Neurogenic shock must always be considered as a cause of hypotension. Spinal cord injury may be missed during initial evaluation, especially in unconscious patients. Intraoperative hemodynamic management of these patients is primarily by judicious administration of fluids and, if needed, vasopressors and inotropes. However, differentiation of neurogenic shock from hemorrhagic shock is important³⁰⁷; often patients are bradycardic and respond to catecholamine infusion readily. Misdiagnosing neurogenic for hemorrhagic shock may lead to excessive fluid infusion and pulmonary edema. The reverse error may also occur: depriving patients with hemorrhagic shock of fluids because of misdiagnosis of neurogenic shock.³⁰⁷ Invasive central hemodynamic monitoring may be indicated in these patients.¹⁶³ In some patients, of course, hemorrhagic and neurogenic shock may coexist.

Cardiac causes of persistent hypotension include myocardial contusion, pericardial tamponade, valvular injury, and septal perforation. Intraoperative TEE can be useful in the differential diagnosis. In myocardial contusion, the RV is most commonly injured. If there is a concomitant increase in pulmonary vascular resistance (e.g., from an associated pulmonary contusion), the RV pressure increases while its output decreases, resulting in an increased CVP. The raised RV pressure causes the interventricular septum to shift toward the left, decreasing left ventricular compliance and increasing its diastolic pressure. The net effect is a decreased cardiac output. In addition to demonstrating wall motion abnormalities, TEE can display the septal shift and altered left ventricular dynamics, information that can be useful during interpretation of elevated cardiac filling pressures.³⁰⁸

In the absence of TEE, a pulmonary artery catheter may be helpful. Equalization of pressures across the cardiac chambers during diastole suggests pericardial tamponade. A similar picture may also be seen in severe myocardial contusion, causing difficulty in differential diagnosis. This effect is rare and usually associated with severe hemodynamic instability. Differential diagnosis in these instances can be established by pericardiocentesis. Septal encroachment into the left ventricle from RV contusion results in an increase in pulmonary artery wedge pressure. Decreasing the rate of fluid infusion in these patients results in a further decrease in cardiac output. Treatment includes fluid infusion, pulmonary vasodilators if the systemic blood pressure is normal, and inotropic support if the systemic blood pressure is low. Absence of response to this treatment is an indication for placement of an intra-aortic balloon pump. Pulmonary artery catheterization is also helpful in demonstrating an oxygen step-up from septal injury. During thoracotomy, a distended RV should also raise the suspicion of a septal defect.

Hypothermia

Shock, alcohol intoxication, exposure to cold, fluid resuscitation, and abnormalities in thermoregulatory mechanisms render the major trauma patient hypothermic during the initial phase of injury. The mortality rate after trauma increases with decreasing temperature. Severe hypothermia, which in the trauma patient is defined as core temperature below 32°C , was associated with a 100% mortality rate in one study.³⁰⁹ The intraoperative risk of hypothermia is also higher for the trauma victim than for electively operated patients. Heat loss increases in patients with spinal cord, extensive soft tissue, and burn injuries, and in those who consumed ethanol before surgery.

The impact of hypothermia on already compromised vital functions may be devastating. There may be reduced cardiac output, cardiac conduction abnormalities, diminished cerebral and renal blood flows, decreased oxygen release from red cells caused by the leftward shift of the O_2 dissociation curve, altered platelet and clotting enzyme function, and abnormalities of K^+ and Ca^{2+} homeostasis.²⁵⁵ These effects may further compromise poor organ perfusion, oxygenation, blood coagulation, and metabolism.

Aggressive therapy and correction of body temperature to normal within a short time appear to decrease mortality rate, blood loss, fluid requirement, organ failure, and length of ICU stay.³¹⁰ Convective warming with forced dry air at 43°C can prevent a temperature drop in most trauma patients but cannot effectively treat severe hypothermia; because of its low specific heat, air has little heat content to give to the cold trauma patient.³¹⁰ Airway rewarming can reduce heat loss caused by latent heat of vaporization, but this technique also transfers very little heat.³¹⁰ Administration of warm iv fluids is the most effective way to prevent and treat hypothermia in the trauma patient, provided that fluids are being administered at a relatively rapid rate. For each liter of fluid given at 40°C to a patient with a body temperature of 33°C , 7 kcal of heat energy is gained. Countercurrent heat exchanging systems (Level 1 Technologies) are more effective than dry heat or still-water bath warmers. They warm the fluid to 40°C , and the delivered fluid temperature is not affected by rapid rates of administration.³⁰³ The most effective method, however, is continuous arteriovenous rewarming, which can be achieved using a modified Level 1 countercurrent system ([Fig. 48-9](#)). The blood exits the body from a percutaneously placed femoral arterial catheter at the patient's own pressure, is warmed in the infusion system, and returned to the body through a venous cannula. Because the circuit tubing is heparin bonded, there is no need for heparinization. Experience with this technique in the ICU has been encouraging.^{310,311}

Figure 48-9. Schematic drawing of the system used for continuous arteriovenous rewarming. (Reprinted with permission from Gentilello LM, Cobean R, Offner PJ *et al*: Continuous arteriovenous rewarming: rapid reversal of hypothermia in critically ill patients. *J Trauma* 32:316, 1992.)

Coagulation Abnormalities

During elective surgery, coagulation abnormalities result primarily from dilution of platelets and coagulation factors (see also [Chapter 10](#)). In trauma, other factors may also be responsible for this complication. These include hypothermia, acidosis, tissue hypoxia, and tissue thromboplastin release. Hypothermia and diminished tissue perfusion aggravate existing coagulation abnormalities,³¹² and hypothermia by itself can cause clotting deficiencies in the absence of platelet or factor deficiency.²⁵⁵ Hypothermia affects platelet morphology, function, and sequestration and retards enzyme activity, slowing the initiation and propagation of both platelet plug and fibrin clot.³¹³ Decreased body temperature may also enhance fibrinolytic activity.³¹³

Perioperative diagnosis of coagulopathy is often made by observing bleeding from wounds or puncture sites, rather than by interpretation of laboratory tests. However, differential diagnosis between consumptive and dilutional coagulopathy requires laboratory testing, although the results of these tests are usually delayed. Usually, the inability to determine the type of coagulopathy does not present a problem because the initial treatment is similar for both conditions. Nevertheless, the diagnosis of DIC has prognostic significance because its treatment involves elimination of its causes. A blood sample without heparin should be sent for measurement of circulating fibrin degradation products (FDP/fdp). An FDP/fdp level $>10 \text{ mg} \cdot \text{ml}^{-1}$ is suggestive of DIC, whereas a value $>40 \text{ mg} \cdot \text{ml}^{-1}$ is diagnostic. In patients who have not received blood products, simultaneous determination of fibrinogen level, platelet count, and PT may be helpful in diagnosis of the DIC. A fibrinogen level $<150 \text{ mg} \cdot$

dl⁻¹, platelet count <150,000, and PT >15 seconds is highly suggestive. If only two of the three are abnormal, FDP/fdp should be measured.

Prompt platelet administration should always be considered once abnormal bleeding is noted. Each unit of platelet concentrate contains 55 billion platelets, which normally increase the platelet count by 5,000–10,000 per microliter (μl). If there is ongoing surgical bleeding, administration of platelets should perhaps be delayed until it is controlled; otherwise the platelets will be wasted. On the other hand, severe thrombocytopenia may contribute to the bleeding. Indications for FFP and cryoprecipitate are not clear. However, it has been shown that transfusion of PRBC in elective surgery results in depletion of coagulation factors earlier than of platelets.^{258,314} Thus, it is not unreasonable to administer FFP or cryoprecipitate simultaneously with platelets in emergency trauma surgery. The minimum dose of FFP for adults is 2 units (~600 ml) and is given within less than 1 hour. Fibrinogen concentration <80 mg · dl⁻¹ is an indication for cryoprecipitate administration. Ten units increase plasma fibrinogen concentration by approximately 100 mg · dl⁻¹.²⁶⁰

In the absence of abnormal bleeding, prophylactic administration of platelets, FFP, or cryoprecipitate is unwarranted even if coagulation tests indicate platelet and factor depletion.³¹⁵ However, once transfusion of factor-deficient PRBC and fluids exceeds one blood volume, clinical coagulopathy is likely even in the absence of shock, hypothermia, or other aggravating factors.^{259,260} Thus, in trauma patients who receive between one and two blood volume replacements, platelet or factor administration is almost always indicated. In hypothermic patients with clinical coagulopathy, the critical treatment is rewarming rather than platelet and coagulation factor administration, although circumstances may require both.^{256,316}

Electrolyte and Acid–Base Disturbances

Intraoperative hyperkalemia may develop as a result of three mechanisms. First, in patients with irreversible shock, cell membrane permeability is altered so that massive K⁺ efflux results in severe hyperkalemia; in this situation, the patient will not survive. Second, after repair of a major vessel, subsequent reperfusion of the ischemic tissues results in a sudden release of K⁺. Third, transfusion at a rate faster than 1 unit every 4 minutes to an acidotic and hypovolemic patient may cause an increase in plasma K⁺ levels.³¹⁷ Massive transfusion of a patient whose aorta is temporarily clamped below the diaphragm to prevent hemorrhage from the abdominal or pelvic vessels can also cause hyperkalemia; the K⁺ load is distributed into a small volume of blood in this instance. Frequent monitoring of serum K⁺, gradual and intermittent unclamping of vascular shunts, and avoiding transfusion at higher rates than needed help reduce the rate of K⁺ increase. If a rise in K⁺ is detected, treatment with regular insulin, 10 units iv, with 50% dextrose, 50 ml; and sodium bicarbonate, 8.4%, 50 ml is indicated. If there is a dysrhythmia, CaCl₂, 500 mg should also be administered.³¹⁸ Insulin and dextrose can be repeated two or three times at 30–45 minute intervals if necessary. Hemodialysis may be indicated in desperate situations.

Metabolic acidosis is caused by shock in most trauma patients. Other causes of metabolic acidosis in this population are alcoholic lactic acidosis, alcoholic ketoacidosis, diabetic ketoacidosis, and CO or CN⁻ poisoning after inhalation injuries. Alcoholic lactic acidosis occurs in patients who become hypoperfused while intoxicated. Under normal circumstances, the liver can clear moderate amounts of lactic acid. In intoxicated patients, however, preferential metabolism of alcohol by the liver interferes with the utilization of lactate by this organ. Alcoholic ketoacidosis may also occur in those who are both starved and deprived of alcohol. Starvation usually results in lipolysis, which in turn produces free fatty acids. Alcohol ingestion prevents the conversion of free fatty acids to ketones. When a starved alcoholic is also deprived of alcohol, free fatty acids easily convert to ketones and produce alcoholic ketoacidosis. The differential diagnosis between hypovolemic, diabetic, and alcoholic acidosis, all of which have anion gaps, requires measurement of blood lactate, urinary ketone bodies, blood sugar, and invasive monitoring to assess intravascular volume. Alcoholic ketoacidosis is treated with iv dextrose, whereas diabetic ketoacidosis is managed with insulin. No specific treatment except iv normal saline exists for alcoholic lactic acidosis.

Treatment of metabolic acidosis involves correction of the underlying cause. This may involve management of hypoxemia, restoration of intravascular volume, optimization of cardiac function, or treatment of CO or CN⁻ toxicity. Symptomatic treatment with sodium bicarbonate has serious disadvantages, including leftward shift of the oxyhemoglobin dissociation curve causing decreased O₂ unloading, a hyperosmolar state secondary to the excessive sodium load, hypokalemia, further hemodynamic depression, overshoot alkalosis a few hours after giving the drug, and intracellular acidosis if adequate ventilation or pulmonary blood flow cannot be provided.³¹⁹ Development of intracellular acidosis is especially likely in patients who are being resuscitated from cardiac arrest. Nevertheless, because of the belief that severe acidosis itself can cause dysrhythmias, myocardial depression, hypotension, and resistance to exogenous catecholamines, to “buy time” some clinicians administer bicarbonate if the pH is <7.2.

Intraoperative Death

Death is a much greater threat during emergency trauma surgery than it is in any other operative procedure. Approximately 0.7% of patients admitted for trauma die in the operating room, accounting for approximately 8% of postinjury deaths.³²⁰ Uncontrollable bleeding is the cause of approximately 80% of intraoperative mortality; brain herniation and air embolism are the most common causes of death in the remaining patients.³²⁰ A multicenter, retrospective study has defined certain features that increase the likelihood of operating room death³²⁰ (Table 48-15). Rapid transport to the operating room, concentrating efforts on life-threatening injuries while deferring definitive surgery, simultaneous thoractomy and laparotomy for thoracoabdominal injuries, appropriate management of retroperitoneal hematoma, early correction of hypothermia and shock, and early packing of severe liver injuries may reduce intraoperative mortality rates.³²⁰

Table 48-15. CLINICAL FEATURES ASSOCIATED WITH INTRAOPERATIVE MORTALITY

EARLY POSTOPERATIVE CONSIDERATIONS

The concerns in the early postoperative period are similar to those of the intraoperative phase. Re-evaluation and optimization of the circulation, oxygenation, temperature, CNS function, coagulation, electrolyte and acid–base status, and renal function are the hallmarks of postoperative management.

Sedation and Analgesia

Pain control in this group of patients may have more than a humanitarian purpose; it can improve pulmonary function, ventilation, and oxygenation in patients with chest injury or a long abdominal incision (see Chapter 54). For sedation in mechanically ventilated patients, both propofol and midazolam infusions alone or in combination are equally effective and safe, although wake-up time in patients receiving midazolam is longer (660 ± 400 minutes) than in those receiving propofol alone (110 ± 50 minutes) or both agents combined (190 ± 200 minutes).³²¹ Head-injured patients tolerate all three regimens well because the ICP, CPP, and SjvO₂ remain unchanged.³²¹ The dose should be titrated to effect, but the usual infusion rates are as follows: midazolam, 0.1–0.2 mg · kg⁻¹ · hr⁻¹; propofol, 1.5–6 mg · kg⁻¹ · hr⁻¹, and the combination, midazolam, 0.1–0.2 mg · kg⁻¹ · hr⁻¹ and propofol, 50–150 mg · kg⁻¹ · hr⁻¹. Larger doses may result in hemodynamic depression. Morphine 0.02–0.04 mg · kg⁻¹ · hr⁻¹ or fentanyl 1–3 μg · kg⁻¹ · hr⁻¹ may be added for analgesia. Small boluses of midazolam (3–5 mg), propofol (50 mg), morphine (2–3 mg), or fentanyl (25–50 μg) may also be given as required.³²¹

Acute Renal Failure

Acute renal failure is a possibility if prolonged shock occurred during early management. In patients who have not received an osmotic load (radiopaque material, mannitol) or diuretic, postoperative determination of 2- or 6-hour creatinine and free water clearances may help predict the development of post-traumatic renal dysfunction.³²² Creatinine clearance <25 ml · min⁻¹ and free water clearance <15 ml · hr⁻¹ suggest the likelihood of acute renal failure. Decreased urine flow rate is not

a good predictor, and the blood urea nitrogen does not rise until at least 24 hours after surgery or trauma.³²²

Abdominal Compartment Syndrome

An abdominal compartment syndrome as a result of intra-abdominal hypertension is a recently appreciated phenomenon that occurs after major abdominal trauma and surgery, although some patients may have the syndrome without surgery.³²³ This complication results from massive edema of intra-abdominal organs produced by shock-induced inflammatory mediators, fluid resuscitation, and surgical manipulation. The significant impairment of cardiac, pulmonary, renal, gastrointestinal, hepatic, and CNS function caused by this syndrome results in a high mortality rate³²³ (Fig. 48-10). Clinically, a tense, distended abdomen should direct the clinician to measure the intravesicular pressure, which reflects the intra-abdominal pressure. The system used for intravesicular pressure measurement is shown in Figure 48-11.³²³ Values >20–25 mm Hg indicate inadequate organ perfusion and necessitate abdominal decompression, which, if delayed, results in progression to multiorgan failure and death. After decompression, the abdominal pressure may remain high for a few days before decreasing to the normal range (3–10 mm Hg). Use of a volumetric pulmonary artery catheter for assessment of preload by left ventricular end-diastolic volume index determination may be more accurate than measuring CVP or PCWP in these patients.³²³

Figure 48-10. Physiologic effects of abdominal compartment syndrome. ICP = intracranial pressure; CPP = cerebral perfusion pressure; CO = cardiac output; PAOP = pulmonary artery occlusion pressure; CVP = central venous pressure; SVR = systemic vascular resistance; PIP = peak inspiratory pressure; Paw = mean airway pressure; Cdyn = dynamic pulmonary compliance; Qsp/Qt = intrapulmonary shunt; Vd/Vt = dead space ventilation; SMA = superior mesenteric artery; pH = intramucosal pH; GFR = glomerular filtration rate. Thromboembolism

Trauma patients are prone to development of thromboembolic complications. The overall incidence of DVT in the proximal femoral veins, the major source of PE, is approximately 18% in trauma patients.³²⁴ However, DVT occurs in 24% of lower extremity injuries, 27% of spine injuries, 20% of major head injuries, and 15% of serious injuries of the face, chest, or abdomen.³²⁴ When injuries involve more than one of these high-risk regions, the likelihood of DVT is even higher. For example, up to 77% of patients with combined head and lower extremity injuries may have both distal and proximal DVT.³²⁴ Fortunately, only a relatively small fraction (approximately 0.3–2%) of severely injured patients have PE.^{324,325} Apart from the type and severity of injury, older age, blood transfusion, and surgery appear to facilitate the development of this complication.³²⁴ Almost half of all cases of PE occur within the first week, suggesting that DVT develops shortly after trauma.³²⁵ In most instances, DVT is asymptomatic, and in many of those in whom leg swelling develops, concurrent lower extremity injuries may be implicated. The diagnosis of proximal DVT in symptomatic patients can be made by duplex ultrasonography, but this method has low sensitivity in the absence of symptoms.³²⁶ Venography, which is the gold standard, can be performed in equivocal cases, although it is associated with complications and inherent logistical problems. Hypoxemia, especially when sudden and associated with dyspnea and hemodynamic abnormalities, is highly suggestive of PE. The definitive diagnosis is established by spiral CT and pulmonary angiography, pulmonary ventilation perfusion scans are infrequently performed. In hemodynamically unstable patients, resuscitation takes precedence over radiologic diagnosis. Management is symptomatic, and includes tracheal intubation, positive pressure ventilation with FIO₂ of 1.0, administration of fluids and inotropes (amrinone or milrinone), and continuous arterial and CVP or pulmonary artery monitoring. TEE is helpful because it may demonstrate RV performance, tricuspid regurgitation, or, in some cases, the thrombus within the pulmonary artery, the right heart chambers, or in transit through a patent foramen ovale to the left atrium.

In patients with relatively minor injuries, PE is treated with anticoagulants. Low-molecular-weight heparin may be used if bleeding is unlikely to exacerbate the injury. Consideration should be given to placement of a vena cava filter if the risk of bleeding is unacceptably high. Other indications for vena cava filter placement are recurrent PE despite full anticoagulation; proximal DVT with contraindications to, or major bleeding during, full anticoagulation; and progression of an iliofemoral clot despite full anticoagulation. Although widely performed in the past, placement of a vena cava filter before development of DVT in high-risk injuries such as pelvic fractures has decreased because of the severity of associated complications and the apparent ineffectiveness of this procedure. The current recommendation for prophylaxis in most trauma patients is low-molecular-weight heparin.³²⁶ Low-dose unfractionated heparin appears to be ineffective in trauma patients.³²⁷ Mechanical devices such as sequential compression devices and foot pumps should be applied as early as possible after injury.

- [Summary](#)
- [Chapter References](#)

Allergic reactions during anesthesia represent an important cause of perioperative complications. Anesthesiologists routinely manage patients during their perioperative medical care where they are exposed to a range of foreign substances, including drugs (*i.e.*, antibiotics, anesthetic agents, neuromuscular blocking agents, sedative hypnotics), polypeptides (protamine, aprotinin), blood products, and environmental antigens (*i.e.*, latex). Anesthesiologists must be able to rapidly recognize and treat anaphylaxis, the most life-threatening form of an allergic reaction.¹ Latex represents an important and potentially overlooked environmental antigen.¹

The allergic response represents just one limb of the pathologic response the immune system can mount against foreign substances. As part of normal host surveillance mechanisms, a series of cellular and humoral elements monitors foreign structures called *antigens* to provide host defense. These foreign substances (antigens) consist of molecular configurations located on cells, bacteria, viruses, proteins, or complex macromolecules.^{1,2,3 and 4} Immunologic mechanisms have the following characteristics: they (1) involve antigen interaction with antibodies or specific effector cells, (2) are reproducible, and (3) are specific and adaptive, capable of distinguishing foreign substances and amplifying reactivity through a series of inflammatory cells and proteins. The immune system serves to protect the body against external microorganisms and toxins and internal threats from neoplastic cells; however, it can respond inappropriately to cause hypersensitive (allergic) reactions. Life-threatening allergic reactions to drugs and other foreign substances observed perioperatively may represent different manifestations of the immune response.^{1,2}

BASIC IMMUNOLOGIC PRINCIPLES

Host defense systems can be divided into cellular and humoral elements.^{1,2,3 and 4} The humoral system includes antibodies, complement, cytokines, and other circulating proteins, whereas cellular immunity is mediated by specific lymphocytes of the T-cell series. Lymphocytes have receptors that distinguish between antigens of host and foreign origin. When lymphocytes react with foreign antigens, they respond to orchestrate immunosurveillance, regulate immunospecific antibody synthesis, and destroy foreign invaders. Individual aspects of the immune response and their importance are considered separately.

Antigens

Molecules capable of stimulating an immune response (antibody production or lymphocyte stimulation) are called *antigens*.⁴ Only a few drugs used by anesthesiologists, such as polypeptides (protamine) and other large macromolecules (dextrans), are complete antigens (Table 49-1). Most commonly used drugs are simple organic compounds of low molecular weight (approximately 1000 daltons). For such a small molecule to become immunogenic, it must form a stable bond with circulating proteins or tissue macromolecules to result in a complete antigen (hapten-macromolecular complex). Small-molecular-weight substances such as drugs or drug metabolites that bind to host proteins or cell membranes to sensitize patients are called *haptens*. Haptens are not antigenic by themselves. Often, a reactive drug metabolite (*i.e.*, penicilloyl derivative of penicillin) is thought to bind with macromolecules to become antigens, but for most drugs this has not been proved.

Figure 49-1. Basic structural configuration of the antibody molecule representing human immunoglobulin G (IgG). Immunoglobulins are composed of two heavy chains and two light chains bound by disulfide linkages (represented by crossbars). Papain cleaves the molecule into two Fab fragments and one Fc fragment. Antigen binding occurs on the Fab fragments, whereas the Fc segment is responsible for membrane binding or complement activation. (Reproduced with permission from Levy JH: Anaphylactic Reactions in Anesthesia and Intensive Care, 2nd ed. Boston, Butterworth-Heinemann, 1992.)

Table 49-1. AGENTS ADMINISTERED DURING ANESTHESIA THAT ACT AS ANTIGENS

Thymus-Derived (T-Cell) and Bursa-Derived (B-Cell) Lymphocytes

The thymus of the fetus differentiates immature lymphocytes into thymus-derived cells (T cells). T cells have receptors that are activated by binding with foreign antigens and secrete mediators that regulate the immune response. The subpopulations of T cells that exist in humans include helper, suppressor, cytotoxic, and killer cells.⁵ The two types of regulatory T cells are helper cells (OKT4) and suppressor cells (OKT8). Helper cells are important for key effector cell responses, whereas suppressor cells inhibit immune function. Infection of helper T cells with a retrovirus, the human immunodeficiency virus, produces a specific increase in the number of suppressor cells. Cytotoxic T cells destroy mycobacteria, fungi, and viruses. Other lymphocytes, called natural killer cells, do not require specific antigen stimulation to initiate their function. Both the cytotoxic T cells and natural killer cells participate in defense against tumor cells and in transplant rejection. T cells produce a spectrum of mediators that influence the response of other cell types involved in the recognition and destruction of foreign substances.

B cells represent a specific lymphocyte cell line that can differentiate into specific plasma cells that synthesize antibodies, a step controlled by both helper and suppressor T-cell lymphocytes.⁵ B cells are also called bursa-derived cells because in birds, the bursa of Fabricius is important in producing cells responsible for antibody synthesis.

