{ss} is then calculated as the product of CL and the mean residence time (i.e. the mean time that each drug molecule resides in the body).

Determination of the area under the curve by the trapezoidal rule



The plasma concentration–time curve is divided into a series of trapezoids subtended by the time of each sample and its corresponding plasma concentration. The area under the curve (AUC) is the sum of the area of each trapezoid and the terminal area

Constant plasma concentrations of drugs

A number of intravenous dose regimens have been used to produce constant [C] of drugs; most of these depend on an initial bolus, followed by a continuous infusion. In one regimen, a bolus dose of (V × required [C]) is given, followed by a continuous infusion of (CL × required [C]) (mg/minute). This method depends on accurate values for V and CL, and may cause transiently high [C].

Recently, combinations of a bolus dose, an exponentially declining initial infusion, and a maintenance infusion (the bolus, elimination and transfer method) have been used to produce a constant [C]. The bolus is designed to fill the central compartment to the required [C]; the exponentially declining infusion compensates for the distribution of the drug to peripheral compartments. The maintenance infusion equals the rate of drug elimination. This method has been used with computer-controlled programmed infusion devices in open-loop and closed-loop control systems.

Non-linear pharmacokinetics

In pharmacokinetic analysis, it is generally assumed that drug disposition and elimination are exponential, first-order processes. In these conditions, $dX/dt = -kX$, where X is the amount of drug in an organ or compartment, and k is a rate constant. These assumptions are not always correct. The enzymic reactions involved in drug metabolism can be saturated by high substrate concentrations (Michaelis–Menten kinetics); similarly, physiological systems that depend on carrier transport can be saturated. Consequently, metabolism and transport occur at maximal, constant rates that are independent of drug concentration (i.e. $dX/dt = -k$). Other biological processes (e.g. protein binding) can also be saturated.

This type of kinetics is known as non-linear, saturation, or zero-order kinetics, and occurs when drugs are eliminated by enzymic or transport processes. In practice, the phenomenon is relatively uncommon, because most drugs are potent agents and their plasma concentrations are relatively low. Nevertheless, non-linear kinetics occurs with ethyl alcohol, salicylates and phenytoin, and after large or repeated doses of thiopental (thiopentone) (e.g. during cerebral resuscitation). It also occurs in drug overdosage; it is unclear whether this reflects saturation of hepatic metabolism or drug toxicity.

Non-linear pharmacokinetics typically reduces V and CL, and prolongs the $t_{1/2}$ of drugs; similarly the AUC is disproportionately raised. By contrast, when drugs are subject to first-order kinetics, V, CL and $t_{1/2}$ are all independent of dose.

Population pharmacokinetics

Population pharmacokinetics results in the derivation of pharmacokinetic parameters that describe drug disposition in an entire population.

Individual data from a large number of subjects are integrated into a single population model, that depends on certain assumptions (e.g. identical individual and population concentration profiles). Individual variability (irrespective of its cause) is incorporated in the model by statistical techniques.

Differences between individual pharmacokinetic constants and population values are then assessed in terms of fixed effects (e.g. age, weight, CL_R, CL_H) and random effects (unexplained variability). Population pharmacokinetics generally attempts to interpret variability in terms of measurable characteristics or fixed effects.

Bioavailability

Bioavailability can be defined as the proportion of the oral dose that is present in the systemic circulation. It is usually derived from the AUC (Figure 3). After intravenous administration, drugs have a fractional bioavailability of 1 (i.e. 100%); consequently, the bioavailability of oral drugs (%) is defined as:

$$\frac{\text{AUC after oral administration}}{\text{AUC after intravenous administration}} \text{ ¥ } 100$$

Many drugs have a high oral bioavailability (e.g. diazepam, phenytoin, warfarin). In general, they are acid-stable, extensively absorbed agents with little first-pass metabolism (i.e. they are not significantly degraded by the gut wall or the liver before they reach the systemic circulation).

In contrast, other drugs have a low oral bioavailability, because of:

- gastrointestinal instability or degradation
- poor absorption
- significant first-pass metabolism.

Some drugs are unstable in gastric acid or are degraded in the small intestine (e.g. benzylpenicillin, heparin, polypeptides). Others are poorly absorbed, usually because of their limited lipid solubility (e.g. neostigmine, glycopyrrolate, gentamicin). Finally, drugs with significant first-pass metabolism have a low bioavailability, because they are extensively broken down by the gut and/or the liver (e.g. morphine, propranolol, lidocaine (lignocaine)).

In some instances, there are variations in the oral bioavailability of different preparations of a single drug. These differences are sometimes related to their *in vitro* dissolution characteristics. When CL_H is dependent on blood flow, any reduction in perfusion may increase systemic bioavailability. Similarly, drugs that inhibit microsomal enzymes (e.g. cimetidine), physiological changes (old age) and pathological factors (hepatic cirrhosis) can impair drug metabolism and affectbioavailability.

Pharmacodynamics: Concentration–Response Relationships and Hysteresis

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Much of the theory regarding drug concentration–response relationships is derived from experiments using *in vitro* preparations bathed in physiological solutions to which known quantities of drugs can be added. Using this system, the responses of the tissue can be related directly to the concentration in the bathing fluid and the characteristic sigmoid log concentration–response relationship can be obtained. Different conditions apply *in vitro*. It is usually feasible to measure only the plasma concentrations of a drug rather than its concentration at the site of action. Thus, a direct relationship between plasma concentration and effect is only obtainable when a drug such as heparin exerts its effect within the plasma. Therefore, plasma concentrations of a drug may not be a good indicator of drug response for several reasons.

Maximum responses
If the drug is a full agonist, it is capable of producing the maximum response that activation of that receptor can produce. Concentrations of drug above this maximum concentration will have no further effect.

Irreversible effects
If the drug acts irreversibly then the response to its administration will outlast its plasma concentration. Some drugs of this type are listed in Figure 1.

Examples of irreversible drugs

Drug	Pharmacological action	Mechanism of recovery
Aspirin	Inhibition of cyclo-oxygenase	Synthesis of new cyclo-oxygenase. Inhibition of enzyme in platelets requires new platelet production
Phenelzine	Non-selective inhibitor of	Synthesis of new enzyme monoamine oxidase
Phenoxybenzamine	α-adrenoceptor blockade	Synthesis of new receptors
Sarin (nerve gas)	Cholinesterase inhibition	Synthesis of new enzyme
Selegiline	Suicide inhibitor of monoamine oxidase B	Synthesis of new enzyme

1

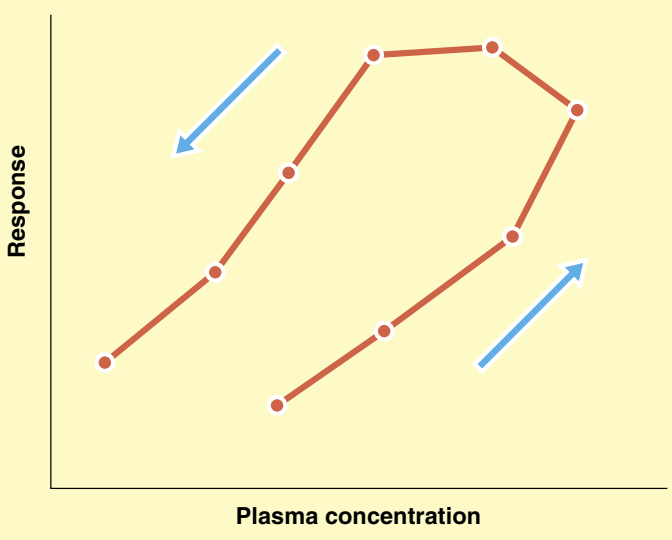
Complex responses
Many drug responses are integrated physiological changes, for example, a fall in blood pressure after a β-adrenoceptor antagonist (e.g. propranolol). This response involves inhibition of renin release from the kidney, a fall in cardiac output, inhibition of noradrenaline release and a reduction in sympathetic output from the CNS. Each component might be directly related to plasma concentration, there is no direct relationship to the final integrated response. Hysteresis may also affect the individual components of the response.

Hysteresis

Most drugs have to move into the biophase (site of action) and then occupy receptors or bind with enzymes before they can exert their effect. When the plasma concentration declines the effects are reversed, but there is a lag phase before observed effects follow the changes in plasma concentration. This phenomenon is known as hysteresis, which may be defined as 'the retardation or lagging of an effect behind the cause of the effect'. The two main reasons for the lag phase are limited access to the site of action or slow receptor kinetics.

Limited access
A few drugs reach the biophase rapidly; they include the highly lipid-soluble compounds that penetrate through cell membranes rapidly (e.g. intravenous anaesthetic agents). These agents would be expected to show little hysteresis though inter-individual variation in the concentration–effect relationship for thiopental (thiopentone) has been ascribed to differences in effect-hysteresis. More significant hysteresis is seen with ionized compounds or poorly lipid-soluble compounds (e.g. morphine). This is sometimes termed anticlockwise hysteresis (Figure 2) because the arrows relating time to the concentration–effect relationship run in an anticlockwise direction.

Anticlockwise hysteresis loop



Concentration–response measurements are made at various times after a dose. The arrows show the direction of time

2

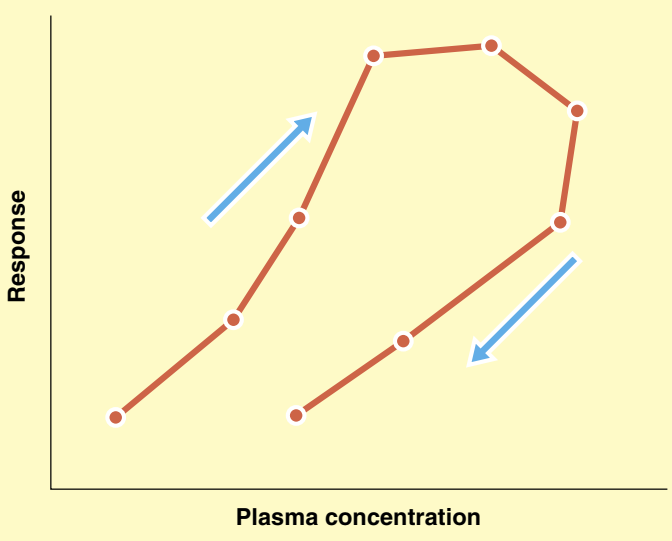
Even drugs whose site of action is outside the CNS can exhibit hysteresis. The slow onset of pancuronium has been ascribed to the slow movement of the ionized compound from the capillary to the junctional cleft. A recent study has demonstrated marked anticlockwise hysteresis with single rectal doses of diclofenac, a weak acid, indicative of the effective biophase being within the CNS. The delay to peak analgesia was 300 minutes after administration while the peak plasma concentration was 60 minutes. The authors highlighted the possible dangers of co-administration of patient-controlled morphine where high morphine use during the time of peak diclofenac plasma concentrations could lead to persistent high concentrations of the active metabolite morphine-6-glucuronide during the peak analgesic activity of the diclofenac. This would predispose the patient to respiratory depression.

It is important that hysteresis should be incorporated into pharmacokinetic and pharmacodynamic modelling of intravenous infusion protocols and the use of context-sensitive half time is a step in the right direction (see *Anaesthesia and Intensive Care Medicine* **2:6:** 250c).

Slow receptor kinetics
The best example of a drug that binds slowly to its receptors is buprenorphine, which may take minutes rather than seconds to reach equilibrium. It is difficult to distinguish this type of hysteresis from limited access hysteresis.

Tolerance
Tolerance describes the phenomenon where the effect of a drug declines despite its continuing presence. On a short time scale, such as a few minutes, this situation is sometimes called desensitization or tachyphylaxis and on a longer time scale, such as days or weeks, the term tolerance is preferred. An example is shown in Figure 3, in which, in contrast to Figure 2, the arrows indicating time on the concentration–response relationship rotate clockwise. Some authors call this clockwise hysteresis, but in order to do this it is necessary to use an alternative definition of hysteresis. A less physics-based definition would be 'Failure of one of two related phenomena to keep pace with the other. Any situation in which the value of one depends on whether the other is increasing or decreasing'.

Clockwise hysteresis loop



Concentration–response measurements are made at various times after a dose. The arrows show the direction of time

3

Tolerance or desensitization can occur as a result of the mechanisms listed in Figure 4. ◆

Mechanisms of desensitization and tolerance

Mechanism	Example
Conformational change in receptors • Binding of agonist but no channel opening • Uncoupling from second messenger system • Loss of modulator binding site	 Nicotinic receptors at the neuromuscular junction β-adrenoceptors and opioid receptors? Benzodiazepine site on $GABA_A$ receptor
Loss of receptors	β-adrenoceptors (slow process) and many hormone receptors
Physiological adaptation	Acetazolamide
Increased metabolism	Many anticonvulsants induce the enzymes responsible for their own metabolism
Exhaustion of mediators	Indirectly acting sympathomimetics (e.g. amfetamine (amphetamine))

Pharmacogenetics: Familial Variation in Drug Response

Maria Alvarez

Maria Alvarez is Specialist Registrar in Anaesthesia in the North West Region, at present working at Central Manchester and Manchester Children's University Hospitals, UK. Her areas of interests include paediatric and obstetric anaesthesia.

Genetically determined variability in drug response is an important clinical problem. It is responsible for the lack of therapeutic effect in some individuals and also explains the idiosyncratic drug reactions that occur in a few individuals. In the future it may be possible to prescribe drugs on an individual basis, to obtain the maximum benefit and to avoid side-effects.

Early genetic observations suggested that the biotransform-ation of foreign compounds by the human body might be governed by inheritance laws. In 1957, it was postulated that hereditary variations occurred in response to drugs and the term pharmacogenetics was used to describe these phenomena. Variation in genotype contributes to variation in pharmacodynamic and pharmacokinetic characteristics of drugs among individuals. Some inborn errors are rare, to the extent that only 1/100,000 people might be affected, others are classical genetic polymorphisms in which the abnormal gene has a frequency of more than 1% in the general population. Many genes are subject to polymorphic variation. In some cases inheritance patterns can determine abnormal responses to drugs used during anaesthetic practice (Figure 1). Much of the work in the field of pharmacogenetics concentrates on polymorphisms in human metabolic enzymes.

Pharmacogenetic diseases relevant to anaesthesia and their inheritance patterns

Inheritance patterns	Protein affected	Response
Autosomal recessive	N-acetyltransferase	Slow/rapid acetylators
Autosomal recessive	Methaemoglobin reductase	Methaemoglobinaemia
Autosomal recessive	Cytochrome P450	Impaired hydroxylation
Autosomal autonomous	Plasma cholinesterase	Suxamethonium apnoea
Autosomal dominant	Ryanodine receptor	Malignant hyperthermia
Autosomal dominant	Porphobilinogen deaminase	Intermittent porphyria

1

Drug metabolism and genetic polymorphism
The main purpose of drug metabolism is to convert lipid-soluble molecules into more polar compounds that can be excreted. The metabolic process is usually divided into two steps:
- phase 1 reactions (non-synthetic or functionalization reactions)
- phase 2 reactions (synthetic or conjugation reactions).

Phase 1 normally results in the oxidation of the parent drug by a non-specific enzyme system, sited in the hepatic endoplasmic reticulum and known as the ‘mixed function oxidase system’. Key components of this system are the cytochrome P450-dependent mono-oxygenases. Phase 2 involves sulphation, glucuronidation or acetylation of unchanged drugs or the products of phase one metabolism. Although most compounds are primarily metabolized by liver enzymes, some agents such as suxamethonium are hydrolysed in plasma by cholinesterase and others are metabolized by different tissues including the gut, kidney and lung. Since the early stages of pharmacogenetics, advances in genotyping technology have been outstanding, one of the most significant steps was the description of variability in drug oxidation mediated by the cytochrome P450 system.

Polymorphisms affecting phase 1 reactions
Most cytochrome P450-mediated drug oxidation in man is catalysed by cytochrome P450 CYP3A4 or cytochrome P450 CYP2D6; both found in liver. CYP3A4 is active primarily in the metabolism of naturally occurring antibiotics, while CYP2D6 metabolizes drugs targeted to the CNS and is also found in brain tissue. Cytochrome P450 determines the biological half-life of most drugs in current clinical use. Therefore, individuality in the expression of its isozymes has therapeutic consequences including:
- no drug effect owing to rapid metabolism and clearance
- lack of pro-drug activation (e.g. conversion of codeine to morphine)
- impaired metabolism leading to accumulation of the drug and toxic side-effects
- activation to toxic products (e.g. paracetamol to N-acetyl-p-benzoquinone immine).

CYP2D6 is not expressed in about 6% of the Caucasian population, which as a consequence, has an altered ability to metabolize a wide range of drugs including β-blockers, antiarrhythmics, tricyclic antidepressants, neuroleptics, opioid analgesics, laudanosine, nitrates, anti-emetics and many other compounds.

Other genetically polymorphic P450 genes include CYP2C19, which normally metabolizes diazepam, CYP2C9, the low activity allele of which is responsible for warfarin toxicity, and CYPIBI for which the phenotypic consequences of variation are not fully understood (see *Anaesthesia and Intensive Care Medicine* **2:8:** 322).

The genes that encode the major enzymes of alcohol metabolism, alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), also exhibit functional polymorphism. The variability in ALDH activity might explain individual and ethnic differences to alcohol intolerance and the variation in susceptibility to ethanol and acetylaldehyde related tissue and organ damage.

Polymorphisms affecting phase 2 enzymes
Phase 2 enzymes including glutathione S-transferase, N-acetyl transferase, sulphotransferase and UDP-glucuronyl transferase (involved in the metabolism of propofol), are also polymorphic and although the consequences of their variability are of less significance than those affecting P450 isozymes both effects can be synergistic.

Polymorphic N-acetylation, due to the presence of multiple alleles at the *NAT2* gene, divides the human population into three possible genotypes:
- homozygote (rapid/rapid)
- heterozygote (slow/rapid)
- homozygote (slow/slow).

These genotypes give rise to two phenotypes: rapid and slow acetylators. This phenomenon applies to drugs including isoniazid, hydralazine, nitrazepam and sulphonamide. For a given dose, slow acetylators have a higher plasma concentration of the drug.

Marked ethnic differences are seen in the distribution of allelic variants of many drug metabolizing enzymes. An example is the presence of the ultra-rapid metabolizer gene, which occurs at frequencies of 20%, 7% and 1.5% in Ethiopian, Spanish and Scandinavian populations, respectively.

Malignant hyperthermia
Malignant hyperthermia is a disorder of the skeletal muscle with an autosomal dominant pattern of inheritance. There is a significant association between susceptibility for the condition and inheritance of DNA markers for the gene coding for ryanodine receptor protein (*RYR1*); about 20 mutations of this gene have been found. Other genetic loci are also associated with malignant hyperthermia in individual families, including a mutation for the gene coding for the dihydropyridine receptor, responsible for excitation–contraction coupling in skeletal muscle. Malignant hyperthermia can be pharmacologically triggered by volatile agents and suxamethonium. For management of the disorder see page 222.

Suxamethonium apnoea
Some people experience prolonged respiratory muscle paralysis following administration of the short-acting depolarizing muscle relaxant suxamethonium, also known as succinylcholine. The cause is a variation in plasma cholinesterase (an enzyme that normally hydrolyses suxamethonium) activity, which is an inherited trait. The pattern of inheritance is autosomal autonomous, with a penetrance between dominant and recessive, so the phenotype is determined by the contribution of each gene. At least four allelic variants of this gene have been identified and are described in more detail elsewhere.

Acute intermittent porphyria
Haem is required for haemoglobin and the cytochromes, including cytochrome P450 function oxidase system. In the UK, 1/10,000 people carry a gene that codes for a defective enzyme (porphobilinogen deaminase) in the haem synthesis pathway. This produces an inborn error of metabolism known as acute intermittent porphyria. Normally patients have no symptoms but acute attacks can be triggered by drugs, including barbiturates, benzodiazepines, cephalosporins, thiazide diuretics and sulphonamides. The result is an increase in the activity of δ-aminolaevulinic acid synthetase with overproduction of δ-aminolaevulinic acid and porphobilinogen which causes abdominal pain, motor neuritis, anxiety and psychosis. It can be fatal.

Hereditary methaemoglobinaemia
The main route for regenerating haemoglobin from methaemoglobin is NADH methaemoglobin reductase, if this enzyme is defective the methaemoglobinaemia produced by oxidizing drugs such as nitrites, nitrates, prilocaine and sulphonamides is prolonged and severe. The reducing agent used to regenerate haemoglobin is methylene blue. ◆

Pharmacokinetic Analysis

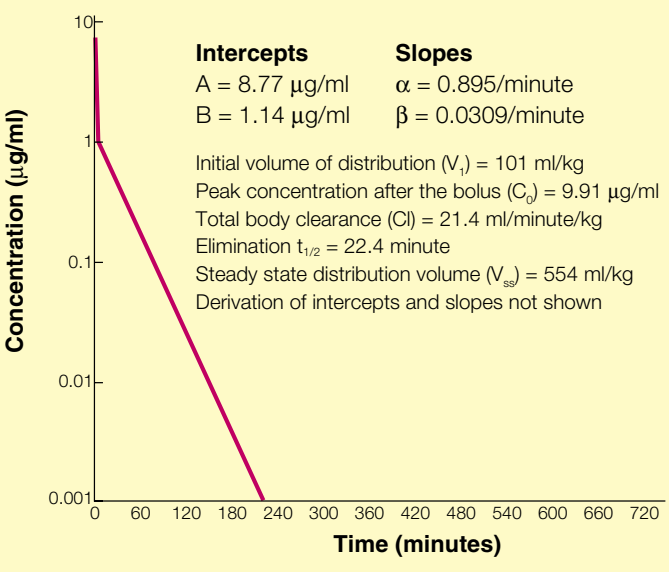
Iain Glen

Iain Glen qualified in veterinary medicine at Glasgow University and became a lecturer in veterinary anaesthesia. Until recently he was a clinical specialist in anaesthesia at AstraZeneca and was closely involved in the development of Diprivan and the Diprifusor target- controlled infusion system.

The purpose of pharmacokinetic analysis is to obtain information on the distribution and elimination of a drug to facilitate the formulation of optimum dosing guidelines. The process involves the administration of a known amount of drug, the collection and analysis of serial blood samples at timed intervals and the use of these data to derive a pharmacokinetic model characterized by a unique set of parameters for each drug. This article explains the rationale behind the derivation of the most important parameters and shows how these parameters influence drug behaviour using lidocaine (lignocaine) and propofol as examples.

Concept of 'compartments'
In pharmacokinetics, a compartment refers to organs or tissues for which the rates of uptake and clearance are similar. For most drugs, the curve for blood or plasma concentration (on a log scale) over time after a bolus injection resembles that in Figure 1. The curve initially falls steeply (distribution phase) as there is rapid movement from the blood into tissues. Thereafter, distribution equilibrium is established as return of drug from well-perfused tissues is balanced by continuing distribution to less well-perfused peripheral tissues, and the slope of this second (elimination) phase represents the rate of removal of drug from the body.

Bi-exponential decline in plasma concentration of lidocaine (lignocaine) after a 1 mg/kg bolus



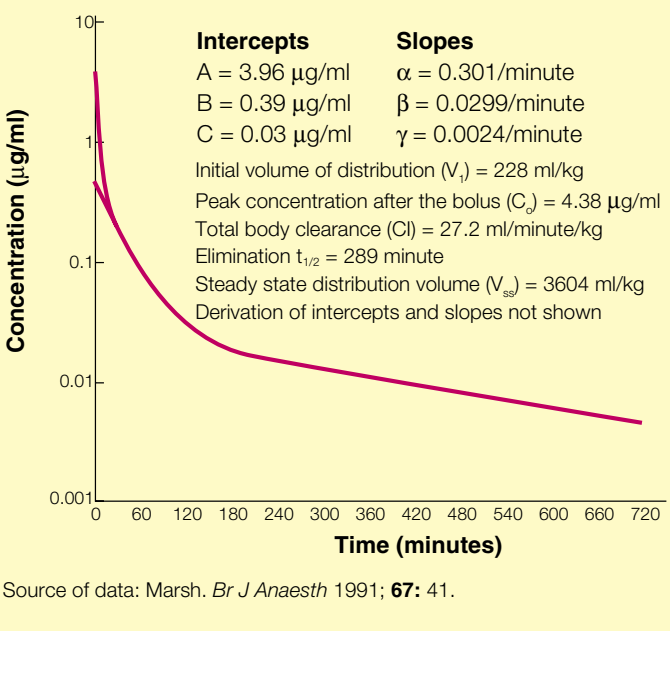
Source of data: Schnider. *Anesthesiology* 1996; **84:** 1043.

1

The two phases are characterized by two exponential terms and from the concentration–time profile, the intercepts A and B and the slopes α and β can be derived. The number of exponentials needed to describe the blood concentration–time curve determines the number of compartments required to characterize the behaviour of a drug. From the primary parameters (A, B, α and β), compartmental model parameters (V_1, k_{10}, k_{12}, k_{21}) can be calculated. The concentration profiles of many anaesthsetic drugs are best described by three phases and therefore a three-compartment model. In these models there are two distribution phases (a rapid and a slower phase) before the terminal elimination phase.

The parameters that best describe the behaviour of a drug are the volumes of distribution (V_1, V_{ss}) and total body clearance (Cl). Loading dose is determined by the initial volume of distribution (V_1) and the maintenance dose by Cl. In the following examples, blood concentration profiles following an intravenous bolus dose of 1 mg/kg of lidocaine (lignocaine) (two-compartment model, Figure 1) or 1 mg/kg of propofol (three-compartment model, Figure 2) are illustrated. The modelling techniques assume linear kinetics – the blood concentration achieved at any time is directly proportional to the dose given.

Tri-exponential decline in blood concentration of propofol after a 1 mg/kg bolus



Source of data: Marsh. *Br J Anaesth* 1991; **67:** 41.

2

Volumes of distribution
V_1, also called the central compartment distribution volume, indicates the apparent space needed to explain the relationship between a given dose and the resulting peak concentration, rather than an actual anatomical volume. The lower the concentration achieved with a given dose, the larger is V_1 and *vice versa*. At equilibrium, drug is distributed throughout all body tissues and the volume required to explain the concentration observed in blood at this time is the steady-state distribution volume (V_{ss}); it equals the sum of the volumes of individual compartments.

$$V_1 \text{ (ml/kg)} = \frac{\text{Dose (μg/kg)}}{\text{A+B (μg/ml) (or A+B+C for a three-compartment model)}}$$

$$C_0 \text{ (μg/ml) (the peak concentration after the bolus)} = \frac{\text{Dose (μg/kg)}}{V_1 \text{ (ml/kg)}}$$

Clearance
The clearance of a drug is a principal determinant of its rate of elimination and is a more useful parameter than elimination half-life ($t_{½}$). Creatinine clearance is an index of renal function. Drug clearance is expressed in units of volume divided by time and is defined as the hypothetical volume of blood from which the substance is completely removed per unit time. If the clearance of a drug is 500 ml/minute, and its concentration in blood is 10 μg/ml, then the amount of drug removed over that minute will be 5000 μg (i.e. 5 mg). If drug is being infused to maintain a steady-state concentration in blood, then the amount required to compensate for clearance is 5 mg/minute. If no further drug is being administered, the amount of drug removed each minute will decrease exponentially with time as the concentration in blood falls. At a given value of Cl, the rate of elimination from the central compartment (k_{10} or k_{el}), which is the rate at which the drug concentration falls as drug is removed each minute, is dependent on V_1:

$$k_{10} \text{ (per minute)} = \frac{\text{Cl (ml/minute/kg)}}{V_1 \text{ (ml/kg)}}$$

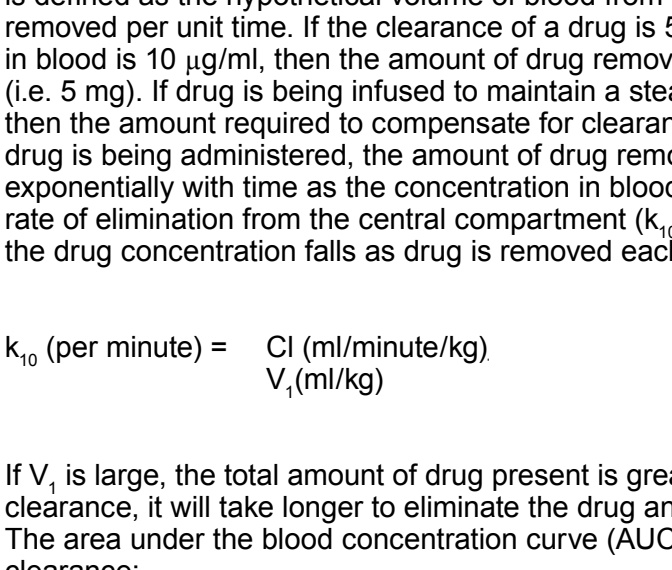
If V_1 is large, the total amount of drug present is greater, such that with constant clearance, it will take longer to eliminate the drug and the value of k_{10} will be smaller. The area under the blood concentration curve (AUC) can also be used to estimate drug clearance:

$$\text{Cl (ml/minute/kg)} = \frac{\text{Dose (μg/kg)}}{\text{AUC (minute/μg/ml)}} \qquad \text{AUC} = \frac{A}{\alpha} + \frac{B}{\beta}$$

Clearance mechanisms: many drugs are cleared by more than one process (e.g. hepatic metabolism and renal excretion) and clearance is the sum of individual organ clearances. In the same way as cardiac output can be determined by the Fick equation as oxygen consumption divided by the difference in oxygen content between arterial and mixed venous blood, the clearance of a drug by an organ such as the liver or kidney is indicated by an arterio-venous concentration difference across the organ. If most of the drug present in arterial blood is cleared by a single transit through an organ the extraction ratio approaches 1 and the drug is said to have a high extraction ratio. Clearance by hepatic metabolism or renal excretion is dependent on the product of blood flow to the organ and the extraction ratio. Thus, a change in organ blood flow will have the greatest effect on the clearance of drugs that are highly extracted by that organ.

Compartmental models
The models most widely applicable to anaesthetic drugs are two- or three-compartment open mamillary models (Figure 3). Drug is administered into the central compartment (V_1) and elimination occurs from this compartment with a rate constant of k_{10}. Distribution occurs from V_1 to a peripheral compartment V_2 (or peripheral compartments V_2 and V_3) with k_{12} and k_{21} being the intercompartmental distribution rate constants.

Two-compartment model for lidocaine (lignocaine)



Source of data: Schnider. *Anesthesiology* 1996; **84:** 1043.