Antibodies

Antibodies are specific proteins called *immunoglobulins* (Ig) that can recognize and bind to a specific antigen.⁶ The basic structure of the antibody molecule is illustrated in [Figure 49-1](#). Each antibody has at least two heavy chains and two light chains that are bound together by disulfide bonds. The Fab fragment has the ability to bind antigen, and the Fc, or crystallizable, fragment is responsible for the unique biologic properties of the different classes of immunoglobulins (cell binding and complement activation). Antibodies function as specific receptor molecules for immune cells and proteins. When antigen binds covalently to the Fab fragments, the antibody undergoes conformational changes to activate the Fc receptor. The results of antigen–antibody binding depend on the cell type, which causes a specific type of activation (*i.e.*, lymphocyte proliferation and differentiation into antibody-secreting cells, mast cell degranulation, and complement activation).

Five major classes of antibodies occur in humans: IgG, IgA, IgM, IgD, and IgE. The heavy chain determines the structure and the function of each molecule. The basic properties of each antibody are listed in [Table 49-2](#).

| | IgG | IgM | IgA | IgD | IgE |
|--|--|-------------|--|----------------------------|----------------------------|
| Heavy chain | γ | μ | α | δ | ε |

Table 49-2. BIOLOGIC CHARACTERISTICS OF IMMUNOGLOBULINS

Effector Cells and Proteins of the Immune Response

Cells

Monocytes, neutrophils (polymorphonuclear leukocytes [PMNs]), and eosinophils represent important effector cells that migrate into areas of inflammation in response to specific chemotactic factors, including lymphokines, cytokines, and complement-derived mediators. The deposition of antibody or complement fragments on the surface of foreign cells is called *opsonization*, a process that facilitates the killing of foreign cells by effector cells. In addition, lymphokines and cytokines produce chemotaxis of other inflammatory cells in a manner described in the following sections.

Monocytes and Macrophages. Macrophages regulate immune responses by processing and presenting antigens to effect inflammatory, tumoricidal, and microbicidal functions. Macrophages arise from circulating monocytes or may be confined to specific organs such as the lung. They are recruited and activated in response to microorganisms or tissue injury. Macrophages ingest antigens before they interact with receptors on the lymphocyte surface to regulate their action. Macrophages synthesize mediators to facilitate both B- and T-lymphocyte responses.

Polymorphonuclear Leukocytes (Neutrophils). The first cells to appear in acute inflammatory reaction are neutrophils that contain acid hydrolases, neutral proteases, and lysosomes. Once activated, they produce hydroxyl radicals, superoxide, and hydrogen peroxide, which aid in microbial killing.

Eosinophils. The exact function of the eosinophil in host defense is unclear; however, inflammatory cells recruit eosinophils to accumulate at sites of parasitic infections, tumors, and allergic reactions.¹

Basophils. Basophils comprise 0.5–1% of circulating granulocytes in the blood.¹ On the surface of basophils are IgE receptors, which function similarly to those on mast cells.

Mast Cells. Mast cells are important cells for immediate hypersensitivity responses. They are tissue fixed and located in the perivascular spaces of the skin, lung, and intestine.¹ On the surface of mast cells are IgE receptors, which bind to specific antigens. Once activated, these cells release a spectrum of physiologically active mediators important to immediate hypersensitivity responses (see [IgE-Mediated Pathophysiology](#) in section on Anaphylactic Reactions). Mast cells can be activated by a series of both immune and nonimmune stimuli.

Proteins

Cytokines/Interleukins. Cytokines are inflammatory cell activators that are synthesized by macrophages to act as secondary messengers and activate endothelial cells and white cells.⁷ Interleukin-1 and tumor necrosis factor are examples of cytokines considered to be important mediators of the biologic responses to infection and other inflammatory reactions. Liberation of interleukin-1 and tumor necrosis factor produces fever, neuropeptide release, endothelial cell activation, increased adhesion molecule expression, neutrophil priming, hypotension, myocardial suppression, and a catabolic state.⁷ The term *interleukin* was coined for a group of cytokines that facilitates communication between and among (“inter”) leukocytes (“leukin”). Interleukins are a group of different regulatory proteins that act to control many aspects of the immune and inflammatory responses. The interleukins are polypeptides synthesized in response to cellular activation and produce their inflammatory effects by activating specific receptors on inflammatory cells and vasculature. T-cell lymphocytes influence the activity of other immunologic and nonimmunologic cells by the production of an array of interleukins that they secrete. A spectrum of different interleukins of this class have been isolated and characterized; they function as short-range or intracellular soluble mediators of the immune and inflammatory responses. The interleukin family of cytokines has been rapidly growing in number because of advances in gene cloning.

Complement. The primary humoral response to antigen and antibody binding is activation of the complement system.⁸ The complement system consists of approximately 20 different proteins that bind to activated antibodies, other complement proteins, and cell membranes. The complement system is an important effector system of inflammation. Complement activation can be initiated by IgG or IgM binding to antigen, by plasmin through the classic pathway, by endotoxin, or by drugs through the alternate (properdin) pathway⁸ ([Fig. 49-2](#)). Specific fragments released during complement activation include C3a, C4a, and C5a, which have important humoral and chemotactic properties (see [Non-IgE-Mediated Reactions](#)). The major function of the complement system is to recognize bacteria both directly and indirectly by the attraction of phagocytes (chemotaxis), as well as the increased adherence of phagocytes to antigens (opsonization), and cell lysis by activation of the

complete cascade.

Figure 49-2. Diagram of complement activation. Complement system can be activated by either the classic pathway (IgG, IgM–antigen interaction) or the alternate pathway (endotoxin, drug interaction). Small peptide fragments of C3 and C5 called anaphylatoxins (C3a, C5a) that are released during activation are potent vasoactive mediators. Formation of the complete complement cascade produces a membrane attack unit that lyses cell walls and membranes. An inhibitor of the complement cascade, the C1 esterase inhibitor, ensures that the complement system is turned off most of the time.

A series of inhibitors regulates activation to ensure regulation of the complement system. Hereditary (autosomal dominant) or acquired (associated with lymphoma, lymphosarcoma, chronic lymphatic leukemia, macroglobulinemia) angioneurotic edema is an example of a deficiency in an inhibitor of the C1 complement system (C1 esterase deficiency). This syndrome is characterized by recurrent increased vascular permeability of specific subcutaneous and serosal tissues (angioedema), which produces laryngeal obstruction and respiratory and cardiovascular abnormalities after tissue trauma and surgery, or even without any obvious precipitating factor.⁹ One of the important pathologic manifestations of complement activation is acute pulmonary vasoconstriction associated with protamine administration.¹

Effects of Anesthesia on Immune Function

Anesthesia and surgery depress a spectrum of nonspecific host resistance mechanisms, including lymphocyte activation and phagocytosis.⁶ Immune competence during surgery can be affected by direct and hormonal effects of anesthetic drugs, by immunologic consequences of other drugs used, by the type of surgery, by coincident infections, and by transfused blood products. Blood represents a complex spectrum of humoral and cellular elements that may alter immunomodulation to a variety of antigens. Although multiple studies demonstrate *in vitro* alterations of immune function, no studies have ever demonstrated their actual importance.⁶ Furthermore, such alterations are likely of minor importance compared with the hormonal aspects of stress responses.

HYPERSENSITIVITY RESPONSES (ALLERGY)

Gell and Coombs³ first described a scheme for classifying immune responses to understand specific diseases mediated by immunologic processes. The immune pathway functions as a protective mechanism, but can also react inappropriately to produce a hypersensitivity or allergic response. They defined four basic types of hypersensitivity, Types I–IV. It is useful first to review all four mechanisms to understand the different immune reactions that occur in humans.

Type I Reactions

Type I reactions are anaphylactic or immediate-type hypersensitivity reactions (Fig. 49-3). Physiologically active mediators are released from mast cells and basophils after antigen binding to IgE antibodies on the membranes of these cells. Type I hypersensitivity reactions include anaphylaxis, extrinsic asthma, and allergic rhinitis.

Figure 49-3. Type I immediate hypersensitivity reactions (anaphylaxis) involve IgE antibodies binding to mast cells or basophils by way of their Fc receptors. On encountering immunospecific antigens, the IgE becomes cross-linked, inducing degranulation, intracellular activation, and release of mediators. This reaction is independent of complement.

Type II Reactions

Type II reactions are also known as antibody-dependent cell-mediated cytotoxic hypersensitivity or cytotoxic reactions (antibody-dependent cell-mediated cytotoxic) (Fig. 49-4). These reactions are mediated by either IgG or IgM antibodies directed against antigens on the surface of foreign cells. These antigens may be either integral cell membrane components (A or B blood group antigens in ABO incompatibility reactions) or haptens that absorb to the surface of a cell, stimulating the production of anti-hapten antibodies (autoimmune hemolytic anemia). The cell damage in Type II reactions is produced by (1) direct cell lysis after complete complement cascade activation, (2) increased phagocytosis by macrophages, or (3) killer T-cell lymphocytes producing antibody-dependent cell-mediated cytotoxic effects. Examples of Type II reactions in humans are ABO-incompatible transfusion reactions, drug-induced immune hemolytic anemia, and heparin-induced thrombocytopenia.

Figure 49-4. Type II or cytotoxic reactions. Antibody of an IgG or IgM class is directed against antigens on an individual's own cells (target cell). The antigens may be integral membrane components or foreign molecules that have been absorbed. This may lead to complement activation, including cell lysis (*upper figure*) or to cytotoxic action by killer T-cell lymphocytes (*lower figure*).

Type III Reactions (Immune Complex Reactions)

Type III reactions result from circulating soluble antigens and antibodies that bind to form insoluble complexes that deposit in the microvasculature (Fig. 49-5). Complement is activated and neutrophils are localized to the site of complement deposition to produce tissue damage. Type III reactions include classic serum sickness observed after snake antisera or antithymocyte globulin, and immune complex vascular injury, and may occur through mechanisms of protamine-mediated pulmonary vasoconstriction.¹

Figure 49-5. Type III immune complex reactions. Antibodies of an IgG or IgM type bind to the antigen in the soluble base and subsequently are deposited in the microvasculature. Complement is activated, resulting in chemotaxis and activation of polymorphonuclear leukocytes at the site of antigen–antibody complexes and subsequent tissue injury.

Type IV Reactions (Delayed Hypersensitivity Reactions)

Type IV reactions result from the interactions of sensitized lymphocytes with specific antigens (Fig. 49-6). Delayed hypersensitivity reactions are predominantly mononuclear, manifest in 18–24 hours, peak at 40–80 hours, and disappear in 72–96 hours. Antigen-lymphocyte binding produces lymphokine synthesis, lymphocyte proliferation, generation of cytotoxic T cells, and the attraction of macrophages and other inflammatory cells. Cytotoxic T cells are generated specifically to kill target cells that bear antigens identical to those that triggered the reaction. This form of immunity is important in tissue rejection, graft-versus-host reactions, contact dermatitis (e.g., poison ivy), and tuberculin immunity.

Figure 49-6. Type IV immune complex reactions (delayed hypersensitivity or cell-mediated immunity). Antigen binds to sensitized T-cell lymphocytes to release lymphokines after a second contact with the same antigen. This reaction is independent of circulating antibody or complement activation. Lymphokines induce inflammatory reactions and activate as well as attract macrophages and other mononuclear cells to produce delayed tissue injury.

Intraoperative Allergic Reactions

Intraoperative allergic reactions occur once in every 5000–25,000 anesthetics, with a 3.4% mortality rate.^{10,11} More than 90% of the allergic reactions evoked by intravenous (iv) drugs occur within 5 minutes of administration. In the anesthetized patient, the most common life-threatening manifestation of an allergic reaction is circulatory collapse, reflecting vasodilation with resulting decreased venous return (Table 49-3). The only manifestation of an allergic reaction may be refractory hypotension.¹² Portier and Richet first used the word *anaphylaxis* (from *ana*, “against,” and *prophylaxis*, “protection”) to describe the profound shock and subsequent death that sometimes occurred in dogs immediately after a second challenge with a foreign antigen.¹³ When life-threatening allergic reactions mediated by antibodies occur, they are defined as anaphylactic. When antibodies are not responsible for the reaction or when antibody involvement in the reaction cannot be proven, the reaction is called *anaphylactoid*.¹⁴ Anaphylactic and anaphylactoid reactions cannot be distinguished from one another on the basis of clinical observation.

| Systems | Symptoms | Signs |
|----------------|---|---|
| Respiratory | Dyspnea Chest discomfort | Coughing Wheezing Sneezing Laryngeal edema Decreased pulmonary compliance Pulmonary pulmonary edema |
| Cardiovascular | Dizziness Malaise Retrosternal oppression | Acute respiratory failure Disorientation Diaphoresis Loss of consciousness Hypotension Tachycardia Dysrhythmias Decreased systemic vascular resistance Cardiac arrest Pulmonary hypertension Lungate (bruit) Flushing Periorbital edema Perioral edema |

Table 49-3. RECOGNITION OF ANAPHYLAXIS DURING REGIONAL AND GENERAL ANESTHESIA

ANAPHYLACTIC REACTIONS

IgE-Mediated Pathophysiology

Antigen binding to IgE antibodies initiates anaphylaxis (Fig. 49-7). Prior exposure to the antigen or to a substance of similar structure is required to produce sensitization, although an allergic history may be unknown to the patient. On re-exposure, binding of the antigen to bridge two immunospecific IgE antibodies located on the surfaces of mast cells and basophils liberates stored mediators, including histamine, tryptase, and chemotactic factors.^{15,16} and ¹⁷ Arachidonic acid metabolites (leukotrienes and prostaglandins), kinins, and cytokines are subsequently synthesized and released in response to cellular activation.¹⁸ The liberated mediators produce a symptom complex of bronchospasm and upper airway edema in the respiratory system, vasodilation and increased capillary permeability in the

cardiovascular system, and urticaria in the cutaneous system. Different mediators are released from mast cells and basophils after activation.

Figure 49-7. During anaphylaxis (Type I immediate hypersensitivity reaction), (1) antigen enters a patient during anesthesia through a parenteral route. (2) It bridges two IgE antibodies on the surface of mast cells or basophils. In a calcium- and energy-dependent process, cells release various substances—histamine, eosinophilic chemotactic factor or anaphylaxis, leukotrienes, prostaglandins, and kinins. (3) These released mediators produce the characteristic effects in the pulmonary, cardiovascular, and cutaneous systems. The most severe and life-threatening effects of the vasoactive mediators occur in the respiratory and cardiovascular systems. (Reproduced with permission from Levy JH: Identification and Treatment of Anaphylaxis: Mechanisms of Action and Strategies for Treatment Under General Anesthesia. Chicago, Smith Laboratories, 1983.)

Chemical Mediators of Anaphylaxis

Histamine stimulates H_1 , H_2 , and H_3 receptors. H_1 receptor activation releases endothelium-derived relaxing factor (nitric oxide) from vascular endothelium, increases capillary permeability, and contracts airway and vascular smooth muscle.^{1,19,20} H_2 receptor activation causes gastric secretion, inhibits mast cell activation, and contributes to vasodilation.¹⁹ When injected into skin, histamine produces the classic wheal (increased capillary permeability producing tissue edema) and flare (cutaneous vasodilation) response in humans.²¹ Histamine undergoes rapid metabolism in humans by the enzymes histamine *N*-methyltransferase and diamine oxidase located in endothelial cells.¹

Peptide Mediators of Anaphylaxis

Factors are released from mast cells and basophils that cause granulocyte migration (chemotaxis) and collection at the site of the inflammatory stimulus.¹⁸ Eosinophilic chemotactic factor of anaphylaxis (ECF-A) is a small-molecular-weight peptide chemotactic for eosinophils.²² Although the exact role of ECF-A or the eosinophil in acute allergic response is unclear, eosinophils release enzymes that can inactivate histamine and leukotrienes.¹⁸ In addition, a neutrophilic chemotactic factor is released that causes chemotaxis and activation.^{18,23} Neutrophil activation may be responsible for recurrent manifestations of anaphylaxis.

Arachidonic Acid Metabolites

Leukotrienes and prostaglandins are both synthesized after mast cell activation from arachidonic acid metabolism of phospholipid cell membranes through either lipoxygenase or cyclo-oxygenase pathways.^{24,25} The classic slow-reacting substance of anaphylaxis is a combination of leukotrienes C_4 , D_4 , and E_4 .²⁵ Leukotrienes produce bronchoconstriction (more intense than that produced by histamine), increased capillary permeability, vasodilation, coronary vasoconstriction, and myocardial depression.²⁵ Prostaglandins are potent mast cell mediators that produce vasodilation, bronchospasm, pulmonary hypertension, and increased capillary permeability.^{18,25} Prostaglandin D_2 , the major metabolite of mast cells, produces bronchospasm and vasodilation.²⁵ Elevated plasma levels of thromboxane B_2 (the metabolite of thromboxane A_2), also a prostaglandin synthesized by mast cells as well as by PMNs, have been demonstrated after protamine reactions associated with pulmonary hypertension.^{26,27}

Kinins

Small peptides called *kinins* are synthesized in mast cells and basophils to produce vasodilation, increased capillary permeability, and bronchoconstriction.^{18,28} Kinins can stimulate vascular endothelium to release vasoactive factors, including prostacyclin, and endothelial-derived relaxing factors like nitric oxide.¹

Platelet-Activating Factor

Platelet-activating factor (PAF), an unstored lipid synthesized in activated human mast cells, is an extremely potent biologic material, producing physiologic effects at concentrations as low as $10^{-10}M$.¹⁸ PAF aggregates and activates human platelets, and perhaps leukocytes, to release inflammatory products. PAF causes a profound wheal-and-flare response, smooth muscle contraction, and increased capillary permeability.¹⁸

Recognition of Anaphylaxis

The onset and severity of the reaction relate to the mediator's specific end-organ effects. Antigenic challenge in a sensitized individual usually produces immediate clinical manifestations of anaphylaxis, but the onset may be delayed 2–20 minutes.^{29,30} The reaction may include some or all of the symptoms and signs listed in [Table 49-3](#). Individuals vary greatly in their manifestations and course of anaphylaxis.^{31,32} A spectrum of reactions exists, ranging from minor clinical changes to the full-blown syndrome leading to death.^{31,33} The enigma of anaphylaxis lies in the unpredictability of occurrence, the severity of the attack, and the lack of a prior allergic history.

Non-IgE-Mediated Reactions

Other immunologic and nonimmunologic mechanisms liberate many of the mediators previously discussed independent of IgE, creating a clinical syndrome identical to anaphylaxis. Specific pathways important in producing the same spectrum of clinical manifestations are considered later.

Complement Activation

Complement activation follows both immunologic (antibody-mediated, *i.e.*, classic pathway) or nonimmunologic (alternative) pathways to include a series of multimolecular, self-assembling proteins that liberate biologically active complement fragments of C3 and C5.^{10,34} C3a and C5a are called *anaphylatoxins* because they release histamine from mast cells and basophils, contract smooth muscle, increase capillary permeability, and cause interleukin synthesis ([Table 49-4](#)). C5a interacts with specific high-affinity receptors on PMNs and platelets, initiating leukocyte chemotaxis, aggregation, and activation.³⁵ Aggregated leukocytes embolize to various organs, producing microvascular occlusion and liberation of inflammatory products such as arachidonic acid metabolites, oxygen free radicals, and lysosomal enzymes ([Fig. 49-8](#)). Antibodies of the IgG class directed against antigenic determinants or granulocyte surfaces can also produce leukocyte aggregation.³⁶ These antibodies are called *leukoagglutinins*. Investigators have implicated complement activation and PMN aggregation in producing the clinical manifestation of transfusion reactions,^{36,37} pulmonary vasoconstriction after protamine reactions,²⁷ adult respiratory distress syndrome,³⁶ and septic shock.³⁸

Table 49-4. BIOLOGIC EFFECTS OF ANAPHYLATOXINS

Nonimmunologic Release of Histamine

Many diverse molecules administered during the perioperative period release histamine in a dose-dependent, nonimmunologic fashion^{39,40,41,42} and ⁴³ (Table 49-5, Fig. 49-9). The mechanisms involved in nonimmunologic histamine release are not well understood, but appear to represent selective mast cell but not basophil activation.^{43,44} (Fig. 49-10). Human cutaneous mast cells are the only cell population that releases histamine in response to both drugs and endogenous stimuli (neuropeptides).¹ Nonimmunologic histamine release may involve mast cell activation through specific cell-signaling activation⁴⁰ (Fig. 49-11). Different molecular structures release histamine in humans, which suggests that different mechanisms are involved. Histamine release is not dependent on the μ receptor because fentanyl and sufentanil, the most potent μ receptor agonists clinically available, do not release histamine in human skin.³⁹ Although the newer muscle relaxants may be more potent at the neuromuscular junction, drugs that are mast cell degranulators are equally capable of releasing histamine.^{39,40} On an equimolar basis, atracurium is as potent as α -tubocurarine or metocurine in its ability to degranulate mast cells.⁴⁰ Newer aminosteroidal agents like rocuronium and rapacuronium at clinically recommended doses have minimal effects on histamine release.^{44,45}

Figure 49-9. Example of an anaphylactic reaction after rapid vancomycin administration in a patient. Hypotension is associated with an increased cardiac output and decreased calculated systemic vascular resistance. Plasma histamine levels 1 minute after the vancomycin administration were $2.4 \text{ ng} \cdot \text{mL}^{-1}$ and subsequently decreased to zero. The patient was given ephedrine, 5 mg, and blood pressure returned to baseline values. (Reproduced from Levy JH, Kettlekamp N, Goertz P *et al*: Histamine release by vancomycin: A mechanism for hypotension in man. *Anesthesiology* 67:122, 1987.)

Figure 49-10. Electron micrograph of human cutaneous mast cell after injection of dynorphin, a κ opioid agonist. The cell outline is rounded and most of the cytoplasmic granules are swollen, exhibiting varying degrees of decreased electron density and flocculence consistent with ongoing degranulation. The perigranular membranes of the adjacent granules at the periphery of the cell are fused to each other and to plasma membrane. Original magnification $\times 72,000$. (Reproduced from Casale TB, Bowman S, Kaliner M: Induction of human cutaneous mast cell degranulation by opiates and endogenous opioid peptides: Evidence for opiate and nonopiate receptor participation. *J Allergy Clin Immunol* 73:778, 1984.)

epidural anesthesia may be partially sympathectomized and may need even larger doses of catecholamines.⁵¹

In hypotensive patients, 5–10- μg boluses of epinephrine should be administered iv and incrementally titrated to restore blood pressure.* Additional volume and incrementally increased doses of epinephrine should be administered until hypotension is corrected. Although infusion is an ideal method of administering epinephrine, it is usually impossible to infuse the drug through peripheral iv access lines during acute volume resuscitation. With cardiovascular collapse, full iv cardiopulmonary resuscitative doses of epinephrine, 0.1–1.0 mg, should be administered and repeated until hemodynamic stability resumes. Patients with laryngeal edema without hypotension should receive subcutaneous epinephrine. Epinephrine should not be administered iv to patients with normal blood pressures.⁵²

Secondary Treatment

Antihistamines. Because H_1 receptors mediate many of the adverse effects of histamine, the iv administration of 0.5–1 mg \cdot kg⁻¹ of an H_1 antagonist such as diphenhydramine may be useful in treating acute anaphylaxis. Antihistamines do not inhibit anaphylactic reactions or histamine release, but compete with histamine at receptor sites. H_1 antagonists are indicated in all forms of anaphylaxis. The H_1 antagonists available for parenteral administration may have antidopaminergic effects and should be given slowly to prevent precipitous hypotension in potentially hypovolemic patients.¹ The indications for administering an H_2 antagonist once anaphylaxis has occurred remain unclear.

Catecholamines. Epinephrine infusions may be useful in patients with persistent hypotension or bronchospasm after initial resuscitation.¹ Epinephrine infusions should be started at 0.05–0.1 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ (5–10 $\mu\text{g} \cdot \text{min}^{-1}$) and titrated to correct hypotension. Norepinephrine infusions may be needed in patients with refractory hypotension due to decreased systemic vascular resistance. It may be started at 0.05–0.1 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ (5–10 $\mu\text{g} \cdot \text{min}^{-1}$) and adjusted to correct hypotension.

Aminophylline. Aminophylline, a nonspecific phosphodiesterase inhibitor, bronchodilates and decreases histamine release from mast cells or basophils in part by increasing intracellular cAMP. In addition, it increases right and left ventricular contractility and decreases pulmonary vascular resistance. Aminophylline should be considered in patients with persistent bronchospasm and hemodynamic stability, although β_2 -adrenergic drugs are the first-line drugs of choice. An iv loading dose of 5–6 mg \cdot kg⁻¹ of aminophylline given over 20 minutes should be followed by an infusion of 0.5–0.9 mg \cdot kg⁻¹ \cdot hr⁻¹.¹

Corticosteroids. Corticosteroids have a series of anti-inflammatory effects mediated by multiple mechanisms, including altering the activation and migration of other inflammatory cells (*i.e.*, PMNs) after an acute reaction.^{53,54} Corticosteroids may require 12–24 hours to work and, despite their unproven usefulness in treating acute reactions, they are often administered as adjuncts to therapy when refractory bronchospasm or refractory shock occurs after resuscitative therapy.⁵⁵ Although the exact corticosteroid dose and preparation are unclear, investigators have recommended 0.25–1 g iv of hydrocortisone in IgE-mediated reactions. Alternately, 1–2 g of methylprednisolone (30–35 mg \cdot kg⁻¹) iv may be useful in reactions thought to be complement mediated, such as catastrophic pulmonary vasoconstriction after protamine transfusion reactions.⁵⁶ Administering corticosteroids after an anaphylactic reaction may also be important in attenuating the late-phase reactions reported to occur 12–24 hours after anaphylaxis.⁴⁸

Bicarbonate. Acidosis develops rapidly in patients with persistent hypotension. This diminishes the effect of epinephrine on the heart and systemic vasculature. Therefore, with refractory hypotension or acidemia, sodium bicarbonate, 0.5–1 mEq \cdot kg⁻¹, may be given and repeated every 5 minutes or as dictated by arterial blood gas values.

Airway Evaluation. Because profound laryngeal edema can occur, the airway should be evaluated before extubation of the trachea.²⁹ Persistent facial edema suggests airway edema. The trachea of these patients should remain intubated until the edema subsides. The development of a significant air leak after endotracheal tube cuff deflation and before extubation of the trachea is useful in assessing airway patency. If there is any question of airway edema, direct laryngoscopy should be performed before the trachea is extubated.

PERIOPERATIVE MANAGEMENT OF THE PATIENT WITH ALLERGIES

Allergic drug reactions account for 6–10% of all adverse reactions.⁵⁷ DeSwarte⁵⁸ suggests that the risk of an allergic drug reaction occurring is approximately 1–3% for most drugs, and that approximately 5% of adults in the United States may be allergic to one or more drugs. Unfortunately, patients often refer to adverse drug effects as being allergic in nature. For example, opioid administration can produce nausea, vomiting, or even local release of histamine along the vein of administration. Patients will say they are “allergic” to a specific drug when in fact their adverse reaction is independent of allergy. Approximately 15% of adults in the United States believe they are allergic to specific medication(s) and therefore may be denied treatment with an indicated drug. To understand allergic reactions, the spectrum of adverse reactions to drugs needs to be considered.

Predictable adverse drug reactions account for approximately 80% of adverse drug effects. They are often dose dependent, related to known pharmacologic actions of the drug, and typically occur in normal patients. Most serious, predictable adverse drug reactions are toxic and are directly related to the amount of drug in the body (overdosage) or to an inadvertent route of administration (*e.g.*, lidocaine-induced seizures or cardiovascular collapse). Side effects are the most common adverse drug reactions and are undesirable pharmacologic actions of the drugs occurring at usual prescribed dosages. Most anesthetic drugs exhibit multiple side effects that can produce precipitous hypotension. For example, morphine dilates the venous capacitance bed, thereby decreasing preload; releases histamine from cutaneous mast cells, thereby producing arterial and venous dilation; slows the heart rate; and decreases sympathetic tone. However, the net effects of morphine on blood pressure and myocardial function depend on the patient's blood volume, sympathetic tone, and ventricular function. Hypotension rapidly develops in a volume-depleted trauma patient in pain who is given morphine. Drug interactions also represent important predictable adverse drug reactions. Intravenous fentanyl or sufentanil administration to a patient who has just received iv benzodiazepines or other sedative–hypnotic drugs may produce precipitous hypotension that results from decreased sympathetic tone.⁵⁹ This represents a dose-dependent, predictable adverse drug reaction that is independent of allergy.

Unpredictable adverse drug reactions are usually dose independent and usually not related to the drugs' pharmacologic actions, but are often related to the immunologic response (allergy) of the individual. On occasion, adverse reactions can be related to genetic differences (*i.e.*, idiosyncratic) in a susceptible individual who has an isolated genetic enzyme deficiency. In most allergic drug reactions, an immunologic mechanism is present or, more often, presumed. Providing that the initiating event involves a reaction between the drug or drug metabolites with drug-specific antibodies or sensitized T lymphocytes is often impractical. In the absence of direct immunologic evidence, criteria that may be helpful in distinguishing an allergic reaction from other adverse reactions include the following: Allergic reactions occur in only a small percentage of patients receiving the drug, and the clinical manifestations do not resemble known pharmacologic actions. In the absence of prior drug exposure, allergic symptoms rarely appear after less than 1 week of continuous treatment. After sensitization, the reaction develops rapidly on re-exposure to the drug. In general, drugs that have been administered without complications for several months or longer are rarely responsible for producing drug allergy. The time span between exposure to the drug and noticed manifestations is often the most vital information in determining which drugs administered were the cause of a suspected allergic reaction.

Although the reaction may produce a life-threatening response in the cardiopulmonary system (anaphylaxis), a variety of cutaneous manifestations, fever, and pulmonary reactions have been attributed to drug hypersensitivity. Usually the reaction may be reproduced by very small doses of the suspected drug or other agents possessing similar or cross-reacting chemical structures. On occasion, drug-specific antibodies or lymphocytes have been identified that react with the suspected drug, although the relationship is seldom diagnostically useful in practice. Even when an immune response to a drug is demonstrated, it may not be associated with a clinical allergic reaction. As with adverse drug reactions in general, the reaction usually subsides within several days of discontinuation of the drug.

Immunologic Mechanisms of Drug Allergy

Different immunologic responses to any antigen can occur. Drugs have been associated with all of the immunologic mechanisms proposed by Gell and Coombs.³ Although more than one mechanism may contribute to a particular reaction, any one can occur. Penicillin may produce different reactions in different patients or a spectrum of reactions in the same patient. In one patient, penicillin can produce anaphylaxis (Type I reaction), hemolytic anemia (Type II reaction), serum sickness (Type III reaction), and contact dermatitis (Type IV reaction).⁵⁸ Therefore, any one antigen has the ability to produce a diffuse spectrum of allergic responses in humans. Why some patients have localized rashes or angioneurotic edema in response to penicillin while others sustain complete cardiopulmonary collapse is unknown. Most anesthetic drugs and agents administered perioperatively have been reported to produce anaphylactic/anaphylactoid reactions^{31,39,40,41,42,43,44} and ^{45,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80} and ⁸¹ (Table 49-7). Muscle relaxants are the most common drugs responsible for evoking intraoperative allergic reactions.⁵⁷ In this regard, there is cross-sensitivity between succinylcholine and the nondepolarizing muscle relaxants. Unexplained intraoperative cardiovascular collapse has been attributed to anaphylaxis triggered by latex (natural rubber), and certain patients, including those with a history of spina bifida, are at a greater risk for reactions.^{1,68} Even vascular graft material has been reported as a cause of intraoperative allergic reactions.⁶⁹

Initial Therapy

1. Stop administration of antigen
2. Reoxygenate airway and administer 100% O₂
3. Discontinue all anesthetic agents
4. Start intravascular volume expansion (2–4 l of crystalloid/colloid with hypotension)
5. Give epinephrine (0.1–0.5 mg IV bolus with hypotension, titrate as needed; 0.1–0.5 mg IV with cardiovascular collapse)

Secondary Treatment

1. Antihistamines (0.5–1 mg/kg diphenhydramine)
2. Corticosteroid infusions (starting dexamethasone 4–8 mg over 2–4 h; methylprednisolone 4–8 mg over 2–4 h; or hydrocortisone 0.5–1 mg/kg over 2–4 h)
3. Vasopressors (5–6 mg/kg over 20 min with persistent hypotension)
4. Corticosteroids (0.25–1 g hydrocortisone; alternatively, 1–2 g methylprednisolone)
5. Sodium bicarbonate (0.5–1 mEq/kg with persistent hypotension or acidosis)
6. Airway extubation (before extubation)

* Methylprednisolone may be the drug of choice if the reaction is suspected to be mediated by complement. Reprinted with permission from Levy FH. Anaphylactic Reactions in Anesthesia and Intensive Care, 2nd ed, p 162. Boston, Butterworth-Heinemann, 1992.

* This dose of epinephrine can be obtained with 0.05–0.1 ml of a 1:10,000 dilution (100 µg/ml) or by mixing 2 mg epinephrine with 200 ml of fluid to yield an 8 µg/ml solution.

Table 49-7. AGENTS IMPLICATED IN ALLERGIC REACTIONS DURING ANESTHESIA

Life-threatening allergic reactions are more likely to occur in patients with a history of allergy, atopy, or asthma. Nevertheless, because the incidence is low, the history is not a reliable predictor that an allergic reaction will occur and does not mandate that such patients should be investigated or pretreated, or that specific drugs be selected or avoided.⁶⁰ Although different mechanisms have been proposed, no one hypothesis has been proved.¹ The drugs and foreign substance listed in [Table 49-7](#) may have both immunologic and nonimmunologic mechanisms for adverse drug reactions in humans.

Evaluation of Patients With Allergic Reactions

Identifying the drug responsible for a suspected allergic reaction still depends on circumstantial evidence indicating the temporal sequence of drug administration. Conventional *in vivo* and *in vitro* methods of diagnosing allergic reactions to most anesthetic drugs are unavailable or not applicable. The most important factor in diagnosis is the awareness of the physician that an untoward event may be related to a drug that the patient received. The physician must always be aware of the ability of any drug to produce an allergic reaction. The history is extremely important when evaluating whether an adverse drug reaction is allergic and whether the drug can be readministered. Although a prior allergic reaction to the drug in question is important, this is rarely the case. Direct challenge of a patient with a test dose of drug is the only way to establish reaction, but this is potentially hazardous and not recommended. Although the anesthesiologist commonly administers small test doses of anesthetic drugs, these are pharmacologic test doses and have nothing to do with immunologic dosages. The demonstration of drug-specific IgE antibodies is generally accepted as evidence that the patient may be at risk for anaphylaxis if the drug is administered.⁵⁸ Different clinical tests are available to confirm or diagnose drug allergy; several are considered in the following section.

Testing for Allergy

After an anaphylactoid reaction, it is important to identify the causative agent to prevent readministration. When one particular drug has been administered and there is a clear correlation between the time of administration and the occurrence of a reaction, testing may be unnecessary, and general avoidance of the drug should be instituted. However, when patients have simultaneously received multiple drugs (e.g., an opioid, muscle relaxant, hypnotic, and antibiotic), it is often difficult to establish which particular drug caused the reaction. Furthermore, the reaction might have been caused by the vehicle or by one of the preservatives. For patients who want to know which drug was responsible and for patients scheduled for subsequent procedures, some degree of allergy evaluation should be undertaken to evaluate the drug at risk. Unfortunately, very few *in vitro* tests exist for anesthetic drugs; therefore, the available allergy tests are discussed.

Leukocyte Histamine Release. Leukocyte histamine is performed by incubating the patient's leukocytes with the offending drug and measuring histamine release as a marker for basophil activation, although false-positive results can occur.³¹ This test is not easy to perform, although modifications allow the use of whole blood instead of isolated PMNs.^{76,82}

Radioallergosorbent Test. The radioallergosorbent test (RAST) allows *in vitro* detection of specific IgE directed toward particular antigens.⁸³ In this test, antigens are linked to insoluble material to make an immunoabsorbent.^{83,84} When incubated with the serum in question, antibodies of different classes directed toward the antigen bind to it. After washing, the antigen–antibody complex on the immunoabsorbent is incubated with radiolabeled antibodies directed against human IgE, and counted in a scintillation counter. The concentration of specific IgE in the patient's serum directed toward the allergen is measured. The RAST is more quantitative than skin tests and avoids the potential of re-exposure.⁸⁴ RAST testing has been used to detect the presence of antibodies to meperidine,⁴⁹ succinylcholine,⁸⁵ and thiopental.⁸⁶ Two major limitations to this test include the commercial availability of the drug prepared as an antigen and false-positive test results in patients with elevated IgE levels.⁸⁷

Enzyme-Linked Immunosorbent Assay. The enzyme-linked immunosorbent assay (ELISA) measures antigen-specific antibodies. The basis of the ELISA is similar to that of the RAST; however, immunospecific IgE directed against the antigen in question is determined by the addition of an anti-IgE coupled to an enzyme such as peroxidase that acts as a chromogen.⁹ A colorless substrate is acted on by peroxidase to produce a colored by-product. The ELISA has been used to demonstrate IgE antibodies to chymopapain and protamine and has been developed to screen for other antibodies to diverse agents.

Intradermal Testing (Skin Testing). Skin testing is the method most often used in patients after anaphylactic reaction to anesthetic drugs after the history has suggested the relevant antigens for testing.^{88,89} Within minutes after antigen introduction, histamine released from cutaneous mast cells causes vasodilation (flare) and localized edema from increased vascular permeability (wheal). Fisher^{67,88} suggests that this is a simple, safe, and useful method in establishing a diagnosis in most cases of anaphylactoid reactions occurring in the perioperative period. If the strict protocols established by Fisher⁸⁸ are used, intradermal reactions are helpful. Intradermal testing is of no value in reactions to contrast media or colloid volume expanders. Cross-sensitivity between drugs of similar structures can often be evaluated on the basis of skin testing. Skin testing to local anesthetics is considered a direct challenge or provocative dose testing.⁹⁰ Local anesthetic drugs are injected in increasing quantities under controlled circumstances. This testing determines if the person can safely receive amide derivatives (e.g., lidocaine) and can also be used to determine if the person is sensitive to the para-aminobenzoic ester agents (e.g., procaine, tetracaine).

Agents Implicated in Allergic Reactions

Multiple agents, including antibiotics, induction agents, muscle relaxants, nonsteroidal anti-inflammatory drugs, protamine, colloid volume expanders, and blood products, are the etiologic agents often responsible for anaphylaxis in surgical patients.¹ However, any agent the patient receives as an injection, infusion, or environmental antigen has the potential to produce an allergic reaction.¹ Almost everything has been reported to produce an allergic reaction at some time, but usually from a case report or small series. The agents most often implicated include antibiotics, blood products, colloid volume expanders, latex, polypeptides, and neuromuscular blocking agents. If patients are truly allergic to a muscle relaxant, there is a potential for cross-reactivity because of the similarity of the active site, a quaternary ammonium molecule, among the different types of relaxants, and alternatives cannot be chosen without some degree of immunologic testing. Because of the ubiquity of latex as a perioperative environmental antigen, latex allergy is considered separately.

Latex Allergy

For the anesthesiologist, latex represents an environmental agent often implicated as an important cause of perioperative anaphylaxis^{91,92,93,94,95,96,97,98} and ⁹⁹(see [Chapter 4](#)). Latex is the milky sap derived from the tree *Hevea brasiliensis* to which multiple agents, including preservatives, accelerators, and antioxidants are added to make the final rubber product. Latex is present in a variety of different products. In March, 1991, the U.S. Food and Drug Administration alerted health care professionals about the potential of severe allergic reactions to medical devices made of latex. The first case of an allergic reaction due to latex was reported in 1979 and was manifested by contact urticaria. In 1989, the first reports of intraoperative anaphylaxis due to latex were reported.

Health care workers and children with spina bifida, urogenital abnormalities, or certain food allergies have also been recognized as people at increased risk for anaphylaxis to latex.^{91,92,93,94,95,96,97,98} and ⁹⁹ Brown *et al*⁹⁵ reported a 24% incidence of irritant or contact dermatitis and a 12.5% incidence of latex-specific IgE positivity in anesthesiologists. Of this group, 10% were clinically asymptomatic although IgE positive. A history of atopy was also a significant risk factor for latex sensitization. Brown *et al*⁹⁵ suggest these people are in their early stages of sensitization and perhaps, by avoiding latex exposure, their progression to symptomatic disease can be prevented. Patients allergic to bananas, avocados, and kiwis have also been reported to have antibodies that cross-react with latex.^{96,97} Multiple attempts are being made to reduce latex exposure to both health care workers and patients. If latex allergy occurs, then strict avoidance of latex from gloves and other sources needs to be considered, following recommendations as reported by Holzman.⁹¹ Because latex is such a ubiquitous environmental antigen, this represents a daunting task.

More important, anesthesiologists must be prepared to treat the life-threatening cardiopulmonary collapse that occurs after anaphylaxis, as previously discussed. The most important preventive therapy is to avoid antigen exposure; although clinicians have used pretreatment with antihistamine (diphenhydramine and cimetidine) and corticosteroids, there are no data in the literature to suggest that pretreatment actually prevents anaphylaxis or decreases its severity.⁴ Two patients in a series reported by Gold *et al*⁹³ were pretreated yet still had life-threatening reactions to latex. Patients in whom latex allergy is suspected should be referred to an allergist for appropriate evaluation and potential *in vitro* testing (RAST) for definitive diagnosis. When this is not possible, patients should be treated as if they were latex allergic, and antigen avoided. Patients with a documented history of latex allergy should wear Medic Alert bracelets.

SUMMARY

Although the immune system functions to provide host defense, it can respond inappropriately to produce hypersensitivity or allergic reactions. A spectrum of life-threatening allergic reactions to any drug or agent can occur in the perioperative period. The enigma of these reactions lies in their unpredictable nature. However, a high index of suspicion, prompt recognition, and appropriate and aggressive therapy can help to avoid a disastrous outcome.

* This dose of epinephrine can be obtained with 0.05–0.1 ml of a 1:10,000 dilution (100 µg · ml⁻¹) or by mixing 2 mg epinephrine with 250 ml of fluid to yield an 8 µg · ml⁻¹ solution.

[Chapter References](#)

Modern drug regimens for medical ailments like hypertension, angina, bronchospasm, or malignancy nearly always involve the use of multiple agents in combination. This strategy is frequently successful because many medical conditions are responsive to groups of drugs that act by different mechanisms and have different dose-limiting toxicities. The goal in each case is to produce increased therapeutic effect (or decreased toxicity) compared with treatment with individual agents. Unfortunately, the mixing of drugs is not without risk, and hundreds of research papers on the benefits and drawbacks of drug interactions appear every year. A sizable industry has now evolved to provide clinicians with reference books and computer databases on the subject.

Anesthesiologists face the same dilemma as all other physicians: drug combinations are a useful and necessary part of practice, but they are occasionally a source of morbidity. This chapter reviews the reasons that drugs are combined and the ways in which the combinations can alter either pharmacokinetics or pharmacodynamics. This is *not* a comprehensive list of anesthetic drug interactions—entire books are devoted to the subject.¹ The examples included have been chosen largely on the basis of proven or likely clinical relevance and the strength of their documentation. When possible, prototypic interactions are illustrated with examples that have direct relevance to anesthesia, although in some cases no such examples are available. The emphasis throughout is on mechanism, but it will quickly be apparent that our understanding of mechanism is incomplete for many pharmacodynamic interactions. Finally, it is important to know how to read the literature, and a short section is devoted to some of the common ways interactions can be studied.

HISTORICAL PERSPECTIVE

Historically, anesthesiologists were trained to regard drug interactions as a danger and something to be avoided. The generations of clinicians who administered open-drop diethyl ether probably had good reason to limit the number of anesthetic drugs administered: ether, by itself, could produce hypnosis, reasonable levels of analgesia, and muscle relaxation. Ventilation and blood pressure were usually well maintained because ether has respiratory stimulant and sympathomimetic properties. Clinicians could adjust the dose of this single agent fairly accurately using Guedel's criteria for pupil size, respiratory pattern, muscle tone, and so forth. All of this meant that a patient requiring even major abdominal surgery could be anesthetized using nothing more than a can of ether and a simple mask.

Before the Second World War, endotracheal intubation and controlled ventilation were usually not options, and muscle relaxants had not been introduced. Clinicians in this era were well served to keep things simple: if an anesthesiologist chose to add morphine to an ether anesthetic, the pupil and respiratory signs would no longer be reliable, muscle relaxation would probably decrease, and ventilatory depression (if it occurred) could not be treated easily.

The introduction of muscle relaxants, opioid-based anesthesia, and modern intravenous (iv) and inhaled anesthetics completely changed these considerations. The signs and stages of ether are no longer applicable, and controlled or assisted ventilation is often necessary because most of these drugs are profound respiratory depressants. Most important, clinicians now realize that anesthetics are highly specific drugs, and no single agent can produce all of the “desirable” components of anesthesia by itself. There is good evidence that even the potent volatile anesthetics are not sufficient to produce optimal anesthetic conditions when given alone. Zbinden *et al*² have shown that even moderately high concentrations of isoflurane in oxygen cannot suppress many cardiovascular responses to surgical stimuli. This finding is reflected in common clinical practice because isoflurane is routinely supplemented with opioids and other drugs to control blood pressure and heart rate.

Our views of what is desirable in anesthesia have also changed markedly. For example, most patients now expect and prefer an iv hypnotic rather than a mask for anesthetic induction. Similarly, the long emergence after ether is no longer expected or acceptable. A smooth recovery, free of pain or delirium is now considered routine within minutes after major surgical interventions. These goals are difficult to accomplish without using multiple drugs.

PROBLEMS CREATED BY DRUG–DRUG INTERACTION

There are almost no data on the true incidence of perioperative drug interaction, although there are data on general inpatient populations. We know that the probability of a drug–drug interaction increases with the number of drugs administered. Hospitalized patients are commonly given 10 or more drugs, and those in intensive care units may be receiving 15–20. In a frequently cited 1966 study, Smith *et al*³ examined the frequency of drug “reactions” in hospitalized patients. The data showed that a linear increase in the number of drugs led to an exponential increase in the number of reactions (Table 50-1). The authors attributed the excess morbidity to drug interaction and concluded that there is a 24% chance of an “adverse interaction” when 10–15 drugs are administered concurrently.

| No. Drugs | No. Patients | No. Reactions | Rate (%) |
|-----------|--------------|---------------|----------|
| 0-5 | 335 | 14 | 4.2 |
| 6-10 | 378 | 28 | 7.4 |
| 11-15 | 132 | 32 | 24.2 |
| 16-20 | 35 | 14 | 40.0 |
| 21+ | 20 | 9 | 45.0 |
| Total | 900 | 97 | 10.8 |

From Smith JW, Seidl LG, Cluff LG: Studies on the epidemiology of adverse drug reactions: V. Clinical factors influencing susceptibility. *Ann Intern Med* 65:629, 1966, with permission.

Table 50-1. ADVERSE DRUG REACTIONS: EFFECT OF TOTAL NUMBER OF DRUGS ADMINISTERED

Most anesthesiologists probably believe that this overstates the magnitude of the problem, at least as it applies to the intraoperative situation. Many patients are routinely taking 3 or 4 antihypertensives, antidepressants, or gastrointestinal drugs in the preoperative period, and most of them receive 5–10 drugs during general

anesthesia, yet we do not normally hear about significant complications attributable to drug interaction. There are a number of possible explanations for this.

1. Interactions may occur, but they usually do not present a problem. In a sense, the practice of anesthesia is the diagnosis and treatment of drug “toxicity.” Anesthesia practitioners are always prepared to titrate drugs and deal with the possibility of significant respiratory, central nervous system (CNS), or cardiovascular depression. Toxicity from a drug interaction is likely to become a source of morbidity primarily when it occurs in a setting where it is not rapidly recognized and treated. This happened when opioid–midazolam combinations were first used by nonanesthesia personnel for endoscopic and radiologic procedures. The unexpectedly large sedative and ventilatory effects led to numerous deaths.⁴
2. Variability in response to anesthetic drugs is the rule: the data on iv opioids⁵ and hypnotics,⁶ for example, show that different patients may have a three- to fivefold difference in the therapeutic and toxic effects of a given dose—even when the drug is given alone. We can assume that this variability is due to a large number of genetic and environmental factors, so the variability introduced by adding a second or third drug is usually only one more source of clinical “noise.”
3. The qualitative nature of most anesthetic interactions is predictable even though the magnitude of the responses might not be known with certainty. It is no secret to an anesthesiologist that two cardiovascular depressants almost always produce more hypotension. Similarly, combinations of CNS depressants produce more, not less, depression. Drugs that interact to produce a totally unexpected or dangerous effect stand out because of their rarity. A notorious example of such an idiosyncratic interaction is the CNS excitation that may occur when meperidine is administered to patients taking monoamine oxidase (MAO) inhibitors (discussed later).
4. Many iv anesthetic drugs (diazepam, meperidine) have large safety margins—especially when respiration is supported—so small changes in drug concentration are not terribly important. The mere fact that a measurable interaction exists does not mean it will cause a difference in outcome or the need for intervention. Clinically meaningful interactions most often involve drugs like warfarin, digoxin, and theophylline, agents with only small differences between therapeutic and toxic concentrations.
5. Finally, it is likely that many instances of anesthetic drug interaction go unrecognized (a clinician must consider the possibility to make the diagnosis). Excessive drug effects are often attributed to some ill-defined patient “sensitivity.” When a drug *fails* to produce an effect, it is because the patient is “tolerant” or “resistant.” It is almost never considered a drug reaction or interaction.