3

In Figure 1, lidocaine (lignocaine) concentrations show an initial short distribution phase followed by a log-linear elimination phase. With propofol (Figure 2) the initial distribution phase lasts longer and is followed by a second distribution phase before the flatter part of the curve (elimination phase) occurs. Metabolism of propofol occurs throughout and the last phase indicates metabolism constrained by the slow return of drug from the periphery. Parameters derived from the intercepts and slopes for these agents have been added to Figures 1 and 2. As the same dose (1 mg/kg) was given with both drugs, the higher initial peak concentration for lidocaine (lignocaine) reflects its lower V_1. Both drugs have high values for clearance, close to hepatic blood flow, and are thus highly extracted agents, despite a marked difference in elimination $t_{½}$ attributable to the much larger V_{ss} of propofol. The intercepts, A, B and C derived from the concentration profile also provide useful information on the contribution of each $t_{½}$ to the decrease in concentration following a bolus dose. In the case of lidocaine (lignocaine), 88% of the decrease occurs during the initial distribution phase. With propofol, 90% and 8.9% occurs during the first and second distribution phases, respectively. Thus, with propofol, the concentration has fallen well below effective concentrations before the slower terminal phase is reached.

Computer simulation

Some aspects of the behaviour of a drug can be derived from pharmacokinetic data, but computer simulation is required to understand the likely consequences of any dosing scheme. V_1, k_{10}, k_{12}, and k_{21} (plus k_{13} and k_{31} if a three-compartment model is required) are the parameters required as inputs for pharmacokinetic simulation programs or the control of an infusion with a target-controlled infusion system. Examples of computer simulation programs that can be obtained via the Internet are PK-SIM, RUGLOOP and STANPUMP (http://anesthesia.stanford.edu/pkpd) and TIVA TRAINER (www.eurosiva.org). They allow possible dosing strategies to be examined and do not require an understanding of the mathematics behind the derivation of the parameters. Figure 4 shows the predicted rates of decline in blood concentrations after a 4-hour infusion of propofol or lidocaine (lignocaine) designed to maintain a blood concentration of 4 μg/ml. Despite the difference in elimination $t_{½}$ between the two agents this simulation shows that the 4-hour context-sensitive half-time (CSHT; the time required for the concentration to fall to 50% of the starting concentration) is similar for the two agents. Predicting the recovery time with propofol depends on the percentage reduction required from the starting concentration to reach the 'waking concentration' and this may be more or less than the 50% of the CSHT. Another merit of computer simulation is the ability to predict the time of peak effect of a drug by the addition of an 'effect compartment' to the model with $t_{½}$ k_{e0} describing the rate that drug concentrations in the biophase equilibrate with those in blood. Such simulations demonstrate the more rapid onset of alfentanil in comparison with fentanyl. ◆

Predicted propofol and lidocaine (lignocaine) concentrations after a 4-hour infusion

Pharmacokinetic Variation

Iain Glen

Iain Glen qualified in veterinary medicine at Glasgow University and became a lecturer in veterinary anaesthesia. Until recently he was a clinical specialist in anaesthesia at Astra Zeneca and was closely involved in the development of Diprivan and the Diprifusor target- controlled infusion system.

The consequence of pharmacokinetic variation is that the administration of a given dose of a drug will result in a range of different drug concentrations in a population of patients. If the concentration is low, lack of efficacy may result and if the concentration is high, side-effects may be increased. An understanding of possible sources of variation in the pharmacokinetic behaviour of a drug can help to ensure that in an individual patient the most appropriate dose to achieve a desired clinical end-point is selected. Variation in the response to a given concentration of drug at the effector site is also important in predicting the overall response to the administration of a particular dose.

Measuring pharmacokinetic variability
Information on pharmacokinetic variability is usually obtained after administration of a drug by serial measurement of its concentrations in blood. In this way, the mean time–concentration profiles, and inter-individual variability at particular time points, can be examined. More sophisticated studies may use the principles of population pharmacokinetic analysis whereby a small number of blood samples are collected from a large and diverse population of patients. Analysis of the data obtained quantifies inter- and intra-patient variability and attempts to link variation to patient characteristics, organ function or co-administered drugs.

Predictions of the likely effect of pathophysiological changes on pharmacokinetic variability may also be obtained from studies in experimental animals, where the contribution of individual organs to total body clearance can be investigated by looking at arteriovenous concentration differences across a particular organ such as the liver or kidney. *In vitro* systems, incorporating recombinant human drug-metabolizing enzymes have been used to investigate drug metabolism and to predict the likelihood of possible pharmacokinetic interactions with other drugs.

Physiological models
Physiological models have been used to predict how blood and tissue concentrations of a drug change with time. These models require detailed information on the mass of different tissues, their blood flow as a proportion of cardiac output and partition coefficients. Once established they can be used to predict the influence of changes in physiological parameters and have particular benefits when modelling drugs the pharmacological effects of which include changes, for example in cardiac output, which could influence their own disposition. One of the earliest models was developed by Price and his colleagues in 1960 and used to demonstrate the importance of redistribution to the termination of the effect of a bolus dose of thiopental (thiopentone). This model also explained the reduced dose requirements of patients in haemorrhagic shock because the fraction of the dose received by the brain was then high and its rate of removal slow, owing to the decreased blood flow to other tissues. Recently, another model for thiopental (thiopentone) disposition in man has predicted greater peak arterial concentrations in patients with low versus high cardiac output and in those who are lean versus the obese. Changes with gender and age were relatively minor. This model indicates that differences in basal cardiac output may explain much of the variability between patients in early thiopental (thiopentone) disposition. As increasingly sophisticated models are developed they may be incorporated in desktop computer simulation programs or in whole-body anaesthesia simulators for teaching and training.

Sources of pharmacokinetic variability

The four main processes that determine the pharmacokinetic behaviour of a drug are absorption from the site of administration, distribution within the body, metabolism and excretion. In many patients, age, weight, physiological changes caused by pregnancy or disease processes, drug interactions, and the effects of anaesthesia and surgery may also affect pharmacokinetics. Assay sensitivity or the duration of sampling may also account for variable results.

Absorption
Gastrointestinal absorption may be slowed by atropine or opiates, which inhibit gastrointestinal motility, or accelerated by metoclopramide, which hastens gastric emptying. Peak blood concentrations of some orally administered drugs are normally limited by first-pass metabolism in the liver. In elderly patients, a reduction in hepatic blood flow may reduce this first-pass effect leading, for example, to increased blood concentrations of propranolol. First-pass metabolism of drugs metabolized by cytochrome P450 (e.g. midazolam, diazepam) may be reduced by inhibitors of this enzyme (e.g. itraconazole, grapefruit juice) leading to increased bioavailability of the hypnotic agents. The addition of a vasoconstrictor to local anaesthetic drugs injected into tissues or the epidural space reduces their systemic uptake leading to prolongation of the local block and a reduction in the peak concentrations obtained in blood. Central neuraxial blockade produces circulatory changes (vasodilatation in regions denervated by the block and compensatory vasoconstriction in other areas) such that differences may occur in venous drug concentrations depending on the sampling site, with values closer to arterial concentrations in vasodilated regions.

Distribution
The initial volume of distribution (V_1) is not simply the circulating blood volume but includes tissues that equilibrate rapidly with the blood concentration. The peak concentration reached after a bolus or short infusion of thiopental (thiopentone) or propofol, is influenced by body weight, changes in blood volume and the mass of rapidly equilibrating tissues, and cardiac output. The greater the cardiac output, the greater the dilution of blood entering the pulmonary artery during the administration of a bolus or short infusion. Thus, peak blood concentrations in the systemic situation may be decreased, and dose requirements increased, when cardiac output is increased, for example with anxiety or hyperthyroidism, in young children compared with adults, and in the later stages of pregnancy. Conversely, a decrease in cardiac output leads to less initial dilution, higher peak concentrations and slower redistribution to peripheral tissues.

The overall volume of distribution at steady state (V_{ss}) depends on the mass of tissue available, the physicochemical nature of the drug (lipid-soluble drugs have a greater V_{ss} than water-soluble agents) and protein binding. Only unbound drug can diffuse across cell membranes, but the total amount of drug in some tissues may be greater than in others because of binding to tissue components. A reduction in plasma albumin is commonly associated with hepatic or renal failure. This leads to decreased plasma binding, an increased free drug concentration and more rapid distribution of drug from plasma, thus increasing V_{ss}.

Muscle mass is greater and adipose tissue mass smaller in men compared with women. Thus, when compared on a ml/kg basis, water-soluble drugs have larger distribution volumes in men and highly lipid-soluble drugs (e.g. diazepam, propranolol) have larger distribution volumes in women. A decline in lean tissue mass with age occurs in men and women.

Metabolism
Drug metabolism occurs primarily in the liver. Drugs such as propranolol or propofol that show total body clearance values close to hepatic blood flow (i.e. about 1.5 litre/minute) are known as high-extraction drugs (Figure 1). For these drugs, clearance depends on liver blood flow and is minimally affected by changes in plasma protein binding because virtually all drug passing through the liver is extracted, whether bound or not. With low-extraction drugs (e.g. phenytoin, warfarin) hepatic clearance is limited by drug-metabolizing enzyme activity and the extent of protein binding influences hepatic clearance. With these drugs, the hepatic extraction ratio is less than the free fraction and any decrease in plasma binding (and increase in free fraction) as a consequence of disease or displacement by a more highly bound drug, can increase their hepatic clearance.

Factors influencing hepatic clearance

Highly extracted drugs
Clearance = Hepatic blood flow (e.g. propranolol)

- Clearance affected by changes in hepatic blood flow
- Enzyme induction/inhibition or changes in protein binding have minimal effect

Poorly extracted drugs
Clearance << Hepatic blood flow (e.g. warfarin)

- Clearance affected by changes in hepatic metabolic activity, enzyme induction or inhibition
- Changes in protein binding may affect clearance

1

Intrinsic hepatic clearance of agents metabolized by cytochrome P450 may be increased by the induction of this enzyme by drugs such as phenobarbital (phenobarbitone), phenytoin or alcohol or decreased by a reduction in hepato-cellular mass or by drugs such as cimetidine, erythromycin or disulfiram, which inhibit this enzyme. With drugs such as propofol, with high intrinsic clearance (principally glucuronidation), impairment of hepatic function leads to little difference in hepatic elimination because the normal liver has a great reserve of metabolic capacity. Variability in the clearance of midazolam has been attributed to inter-individual genetic differences in the activity of the P450 isoform CYP3A.

Excretion
In patients with renal failure, drugs excreted by the kidney, including digoxin, some antibiotics and neuromuscular blocking drugs, show decreased clearance, closely parallel to that of creatinine. In general, a reduction in protein binding has only a small effect on renal excretion. Diuretic drugs increase the excretion rate of renally cleared drugs.

Weight and gender
Some gender-related changes in drug distribution are mentioned above. Where a clear relationship between body weight and volume of distribution or clearance of a drug has been demonstrated, reduced variability can be expected by dosing on a mg/kg basis. In obese patients, the increase in total body weight correlates with an increase in propofol clearance. Clearance of midazolam is not increased in obese volunteers and it would be more appropriate to adjust infusion rates based on ideal as opposed to total weight. A recent model for remifentanil advocates scaling of V_1 to age and lean body mass. Women have less efficient clearance of drugs such as propranolol, temazepam and lidocaine (lignocaine). Gender has little effect on the kinetics of remifentanil or propofol, though a recent study described a 10% increase in propofol clearance in elderly women compared with elderly men.

Age
Some drug-metabolizing enzymes are immature in neonates. In general, drugs that have high intrinsic clearance are relatively unaffected by immature metabolic pathways whereas drugs with lower intrinsic clearance (e.g. thiopental (thiopentone)) are affected to a greater extent. Maturation usually occurs rapidly and infants are likely to show an increase in V_1 and clearance relative to adults. In elderly patients, the usual trend is a decrease in V_1 and clearance, which may be related to a decline in hepatic blood flow. With midazolam, a reduction in clearance in elderly men leads to a prolongation of the elimination half-life following intravenous dosing and increased bioavailability of an oral dose. Similar differences were not found between elderly and young women. Remifentanil and propofol show age-related decreases in clearance and central volume of distribution. The albumin concentration in plasma, and thus plasma protein binding, tends to be reduced in elderly patients, with the increased free fraction leading to enhanced distribution to extravascular tissues. Reduced renal function with advancing age reduces the clearance of drugs that are normally excreted by the kidney.

Pregnancy
In later pregnancy, cardiac output increases and plasma volume increases by 50% in the third trimester. A reduction in plasma protein binding favours distribution into extravascular tissues. These changes may explain the larger V_{ss} and longer elimination half-life of thiopental (thiopentone) in patients undergoing caesarean section.

Pathological conditions
The magnitude of any effect (decreased clearance) depends on the importance of hepatic metabolism or renal excretion for each drug. Impairment of hepatic metabolic activity is likely to have the greatest effect on drugs such as theophylline, pancuronium and vecuronium, which in healthy patients have low intrinsic hepatic clearance. Increased V_{ss}, decreased clearance and increased elimination half-life have been observed with diazepam in patients with alcoholic cirrhosis, whereas the pharmacokinetics of propofol are not significantly affected by moderate cirrhosis.

Renal excretion is important for a number of commonly used neuromuscular blocking drugs with 50–60% of pancuronium and 20–30% of the administered dose of vecuronium eliminated by this route. The elimination of both atracurium, by Hofmann degradation, and remifentanil, metabolized by circulating and tissue esterases, is independent of hepatic and renal function and is unaffected by renal or hepatic failure.

When propofol is used as a sedative in ICU patients over several days, clearance values are similar to those seen during anaesthesia. A longer elimination half-life has been seen in ICU patients, possibly related to the longer period of sampling, but this is unlikely to delay recovery after long infusions.

Smoking and alcohol
Smoking induces cytochrome P450, thereby increasing the clearance of drugs metabolized by oxidative pathways in the liver. High alcohol intake also induces drug metabolizing activity such that dose requirements may be increased but much of this effect may be related to pharmacodynamic changes in alcoholic patients. As alcoholism progresses towards liver failure, the enhancement of hepatic metabolism is reversed.

Other drugs
A number of examples of drugs affecting the absorption, distribution or metabolism of other drugs have been given above. In general, these are drugs that affect volume of distribution by changes in cardiac output or changes in their unbound fraction; or that affect clearance by inducing or inhibiting hepatic enzyme activity. Anaesthetic drugs with negative inotropic effects (e.g. halothane), slow the peripheral distribution of other agents by reducing cardiac output, thus tending to increase the blood concentration of co-administered agents. Such drugs also reduce the clearance of highly extracted drugs (e.g. lidocaine (lignocaine), propofol, fentanyl, propranolol) by reducing hepatic blood flow. A drug such as propofol, at high concentrations, could reduce its own clearance, thus contributing to intra-patient variability in kinetics at different depths of anaesthesia. The co-administration of alfentanil and propofol leads to elevated concentrations of both.

Anaesthesia and surgery
The haemodynamic effects of anaesthetic drugs may alter the distribution and clearance of other agents. In addition, the haemodynamic response to painful stimuli, as a result of inadequate anaesthesia, may modify drug distribution and reduce hepatic and renal blood flow. During abdominal surgery, pressure on major blood vessels may result in temporal variation in drug distribution and clearance. In anaesthesia for cardiopulmonary bypass, a transient decrease in drug concentrations in blood can be expected with haemodilution at the onset of bypass. However, because the greatest amount of drug is present in peripheral compartments rather than the circulation, equilibration across compartments restores blood concentrations. Induced hypothermia reduces hepatic metabolic efficiency leading to an increase in drug concentration if a constant administration rate is maintained. With both thiopental (thiopentone) and propofol an increase in unbound fraction has been observed.

Predicting the effects of pharmacokinetic variation

Predicting the clinical consequences of observed changes can be complex because of the interrelationship between different pharmacokinetic parameters. The blood concentration achieved after the intravenous administration of a given loading dose is principally dependent on the initial volume of distribution:

$$\text{Concentration} = \frac{\text{Dose}}{\text{Volume}}$$

Thus, any factor that decreases V_1 increases the peak blood concentration and *vice versa*. As the duration of drug administration increases and steady-state conditions are approached, the rate of infusion required to maintain a particular drug concentration is principally dependent on the clearance of the drug:

Rate of infusion = concentration at steady state x clearance

If clearance is increased, the infusion rate required is increased and *vice versa*.

Distribution occurs not only within V_1 but also to peripheral tissues (V_2 and possibly V_3 if a three-compartment model is appropriate). The sum of these volumes is V_{ss}. Elimination half-life ($t_{½}$) is influenced by the total volume of drug to be cleared (V_{ss}) and the rate of clearance. Elimination half-life is increased if V_{ss} is increased in the presence of unchanged clearance or if clearance is decreased with no change in V_{ss}. Alterations of V_{ss} and clearance in the same direction may have little influence on elimination half-life depending on the magnitude of the respective changes. The elimination half-lives of many drugs used in anaesthesia are a poor indicator of duration of action. With drugs whose kinetics fit multicompartment models, blood concentrations may have declined below effective levels before the terminal phase becomes dominant in the elimination profile. A more useful descriptor for comparing different drugs is the context sensitive half time (CSHT), which is the time required for the blood concentration to fall to 50% of the concentration that has been maintained for a specified duration. This descriptor emphasizes the importance of the duration of administration and takes account of the significant contribution of continuing distribution in lowering the blood concentration. Elimination half-life is independent of duration of administration whereas estimations of CSHT for fentanyl indicate that recovery is rapid after short infusions but delayed after prolonged administration.

Implications for target controlled infusion
Target controlled infusion systems, such as *Diprifusor* for the administration of propofol, use a pharmacokinetic model that represents an average patient. The amount of drug delivered at a given target concentration setting is standardized to the body weight of the patient but the blood concentration achieved varies between patients, such that titration of the target setting to the requirement of each patient is required. With target controlled infusion, a steady-state blood concentration is achieved more rapidly and titration is facilitated by the ability to make proportional changes to the blood concentration in a controlled manner.

Managing pharmacokinetic variability

Pharmacokinetic variability is a feature of biological variability and it is impossible to adjust dosage to achieve the effect desired in every patient. Pharmacokinetic and pharmacodynamic variability can be accounted for, if a drug can be titrated to achieve a desired effect. An understanding of potential sources of pharmacokinetic variability can guide the direction in which titration may be required. Drugs for which the therapeutic effect cannot be achieved by individual dose titration and for which the therapeutic margin is small may require therapeutic monitoring of drug concentrations. ◆

Pharmacological Control of Blood Sugar

Leonard Best

Leonard Best is Senior Lecturer in Cell Physiology at Manchester University. He obtained his BSc in Biochemistry at Sheffield University and his PhD in Endocrinology at Aston University. His research interests include the physiology of the pancreatic β cell, mechanisms of glucose sensing by islet cells and hypothalamic neurons and glucose toxicity.

Under normal physiological circumstances, the blood glucose concentration is controlled by circulating hormones. Normal fasting blood glucose concentrations are 3.3–5.6 mmol/litre. A significant fall below this range induces the release of glucagon from the pancreatic islet α cells. This hormone stimulates glucose synthesis from certain metabolic intermediates and causes the breakdown of glycogen to glucose in the liver, from which the glucose is released into the blood. Cortisol released from the adrenal cortex in response to stress or starvation also raises hepatic glucose output. Following a meal, and largely as a result of raised blood glucose levels, the pancreatic islet β cells release insulin. This hormone stimulates glycogen synthesis in the liver and promotes glucose uptake into peripheral tissues (predominantly skeletal muscle and adipose tissue). Insulin also stimulates the metabolic disposal of glucose in peripheral tissues, notably glycogen synthesis in muscle and glucose conversion to triglyceride in adipose tissue. Administration of insulin and glucagon, together with a wide variety of pharmacological agents, can be used in the treatment of abnormal blood glucose homeostasis (Figure 1).

Agents that affect blood glucose concentration

Agents that lower blood glucose
Insulin – stimulates glucose uptake and metabolism in peripheral tissues
Hypoglycaemic sulphonylureas – stimulate insulin release
Meglitinides – stimulate insulin release
Biguanides – have insulin-like action
Thiazolidinediones – have insulin-sensitizing action
α-glucosidase inhibitors – inhibit digestion of starches to glucose in gut

Agents that raise blood glucose
Glucagon – stimulates hepatic glucose output
Diazoxide – inhibits insulin release

1

Diabetes mellitus

A major clinical application for agents that influence blood glucose levels is the treatment of diabetes mellitus. Diabetes is a common condition. In the UK, there are about 1.4 million diagnosed cases, representing about 3% of the population, and it is likely that an additional 1 million individuals have undiagnosed diabetes. The incidence of diabetes mellitus is increasing, possibly by 4–5% per year. At present, it is the fourth most common cause of death in developed countries. Diabetes mellitus is a heterogeneous condition, but consists of two principal types. Type I diabetes is also known as insulin-dependent diabetes, but is often referred to as juvenile-onset diabetes, because it is usually manifest before the age of 40 years (most commonly between 10 and 16 years). Type II, non insulin-dependent diabetes, is commonly referred to as maturity-onset diabetes, because it usually appears in those over 40. About 80–90% of diabetic patients are not insulin dependent.

Aetiology

Both types of diabetes result from insufficient insulin, but their aetiology is distinct. Type I diabetes is the result of an auto-immune condition whereby the body mounts an immunological attack specifically on the insulin-producing pancreatic β cells. This results initially in impaired function and eventually in destruction of the β cells. The initial trigger for the autoimmune response is unknown, but it is likely that a combination of genetic susceptibility and environmental factors (possibly including viral infections) plays an important role.

Type II diabetes is thought to result from impaired β cell function and reduced insulin release in response to a rise in blood glucose concentration. This condition is also often associated with obesity and with insulin resistance, where the sensitivity of peripheral tissues (notably skeletal muscle, adipose tissue and the liver) to insulin is reduced. Susceptibility involves a genetic predisposition, while age, poor diet, high body weight and sedentary lifestyle are contributory factors. Some pharmacological agents exert diabetogenic actions and can precipitate or unmask diabetes mellitus. These include immunosuppressive drugs, certain diuretics, glucocorticoids and some oral contraceptives. Diabetes can also be precipitated by pregnancy.

Symptoms and complications

Insufficient insulin release or impaired insulin action results in hyperglycaemia. This leads to glucosuria, polyuria and thirst. Type I diabetes is often associated with ketoacidosis, where fat is broken down to free fatty acids, which are then converted in the liver to ketoacids (acetoacetate, β-hydroxybutyrate). These substances provide an alternative energy supply to tissues starved of glucose through lack of insulin. However, their formation can result in a significant fall in blood pH, leading to functional and metabolic disturbances, and in extreme cases, coma.

Long-term complications are discussed on page 317. In general, their incidence and severity increases with inadequate control of hyperglycaemia, and it seems likely that they arise, at least in part, as a consequence of prolonged exposure of tissues and/or the microvasculature to raised glucose levels. This phenomenon has been termed glucose toxicity. Thus, the major objective in the treatment of diabetes is the long-term control of blood glucose levels.

Treatment

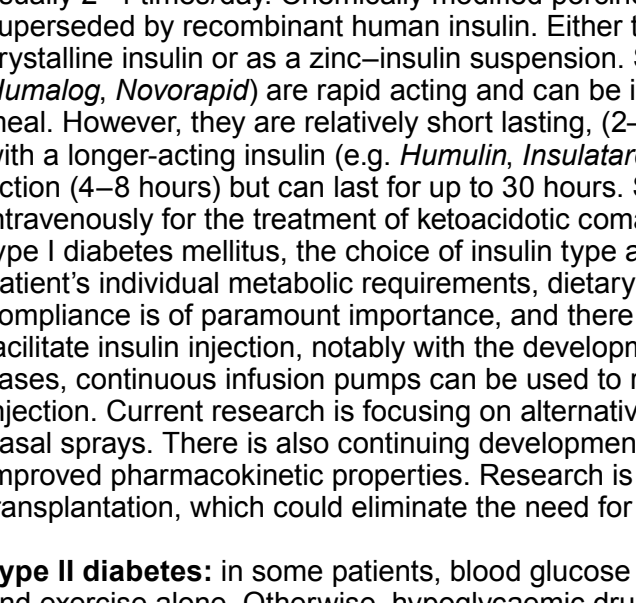
An important factor in the management of both types of diabetes is diet, which should be low in fat and simple sugars with a relatively high proportion of complex carbohydrate. Such a diet provides a limited rate of glucose absorption from the gut and avoids large increases in glycaemia. Physical exercise should be encouraged because it increases glucose uptake and utilization in peripheral tissues, especially skeletal muscle, and thus has an insulin-sparing action. Exercise also reduces body weight and blood pressure and improves cardiovascular function, all of which are of benefit in diabetes.

Type I diabetes: treatment almost invariably involves subcut-aneous insulin injection, usually 2–4 times/day. Chemically modified porcine insulin is gradually being superseded by recombinant human insulin. Either type can be administered as soluble crystalline insulin or as a zinc–insulin suspension. Soluble insulin preparations (e.g. *Humalog*, *Novorapid*) are rapid acting and can be injected 5–30 minutes before a meal. However, they are relatively short lasting, (2–8 hours) and may require mixing with a longer-acting insulin (e.g. *Humulin*, *Insulatard*), which has a slower onset of action (4–8 hours) but can last for up to 30 hours. Soluble insulin can be injected intravenously for the treatment of ketoacidotic coma. For the day-to-day treatment of type I diabetes mellitus, the choice of insulin type and mixture is determined by the patient's individual metabolic requirements, dietary and exercise regimens. Patient compliance is of paramount importance, and there has been considerable effort to facilitate insulin injection, notably with the development of pen-type injectors. In some cases, continuous infusion pumps can be used to reduce or eliminate the need for injection. Current research is focusing on alternative routes of administration such as nasal sprays. There is also continuing development of chemically modified insulins with improved pharmacokinetic properties. Research is directed at the possibility of islet transplantation, which could eliminate the need for insulin therapy.

Type II diabetes: in some patients, blood glucose levels can be controlled by diet and exercise alone. Otherwise, hypoglycaemic drugs can be used. There are several classes of oral hypoglycaemic agent that act in different ways, most commonly by stimulating insulin output from the pancreas or by enhancing glucose uptake and utilization by peripheral tissues. They can be used individually or, more commonly, combined in a stepwise manner to optimize glycaemic control. For example, sulphonylureas are potent drugs and therefore are preferable for use in more severely hyperglycaemic patients with little or no insulin resistance. On the other hand, the biguanides, thiazolidinediones and α-glucosidase inhibitors may be of greater value in the treatment of mildly hyperglycaemic patients and those with insulin resistance. Oral hypoglycaemic drugs may also be used in combination with insulin therapy to reduce insulin requirement.

Hypoglycaemic sulphonylureas – the first-generation sulphonylureas, tolbutamide and chlorpropamide, are largely obsolete and second-generation drugs, including glibenclamide (also called glyburide in the USA), gliclazide and glipizide, are in widespread use. Recently developed third-generation sulphonylureas (e.g. glimepiride) are more selective and show fewer side-effects. Sulphonylureas act by directly stimulating insulin release from the pancreatic β cell. The drug binds to a specific protein on the cell surface (the sulphonylurea receptor, SUR1; Figure 2) which forms part of a potassium channel (the K_{ATP} channel). Sulphonylurea binding to the SUR results in closure of the channel which depolarizes the β cell membrane. This leads to opening of voltage-sensitive calcium channels and calcium entry into the cell which is the trigger for insulin release. Some sulphonylureas, especially third-generation drugs, may also increase insulin sensitivity. Side-effects of the sulphonylureas include nausea, skin rash and hypoglycaemia. The latter is caused by excessive insulin release and can be prolonged.

The pancreatic β cell K_{ATP} channel complex



2

Meglitinides (e.g. repaglinide, nateglinide) act in a similar manner to the sulphonylureas, exerting a direct stimulatory effect on insulin release from the pancreatic β cells. Side-effects include nausea and skin rashes, but because meglitinides have a more rapid action and shorter duration than sulphonylureas, they may elicit a more physiological insulin profile during meals with a reduced tendency to provoke hypoglycaemia.

Biguanides – metformin, the most commonly used biguanide, lowers blood glucose levels in a number of ways, including reduced hepatic glucose output and increased glucose uptake into muscle and adipose tissue. Biguanides may also impair glucose absorption from the gut and reduce hyperlipidaemia**.** Side-effects include stomach upsets and nausea.

Thiazolidinediones are a relatively new class of drug that include rosiglitazone, troglitazone and pioglitazone. Thiazolidinediones increase the sensitivity of tissues to insulin, thereby counteracting the insulin resistance often associated with type II diabetes. Their mechanism of action involves binding to the nuclear peroxisome proliferator-activated receptors (PPAR). This alters the transcription of genes involved in carbohydrate and fat metabolism, ultimately increasing insulin-mediated glucose disposal in peripheral tissue (especially skeletal muscle). Side-effects include headaches, oedema and weight gain.

α-glucosidase inhibitors (e.g. acarbose) impair the enzymatic hydrolysis of complex carbohydrates in the gut, thereby reducing the rate of glucose liberation and absorption into the blood following a meal. Side-effects include diarrhoea.

Hypoglycaemia

Hypoglycaemia is a potentially hazardous side-effect in the treatment of diabetes mellitus, both with insulin injection and hypoglycaemic sulphonylureas. Precipitating factors include missing a meal and unaccustomed exercise. In severe cases, hypoglycaemia can result in coma and rapid action must be taken to restore blood sugar levels. This can be achieved by oral glucose (3–4 lumps of sugar with water) if the patient is conscious or by intravenous infusion (50 ml of 50% glucose solution) if unconscious. A number of hyperglycaemic agents are also available.

Glucagon is a peptide hormone and can be injected by any route (subcutaneous, intramuscular, intravenous) for the treatment of acute hypoglycaemia if glucose administration is impossible. Glucagon acts by mobilizing liver glycogen and thus increasing hepatic glucose output.

Diazoxide is usually reserved for the treatment of chronic hypoglycaemia caused by excessive insulin release. This can be the result of an insulinoma or prolonged hypoglycaemia and hyperinsulinaemia in infancy (PHHI) which is relatively rare. PHHI is characterized by a constantly high output of insulin and is thought to result from a genetic defect in the sulphonylurea receptor whereby the β cell is permanently depolarized and thus actively secreting. Diazoxide is given orally and raises blood glucose levels by a direct inhibition of insulin release from the pancreatic β cell. The drug binds to the sulphonylurea receptor associated with the K_{ATP} channel (Figure 2) but, in contrast to the sulphonylureas and meglitinides, this results in activation of the potassium channel thereby hyperpolarizing the cell membrane and preventing calcium entry and insulin release.

Anaesthetic management

For the anaesthetic management of the diabetic patient see elsewhere. ◆

Pharmacological Effects of Drug Degradation Products

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Most drugs are lipophilic and can cross biological membranes to their site of action. However, lipophilicity hinders their elimination from the body, therefore metabolism of these drugs to more polar compounds that can be excreted via the kidney is essential to terminate their action. Generally metabolites are inactive, but sometimes drugs are converted into metabolites that are pharmacologically active. A pro-drug is inactive in its own right but is metabolized in the body to an active compound. Alternatively, the parent drug may be active and then metabolized into another active drug that may have beneficial or adverse effects.

Pro-drugs

Many pro-drugs were discovered long after the drug had been introduced into therapeutics. For example, phenacetin was introduced into therapeutics in 1887 and was widely used as an analgesic. It was not until 1949 that paracetamol was recognized as the active metabolite and began to take over the market share from phenacetin, which was then being implicated in analgesic abuse nephropathy.