WHY COMBINE DRUGS?

The goal of combining drugs is to decrease toxicity while maintaining or increasing efficacy. It is interesting to see how this principle has been applied in other areas of medicine.

1. Combination therapy is relatively straightforward in the treatment of hypertension. For example, a β -adrenergic antagonist and a vasodilator have at least additive effects on blood pressure, but their side effects are different and (presumably) nonadditive. Lower doses of each drug may be used in combination, so dose-related side effects are decreased.
2. The goals are different in combination chemotherapy for malignancy. To produce the maximum decrease in tumor burden, each chemotherapeutic drug is given at its maximally tolerated dose, an end point determined by its toxic effects on some normal cell population. Drugs such as alkylating agents and vinca alkaloids are combined because they have different dose-limiting organ toxicities (bone marrow and nerve, respectively), so each drug can be given at a full tumor-suppressing dose.
3. Finally, multiple-drug therapy is not usually the first choice for epilepsy. The mainstay drugs for prophylaxis of grand mal seizures (phenytoin, carbamazepine) have similar dose-limiting side effects such as ataxia and drowsiness. There is little to be gained by combining these drugs, so monotherapy tends to be the preferred mode of treatment.

PHARMACEUTICAL INTERACTIONS

A *pharmaceutica* interaction is a chemical or physical interaction that occurs before a drug is administered or absorbed systemically. The most obvious pharmaceutical interactions are the incompatibilities that can occur between iv drugs in solution:

- Precipitation of barbiturate may occur when thiopental or ketamine is injected together with succinylcholine into the iv line.
- Bicarbonate can decrease the solubility of bupivacaine and cause it to precipitate out of solution.
- Catecholamine solutions (norepinephrine, epinephrine) can be inactivated if they are alkalized by the addition of sodium bicarbonate, a circumstance that could occur during cardiopulmonary resuscitation.

The number of these incompatibilities is very large, and the anesthesiologist is well advised to avoid mixing drugs unless they are known to be compatible. Information on specific iv drug incompatibilities is readily available from most hospital pharmacists.

Occasionally two drugs may interact chemically to form a toxic compound.

- The halogenated anesthetics, desflurane, enflurane, and isoflurane have been shown to interact with dry soda lime or baralyme to produce carbon monoxide.⁷ Desiccation of soda lime is most likely to occur when oxygen has been left flowing through the canister overnight. Older anesthesiologists recall that trichloroethylene interacted with soda lime to produce the neurotoxin, dichloroacetylene.
- Nitric oxide (NO) is a selective pulmonary vasodilator that has been approved in the United States for treatment of primary pulmonary hypertension in the newborn.⁸ If NO is allowed more than fleeting contact with oxygen, it forms nitrogen dioxide (NO₂). The latter compound can be quite toxic, and concentrations >110 ppm can produce pulmonary edema and alveolar hemorrhage. The problem is circumvented by allowing oxygen and NO to mix in the breathing circuit just before administration.

PHARMACOKINETIC INTERACTIONS

A *pharmacokinetic* interaction occurs when one drug alters the absorption, distribution, metabolism, or elimination of another. Many of the basic pharmacokinetic principles underlying these interactions are reviewed in [Chapter 11](#).

Absorption

Alteration of absorption may occur because of direct chemical or physical interaction between drugs in the body or because one drug alters the physiologic mechanisms governing absorption of the second:

- Orally administered tetracycline can be inactivated by chelation if it is given together with antacids containing polyvalent cations like Mg²⁺, Ca²⁺, or Al³⁺.
- Oral antidiarrheal drugs like kaolin and pectin can physically adsorb digoxin and prevent it from being absorbed.
- The bile acid-binding resin, cholestyramine, can bind to warfarin and prevent its absorption. On the other hand, it can also reduce the absorption of vitamin K and other fat-soluble compounds.

Another interaction of significance to anesthesiologists is the delay of gastric emptying produced by a variety of medications like opioids and anticholinergics.

Opioids produce hypertonus of smooth muscle, reduction of peristalsis, and contraction of sphincters throughout the gastrointestinal tract, and it appears that both central and peripheral mechanisms play a role in this effect. There are two important implications of delayed gastric emptying:

1. Opioid-premedicated patients are at increased risk for having a “full stomach” at the time of anesthesia induction.
 - Murphy *et al*⁹ showed that when volunteers were given 500 ml of distilled water to drink, 0.09 mg · kg⁻¹ of morphine increased the half-time for gastric emptying from 5.5 to 21 minutes.
2. The overall absorption of other drugs may also be reduced because the primary site for absorption of most orally administered drugs is the small intestine, and gastric emptying is rate-limiting.
 - Asai *et al*¹⁰ have demonstrated in patients that morphine significantly reduces the absorption of oral acetaminophen.

Changes in regional blood flow (vasodilators, vasoconstrictors) can affect the absorption of parenterally administered drugs. Shock or congestive heart failure decrease perfusion of peripheral tissues like skin and muscle, so the onset and intensity of effect may become unpredictable for drugs given by intramuscular or subcutaneous injection.

- Local administration of epinephrine and other vasoconstrictors retards absorption of local anesthetics and therefore prolongs their effects.
- Numerous drugs can affect the pulmonary uptake of other drugs. Opioids and other drugs that decrease effective pulmonary ventilation have the potential to alter

- The classic example of such an interaction is drug displacement of bilirubin in infants. Premature infants have immature glucuronyl transferase and are unable to conjugate bilirubin formed by destruction of erythrocytes. Much of the load of unconjugated bilirubin is bound to albumin and thus prevented from entering tissues. Sulfonamides and other drugs can compete for albumin binding sites, and the bilirubin they displace can enter tissues. Excessive levels of bilirubin in the brain can lead to kernicterus, a potentially fatal problem. This effect was discovered accidentally in 1956 during a clinical drug trial. When premature infants were given a penicillin–sulfonamide mixture, the mortality rate increased, and many were found to have kernicterus at autopsy.¹⁷
- The same mechanism has been described for numerous drug–drug interactions. Highly bound, potentially toxic drugs like warfarin and phenytoin may be displaced by other highly bound drugs. Warfarin is >98% bound to albumin, meaning that only 1–2% of the circulating drug accounts for the entire biologic effect. Phenylbutazone is a nonsteroidal anti-inflammatory drug (NSAID) that competes effectively for the same binding sites. If phenylbutazone displaces only 2% of warfarin, this theoretically doubles the free (active) fraction and greatly increases the anticoagulant effect.

The displacement interaction has been dogma for years, but the true clinical relevance of this type of interaction is actually not clear.¹⁸ The argument has been made that, for many drugs, altered plasma protein binding causes only small or temporary changes in effect. The reasoning is as follows:

1. Most drugs are widely distributed in the body, and most of the administered dose is found outside of the vascular space. In the case of warfarin, over two thirds of the total is *extravascular*. Even a large change in plasma unbound fraction (*e.g.*, 10%) will therefore release only 3–4% of total warfarin in the body.
2. The body acts as a sink or buffer against large changes in unbound fraction (any unbound drug ultimately is distributed into peripheral tissues).

Some caution is still warranted for anesthesiologists and other clinicians who use iv drug regimens with doses often in the toxic range (*e.g.*, high doses of opioids, hypnotics, and muscle relaxants). In these circumstances, it is possible that even a temporary change in drug concentration can have clinical consequences.

Metabolism

There are numerous examples in anesthesia of drugs that increase or decrease the metabolism of others. Interactions may occur in extrahepatic or hepatic sites of metabolism.

Many drugs—especially those with ester linkages—undergo hydrolysis by specific or nonspecific esterases found in blood and peripheral tissues.

- Drugs given to inhibit acetylcholinesterase at the motor end plate usually inhibit butyrylcholinesterase (pseudocholinesterase) in plasma. Thus, administration of neostigmine or pyridostigmine intensifies and prolongs the effects of succinylcholine and could theoretically affect ester local anesthetics (procaine, chlorprocaine, tetracaine, cocaine) as well. Enzyme inhibition probably needs to be substantial (<20% of normal activity remaining) before the clinical effects of these local anesthetics become prolonged.^{19,20} The prolongation of effect depends on the specific inhibitor. Neostigmine, for example, can prolong the effect of succinylcholine by several hours. The organophosphate, echo-thiophate, is a powerful miotic used topically for refractory glaucoma. This compound irreversibly inhibits pseudocholinesterase.^{19,21} The effect persists for weeks, so the risk for interaction is prolonged.
- Drugs like esmolol and remifentanyl are hydrolyzed by so-called “nonspecific” esterases in blood and peripheral tissues.²² These drugs are not good substrates for cholinesterases, so they are not subject to this interaction.²³ The nonspecific esterases constitute a large group of isozymes with extremely high capacity and low substrate specificity. This enzyme system is not likely to be involved in drug–drug interactions because inhibition of any one isozyme usually does not affect overall drug clearance.

Monamide Oxidase Interactions

The enzyme, MAO, is found in tissues throughout the body, with the largest amounts found in liver, kidney, and brain. MAO is located on the outer surface of mitochondria in the presynaptic terminals of noradrenergic, dopaminergic, and serotonergic neurons in the CNS and periphery. It acts to regulate the presynaptic pool of norepinephrine, dopamine, epinephrine, and serotonin available for synaptic transmission (see [Chapter 12](#)). MAO exists in two isoforms: MAO-A preferentially metabolizes serotonin, dopamine, and norepinephrine, whereas MAO-B preferentially metabolizes phenylethylamine and tyramine.

The MAO inhibitors (MAOI) are used mainly for the treatment of refractory endogenous depression and certain other mood disorders. They have gained some notoriety in medicine because they are the cause of more clinically important drug–drug interactions than almost any other class of drugs. Many of the purported interactions are poorly documented, although they cannot be discounted completely.

There are currently only three MAOI marketed in the United States. Phenelzine (Nardil) is an older, nonselective MAOI derived from hydrazine. It irreversibly inhibits the enzyme, and synthesis of new enzyme can take 10–14 days. Tranylcypromine (Parnate) is a slightly shorter-acting MAOI derived from amphetamine. The newest member of this class is selegiline (deprenyl, Eldepryl), a selective MAO-B inhibitor used as an adjunct in the treatment of Parkinson's disease. The antibiotic furazolidone and the chemotherapeutic drug procarbazine also cause substantial inhibition of MAO and can potentially cause many of the same interactions. The herbal supplement St. John's Wort has been used for depression and was originally thought to have some MAOI effects. This has not been borne out in subsequent studies.

Reported MAOI interactions are broadly of two types: the first group involves drugs that affect sympathetic neurotransmission:

- The well-known interaction with indirect-acting sympathomimetic drugs (ephedrine, amphetamine, metaraminol) occurs because MAOI treatment increases the amount of presynaptic transmitter that can be released by these drugs. Normal doses of ephedrine can produce exaggerated sympathetic responses, including severe hypertensive crises. Deaths have been attributed to severe hyperpyrexia and cerebral hemorrhage.
- The “wine and cheese” reaction is essentially the same interaction. Many foods like aged cheese contain tyramine, a phenylethylamine that has ephedrine-like actions at sympathetic nerve endings. Normally, exogenous tyramine is degraded by MAO in the gut wall and liver, but patients on an MAOI may achieve high systemic concentrations and consequently have hypertensive crises.
- Paradoxically, a patient who has been taking an MAOI for some time may actually have *decreased* adrenergic responsiveness (some of the older MAOIs were marketed as treatments for hypertension). Even with good dietary compliance, these patients absorb some tyramine. Chronic exposure to low levels of tyramine allows this compound to be taken up by adrenergic terminals (in place of tyrosine), where it is metabolized to octopamine (rather than norepinephrine). Octopamine is a “false transmitter” with little activity, so sympathetic nerve function may eventually be impaired.
- Because MAO plays only a small role in the metabolism of compounds in the synaptic cleft, the response to sympathomimetics that act directly on postsynaptic receptor sites (phenylephrine, norepinephrine, epinephrine) should be affected less by such interactions. In a small study of four healthy volunteers (two receiving tranylcypromine and two receiving phenelzine), there was a moderate (twofold) increase in the response to phenylephrine, but the responses to norepinephrine and epinephrine were not exaggerated.²⁴ This is reassuring, but any sympathomimetic drug should still be administered with caution to patients on an MAOI.
- Adverse interactions have been described with older MAOIs and levodopa,²⁵ possibly because both drugs increase dopamine concentrations. Nevertheless, there is a small beneficial effect in patients with Parkinson's disease receiving levodopa and selegiline (the MAOI is given in this case to prevent free radical formation thought to be involved in neuronal degeneration).²⁶
- Inhibition of norepinephrine reuptake by tricyclic antidepressants (TCAs) increases the amount of neurotransmitter in the synaptic cleft. This would seem to be a recipe for adverse interaction with MAOIs, but with careful monitoring, this combination has been used successfully for therapy.

The second group of MAOI interactions involves CNS depressants. As stated previously, many of these are poorly documented, and the mechanisms are unknown.

- The most important interaction is unquestionably with meperidine. When meperidine is given to a patient on an MAOI, a life-threatening reaction may occur, accompanied by excitation, hyperpyrexia, hypertension, profuse sweating, and rigidity.²⁷ This may progress to seizures, coma, and death. The reaction does not occur in every instance. It has also been described with selegiline,²⁸ but not yet with experimental inhibitors selective for MAO-A. There are one or two case reports suggesting that a toxic interaction may occur with the antitussive, dextromethorphan.²⁹ Other than some poorly documented case reports, the evidence suggests that other opioids like morphine and fentanyl do not produce this interaction.³⁰ The mechanism of meperidine–MAOI interaction is unknown, but animal models suggest that it involves elevations in brain concentrations of serotonin.³¹
- Anecdotal reports have appeared regarding adverse MAOI interactions with other psychotropic drugs, including alcohol, phenothiazines, benzodiazepines, and barbiturates,^{32,33} but the evidence is weak. Some wines, like Chianti, could be dangerous because they contain tyramine. It is possible (but probably not advisable) to use ketamine for induction of anesthesia in such patients.³⁴

Should MAOIs be discontinued before elective surgery? The issue is still a matter of debate,³⁵ although drug package inserts usually advise an extremely conservative position (*i.e.*, waiting 2 weeks for the enzyme to regenerate). Current clinical opinion probably favors continuing MAOI therapy up to the time of surgery, and our own anecdotal experience supports this view. Most patients are receiving these drugs for moderate to severe psychiatric disorders that have not responded to other treatments. It is unpleasant and possibly risky for a patient with refractory depression to endure 2–3 weeks without effective therapy. If a general anesthetic is planned,

it seems prudent to use the fewest possible drugs. Avoiding drugs with substantial sympathetic effects (e.g., pancuronium, cocaine, ketamine) probably makes sense.

There is little doubt that patients taking MAOIs have the potential for perioperative hemodynamic instability, yet β blockers, direct vasodilators, and direct-acting pressors appear to be safe and effective treatments in most circumstances. Roizen³⁶ has concluded, "The major problem with continuing MAO inhibitors preoperatively is not the hemodynamic fluctuations that might occur . . . but rather the rare instance of hyperpyrexia following narcotic administration. . . ." Because opioids like fentanyl appear safe, and there are no major interactions with local anesthetics or NSAIDs, providing analgesia without meperidine should not be a hardship.

Hepatic Biotransformation

Many anesthetic drugs undergo oxidative metabolism by one of the isoforms of cytochrome P-450 found in liver microsomes. The P-450 isoforms have low substrate specificity, which means that drugs of diverse structures, such as general inhalation anesthetics, meperidine, barbiturates, and benzodiazepines, can be biotransformed by a single group of enzymes. It is not surprising that inhibitors or inducers of these enzymes can also affect the clearance of broad groups of drugs.

The removal of drug from the blood by hepatic biotransformation (hepatic clearance) is a function of two independent variables, the hepatic blood flow and the intrinsic clearance (the maximal ability of the liver to metabolize that drug). The intrinsic clearance is often expressed as the *extraction ratio* (ER)—the fraction of drug that can be metabolized in a single pass through the liver (see [Chapter 11](#))

$$ER = \frac{C_a - C_v}{C_a}$$

where C_a is the drug concentration coming to the liver (mixed portal vein + hepatic artery) and C_v is the drug concentration leaving (hepatic vein). So,

$$\text{Hepatic clearance} = ER \times \text{hepatic blood flow}$$

Drugs may be classed broadly as "high extraction" and "low extraction," a distinction with important implications for drug interaction:

A high-extraction drug (e.g., lidocaine, propranolol) may have an ER of 0.7–0.8 or more (70–80% is cleared in one pass through the liver). For these drugs, hepatic blood flow is the rate-limiting factor in overall hepatic clearance, that is, the delivery of drug to the liver determines the amount cleared. Clearance is decreased by drugs or maneuvers that lower hepatic blood flow, such as β blockade, cimetidine, halothane, hypotension, and upper abdominal surgery. The clearance of these rapidly metabolized drugs is much less sensitive to changes in enzyme activity. Nor does plasma protein binding have a large effect: the enzymes are so active that a drug like lidocaine is simply stripped off its binding proteins as it traverses the liver.

- Decreases in hepatic blood flow secondary to decreased cardiac output elevate lidocaine concentrations in humans.³⁷
- Pressor administration can also accomplish the same thing. This effect was elegantly demonstrated by Benowitz *et al*³⁸ in rhesus monkeys ([Fig. 50-1](#)). Steady-state infusions of lidocaine were established, and then hepatic blood flow was increased or decreased by infusions of isoproterenol or norepinephrine, respectively. During isoproterenol infusion, the concentration of lidocaine decreased, indicating increased clearance. During norepinephrine infusion, lidocaine concentrations increased.

Figure 50-1. The effects of increasing or decreasing hepatic blood flow with isoproterenol (A) and norepinephrine (NE) (B) on steady-state arterial lidocaine concentrations in the rhesus monkey. The pressors were administered during the period indicated by the shaded bar. The dashed lines show the steady-state concentration expected in the absence of pressors. (From Benowitz N *et al*: Lidocaine disposition kinetics in monkey and man: II. Effects of hemorrhage and sympathomimetic drug administration. *Clin Pharmacol Ther* 16:99, 1974, with permission.)

- Lidocaine clearance is decreased and toxicity is increased when patients are treated chronically with cimetidine.³⁹ It is not clear whether single-dose premedication with cimetidine produces the same effect.
- Other high-extraction drugs, such as morphine and sufentanil, are affected the same way. The clearance of morphine may be very slow in a patient with congestive heart failure and hepatic congestion.

Low-extraction drugs like diazepam, alfentanil, or mepivacaine have ERs of 0.3 or less. These drugs behave quite differently because hepatic enzyme activity is rate limiting (hepatic clearance is limited by intrinsic clearance). Stimulation or inhibition of enzyme activity can have a large effect on overall pharmacokinetics. Protein binding is also more likely to affect clearance because the bound forms of these drugs are protected from hepatic metabolism.

The most common reason for increased intrinsic clearance is enzyme induction. Many drugs of importance in anesthesiology are metabolized by the cytochrome P-450 enzymes (so-called microsomal or CYP enzymes). Several families and numerous subfamilies of these enzymes have been identified based on the homology of their amino acid sequences. The most important subfamily appears to be CYP3A, which is found in greatest abundance in human liver and is responsible for the metabolism of a huge number of drugs. Other subfamilies play important roles in drug metabolism, such as CYP2C19 (diazepam) or CYP2E1 (defluorination of volatile anesthetics). There are hundreds of drugs and environmental toxins that can stimulate or "induce" microsomal enzymes. Typically, a single inducer can affect the products of several gene families. For example, phenobarbital can increase the amount of the P-450 enzymes CYP2B, 2C, 2E, 3A, and 4B.⁴⁰ The increase in the quantity of enzyme protein can therefore increase the clearance of many drugs simultaneously. Not all inducers affect the same enzymes, however.

Treatment with an enzyme inducer ([Table 50-3](#)) can make an otherwise stable drug regimen ineffective or inconsistently effective.

| Inducers | Inhibitors |
|---------------|--------------|
| Phenobarbital | Cimetidine |
| Phenytoin | Ketoconazole |
| Rifampicin | Erythromycin |
| Carbamazepine | Disulfiram |
| Ethanol | Ritonavir |

Table 50-3. DRUGS THAT INDUCE OR INHIBIT HEPATIC DRUG METABOLISM IN HUMANS

- A classic example is the interaction between phenobarbital and coumarin-type anticoagulants (Fig. 50-2).

Figure 50-2. Effect of phenobarbital on plasma levels of bishydroxycoumarin. The anticoagulant was given at a dose of $75 \text{ mg} \cdot \text{day}^{-1}$. Phenobarbital, $65 \text{ mg} \cdot \text{day}^{-1}$, was given during the periods indicated on the x-axis. Induction of hepatic enzymes decreased anticoagulant concentrations and reduced the effect. (From Cucinell SA, Conney AH, Sansur M *et al*: Drug interactions in man: I. Lowering effect of phenobarbital on plasma levels of bishydroxy coumarin [dicumarol] and diphenylhydantoin [Dilantin]. *Clin Pharmacol Ther* 6:420, 1965, with permission.)

Increased metabolism may also result in the production of an active or toxic metabolite.

- In rat microsomal preparations, the liberation of inorganic fluoride by isoflurane, methoxyflurane, and enflurane can be increased by pretreatment with barbiturates,⁴¹ but this interaction appears to be clinically important only for methoxyflurane.⁴² In humans, phenobarbital does not induce the defluorination of enflurane.
- Reductive pathways also involve P-450 enzymes, and the production of toxic reduced intermediates has been postulated as a mechanism for halothane hepatitis. In animal models, administration of halothane after enzyme inducers can lead to centrilobular necrosis.⁴³ The clinical relevance of this finding is unknown.

There are many examples of drugs that inhibit the hepatic biotransformation of other drugs.

- When two drugs are substrates for the same P-450 enzymes, they can interact competitively and reduce the clearance of both. For example, it has been demonstrated that midazolam and fentanyl are competitive inhibitors *in vitro* of metabolism by CYP3A4.⁴⁴ This pharmacokinetic interaction is probably far less important than the pharmacodynamic interaction between these drugs (described later).
- Another study concluded that propofol competitively inhibits CYP3A4, and it can reduce the clearance of midazolam by 37%.⁴⁵ Propofol itself appears to be metabolized by a different isoform, CYP1A2.⁴⁶
- Alfentanil and erythromycin are both metabolized by CYP3A4, and the antibiotic has been greatly shown to prolong the effect of the opioid.⁴⁷ Sufentanil and fentanyl are also metabolized by CYP3A4,⁴⁸ but the clearance of sufentanil is not changed by erythromycin.⁴⁹ Perhaps this is because these are higher-clearance opioids.
- Cimetidine has an imidazole group that binds to the heme iron of cytochrome P-450 and forms an inactive complex. Cimetidine inhibits the metabolism of many drugs, including warfarin, diazepam, phenytoin, and morphine. Several studies have demonstrated that coadministration of cimetidine and diazepam causes clinically significant elevations in the concentration of both diazepam and its active metabolite.⁵⁰ As stated previously, cimetidine can decrease hepatic blood flow, so it can also decrease the clearance of high-extraction drugs.³⁹
- Protease inhibitors like saquinavir⁵¹ and ritonavir⁵² can inhibit the metabolism of midazolam and fentanyl, respectively, by inhibiting CYP3A4.
- Other imidazole drugs like the antihistamine, astemizole, and the antifungals, ketoconazole and itraconazole, can inhibit a wide variety of microsomal enzymes. The antifungals, in particular, have been shown to decrease the clearance (and increase the toxicity) of glyburide, terfenadine, digoxin, midazolam, theophylline, and warfarin.
- The related benzimidazole, etomidate, blocks the synthesis of cortisol and aldosterone by inhibiting the P-450-dependent mitochondrial enzymes, 17 α - and 11 β -hydroxylase.⁵³ Etomidate can inhibit the metabolism of other drugs, but the effects do not appear to be clinically important.

Drug Elimination

The final category of pharmacokinetic interaction is through alteration in drug elimination. These interactions usually involve altered renal clearance, but they may also involve changes in pulmonary excretion.

The mechanism for ion-trapping was discussed earlier. Ion trapping can be the basis for large changes in renal drug excretion when the pK_a of the drug is close to the normal range of urine pH.

- A weak acid like phenobarbital ($pK_a = 7.4$) is largely nonionized when the urine pH is 6.0. This means that much of the filtered drug is in a relatively lipid-soluble form and available for tubular reabsorption. If the urine pH is raised to 8 or 9 with sodium bicarbonate, most of the phenobarbital becomes ionized, reabsorption decreases, and clearance increases. For a weak base, the reverse situation is true—excretion can be promoted when the urine is acidified. This type of interaction is used therapeutically in certain cases of drug overdose.

Organic anions and cations are actively secreted by separate transporters in the renal tubule. The cation system handles the elimination of atropine, isoproterenol, neostigmine, and meperidine. The anion system is involved in the excretion of salicylate, penicillins, cephalosporins, and most of the potent diuretics. The various anions and cations can compete for their respective transport sites.

- Probenecid inhibits the secretion of penicillin, increasing plasma concentrations and prolonging the duration of action.
- Quinidine has been shown to decrease both the volume of distribution and the renal clearance of digoxin, and plasma digoxin concentrations may increase by 2–5 fold.⁵⁴ The renal effect is thought to be due to a reduction in tubular secretion of digoxin.

PHARMACODYNAMIC INTERACTIONS

Up to this point, we have been discussing pharmacokinetic interactions that change the amount of active drug reaching receptor sites. A *pharmacodynamic* interaction occurs when one drug alters the sensitivity of a target receptor or tissue to the effects of a second drug. This means that the dose–response or concentration–response curve for one drug is shifted by another (Fig. 50-3). It is often difficult to assign a specific mechanism to these interactions. We commonly classify them by their direction and intensity, that is, additive, antagonistic, or supra-additive (synergistic).

Figure 50-3. Dose–response curves for loss of consciousness after an intravenous bolus dose of propofol (Prop) alone, propofol plus midazolam (Midaz), propofol plus alfentanil (Alfent), or all three drugs. Drug combinations were given as constant ratios, based on the measured ED_{50} s of the individual drugs. Both the benzodiazepine and the opioid shifted the dose–response curve for propofol significantly to the left. (From Short TG, Plummer JL, Chui PT: Hypnotic and anaesthetic interactions between midazolam, propofol and alfentanil. *Br J Anaesth* 69:162, 1992, with permission.)

Additive interactions are most likely to occur when drugs with identical mechanisms are combined. The clinician normally expects additivity when combining two benzodiazepines, two fentanyl analogues, or two volatile anesthetics. Most additive interactions tend not to be particularly surprising, although some are clinically useful.

- The administration of two aminosteroid nondepolarizing muscle relaxants like rocuronium and vecuronium gives an additive effect⁵⁵ (Fig. 50-4). Notably, the interactions between nondepolarizing relaxants of different chemical classes is often synergistic (see later).

Figure 50-4. The interaction of rocuronium and vecuronium is additive in man. Log dose-probit graph plots twitch height (TH) as percentage of control value. Dose is given in terms of ED₅₀ multiples. *Dark diamonds, dark squares, and open circles* represent rocuronium, vecuronium, and the combination, respectively. The dose–response curve for the combination cannot be distinguished from those of the individual drugs. (From Naguib M, Samarkandi AH, Bakhamees HS *et al*: Comparative potency of steroidal neuromuscular blocking drugs and isobolographic analysis of the interaction. *Br J Anaesth* 75:37, 1995, with permission.)

- The interaction of two volatile anesthetics or nitrous oxide with volatile anesthetics is additive.^{56,57} and ⁵⁸
- In animals, mixtures of lidocaine–tetracaine or lidocaine–etidocaine produce approximately additive CNS toxicity when given iv.⁵⁹

The most common *antagonistic drug interactions* in anesthesia are those involving deliberate reversal with competitive antagonists such as neostigmine, naloxone, or flumazenil. Pharmacodynamic antagonism that is *unintended* is a much less common event.

- There is an antagonistic interaction between succinylcholine and the nondepolarizing relaxants.⁶⁰
- When epidural morphine or fentanyl is administered after establishing a block with 2-chloroprocaine, both the duration and the intensity of opioid analgesia are decreased.⁶¹ The mechanism for this interaction is unclear.
- Several years ago, we studied the memory effects of the drugs butorphanol and midazolam, both alone and in combination.⁶² As expected, the anterograde amnesic effects of midazolam were profound, whereas the opioid agonist–antagonist produced much less amnesia (Fig. 50-5). When butorphanol was combined with midazolam, the mixture had less amnesic effect than midazolam alone. In this instance, the opioid may simply have been diluting the effects of the benzodiazepine.

Figure 50-5. Memory scores of patients 5 minutes after receiving butorphanol, midazolam, or the combination. L, M, and H signify low, medium, and high doses (7.1, 22.5, and 71.4 $\mu\text{g} \cdot \text{kg}^{-1}$ butorphanol; 4.3, 13.6, and 42.9 $\mu\text{g} \cdot \text{kg}^{-1}$ midazolam; or 3.6 + 2.2, 11.3 + 6.8, and 35.7 + 21.5 $\mu\text{g} \cdot \text{kg}^{-1}$ butorphanol and midazolam in combination). The *dashed line* indicates mean pretreatment value. Midazolam, but not butorphanol, produced a profound anterograde amnesic effect. Giving one-half the dose of each drug in combination produced an effect that was less than that after midazolam alone. (From Dershwitz M, Rosow CE, DiBiase PM *et al*: A comparison of the sedative effects of butorphanol and midazolam. *Anesthesiology* 74:717, 1991, with permission.)

The most interesting and clinically important interactions tend to be the *synergistic interactions*, in which small doses of two or more drugs can sometimes produce very large effects. Synergy is most likely to occur when drugs of different classes, or even those with slightly different mechanisms, are used to produce the same effects.

- The potentiation of opioids by NSAIDs is a classic and useful interaction between analgesic drugs with completely different mechanisms.^{63,64,65} and ⁶⁶
- The potentiation of nondepolarizing relaxants by the various volatile anesthetics is a useful interaction on a daily basis. The exact mechanism is unknown, but several theories have been proposed, including increased blood flow to muscle, depression of centrally mediated muscle tone, decreased neurotransmitter release, and decreased sensitivity of postjunctional or muscle membranes.
- A much subtler supra-additive interaction occurs between aminosteroid and benzylisoquinoline relaxants. Pancuronium and *d*-tubocurarine were shown to produce a synergistic relaxant effect in combination,⁶⁷ and this is also seen with similar combinations across these two chemical classes (atracurium and vecuronium, *d*-tubocurarine and vecuronium, mivacurium and rocuronium⁵⁵). Various mechanisms have been proposed, including multiple binding sites⁶⁸ (presynaptic for aminosteroids versus postsynaptic for benzylisoquinolines) and allosteric interactions between separate agonist and antagonist binding sites.⁶⁹
- Another clinically important synergistic interaction occurs between barbiturates and benzodiazepines (discussed later), hypnotics with related mechanisms of action. Both drugs act on the γ -aminobutyric acid-A (GABA_A)–chloride ionophore complex, and both ultimately cause CNS depression by increasing neuronal chloride conductance. However, the mechanisms of action are slightly different: benzodiazepines act indirectly by facilitation of GABA action; barbiturates bind to a separate site and affect the chloride channel more directly.

STUDYING DRUG INTERACTIONS

As already discussed, a study that demonstrates that a drug–drug interaction exists does not necessarily establish its mechanism, its magnitude, or its clinical relevance. What information do we need to conclude that an interaction is pharmacodynamic rather than pharmacokinetic? How do we know it is really synergistic? Let us consider four possible ways to study the benzodiazepine–barbiturate interaction mentioned earlier.

1. In the simplest study design, two groups of patients are randomly assigned to receive midazolam–thiopental or placebo–thiopental. The percentage that becomes unresponsive in each group is assessed at a standard time after thiopental administration. The data show that midazolam increases the percentage unresponsive.

Such a study is severely limited: it tells us that an interaction has occurred, but the results cannot be generalized beyond the conditions examined (a single dose of midazolam, a single dose of thiopental). Nothing may be inferred about mechanism.

2. A more complex (but more useful) experiment would be to study a series of thiopental doses (a dose–response curve) in the presence and absence of midazolam. This would show that the dose of thiopental required to produce hypnosis in half the patients (ED₅₀) is decreased by midazolam.

These results allow us to conclude that the interaction occurs over a range of thiopental doses relevant to clinical practice. The data still apply only to a single

dose of midazolam, and they tell us nothing about the mechanism of the interaction.

3. A further useful modification of this experiment is to administer the thiopental by a constant-rate infusion and measure its concentration at the point response is lost. The data show that similar concentrations of thiopental are achieved in both groups, but the concentration needed to produce hypnosis in half the patients (the ED_{50}) is decreased.

This tells us that midazolam has not changed the pharmacokinetics of thiopental, so the interaction must have a pharmacodynamic mechanism.

4. Finally, how can we determine that this pharmacodynamic interaction is truly synergistic, that is, more than expected from simple addition? There are a number of experimental designs for quantitatively assessing the effects of drug combinations, and these have been reviewed in the clinical literature.⁷⁰ Two of the most common techniques used by experimental pharmacologists are algebraic (fractional)⁷¹ and isobolographic^{72,73} analysis, and clinical anesthesia studies using this method are increasingly more common. The interaction of thiopental and midazolam was studied with an isobolographic technique, and the results are shown in Figure 50-6.⁷⁴ In general, this analysis requires a minimum of three dose–response experiments, one with each drug alone and one with the drugs in combination. The drug combination can be studied as a fixed ratio, or one of the drugs can be given at a fixed dose and the dose of the second drug varied. From these experiments, three estimates of ED_{50} are made, and an isobologram is constructed as shown in Figure 50-6. The ED_{50} s for thiopental and midazolam alone are graphed on the two axes, and these points are connected by the theoretic “line of additivity.” If the two drugs are simply additive when combined, we would expect the ED_{50} of the mixture to fall somewhere along this line. Because the actual ED_{50} of the mixture is significantly less than predicted by this line, the interaction is synergistic (an ED_{50} greater than predicted would have signified antagonism).

Figure 50-6. Isobolographic analysis of the interaction between midazolam and thiopental in humans (see text for details). The ED_{50} of the combination was significantly less than predicted by the dotted “line of additivity.” (Redrawn from data of Tverskoy M, Fleishman G, Bradley EL Jr, Kissin I: Midazolam-thiopental anesthetic interaction in patients. *Anesth Analg* 67:342, 1988, with permission.)

SPECIFIC INTERACTIONS AFFECTING HEMODYNAMICS

The treatment of hypertension, angina, dysrhythmias, and congestive heart failure involves the use of drugs with powerful effects on autonomic function and cardiovascular homeostasis. Until the 1970s, the teaching was generally that cardiovascular depressant or stimulant medications should be discontinued before surgery because they interfered with protective responses to the trauma of anesthesia and surgery. There is now a substantial body of evidence showing that most cardiovascular medications need not and should not be stopped before surgery. Hypertensive patients who remain well controlled are less likely to have wide swings in pressure during surgery. Even small doses of β blockers given before surgery can reduce the incidence of myocardial ischemia and improve outcome.^{75,76} One week of perioperative treatment with atenolol can produce long-term benefits.^{77,78} Conversely, the abrupt discontinuation of vasoactive medications can actually increase cardiovascular instability, and in the case of β blockers and clonidine, the rebound hypertension and dysrhythmias may be dangerous.

Given the foregoing observations, it is fortunate that most cardiovascular drug–drug interactions are simply extensions of the known pharmacology of the agents (Table 50-4). In short, the hypotensive effects of general or regional anesthesia may be increased by all antihypertensive medications. Using similar logic, the antidysrhythmic drugs like amiodarone or bretylium increase the possibility of bradycardia, hypotension, and decreased cardiac output.

| Class | Drugs | Effects |
|--|---|---|
| α Blockers | Phenylephrine Phenolamine Prazosin | Hypotension Reflex tachycardia |
| β Blockers | Propafenone Metoprolol Atenolol | Hypotension Decreased contractility Bradycardia AV Block |
| Mixed α/β Blocker | Labetalol | Hypotension Bradycardia AV Block |
| Calcium channel blockers | Verapamil Diltiazem Nifedipine Nicardipine Nimodipine | Hypotension Decreased contractility Bradycardia AV Block |
| Direct vasodilators | Nitroglycerin Nitroprusside Hydralazine | Hypotension Reflex tachycardia |
| Angiotensin-converting enzyme inhibitors | Captopril Enalapril Lisinopril | Hypotension Hypokalemia |
| Angiotensin II blocker | Losartan | Hypotension Hypokalemia |
| Diuretics | Furosemide Bumetanide Torsemide | Hypotension Hypokalemia Fosfite vasodilation |

AV = atrioventricular.

Table 50-4. EFFECTS OF ANTIHYPERTENSIVE DRUGS DURING ANESTHESIA

With few exceptions, there is little reason to withhold most vasoactive medications before surgery. It may be prudent to stop diuretic treatment before procedures with large anticipated fluid requirements or significant use of nephrotoxic antibiotics. Some studies suggest that continuation of the angiotensin-converting enzyme inhibitors (ACEI) leads to a very high incidence of severe hypotension during induction of general anesthesia.^{79,80} In hypertensive patients, ACEI-induced hypotension is due to left ventricular diastolic dysfunction coupled with anesthetic-induced reduction in preload. There is by no means complete agreement that ACEIs should always be withheld before surgery, and some have found them to be beneficial during surgery.⁸¹ The adverse effects are most likely to be problematic in patients with moderate to severe pre-existing cardiovascular dysfunction, and there seems to be no reliable way to predict the magnitude of hypotension. These considerations may or may not apply to patients receiving ACEIs for chronic congestive heart failure. ACEIs are given to these patients for afterload reduction; they improve baroreceptor sensitivity, reduce ventricular remodeling, and decrease the mortality rate. Use of ACEIs in this population may not increase the already high incidence of hypotension during induction.⁸²

Most perioperative hemodynamic interactions involve the use of cardiovascular depressants. It is also useful to consider several groups of patients who are treated (or “self-treat”) before surgery with cardiovascular *stimulants*.

1. Patients with bronchospasm may require treatment with rapid-acting β_2 agonists (albuterol, terbutaline) or phosphodiesterase inhibitors (theophylline). These patients are at increased risk for tachydysrhythmias and ectopic rhythms. Similar considerations apply to the patient receiving the intravenous β_2 agonist, ritodrine, for premature labor.
2. Patients who receive TCAs like imipramine, desipramine, amitriptyline, and nortriptyline present several possible scenarios for adverse drug interaction. The drugs work by blocking presynaptic reuptake of norepinephrine or serotonin, so they can theoretically increase the effects of direct- or indirect-acting agonists at these synapses. Most TCAs have prominent anticholinergic effects as well. In therapeutic doses and in overdose situations, TCAs can create a range of cardiovascular toxicity that includes sinus tachycardia, prolonged PR, QRS, QT intervals, ST segment and T-wave changes, bundle-branch block, dysrhythmias, second- and third-degree atrioventricular block, postural hypotension, decreased myocardial contractility, congestive heart failure, myocardial infarction, and sudden death.⁸³ In spite of this, hypotension and tachydysrhythmias are not common intraoperative problems with TCAs. This may reflect the fact that during chronic administration, TCAs act to *down-regulate* central adrenergic and serotonergic receptors. In patients taking these older antidepressants, it seems reasonable to avoid pancuronium, halothane, and other agents with the potential to increase the incidence of dysrhythmias. Should TCA-induced hypotension occur, there is disagreement about the best way to treat it.⁸³ One case report⁸⁴ describes a patient on chronic nifedipine and nortriptyline therapy who had hypotension that was resistant to ephedrine, phenylephrine, and dopamine (norepinephrine was eventually successful).
3. Finally, all of us must be prepared to treat patients who are acutely or chronically intoxicated with cocaine. In addition to its local anesthetic properties, cocaine

decreases norepinephrine reuptake, like TCAs. Acute intoxication presents a particular challenge. Young, otherwise healthy people may present with fulminant hypertension, tachycardia, and myocardial ischemia (the latter may be severe because cocaine can induce a thrombotic diathesis). From the standpoint of drug interaction, acute cocaine intoxication resembles pheochromocytoma: these patients need both vasodilators and β blockers. Administration of a β blocker alone may allow unopposed α -adrenergic stimulation and a huge increase in systemic vascular resistance. Patients with chronic cocaine intoxication are less of a problem, but they are still at risk for dysrhythmias (avoiding halothane, pancuronium, atropine, and sympathomimetics still seems like a good idea). Chronic cocaine exposure increases halothane minimum alveolar concentration (MAC) in dogs⁸⁵ and isoflurane MAC in sheep,⁸⁶ and it may increase the sedative effects of benzodiazepines in humans.⁸⁷ This is an interesting contrast to chronic treatment with amphetamine, which appears to decrease MAC in dogs.⁸⁸ It might be thought that the adrenergic overactivity induced by cocaine would produce receptor down-regulation over time, but several animal studies suggest that chronic cocaine treatment does not decrease brain catecholamine content or sympathetic responsiveness over time.^{89,90} The relevance of these data to human cardiovascular responses remains to be proven.

SPECIFIC INTERACTIONS AFFECTING ANALGESIA OR HYPNOSIS

As stated previously, combinations of CNS depressants almost always produce additive or synergistic increases in CNS effect. These interactions are usually useful and predictable. All of the common iv and inhaled anesthetic agents have been tested in combination in humans. The following sections highlight some of the most important interactions.

Opioid-Hypnotic

This is arguably the most commonly used synergistic combination in iv anesthesia.

- Fentanyl and alfentanil have been shown to reduce the requirement for thiobarbiturates, and there is some evidence that the interaction is a beneficial one. Reducing the total dose of thiopental⁹¹ or thiamylal⁹² during short procedures decreases the time to awakening and orientation.
- Opioids also potentiate propofol, but it has been much more difficult to show that the combination improves recovery compared with propofol alone. Short *et al*⁹³ found that a small dose of alfentanil can reduce the hypnotic ED₅₀ of propofol by 50% (see Fig. 50-3). A typical premedication dose of fentanyl (100 μg) has been shown to decrease induction time and reduce the propofol requirement, but in extremely short outpatient cases it did not significantly improve recovery time or the subjective assessment of the quality of anesthesia.⁹⁴
- During total iv anesthesia, infusions of remifentanil or alfentanil tremendously reduce the infusion rate of propofol needed to suppress responses to surgical stimuli^{95,96} (Table 50-5). Target effect-site concentrations of only 1–2 $\mu\text{g} \cdot \text{ml}^{-1}$ of propofol produce adequate anesthesia in many cases. There are concentrations routinely achieved with propofol doses used for conscious sedation (25–50 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$).

| | Target Effect Site Concentration of Propofol ($\mu\text{g} \cdot \text{ml}^{-1}$) | | |
|------------|---|-----|-----|
| | 1 | 2 | 4 |
| Intubation | 0.6 | 0.3 | 0.2 |
| Incision | 0.4 | 0.3 | 0.2 |

* Propofol was administered by computer-controlled infusion to target three specific effect-site concentrations.
From Fragen RJ, Randel GI, Librojo ES *et al*: The interaction of remifentanil and propofol to prevent response to tracheal intubation and the start of surgery for outpatient knee arthroscopy. *Anesthesiology* 81:A376, 1994, with permission.

Table 50-5. REMIFENTANIL INFUSION RATES ($\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) IN COMBINATION WITH PROPOFOL, WHICH PREVENTED RESPONSES TO INTUBATION AND INCISION IN MOST PATIENTS*

Opioid-Benzodiazepine

This important interaction was alluded to earlier, and it illustrates why opioids are so commonly used in combination with diazepam or midazolam. Opioids are highly selective CNS depressants; they can produce sedation, but they are relatively weak hypnotics. Even huge doses of fentanyl and its congeners do not dependably produce sleep by themselves.⁹⁷ We have demonstrated, for example, that alfentanil doses as high as 100–200 $\mu\text{g} \cdot \text{kg}^{-1}$ cannot always induce unconsciousness in unpremedicated patients.⁹⁸ Such opioid doses uniformly produce apnea, rigidity, and profound analgesia.

Kissin and coworkers⁹⁹ found, however, that a tiny dose of alfentanil (3 $\mu\text{g} \cdot \text{kg}^{-1}$) is sufficient to reduce the hypnotic ED₅₀ of midazolam by 50%. This dose is subanalgesic and subhypnotic when given alone.

This means that a small dose of opioid (50 μg fentanyl, 500 μg alfentanil) may have almost no hypnotic effect by itself, but can still be an extremely effective potentiator of other hypnotics. It also means that when fentanyl and midazolam are combined for conscious sedation, the opioid is producing sleep as well as analgesia.

Benzodiazepine-Hypnotic

The theoretic basis for the interaction between barbiturates and benzodiazepines was discussed earlier, and the thiopental–midazolam interaction is shown in Figure 50-6.

- Thiopental–midazolam interaction has been studied in humans, and the combination was found to have 1.8 times the expected potency of the individual agents.^{74,100} Similar results have been described with the combination of midazolam and methohexital.¹⁰¹
- Propofol also acts by modulation of GABA neurotransmission, and its hypnotic effects are potentiated when it is combined with midazolam.⁹³

The clinical benefits of benzodiazepine premedication are most obvious during the preoperative period. Intraoperative benefits (*i.e.*, increased efficacy or reduced toxicity) of benzodiazepine–hypnotic combinations have not been demonstrated. The patient premedicated with midazolam needs less thiopental or propofol for induction (or maintenance), but it is not known whether this results in a smoother anesthetic or more rapid awakening.

Volatile Anesthetic–Opioid

Opioids produce dose- and concentration-dependent decreases in MAC for all of the inhalation anesthetics.

- A steady-state plasma fentanyl concentration of 1.67 $\text{ng} \cdot \text{ml}^{-1}$ decreases human isoflurane MAC by 50%¹⁰² (Fig. 50-7).

Figure 50-7. The interaction between fentanyl and isoflurane. The solid line represents the concentration of the two drugs that prevents movement in 50% of

patients. MAC = minimum alveolar concentration; CI = confidence interval. (From McEwan AI, Smith C, Dyar O *et al*: Isoflurane minimum alveolar concentration reduction by fentanyl. *Anesthesiology* 78:864, 1993, with permission.)

- Opioid partial agonists like nalbuphine and butorphanol produce smaller reductions in MAC.¹⁰³
- Animal data consistently show that an approximately 70% reduction in MAC is the maximum effect obtainable with a full agonist like fentanyl.¹⁰⁴ The mechanism for this interaction is unknown, but Licina *et al*¹⁰⁵ showed that administration of lumbar intrathecal morphine (15 $\mu\text{g} \cdot \text{kg}^{-1}$) does not alter halothane MAC in humans. This suggests that the effect may be due to supraspinal opioid actions. These findings are particularly interesting in view of the work by Rampil *et al*,¹⁰⁶ who showed that MAC in the rat is not altered when the cerebral cortex and all other precollicular brain structures are removed. MAC therefore appears to reflect an action of the volatile anesthetics on the spinal cord, whereas MAC reduction by opioids is most likely to be mediated by structures in the brain stem or higher. One possible site for interaction is the locus ceruleus (LC; see later).

Opioids and volatile agents are often combined to smooth the intraoperative and postoperative course. In some patients, the combination of opioid and volatile agent is hemodynamically better tolerated than the volatile agent alone. Addition of an opioid may also reduce the incidence of emergence delirium.