Other drugs have been designed as pro-drugs because they confer therapeutic advantages. Parkinson's disease is associated with a loss of dopamine from the nigrostriatal tracts and can be treated by replacing dopamine. However, dopamine is poorly absorbed, therefore its precursor, inactive levodopa, is given and it is converted to dopamine within the body.

Zidovudine is converted to its active triphosphate metabolite only in cells containing reverse transcriptase, which is present only in cells infected with the human immunodeficiency virus. Some other pro-drugs are listed in Figure 1.

Pro-drugs

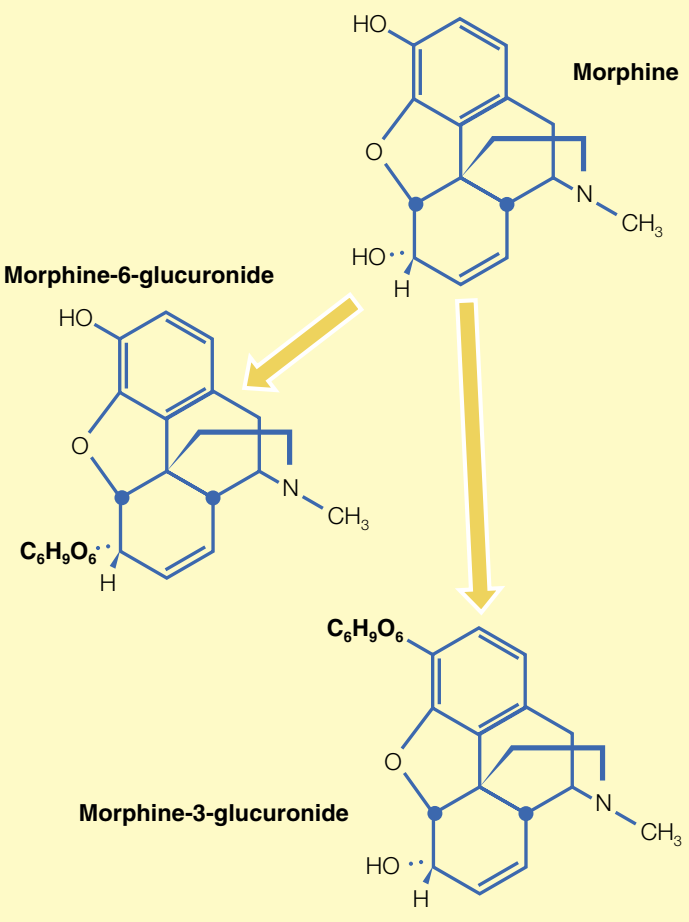
Pro-drug	Active metabolite	Comment
• Azathioprine	Mercaptopurine	Immunosuppressant
• Cyclophosphamide	Phosphoramide mustard	Converted to an alkylating agent by the liver Reduces potential intestinal toxicity
• Enalapril	Enalaprilat	Angiotensin converting enzyme inhibitor Active metabolite can be given only intravenously because it is not absorbed orally
• Cortisone	Hydrocortisone	Cortisone is better absorbed orally
• Sulphasalazine	5-aminosalicylic acid	Metabolized to active agent by bacteria in the large intestine Gives a local anti-inflammatory action in ulcerative colitis
• Aciclovir	Aciclovir triphosphate	Metabolized by herpes viruses and the host viral infected cell
• Benorylate	Salicylic acid and paracetamol	Parent drug is highly lipid soluble Conversion occurs in the liver so intestinal toxicity of acid is reduced

1

Drugs where parent and metabolite have similar pharmacological activity

The opioid analgesic morphine is a typical example of this type of drug. Morphine has an elimination half-time of 3 to 4 hours and it is metabolized in the liver to glucuronides (Figure 2). Morphine-6-glucuronide is a more potent analgesic than the parent drug and may contribute significantly to the therapeutic actions of morphine. Glucuronides are excreted in the urine, therefore the dose of morphine may require reduction in cases of renal failure. It has been suggested that the analgesic effects of morphine-6-gluronide are mediated by a splice variant of the μ opioid receptor but no significant clinical difference between the pharmacological actions of the parent and metabolite have been reported. In contrast, morphine-3-glucuronide has been reported to have some opioid antagonistic properties but the importance of this in the overall activity of morphine is unclear.

Metabolism of morphine



2

Benzodiazepines are renowned for being metabolized to active compounds, often with longer half-lives that the parent drug. Diazepam has a half-life of 20–40 hours and is metabolized to nordiazepam with a half-life of over 60 hours. Nordiazepam has its own active metabolite of oxazepam with a half-life of 8–12 hours. Oxazepam is conjugated with glucuronide before excretion and this final metabolite is devoid of pharmacological action. These active metabolites may contribute significantly to the hangover effects of these anxiolytics and some clinicians prefer to use compounds that are metabolized only to inactive compounds (e.g. oxazepam, lorazepam).

Two antidepressant compounds, imipramine and amitriptyline, are metabolized to desmethylimipramine and nortriptyline, respectively, which have antidepressant actions of their own.

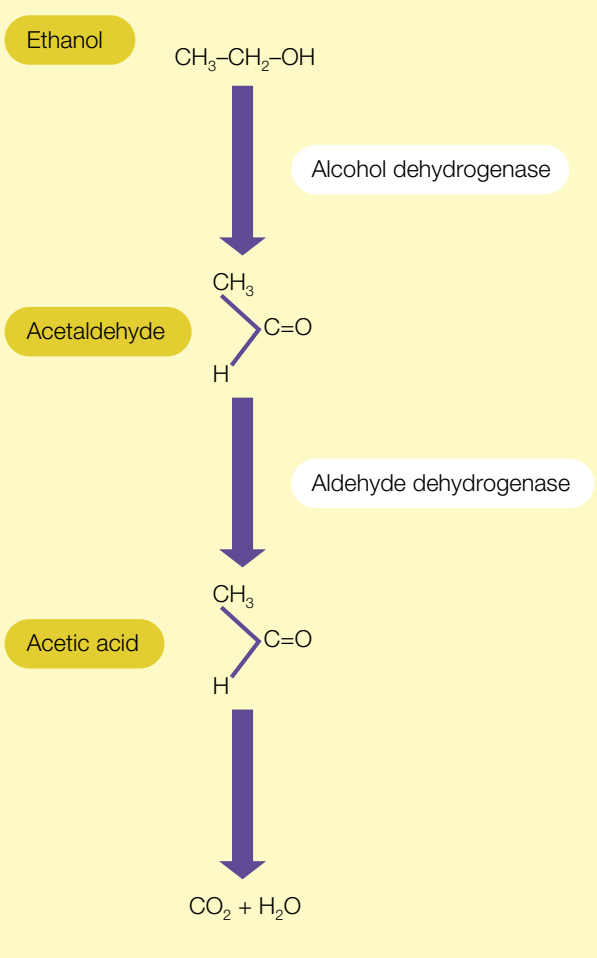
Drugs producing toxic metabolites

In therapeutic doses, paracetamol is conjugated with glucur-onide or sulphate and excreted harmlessly. If the enzymes responsible for conjugation are saturated, then paracetamol is metabolized by the mixed function oxidase system to N-acetyl-benzoquinoneimine. This toxic metabolite is conjugated with glutathione. If glutathione is depleted then the toxic metabolite accumulates and binds with cell macromolecules to cause cell death, particularly in the liver and kidney.

The toxic effects of inhalational anaesthetics may be related to their metabolites in that the most metabolized ones, methoxyflurane and halothane, are associated with renal and hepatic toxicity, respectively. Methoxyflurane is mainly of historical interest. Up to 70% of the inhaled drug was metabolized to free fluoride and oxalic acid. Both these metabolites are nephrotoxic and the incidence of toxicity was such that the popularity of methoxyflurane waned rapidly. Halothane is not normally metabolized to fluoride ion, but its oxidative metabolite, trifluoroacetyl chloride can be covalently bonded to some hepatic proteins, which may, in susceptible individuals, act as antigens. Hepatotoxicity results from the antigen/antibody reaction. Despite the rarity of this problem, it eroded the popularity of halothane and preference is now given to less metabolized agents, which are not thought to pose a similar threat.

Another anaesthetic, ethanol, has an active metabolite acetaldehyde (Figure 3).

Metabolism of ethanol



3

Acetaldehyde produces headache and vomiting, a property that is used in the use of disulphiram in ethanol aversion therapy. Disulphiram inhibits aldehyde dehydrogenase causing a build-up of the aldehyde whenever ethanol is consumed.

Methanol, a common industrial solvent, is metabolized by the same pathway, but the metabolites (formaldehyde and formic acid) have significantly greater toxicity than the equivalent ethanol metabolites. Methanol intoxication can result in blindness. The affinity of ethanol for alcohol dehydrogenase is 100-fold greater than the affinity of methanol for the enzyme. Thus, ethanol can be used competitively to inhibit the metabolism of methanol in cases of methanol poisoning. Similarly, ethanol can be used to treat ethylene glycol toxicity. Ethylene glycol is metabolized by the same route, yielding nephrotoxic metabolites. ◆

Pharmacological Modulation of Myocardial Function, Vascular Resistance and Blood Pressure: Drugs used During Cardiopulmonary Resuscitation

Roger Small

Roger Small is Reader in Pharmacology in the School of Biological Sciences at Manchester University. He qualified with a BSc in Pharmacy from Manchester University and his research interests have focused on the electrophysiology and pharmacology of smooth muscle, notably that of the airways.

This article describes the pharmacology of modulators of cardiac function, antihypertensive drugs, vasopressor drugs and agents used during cardiopulmonary resuscitation. The present discussion of drugs used to modulate myocardial function includes inotropic agents and anti-anginal drugs; the pharmacology of antidysrhythmic drugs will be addressed in a future issue.

Modulators of myocardial function

Positive inotropic agents

Inotropic agents increase myocardial contractility and thus increase cardiac output.

Cardiac glycosides

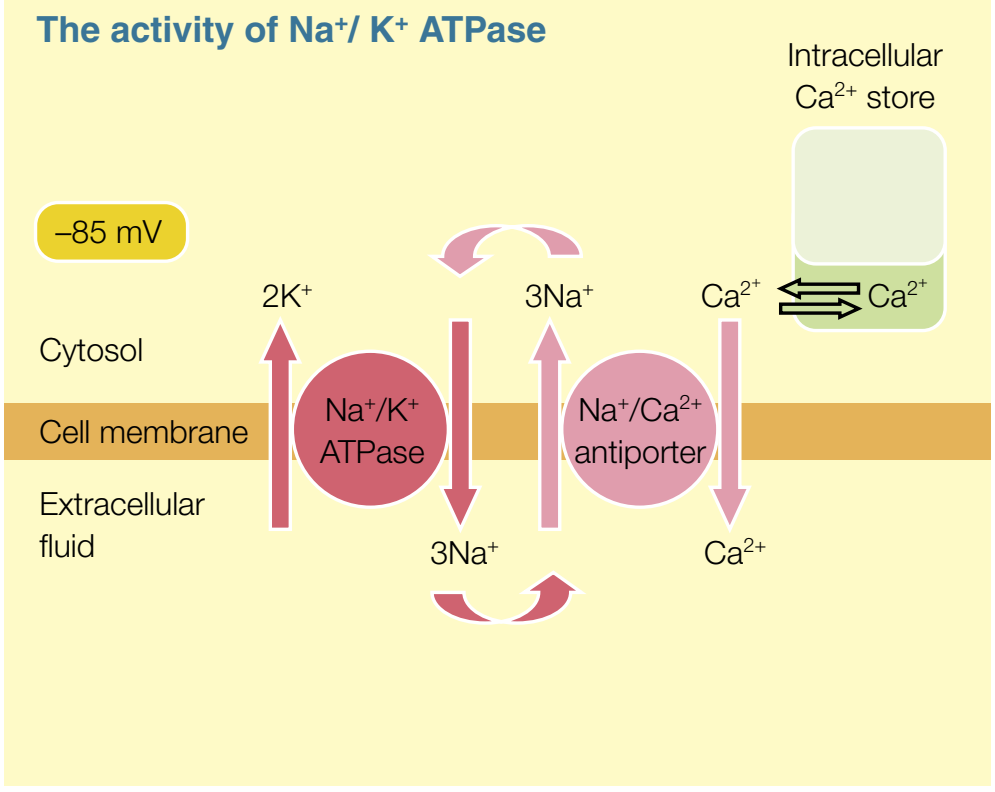
Digoxin is a cardiac glycoside; it binds to the extracellular surface of the α-subunit of plasmalemmal Na^+/K^+ ATPase (Figure 1) and inhibits this transporter. Na^+/K^+ ATPase utilizes the energy derived from the hydrolysis of ATP to transport $2K^+$ ions into the cell while extruding $3Na^+$ ions. The enzyme is thus electrogenic and helps to generate the transmembrane potential of the cell. The activity of Na^+/K^+ ATPase is intimately linked to that of the Na^+/Ca^{2+} antiporter. Na^+ ions extruded by the activity of Na^+/K^+ ATPase are transported back into the cell by the Na^+/Ca^{2+} antiporter. During this process Ca^{2+} is extruded into the extracellular fluid. By regulating the cytosolic concentration of Ca^{2+}, the Na^+/Ca^{2+} antiporter helps to control the content of the intracellular Ca^{2+} store (Figure 1). Digoxin-induced inhibition of Na^+/K^+ ATPase results in cellular depolarization, increased cytosolic Na^+ and, thus, inhibition of the Na^+/Ca^{2+} antiporter. Ca^{2+} ions that would have been extruded by the antiporter are redirected to the intracellular Ca^{2+} store. Treating a contracting cardiac muscle cell with digoxin results in a larger rise in the cytosolic free Ca^{2+} concentration and thus more forceful contraction. The shape of the action potential is not significantly altered by digoxin, therefore the positive inotropic action of the glycoside results from increased release of Ca^{2+} from the (more completely filled) intracellular store rather than from increased cellular influx of Ca^{2+}.

Digoxin depresses conduction through the atrioventricular (AV) node. The mechanisms underlying this effect include depolarization of nodal cells, the activation of baroreceptors (triggered by a rise in blood pressure secondary to increased cardiac output) or the direct stimulation of central vagal centres. The latter two effects increase vagal tone to the AV node. In addition, digoxin may directly sensitize the nodal cells to acetylcholine.

The depressant action of digoxin on the AV node is exploited in the treatment of supraventricular arrhythmias (e.g. atrial fibrillation). Digoxin may convert atrial tachycardia into atrial flutter, or atrial flutter into atrial fibrillation. However, conduction through the AV node is depressed, therefore a slower and more stable ventricular rate is achieved. The positive inotropic action of digoxin is exploited in the treatment of congestive cardiac failure in patients remaining symptomatic despite optimal treatment with angiotensin converting enzyme (ACE) inhibitors (see below) and diuretics. Digoxin does not increase the life expectancy of patients with congestive cardiac failure. It does, however, suppress symptoms and reduce the patients' need for hospitalization.

Digoxin has a low therapeutic index (about 2:1). Signs of toxicity include nausea and vomiting, disturbances of vision (acuity and colour) and ventricular tachydysrhythmias. The tachydysrhythmias result from increased automaticity of Purkinje fibres, which thus act as ventricular ectopic foci. The toxicity of digoxin is increased by hypokalaemia (e.g. the use of diuretics that promote K^+ excretion and conditions such as secondary hyperaldosteronism). The treatment of digoxin toxicity includes stopping its administration and correcting any hypokalaemia (KCl tablets or intravenous infusions containing KCl + NaCl or KCl + glucose). Ventricular tachydysrhythmias may be controlled by propranolol or phenytoin. Digoxin-specific antibody fragments (e.g. *Digibind*) may be given by intravenous infusion in order to neutralize the glycoside.

The activity of Na^+/K^+ ATPase



1

Inhibitors of cyclic nucleotide phosphodiesterase: cyclic nucleotide phosphodiesterase catalyses the hydrolysis of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP) to yield the less biologically active AMP or GMP, respectively. There are several isoenzymes of phosphodiesterase, which have different substrate specificity (cAMP or cGMP), tissue distribution and sensitivity to inhibitors. The activity of phosphodiesterase type 3 is strongly expressed in cardiac muscle, its inhibition leads to an increase in the cAMP content of cardiac muscle and thus an increase in the rate and force of contraction.

Enoximone and milrinone are selective inhibitors of phosphodiesterase type 3. When used to treat congestive cardiac failure, they may have some haemodynamic benefit. However, they tend to induce ectopic beats and tachydysrhythmias. By inhibiting phosphodiesterase type 3 in vascular smooth muscle, they cause vasodilatation, headache and hypotension. They do not increase the life expectancy of patients with cardiac failure.

Sympathomimetic inotropes

Dopamine is a metabolic precursor of noradrenaline and adrenaline. It is a neurotransmitter in the brain and, possibly, in the periphery. Dopamine is a directly acting agonist at α_1- and β_1-adrenoceptors. It is also an indirectly acting sympathomimetic, because it can displace noradrenaline from neuronal storage vesicles. It can also activate dopamine D_1-receptors in the renal vasculature. Dopamine produces a mixture of effects on the cardiovascular system. The force of cardiac contraction is increased owing to the activation of cardiac β_1-adrenoceptors. Vasodilatation (D_1-receptor activation) may occur in the renal and mesenteric vascular beds while vasoconstriction (activation of α_1-adrenoceptors) may occur elsewhere.

Dopamine is used in the treatment of cardiogenic shock following myocardial infarction or cardiac surgery. It has a short half-life (2 minutes), and is therefore administered by intravenous infusion into a central, rather than a peripheral, vein. At relatively low dose rates (e.g. 2–5 μg/kg/minute) renal perfusion may be improved. Higher dose rates yield a better improvement in cardiac output, but the renal vasodilator action may be lost as a consequence of α_1-adrenoceptor activation.

Dobutamine is an agonist that acts directly on adrenoceptors. It is relatively selective for the α_1-adrenoceptor but may also activate the β_1-adrenoceptor. It increases the force of cardiac contraction with relatively little effect on cardiac rate. Why dobutamine should have little chronotropic effect is poorly understood. Dobutamine has a half-life of about 2 minutes. It is administered by intravenous infusion in order to improve cardiac output in septic shock or in cardiogenic shock associated with myocardial infarction, cardiac surgery or cardiac myopathy.

Xamoterol is a partial agonist at β_1-adrenoceptors. Its use is restricted to the treatment of mild heart failure. In moderate or severe cardiac failure, increased sympathetic neural tone plays a more important role in maintaining cardiac output. Xamoterol is contraindicated in this situation, because, as a partial agonist at β_1-adrenoceptors, it reduces the effects of neurally released noradrenaline (a full agonist) and may thus aggravate the condition.

Dopexamine is a directly acting agonist at both β_2-adrenoceptors and dopamine D_1-receptors. By activating the relatively small number of cardiac β_2-adrenoceptors it can improve cardiac output. It may improve renal perfusion by the activation of dopamine D_1-receptors. Dopexamine is used in the treatment of chronic heart failure or heart failure secondary to cardiac surgery; it is administered by infusion into a central vein or a large peripheral vein.

Anti-anginal drugs

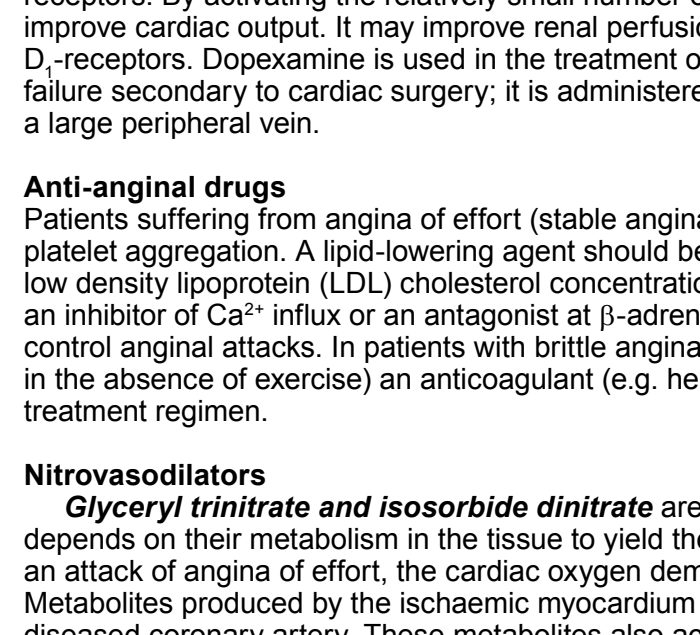
Patients suffering from angina of effort (stable angina) should receive aspirin to inhibit platelet aggregation. A lipid-lowering agent should be prescribed if the patient's plasma low density lipoprotein (LDL) cholesterol concentration is elevated. A nitrovasodilator, an inhibitor of Ca^{2+} influx or an antagonist at β-adrenoceptors may be prescribed to control anginal attacks. In patients with brittle angina (when attacks are experienced in the absence of exercise) an anticoagulant (e.g. heparin) should be added to the treatment regimen.

Nitrovasodilators

Glyceryl trinitrate and isosorbide dinitrate are prodrugs; their biological activity depends on their metabolism in the tissue to yield the active principle (Figure 2). During an attack of angina of effort, the cardiac oxygen demand exceeds the oxygen supply. Metabolites produced by the ischaemic myocardium evoke maximal dilatation of the diseased coronary artery. These metabolites also activate the sensory nerve terminals that mediate the sensation of anginal pain. Since myocardial ischaemia itself promotes maximal dilatation of the diseased coronary artery, that artery cannot represent a major site of action for the nitrates in relieving the anginal attack. Low doses of organic nitrates dilate capacitance veins. As a result, the venous filling pressure of the heart is reduced. Since the myocardial fibres are less stretched at the end of diastole and they contract less forcibly (Starling law), stroke volume is reduced. This is partly compensated for by a reflex tachycardia. Nevertheless, a fall in cardiac output occurs. The main effect of the nitrates in alleviating an attack of angina of effort is to reduce the cardiac work rate by reducing the preload. In this way, the imbalance between cardiac oxygen demand and supply is restored. In higher doses, the organic nitrates also dilate arterioles, and thus reduce peripheral resistance and cardiac afterload. Nitrate-induced arteriolar dilatation also corrects the imbalance between cardiac oxygen demand and supply, by reducing the cardiac work rate. The organic nitrates may also dilate collateral vessels in the ischaemic myocardium, thus improving blood flow distal to the point of occlusion in the diseased artery. Glyceryl trinitrate is ineffective if swallowed because it is metabolized to inorganic nitrate in the liver. It is administered as sublingual tablets, a buccal spray, transdermal patches, an ointment or as an intravenous injection. The duration of action of the sublingual tablets is 20–30 minutes.

Isosorbide dinitrate is effective when swallowed and its activity depends on its metabolism to the mononitrate form. It can be administered by a variety of routes. The duration of action of the sustained-release tablets can be up to 12 hours. For this reason the development of tolerance (depletion of tissue SH groups) is more likely than for glyceryl trinitrate. Side-effects of the nitrates include skin flushing, sweating, throbbing headache, orthostatic hypotension and reflex tachycardia.

Vasodilatation induced by organic nitrates



GTP, guanosine triphosphate; cGMP, cyclic guanosine monophosphate

2

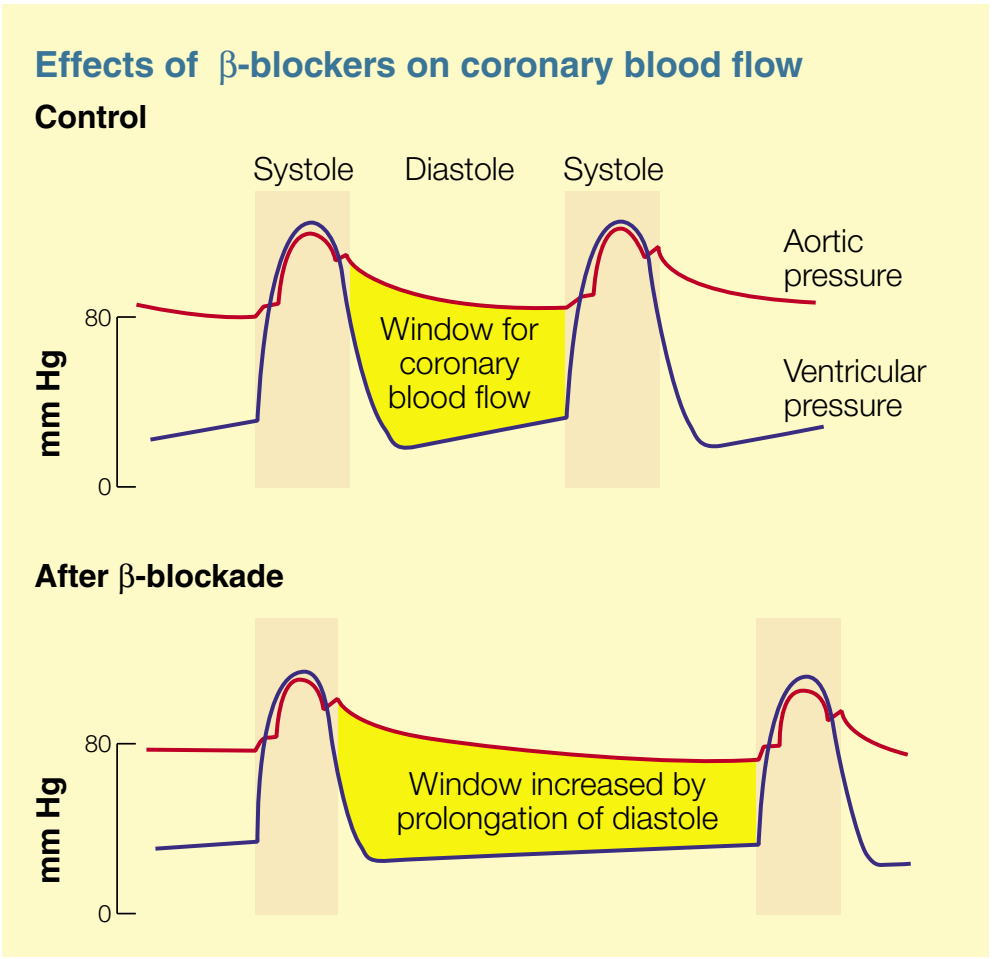
Ca^{2+} influx inhibitors

Nifedipine, verapamil and diltiazem – nifedipine (a dihydropyridine), verapamil (a phenylalkylamine) and diltiazem (a benzothiazepine) each inhibit the cellular influx of Ca^{2+} through the L-type voltage-sensitive Ca^{2+} channel. The binding site for nifedipine is on the extracellular surface of the α-subunit of the L-type Ca^{2+} channel. For this reason, blockade of the L-type channel by nifedipine shows no dependency on the frequency at which the channel opens (i.e. no use-dependency). However, binding of nifedipine to the L-type channel is enhanced if the resting membrane potential of the cell is relatively low, a situation in which a significant proportion of the channels will be in an inactivated state. The resting membrane potential of vascular smooth muscle is about –50 mV while that of the ventricular myocardium is about –85 mV, therefore nifedipine will preferentially bind to the L-type channels of vascular smooth muscle. For this reason, nifedipine is more potent in depressing the activity of vascular smooth muscle than that of cardiac tissue. The principal effect of nifedipine in relieving angina of effort is to dilate both arterioles and capacitance veins. By this means, cardiac preload and afterload are both reduced. The cardiac work rate is reduced and the imbalance between cardiac oxygen demand and supply is corrected.

Verapamil and diltiazem each have a binding site on the α-subunit of the L-type Ca^{2+} channel at its intracellular surface. These drugs can gain access to their binding sites only by passing through the open pore of the L-type Ca^{2+} channel. Thus, their activity is dependent on the frequency of channel opening (use-dependent action). Since the L-type Ca^{2+} channels of cardiac tissue open more often than those of vascular smooth muscle, verapamil and diltiazem are more potent in depressing the activity of cardiac tissue than that of vascular smooth muscle. The principal effect of these drugs in relieving angina of effort is to reduce the rate and force of cardiac contraction directly. They may secondarily reduce cardiac afterload by dilating arterioles. By reducing the cardiac work rate, the imbalance between cardiac oxygen demand and supply is corrected. Side-effects of the inhibitors of Ca^{2+} influx are described below.

Antagonists at β-adrenoceptors

Propranolol and atenolol – sympathetic neural tone to the heart is increased during physical exercise. Noradrenaline, released from the nerves, activates β_1-adrenoceptors to increase the rate and force of cardiac contraction. Propranolol and atenolol act as antagonists at β-adrenoceptors. Propranolol has approximately equal affinity for β_1- and β_2-adrenoceptors whereas atenolol is relatively selective for β_1-adrenoceptors. By competing with noradrenaline for occupancy of the cardiac β_1-adrenoceptors, these agents attenuate the cardiac effects of exercise. Cardiac work rate is thus reduced and, in the patient with angina of effort, the imbalance between cardiac oxygen demand and supply is corrected. Coronary blood flow is relatively low during systole because the contracting ventricular muscle tends to compress the arteries that run through it. Most of the coronary blood flow therefore occurs during diastole. By reducing cardiac rate, the antagonists at β-adrenoceptors prolong diastole. Improved coronary blood flow may thus contribute to their anti-anginal effects (Figure 3). Side-effects of the antagonists at β-adrenoceptors are described below.