Is there any evidence that the combination speeds awakening? Reduction of MAC clearly leads to lower end-tidal concentrations at the end of surgery. Faster emergence occurs only if the concentration of inhaled agent that produces hypnosis (*e.g.*, “MAC-awake,” the concentration at which 50% of subjects respond to voice) is not reduced by a comparable amount. A few data indicate that MAC-awake is not decreased by opioids, suggesting that the combination improves recovery.¹⁰⁷ There have been no studies specifically designed to test this hypothesis.

Other iv agents such as lidocaine,¹⁰⁸ midazolam,¹⁰⁹ and α_2 agonists (see later) have been shown to decrease MAC in experimental animals. For lidocaine and midazolam, the plasma concentrations required to produce a meaningful decrease in MAC are so high that the interaction is unlikely to have clinical utility. There is some evidence that the simultaneous use of volatile anesthetics and benzodiazepines causes increased cortical binding of the latter.¹¹⁰

α_2 Agonist Interactions

It has long been known that drugs that depress central sympathetic nervous system function can produce sedation and potentiate anesthesia. Older antihypertensives like reserpine and α -methyl dopa can produce drowsiness and reduce halothane MAC.¹¹¹ The newer autonomic modulators— α_2 agonists like clonidine or dexmedetomidine—are powerful sedatives and analgesics in humans.

- In animals, dexmedetomidine produces marked potentiation of opioid analgesia and benzodiazepine-induced hypnosis.¹¹²
- Dexmedetomidine also lowers halothane MAC by nearly 100% through a specific postsynaptic α_2 mechanism.¹¹³

What is the neural basis for this effect? Dexmedetomidine interacts with both presynaptic and postsynaptic α_2 -adrenergic receptors to decrease central sympathetic tone. Its hypnotic effect is due largely to depression of function in the LC, the main adrenergic nucleus in the brain.¹¹⁴ There is evidence to suggest that the LC is an important site for control of sleep, attention, memory, analgesia, and autonomic function.¹¹⁵ The LC contains receptors for glutamate, GABA, acetylcholine, opioids, and benzodiazepines, and experimental evidence suggests that it may be the site for some important anesthetic drug effects and interactions:

1. The LC is the rostral portion of an important descending inhibitory pathway, which plays a part in the production of opioid analgesia.¹¹⁶
2. In the rat, destroying the LC produces a state of narcolepsy and decreases halothane MAC by 30–40%.¹¹⁷
3. Agonists at GABA, opioid, and α_2 receptors are all inhibitory when injected into the LC. These drugs all have sedative-hypnotic properties, and all of them lower the requirement for volatile anesthetics.
4. Acetylcholine and glutamate receptor agonists are excitatory in the LC, and antagonists at these receptors (*e.g.*, scopolamine, ketamine) are hypnotics. Some glutamate effects are mediated by NO, and inhibitors of neuronal NO synthase can decrease the requirement for halothane¹¹⁸ and isoflurane.¹¹⁹

Three-Way Interactions

In clinical practice, it is common to combine more than two drugs with sedative–hypnotic effects. We have relatively little information on what happens when a third drug is added to two that already have synergistic effects.

- Short *et al*⁹³ performed a clinical study of hypnotic interactions among propofol, midazolam, and alfentanil (see Fig. 50-3). Propofol requirement was reduced by 82% with the three-way combination, but it produced less potentiation than would have been predicted by adding the effects of the two-way combinations.
- Vinik *et al*¹²⁰ studied the same combination and also found profound hypnotic synergism: the dose of propofol could be decreased by 86% in the presence of alfentanil and midazolam. The data also suggested that the interaction between midazolam and alfentanil was a marked potentiation, but the addition of propofol did not produce significant additional change. Figure 50-8 shows the data from this experiment analyzed with a three-way isobologram.¹²⁰

Figure 50-8. ED₅₀ isobolograms for the three-way hypnotic interactions among midazolam, alfentanil, and propofol. The viewer can imagine a triangular “plane of additivity” with its corners at the individual ED₅₀ values. The ED₅₀ for the triple combination was significantly lower than predicted by additivity. (From Vinik HR, Bradley EL Jr, Kissin I: Triple anesthetic combination: Propofol-midazolam-alfentanil. *Anesth Analg* 78:354, 1994, with permission.)

- A three-way interaction involving enflurane, dexmedetomidine, and fentanyl was investigated in dogs. Salmenpera *et al*¹²¹ found that each of the two iv agents lowered enflurane MAC, and combining the three drugs produced a MAC reduction that was probably greater than predicted by simple additivity. In this case, the three-way combination produced more bradycardia than enflurane alone.

MODELS FOR THE FUTURE: DRUG INTERACTION DURING TOTAL INTRAVENOUS ANESTHESIA

Anesthesia must always be titrated to effect, but the clinician usually begins dosing each drug with some notion of a “normal” dose range and a reasonable incremental dose. As additional drugs are added to the anesthetic, these doses need to be modified. Are there any reliable data to guide the administration of anesthetic drugs in combination? The answer for most routine balanced anesthetics is probably “no.” As we have seen, almost all anesthetic drugs interact in a nonlinear, synergistic fashion, and the magnitude of the interaction depends on the specific doses of each agent. If the drugs are given by bolus injection or variable-rate infusion, the interaction changes constantly with time. Predicting anesthetic interaction, then, is like aiming at a moving target. Even a relatively simple anesthetic seems to require the analysis of an impossibly large number of potential variables.

In spite of the obstacles, there have been some attempts to apply quantitative models to total iv anesthesia (TIVA). The TIVA technique offers several advantages in this regard:

1. Anesthesia is often induced and maintained with only two drugs, a rapid-acting hypnotic (*e.g.*, propofol) and a rapid-acting opioid (*e.g.*, alfentanil, remifentanyl). The pharmacokinetics and pharmacodynamics of these drugs are exceptionally well studied.

- The drugs have pharmacokinetics well suited to administration by continuous infusion with microprocessor-driven pumps. During anesthesia, plasma concentrations of the drugs may be held relatively constant, so blood and brain attain pseudoequilibrium. The researcher may vary the infusion of each drug independently and relate stable plasma concentrations to clinical effects.

In a frequently cited study, Vuyk and colleagues⁹⁶ gave computer-controlled infusions of propofol and alfentanil to women undergoing lower abdominal surgery. First, the target concentration of alfentanil was held constant and propofol was varied; then, the reverse experiment was done. The onset of sleep and the time to awakening were measured, as was presence or absence of somatic and hemodynamic responses to laryngoscopy, intubation, incision, and opening of peritoneum. Arterial blood samples were collected, and the EC_{50} of alfentanil for each clinical end point was related to blood propofol concentration. As expected, the data showed that propofol potentiated the analgesic effects of alfentanil, and alfentanil potentiated the hypnotic effects of propofol. More important, the authors were able to relate various concentrations of each agent to a given end point.

The interest in these data lies in the way they can be used to simulate drug interactions.¹²² In Figure 50-9, Vuyk *et al* have simulated the time to regain consciousness at different ratios of propofol and alfentanil. The graph is a somewhat complex, but it is worth considering for a few moments. Vuyk and colleagues assume that a 180-minute anesthetic has been given with propofol and alfentanil targeted at various combinations. Each combination is sufficient to prevent response to intraabdominal surgery in 50% of patients. The three-axis graph relates the concentrations of each drug to the time after discontinuation of the infusions. At time 0 (the floor of the graph), we see the steady-state concentrations just when the infusions are stopped. The disappearance of drug differs depending on how much of the mixture is propofol and how much is alfentanil, and the family of plasma decay curves is depicted on the graph surface. The curved line that crosses the time versus concentration surface identifies the time at which a patient has a 50% probability of awakening. The fastest emergence (10 minutes) occurs when propofol and alfentanil are targeted at concentrations of $3.5 \mu\text{g} \cdot \text{ml}^{-1}$ and $85 \text{ng} \cdot \text{ml}^{-1}$, respectively. Emergence will be significantly longer if the anesthetic is mostly propofol or mostly alfentanil.

Figure 50-9. Computer simulation of the decay in blood propofol and plasma alfentanil concentrations during the first 40 minutes after the termination of a computer-controlled infusion (see text for details). (From Vuyk J, Lim T, Engbers FHM *et al*: The pharmacodynamic interaction of propofol and alfentanil during lower abdominal surgery in women. *Anesthesiology* 83:8, 1995, with permission.)

How will these data help anyone give an anesthetic? What if the infusion is much shorter or longer than 180 minutes? What if the patients are old and sick? What if the anesthesiologist does not have a computer or an infusion pump? The answer could be another set of questions: "What is the value of knowing that the MAC of halothane is 0.74 vol%, the induction dose of propofol is $2.5 \text{mg} \cdot \text{kg}^{-1}$ or the analgesic dose of morphine is $0.1 \text{mg} \cdot \text{kg}^{-1}$?" We all understand that the value of such numbers is to give us a frame of reference for titrating the agents. The value of Vuyk and colleagues' model is not as a "recipe" for a good iv anesthetic—it is a way to think about dosing guidelines for two or more drugs simultaneously. This was a difficult study to perform and analyze, but it is likely to be repeated with other drugs and other populations. It is not far-fetched to imagine that the U.S. Food and Drug Administration will some day require information on "optimal combinations" for each new pharmacologic agent.

[Chapter References](#)

Not all anesthesia is given within a hospital operating room. Advances in medical technology, improved monitoring devices, the development of newer anesthetic agents, and economic pressures have changed the landscape of contemporary surgery. Anesthesiologists work at sites far removed from the conventional operating rooms where they received the bulk of their training. Anesthesia is provided in ambulatory care centers, both in hospitals or freestanding, and in remote areas such as surgeons' and dentists' offices. Additionally, anesthesia is provided for procedures performed in other departments throughout the hospital by radiologists, urologists, gastroenterologists, and cardiologists.

The role of the anesthesia provider in these different settings is to give thoughtful care, ensure the comfort and safety of the patient, and facilitate performance of the procedure. Doing this in remote sites presents additional challenges. The risks and benefits of providing anesthesia away from a hospital operating room have to be weighed carefully. Discussions with surgeons, dentists, and others performing interventional procedures have to include contingencies for adverse outcomes. Additional plans and agreements have to be developed and put into place to optimize patient safety.

GENERAL PRINCIPLES

It is important to have a single standard of patient care. This continually evolves with medical advances and is based on scientific principles and documented clinical outcomes. The standards are to apply regardless of the site at which medical care is delivered. Monitors and anesthesia equipment at alternative sites should be comparable to those within conventional operating rooms. The American Society of Anesthesiologists (ASA) established guidelines for nonoperating room anesthetizing locations¹ which state that uniformity of anesthesia equipment enhances safety and that regularly scheduled maintenance of the equipment is essential. Providers need to be particularly vigilant in their care for patients because the remote location may preclude obtaining immediate help from other qualified personnel. Thorough preoperative and preprocedural preparation is important. The provider must become familiar with all of the anesthesia equipment and the physical layout of the site, and must have a clear understanding of whom to call should an adverse outcome occur. The guidelines emphasize the importance of a reliable source of suction, oxygen supplies, and equipment to perform cardiopulmonary resuscitation.

Several problems are specific to the alternative site. Many of these facilities were not designed with an eye toward fulfilling the ASA guidelines or meeting the needs of anesthetic care for the patient. It is important that the areas be large enough to house routine anesthesia equipment, including self-inflating bags to deliver positive-pressure ventilation, oxygen cylinders, emergency resuscitation drugs, and a defibrillator. A reliable source of suction, appropriate lighting, a sufficient number of electrical outlets, and adequate space for anesthesia personnel to work are essential. Two-way communication systems between the provider and support staff should be established and tested so that backup personnel can be immediately called if help is needed.¹ Unless safeguards are taken and energies are directed toward careful planning, alternative sites for anesthesia care may be more dangerous for patients than conventional hospital operating rooms.

The standards for monitoring in remote sites should be the same as those in the operating room. This applies whether the patient is receiving monitored anesthesia care, regional anesthesia, or a general anesthetic. Blood pressure and heart rate should be obtained frequently and documented at least every 5 minutes. An electrocardiogram (ECG) should be continuously displayed, as well as the SpO₂ from a pulse oximeter. If the patient undergoes a general anesthetic, the provider should continuously monitor ventilation with qualitative or quantitative end-tidal carbon dioxide measurements. The off-site facility should be as carefully maintained as the operating room and have modern anesthesia equipment available.¹ If general anesthesia is provided with volatile agents, the anesthesia machine must be equipped for the scavenging of waste anesthetic gases.¹ The oxygen concentration delivered to the patient should be monitored by an oxygen analyzer equipped with a low-concentration alarm. Although not mandatory, it is preferable to have a central oxygen supply instead of relying on tanks. Finally, all sites should have state-of-the-art patient physiologic monitors. This is particularly evident in radiology suites where the anesthesiologist must often leave the patient's side during treatment.

At the conclusion of a procedure in alternative locations, provision for recovery of the patient should be comparable to that for those treated in an operating room. Areas should be designated for patient recovery and assessment criteria should be established for discharge home. In areas remote from the hospital, patient transport and recovery within a post-anesthesia care unit (PACU) can maximize safety for the patient and convenience for the staff. Appropriate monitoring equipment, oxygen, power supplies, medications, and resuscitation equipment should be available in all recovery areas.

ANESTHESIA CARE

Anesthesia care spans a continuum (Fig. 51-1). *Light sedation* is the least invasive form in which medication is administered *via* oral (po), rectal (pr), intramuscular (im), or intravenous (iv) routes. The medications are provided primarily for the patient's comfort. Several procedures in the radiology suites are painless but require the patient to lie absolutely still during imaging. Patients are usually anxious about the potential findings, and the procedures can be highly stressful. Additionally, they occur with noisy equipment in cramped quarters. After obtaining iv access and administering oxygen by nasal cannulae, light sedation can be achieved with fentanyl, 2–4 µg · kg⁻¹, midazolam 2–5 mg, and/or droperidol 2–4 mg. The goal should be to titrate the medications to patient comfort. Ideally, the patient will be completely still and less acutely aware of the surroundings, yet able to breathe normally, respond to verbal commands, and protect the airway.

Sedation and Analgesia for Procedures is a Continuum:

Figure 51-1. Anesthesia care spans a continuum. (Reprinted with permission from Kaplan RF: 1996 Annual Refresher Course Lectures. ASA Annual Meeting, October, 1996, No. 531, p 1. American Society of Anesthesiologists, Park Ridge, Illinois, 1996.)

Although the terms are not well differentiated because of overlap, the aim is to achieve a level of “conscious sedation” as opposed to “deep sedation.” *Conscious sedation* is a state in which the patient is calm and relaxed, yet able to respond to verbal or physical stimulation. The patient is able to maintain a patent airway and protective airway reflexes during this minimally depressed level of consciousness.² *Deep sedation* is more hazardous. In this state, there is a controlled, depressed level of consciousness. There may be a loss of protective airway reflexes and a loss in the patient's ability to independently maintain his or her airway. The patient may be difficult to arouse immediately; and adverse physiologic changes including hypotension, respiratory depression, and apnea may occur.³ In many situations these levels of sedation are inadequate for the procedure. For example, the patient may move too much during conscious sedation for an accurate image to be obtained. If additional sedation is provided, the patient may become too sedated, such that the airway becomes unprotected and jeopardized. In these situations, a general anesthetic must be administered.

Dentists and doctors from a variety of specialties administer sedatives and analgesics to their patients to provide conscious sedation. Their interventions are performed at sites far removed from operating rooms with no availability of anesthesiologists for backup help. Several specialty organizations have developed guidelines to maximize the safe use of sedatives and analgesics. These include standards for monitoring as well as working definitions of the level of sedation that is desired.^{2,4,5} The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) defined anesthesia care as the administration of iv, im, or inhalational agents that may result in the loss of the patient's protective reflexes. JCAHO standards require that the anesthesia service of a hospital participate with nonanesthesiology departments in setting up a uniform quality of care.^{6,7} The expectation is that nonanesthesiology practitioners will administer conscious sedation with appropriate training and with the use and understanding of monitoring. Personnel from the anesthesiology department should be involved in patient care if deep sedation or general anesthesia is required within a JCAHO-approved facility. The ASA Standards for Basic Anesthetic Monitoring should apply in all cases involving anesthesiology personnel.⁸

Guidelines for the establishment of nonoperating room anesthetizing locations have been established.¹ In the office environment, however, little regulatory oversight is in place at the present time. Relatively few of these sites have sought approval from regulatory bodies. As the economics and politics of medicine continue to change, the sites and individual practitioners working at remote sites will begin to seek credentialing from the various regulatory bodies.

Monitored anesthesia care (MAC), regional, and general anesthesia can be provided at nonoperating room locations both within and outside of the hospital. Experience has shown that safe and efficient care can be provided at areas that are far removed from the operating room. The choice of technique should be dictated by the requests of the patient, the specific medical condition, the requirements for the particular procedure, and the expertise of the practitioner. No single drug or drug dosage is optimal in all situations. A sedative or amnestic may be appropriate and sufficient for some patients; others may require the additional use of an opioid. With some agents, such as the benzodiazepines, variability in response from patient to patient is large. Substitute medications may be indicated. The practitioner's familiarity with the procedure and the patient's response to drug titration should guide drug administration. These principles apply regardless of the anesthetic, analgesic, or sedative chosen.

RADIOLOGY AND RADIATION THERAPY

A common alternative site where anesthesia services are required is within the radiology department. Diagnostic and therapeutic procedures performed by radiologists include angiography, magnetic resonance imaging (MRI), and computed tomography (CT). In more recent years, interventional radiology has become more aggressive in treating patients with advanced disease states. Procedures undertaken include angiographic embolization of arteriovenous malformations and aneurysms, removal of vascular occlusions, creation of vascular shunts, placement of stents, external beam radiation, and intraoperative radiation therapy. Most of these procedures are relatively painless. But the patient must remain motionless if the intervention is to be made successfully. An exception is the use of sclerotherapy to obliterate the vessels leading to an arteriovenous malformation. This is quite painful. Also, patients experience brief periods of pain during angiography with cannulation of the vessel and subsequent injection of the contrast dye. Dye injections are described as episodes of burning. Finally, owing to a variety of factors, some patients are unable to lie still for prolonged procedures.

Most adult patients who have received adequate teaching and reassurance before and during the procedures are able to tolerate interventions without sedation. The more invasive procedures are difficult to tolerate without at least some degree of sedation. For some procedures, such as those done by neuroradiologists, the anesthesia care requires greater skill and finesse. Brief periods of intense sedation and analgesia are required for arterial catheterization (usually femoral) and can be accomplished with the use of short-acting agents. Then, a lesser level of sedation is required for the remainder of the procedure, when patient cooperation is necessary. Transfemoral access is obtained with the placement of a large introducer sheath. Through this sheath a coaxial catheter is positioned, with fluoroscopy, to the general region of interest. Finally, a much smaller, superselective catheter is introduced for the injection of embolic agents, sclerosing agents, or filaments (Fig. 51-2).

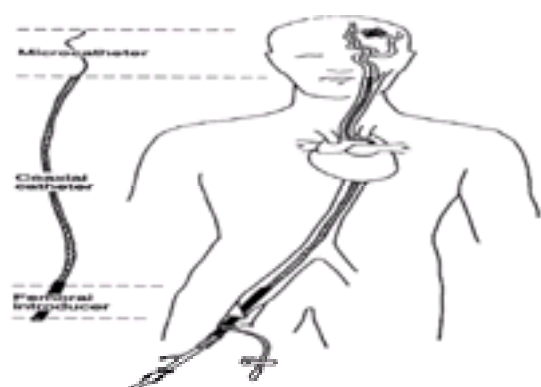

Figure 51-2. Representation of a superselective catheter. (Reprinted with permission from Young WL, Pile-Spellman J: Anesthetic considerations for interventional neuroradiology. *Anesthesiology* 80:427, 1994.)

Patients with intracranial hypertension, trauma, decreased levels of consciousness, or a compromised airway can be particularly challenging. Similarly, when patients are confused or combative and either unwilling or unable to remain motionless, an additional level of anesthesia skill will be required. Many of these patients suffer from claustrophobia, movement disorders, or simply cannot tolerate the radiologic procedures. Pediatric patients have additional needs that must be addressed. It is difficult to perform these procedures on children without the use of general anesthesia. Most children cannot tolerate the interventions owing to separation anxiety and fear of the medical staff and equipment. If arterial catheterization or other painful procedures are to be performed, general anesthesia is usually required.

Contrast Agents and Adverse Reactions

Contrast agents are required for many radiologic procedures. The newer agents have a low osmolality and are nonionic. Adverse reactions to the intravascular injection of these contrast dyes are diminished; fatal reactions occur in approximately 1 of 100,000 procedures.^{9,10 and 11} Many factors contribute to the development of adverse

reactions: the method of injection (either slow infusion or bolus), the type of dye employed, and the total dose administered. The specific technique performed and the site studied also influence the degree and severity of adverse reactions. Coronary artery and cerebral angiography are associated with a high risk of reactions.⁹ Patients with a history of atopy or allergy to shellfish or seafood are more prone to contrast-related adverse reactions.^{9,12} Adverse reactions are classified as mild, moderate, or severe (Table 51-1).

| Mild | Moderate | Severe |
|-----------------|--------------|-----------------------|
| Urticaria | Tissue edema | Prolonged hypotension |
| Chills | Bronchospasm | Cyanosis |
| Fever | Hypotension | Anoxia |
| Facial flushing | Seizures | Pulmonary edema |
| Nausea | | Angina |
| Vomiting | | Dysrhythmias |

Adapted from Goldberg M: Systemic reactions to intravascular contrast media. *Anesthesiology* 60:45, 1984.

Table 51-1. ADVERSE REACTIONS TO CONTRAST MEDIA

Nausea and vomiting are mild reactions to dye injection. These, however, occur as prodromal symptoms in as many as 20% of all anaphylactoid reactions.⁹ Hypotension, urticaria, and bronchospasm are also common side-effects. Hypotension frequently occurs with dye reactions. It may be preceded by a brief period of systemic hypertension. This elevation in blood pressure is a function of the high osmolarity of the injectate. Older contrast dyes consist of iodine-containing anions ionically linked to one of several cations, such as magnesium, calcium, and methylglucamine. The dyes are hyperosmolar when compared with blood plasma. Their osmolarities can be as high as 2100 mOsmol · l⁻¹. Newer agents are nonionic and have osmolarities in the 600–700 mOsmol · l⁻¹ range. Patients receiving contrast usually diurese large volumes of urine because of the osmotic load of the dye. Adequate hydration of these patients should be assured to prevent worsening of pre-existing hypovolemia or azotemia. Patients with renal dysfunction need extra care.¹³ Many centers advocate the use of a Foley catheter in procedures lasting longer than 1 hour when dye loads are administered.

If patients have a history of a reaction to dyes or if a dye reaction is anticipated, prophylactic treatment with diphenhydramine, 25–50 mg iv, and/or steroids (methylprednisolone, 100–1000 mg iv, or prednisone, 50 mg po given in two doses prior to the procedure) is beneficial.^{14,16} The medical treatment of adverse reactions following dye injection should be tailored to the severity of the reaction. Supportive care may be all that is necessary. Establishing intravenous access, administering fluids, airway management, and frequent monitoring of the patient's hemodynamic and respiratory functions are essential. In addition, there should be immediate access to oxygen and emergency drugs, including epinephrine, atropine, diphenhydramine, steroids, benzodiazepines, and methylxanthines (such as aminophylline).

Protection from Ionizing Radiation

Patients, physicians, and other health care workers are frequently exposed to ionizing radiation, usually in the form of X-rays. Exposure to gamma radiation or, rarely, alpha or beta radiation from radioactive isotopes may also occur during implantation or removal procedures. Ionizing radiation exposure may occur directly from the source, as leakage from the ionizing device, or as scatter from the equipment. Direct exposure must be avoided. High radiation exposure occurs with fluoroscopy or digital subtraction angiography. The dose delivered to the patient's skin during these procedures may be greater than 8000 mrem. During fluoroscopy for cardiac angiography, the total delivered dose may be greater than 75,000 mrem.^{17,18}

Radiation exposure during fluoroscopy is often from scatter. A single CT scan exposes the patient to ~1–3 cGy.¹⁷ Fortunately, the exposure of health-care workers to the radiation emitted from a CT scanner is relatively low. The beam of radiation is highly focused. Radiation intensity and exposure decrease with the inverse square of the distance from its source.¹⁶ A minimum distance of 3–6 feet is recommended. With the routine use of a lead apron, protective goggles, and thyroid shield, exposure to radiation can be kept to a low level by maximizing the distance from the energy source. Radiation dosages and terminology are listed in Table 51-2.

| Term | Definition |
|---|---|
| Radiation absorbed dose | A measure of an absorbed dose equal to 100 erg · g ⁻¹ of any absorber (SI units Gray [Gy]: 1 Gy = 100 rad) |
| Roentgen | Total dosage of either X-rays or gamma rays; 1 roentgen = 86.9 erg · g ⁻¹ of dry air |
| Roentgen-equivalent-man (rem) | Dose of ionizing radiation with the same biologic tissue effect as 1 rad of X-rays |
| Maximum Dose Recommended by the National Council of Radiation Protection | |
| Exposure | <100 mrem · wk ⁻¹ <5000 mrem · yr ⁻¹ |

Adapted from Davies D: Subspecialty monitoring techniques—miscellaneous. In Gravenstein N (ed): *Problems in Anesthesia Monitoring*, p 138. Philadelphia, JB Lippincott, 1987.