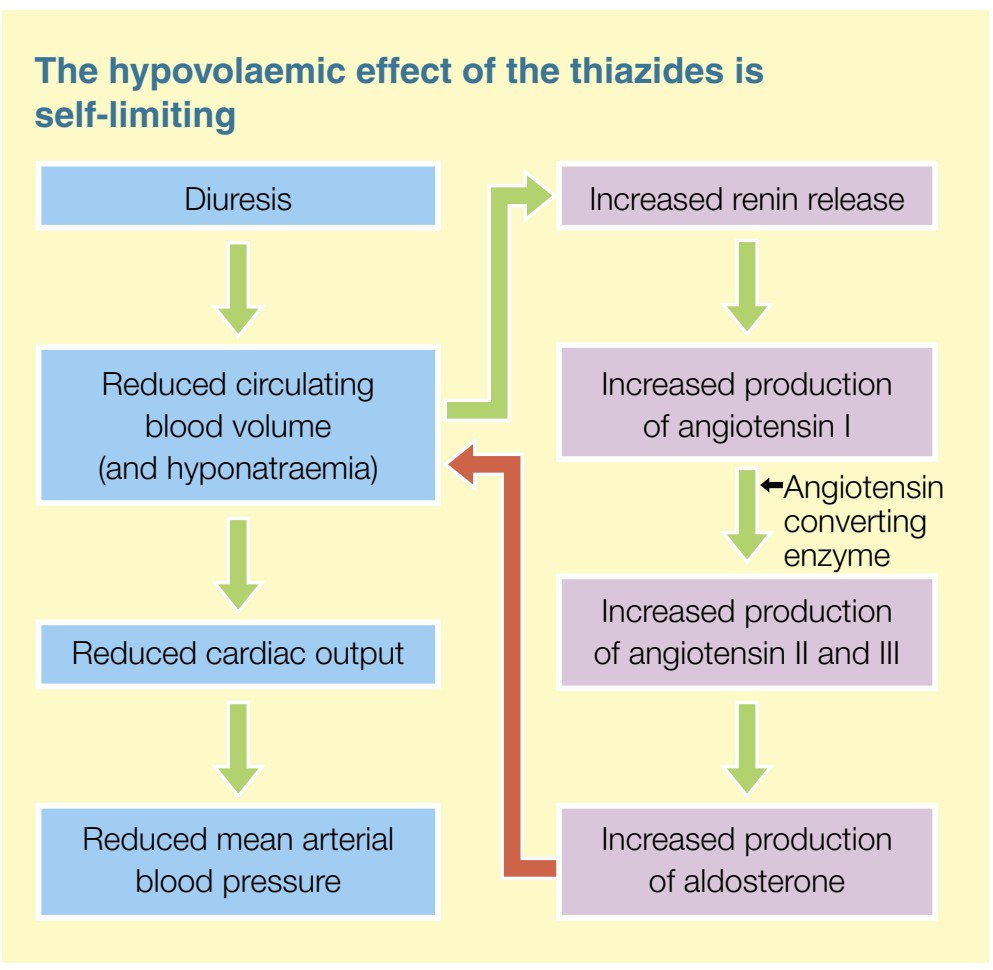


3

Antihypertensive drugs

Thiazide diuretics

Bendrofluazide (bendroflumethiazide) and chlortalidone (chlorthalidone) inhibit Na^+ and water reabsorption in the renal distal convoluted tubule. The resultant diuresis leads to a reduction in circulating blood volume thereby lowering cardiac output and mean arterial blood pressure. However, the resultant hyponatraemia and reduced renal blood perfusion activate the renin–angiotensin system so that the thiazide-induced effect on circulating blood volume and plasma Na^+ concentration is self-limiting (Figure 4). Despite this, the reduction in mean arterial blood pressure is maintained. The sustained hypotensive effect results from thiazide-induced opening of K^+ channels in the plasmalemma of arteriolar smooth muscle cells with resultant arteriolar dilatation and reduced peripheral resistance. Side-effects of the thiazides include hypokalaemia (stimulation of Na^+/K^+ exchange in the renal collecting ducts), aggravation of gout (competition with uric acid for active secretion into the renal proximal convoluted tubule), hyperglycaemia and impotence (reversible on cessation of treatment and of low incidence). A low dose of thiazide (e.g. bendrofluazide (bendroflumethiazide), 2.5 mg/day) produces a near-maximal lowering of blood pressure with little biochemical disturbance. Higher doses do not confer additional advantage.



4

Antagonists at β-adrenoceptors

Propranolol and atenolol: the mechanism by which these agents reduce blood pressure may involve a reduction in cardiac output (blockade of cardiac β_1-adrenoceptors), a reduction in renin release (blockade of β_1-adrenoceptors on renal juxtaglomerular cells), a central action involving reduced outflow of sympathetic neural impulses to the periphery, or a combination of these actions. Side-effects of the antagonists at β-adrenoceptors include the aggravation of bronchial asthma (blockade of β_2-adrenoceptors on airways smooth muscle), the precipitation of cardiac failure (blockade of cardiac β_1-adrenoceptors), and aggravation of both Raynaud's phenomenon (cold hands) and claudication. The antagonists at β_1-adrenoceptors also mask the sympathetically mediated sweating and tremor that warns the insulin-dependent, diabetic patient of impending hypoglycaemia. Propranolol is relatively lipid soluble, can cross the blood–brain barrier and may induce vivid dreams. Atenolol is more water-soluble and is less likely to cross the blood–brain barrier.

Ca^{2+} influx inhibitors

Nifedipine, verapamil and diltiazem: the antihypertensive action of nifedipine stems mainly from its ability to dilate arterioles and thus to reduce peripheral resistance. In contrast, the antihypertensive actions of verapamil and diltiazem involve a direct reduction in cardiac output and a fall in peripheral resistance owing to arteriolar dilatation. Side-effects of nifedipine include flushing, headaches, dizziness and ankle swelling. Verapamil and diltiazem may also cause constipation, bradycardia, heart block and precipitation of cardiac failure.

ACE inhibitors

Captopril and enalapril: the ACE inhibitors are used to control hypertension when thiazides and β-adrenoceptor antagonists have failed to produce adequate lowering of blood pressure, are contraindicated or are poorly tolerated. ACE inhibitors can cause a profound fall in blood pressure, therefore the first dose (e.g. captopril, 12.5 mg) is best given at bedtime. ACE catalyses the conversion of angiotensin I to angiotensin II (vasoconstrictor and stimulant of aldosterone secretion), and is also responsible for the inactivation of bradykinin (a vasodilator). The hypotensive effects of the ACE inhibitors thus result from reduced production of angiotensin II and reduced metabolic inactivation of bradykinin. Side-effects of ACE inhibitors include angioedema and a dry cough, both triggered by the accumulation of bradykinin. ACE inhibitors interfere with the renin–angiotensin system, therefore they may act synergistically with thiazide diuretics. ACE inhibitors should be avoided in patients with renal artery stenosis, because they can reduce glomerular filtration to a level that promotes renal failure.

Antagonists at the angiotensin II receptor

Loasartan and valsartan compete with angiotensin II for occupancy of its receptors on vascular smooth muscle. The resultant arteriolar dilatation leads to a fall in peripheral resistance and thus a fall in mean arterial blood pressure. Unlike the ACE inhibitors, they do not inhibit the metabolism of bradykinin and therefore do not cause angioedema or dry cough. In view of the risk of precipitating renal failure, great caution should be exercised when using angiotensin II antagonists in patients with renal artery stenosis.

Antagonists at α-adrenoceptors

The α_1- and α_2-adrenoceptors found in vascular smooth muscle mediate vasoconstriction. The plasmalemma of the noradrenergic nerve terminal bears α_2-adrenoceptors, which mediate inhibition of noradrenaline release. These presynaptic or prejunctional receptors are activated during the noradrenergic neurotransmission process and exert negative feedback control over transmitter release.

The use of non-selective antagonists at α-adrenoceptors results in a fall in peripheral resistance and thus a fall in blood pressure. This hypotensive effect is accompanied by a reflex tachycardia as a result of baroreceptor activity. However, blockade of the α_2-adrenoceptors on noradrenergic neurons supplying the heart augments noradrenaline release at that site, thus accentuating the reflex tachycardia. For this reason, antagonists at both the α_1- and α_2-adrenoceptors find little use in the treatment of essential hypertension.

Prazosin is a competitive antagonist that is relatively selective for the α_1-adrenoceptors. It lowers blood pressure by blocking α_1-adrenoceptors on arterioles and thus reducing peripheral resistance. Its hypotensive effect is accompanied by an acceptable degree of reflex tachycardia. It is used to control hypertension when other therapies have proved ineffective or unacceptable. Side-effects include postural hypotension and retrograde ejaculation of seminal fluid into the bladder resulting from blockade of α_1-adrenoceptors in the smooth muscle of the bladder neck.

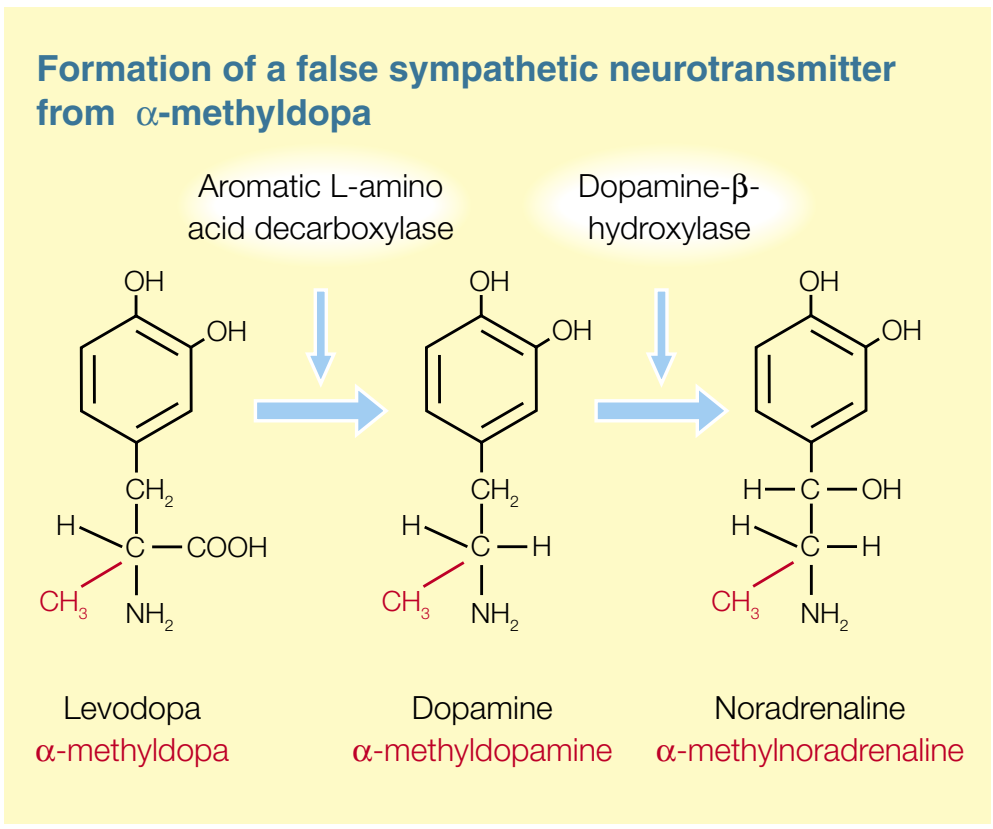
Phenoxybenzamine is an alkylating agent and an irreversible antagonist at both α_1- and α_2-adrenoceptors. It is used (in conjunction with an antagonist at α-adrenoceptors) to prevent hypertensive crises during the surgical removal of a phaeo-chromocytoma or in the long-term management of inoperable phaeochromocytoma.

Phentolamine is a competitive antagonist at both α_1- and α_2- adrenoceptors. It is sometimes used used as a diagnostic test for phaeochromocytoma. In the presence of excessive amounts of circulating catecholamines, the test dose of phentolamine induces a greater fall in blood pressure than otherwise expected.

Centrally acting antihypertensive drugs

Methyldopa is a prodrug, requiring metabolic conversion to yield its active principle, α-methylnoradrenaline (Figure 5). α-methylnoradrenaline is handled by the noradrenergic neuron in the same way as noradrenaline. It is retained in the granular storage vesicles and may be released into the junctional or synaptic cleft when the neuron terminal is invaded by a nerve action potential. α-methylnoradrenaline is thus said to function as a false transmitter. Measured at postjunctional α_1- or α-adrenoceptors, the potencies of noradrenaline and α-methylnoradrenaline are approximately equal. However, measured at the α_2-adrenoceptors on the noradrenergic neuron terminal, the potency of α-methylnoradrenaline exceeds that of noradrenaline. Thus, release of this false transmitter from the nerve terminal causes exaggerated feedback inhibition of neurotransmitter release. The noradrenergic neurotransmission process is therefore inhibited.

Methyldopa is actively transported into the CSF and brain. It inhibits noradrenergic neurotransmission within the medullary centres that regulate blood pressure. The outflow of sympathetic nerve impulses to the heart and blood vessels is reduced and blood pressure therefore falls. Methyldopa is considered safe for antihypertensive use in patients suffering from bronchial asthma and in toxaemia of pregnancy. Side-effects include drowsiness, depression, and salt and water retention. In about 20% of patients, methyldopa induces antibodies to rhesus antigens on erythrocytes (positive Coomb's test). In less than 1% of patients this may lead to haemolytic anaemia.



5

Clonidine is a potent, directly acting agonist at the 2-adrenoceptors on the noradrenergic neuron terminal. Its mechanism of hypotensive action is similar to that of -methylnoradrenaline. Side-effects include drowsiness, depression, and salt and water retention. Sudden withdrawal of clonidine may provoke a hypertensive crisis.

Ganglion-blocking drugs

Trimetaphan camsylate: the nicotinic acetylcholine receptor in autonomic ganglia is a ligand-gated cation channel. Trimetaphan acts as an antagonist of acetylcholine at this receptor, not by competing with acetylcholine for occupancy of its binding site, but by blocking the cation channel pore. The blockade of transmission through sympathetic ganglia produced by trimetaphan leads to arteriolar dilatation, a fall in peripheral resistance and thus a fall in blood pressure. Trimetaphan is administered by intravenous infusion to lower blood pressure in certain types of surgery, particularly if a bloodless field of operation is required.

Other antihypertensive drugs

Hydralazine is a vasodilator and thus lowers blood pressure by reducing peripheral resistance. Its mechanism of action may involve interference with the ability of the intracellular second messenger, inositol trisphosphate, to induce the release of Ca^{2+} from the endoplasmic reticulum of the vascular smooth muscle cell. Side-effects include reflex tachycardia and fluid retention. It also tends to induce an autoimmune condition similar to systemic lupus erythematosus.

Sodium nitroprusside is a vasodilator that lowers blood pressure by reducing peripheral resistance. Its mechanism of action is similar to that of the organic nitrovasodilators (Figure 2). Sodium nitroprusside is useful in the emergency lowering of blood pressure. The effects of an intravenous infusion are seen within 1–2 minutes, but the hypotensive effect wanes rapidly when the infusion is stopped. Sodium nitroprusside is metabolized in the blood and liver to form thiocyanate. Accumulation of this toxic metabolite limits the time for which the drug may be infused.

Vasopressor agents

Sympathetic block is a hazard of spinal or epidural anaesthesia. The hypotension that results from sympathetic block may be treated using sympathomimetic vasoconstrictor agents. These drugs acivate α_1-adrenoceptors (and in some cases 2-adrenoceptors) on vascular smooth muscle either directly or indirectly. The resultant arteriolar constriction increases peripheral resistance and thus restores blood pressure. However, this effect may occur at the expense of reduced perfusion of vital organs, such as the kidney. Sympathomimetic agonists that are not substrates for the neuronal uptake process for noradrenaline (e.g. methoxamine, phenylephrine and metaraminol) may evoke a long-lasting elevation of blood pressure.

Noradrenaline acid tartrate (norepinephrine bitartrate): noradrenaline is the neurotransmitter of most postganglionic sympathetic neurons. It also has a transmitter role in the CNS. Noradrenaline is a directly acting agonist at all types of adrenoceptor. It not only evokes vasoconstriction, but also stimulates the heart.

Methoxamine hydrochloride is a directly acting agonist exhibiting selectivity for 1- and α2-adrenoceptors. It thus has no direct stimulant effect on the heart. Its vasoconstrictor action is useful in the correction of hypotension associated with tachycardia.

Phenylephrine hydrochloride is a directly acting agonist exhibiting selectivity for the α1- adrenoceptor. It has no direct stimulant effect on the heart.

Metaraminol is a directly acting agonist at both α- and β-adrenoceptors. It evokes vasoconstriction and stimulates the heart.

Ephedrine hydrochloride has little direct action on adrenoceptors. Ephedrine is a substrate for the neuronal noradrenaline uptake process. Ephedrine stoichiometrically (molecule for molecule) displaces noradrenaline from its storage vesicles. Much of the displaced noradrenaline escapes to activate the postjunctional adrenoceptors and mediate the (indirect) sympathomimetic effect of ephedrine. The noradrenaline released by ephedrine evokes vasoconstriction and stimulates the heart. This makes ephedrine particularly useful when hypotension is associated with bradycardia. The vasoconstrictor action of ephedrine may be susceptible to tachyphylaxis (depletion of neuronal noradrenaline stores) and is reduced when the neuronal uptake process is inhibited (e.g. abuse of cocaine).

Adrenaline (epinephrine) is the principal hormone secreted by the chromaffin cells of the adrenal medulla. It may also have neurotransmitter and neuromodulatory roles within the CNS. Adrenaline (epinephrine) is a directly acting agonist at both - and β-adrenoceptors. It is vital in the treatment of anaphylactic shock. Features of this condition include laryngeal oedema, bronchospasm and profound hypotension. Treatment consists of securing the airway and administering oxygen. Restoration of blood pressure is attempted by laying the patient flat with both feet raised. Adrenaline (epinephrine), 500 µg, is administered by intramuscular injection every 5 minutes until improvement occurs. In the severely ill patient, adrenaline (epinephrine), 500 µg for an adult, may be given by slow intravenous injection at a rate of 100 µg/minute, the infusion being terminated when improvement is observed. Adrenaline reduces capillary permeability and thus prevents further fluid loss to the interstitial compartment. It also restores blood pressure by increasing cardiac output (direct cardiac stimulation) and peripheral resistance (arteriolar constriction). These useful vascular and cardiac effects of adrenaline are mediated through the activation of α- and β-adrenoceptors, respectively. Adjunctive measures include the slow intravenous injection of an antagonist at histamine H1-receptors (e.g. chlorpheniramine) or the intravenous injection of hydrocortisone.

Agents used in cardiopulmonary resuscitation

Adrenaline (epinephrine), 1 mg injected into a central or peripheral vein, is used in the management of cardiac arrest. If a peripheral vein is used, the adrenaline (epinephrine) injection is followed by normal saline, 20 ml, to promote drug entry into the circulation. The adrenaline challenge is repeated every 2–3 minutes until resuscitation is successful or is abandoned. This treatment aims to evoke arteriolar constriction (α-adrenoceptor activation), and increase the rate and force of cardiac contraction (β-adrenoceptor activation). These effects of adrenaline maintain systemic vascular resistance, and help to promote cerebral and coronary blood flow.

Atropine is a competitive antagonist at the various subtypes of muscarinic acetylcholine receptor. There is little evidence to suggest that atropine is useful in the treatment of asystolic cardiac arrest. However, by antagonizing the effects of acetylcholine on the sinoatrial node and the AV node, atropine improves sinus automaticity and AV conduction, respectively. It is useful in the management of hypotension associated with sinus, atrial or nodal bradycardia. Side-effects include blurred vision, dry mouth, urinary retention and acute confusional states.

Calcium: for most cases of cardiac arrest, there is little evidence to suggest that the intravenous injection of Ca^{2+} salts has any beneficial effect. Indeed, high plasma concentrations of Ca^{2+} can be detrimental to the ischaemic myocardium and can impair recovery from cerebral ischaemia. For this reason, Ca^{2+} is administered during resuscitation only if there is evidence of dissociation between the electrical and mechanical activity of the myocardium. Such dissociation may result from severe hyperkalaemia, severe hypocalcaemia or overdose with Ca^{2+} influx inhibitors. In such cases, $CaCl_2$ may be administered by rapid intravenous injection. However, if some cardiac output exists, the injection should be given slowly to minimize the risk of slowing the heart and inducing arrhythmias.

Pharmacological Treatment of Respiratory Tract Infections

Roger Small

Roger Small is Reader in Pharmacology at the University of Manchester, UK. He graduated in pharmacy from Manchester University and studied pharmacology at postgraduate level. His research interests include the electrophysiology of airways smooth muscle and the actions of established and novel anti-asthma drugs.

The treatments in this article are those recommended in edition 42 of the British National Formulary. Any treatment should take into account factors such as the patient's history, the treatment situation (community or hospital-based medicine) and whether a bacteriological diagnosis has been made (causative microorganism; presence or absence of drug-resistant strains).

Bacterial infections

Epiglottitis caused by *Haemophilus influenzae*

The currently recommended treatment for epiglottitis caused by *H. influenzae* is intravenous cefotaxime or chloramphenicol.

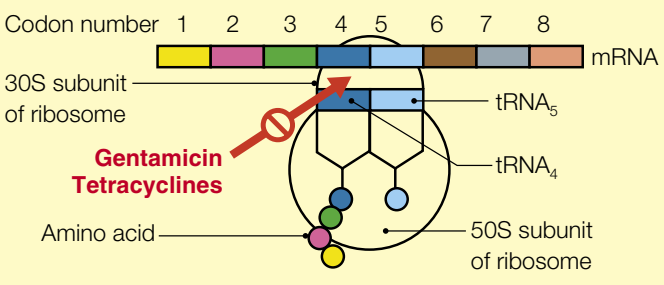
Cefotaxime is a third-generation cephalosporin. Its mechanism of antibacterial action is similar to that of penicillin. The cephalosporins and penicillins are structural analogues of D-alanyl-D-alanine. As such they are able to inhibit the transpeptidase reaction in the biochemical pathway by which the peptidoglycan of the bacterial cell wall is synthesized. The transpeptidase reaction occurs outside the cell membrane and involves the formation of peptide cross-links between the tetrapeptide side-chains of muramic acid molecules. The cell wall outside the cell membrane normally protects the bacterium from the osmotic effects of its environment, therefore interruption of cell wall synthesis by penicillins and cephalosporins leads to bacterial swelling and lysis. In contrast to bacteria, mammalian cells have a cell membrane only and do not possess a cell wall. The antibacterial action of penicillins and cephalosporins thus exhibits selectivity with a qualitative, biochemical basis.

Compared with the second-generation cephalosporins, cefotaxime has less activity against Gram-positive bacteria but more activity against Gram-negative bacteria. It has some activity against pseudomonads. Following its intravenous administration, cefotaxime is widely distributed throughout the body and is able to cross the blood–brain barrier. Its plasma half-life is 2 hours and excretion is mainly by renal tubular secretion. The unwanted effects of cefotaxime include diarrhoea and allergic reactions.

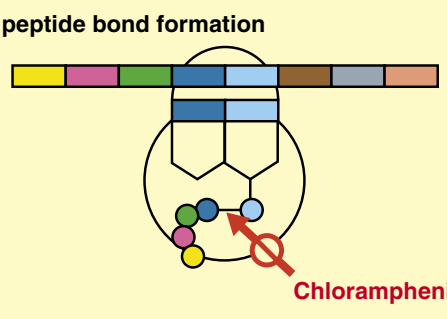
Chloramphenicol has such serious haematological effects that its systemic use should be reserved for the treatment of life-threatening conditions. Epiglottitis caused by *H. influenzae* can lead to obstruction of the respiratory tract in which case treatment with intravenous chloramphenicol may be justified. Chloramphenicol binds to the 50S subunit of the bacterial ribosome, thereby inhibiting the transpeptidation step in bacterial protein synthesis (Figure 1). To some extent chloramphenicol can also bind to the 70S ribosomes in mammalian cells and may thus inhibit mitochondrial protein synthesis. The antimicrobial action of chloramphenicol therefore exhibits selectivity with a quantitative, biochemical basis. Chloramphenicol has a wide spectrum of bacteristatic activity against both Gram-negative and Gram-positive organisms. However, it exerts bactericidal activity against *H. influenzae*. Resistance to chloramphenicol reflects the bacterial production of the enzyme chloramphenicol acetyltransferase.

Mechanisms by which some antibiotics interfere with bacterial protein synthesis

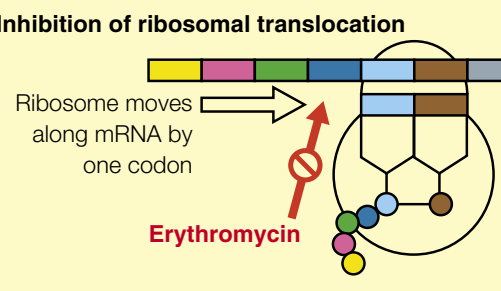
Impairment of function of 30S subunit of ribosome



Inhibition of peptide bond formation



Inhibition of ribosomal translocation



1

Following its intravenous administration, chloramphenicol is widely distributed throughout the body and penetrates the CSF. Its plasma half-life is 2 hours. Chloramphenicol is mainly biotransformed in the liver but about 12% is excreted unchanged in the urine. The most serious unwanted effect of chloramphenicol is aplastic anaemia, which may prove fatal in 1/50,000 patients. In neonates, chloramphenicol should be administered with particular care, because the immature liver and kidney may not be able to biotransform the drug adequately leading to inadequate excretion of the unchanged drug. The resultant high plasma concentrations of chloramphenicol may cause 'grey baby' syndrome.

Exacerbations of chronic bronchitis

Streptococcus pneumoniae and *H. influenzae* are commonly causative in chronic bronchitis. *Staphylococcus aureus* is a less common cause. Exacerbations of chronic bronchitis may be treated with a broad-spectrum penicillin (e.g. ampicillin, amoxicillin (amoxycillin)), a tetracycline (e.g. tetracycline, oxytetracycline, doxycycline) or a macrolide antibiotic (e.g. erythromycin, azithromycin, clarithromycin).

Ampicillin and amoxicillin (amoxycillin; a derivative of ampicillin) interfere with bacterial cell wall synthesis as described above for cefotaxime. They are effective against certain Gram-positive and Gram-negative organisms. Both are inactivated by β-lactamases including those produced by *Staph. aureus*. Therefore, most staphylococci are resistant to ampicillin and amoxicillin (amoxycillin). About 15% of strains of *H. influenzae* are also resistant to these β-lactam antibiotics. However, amoxicillin (amoxycillin) can be prescribed (in the form of co-amoxiclav) in combination with the β-lactamase inhibitor, clavulanic acid. This renders amoxicillin (amoxycillin) effective against strains of *Staph. aureus, H. influenzae* and *Klebsiella* that would otherwise be resistant.

Ampicillin and amoxicillin (amoxycillin) are both absorbed from the gastrointestinal tract though absorption of ampicillin may be impaired by the presence of food in the stomach. Both agents have a plasma half-life of 80 minutes. Ampicillin is excreted in the bile and both agents are actively secreted into the urine. Unwanted effects of both include diarrhoea, maculopapular rashes and the allergic reactions characteristic of penicillins. Co-amoxiclav can cause cholestatic jaundice.

The tetracyclines are broad-spectrum antibiotics that are actively accumulated by susceptible microorganisms. Bacteria can become resistant to the tetracyclines by developing active extrusion processes that reduce the antibiotic concentration within the microbial cell. By binding to the acceptor site on the 30S subunit of the bacterial ribosome, the tetracyclines prevent the binding of aminoacyl-tRNA and interrupt protein synthesis (Figure 1). The tetracyclines have a similar effect on the 70S ribosomes in the mitochondria of mammalian cells. For this reason, the antibacterial action of the tetracyclines has selectivity with a quantitative rather than a qualitative biochemical basis. The tetracyclines exert bacteriostatic effects against a wide range of Gram-positive and Gram-negative microorganisms including *Mycoplasma pneumoniae, Rickettsia, Chlamydia* and some protozoa.

Absorption of tetracyclines from the gastrointestinal tract is variable. Only 30% of an oral dose of chlortetracycline is absorbed. For tetracycline and oxytetracycline this rises to 60–80%. For doxycycline and minocycline, absorption is virtually complete. The tetracyclines tend to form chelates with metal ions, therefore their absorption from the gastrointestinal tract is inhibited by ingestion of Ca^{2+} (dairy products), Al^{2+}, Mg^{2+} (antacids) and ferrous sulphate. Following absorption, the tetracyclines are widely distributed throughout the body and can cross the placenta to reach the fetus. They are excreted in the bile (the main route for doxycycline) and in the urine.

Unwanted effects include gastrointestinal disturbances (of which the worst is pseudomembranous colitis), skin rashes, allergic reactions and hepatotoxicity. Tetracycline-induced inhibition of protein synthesis may lead to the accumulation of nitrogenous waste products in the blood and aggravate renal failure. Tetracyclines should not be prescribed to pregnant women or children under 12 years of age because they form chelates with calcium ions causing bone deformities and staining of teeth.

Macrolide antibiotics (erythromycin, azithromycin, clarithromycin) bind to the 50S subunit of the bacterial ribosome, thus inhibiting the translocation step in bacterial protein synthesis (Figure 1). This antibacterial action may be bacteriostatic or bactericidal depending on the antibiotic, its concentration and the target microorganism. The binding site for the macrolides on the subunit of the bacterial ribosome is identical to that of chloramphenicol, and competition may occur. Erythromycin is effective against many Gram-positive and some Gram-negative organisms. Its action is similar to that of penicillin and it is useful in patients who are allergic to penicillin. Azithromycin is more effective than erythromycin against *H. influenzae*. The same is true for the active metabolite of clarithromycin.

The macrolides are absorbed from the gastrointestinal tract and are widely distributed in the body, though they do not cross the blood–brain barrier. The plasma half-life of erythromycin is 90 minutes and significantly longer for clarithromycin and azithromycin. Azithromycin is relatively resistant to biotransformation but erythromycin is deactivated in the liver and clarithromycin is converted to an active metabolite. Unwanted effects of the macrolides include gastrointestinal disturbances. Erythromycin has also been reported to cause skin rashes and cholestatic jaundice.

Uncomplicated, community-acquired pneumonia

Uncomplicated community-acquired pneumonia is caused by *S. pneumoniae* (30–50% of cases), *H. influenzae* (5–15%), *M. pneumoniae* (0–20%, according to a 4-year cycle of epidemics), *Chlamydia pneumoniae* (about 10%) and *Staph. aureus* (about 3%, increasing during epidemics of influenza or measles). *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* are relatively uncommon causes of community-acquired pneumonia.

Uncomplicated, community-acquired pneumonia may be treated with amoxicillin (amoxycillin) or ampicillin. Erythromycin may be used if the patient is allergic to penicillins or an atypical pneumonia is suspected. If the patient has no history of chest infection, the causative organism is probably *S. pneumoniae* and it may be better to use benzylpenicillin, a highly potent penicillin, rather than amoxicillin (amoxycillin) or ampicillin. Benzylpenicillin is bactericidal against some Gram-positive cocci and bacilli and some Gram-negative cocci. It is hydrolysed by gastric acid, therefore it is administered by intravenous or intramuscular injection. It is widely distributed throughout the body but does not penetrate the CSF unless the meninges are inflamed. It is eliminated by renal tubular secretion. Its unwanted effects are characteristic of the penicillin group and mainly comprise hypersensitivity reactions.

Staph. aureus produces β-lactamase and pneumonia caused by this organism is best managed by adding flucloxacillin, a lactamase-resistant penicillin, to the treatment regimen. Flucloxacillin is resistant to gastric acid but is nevertheless poorly absorbed after oral administration. Food further impairs absorption of flucloxacillin from the gastrointestinal tract but it can be administered by intramuscular or intravenous injection. Protracted treatment with flucloxacillin (over 2 weeks) has been associated with cholestatic jaundice.

Severe community-acquired pneumonia of unknown aetiology

A macrolide antibiotic (e.g. erythromycin) in combination with cefuroxime or cefotaxime is recommended for the treatment of severe, community-acquired pneumonia of unknown aetiology. Cefuroxime is a second-generation cephalosporin that is relatively resistant to β-lactamase. Compared with the first-generation cephalosporins, cefuroxime is less effective against Gram-positive organisms but more effective against Gram-negative organisms. Cefuroxime can be administered orally or parenterally. It is widely distributed in the body and can cross the blood–brain barrier. Its plasma half-life is 90 minutes. Cefuroxime is mainly eliminated by active secretion in the kidney. If *Staph. aureus* is suspected as a cause of this type of pneumonia, flucloxacillin should be added to the treatment regimen.