Table 51-2. RADIATION TERMINOLOGY AND DOSAGE

SPECIFIC RADIOLOGIC PROCEDURES

Angiography

Simple angiographic studies are usually straightforward and do not require the participation of anesthesia personnel. Many radiologists are adept in the use of local anesthesia and are safely able to provide a light level of conscious sedation for their patients. Complex interventional radiologic procedures take longer periods of time and usually require concurrent care from an anesthesiologist. The techniques and medications chosen for use are dictated by the needs of the radiologist and the patient's underlying medical condition. The required level of anesthesia may range from monitored anesthesia care, with or without sedation, to general anesthesia with placement of an endotracheal tube. Attention to hydration is essential since patients will have fasted prior to the procedure and an osmotic diuresis will occur after contrast dye has been given.

The patient must be positioned comfortably and in a position suitable for the procedure, yet with an eye to providing necessary access for the anesthesiologist. A preformed headrest is helpful in minimizing unwanted movement; a support under the patient's knees provides flexion and reduces back discomfort during long cases. This does not interfere with catheter placement within the femoral veins or arteries. Arms should be padded and tucked at the sides of the body or comfortably restrained on arm boards. Monitors and iv lines often require additional extensions since the anesthesiologist is usually several feet away from the patient during the intervention. This arrangement minimizes radiation exposure and allows for movement of the imaging machinery. For therapeutic procedures, a larger-bore iv may be necessary. If the patient is not anesthetized, oxygen should be delivered by nasal cannula or face mask. An end-tidal CO₂ monitoring port allows for the documentation of exhaled air and confirms respiration.

When administered by appropriately trained personnel, propofol is particularly useful as a sedative during angiographic procedures. It can be initiated at small doses (20 µg · kg⁻¹ · min⁻¹), then rapidly titrated up or down as needed; and, when discontinued, it allows a rapid return to consciousness at the conclusion of the procedure. The goal is to provide sedation while allowing the patient to maintain the airway. Peripheral body temperature should be monitored, and all attempts made to maintain normothermia. Shivering results in patient movement and, aside from exposing the patient to discomfort and additional risks, will obscure details of the image. When femoral artery cannulation is performed, the pulse oximeter probe can be placed on a toe of the leg that is cannulated. In addition to permitting measurement of SpO₂, placement at this site will allow early detection of femoral artery obstruction or distal thromboembolism. Locating the device on the toe is also useful once the catheter is removed and pressure applied to the vessel. Overly vigorous pressure can completely compress the vessel and stop blood flow to the foot. This will be detected by a

corresponding fall in SpO₂.¹⁶

Specific angiographic procedures deserve special attention. In many of these procedures, “roadmapping” is employed in which a bolus of contrast agent is injected into the circulation to outline the vascular anatomy. Once this is obtained, the image is superimposed on live fluoroscopic imaging. The radiologist can correlate the progress of the microcatheter as it is advanced to a specific site. Although deep sedation has been used, this procedure usually requires general anesthesia with dense muscle relaxation and occasional periods of apnea. Movement during these procedures will slow the procedure. Time must then be spent for a repeat injection of dye to make another roadmap consistent with the patient’s different position.¹⁶

Cerebral Angiography

Cerebral angiography is indicated for a variety of disorders including cerebrovascular disease, brain tumors, arteriovenous malformations, and cerebral aneurysms.¹⁵ Medical conditions that increase the risk of complications during and following angiography include a history of cerebrovascular disease, stroke, diabetes, seizures, and transient ischemic attacks. Determining the patient’s medical history from a reliable source is vital. Continuous arterial blood pressure monitoring is often necessary in addition to standard ASA monitors. This is particularly true whenever the systemic pressure will be modified with the use of vasoactive drugs. Radiologists may request changes in blood pressure to help with the placement of the catheters and to determine that blood flow to watershed areas will be adequate when the normal blood pressure is lowered somewhat, as occurs during sleep.

General anesthesia is required in patients who are unable to cooperate or who require airway protection. For patients presenting for cerebral angiography who are at risk for intracranial hypertension, control of arterial blood pressure and carbon dioxide partial pressure levels is mandatory.^{15,16,19} Proper positioning of the patient (head up, head in the midline position, no compression of neck veins) will help to minimize increases in intracranial pressure (ICP). Tracheal intubation is challenging in these patients. Special care must be used to provide an adequate depth of anesthesia before the stimulus of laryngoscopy and intubation, since these maneuvers may increase blood pressure and the ICP. Once tracheal intubation is accomplished, mild hyperventilation will improve the quality of the angiographic study by inducing cerebral vasoconstriction, slowing the cerebral circulation, reducing dye washout, and increasing dye concentration within the brain. This allows for a more detailed image.¹⁶

Hypotension and bradycardia are occasionally seen during cerebral angiography once contrast dye is injected. These changes usually respond to administration of iv fluid and small doses of atropine.¹⁹ Because contrast material may cross the blood–brain barrier, some of the dye can enter the brain and cause seizures. Whether this is a result of direct toxicity of the dye or activation of the chemoreceptor trigger zone is unclear.^{9,19,20} Other complications of the procedure include embolization of plaques, bleeding, thrombosis, and hematoma at the arterial puncture site.²⁰ The overall incidence of complications from cerebral angiography ranges from 8 to 14%.^{16,20,21} A standard management plan needs to be in place should the patient develop a neurologic catastrophe such as hemorrhage or stroke. Members of the care team must know the course of action to be taken as soon as the complication is recognized (Fig. 51-3).^{15,16}

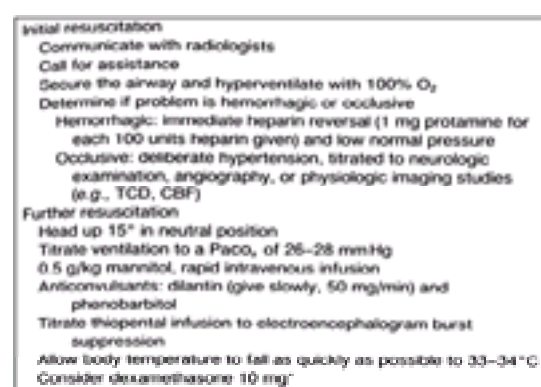

Figure 51-3. Acute management of neurologic catastrophes. (Reprinted with permission from Young WL, Pile-Spellman J: Anesthetic considerations for interventional neuroradiology. *Anesthesiology* 80:427, 1994.)

Coagulation

Careful management of coagulation is required during and after angiography and other invasive cardiovascular procedures. The goal is to prevent thromboemboli. Anticoagulation guidelines are controversial for the individual procedures; most agree that higher levels are indicated whenever test or permanent occlusions are performed. Intravenous heparinization is performed routinely during superselective catheterizations because so much endothelial damage is created by the physical passage of the catheter itself. After placement of the femoral introducer catheter, a baseline activated clotting time (ACT) is measured, heparin 5000 U · 70 kg⁻¹ is given and another ACT obtained. Usually, the target measurement for ACT is 2.5 times the baseline level. Repeat ACTs should be measured hourly throughout the procedure to confirm adequate anticoagulation. The risks from excessive anticoagulation are small in comparison to thrombus formation. A heparin–ACT plot can be generated during long procedures to anticipate the need for subsequent doses. This makes it easier to follow trends. In many centers, heparin is continued throughout the first night of the case. The effects of the heparin are then allowed to dissipate. Only at this point is the introducer catheter sheath removed from the groin and pressure applied.¹⁶

Superselective Functional Examination

Superselective testing is performed following meticulous catheter placement within a segment of the brain (see Fig. 51-2). The procedure allows for the assessment of specific neurologic function or dysfunction at a particular site. The technique is used immediately prior to therapeutic embolization in patients who suffer from arteriovenous malformations. It is also used to isolate the seizure focus in patients with intractable epilepsy. Patients are given sedation and analgesia for the catheter placement through the skin, but they must then be awake and able to respond. A directed and detailed neurologic assessment is performed immediately prior to the procedure. Sedation is then stopped such that the patient is awake and able to respond to questioning. It may be necessary to use naloxone or flumazenil to antagonize opioids and/or benzodiazepine sedatives. Once catheter placement is confirmed, a small dose of sodium amobarbital (30 mg) or lidocaine (30 mg) mixed with contrast agent is injected through the catheter. The doses and volumes are tailored to fit the clinical situation and information that is to be obtained. Amobarbital is used to investigate areas of gray matter; lidocaine is used to evaluate white matter tracts. Immediately after the barbiturate is administered, a repeat neurologic examination is performed. Attention is directed toward “quiet areas” that would be missed if only a sensory or motor examination were performed. Patients are awake for these procedures and asked to answer specific questions. This indicates that parts of the brain involved in the use of language are intact. The changes that are seen following this “anesthesia” of a selected site in the brain are used to predict the changes that will be associated with embolization or resection at that site.

Embolization Procedures

Angiographic embolizations are performed to treat cerebral vascular malformations, aneurysms, cavernous sinus fistulas, and brain tumors. A successful arterial embolization offers a relatively safe, nonsurgical cure provided in the radiology suite. If an open procedure is subsequently required, the embolization can minimize bleeding that will occur during the craniotomy. Anesthetic management for embolization is similar to that for standard angiographic procedures. Choice of sedation and use of either regional or general anesthesia depend on patient preference and the clinical indications. Awake but sedated patients may help with detection and avoidance of neurologic complications during intracranial embolization, but embolizations can be painful and lengthy procedures. Some interventional radiologists insist on general anesthesia with dense neuromuscular blockade.

Once the patient is positioned for the procedure, sophisticated imaging techniques, including digital subtraction, allow the catheter to be placed immediately before treatment. Deliberate hypotension is induced to slow the flow of blood in an arteriovenous malformation. This occurs directly before the injection of glue or foreign bodies to occlude the lesion. Since many of the patients are young and otherwise healthy, large amounts of medications are sometimes required. Esmolol, administered as a 1-mg · kg⁻¹ bolus with a starting infusion of 0.5 mg · kg⁻¹ · min⁻¹, can be used to reduce blood pressure to targeted levels. Labetolol, nitroprusside, and nitroglycerine can also be utilized to achieve hypotension. One must be aware of the potential danger of “overshooting” and causing episodes of profound hypotension. If the blood pressure is to be elevated, phenylephrine, administered as a 1-µg · kg⁻¹ bolus or as an infusion, is effective. Increasing the blood pressure is required if neurologic deficits are noted with planned or inadvertent vascular occlusions. The increase in blood pressure will increase blood flow through the collateral circulation to the areas of ischemia and can serve as an important temporizing measure.^{15,16}

Embolizations are performed by selectively thrombosing an arteriovenous malformation. This is done by the careful introduction of small foreign bodies (pieces of polymeric plastics, detachable balloons, or threads of various materials) at the site of the pathology. Balloons can be inflated to a large diameter such that aneurysms or feeder vessels are occluded through small percutaneous arteriotomies. Sclerosing agents, such as *N*-butyl cyanoacrylate or ethyl alcohol, can also be employed to close the vascular malformation. Patients must be examined during and following the procedure because disruption of a vessel's integrity will allow for flow of these solids and sclerosing liquids into adjacent vascular beds within the brain. The procedures are highly invasive. If complications arise, contingency plans should be in place for emergent patient transport to the operating room for a craniotomy.

The cumulative dose of contrast dye used during these procedures is quite high because the angiographic catheter positioning must be tested repeatedly. All of the dyes act as osmotic diuretics; in addition, the use of diuretics such as furosemide or mannitol may be indicated for the procedure. Adequate hydration is necessary and a Foley catheter desirable. Nausea and vomiting are common complications. Metoclopramide, ranitidine, droperidol, and ondansetron are all useful adjuvant drugs.

Computed Tomography

Computed tomography (CT) scanning is noninvasive and painless. It is frequently used for intracranial, thoracic, and abdominal imaging. Interventional CT scanning is essential for needle placement for nerve blockade, biopsy, and needle aspiration of masses.²² The early CT scanners generated a cross-sectional image of the patient and took several minutes. It was essential that the patient be motionless during this time.¹⁹ Modern scanners obtain a cross-sectional image in just a few seconds, and state-of-the-art spiral scanners can image a slice of the body in less than 1 second. Thus, the problems with motion artifacts are greatly minimized. The majority of adult patients will tolerate CT scanning without anesthesia if given verbal assurances. Sedation or general anesthesia is usually required only during procedures for children or for adults who have difficulty remaining still. Patients requiring a more intensive level of care (e.g., following trauma) usually need the continuous presence of an anesthesiologist.

Children experience fear and separation anxiety when inside the scanning room. It is usually wiser to induce pediatric patients away from the scanner and position them once they are anesthetized. Temperature monitoring and attention to patient warming is necessary since the CT suites are cool, and hypothermia will develop rapidly in an anesthetized child. For patients undergoing general anesthesia or deep sedation, the primary concerns are related to airway management and adequate oxygenation. Positioning and movement of the gantry during various procedures may cause kinking of the endotracheal tube or disconnection of the anesthesia circuit. These problems must be anticipated. Also, patients undergoing emergency procedures and those who receive oral contrast agents are considered to have full stomachs and must be treated appropriately for airway protection.²³

Stereotactic-guided needle placement and surgery is performed using CT scanning. Most of these procedures involve biopsies or aspirations, often of intracranial masses. The stereotactic approach minimizes injury to adjacent structures. It involves placement of a radiolucent frame around the head. The frame is held in place by pins inserted directly into the skull. This aspect of the procedure is painful. Transient deep sedation or general anesthesia may occasionally be necessary in combination with the injection of local anesthetic at the insertion sites. Sedation must be used with caution in patients with suspected intracranial hypertension. If the sedation causes hypoventilation, the arterial CO₂ will rise and the cerebral blood vessels will dilate, further increasing ICP. Once the frame is affixed to the skull, the patient can be positioned on the gantry and a motionless field is assured.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides more detail of intracranial, spinal, and soft tissue lesions than does CT. MRI is noninvasive and produces no ionizing radiation. There are no reports of harm from tissue contact with the magnetic field itself. The device has gained universal popularity, and is one of the most important advances in imaging during the past decades. The patient is placed in a cylindrical tunnel surrounded by a high-intensity magnetic field coil. A high-quality image takes from 30 minutes to an hour to obtain. During this time the patient must remain motionless inside the magnetic bore, or the image will be degraded by artifact.^{24,25}

Several days of energy input are required to establish the MRI's intense magnetic field. The field is constantly present, even in the absence of a patient to study. It is rarely allowed to fade away; this is done only in an emergency.^{24,25} The way in which the device works is straightforward. Atoms with an odd number of protons in their nuclei, most notably, hydrogen, are aligned in one direction by the magnetic field.²² Once this alignment occurs, the atoms comprising the tissues are subjected to intense radiofrequency pulses that temporarily change the protons' orientations. As the radiofrequency pulses are discontinued, the protons return to their original alignment (*i.e.*, they "relax") within the original magnetic field. In conforming to this orientation, they give off energy. It is this release of energy over a variable time span that is measured and used to generate the MRI image. The time it takes for the energy to dissipate as realignment is achieved is termed the *relaxation time*. These times are specific for given tissues.^{22,26} The hydrogen atom is particularly useful in imaging. It is present in all tissues both as mobile water and as immobile triglycerides. Since the chemical environments surrounding these atoms differ from site to site, their relaxation rates differ, and body structures are differentiated by the images created.

High energy levels are used to generate the magnetic fields of the MRI. Ferromagnetic equipment cannot be safely used near the scanner.^{24,25} Standard monitoring equipment must be modified to allow for proper function of the devices and to prevent distortion of the image. There are several types of physiologic monitors, oxygen-powered ventilators, laryngoscopy equipment, and anesthesia machines that can be used within the MRI suite.^{24,25} Most of the equipment differs in that it is made of aluminum or other nonferromagnetic material. Absolute and relative contraindications for MRI scanning include patients with cardiac pacemakers near the site for scanning, aneurysm clips, or intravascular wires.^{22,27,28,29} and ³⁰ It has been suggested that MRI be avoided in women in the first trimester of pregnancy, although no strong data support such avoidance.³¹ Large metal implants in patients may heat up when subjected to torque from the magnet's force. These sites should be monitored for temperature changes when the patient is within the magnetic field.

Anesthetic management of patients during MRI is similar to that for CT scanning. The environment for the MRI, however, is significantly different in that it is very confining. With a closed MRI, the patient is positioned on a long, thin table. This table is then advanced into the magnetic bore. The incidence of claustrophobia or anxiety-related problems for awake patients within the gantry ranges from 7–30%.³² Procedures that require a long duration are uncomfortable for even the most cooperative patient. The equipment is noisy. Continual reassurances by the staff are helpful for the patient. When sedation or general anesthesia is required, the provider must pay particular attention to the patient's position and the placement of the anesthesia circuitry. Propofol (1–2-mg · kg⁻¹ bolus followed by an infusion of 100 µg · kg⁻¹ · min⁻¹, titrated to effect) is commonly used in spontaneously breathing patients. This tends to avoid some of the issues regarding incompatible anesthesia equipment close to the magnetic field. Direct access to the patient during the procedure is difficult. Although the anesthesiologist can remain in attendance in the scanning room, most people prefer to stay outside due to the excessive noise. Open MRI scanners have been developed over the last few years. The patient is still positioned on a narrow table, but the gantry is larger and there are fewer complaints of patients' feeling confined. As the technology continues to improve, the images from these newer models will rival those from the conventional devices.

Monitoring of MRI patients receiving sedation and regional or general anesthesia should include continuous ECG, automated blood pressure cuff, and pulse oximetry. ECG telemetry and capnography systems minimize distortion of the MRI signal while permitting accurate patient assessments.²⁸ When general anesthesia is required, induction is usually performed in a room adjacent to the MRI. Laryngoscopy is difficult within the MRI suite because the magnetic field affects conventional laryngoscope batteries. Anesthesia machines and ventilators constructed specifically for use in MRI are commercially available but are expensive. If the anesthesia machine is kept outside of the MRI, extra breathing tubing will be required to reach the patient. Mapleson and Bain circuits are used with MRI and may provide additional visual and tactile monitoring of the patient's breathing and airway.²⁴ As always, vigilance is required in caring for the patient during this procedure. Unusual complications must be anticipated and measures taken to prevent them. For example, a tissue burn from the heating of a pulse oximetry probe placed within the MRI magnetic field has been reported.³³

Radiation Therapy

Two different types of radiation therapy commonly require anesthesia care—external beam radiation treatments (usually for children with malignancies) and intraoperative radiation to tumor masses that cannot be completely resected. Four general groups of radiation-sensitive malignancies occur in children: (1) central nervous system leukemias, (2) radiosensitive ocular tumors, (3) intracranial tumors, and (4) a variety of intra-abdominal tumors. These patients should be examined before each treatment for signs or symptoms of sepsis or increased ICP. [Table 51-3](#) lists several radiosensitive tumors for which external beam radiation has proved useful.

Neuroblastoma
Retinoblastoma
Medulloblastoma
Wilms' tumor
Rhabdomyosarcoma
Leukemia

Table 51-3. COMMON RADIATION-SENSITIVE TUMORS

Patients are typically scheduled for a series of treatments over several weeks. Radiation doses are in the range of 180–250 cGy. Since the dose is so high, all medical personnel must leave the room during the actual treatment. Direct observation of the patient is not possible. Closed-circuit television and telemetric microphones are used. Standard monitoring is interfaced with the remote location. Television cameras are mounted so that anesthesiologists may observe the patient and anesthesia equipment in one scene. In the event of a problem with the patient or a circuit disconnect, shutdown of the radiation beam and immediate access to the patient are crucial (within 20–30 seconds).³⁴

The need for patient immobility is a primary reason anesthesia is required for these procedures. It is difficult for children to keep completely still with the use of sedation only. If it is attempted, airway management problems increase, and the recovery period is greatly prolonged. General anesthesia offers several advantages to conscious sedation. The treatments proceed with efficiency and precision, while patient and parent satisfaction is high. Use of a general anesthetic is especially important when a radiation therapy site treats 20–30 patients each day. General anesthesia may be tailored to the procedures with the use of agents and techniques that are of short duration. Most of the children in this subset of patients have indwelling catheters that facilitate iv induction. Airway management will vary with the individual patient and clinical situation. Since there is no surgical stimulation, patients can be maintained at light levels of anesthesia. Emergence and recovery are rapid. Changes in treatment plans or modification in anesthetic regimen may be necessary as the patients' conditions change.

Extremely high radiation levels are used as palliation for a variety of tumors. Intraoperative radiation therapy treatments are provided after the masses are exposed to view. Patients with pancreatic, colon and rectal cancers, radiation-sensitive sarcomas, and specific types of ovarian cancers receive this form of treatment.³⁴ Doses of 5000–6000 cGy may be used during a single, intraoperative treatment. These patients typically suffer from advanced cancers. They will have the attendant nutritional deficiency, dehydration, electrolyte imbalances, and coagulopathies that often complicate anesthetic management.

Some newer hospitals are equipped with combination radiation therapy/operating room suites; however, most centers require that surgical exploration be performed in the traditional operating room. The anesthetized patient is subsequently transported to the radiology suite. Often, this can be a considerable distance. Portable monitors and methods for delivery of oxygen and agents to maintain general anesthesia during transport are all required. Intravenous anesthetics tend to be more efficacious than inhaled agents.³⁴ The standards for monitoring are the same as for procedures performed exclusively within the operating room.

Requirements for patient monitoring for intraoperative radiation are comparable to those described for external beam radiation. Personnel must leave the room during the actual treatment. Equipment interfaced to an external control desk allows careful monitoring with observation of the patient and anesthesia equipment with closed-circuit television. After treatment, patients must be transported back to the operating room for surgical closure. Occasionally, closure can be performed in radiology and the patient taken directly to the PACU.

Cardiac Catheterization

Anesthetic care is needed for patients who cannot keep still during imaging procedures or who require an increased level of care due to the severity of their underlying disease. Anesthesia is usually needed when a patient undergoes a cardiac catheterization, angioplasty, atherectomy, or a valvuloplasty.

Catheterization of children is most commonly performed to diagnose suspected congenital heart disease (CHD).³⁵ Presenting signs and symptoms include cyanosis, dyspnea, failure to thrive, and congestive heart failure. Adequate premedication and sedation are important to alleviate anxiety and fear. Anxiety, with its corresponding increases in heart rate and blood pressure, will exacerbate several cardiopulmonary abnormalities. The changes are particularly dangerous for patients with intracardiac shunts. Rapid changes follow myocardial depression from dye loads or anesthetic induction agents that produce abrupt falls in preload or afterload. They are also seen with excessive sympathetic stimulation. Normocarbia should be maintained. When patients are dependent on blood flow through a patent ductus arteriosus (*e.g.*, coarctation of the aorta), high oxygen tensions should be avoided since elevations in oxygen partial pressures can lead to ductal closures. In these patients, prostaglandin E₁ infusions can be used to maintain the patency of the ductus. Polycythemia is commonly seen in cardiac patients with cyanotic CHD. The elevated hematocrit increases the blood viscosity and the risk of deep vein thrombosis. Lowering the hematocrit, however, can be detrimental in that it lowers the oxygen delivery to the peripheral tissues. The depth of analgesia, sedation, or general anesthesia must be titrated to prevent tachycardia, hypertension, and changes in cardiac function. The pharmacokinetics of anesthetic agents are affected by left-to-right and right-to-left cardiovascular shunts. Some of these patients have morbidity from dysrhythmias. Atropine premedication, especially for those children with cyanotic disease, is important. During cardiac catheterization in children, the information obtained from standard monitoring with an ECG, pulse oximeter, and blood pressure cuff is augmented with catheterization data and arterial blood gas analyses.