Suspected atypical pneumonia
Suspected atypical pneumonia may be treated with a macrolide antibiotic (e.g. erythromycin). If *C. pneumoniae* or *M. pneumoniae* is the suspected cause a tetracycline may be used as an alternative to a macrolide. If *Legionella pneumophila* is suspected to be the causative microorganism, rifampicin should be added to the treatment with a macrolide. Rifampicin is an antibiotic that directly interferes with DNA-dependent RNA polymerase in bacteria but does not affect the homologous enzyme in the nuclei of mammalian cells. It enters phagocytic cells and is therefore active against intracellular microorganisms. It is bactericidal against a variety of bacteria including *L. pneumophila* and *Mycobacterium tuberculosis*. However, resistance to rifampicin can develop quite quickly through the production of an altered DNA-dependent RNA polymerase.

Rifampicin is suitable for oral administration and is widely distributed throughout the body. The plasma half-life is 1–5 hours and rifampicin is excreted partly in the bile (as metabolites) and partly in the urine. Rifampicin imparts an orange–red colour to secretions such as tears and urine. Unwanted effects of rifampicin include hepatotoxicity and gastrointestinal disturbances. It induces hepatic microsomal enzymes and may therefore reduce the efficacy of oestrogen-containing oral contraceptives, corticosteroids, sulphonylureas, warfarin and phenytoin.

Hospital-acquired pneumonia
Hospital-acquired pneumonia may be caused by *K. pneumoniae* (10–20% of cases), *P. aeruginosa* (10–15%), *S. pneumoniae* (about 10%), *Staph. aureus* (about 10%) or *H. influenzae* (about 5%). *M. pneumoniae* is a relatively uncommon cause.

A broad-spectrum cephalosporin, such as cefotaxime or ceftadizime, is indicated for the treatment of hospital-acquired pneumonia. If *P. aeruginosa* infection is suspected, ceftadizime may be particularly useful. Ceftadizime is a third-generation cephalosporin with good activity against *P. aeruginosa* and other Gram-negative bacteria. It is administered by intramuscular or intravenous injection and has a plasma half-life of 1.5 hours. It is not metabolized. An anti-pseudomonal penicillin (e.g. ticarcillin or piperacillin) may be used as an alternative to ceftadizime. Ticarcillin is a carboxypenicillin that is effective against *P. aeruginosa* and other Gram-negative bacteria. Absorption of ticarcillin from the gastrointestinal tract is poor and it is administered by intravenous infusion. Piperacillin is a ureidopenicillin with a broad spectrum of antibacterial activity. It is more active than ticarcillin against *P. aeruginosa.* Like ticarcillin, it is poorly absorbed from the gastrointestinal tract and is administered by the intramuscular or intravenous routes. Both ticarcillin and piperacillin are susceptible to β-lactamase. They can be administered together with a β-lactamase inhibitor such as clavulanic acid (ticarcillin) or tazobactam (piperacillin). In the presence of tazobactam, piperacillin is the penicillin that exhibits the broadest spectrum of antimicrobial activity.

When hospital-acquired pneumonia causes severe illness, an aminoglycoside such as gentamicin can be added to the treatment regimen. The aminoglycoside antibiotics enter susceptible bacterial cells by an oxygen-dependent transport process. For this reason they have little effect against anaerobic organisms. Once inside the aerobic bacterial cell, the amino-glycosides bind irreversibly to the 30S subunit of the bacterial ribosome, distorting the subunit so that reading of codons on the mRNA strand is impaired and protein synthesis is interrupted (Figure 1). This leads to the eventual disruption of the bacterial cell membrane.

Gentamicin is a highly polar, water-soluble base that is poorly absorbed from the gastrointestinal tract. It is administered by intramuscular or slow intravenous injection. Its distribution is restricted to the extracellular compartment and it penetrates the CSF poorly. Gentamicin is excreted by glomerular filtration. Its unwanted effects are dose-related and include ototoxicity and nephrotoxicity. The likelihood of these unwanted effects is increased with renal impairment.

Tuberculosis
Treatment of tuberculosis requires specialized knowledge, particularly if the infection involves extrapulmonary tissue or drug-resistant organisms. The Joint Tuberculosis Committee of the British Thoracic Society has recommended that the treatment of tuberculosis should comprise an initial phase lasting for 2 months and should involve the use of at least three antitubercular drugs. The object of this initial phase of treatment is to reduce the infecting population of mycobacteria as quickly as possible, to minimize the chance of resistant strains emerging. The recommended drugs include rifampicin, isoniazid, pyrazinamide and ethambutol. Ethambutol may be omitted if the risk of isoniazid resistance is low. After the initial phase, the continuation phase of therapy comprises the administration of rifampicin and isoniazid in combination for 4 months. Where resistant organisms are suspected, the continuation phase may involve alternative antitubercular drugs (only first-line agents are considered in this article). Where extrapulmonary infection is present the continuation phase of treatment may require extension.

Rifampicin is described above. It forms a crucial part of any treatment regimen for tuberculosis.

Isoniazid is a prodrug that exerts a highly selective action against mycobacteria. It is able to diffuse into mammalian cells to reach intracellular microorganisms. Isoniazid is actively accumulated by tubercle bacilli and, following its conversion to an active metabolite, interferes with the synthesis of mycolic acid and thus cell wall synthesis. Mycolic acids are unique to mycobacteria and this helps to explain the selectivity of action not only of isoniazid but also of pyrazinamide and ethambutol (see below). Isoniazid is bacteriostatic for resting microorganisms but bactericidal towards those that are rapidly dividing. If isoniazid is used in the absence of any other antitubercular drug, resistance develops rapidly. The most common resistance mechanism is reduced conversion of the prodrug into its active metabolite. However, cross-resistance between isoniazid and other antitubercular drugs does not occur.

Isoniazid is well absorbed from the gastrointestinal tract and widely distributed in the body. It readily penetrates the CSF and readily diffuses into cell interiors. It is acetylated in the liver at a rate that is genetically determined. Slow acetylators are more likely to develop unwanted effects such as peripheral neuropathy and hepatitis. The likelihood of isoniazid-induced peripheral neuropathy can be reduced by the co-administration of pyridoxine.

Pyrazinamide is relatively specific for mycobacteria. Its bactericidal action involves interference with the gene that encodes for mycobacterial fatty acid synthase. This leads to interruption of mycolic acid synthesis and thus the synthesis of the bacterial cell wall. The action of pyrazinamide proceeds best at a slightly acidic pH. Furthermore, *Mycobacterium tuberculosis* normally resides in an acidic phagosome within a macrophage. These conditions are ideal for the action of pyrazinamide. However, resistance to pyrazinamide develops rapidly when it is used in the absence of any other antitubercular drug.

Pyrazinamide is well absorbed from the gastrointestinal tract and is widely distributed throughout the body. It readily penetrates the CSF. Its plasma half-life is 9–10 hours. It is excreted by renal glomerular filtration mainly in the form of metabolites. Unwanted effects include hyperuricaemia, arthralgia and hepatic dysfunction.

Ethambutol is relatively specific for mycobacteria. It is taken up by mycobacterial cells and, after a delay of about 24 hours, it produces a bacteriostatic effect. This involves interference with the activity of arabinosyl transferase enzymes that are involved in cell wall synthesis. Resistance to ethambutol develops rapidly if used in the absence of any other antitubercular drug and results from changes in the gene that encodes for arabinosyl transferase.

Ethambutol is well absorbed from the gastrointestinal tract and can penetrate the CSF. Its plasma half-life is 3–4 hours. Ethambutol is partly metabolized but is mainly excreted unchanged in the urine. Unwanted effects include optic neuritis leading to reduced visual acuity and reduced ability to differentiate between red and green. These changes in vision are reversible, provided that the drug is withdrawn at an early stage. Ethambutol should be avoided, or its dose reduced, if there is renal insufficiency.

Fungal infections of the respiratory tract

Aspergillosis and cryptococcosis
Anti-asthma drugs, including inhaled or oral glucocortico-steroids, are indicated for allergic bronchopulmonary aspergillosis and for patients with well-developed aspergillomas. In the latter case, excision of these balls of fungal hyphae may be practicable. Where *Aspergillus* or *Cryptococcus* infections have disseminated from the respiratory tract to reach other tissues, or where there is a danger of this happening, ampho-tericin by slow intravenous injection is the treatment of choice.

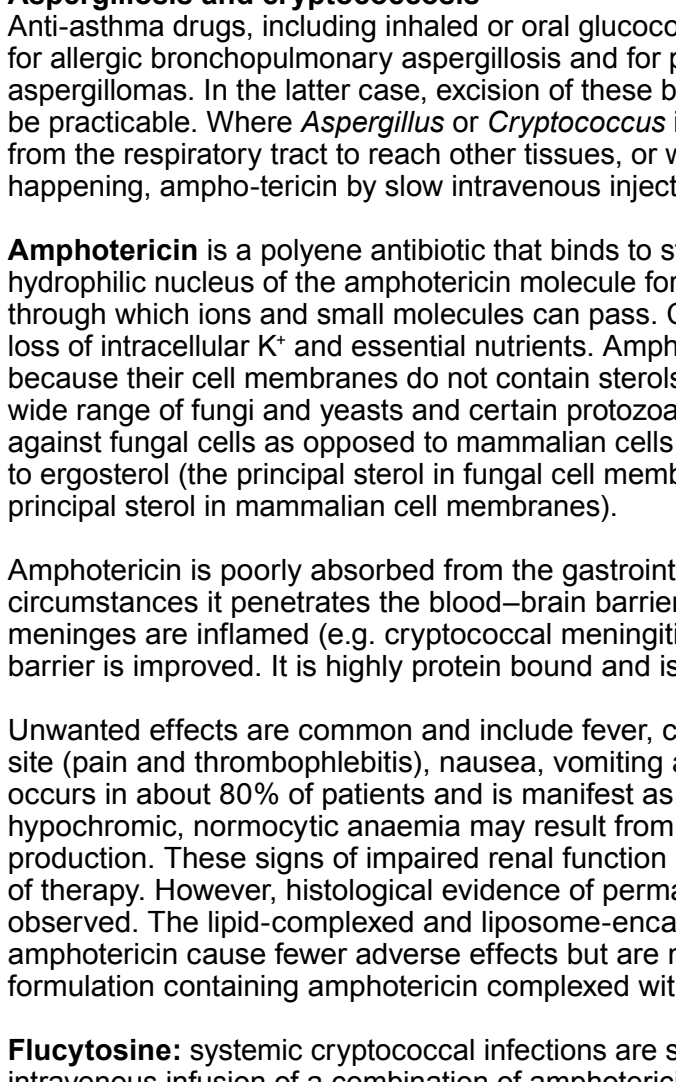
Amphotericin is a polyene antibiotic that binds to sterols in cell membranes. The hydrophilic nucleus of the amphotericin molecule forms a pore in the cell membrane through which ions and small molecules can pass. Cell death may result from the loss of intracellular K^+ and essential nutrients. Amphotericin does not affect bacteria because their cell membranes do not contain sterols. However, it is effective against a wide range of fungi and yeasts and certain protozoa. The drug exhibits some selectivity against fungal cells as opposed to mammalian cells because it binds more avidly to ergosterol (the principal sterol in fungal cell membranes) than to cholesterol (the principal sterol in mammalian cell membranes).

Amphotericin is poorly absorbed from the gastrointestinal tract. Under normal circumstances it penetrates the blood–brain barrier poorly. However, when the meninges are inflamed (e.g. cryptococcal meningitis) penetration of the blood–brain barrier is improved. It is highly protein bound and is slowly excreted by the kidney.

Unwanted effects are common and include fever, chills, irritation at the injection site (pain and thrombophlebitis), nausea, vomiting and tinnitus. Renal toxicity occurs in about 80% of patients and is manifest as uraemia and hypo-kalaemia. A hypochromic, normocytic anaemia may result from suppression of erythropoietin production. These signs of impaired renal function usually resolve on cessation of therapy. However, histological evidence of permanent renal damage is often observed. The lipid-complexed and liposome-encapsulated formulations of amphotericin cause fewer adverse effects but are more expensive than the standard formulation containing amphotericin complexed with a bile salt.

Flucytosine: systemic cryptococcal infections are sometimes treated by the intravenous infusion of a combination of amphotericin and flucytosine. This combination widens the antifungal spectrum and reduces the likelihood that resistance to flucytosine will develop. Flucytosine is a fluorinated pyrimidine and acts as a prodrug. It is taken up by both mammalian and fungal cells. Within the fungal cell, flucytosine is de-aminated to form 5-fluorouracil. This is metabolized to form 5-fluorodeoxyuridylic acid which acts as an inhibitor of thymidylate synthase (Figure 2). Fungal DNA synthesis is therefore impaired. Equivalent metabolism of flucytosine does not occur within mammalian cells, therefore the antifungal activity of flucytosine exhibits a high degree of distributional selectivity. Flucytosine is widely distributed throughout body fluids including the CSF. 80–90% is excreted unchanged in the urine.

Metabolism of 5-flucytosine by fungal cells



2

Itraconazole and fluconazole: as an alternative to amphotericin, systemic infection with *Aspergillus* may be treated with oral itraconazole. Similarly, systemic infection with *Cryptococcus* may be treated with oral or intravenous fluconazole. Itraconazole and fluconazole are second-generation (triazole) imidazole, anti-fungal drugs. Their activity against *Cryptococcus* is greater than that against *Aspergillus*. These imidazole derivatives are inhibitors of sterol 14-α-demethylase, a microsomal cytochrome P450-dependent enzyme system. Itraconazole and fluconazole thus impair the synthesis of fungal ergosterol and cause the accumulation of 14-α-methylsterols in the fungal cell membrane. This disturbs the way in which phospholipids are arranged in the cell membrane, impairs the activity of membrane-associated enzymes such as Na^+/K^+-ATPase and thus inhibits fungal growth. The inhibitory action of these imidazole derivatives against fungi rather than mammalian cells exhibits selectivity with a quantitative biochemical basis.

Absorption from the gastrointestinal tract is good in the case of fluconazole but variable for itraconazole. Fluconazole enters most body fluids including the CSF; itraconazole does not enter the CSF. Fluconazole is excreted largely unchanged in the urine (90%) and faeces (10%). Itraconazole undergoes extensive hepatic metabolism and its inhibition of cytochrome P450 enzymes leads to the possibility of many drug interactions. Unwanted effects of these agents include nausea, headache and, more rarely, exfoliative skin lesions and hepatitis.

Viral infections of the respiratory tract

Respiratory syncytial virus (RSV)

Palivizumab: prophylaxis against RSV for at-risk infants can be provided by the humanized, monoclonal anti-IgG antibody, palivizumab. It acts to prevent the entry of RSV into host cells. Unwanted effects following its intramuscular injection include irritation at the injection site, fever and nervousness.

Ribavirin: treatment of RSV infection in infants may involve the administration of ribavirin as an aerosol. The drug may reduce the time for which mechanical ventilation is required, but there is little evidence to suggest that it reduces mortality or respiratory deterioration. Ribavirin is a purine nucleoside analogue. It inhibits a wide range of DNA and RNA viruses by mechanisms that have yet to be elucidated. It is taken up by host cells and converted to the mono-, di- and tri-phosphate derivatives by host cell enzymes. The monophosphate inhibits inosine 5'-phosphate dehydrogenase and interrupts guanosine triphosphate (GTP) synthesis and therefore nucleic acid synthesis. The triphosphate inhibits GTP-dependent 5'-capping of viral mRNA. Ribavirin therefore inhibits RSV by altering cellular nucleotide pools and by inhibiting viral mRNA.

Ribavirin is taken up by cells, therefore its apparent volume of distribution is large. Its binding to plasma proteins is negligible. It is eliminated by metabolism in the liver and by renal excretion as unchanged drug and its metabolites. Unwanted effects of ribavirin administered by aerosol include conjunctival irritation, rash and a transient worsening of pulmonary function; anaemia and haemolysis are less common. Ribavirin is teratogenic, therefore women of child-bearing age should avoid exposure to the aerosol.

Influenza

Vaccination provides the mainstay of prophylaxis against influenza. However, both the type A and the type B influenza viruses are constantly changing their complements of haem-agglutinin and neuraminidase and thus their antigenic properties. It is therefore important to use vaccine that has been prepared against the currently prevalent strain, or strains, of the virus. Such vaccines are recommended for use only in patients judged to be at high risk, including those suffering from chronic respiratory disease, chronic cardiac disease, chronic renal failure or diabetes mellitus. Other at-risk patients include those who are immunocompromised, those over 65 years of age and residents in long-stay homes for the elderly. The preparation of influenza vaccines involves growing the relevant viral strains on the chorioallantoic membranes of hens' eggs and therefore their use is contraindicated in those who are allergic to eggs.

Amantadine may be used as a prophylactic agent in outbreaks of influenza caused by the type A virus but not those caused by the type B virus. Prophylaxis provided by amantadine is reserved for unimmunized patients while their vaccination takes effect. It may also be used for at-risk patients in whom the vaccine is contraindicated or, during epidemics, for protecting essential healthcare workers from infection. In the type A virus, amantadine interferes with the action of viral M_2 protein. This protein acts as an ion channel that is important in the early stages of viral replication and in the budding of new viral particles from the infected host cell. Amantadine thus has dual actions against the type A virus. It is well absorbed from the gastrointestinal tract and has a large apparent volume of distribution. Amantadine is eliminated mainly by excretion unchanged in the urine. Its unwanted effects include dizziness, insomnia and slurred speech.

Zanamivir is a sialic acid derivative that is effective against influenza viruses. However, the National Institute for Clinical Excellence has recommended that it should not be used to treat adult sufferers of influenza who are otherwise healthy. It should be reserved for times when influenza is circulating in the community and then only for at-risk patients who are able to commence treatment within 48 hours of the onset of symptoms. Zanamivir specifically inhibits the neuraminidases of influenza viruses A and B. The budding of new viral particles from the infected host cell is thus prevented and their spread within the respiratory tract is reduced. Zanamivir is administered by inhalation. Its unwanted effects include skin rashes, gastrointestinal disturbances and bronchospasm. It should be administered with caution if there is a history of bronchial asthma or chronic obstructive pulmonary disease.◆

Pituitary, Adrenal and Thyroid Dysfunction

Nick Ashton

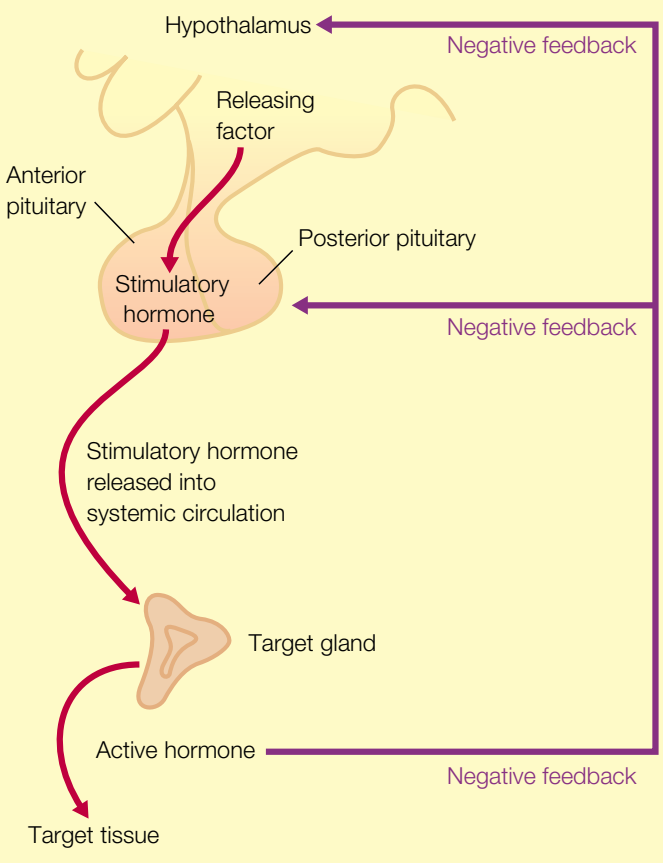
Nick Ashton is Lecturer in Physiology at the University of Manchester School of Biological Sciences. He qualified from the Universities of Sheffield and Manchester, and held positions in Newfoundland, Canada, and Sunderland. His research interests include hormonal regulation of renal function and blood pressure.

The hypothalamo-pituitary unit

The hypothalamus is located inferior to the thalamus. It synthesizes or regulates all the hormonal products of the pituitary gland. The pituitary releases regulatory hormones controlling a variety of physiological functions including growth, sodium regulation and milk secretion. The pituitary is divided into two distinct regions; the anterior lobe (adenohypophysis or pars distalis) and the posterior lobe (neurohypophysis or pars nervosa). The posterior pituitary stores and secretes oxytocin and vasopressin, which are synthesized in neurons located in the paraventricular and supraoptic nuclei of the hypothalamus. The axons of these neurons pass down the pituitary stalk into the posterior lobe of the pituitary where the peptide hormones are stored. The hypothalamus regulates the anterior pituitary by releasing regulatory factors into the hypothalamo-hypophyseal portal system from where they pass to the anterior lobe.

Feedback loops and dysfunction: regulation of hypothalamo-pituitary function is hierarchical and dependent on feedback loops. A typical stimulatory pathway (Figure 1) involves a releasing factor secreted by the hypothalamus stimulating the anterior pituitary to release a stimulatory hormone into the general circulation where it stimulates the target gland to release the active hormone. Increasing plasma concentrations of this hormone inhibit further secretion of the hypothalamic releasing factor and the stimulatory hormone, restoring the plasma concentration to basal levels. If there is a breakdown in this feedback system, chronic stimulation or inhibition may occur, resulting in unregulated secretion of hormones.

Negative feedback control of hypothalamo-pituitary axis



1

Adrenal gland

The two adrenal glands are situated superior to the kidneys. They each weigh 4–5 g and are divided into two distinct regions, the outer cortex which comprises 90% of the gland and the inner medulla. The cortex is responsible for the synthesis of three steroid groups (mineralocorticoids, glucocorticoids, androgens); catecholamines are the main product of the medulla.

The adrenal cortex comprises three zones. The zona glomerulosa, which synthesizes the main mineralocorticoid aldosterone, is the outermost zone. Below that lies the zona fasciculata which secretes the glucocorticoids, primarily cortisol, and then the zona reticularis which secretes androgens (dehydroepiandrosterone and androstenedione). All adrenal steroids are derived from cholesterol and are produced by a series of hydroxylations. The specificity of steroid product in each zone is determined by the presence or absence of hydroxylase enzymes. Thus, cells in the zona glomerulosa that possess 18-hydroxylase are able to convert corticosterone to aldosterone, but lack 17α-hydroxylase, which is essential for the synthesis of cortisol and androgens. Conversely, cells in the fasciculata and reticularis lack 18-hydroxylase and cannot produce aldosterone.

Cortisol synthesis is regulated by corticotrophin releasing hormone (CRH) which stimulates pituitary secretion of adrenocorticotrophin (ACTH), leading to cortisol release. This is pulsatile in nature, reaching a peak in the early hours before waking. ACTH stimulates the rate-limiting conversion of cholesterol to pregnenolone by binding to adrenocortical cells, activating cAMP and phosphoprotein kinases. Aldosterone synthesis is stimulated by high plasma [K^+] and angiotensin II, which stimulates the rate-limiting conversion of cholesterol to pregnenolone and the 18-hydroxylation of corticosterone to aldosterone.

Hydroxylase enzyme deficiency

Defects in hydroxylase enzyme activity lead to metabolic errors in steroid synthesis. There are six categories of congenital adrenal hyperplasia (Figure 2), transmitted by autosomal recessive disorders, which result in low concentrations of cortisol, high concentrations of ACTH and varying degrees of genital ambiguity. In Types I, II and III which are characterized by deficiency of the enzymes 21α-hydroxylase (I and II) and 11β-hydroxylase, steroid synthesis is shifted towards androgen production and as a result girls are born with ambiguous genitalia. In Types IV–VI the defects occur earlier in the synthesis pathway, resulting in a reduction in androgen synthesis and thus female or ambiguous genitalia in boys.

Chromosomal and phenotypic sex mismatch in hydroxylase enzyme deficiency

Enzyme deficiency	21α-hydroxylase		11β-hydroxylase		17α-hydroxylase		3β-hydroxysteroid dehydrogenase		P450 scc side-chain cleavage	
Type	I and II		III		IV		V		VI	
Chromosomal sex	XX	XY	XX	XY	XX	XY	XX	XY	XX	XY
Phenotypic sex	Ambiguous	Male	Ambiguous	Male	Female	Female /ambiguous	Female	Ambiguous	Female	Female

2

Adrenal insufficiency

Addison's disease was first described by Thomas Addison in 1855. This rare condition (39/1,000,000 in the UK) arises through tuberculosis (20%) or autoimmune disease (80%). Clinical features (e.g. tiredness and weakness) are often non-specific, but patients may present with acute features such as shock, malaise, vomiting and postural hypotension. Other features include skin pigmentation (80–90% of cases) caused by excess melatonin or vitiligo (depigmentation in 10–20% of cases). Acute adrenal crisis may occur following infection, trauma, surgery, dehydration owing to lack of salt, vomiting or diarrhoea. Abdominal pain may occur accompanied by weakness, apathy and confusion. Hypotension, shock, fever, vomiting and tachycardia are common; shock and coma may lead to death in untreated cases.

Measurement of plasma cortisol and ACTH, or the cortisol response to ACTH are necessary to diagnose primary adrenal insufficiency. Metyrapone, 2–3 g orally (overnight test) or 750 mg every 4 hours for six doses (3-day test), is used to assess secondary adrenal insufficiency caused by pituitary ACTH deficiency because it blocks the conversion of 11-deoxycortisol to cortisol by inhibiting 11β-hydroxylase, thereby stimulating ACTH by removing negative feedback on the pituitary. ACTH then stimulates an increase in plasma 11-deoxycortisol in normal individuals (> 0.19 μmol/litre the following morning). Treatment includes glucocorticoid replacement therapy (hydrocortisone) in all patients and replacement of mineralocorticoids (9α-fludrocortisone) in some.

Adrenal excess

Hyperaldosteronism: primary hyperaldosteronism (Conn's syndrome) results in excessive aldosterone secretion and accounts for up to 2% of hypertensive cases. In most instances (70%) it arises through a unilateral adenoma, though bilateral hyperplasia of the zona glomerulosa may also be the cause. In both cases the result is severe hypertension and hypokalaemia. Trilostane, which inhibits 3β-hydroxysteroid dehydrogenase/delta 5–6 isomerase, blocks the 3β-dehydrogenation of preg-nenolone to progesterone and 17-hydroxypregnenolone to 17-hydroxyprogesterone, reduces aldosterone production. Secondary hyperaldosteronism arises as a consequence of renal artery stenosis leading to excessive renin secretion and inappropriately high plasma aldosterone concentrations owing to reduced renal blood flow. Angioplasty relieves the stenosis. ACE inhibitors are inadvisable because glomerular filtration is maintained in the affected kidney by high angiotensin II levels.

Cushing's syndrome was first described clinically by Harvey Cushing in 1932. It is a group of related disorders in which there is excessive glucocorticoid secretion. Some are ACTH-dependent while others are ACTH-independent. In the ACTH-dependent forms, which include most spontaneous cases (83%), excessive ACTH secretion either by the pituitary (Cushing's disease is four times more likely in women) or an ectopic tumour (bronchial and gastrointestinal carcinomas, neuroendocrine tumours of pancreatic islets) stimulates the adrenal gland to secrete glucocorticoids. In the ACTH-independent form adenomas (1.5–6 cm) and carcinomas (> 6 cm, usually in children) of the adrenal result in unregulated glucocorticoid secretion. However, the most common cause is the therapeutic (mis)use of synthetic glucocorticoids or ACTH. The glucocorticoids have a variety of permissive roles throughout the body therefore their excess results in many diverse clinical features. These include weight gain, central obesity, 'moon' face, muscle weakness, backache, malaise, depression or psychosis, hirsutism, striae, hypertension and sexual dysfunction.

Diagnosis – the common underlying feature of all forms of Cushing's syndrome is an inappropriately high plasma cortisol concentration. However, a single measurement of plasma cortisol is of little diagnostic value because it has a normal diurnal variation, being higher in the early morning. Cortisol may also be influenced by other factors, including stress, alcohol, depression, obesity and coma. Cushing's syndrome may also be intermittent. A more useful approach is to determine whether the plasma ACTH or plasma cortisol levels can be suppressed by the normal feedback loops.

An initial screening of plasma ACTH differentiates between the dependent and independent forms. Normal plasma ACTH falls in the range 2–11 pmol/litre; in the ACTH-independent form, plasma ACTH is suppressed below 2 pmol/litre, in the ACTH-dependent pituitary form plasma levels are modestly elevated at 4–40 pmol/litre, whereas in ectopic forms the levels may exceed 600 pmol/litre. Further confirmation can be achieved using the dexamethasone suppression test.

In the overnight low-dose test, dexamethasone, 1 mg, is given orally at 11 p.m. and plasma cortisol measured the following morning. Dexamethasone suppresses ACTH therefore this results in a low cortisol level (< 0.137 μmol/litre) in normal individuals, but those with Cushing's syndrome display high levels (> 276 μmol/litre). The 2-day test involves dexamethasone, 0.5 mg orally, administered every 6 hours for 2 days. 24-hour urine samples are collected before dexamethasone and during the second day of treatment. Normal individuals show a sup-pression of urinary 17-hydroxycorticosteroid to less than 10 μmol/24 hours. The high-dose test is useful in differentiating between a pituitary and ectopic source of ACTH. In the single dose form, a baseline plasma cortisol measurement is obtained in the morning, then dexamethasone, 8 mg, is given orally at 11 p.m. followed by a second plasma cortisol sample the following morning. In those with a pituitary tumour (Cushing's disease), plasma cortisol is suppressed by more than 50% whereas those with an ectopic tumour show little or no suppression. In the 2-day test dexamethasone, 2 mg orally, is administered every 6 hours. In most cases, those with a pituitary tumour show more than 50% suppression of urinary 17-hydroxy-corticosteroid while those with an ectopic tumour show little suppression.

Thyroid gland

The normal adult thyroid gland comprises two lobes joined by an isthmus. It originates as an outpouching of the floor of the pharynx, lying over the second and third tracheal rings, and comprises numerous spherical follicles of epithelial cells enclosing a colloid space. Interspersed between follicles are calcitonin-secreting parafollicular or C cells and connective tissue.

The principal hormonal products of the thyroid are tri-iodothyronine (T3) and thyroxine (T4), which are synthesized from tyrosine and iodine (Figure 3). Inorganic iodide is actively transported into the follicular cells where it is oxidized by thyroid peroxidase and linked to tyrosine to form 3-monoiodotyrosine and 3,5-diiodotyrosine. Further oxidation occurs in the colloid space to produce the biologically active 3',3,5-triiodotyrosine (T3) and 3'5',3,5-tetraiodotyrosine (thyroxine, T4). T3 and T4 are stored in the colloid space bound to thyroglobulin before reuptake into the follicular cell by endocytosis, where they are uncoupled from thyroglobulin by proteolysis and released into the circulation. Although both T3 and T4 are synthesized in the thyroid, most circulating T3 is produced by conversion of T4 in the kidney, liver and heart. The circulating concentration of T4 (65–155 nmol/litre) is 50 times that of T3 (1.5–2.9 nmol/litre); both are predominantly bound to the plasma protein thyroxine binding globulin, with 15% bound to albumin.

Physiological actions of T3 and T4

- Fetus – brain and skeletal growth
- Metabolic rate – increases oxygen consumption and heat production via Na^+:K^+-ATPase
- Cardiovascular effects – increases cardiac contractility
- Sympathetic effects – increases cardiac β-adrenergic receptors and decrease α-adrenergic receptors
- Pulmonary effects – maintains hypoxic and hypercapnic drive in respiratory centre
- Gastrointestinal effects – stimulate gut motility
- Skeletal effects – increase bone turnover
- Neuromuscular effects – essential for normal development of the CNS
- Lipid and carbohydrate effects – stimulate gluconeogenesis and glycogenesis
- Endocrine effects – decrease half-life of many hormones (e.g. cortisol) and drugs

3

Activity of the thyroid gland is regulated by the hypothalamic thyrotrophin-releasing hormone (TRH) and the anterior pituitary thyroid-stimulating hormone (TSH). TRH is synthesized in the supraoptic and supraventricular nuclei of the hypothalamus and is released into the hypothalamo-hypophyseal portal system in a pulsatile fashion about every 1.8 hours. TRH release is also stimulated by low plasma T3 and T4 concentrations, vasopressin, α-adrenergic catecholamines, exposure to cold (in the newborn); it is inhibited by high plasma T3 and T4 concentrations, α-adrenergic blockers and hypothalamic tumours. TRH stimulates secretion of TSH from the anterior pituitary, which acts as the primary regulator of thyroid function, stimulating thyroid cell growth and changes in morphology, thereby accelerating thyroglobulin resorption (Figure 4). It also increases iodide uptake and metabolism, thyroglobulin mRNA and lysosomal activity releasing free T3 and T4 from thyroglobulin. These actions are mediated via the TSH receptor (TSH-R) which activates both cAMP and phospholipase C. TSH secretion is also stimulated by low T3 concentrations and is inhibited by high T3 and T4 concentrations, somatostatin, dopamine, dopamine agonists (e.g. bromocriptine) and gluco-corticoids. The thyroid hormones exert long-term effects with slow onset owing to their genomic mode of action. T3 is the active form of the hormone; T4 is converted to T3 inside the target cell by 5'-deiodinase where it binds to the T3 receptor that is part of the nuclear receptor family.

Circulating TSH and T4 and the TSH response to TRH administration in hypothyroidism

	Primary hypothyroidism	Secondary hypothyroidism	Hypothalamic hypothyroidism	Non-thyroid origin
TRH	Exaggerated TSH response	No TSH response	Normal or delayed TSH response	Normal or low TSH response
TSH	High	Low	Low	Normal or low
T4	Low	Low	Low	Low

T4, thyroxine; TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone

4

Hypothyroidism
Hypothyroidism arises through several mechanisms, including iodine deficiency (the most common cause of goitre), auto-immunity (the most common cause in non-iodine-deficient areas), surgery, radioiodine therapy or excessive iodine intake (e.g. chronic ingestion of proprietary cough medicines). Congenital failure of the hypothalamo–pituitary–thyroid axis is less common (1/4,000 births), but acquired hypothyroidism, especially primary hypothyroidism occurs in 2–4% of women (10 times less common in men).

The symptoms of hypothyroidism in newborns include respiratory difficulty, jaundice, cyanosis, poor feeding and retardation of bone development. In children, the main features are retarded growth and mental development, though precocious puberty may occur. Adults typically show fatigue, cold intolerance, weight gain, constipation and menstrual irregularities. Skin is cool, rough and dry, face and hands are puffy and the voice is hoarse. In severe untreated cases the end-stage is myxoedema coma, which is typified by progressive weakness, hypothermia, hypoventilation, hypoglycaemia, hyponatraemia, shock and death. Coma may be precipitated by heart failure, pneumonia, pulmonary oedema or administration of sedative or narcotic drugs.

Hypothyroidism is treated with levothyroxine (T4) which is readily converted to T3. Doses vary from 0.05 to 0.2 mg/day depending on body weight and age. Myxoedema coma is an acute medical emergency often requiring mechanical ventilation. Levothyroxine is administered intravenously, because of poor absorption in these patients, and adrenal support may also be required in case of autoimmune adrenal disease or pituitary insufficiency.

Hyperthyroidism
Hyperthyroidism occurs in 1.8% of the adult population, mainly in women (10:1). It is usually caused by autoimmune thyroid disease, commonly Graves' disease, though there are other rarer causes. Classical Graves' disease is typified by hyperthyroidism, goitre, eye signs (exophthalmos, lid retraction) and dermopathy (pretibial myxoedema). The cause of autoimmunity in Graves' disease is not fully understood, but there appears to be a familial component. T lymphocytes are sensitized to antigens in the thyroid, stimulating B lymphocytes to synthesize antibodies. Antibodies bind and activate TSH receptors, leading to unregulated production of thyroid hormones. A number of factors have been associated with the onset of autoimmune disease, including pregnancy, iodine excess, lithium therapy, viral or bacterial infection and glucocorticoid withdrawal.

Patients present with palpitations, nervousness, hyperkinesia, diarrhoea, sweating and heat intolerance and eye signs, ranging from little or no effect to loss of sight. Blood analysis reveals high circulating T3 and T4, low TSH and the presence of TSH-R antibodies. Treatment involves the management of the hyperthyroidism, rather than addressing the autoimmune mechanisms. Antithyroid drug therapy is used in younger patients with mild disease. The thioureylenes carbimazole, propylthiouracil or methimazole (not licensed in the UK) are given orally until the disease goes into remission, but this may take 15 years, and relapse is common (60–80%). Their mode of action is unclear, but they are thought to inhibit the iodination of tyrosyl residues in thyroglobulin. An alternative approach is to block thyroid activity with methimazole and then replace levothyroxine until the gland has returned to normal size. This results in long-term remission in up to 80% of cases. In patients with large glands, subtotal thyroidectomy may be used or radioactive iodine administered. ^{131}I emits β-particles and γ-rays, the former causing localized cytotoxicity when taken up into the thyroid gland, thereby selectively destroying thyroid cells and reducing gland mass. ◆

Plasma Expanders

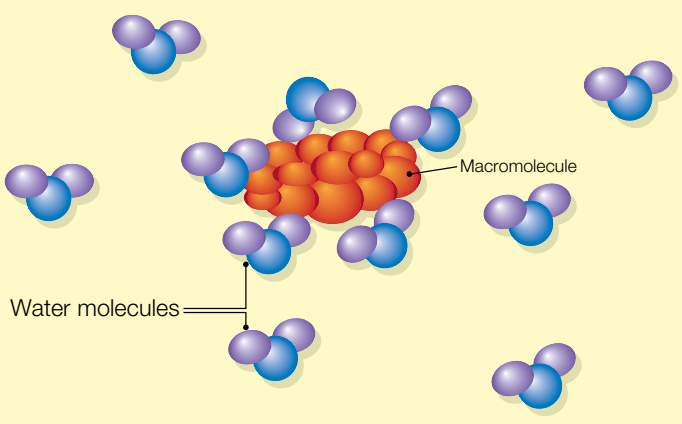
Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

Provided capillary permeability is normal, colloidal solutions containing albumin, dextrans, gelatins or hydroxyethylated starch may be used as plasma expanders.

A colloid is defined as a solution containing large organic molecules dispersed in a solution. Organic molecules that contain polar covalent bonds attract a sphere of water molecules around them that hold them in solution (Figure 1). A colloid differs from a suspension in that the molecules remain in solution and do not settle out due to the force of gravity. A colloidal solution exerts a colloid osmotic pressure when in contact with a semipermeable membrane tending to draw fluid into the colloidal solution. When rehydration therapy is required, the advantages of using colloidal solutions over crystalloid (salts) solutions are that the volume infused is smaller, there is a prolonged increase in plasma volume and peripheral oedema is minimal. However, colloids are more expensive, have less effect in increasing urinary flow and are less effective in restoring interstitial volume. The relative merits of various fluid therapies during and after anaesthesia are more pertinent to clinical practice than to pharmacology.

Water associated with a macromolecule to form a colloidal solution



1

Human albumin

Albumin is a protein (molecular weight 65 kDa), the main function of which in the blood is to maintain the colloid osmotic pressure of about 25 mm Hg. It is prepared from human plasma and is available as a concentrate containing 15–25% total protein or as an isotonic solution containing 4–5% protein. A stabilizer such as sodium caprylate may be included, but no antibacterial agent is present. It is sterilized by filtration and heated at 60°C for 10 hours. The latter reduces the risk of viral transmission. All commercially available solutions and those supplied by blood banks have been incubated and checked for microbial contamination before delivery. Human albumin is used to replace plasma volume and to restore colloid osmotic pressure in acute hypovolaemic shock, burns and other conditions associated with albumin loss. Side-effects are rare, but include allergic reaction such as anaphylactic shock. Human albumin is generally more expensive than other plasma expanders and recent evidence suggests that the use of albumin rather than other plasma expanders is not associated with better survival or change in morbidity.

Dextrans

Dextrans are polysaccharides produced by bacteria (usually *Leuconostoc mesenteroides*) growing on a sucrose substrate. All dextrans are composed of a-D-glucopyranosyl units and differ only in chain length or degree of branching. Hydrolysis and fractionation of the native dextrans produced by the bacteria result in dextrans containing different average molecular weights. The two used most commonly are dextran 40 (average molecular weight 40 kDa) and dextran 70 (average molecular weight 70 kDa). The former is infused as a 10% solution and the latter as a 5.5–6.5% solution.

The colloidal osmotic pressure of dextran 70 is similar to plasma, while dextran 40 exerts a greater osmotic pressure, thus drawing more extracellular fluid into the circulation. However, this effect is short lived and must be balanced against the greater incidence of renal complications. 70% of dextran 40 is rapidly excreted via the kidney and if urine flow is reduced the high urinary concentration of dextran can increase urinary viscosity inducing oliguria or renal failure. This problem is less with dextran 70, which is only 50% excreted unchanged. The remainder of both dextrans is metabolized to glucose.

Dextrans are used in the treatment of hypovolaemic shock and for improving circulatory flow to minimize thromboembolic disorders postoperatively. They have some antithrombotic effects that seldom cause a problem unless the patient has a clotting factor deficit. Hypersensitivity reactions to dextrans (e.g. fever, joint pain, urticaria, hypotension, bronchospasm) have been reported occasionally; severe hypersensitivity reactions are rare.

Gelatin solutions

Gelatin is a purified protein obtained from hydrolysis of animal collagen. The three groups commonly used as plasma expanders are oxypolygelatin, urea-linked gelatin (polygeline *Haemaccel*) and modified fluid (succinylated) gelatins. The average molecular weight is 30–35 kDa and thus gelatins remain in the circulation for a shorter time than dextrans. Gelatin solutions are used to treat hypovolaemic shock. In general, side-effects are few and there is little effect on platelet function, thus making gelatins safer than dextrans for patients with haematological deficits.

Intravenous preparations of polygeline contain calcium ions and are incompatible with citrated blood. They should be used with caution in patients being treated with cardiac glycosides. As with other plasma expanders, hypersensitivity reactions have been reported. At one time they were thought to be more common with polygeline solution, but the removal of excess hexa-methylene di-isocyanate remaining from the manufacturing process seems to have reduced this problem.

The possibility that such preparations may be contaminated with prion proteins from cattle suffering from bovine spongiform encephalopathy has caused some concern.

Hydroxyethylated starch

The branched component of starch, amylopectin, was originally studied as a potential plasma expander because its close structural relationship to glycogen should ensure its non-toxicity. Unfortunately, the rapid breakdown of amylopectin by plasma amylase to small easily excreted pieces meant that the persistence of the compound in the plasma was too short for a useful clinical effect. However, reducing the number of bonds available for hydrolysis by amylase allowed amylopectin derivatives to persist for a longer period of time in the plasma.

Hydroxyethyl starch is an example of such a product and it is prepared by treating starch with pyrimidine and ethylene chlorohydrin. The exact composition of this starch derivative has not been determined, but it contains 90% amylopectin in which 7–8 of the OH groups found in 10 glucopyranosyl units are esterified with CH_2CH_2OH. There are two preparations, hetastarch (molecular weight 450 kDa) and pentastarch (molecular weight 250 kDa) of which the former is more often used. Hetastarch is broken down relatively slowly by α-amylase in the blood and the kidney excretes the smaller molecules. Hypersensitivity reactions have been reported, but there is some evidence that the incidence is lower than with other plasma expanders. Hetastarch has little effect on blood coagulation though there is a reduction in factor VIII; an effect that is less likely with pentastarch. Figure 2 gives the intravascular half-lives of plasma expanders. ◆

Colloidal solutions used as plasma expanders

Colloid	Composition	Intravascular half-life (hours)
Albumin	Protein	> 24
Dextran 40	Polysaccharide	2–3
Dextran 70	Polysaccharide	6–12
Gelatin	Protein	< 4
Hetastarch	Amylopectin derivative	> 24
Pentastarch	Amylopectin derivative	10
Polygeline	Protein	< 4

Premedication

Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology for postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

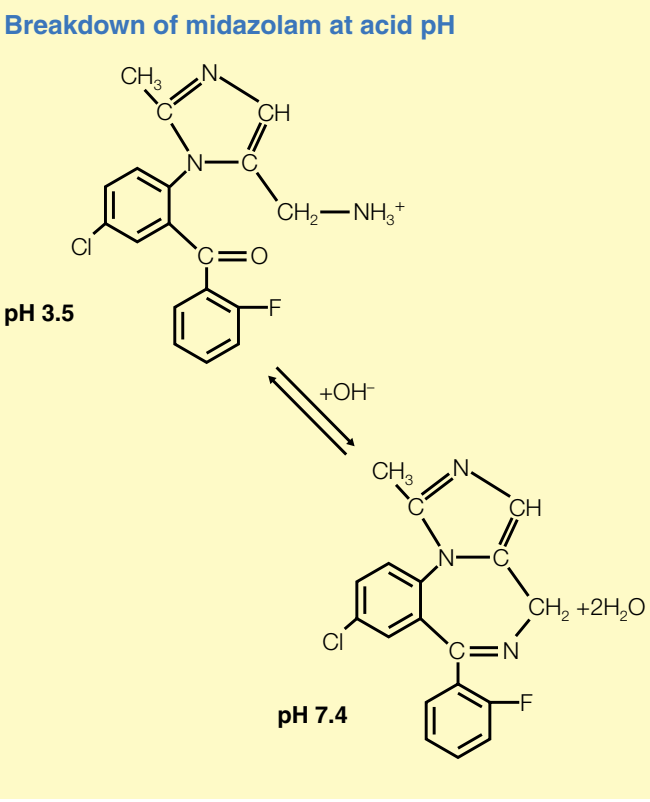
Clinical aspects of premedication are discussed in **CLINICAL ANAESTHESIA**. The present article concentrates on the pharmacology of the drugs used.

Anxiolytics and sedatives

The basic pharmacology of anxiolytics and sedatives is discussed on page 233. The agents selected from this group for use in premedication are the benzodiazepines with a relatively short duration of action such as temazepam and midazolam. Occasionally a longer acting drug (e.g. diazepam) is selected for procedures in which long duration of sedation is required. All these agents potentiate γ-aminobutyric acid (GABA) transmission through $GABA_A$ receptors by an action at a distinct binding site separate from that which binds GABA. The benzodiazepines used in premedication have no selectivity for the various subtypes of benzodiazepine receptors discussed elsewhere.

Midazolam is unusual in that it is soluble in acidified water because its lipid-soluble ring structure breaks down at acid pH (Figure 1). This simplifies intravenous administration, which does not require the solvents or emulsions needed with other parenteral benzodiazepines. In addition, it has a short half-life of less than 3 hours. Midazolam is metabolized to α-hydroxymidazolam, which has pharmacological activity. After intravenous administration this metabolite has a negligible role in the action of the drug but, after oral administration, the first-pass metabolism of the drug in the liver, may lead to a significant build-up of the active metabolite.

Breakdown of midazolam at acid pH



1

Temazepam (half-life 4−10 hours) is available for administration only by mouth as either a tablet or an elixir. It is often listed as not having an active metabolite but it can be demethylated to oxazepam though this is a minor pathway and does not contribute greatly to the drug's activity.

Lorazepam (half-life 8−12 hours) can cause profound anterograde amnesia. It is not considered to have an active metabolite.

Anti-emetic drugs

The anatomy and physiology of vomiting has been relatively little studied. The vomiting reflex protects the body from ingested toxins that have not been detected by sight, taste or smell. Irritation or distention of the upper gastrointestinal tract (in particular distention of the duodenum) may also induce nausea and vomiting. Thus, vagal and, to a lesser extent, sympathetic afferent impulses travelling from the gastrointestinal tract to the vomiting or emetic centre can induce vomiting. These afferent impulses are initiated by mechanoreceptors that detect distention or mucosal chemoreceptors that detect acids, alkalis, irritants and probably bacterial toxins. Induction of vomiting, for example with cytotoxic drugs, is associated with mucosal damage and the liberation of 5-HT from the enterochromaffin cells. The released 5-HT probably stimulates the vagal afferent nerves by interaction with a $5\text{-}HT_3$ receptor. Substance P released from the gastric mucosa acts on tachykinin NK_1 receptors and may function cooperatively with 5-HT (acting on $5\text{-}HT_3$ receptors) in the upper gastrointestinal tract to induce vomiting.

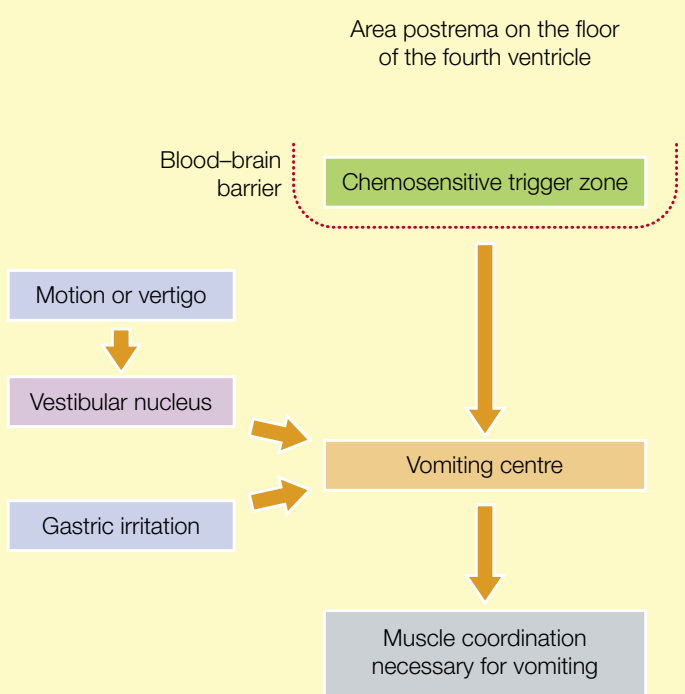
Vomiting can also be induced by chemicals carried in the blood, which are detected by the chemosensitive trigger zone in the area postrema on the caudal floor of the fourth ventricle (Figure 2). From a pharmacological point of view it is interesting and exploitable that the chemosensitive trigger zone is functionally outside the blood−brain barrier. Animal studies have shown that the area postrema contains high concentrations of $5\text{-}HT_3$, dopamine (D_2) and opioid receptors. In humans, drugs acting as agonists at these receptors cause nausea and vomiting. Antagonists at $5\text{-}HT_3$ and D_2 receptors are effective anti-emetic agents, but opioid antagonists are not.

Motion sickness involves the vestibular system and labyrinthine stimulation enhances the emetic effects of other vomiting triggers. Muscarinic cholinergic and histamine H_1 receptors are present in the vestibular nuclei.

Both the vestibular system and the chemosensitive trigger zone send impulses to the vomiting centre that initiate the sequence of smooth and skeletal muscle contraction associated with vomiting. The vomiting centre is a physiological rather than an anatomical structure but is found close to the area postrema. Both muscarinic cholinergic and histamine H_1-receptors are found in this area. Vomiting can also occur as a result of inputs from higher centres such as the limbic system though the mechanisms are uncertain.

The receptors involved in emesis and useful anti-emetic drugs are summarized in Figure 3.

Induction of vomiting



2

Neurotransmitters involved in nausea and vomiting

Vomiting trigger	Neurotransmitter	Receptors involved	Anti-emetic drugs
Irritation and/or distention of the gastrointestinal tract	5-HT	$5\text{-}HT_3$	Ondansetron, granisetron
Toxins and chemicals acting on the chemosensitive trigger zone	Dopamine	D_2	Droperidol, domperidone, prochlorperazine, perphenazine, metoclopramide
	5-HT	$5\text{-}HT_3$	Ondansetron, granisetron
Motion on vestibular nuclei	Acetylcholine	Muscarinic	Hyoscine, atropine
	Histamine	H_1	Cyclizine, promethazine
Input directly to vomiting centre	Acetylcholine	Muscarinic	Hyoscine, atropine,
	Histamine	H_1	Cyclizine promethazine

3

Anti-emetic drugs in anaesthesia

The mechanism by which postoperative nausea and vomiting (PONV) occurs is unclear and almost certainly multifactorial. The risk factors for PONV are given in **PERIOPERATIVE CARE**. There are no animal models of PONV, therefore drug treatment has been restricted to trials of agents that are effective anti-emetics in other situations, rather than a rational design of drugs based on an understanding of the condition.

Dopamine receptor antagonists

Dopamine is involved in emesis and dopamine antagonists are effective anti-emetics. Most dopamine antagonists (e.g. droperidol) have no selectivity for the dopamine receptors in the chemosensitive trigger zone. By their action on dopaminergic systems in other part of the brain, dopamine antagonists also produce hyperprolactinaemia and extrapyramidal motor disturbances similar to Parkinson's disease. An exception is domperidone, which is less likely to cross the blood−brain barrier than other agents, and thus is less prone to, but not free from, extrapyramidal actions. There is some debate concerning the effectiveness of domperidone in PONV. There are also reports of severe cardiac arrhythmias after large doses, which resulted in the withdrawal of the parenteral preparation. These three factors have caused a loss of interest in domperidone from an anaesthetic point of view. Interestingly, despite its adverse effects, droperidol is still the standard anti-emetic with which others are compared.

Metoclopramide and domperidone have additional prokinetic activity (enhanced gastric and upper intestinal motility) that may contribute to their anti-emetic effects. The prokinetic action has been attributed to an agonist action of metoclopramide on $5\text{-}HT_4$ receptors. In addition, metoclopramide has some $5\text{-}HT_3$ antagonistic effects at higher doses.

Dopamine antagonists are not useful for motion sickness unless they have coincident muscarinic cholinoceptor antagonist properties.

Muscarinic cholinoceptor antagonists

In the treatment of PONV, the muscarinic receptors present in the vomiting centre are an important target. Two muscarinic antagonists (hyoscine, atropine) are used as anti-emetics in anaesthesia. Both are lipid soluble and penetrate the brain to reach the vomiting centre. Intramuscular hyoscine is more effective as an anti-emetic than intramuscular atropine but is associated with increased drowsiness and delayed recovery from anaesthesia. In order to increase its duration of action, hyoscine has also been used as a transdermal preparation. The patch needs to be applied several hours before the emetic stimulus to enable an adequate plasma concentration to be obtained. Several authors have demonstrated the efficacy of transdermal hyoscine in PONV, but others have failed to detect a significant difference from placebo. Negative results were more likely when the duration of patch application was short or additional premedication drug administration was uncontrolled. Muscarinic receptors are found in the periphery, associated with the effector organs of the parasympathetic nervous system. Thus, typical anti-muscarinic adverse effects such as dry mouth and blurred vision are common, though not usually serious.

Histamine H_1-receptor antagonists

Histamine H_1 and muscarinic receptors are present in both the vomiting centre and the vestibular nucleus. The antihistamine drugs used to treat nausea and vomiting also have additional anti-muscarinic activity, therefore it is unclear which property is more important regarding their anti-emetic action. Cyclizine has been used to treat PONV and most reports demonstrate efficacy with few side-effects such as sedation. Promethazine is a markedly sedative drug and has been used by anaesthetists to premedicate children, but whether this is for its sedative effect or anti-emetic effect is debatable. Oral dimenhydrinate given at least 1 hour before surgery has also been used to prevent PONV. Second-generation antihistamines (e.g. terfenadine, astemizole) are ineffective anti-emetics because they do not cross the blood−brain barrier. Neither muscarinic antagonist nor antihistaminic drugs are useful in treating emesis due to chemotherapy.

5-HT$_3$ receptor antagonists

5-HT is released by cytotoxic agents and contributes to nausea and vomiting by actions in the gastrointestinal tract and the brain. In addition, dopamine antagonists may be ineffective in the severe emesis induced by chemotherapy. These observations prompted the successful trial of 5-HT$_3$ antagonists (e.g. ondansetron) in chemotherapy-induced emesis. Subsequently, oral ondansetron was found to be effective in PONV, which has been confirmed, using the oral and intravenous route. Generally the adverse effects of ondansetron were mild with no signs of the extrapyramidal symptoms or dry mouth seen with alternative anti-emetics. Granisetron is also effective in PONV but other 5-HT$_3$ antagonists (e.g. dolasetron, tropisetron) have been used successfully only in the treatment of patients given emetogenic chemotherapy.

Comparative studies between individual 5-HT$_3$ antagonists in PONV have not been carried out, but there are some reports of comparisons with other anti-emetics; recent examples involving intravenous ondansetron are summarized in Figure 4.

Most clinical trials involving ondansetron used single doses and the equivalence of the dose of comparator may be questioned. However, in general, the 5-HT$_3$ antagonists appear to be more effective and to exhibit fewer adverse effects than alternative anti-emetics used for PONV. The cost of treating all patients at risk of PONV with these relatively new agents must be considered.

Comparisons between intravenous ondansetron and other anti-emetics for postoperative nausea and vomiting

Comparator (intravenous)	Surgery	Result
• Metoclopramide	Laparoscopic	Ondansetron superior to metoclopramide in cholecystectomy females (males showed little nausea or vomiting)
• Dimenhydrinate	Adenotonsillectomy	42% of children vomited with ondansetron compared with 79% with dimenhydrinate
• Droperidol	Laparoscopy	Both drugs equally effective in preventing nausea, though ondansetron slightly superior in preventing vomiting
• Droperidol	Strabismus surgery	Ondansetron and droperidol were equally effective and better than metoclopramide in decreasing pre-discharge vomiting but none were effective in decreasing post-discharge vomiting

4

Other anti-emetics

Although the glucocorticosteroids and the cannabinoid nabilone have been used as anti-emetics for cancer chemotherapy, they have not been used extensively in anaesthesia. The intravenous anaesthetic propofol has also been used to treat PONV in a patient-controlled trial. Although sedation could be a problem if the dose was too high, moderate doses were effective and, when compared with placebo, shortened the stay in the post-anaesthetic care unit.

Anti-muscarinic drugs

When anaesthetic drugs included diethyl ether (which produced copious bronchial and salivary secretions) and cyclopropane (which caused cardiac slowing) premedication with an antagonist at muscarinic cholinoceptors was considered essential. Now that these drugs are seldom administered, the rationale for routine anti-muscarinic premedication has gone. However, the drugs are still sometimes used for specific indications, such as procedures causing excessive parasympathetic stimulation (e.g. haemorrhoidectomy) and for patients with obstructive airway disease. Typical pharmacological effects of antagonists at the muscarinic receptors for acetylcholine are listed in Figure 5. The mechanism of the sedative effects of hyoscine with low doses is unknown as higher doses have similar excitatory effects as atropine. Glycopyrronium is a quaternary compound that does not penetrate the CNS and thus is devoid of CNS actions.

Effects of muscarinic antagonists

Inhibition of secretions:
- dry mouth and skin

Relaxation of:
- bronchial muscle
- biliary tract
- bladder and urinary tract (possibility of urinary retention)

Reduction of intestinal motility

Tachycardia (low doses of atropine can cause bradycardia by a central action)

Mydriasis

Cycloplegia

CNS actions:
- anti-emetic
- sedation (hyoscine)
- excitation (atropine)
- inhibition of the symptoms of Parkinson's disease

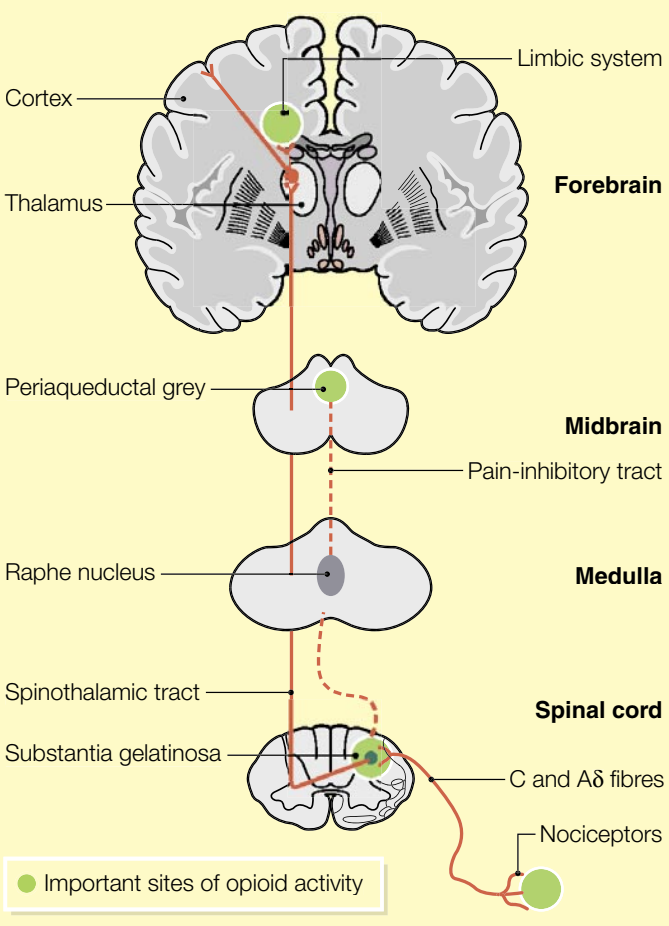
5

Analgesic drugs

The use of analgesic drugs as premedication in patients with preoperative pain is accepted, but their use as prophylactic (or pre-emptive) treatment for postoperative pain is more controversial. Opioids, non steroidal anti-inflammatory drugs (NSAIDs) and paracetamol have all been used for both purposes. Opioids mimic the actions of the endogenous opioid peptides acting on μ opioid receptors at various sites in the pain pathway (Figure 6) while NSAIDs and paracetamol inhibit the cyclo-oxygenase enzyme responsible for prostaglandin formation from arachidonic acid. In the periphery, prostaglandins sensitize nociceptors to pain mediators such as 5-HT and bradykinin. Within the spinal cord, prostaglandins enhance nociceptive processes and within the cerebral blood vessels they cause vasodilatation which leads to headache (Figure 7).

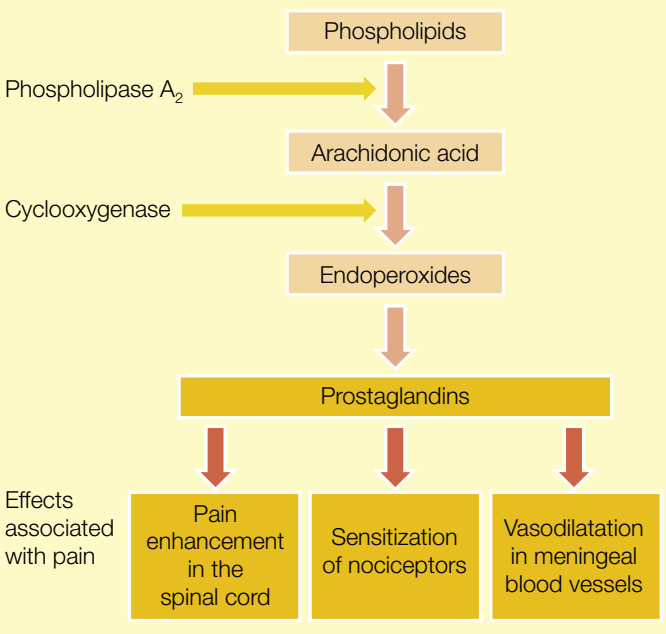
There is no evidence that the prophylactic use of NSAIDs or paracetamol has any beneficial effect though a reduction in subsequent postoperative opioid requirements has been reported. Pre-emptive opioid administration has been useful in some trials, but the trial designs were not perfect and more information is required before recommendations can be made.

Sites of opioid activity



6

Action of prostaglandins



7

Clonidine

Clonidine is a α_2-adrenoceptor agonist that has been used to lower blood pressure via inhibition of noradrenaline release (peripheral presynaptic action) and inhibition of sympathetic outflow (central action). Sedation has always been a consistent side-effect of the antihypertensive action of this class of drugs and anaesthetists needing to reduce anaesthetic requirements have exploited this property. Clonidine also has useful analgesic activity by mimicking the action of noradrenaline released in the dorsal horn of the spinal cord by the descending inhibitory pain pathways (Figure 6).

Receptors, Agonists and Antagonists

Michael Hollingsworth
Barbara J Pleuvry

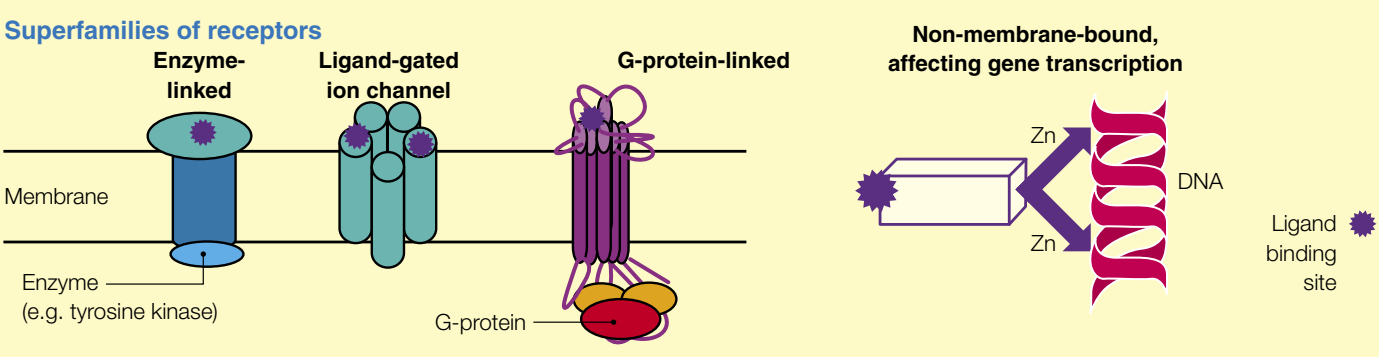
Michael Hollingsworth is Senior Lecturer in Pharmacology in the School of Biological Sciences at Manchester University, UK. He teaches pharmacology to medical, dental and science students.

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. She is a pharmacist by first degree but has been involved in teaching pharmacology to postgraduates and undergraduates for over 30 years. Her research interests include pain, analgesia and anticonvulsant drugs.

An understanding of the pharmacological basis of drug action can provide a scientific framework for therapeutic use. The molecular mechanism of a drug often explains its effect and the magnitude and timing of its action.

Drug receptors

Different types of drug receptors are shown in Figure 1.



1

Ion channels

Cell plasma membranes contain ligand-gated and voltage-gated ion channels. At the neuromuscular junction, acetylcholine, and its structural analogue suxamethonium, bind to the nicotinic receptor, which is part of the sodium channel. Interaction of the drug with its receptor causes a conformational change, opening the channel, allowing influx of sodium ions into the skeletal muscle cells and triggering contraction. This explains why the onset of action of suxamethonium is rapid once it has reached its site of action.

Other drugs act on voltage-gated ion channels, examples are local anaesthetics acting on sodium channels in neurons and calcium channel blockers (e.g. nifedipine) acting on smooth and cardiac muscle. The pharmacology of drugs acting on both types of ion channels is described on page 324.

G-protein-linked receptors

Receptors linked by guanosine-binding proteins (G-proteins) to either ion channels or enzymes are also important for drug action. Salbutamol interacts with β-adrenoceptors to activate the enzyme adenylyl cyclase indirectly, thus increasing the conversion of adenosine triphosphate (ATP) to the second messenger cyclic adenosine monophosphate (cAMP), which in turn phosphorylates many key intracellular proteins resulting, for example, in bronchial relaxation. The muscarinic receptor for acetylcholine in the heart is linked via G-proteins to a potassium channel, opening of which causes bradycardia. This triggering of a biochemical cascade or indirect opening of an ion channel occurs within seconds so the onset of drug action by this type of mechanism is usually rapid. Many drugs have G-protein-coupled receptors as their site of action.

The existence of G-proteins was deduced when it was observed that stimulation of second messenger systems, such as adenylyl cyclase, required the receptor agonist and the presence of guanosine triphosphate (GTP). The G-protein was found to be three different proteins joined together, a heterotrimer, with subunits called α, β and γ, in order of decreasing molecular weight. An agonist–receptor complex causes a conformation change in the intracellular domain of the receptor to a form that has high affinity for the G-protein, which is freely diffusible in the plane of the cell membrane. The process of binding of the receptor to the G-protein catalyses the dissociation of guanosine diphosphate from the α subunit of the G-protein and it is exchanged for intracellular GTP, which causes dissociation of the α subunit from the β and γ subunits. The latter two proteins originally appeared to be involved in anchoring the protein to the plasma membrane but subsequent studies have suggested an independent signal transduction role. The
α subunit modulates the action of a given effector, which is not always adenylyl cyclase. The α subunit has GTPase activity and converts GTP to GDP followed by reassociation with the other two subunits and the cessation of the signal. In its resting state the G-protein complex is not associated with any particular receptor and can interact with several different receptors and effectors.

Many variants of the α, β and γ subunits have been described and the number is growing. Two bacterial toxins (pertussis and cholera) have been useful in distinguishing the type of G-protein involved in a particular situation. Cholera toxin causes persistent activation of the G-protein (Gs), which stimulates adenylyl cyclase causing the excessive secretion of fluid from the gastrointestinal epithelium characteristic of cholera. Pertussis toxin has no effect on Gs but prevents the actions of other G-proteins such as Gi, which inhibits adenylyl cyclase activity. Several other G-proteins are inhibited by pertussis toxin and thus its functional effects are less obviously explicable in terms of G-protein inhibition.

G-protein effectors

Adenylyl cyclase
Stimulated by Gs
Inhibited by Gi
Produces second messenger cAMP

Guanylyl cyclase
Produces second messenger cGMP

Phospholipase C
Activated by Gq
Produces second messengers inositol 1,4,5,-triphosphate (IP_3) and diacylglycerol (DAG)

Phospholipase A_2
Produces second messenger arachidonic acid

Ion channels
Particularly Ca^{2+}, Na^+ and K^+

2

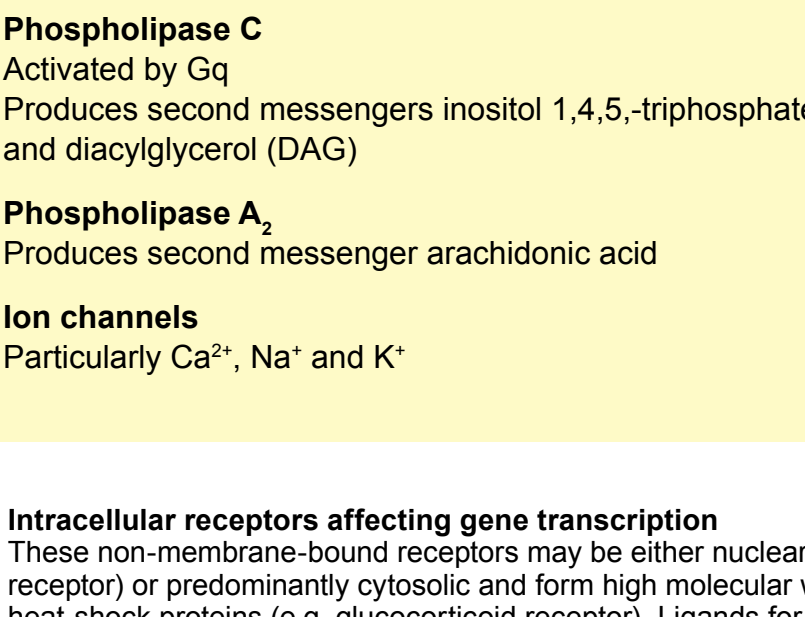
Intracellular receptors affecting gene transcription

These non-membrane-bound receptors may be either nuclear (e.g. thyroid hormone receptor) or predominantly cytosolic and form high molecular weight complexes with heat-shock proteins (e.g. glucocorticoid receptor). Ligands for these receptors must be lipid soluble and pass into the cell. The presence of a ligand leads to the dissociation of the receptor from the heat-shock proteins and the receptor−ligand complex moves into the nucleus. The binding of the ligand to the receptor results in an uncurling of the receptor protein to reveal the DNA binding domain. The DNA binding domain consists of two ‘zinc fingers’ which contain cysteine residues surrounding a zinc atom. These fingers are thought to wrap round the DNA helix at hormone-responsive elements in the strand. An increase in RNA polymerase activity and the production of a specific mRNA occurs and protein production is enhanced. A well-documented example is the increase in lipocortin production induced by glucocorticoid drugs. This sequence of events is relatively slow, thus the time to onset of action of drugs acting via this mechanism is measured in hours or days.

Agonists

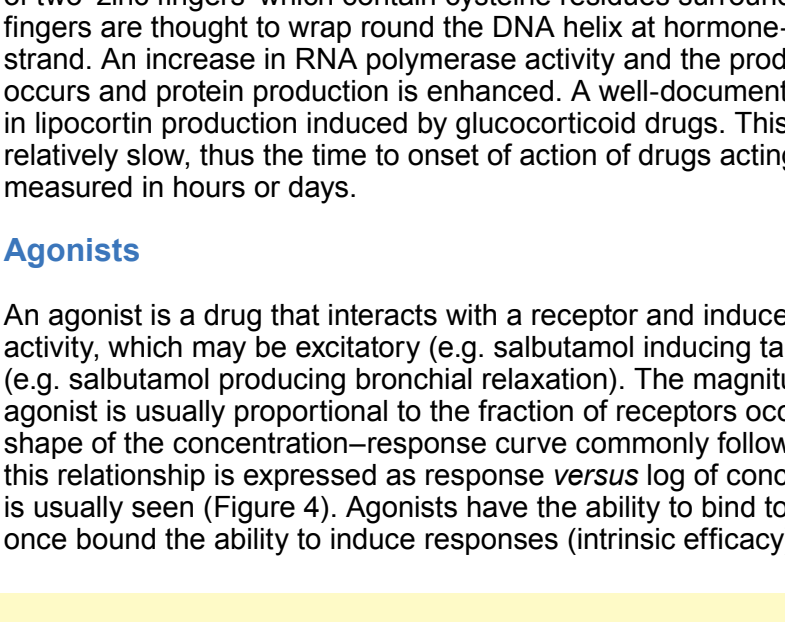
An agonist is a drug that interacts with a receptor and induces changes in cellular activity, which may be excitatory (e.g. salbutamol inducing tachycardia) or inhibitory (e.g. salbutamol producing bronchial relaxation). The magnitude of response to an agonist is usually proportional to the fraction of receptors occupied and therefore the shape of the concentration–response curve commonly follows a hyperbola (Figure 3). If this relationship is expressed as response *versus* log of concentration a sigmoidal curve is usually seen (Figure 4). Agonists have the ability to bind to receptors (affinity) and once bound the ability to induce responses (intrinsic efficacy).

Hyperbolic concentration–response curve for a typical drug



3

Sigmoidal log concentration–response curve for a typical drug



4

Antagonism

Antagonism broadly describes the situation when the pharm-acological effect of two drugs is less than the sum of their individual effects. Some of the methods of drug antagonism are described below.

Chemical antagonism

This uncommon type of antagonism occurs when one drug chemically interacts with a second drug and reduces the effect of the second drug. An example is the ability of desferrioxamine to reduce the toxicity caused by the iron from ferrous sulphate tablets. Desferrioxamine, by chelating the iron, enhances its removal from the body and reduces toxicity.

Pharmacokinetic antagonism

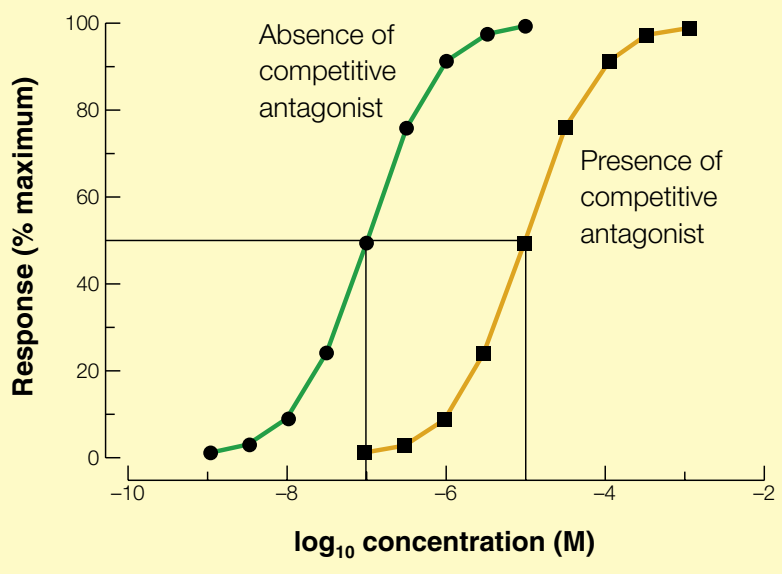
With pharmacokinetic antagonism, one drug alters the handling by the body of the second drug, reducing the effect of the latter. One example is the ability of rifampicin (used to treat tuberculosis) to enhance the liver metabolism of drugs such as ethinyloestradiol (a component of the oral contraceptive pill) reducing the steady-state concentration of ethinyloestradiol.

Pharmacodynamic antagonism

Pharmacodynamic antagonism can occur at a common receptor or at different receptors.

Common receptor: in practice, the most important type of antagonism is where an antagonist interacts with the same receptor as an agonist. Most of these drugs are competitive antagonists. When the antagonist binds to the receptor, it does not induce a response but prevents the binding, and hence action, of the agonist. The competitive antagonist has affinity but no intrinsic efficacy. Competitive antagonists do not form strong bonds with the receptor proteins and their effects are reversible on removal from the site of action. If the concentration of the agonist is sufficient a response is observed even in the presence of a competitive antagonist. The consequence of this interaction is that the log concentration–response curve is shifted to the right (Figure 5).

Log concentration–response curve for an agonist



5

The pharmaceutical industry has been successful in developing chemical analogues that are competitive antagonists of naturally occurring agonists. Examples are promethazine and ranitidine at histamine H_1- and H_2-receptors, respectively, propranolol at β-adrenoceptors, losartan at angiotensin receptors, naloxone at opioid receptors and atracurium at nicotinic acetylcholine receptors. Therapeutically competitive antagonists are used for their ability to reduce the effects of endogenously released agonists.

Some antagonists form strong, usually covalent, bonds with the receptor. They are known as non-equilibrium antagonists because the degree of antagonism increases with time and does not come to equilibrium, unlike competitive antagonists. Their effect is not readily reversible for the same reason. Often they are called non-competitive antagonists but that termin-ology is incorrect because they do compete with agonists for binding to receptors. An example of such an antagonist is phenoxybenzamine, which is a non-equilibrium antagonist at α-adrenoceptors.

Different receptor: antagonism can be produced even if the two drugs interact with different receptors. For example, high doses of nicotine act at peripheral ganglia to release noradrenaline from postsynaptic nerve endings and induce, say, tachycardia via β-adrenoceptors in the sino-atrial node. Propranolol would be able to reduce the effect of nicotine by acting as an antagonist at the β-adrenoceptors. This type of antagonism is indirect because the antagonist and agonist do not interact with the same site.

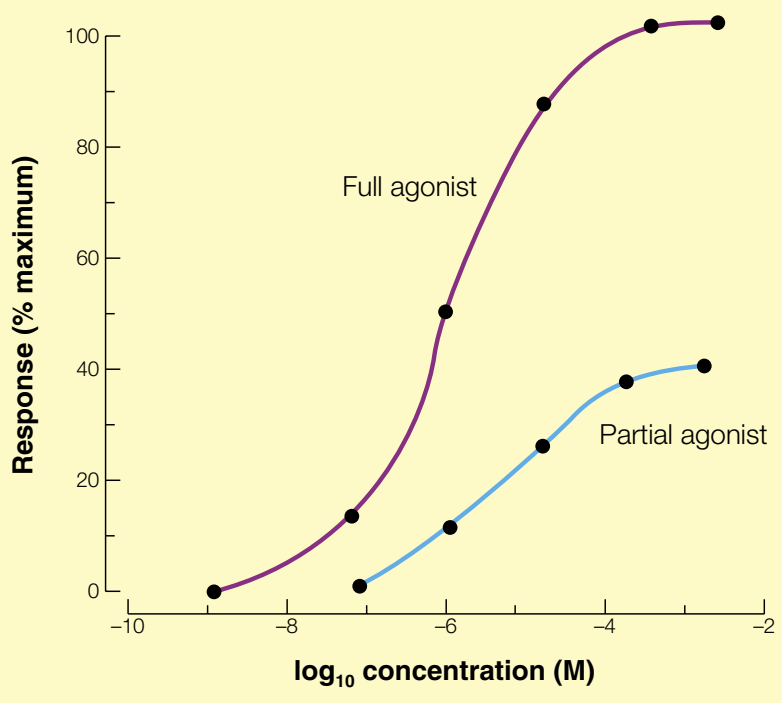
Antagonism can occur between two agonists and is called functional or physiological antagonism. For example, the agonist histamine will produce bronchoconstriction by acting as an agonist at histamine H_1-receptors while salbutamol will induce bronchodilatation as an agonist at β_2-adrenoceptors. If the two drugs are given in combination, the total effect they produce is less than the sum of their individual effects − the definition of antagonism.

Partial agonist and inverse agonists

A partial agonist has the properties of both agonists and competitive antagonists. When given alone, such compounds exhibit agonist properties but their maximal effect is less than that of a full agonist (Figure 6). When given with a full agonist, partial agonists reduce the effects of the full agonist. Partial agonists thus have affinity for receptors and some intrinsic efficacy but less than that of full agonists. Examples are buprenorphine at opioid receptors and alprenolol at β-adrenoceptors.

Recent years have seen the development of inverse agonists. In some artificial systems using G-protein-coupled receptors activity can be observed in the absence of agonist (constitutive activity). An inverse agonist is able to reduce the continuing activity in this system by interacting with the receptor and is described as having negative intrinsic efficacy. Some benzodiazepines are inverse agonists. Inverse agonists have therapeutic potential if there are pathophysiological situations where such constitutive activity occurs, but this awaits future research.

Log concentration–response curve for a full and a partial agonist



6

Potency, relative potency and maximum effect

The properties of many drugs are independent of their mechanism of action and there are useful descriptors to enable one drug to be compared with another. For most drugs, the relationship between response and concentration is hyperbolic (Figure 3). From such a curve the effective concentration producing 50% of maximal response (EC_{50}) can be determined. The potency of a drug is the reciprocal of the EC_{50} and therefore a drug that produces an effect at low concentrations is potent. If the effect is measured *in vivo* then dose substitutes for concentration. As explained above, such data are often expressed as response *versus* log concentration (or dose). It is then easy to compare the potencies of two drugs in terms of their log relative potencies, which can be antiloged to give their relative potencies.

Not all drugs have the same maximal effect on a system. Figure 7 illustrates the pain relief that might be induced by morphine and aspirin. Morphine is more potent (less drug is needed for a similar effect) and has a greater maximal effect than aspirin.

Log dose–response curves for two drugs illustrating the difference in their maximal effects

Regulation of Drug Licensing

Rachel M Morten

Rachel M Morten is a Regulatory Affairs Consultant. She has worked in regulatory affairs for over 18 years and set up ChapelPharma in 1995. Typical projects have included licence maintenance, Marketing Authorizations and orphan drug applications for products in many therapeutic areas. Her principal interest is in new product development.

The drug licensing laws govern all aspects of pharmaceutical products. They cover not only the conduct of clinical trials, research and the approval of new Marketing Authorizations, but the control of a medicinal product throughout its marketed life. This includes the changes that may be made to the formulation, packaging or indications, and also the pharmacovigilance of the product. All of these activities aim to ensure the safety of the product to the patient and to those who administer it. This article introduces the legislation that affects product labelling, the conduct of clinical trials and pharmacovigilance.

The need for controls over pharmaceutical products was highlighted by the thalidomide tragedy in the 1960s. This prompted the introduction in the UK of the Medicines Act in 1968, which although now influenced by decisions made at a European level, is still in existence today.

At about the same time, the European Community was established to promote the economic and political integration of its Member States. The main objective of the now enlarged European Union is to establish a common market that allows free movement of goods, people, services and capital.

Pharmaceutical products are not exempt from this harmonization and are governed by many European laws that are incorporated into each Member State's national legislation.

European legislation

The two types of European legislation that have a legal basis are Regulations and Directives (Figure 1). They are supplemented by guidance documents and Points for Consideration.

Figure 2 lists the main legislation that governs the regulatory approval and sale of pharmaceutical products in Europe.

European legislation

Regulations
Cover European policy and procedural issues. European Member States must abide by every aspect of a Regulation

Directives
Cover issues such as the content of a Marketing Authorization Application (MAA), the procedure for MAAs, labelling, distribution, pharmacovigilance and manufacturing controls. The Member States must incorporate the laws into their own national legislation, but interpretation of the Directives depends on each Member State (which is why there still appear to be national differences)

Guidelines
Provide scientific guidance on, for example, the design and type of studies that are required to support an MAA. They have no legal basis. However, failure to follow a particular guideline would need to be justified in the MAA

Points for Consideration
Points that applicants should consider when conducting studies to support the MAA. They have no legal basis. They are often introduced when new issues arise that Regulatory Authorities feel should be addressed (e.g. Points to Consider for new Anti-Fungal Agents for Invasive Fungal Infections, which was released for consultation in July 2002)

As time goes on and more experience is gained, it is usual for the Points for Consideration document to be fleshed out into a more formal Guideline

1

Legislation governing the regulatory approval and sale of pharmaceutical products in Europe

- Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the Community code relating to medicinal products for human use

- Council Regulation (EEC) No 2309/93, of 22 July 1993, laying down Community procedures for the authorization and supervision of medicinal products for human and veterinary use and establishing a European Agency for the Evaluation of Medicinal Products. (Amended by Commission Regulation (EC) No 649/98 of 23 March 1998 amending the Annex to Council Regulation (EEC) No 2309/93)

These documents can be accessed electronically at http://pharmacos.eudra.org/F2/eudralex

2

Summary of product characteristics

It is a requirement of Directive 2001/83/EC that all Marketing Authorization Applications include a proposed Summary of Product Characteristics (SmPC).

The SmPC is the basis on which the Patient Information Leaflet and all labelling is based. Once approved, products must be used only for the indications and the patient population included on the label. Physicians using products outside the terms of their Marketing Authorization take full responsibility for the patient's safety.

At the start of any new product development, the first question that should be asked by the project team is 'What profile do we want the product to have?' Without answering this question, it is difficult to ensure that the development work is focused and that clinical trials will support the desired indication. The easiest way to begin thinking about this is to prepare a draft SmPC.

The statements in the SmPC must be supported by the clinical, preclinical and formulation studies that are undertaken during the product's development.

When the commercial need for a product is identified, it is the proposed indication on the SmPC that must drive the clinical development programme. For example, if a product is indicated for use in chronic pain, it is necessary to provide clinical data that show a statistically significant improvement in patients with chronic pain. Providing data on patients with acute pain may provide some supportive data but would not be sufficient to obtain approval of a Marketing Authorization.

Conducting clinical trials

Before 1992 there was no harmonization in Europe for the approval to conduct clinical trials. Each European country had its own legislation and *modus operandi*. The only harmonization was the need for all trials to be conducted to Good Clinical Practice as noted in Annex 1 of Directive 2001/83/EC and Guideline ICH E6 (CPMP/1CH/135/95). On 1 May 2001 the Clinical Trial Directive was published (Directive 2001/20/EC). This came into effect on 1 May 2003, when all Member States should have incorporated the terms of the Directive into their own national legislation. However, application will now be delayed until May 2004.

This Directive standardizes the rules for obtaining clinical trial authorizations in all Member States. This Directive has introduced several changes, including the following.

- The need for approval before all trials can begin (Phases I–IV). This has been a major change for the UK because previously trials in healthy subjects (most Phase I) were exempt from the need for a Clinical Trial Approval.
- A standardization of the documentation needed for submission to the regulatory authorities and ethics committees. In the UK, the simplified DDX (Doctors and Dentists Exemption) application process ceases to exist. All applications for investigational use must include the same documentation and follow the same procedure.
- A standard time to approval of 30 days, extendable to 60 days for a clinical trial application, with only a single clock stop permitted to ask questions (the approval time can be extended by 30 or 90 days for biotech products and there is no limit for gene and cell therapy products). In the UK, this could be longer than the CTX (Clinical Trial Exemption) approval time, which was
32 days. However, the MHRA (Medicines and Healthcare products Regulatory Agency) has indicated that it will review
Phase I trial applications in an average of 14 days and no later than 21 days.
- Clinical trial material must be manufactured to standards of Good Manufacturing Practice (GMP). However, there is unlikely to be a need for a Manufacturer's Licence or a Qualified Person to cover reconstitution and packaging of clinical trial material by a hospital pharmacist.
- The introduction of inspections to ensure compliance with Good Clinical Practice (GCP) and Good Manufacturing Practice.

In addition to the Clinical Trial Directive, there are (at the time of writing) 12 detailed guidelines covering all aspects of clinical trials. These guidelines are another step towards harmonizing the standard of many activities associated with conducting clinical trials. Copies of these can be found at http://pharmacos.eudra.org/F2/pharmacos/docs.html.

Pharmacovigilance

During the clinical trials of a new product, and post marketing, the need for monitoring the side-effects of the product are paramount. Pharmacovigilance is the term used to describe all of the activities surrounding the diagnosis, assessment and reporting of adverse events.

Physicians should be aware of the definition of an adverse event/reaction and serious adverse events/reactions. These are given in Annex 1 of Directive 2001/20/EC. The reporting times following occurrence of serious adverse reactions are also clearly defined in Article 17 of the Directive. These are 7 days for serious unexpected reactions that are fatal or life-threatening and 15 days for all other suspected serious unexpected adverse reactions. ◆

Supplementary Drugs in Anaesthesia

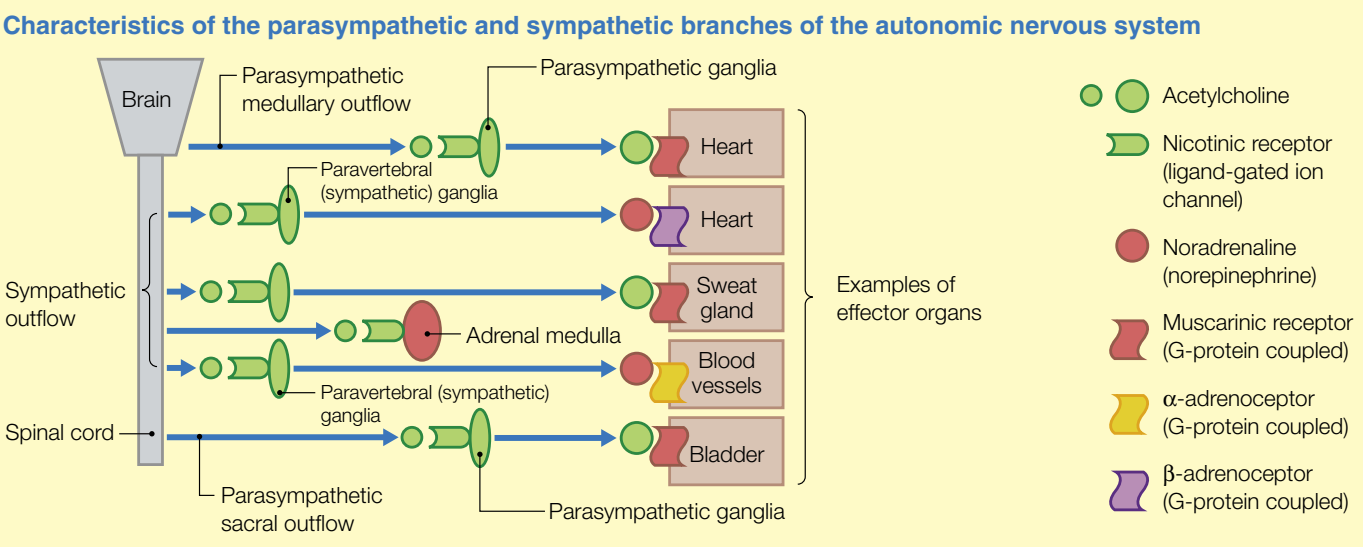
Barbara J Pleuvry

Barbara J Pleuvry is Senior Lecturer in Anaesthesia and Pharmacology at the University of Manchester, UK. Her research interests include pain, analgesia and anticonvulsant drugs.

Many supplementary drugs are given as part of a general anaes-thetic regimen. The hypnotics and sedatives are discussed in **PHARMACOLOGY**. This article deals with the drugs affecting the autonomic nervous system that are given before, during and after the anaesthetic agent.

The autonomic nervous system consists of the parasym-pathetic and sympathetic branches, and most pharmacological discussions concentrate on the efferent outflows of these two systems. The characteristics of these pathways are shown in Figure 1. In contrast to the somatic efferent pathways, in which a single motor neuron connects to the ventral horn of the spinal cord, the autonomic efferent pathway has two neurons that synapse at ganglia. In the case of the sympathetic nervous system, these ganglia lie close to the spinal cord in the paravertebral chain such that the pre-ganglionic fibre is short and the post-ganglionic fibre is long. The ganglia of the parasympathetic nervous system lie on or close to their effector organs so that the post-ganglionic neuron is short.

Characteristics of the parasympathetic and sympathetic branches of the autonomic nervous system



1

Cholinergic neurotransmission in the autonomic nervous system

Acetylcholine (ACh), interacting with nicotinic receptors (Figure 2), is the neurotransmitter at all autonomic ganglia. Thus drugs that stimulate or block these receptors do not differentiate between the sympathetic and parasympathetic ganglia. Nicotinic receptors are also found at the motor end-plate of skeletal muscle, but the molecular characteristics of the two receptors are different such that some nicotinic agonists and antagonists can have selectivity for the autonomic ganglia over the neuromuscular junction.

Actions of acetylcholine at nicotinic receptors

Stimulation of sympathetic and parasympathetic ganglia

- Increased blood pressure
- Tachycardia
- Variable effects on gastrointestinal motility
- Increased secretions
- Bladder contraction

Stimulation of skeletal muscle enabling movement

2

Trimetaphan
A number of fairly selective ganglion blockers have been developed, but only trimetaphan still has significant use in anaesthesia. Trimetaphan is used to induce controlled hypotension in surgery. Its mechanism of action involves ganglion blockade (inhibiting the sympathetic tone maintaining blood pressure), release of histamine to cause peripheral vasodilatation and a direct vasodilator effect. The principal advantage of trimetaphan over other ganglion-blocking agents is that it is short acting and can be given as an infusion to provide fine control of blood pressure. The effects of ganglion blockade on other effector systems depend on the dominant autonomic tone (sympathetic or parasympathetic; Figure 3).

Effect of ganglion blockade in a fit young adult

Effector	Predominant tone	Effect of ganglion blockade
Arteries	Sympathetic (noradrenaline; norepinephrine)	Vasodilatation
Veins	Sympathetic (noradrenaline; norepinephrine)	Vasodilation
Ciliary muscle	Parasympathetic (acetylcholine)	Cycloplegia
Iris		Parasympathetic
(acetylcholine)	Mydriasis	
Heart	Parasympathetic (acetylcholine)	Tachycardia
Gastrointestinal tract	Parasympathetic (acetylcholine)	Constipation
Salivary gland	Parasympathetic (acetylcholine)	Dry mouth (xerostomia)
Sweat glands	Sympathetic (acetylcholine)	Dry skin (anhidrosis)

3

ACh interacts with G-protein-coupled muscarinic receptors on parasympathetic effector systems and some sympathetic effector systems, such as the sweat glands (Figure 4). Five subtypes of muscarinic receptor (M_1–M_5) have been identified. Their physiological role is uncertain and they will be alluded to only when selective agonists or antagonists have a clinical efficacy. Pirenzepine, for example, is an antagonist with selectivity for M_1 receptors and is used to inhibit gastric secretion in the treatment or prevention of gastric ulcers. Agonists at muscarinic receptors have limited use in anaesthesia, but muscarinic antagonists are used in premedication (see Anaesthesia and Intensive Care Medicine 2:6: 245), during surgery to reverse bradycardia and in conjunction with neostigmine during reversal of neuromuscular blockade.

Actions mediated by acetylcholine acting on muscarinic receptors in the autonomic nervous system

- Bradycardia
- Decreased cardiac output
- Vasodilatation (via release of nitric oxide)
- Contraction of smooth muscle
  - Bronchi
  - Intestine
  - Bladder
- Stimulation of exocrine glands
  - Salivation
  - Lacrimation
  - Sweating
  - Bronchial secretion
- Miosis
- Contraction of ciliary muscle (accommodation of the eye)

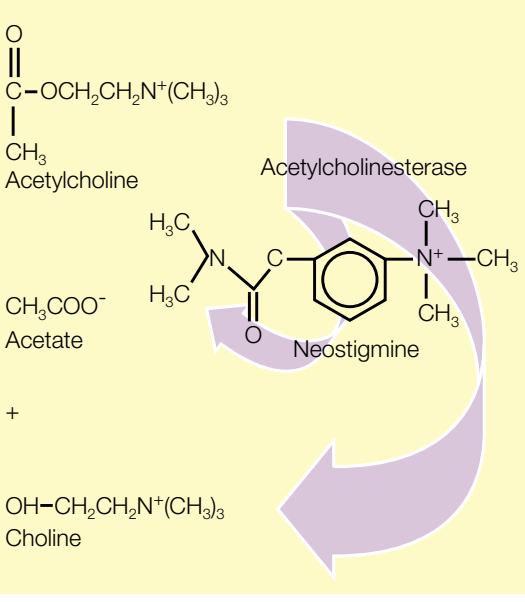
4

Anticholinesterase agents
The action of ACh is terminated by metabolism to choline and acetate by acetylcholinesterase (Figure 5). Acetylcholinesterase has two distinct active sites, an anionic site that attracts cationic groups and an esteratic site that produces catalytic hydrolyses of susceptible esters. In the case of ACh, acetate is removed from the molecule and temporarily transferred to a serine-OH group present on the enzyme. Choline is freed and the serine acetyl group is rapidly hydrolysed.

Neostigmine is an inhibitor of acetylcholinesterase. Like ACh it binds to both the anionic and esteratic sites on the acetyl-cholinesterase molecule but instead of an acetyl group it has a carbamyl group (Figure 5). The carbamyl group is transferred to the serine residues, but it only slowly hydrolyses from the enzyme, resulting in a relatively long inhibition of the enzyme.

Edrophonium is a very short-acting anticholinesterase agent. It is a quaternary ammonium compound that binds only to the anionic site of the enzyme and is thus readily reversible. Its major clinical use is for the diagnosis of myasthenia gravis, but it has been used in anaesthesia as an alternative to neostigmine. When reversing neuromuscular blockade, anticholinesterase agents preserve the action of ACh at the neuromuscular junction, thus antagonizing the competitive blockade of nicotinic receptors by neuromuscular blocking agents (see page 281). Unfortunately, ACh is also preserved at muscarinic sites and this could lead to excessive activation of the receptors with resultant bradycardia. This is prevented by the co-administration of a muscarinic antagonist, usually atropine. Atropine reverses all of the muscarinic effects of ACh listed in Figure 4. Glycopyrrolate is sometimes used as an alternative to atropine because it is devoid of CNS effects and its placental transfer is minimal. In addition, it has less effect on heart rate and pupil size.

Metabolism of acetylcholine



5

Adrenergic neurotransmission in the autonomic nervous system

Many drugs in this group are used to modulate myocardial function, vascular resistance and blood pressure, and some aspects of their pharmacology are discussed in **PHARMACOLOGY**. The neurotransmitter used at most sympathetic effector organs is noradrenaline (norepinephrine). Exceptions to this are ACh released at the sweat glands and possibly in skeletal muscle blood vessels and noradrenaline (norepinephrine) released from the adrenal medulla. The major subdivisions of the α- and β-adrenoceptors, and the principal pharmacological effects of their stimulation relevant to the autonomic nervous system are shown in Figure 6.

Sympathomimetic drugs
Both noradrenaline (norepinephrine) and adrenaline (epi-nephrine) act on all adrenoceptors, though noradrenaline (nor-epinephrine) has more activity on α-receptors than adrenaline (epinephrine). This means that intravenous administration of noradrenaline (norepinephrine) results in a decrease in heart rate. This is caused by the baroreceptor reflex response to the increase in blood pressure that occurs as a consequence of intense α-receptor-induced vasoconstriction increasing peripheral resistance. Adrenaline (epinephrine), in contrast, causes vasoconstriction, some vasodilation in skeletal muscle blood vessels and a moderate increase in heart rate.

Monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) (Figure 7) break down, both noradrenaline (norepi-nephrine) and adrenaline (epinephrine) so that their plasma elimination half-life ($t_{1/2}$) is a matter of minutes. More prolonged α-adrenoceptor stimulation can be achieved with a non-selective α-adrenoceptor agonist, such as methoxamine. Clonidine is usually used in anaesthesia for its sedative, general anaesthetic-sparing and analgesic effects that are mediated by α_2-adrenoceptor activation in the CNS. In the periphery, by reducing noradrenaline (norepinephrine) release via an action on presynaptic receptors, clonidine has been used as an antihypertensive agent, but is usually considered to be too long acting to be used for this purpose in anaesthesia.

Hypotensive complications in obstetric anaesthesia may be treated with ephedrine. This drug has direct effects on β- and β-adrenoceptors, and releases noradrenaline (norepinephrine) from sympathetic nerve endings. This combination of effects is less likely (than α-adrenoceptor agonists) to reduce placental perfusion and thus preserves fetal oxygenation. However, it does cross the placental barrier and the blood–brain barrier in the mother where it has an amphetamine-like effect.

Dopamine is another agent that combines β- and β-adrenoceptor stimulation. In addition, it causes renal and mesenteric vasodilatation by an action on dopamine (D_1) receptors in the vasculature. Its major use in anaesthesia is as an inotrope in low cardiac output states. Similarly, dobutamine (a β_1-selective agonist) and dopexamine (a β_2- and D_1-receptor agonist) are mainly used as inotropic agents.

Adrenoceptors

α_1-receptor

Principal responses to stimulation	**Selective agonist**
Contraction of smooth muscle in: • blood vessels • bronchi • gastrointestinal tract and bladder • sphincters • uterus • radial muscle of iris	Phenylephrine **Selective antagonist** Prazosin
Relaxation of smooth muscle in: • gastrointestinal tract	

α_2-receptor

Principal responses to stimulation	**Selective agonist**
Contraction of smooth muscle in blood vessels	Clonidine Dexmedetomidine
Decreased release of noradrenaline (norepinephrine) and acetylcholine	**Selective antagonist** Yohimbine[1]

β_1-receptor

Principal responses to stimulation	**Selective agonist**
Increase in: • heart rate • force of cardiac contraction	Dobutamine, Xamoterol **Selective antagonist** Atenolol
Increased release of noradrenaline (norepinephrine)	

β_2-receptor

Principal responses to stimulation	**Selective agonist**
• blood vessels • bronchi • gastrointestinal tract • bladder • radial muscles of iris	Salbutamol **Selective antagonist** Butoxamine[1]
Tremor and increased skeletal muscle mass Glycogenolysis	

β_3-receptor

Principal responses to stimulation

Thermogenesis
Lipolysis

[1] Not clinically available.

Drugs that block adrenoceptors

The selective α_1-adrenoceptor antagonist prazosin, and the selective and non-selective β-adrenoceptor antagonists are mainly used for the treatment of chronic hypertension. As supplementary drugs used in anaesthesia, β-adrenoceptor antagonists are mainly used to treat cardiac dysrhythmias associated with dental extractions, cardiac or vascular procedures, thyroidectomy and the removal of phaeochromocytoma. The various agents are compared in Figure 8. Additional properties, such as sodium channel blockade (local anaesthetic actions) or potassium channel blockade, may contribute to the anti-dysrhythmic actions of some agents. Typical adverse effects of excessive dosage are bradyarrhythmias and hypotension.

Comparison of β-adrenoceptor antagonists

Drug	Receptor	Local selectivity	Partial anaesthetic action	Comments agonist action
Atenolol	β_1	No	No	Does not penetrate to the CNS
Esmolol	β_1	No	No	Rapidly metabolized by esterases in RBCs
Oxprenolol	β_1, β_2	Yes	Yes	CNS actions: euphoria and vivid dreams. Partial agonists should cause cardiac failure, but clinical evidence is equivocal
Propranolo	β_1, β_2	Yes	No	CNS actions: euphoria and vivid dreams
Sotalol	β_1, β_2	No	No	Racemic mixture that also blocks potassium channels

Therapeutic Problems of Solid Organ Transplantation

Marc J Clancy

Marc J Clancy is a Specialist Registrar specializing in transplant surgery on the Northwest Regional Rotation. He graduated from Cambridge and Oxford Universities and trained at the Royal Free Hospital, London. He is a lecturer at the University of Manchester with research interests in chronic rejection and alternative forms of renal replacement therapy.

Solid organ transplantation provides an effective treatment for organ failure incompatible with life. This comes at the price of immunosuppression and a variety of potential complications, each presenting its own diagnostic and therapeutic problems.

Donor management: most transplant organs come from donors diagnosed with brainstem death. The autonomic, metabolic and endocrine changes induced by brainstem death produce a state of extreme cardiovascular instability. Up to 25% of potential organs are unusable owing to sudden hypotension or cardiac arrest. Meticulous donor care has benefits that are discernible many years after transplantation. The main components of organ maintenance therapy are:

- monitored fluid therapy
- inotropes
- vasopressors
- levothyroxine
- steroids
- insulin/dextrose infusion.

Problems common to all visceral transplants

Hyperacute rejection

Hyperacute rejection is a rapid reaction of pre-existing antibodies in the recipient plasma to antigens on the transplanted organ. It occurs within minutes to hours of surgery and leads to rapid thrombosis of supplying vessels with graft loss. This cross-reactivity can be identified by a transplant 'cross-match' in which donor cells and recipient serum are mixed and stimulation assayed. A positive cross-match indicates sensitization of the recipient to donor tissue, resulting from previous transfusion, transplant or pregnancy. In such cases, the risk of hyperacute rejection is sufficiently high that it is regarded as a contra-indication for kidney transplantation.

Acute rejection

Immediately the transplanted organ is perfused by recipient blood, the recipient immune system recognizes it as foreign. Within days of transplantation an acute inflammatory infiltrate, consisting predominantly of T cells, invades the allograft. This leads to tissue damage and graft hypofunction and without treatment would usually proceed to graft loss. Only if the graft is not recognized as foreign (e.g. a kidney from an identical twin) would this process not occur. In the early years of clinical transplantation, acute rejection was the major therapeutic barrier to a successful outcome. In the 1970s, up to 50% of transplanted kidneys were lost within 1 year largely through acute rejection. Most centres now report at least 85% 1-year survival rates.

Ciclosporin (cyclosporin) was developed in Cambridge in the late 1970s. Before then, the main agents used to treat rejection were glucocorticosteroids, azathioprine and antilymphocyte sera produced in animals. These agents still have a role, but the mainstay of immunosuppressive regimens is ciclosporin (cyclosporin). This cyclical fungal peptide is thought to act by inhibition of calcineurin, leading to decreased transcription of the cytokine genes mediating acute rejection. In the mid-1990s, tacrolimus (FK506/prograf) was introduced as an alternative to ciclosporin (cyclosporin). It is thought to work via a similar mechanism and has similar side-effects. Some units have adopted it as a baseline immunosuppressive. Recently, mycophenolate mofetil (MMF) and rapamycin (sirolimus) have been used but any advantage they have is unproven.

Most transplants are between non-identical people, therefore acute rejection is assumed and a baseline immunosuppressive protocol is used. Typically this involves monotherapy (with ciclosporin (cyclosporin) or FK506) or 'triple therapy' with a lower dose of one of the former plus a daily dose of glucocorticosteroid and azathioprine. The incidence of histological (subclinical) acute rejection in the first 3 months after kidney transplantation is about 30% with ciclosporin (cyclosporin) and less than 5% with FK506.

Immunosuppressive treatment reduces the frequency of clinically significant rejection episodes. However, the powerful immunological rejection process breaks through regularly and further treatment is required to restore or maintain graft function. In kidney transplantation, a rise in serum creatinine can indicate acute rejection. After the exclusion of other causes, which often requires a biopsy, a 'pulse' of glucocorticosteroids, 0.5 or 1 g/day i.v. for 3 days, is normally given. In acute cellular rejection of a liver transplant for example, a glucocorticosteroid pulse resolves about 75% of acute rejection episodes. In severe glucocorticosteroid-resistant rejection, a further therapeutic option is the use of an antilymphocyte globulin. This treatment requires careful monitoring of T cell levels and produces severe immunosuppression. Patients are usually nursed in isolation. Changing the baseline immunosuppressive from ciclosporin (cyclosporin) to FK506 is also effective in some cases of refractory rejection.

Infections

Immunosuppressive treatment leads to an increased incidence of most common infections. Patients also become susceptible to opportunist infections including cytomegalovirus (CMV) and *Pneumocystis carinii*.

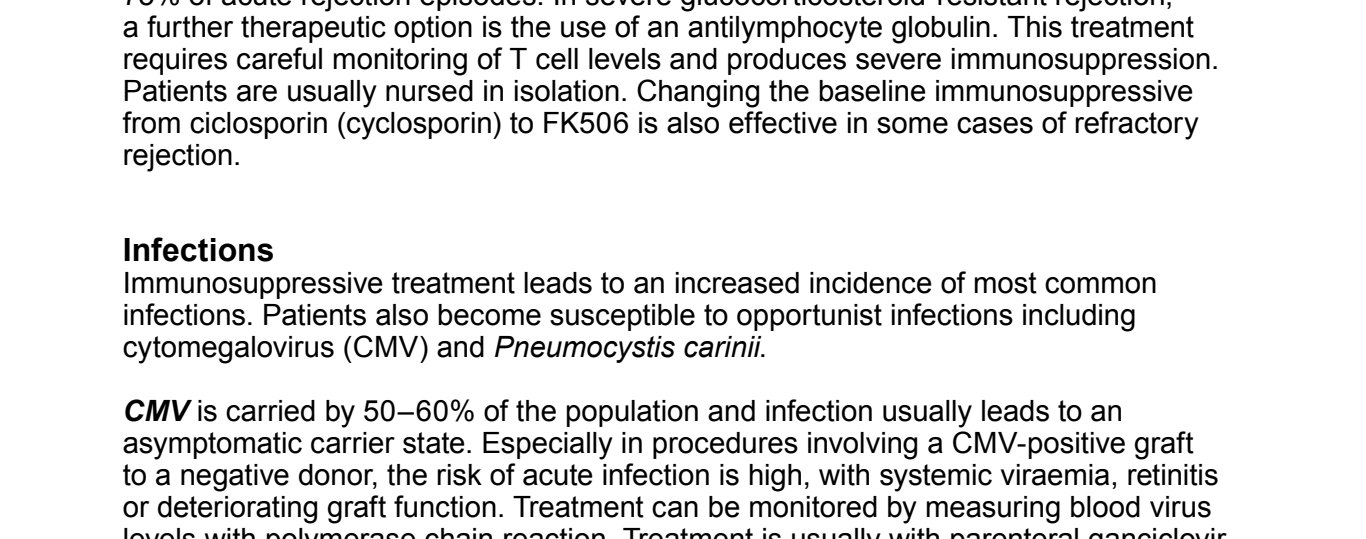
CMV is carried by 50–60% of the population and infection usually leads to an asymptomatic carrier state. Especially in procedures involving a CMV-positive graft to a negative donor, the risk of acute infection is high, with systemic viraemia, retinitis or deteriorating graft function. Treatment can be monitored by measuring blood virus levels with polymerase chain reaction. Treatment is usually with parenteral ganciclovir (gancyclovir) but oral antiviral preparations and prophylaxis have a role.

P. carinii pneumonia is an infrequent cause of respiratory infection in transplant patients. If prophylaxis is not given, there is a 5% incidence of pneumonia due to *P. carinii*. Acute pneumonia usually responds to a combination of trimethoprim (sulfamethoxazole (sulphamethoxazole) and cotrimoxazole). Many patients receive this as prophylaxis and in kidney transplants it is also prophylaxis against most urinary pathogens. Sensitivity to the sulphonamide component is common and aerosolized pentamidine is the second-line therapy.

Papilloma virus – cutaneous warts are a common complication of the long-term immunosuppression needed for a successful graft. Standard topical treatment or cryotherapy may not be sufficient and extensive areas of infection often require surgery.

Chronic rejection

Most episodes of acute rejection are rapidly resolved, but there is a steady loss of transplants with time. The most significant cause in all organs is a chronic fibrotic process affecting the graft and its vasculature (Figure 1). This is commonly called chronic rejection but is better termed chronic transplant vasculopathy in the heart or chronic allograft nephropathy in the kidney. This chronic, progressive and currently untreatable condition is incompletely understood. Epidemiological analysis suggests it is caused by chronic alloimmune damage, chronic immunosuppressive toxicity and the effects of the period of ischaemia followed by reperfusion at the time of grafting. Ciclosporin (cyclosporin) and FK506 are profibrotic so regimens without these agents are being evaluated in clinical trials. Antifibrotic agents (e.g. antibody raised against transforming growth-factor β) may also be beneficial but none has reached clinical practice.



Microscopic appearance of acute and chronic vascular rejection in the kidney. **a** Acute vascular rejection showing an intimal arteritis and a lymphocytic infiltrate in the surrounding interstitium. **b** Chronic vascular rejection shows intimal fibrosis and atrophy of adjacent tubules. The chronic damage created by **a** is strongly implicated in the development of the fibrosis that characterizes **b**.

Immunosuppressive side-effects

The side-effects of steroids and azathioprine are long established (Figure 2). The calcineurin inhibitors (ciclosporin (cyclosporin), FK506) are erratically absorbed and metabolized. Therapeutic monitoring with trough or D-2 levels (blood sample is taken 2 hours after the oral dose) is required to maintain immunosuppressive levels while avoiding the acute toxic effects that include tremor, nausea and vomiting as well as acute renal impairment.

Side-effects of immunosuppressive treatment (excluding infections)

Steroids (prednisolone)
- Mineralocorticoid effects (e.g. fluid retention, hypertension)
- Cushing's syndrome
- Diabetes
- Osteoporosis

Ciclosporin (cyclosporin)
- Nephrotoxic (high creatinine, implicated in chronic rejection)
- Neurotoxic (tremor, fits)
- Gum hypertrophy
- Hirsutism
- Hypertension
- Hyperlipidaemia
- ?Accelerated atherosclerosis

FK506
- Gastrointestinal disturbances
- Anxiety/depression
- Cardiomyopathy in children reported

Azathioprine
- Hypersensitivity
- Bone marrow suppression
- Hair loss

Mycophenolate mofetil (MMF)
- Gastrointestinal disturbances
- Pancreatitis
- Cough
- Rhinitis

Rapamycin (sirolimus)
- Lymphocele
- Gastrointestinal disturbances
- Anaemia
- Thrombocytopenia

Vascular complications

All visceral transplants entail anastomosis between the recipient vascular system and the corresponding vessels in the donor. Haemorrhage is rare and usually due to technical failure. Acute arterial and venous thrombosis is a significant cause of graft loss (2–4% of kidneys) and revascularization is seldom possible. Vascular stenosis commonly develops at anastomoses or within transplant vessels. These may be treated conservatively, by surgery, angioplasty, stenting, coumarin anticoagulation or antiplatelet therapy.

Kidney

Recipient care: most patients on the waiting list are in a reasonable state of health and many are maintained by dialysis. Most require dialysis before surgery to optimize their blood biochemistry. Preoperative blood transfusion is occasionally required but is to be avoided because of its sensitizing effect.

Tissue matching for major histocompatibility (MHC) antigens is routine and forms a major part of the UK scoring system for the allocation of cadaveric kidneys. A highly matched donor, differing by none or only one allele at the 6 MHC loci has an excellent expected graft survival time. This is termed a beneficial match and accorded priority in organ allocation.

Problems specific to kidney transplantation

Primary non-function – organs are scarce, necessitating the use of borderline organs, which may have donor pathology or long ischaemic periods. Often such organs exhibit acute tubular necrosis and do not function for days or weeks following implantation. In these cases, patients need continuing support with dialysis and erythropoietin therapy.

Urinary tract complications – an acute urinary leak, slowly presenting ureteric stenosis or acute obstruction are common. Irritant urine is painful and leaks usually require surgical repair. If hydronephrosis or subfunction results from ureteric narrowing or external compression, the renal tract may be decompressed by a ureteric stent or a percutaneous nephrostomy. Compressive lymphatic collections (lymphoceles) sometimes require long-term drainage because they often recur after aspiration.

Recurrence of original pathology is a significant cause of renal transplant dysfunction and loss, particularly the more aggressive of the glomerulonephritides. These conditions are treated with similar agents to the original conditions. Steroids are the mainstay of treatment but chemotherapy or plasmapheresis is sometimes indicated.

Liver

Recipient care*:* liver recipients vary from entirely stable to very ill, encephalopathic ITU patients. This is reflected in the stringency with which the transplant team assesses the donor liver suitability. Tissue matching is not performed but compatibility of ABO blood group antigens and size is routinely sought.

Problems specific to liver transplantation

Reperfusion syndrome – on reconnection with the recipient circulation, inflammatory mediators and cold perfusion solution are washed out of the extensive hepatic vascular bed and enter the systemic circulation. This can produce hypotension and cardiac irregularities. Awareness, prophylactic optimization of vascular filling and venting of initial portal blood can help to avoid difficulties, but further treatment with vasoactive drugs is often necessary.

Bleeding/coagulopathy is a major sequel to loss of hepatic synthetic function. A liver transplant is a huge procedure; extensive dissection is needed to remove the native organ and significant blood loss is unavoidable. Transfusion requirements are often high with large quantities of clotting factors needed. The use of aprotinin has led to a reduced mean transfusion requirement but the possibility of increased thrombotic complications remains.

Mechanical/biological assist devices – there is no hepatic equivalent of dialysis but bioartificial livers (which connect the circulation to external human or animal hepatocytes) and molecular adsorbent recirculating systems (which provide a modified form of dialysis capable of removing some toxins and waste products) are potential therapeutic tools to maintain recipients preoperatively and in the early phase following transplantation.

Neurological problems – fitting is common in encephalo-pathic, urgent recipients and prophylactic anticonvulsants are normally used. This tendency can be exacerbated by neuro-toxic immunosuppressives such as FK506 and ciclosporin (cyclosporin).

Biliary complications – fine biliary anastomoses with their tenuous blood supplies often cause complications.

Nutrition – in contrast to a kidney transplant, in which a retroperitoneal approach is used, or a heart transplant, in which sternotomy is required, a liver transplant is an extensive intraperitoneal procedure. Much handling and retraction of the viscera is needed and paralytic ileus results, therefore it may be some time before oral feeding can commence. Coupled with the high incidence of cachexia/malnutrition preoperatively this indicates the importance of nutritional support. Total parenteral nutrition is often required, but some surgeons prefer enteral feeding via jejunostomy or a nasojejunal tube. Dietitian input and oral supplementation are required long after oral feeding is re-established.

Heart

Recipient care: unlike kidney transplantation, which might be termed semi-elective, most heart transplants involve critically ill patients who already require intensive levels of management. Inotropic support or even mechanical assist devices may be required to maintain the recipient before grafting. In the USA, the use of long-term mechanical assist devices is common. In less urgent recipients, heart failure must be optimized with standard medical therapy to give the best chance of success.

Problems specific to heart transplantation

Bypass – cardiac transplantation requires cardiopulmonary bypass with its attendant complications.

Rhythm – the usual surgical technique entails anastomosing the donor heart to the remnants of the two recipient atria. This disrupts conduction and can produce atrial arrhythmias and dysfunction. Anastomosis of an intact donor heart to the two cavae, preserving the donor atrium, is an alternative.

Rate/output control – a newly transplanted heart is de-innervated and rate/output control is reliant on circulating factors only. Temporary cardiac pacing is usually necessary to ensure adequate ventricular function.

Bleeding – the anticoagulation needed for a heart bypass means blood loss is a significant problem. Support with blood products and the use of aprotinin are the main therapies. ◆

Amplifiers and Biological Signals

John Chapman

John Chapman is Consultant Anaesthetist at Derriford Hospital, Plymouth, UK. He qualified from the Royal Free Hospital, London, and trained in anaesthesia at Westminster and United Bristol Hospitals. He maintains an interest in aviation and underwater medicine.

Medical monitoring equipment is now so convenient, reliable and compact that almost any physiological variable can be measured, displayed and recorded in real time and in difficult electrically 'noisy' environments such as operating theatres and MRI scanners. The technical advances and miniaturization of electronic devices that have made this possible have come mainly from the needs of space exploration and computing.

Biological signals
Biological voltages (Figure 1) are small, measured in thousandths or millionths of a volt, and except when needle electrodes are used, are detected through the resistance of the skin. Sometimes two signals are present at once, for example muscle action potentials can overlay the ECG and filtering may be necessary to separate them. The interfering signal may be larger than the desired signal and special separation techniques are available.

Biological signals

Frequency	Voltage
EEG	
0.5–100 Hz routine	0.5–100 μV
0.05–150 Hz diagnostic	Up to 1 mV recorded directly from brain surface
ECG	
0.5–30 Hz theatre monitor	100 μV–3 mV
0.05–100 Hz diagnostic	
EMG	
1–20,000 Hz	About 1 mV

1

Signal-to-noise ratio
The signal-to-noise ratio compares the power in the signal with the power of the interference and is measured on a logarithmic scale in decibels. Familiar examples of interference degrading the signal-to-noise ratio are hiss on a radio, 'snow' on a television picture, and the loss of quality on a video tape that has been copied several times.

The signal to be amplified has travelled along a wire to the amplifier, and can pick up small voltages from nearby interference sources such as mains wiring, fluctuating magnetic fields, radio signals and surgical diathermy. Therefore, the signal may be contaminated with a variety of voltages over a wide range of frequencies.

The passage of an electrical current through any conductor inevitably generates small random voltages and therefore noise is generated in the amplifier itself and combines with the signal. Useful information can be swamped by unwanted electrical noise and the smaller the original signal the bigger the problem.

Amplifiers
An amplifier is a device that allows a small electrical signal, containing very little power, to control an external power source to reproduce the signal at a higher level. An example is a public address system that takes a signal of a few millivolts from a microphone and uses it to control the electrical power fed to hundreds of loudspeakers in a stadium, totalling thousands of watts.

The bandwidth of an amplifier is the range of frequencies it reproduces accurately. An amplifier must be designed to suit the signal it has to process; for example a good audio amplifier deals with audible frequencies of 15–20,000 Hz, and a radio frequency amplifier must be able to handle the frequencies the radio is to receive, from hundreds of thousands to tens of millions of Hz.

Biological amplifiers: an ECG amplifier is designed to reproduce the frequencies present in the ECG, from less than 0.5 Hz if the pulse rate were 30 beats/minute, to 100 Hz to reproduce detail in the QRS complex, and higher again if it is to be able to show very brief pacing artefacts.

Any stray signal at the mains frequency (which is 50 Hz in Europe and 60 Hz in the USA) falls within the bandwidth of the amplifier and distorts the display unless filtered out (Figure 2). Biological amplifiers are normally fitted with a notch filter, which in the UK blocks frequencies of 48–52 Hz.