Adults rarely require more than conscious sedation for catheter insertion and performance of the procedure. Some studies have shown benefit from general anesthesia during angioplasty procedures for acute myocardial infarction, but the main benefit seems to be enhanced patient satisfaction during the procedure itself.³⁶ Patients undergoing atherectomy will experience discomfort during the excision of the atheroma. A need for increased analgesia should be anticipated and provided at the appropriate time. Monitoring should focus on the detection and management of ischemic episodes and cardiac dysrhythmias. Additionally, catheter insertion may stimulate a conduction block, although these acute changes are usually transient and have minimal hemodynamic significance. Episodes of ischemia, ventricular tachycardia, and fibrillation can occur subsequent to the administration of contrast media. Immediate access to oxygen, nitroglycerin, vasopressors, inotropes, resuscitative agents, and a defibrillator is required. If acute decompensation occurs during catheterization, cardiopulmonary resuscitation (CPR) is indicated. Direct access to the patient may be difficult because the fluoroscopic equipment is in the way. A plan must be formulated, agreed upon, and in place to obtain immediate access to the patient in the event of this complication.

CARDIOVERSION

Most cardioversions are scheduled in advance. There is adequate time for optimal preparation of the patient and the equipment. Patients scheduled for elective cardioversion need sedation and airway management for a very short period of time. Occasionally, anesthesia is needed for emergency cardioversion. This is almost always a result of an acute change causing severe hemodynamic instability. In this situation, adherence to basic ACLS protocols will provide a satisfactory plan of action. The algorithms indicate what medications and procedures are to be employed.

Elective cardioversions are often performed in areas near the operating room, usually in the PACU. They are typically performed early in the morning before these sites fill with patients following surgery. Additional anesthesia personnel are available should help be needed, and the site is well stocked with additional drugs, airway management equipment, and anesthetic agents. Atrial fibrillation and atrial flutter are the most common dysrhythmias treated with elective cardioversion. These will occur spontaneously or subsequent to valvular heart disease or recent coronary artery bypass grafting. Supraventricular tachycardias, which are refractory to medical management, are also treated with cardioversions.

Although the procedure is brief, a detailed history and physical examination should be performed for each patient. The current health status, use of concurrent medications, particularly heparin or coumadin, and history of prior gastroesophageal reflux are important considerations. Patients should be kept NPO in preparation for the procedure. A high level of anticoagulation is often required before cardioversion is performed. This will decrease the chance that thrombotic emboli will be showered into the pulmonary or systemic vascular systems. Any history of previous thromboembolization should be noted, and a brief neurologic assessment performed immediately prior to the procedure. This will allow assessment of acute post-procedure CNS dysfunction. Many of these patients will have coexisting cardiovascular disease and myocardial dysfunction.

Standard monitoring is routinely employed. Invasive monitoring is rarely required for cardioversion. The patient's physical status and general medical condition will dictate special monitoring needs. Intubating equipment, medications, supplemental oxygen, and a method to provide positive-pressure ventilation, suction, and

resuscitation equipment should be readily available. A variety of iv agents have been used successfully, including the benzodiazepines, thiopental, methohexital, etomidate, and propofol.^{37,38,39,40,41 and 42} Although midazolam is associated with longer recovery times, reversal with flumazenil is effective and causes a more rapid awakening.^{37,41,42 and 43} Etomidate provides more hemodynamic stability than many of the other agents; however, the myoclonus, which it induces in 40% of patients, may interfere with ECG interpretation. In some centers, this side-effect precludes its use. Propofol produces hypotension when given as a bolus because it is a direct myocardial depressant. A slow induction with a low-dose infusion can attenuate this drop in systemic blood pressure.^{38,41}

Adequate preoxygenation is performed before the induction of anesthesia. The onset of unconsciousness is often delayed in these patients because the dysrhythmia decreases the cardiac output and prolongs the circulation time. Once the patient is assessed and the level of anesthesia is found to be adequate, a synchronized countershock is administered. The airway is maintained and ventilation supported until the patient regains consciousness. The patient must be closely monitored following cardioversion for recurrence of the dysrhythmia or a different rhythm disturbance. Once the patient is awake and alert, outpatient discharge or admission to a monitored bed is individualized.

Some centers are routinely performing transesophageal echocardiographic examinations immediately prior to cardioversion in order to evaluate for the present of thrombus in the atria.⁴⁴ This complicates the anesthetic management since the patient must be sufficiently obtunded to tolerate esophageal placement of the probe, yet control of the airway is not readily achieved. One approach is to topically anesthetize the patient's airway prior to the procedure so that deep levels of sedation can be avoided.

ELECTROCONVULSIVE THERAPY

In the 1930s, mental health clinicians observed that patients who suffered from both schizophrenia and occasional seizure activity experienced improvements in their schizophrenic states following a seizure. This observation led to the development of pharmacologically induced seizures as a treatment for mental illnesses.⁴⁵ For a time, hypoglycemic states were deliberately caused by insulin injections to elicit grand mal seizures. Glucose was subsequently administered for rescue. Electroconvulsive therapy (ECT) was introduced in the late 1930s as an alternative mechanism for seizure induction, and it continues to be used today for the treatment of a number of major affective disorders.^{45,46} Its use has been studied extensively, and it is found to be a relatively safe procedure with a mortality rate of 2–4 per 100,000 treatments. The most common use of ECT today is for the treatment of severe depression. ECT is also used as the initial treatment for the acutely ill patient for whom a rapid clinical response is essential, for example, severe catatonia in previously healthy young people. The therapy is also used after unsuccessful trials of antidepressant medications in patients with recurrent episodes of depression. The cellular and physiologic mechanisms for the beneficial effects are unknown, but various theories have been suggested.^{45,46,47,48,49 and 50} Empirically, the treatment seems to work, and it has strong supporters.

Depression is a psychological and biologic disorder.^{47,48} Patients are afflicted with persistent feelings of worthlessness, anorexia/hyperphagia, insomnia/hypersomnia, and unhappiness. Signs of poor nutritional status and dehydration are often present. Patients are often noncompliant with medication regimens. Depression may occur as a primary illness or appear as a secondary manifestation of another disease. For instance, patients afflicted with Parkinson's disease, acquired immune deficiency disease, or cerebrovascular accidents commonly suffer from depression.⁴⁸ Firstline treatments for depression are pharmacotherapeutic agents such as tricyclic antidepressants, monoamine oxidase (MAO) inhibitors, and selective serotonin-reuptake inhibitors (SSRI). Patients presenting for ECT may also take a variety of other psychotropic and mood-enhancing agents. In addition, since depression tends to affect an older population with pre-existing illnesses, patients may commonly take medications for their concurrent medical problems. The likelihood of drug interactions during anesthesia is high.⁵¹

Tricyclic antidepressants are structurally related to the phenothiazines. They block the reuptake of catecholamines at the presynaptic nerve terminals. They increase circulatory catecholamine levels and increase the patient's resting vascular tone. Administration of sympathomimetic drugs, such as ephedrine, may generate an exaggerated pressor response. Most of these agents also have anticholinergic properties. MAO inhibitors block the enzyme monoamine oxidase. As a result of this inhibition, additional neurotransmitter accumulates within the nerve terminals. Indirect-acting sympathomimetics can precipitate hypertensive crises because of the release of these additional neurotransmitters. Sympathomimetic drugs should be avoided or used in greatly reduced doses for these patients. MAO inhibitors also exaggerate the effects of direct-acting sympathomimetics like phenylephrine, but to a lesser extent. There is a controversy as to the concurrent use of MAO inhibitors in patients scheduled for ECT. For a time it was thought that these medications should be discontinued several weeks prior to the therapy,⁴⁵ but clinical experience has shown that problems during ECT are rarely encountered.⁵¹ Many depressed patients need the medication up to and following the ECT. The use of meperidine is specifically contraindicated in patients who receive MAO inhibitors. Although the mechanism is not understood, in combination, the two agents interact to cause a hypermetabolic syndrome that can be fatal. Fluoxetine blocks the neuronal uptake of serotonin but has not been shown to have adverse interaction with anesthetic agents or with ECT. Lithium is used to treat manic-depressive illness as well as recurrent depression. It acts by interrupting action of the sodium–potassium pump at the cell membrane. This, in turn, alters the transmembrane potential and interferes with the production of cyclic adenosine monophosphate. Elevated lithium levels can prolong the time until awakening from general anesthesia; they can produce ECG changes and prolong the action of some neuromuscular blocking agents.^{45,46,51}

The therapeutic effect produced by ECT is caused by the grand mal seizure, not by the electrical stimulus.^{52,53} The smallest electrical stimulus that will evoke the seizure is used. This is characteristically a short, square-pulse wave. It is effective at producing the seizure while minimizing the side-effects of memory loss and confusion.^{45,54} The duration of the seizure is also of clinical importance. Seizures lasting less than 30 seconds are often not as therapeutic. Electrical stimulation usually results in production of a grand mal seizure lasting up to several minutes and consisting of a short, 10–15-second tonic phase followed by a more prolonged clonic phase, which lasts 30–60 seconds. The cumulative seizure duration for effective therapy is thought to be 210–1000 seconds.⁵⁵ As a result, most patients receive 10–20 treatments over several weeks.

The seizure itself causes physiologic changes (Table 51-4). The initial stimulation produces a transient period of increased vagal tone. Bradycardia and some degree of hypotension are measured. This is followed by a period of increased sympathetic output, which corresponds to the clonic phase of the seizure. The patient becomes tachycardic and hypertensive. This phase can be a major physiologic stress, resulting in myocardial ischemia or infarction. To anticipate and prevent these stresses, a number of treatment regimens have been suggested. These include the use of beta-blockers, opioids, and short-acting vasodilators. The agents need to be tailored to the situation since pronounced bradycardia and asystole have occasionally been reported following their use.⁵⁶

| Cardiovascular Effects | |
|------------------------|---|
| Initial Phase | Bradycardia Hypotension |
| Later Phase | Tachycardia Dysrhythmias Hypertension Increased systemic and myocardial oxygen consumption |
| Cerebral Effects | |
| | Increased cerebral blood flow Elevated intracranial pressure Increased oxygen consumption |
| Other Effects | |
| | Elevated intraocular pressure Elevated intragastric pressure |

Table 51-4. PHYSIOLOGIC EFFECTS OF ELECTROCONVULSIVE THERAPY

Anesthetic Considerations

As always, a history and physical examination are performed on all patients. Any interval change is documented since different personnel may be involved in the care of the patient over several weeks of treatment. A review of the record from prior ECT treatments is particularly helpful to note the doses used and the responses to the agents. Patients with pre-existing cardiac or cardiovascular disease, including recent myocardial infarction, congestive heart failure, valvular heart disease, or thoracic aneurysm, require additional planning and monitoring. The benefits of successful treatment have to be weighed against the risks of the acute physiologic changes. For particularly ill patients, invasive cardiovascular monitoring may be indicated, as well as continued close monitoring throughout the recovery period.^{52,57} ECT should rarely be performed on patients with intracranial mass lesions because of the risk of elevated ICP and possible brain herniation. In patients with recent cerebrovascular accidents, ECT should be performed only after resolution of the acute insult has been achieved. This usually entails a waiting period of approximately 3 months.^{45,52} Patients with retinal detachment are at increased risk because of the concomitant rise in intraocular pressure. Other relative contraindications to ECT include pregnancy, presence of long bone fractures, thrombophlebitis, and acute or severe pulmonary disease.^{45,46,52} If a pregnant patient is treated, close monitoring of the fetus should be performed. Esophageal reflux and hiatal hernia are common findings in patients receiving ECT.^{45,52} Pretreatment with sodium citrate, histamine

antagonists, or metoclopramide may be indicated.

The anesthetic focus for ECT includes amnesia, airway management, prevention of bodily injury from the seizure, control of hemodynamic changes, and a smooth, rapid emergence.^{45,46,52} Preoxygenation is routinely administered before each treatment. Barbiturates are most commonly employed (methohexital 0.5–1 mg · kg⁻¹ or thiopental 1.5–3 mg · kg⁻¹). Methohexital causes a lower incidence of dysrhythmias when compared with other induction agents.⁵⁸ Etomidate is associated with seizures of longer duration. Propofol is effective for ECT, and its effect on outcome is similar to that of barbiturate use.^{59,60} Several investigators have noted that it tends to result in seizures of shorter duration, however. Muscle relaxants are needed to prevent injury to the patient during the grand mal seizure. Succinylcholine is most commonly used because of its rapid onset and short duration. Doses range from 0.5–1.0 mg · kg⁻¹.

ANESTHESIA FOR DENTAL SURGERY

Most dental procedures are performed in the office with no sedation and only local anesthesia injected at the site. Anesthesia may be required during more complicated or prolonged cases and when patients are uncooperative, phobic, or mentally challenged.

Providing anesthesia for mentally challenged and pediatric patients can present unique difficulties. Mentally challenged children can have a number of associated problems. Cardiac disease, including conduction abnormalities and structural defects, are associated with trisomy 21. Macroglossia, hypoplastic maxilla, palatal abnormalities, or mandibular protrusion are airway anomalies often seen in these patients.⁶¹ If the patient is in the head-up position in the dental chair, vasodilating and myocardial depressant effects of anesthetics can be pronounced, especially in patients with cardiovascular diseases. Patients with neuromuscular diseases may have a history of aspiration and episodes of chronic recurrent pneumonitis that must be addressed before therapy.

When providing dental anesthesia, standard monitoring devices should be employed. Availability of temperature monitoring is important for children who may be susceptible to malignant hyperthermia. Both the anesthesiologist and the dentist should assure that the airway is protected. Blood, saliva, and dental debris will enter the trachea if precautions are not taken. Airway obstruction is always a concern if throat packs are used to prevent the swallowing of blood.

The range of anesthetic techniques depends on the condition of the patient. Different strategies have been suggested to facilitate induction and maintenance.^{62,63,64} and ⁶⁵ For the mentally challenged patient, or children, ketamine is commonly recommended for use as a primary anesthetic agent or to facilitate induction. It has the advantage of administration through oral, intramuscular, or intravenous routes. In addition, preservation of laryngeal and oropharyngeal reflexes makes it well suited for dental surgery. If intravenous access is difficult to achieve prior to induction in uncooperative patients, an im dose of ketamine, e.g., 2 mg · kg⁻¹, can provide a sufficient depth of anesthesia for iv placement within a few minutes.⁶³ In more cooperative, anxious patients, oral ketamine (0.5–8 mg · kg⁻¹) premedication smooths induction. Oral midazolam is also popular. A dose of 0.5 mg · kg⁻¹ is dissolved in a small amount of liquid. Oral premedication, which obtunds the patient prior to needle sticks and masks, causes less anxiety for the patient and the parent.

Ketamine stimulates the sympathetic nervous system and acts to increase the heart rate and blood pressure. It also causes additional salivation. Glycopyrrolate, scopolamine, and atropine are often used. If iv access is available, barbiturates (methohexital, thiopental, and thiamylal) and propofol are well suited for induction.⁶⁵ Anesthesia can be maintained with intravenous infusions or inhalation agents. The use of inhalational agents requires that scavenging systems be in place so that waste gases do not contaminate the office.⁶⁶ Concerns about the possibility of triggering malignant hyperthermia need to be addressed and dantrolene must be immediately available. A continuous remifentanyl or alfentanil infusion can be a useful iv technique for oral restorations in children. In conjunction with amnestic agents, it provides stable maintenance and permits a more rapid emergence. A disadvantage is that postoperative nausea and vomiting can be a problem and keep the patient in the facility for a long period of time.⁶⁴ After induction, nasal–tracheal intubations are most commonly used for dental procedures. The dentist or oral surgeon will have easier access for the work to be performed. Because of bleeding and the use of oropharyngeal packing, patients need close observation during emergence and recovery. Emergence excitation, shivering, residual sedation, pain, episodes of nausea, and respiratory obstruction need to be addressed as the patient returns to his or her baseline of mental functioning and is readied for discharge home.

TRANSPORT OF PATIENTS

Patients who receive anesthesia or sedation within the hospital but at sites removed from the operating room often require transport to the PACU after the procedure is completed. This transport entails moving a sedated or recovering patient significant distances, often by way of elevators. The ASA standards state that these patients should be accompanied by a member of the anesthesia team and that evaluation, monitoring, treatment, and support appropriate to the patient's medical condition be maintained.⁸ Vigilance is especially important because hypoxemia following the use of sedation or general anesthesia is particularly dangerous with the additional distractions associated with patient transport.^{67,68} and ⁶⁹ While in transit, the lighting is less intense and the visual recognition of hypoxemia becomes more difficult. Supplemental oxygen is usually indicated for both children and adults.^{70,71} Monitoring, in addition to auditory and tactile awareness, should include a noninvasive blood pressure device, ECG, and pulse oximetry. For critically ill patients who are transported to ICUs, more sophisticated monitors that permit continuous displays of vital signs may be required. Small, lightweight monitors have been designed specifically for patient transport. Many are equipped with modules such that the transducers used at the remote location can plug directly into their bases.

When critically ill patients are transported within the hospital, the personnel need to have additional supplies available. These include emergency medications, vasopressor agents, drugs for resuscitation, and, at times, a portable defibrillator. Patients who need ventilatory support should be transported with a self-inflating bag and the equipment needed to maintain an airway and reintubate the trachea should the endotracheal tube become dislodged. Oxygen-powered portable ventilators are available should the patient be difficult to ventilate manually. The stretcher needs to be equipped with a pole that can hold infusion pumps, transducers, and display screens. Tanks must contain an adequate supply of oxygen. Battery power and access to wall power should be assessed before transport is begun. The battery-powered supplies and quantity of oxygen must exceed the anticipated need in case unplanned delays occur during the transport back to the ICU.

OFFICE-BASED ANESTHESIA

Office-based anesthesia is an old endeavor that has regained popularity. Anesthetics that were once administered exclusively in the hospital or ambulatory surgery center are again being routinely provided directly within a surgeon's office. Medical advances have decreased the morbidity and mortality. Minimally invasive surgical techniques and short-acting agents now allow invasive procedures to be performed at sites far removed from the hospital.

Twenty-eight million people undergo a surgical procedure of some type each year.⁷² Most of them require some form of concurrent anesthesia. All estimates indicate that the number of cases performed annually will increase as the U.S. population ages. For example, the number of patients over the age of 65 who will undergo noncardiac surgery is predicted to double from 7 to 14 million during the next three decades.⁷³ The total number of surgical procedures performed at that time will also increase from 28 to just under 40 million cases annually.

As this demand for surgical procedures has increased, a trend away from conventional sites of care has emerged.⁷⁴ The number of elective surgical procedures performed in hospital operating rooms has markedly declined. Initially, the move was from operating rooms to other sites within the hospital and to freestanding surgical centers. Now, a greater number of cases are performed directly within the surgeon's office.⁷⁵ This rate of rise has been dramatic. In the early 1980s, 80% of surgical procedures were performed in operating rooms for hospital inpatients, 18% for outpatients, and just 2% in freestanding clinics and offices. By 1994, approximately 35% of operations were performed for hospital inpatients and 57% for hospital outpatients, i.e., those presenting to freestanding clinics and outpatient surgery centers. The number of elective procedures performed directly within the physician's office had climbed to 8% (Fig. 51-4). This trend should continue. Estimates indicate that 14–20% of all elective surgery will be performed in the surgeon's office by the year 2001.^{74,75} The total volume of surgical procedures will continue to increase following changes in the marketplace: an older, sicker population and an increased demand for services.

Figure 51-4. Location of anesthesia procedures. (Reprinted with permission from ASA Newsletter 60:11, 1996.)

Operations performed in the office tend to be less invasive than those in the hospital operating room, and they do not require prolonged recovery. Thus, patients often infer that the procedure will be flawless, and that no delays or complications can arise. Consequently, even minor discomforts and inconveniences can result in exaggerated patient complaints. Patients need to be specifically prepared for an operation in an office. They have to understand that anesthetics are potent medicines and that side-effects do, indeed, occur. Since it is impossible to consistently perform flawless work, it is mandatory that all of the care providers plan ahead to anticipate complications and problems. What, specifically, will occur if the escort does not arrive on time? Or what if the patient is nauseated when it's time for the office to close? How will the practitioners maintain identical standards of patient care in an office, given that most standards were formulated with a hospital operating room in mind? Unusual outcomes are always just around the corner. The criteria for preoperative screening, intraoperative monitoring, oral intake restrictions, discharge criteria, and the need for an escort must be met for every patient, regardless of the planned anesthetic.

More invasive procedures are being performed in offices on a daily basis. This move is led by the plastic surgeons who offer cosmetic procedures to cash-paying patients, in which case prior approval for payment from the insurance company need not be sought. Other cases that are also leaving the hospital and surgical center at a rapid rate include ophthalmologic procedures and those involving assisted fertilization.^{74,75} and ⁷⁶

Although economic factors cannot be ignored, medical advances are the most significant factors allowing a shift to performing surgery in less intensive settings. Examples of developments include new minimally invasive technology (e.g., laparoscopic and arthroscopic),^{79,80} and ⁸¹ better trained anesthesia providers, improved monitoring devices, short-acting anesthetics, and improved medications for postoperative pain and nausea.^{72,74,75,77,78}

Progress in Anesthetic Devices and Monitors

New devices permit improved monitoring and anesthetic care of patients in an office setting. Pulse oximetry noninvasively measures oxygenation and the heart rate.^{82,83} and ⁸⁴ It is relatively inexpensive and allows for continuous monitoring. The laryngeal mask airway (LMA) provides a less invasive method than tracheal intubation for airway management.^{85,86} Its use has increased over the past few years, in large part because it eliminates the need for laryngoscopy and tracheal intubation. A shortcoming with the LMA is that it cannot reliably protect against the risk of aspiration.⁸⁶ Therefore, it is not commonly used in obese patients, patients with pulmonary disease, pregnant patients, or those with a history of symptomatic hiatal hernia. With appropriate patient selection and a well-placed device, positive-pressure ventilation can be used for some surgical procedures. Most practitioners agree that LMAs are most appropriate in spontaneously breathing patients, or with controlled ventilation when the inflating pressures are under 20 cm H₂O. The device has also proved useful when unexpectedly difficult airways are discovered after induction.

Financial incentives for health care providers have completely changed under managed care organization. Under contracts with capped reimbursements, physicians must perform procedures economically in order to remain viable. Often this translates into performing cases in offices, far removed from hospitals and freestanding surgical centers. The availability of sophisticated computer programs and data entry systems has allowed third-party payers to look more closely at surgical outcomes in an attempt to justify the moneys paid to providers. HMO Blue in New Jersey, for example, offers a 15% bonus on certain procedures if they are performed directly within offices instead of hospitals or surgical centers.⁷⁶ The financial pressures that surround contemporary health care mandate this shift. The overall emphasis on cost-effectiveness with lower total reimbursements speeds the change.

Many surgeons prefer to work in their own offices because of the lower cost, increased convenience, and improved profit margin. Few would argue with the observation that the physician is better able to perform a simple procedure at minimal cost in his own office. This is particularly true for gynecologic, ophthalmologic, dental, plastic, and urologic procedures. Yet, in the past few years, other more invasive procedures have moved to the offices, including appendectomy, laparoscopic herniorrhaphy, and laparoscopic cholecystectomy. Specific cost comparisons are difficult to perform. The developing science of cost analysis in medicine is able to differentiate direct, indirect, and intangible costs. Attempts are being made to distinguish cost savings from cost shifting. Several studies have compared the cost savings realized in performing cases in offices as opposed to hospitals and ASCs. One in particular compared the "office costs" with "hospital charges" for identical surgical procedures. For inguinal herniorrhaphy performed conventionally, the comparison is roughly \$900 versus \$2200. When the same procedure is performed laparoscopically, the comparisons are \$1500 to \$5500. The cost of an "in-office" laparoscopic cholecystectomy is \$1900 versus the hospital charges of \$6400. The potential savings to the patient and insurer, as well as increased profits for the surgeon, are large.⁸⁷

Preparation for In-Office Anesthetic Care

Safe care for a patient in an office requires planning. The anesthesiologist is in the best position to understand nuances of office set-up, equipment requirements, and criteria for satisfactory recovery. The anesthesiologist can assume the role of perioperative manager. Anesthesia spans a continuum from minimally to maximally invasive control of consciousness and life-sustaining reflexes (see Fig. 51-1). Appropriate care in some settings allows the patient to breathe room air with no airway manipulation and no depression of reflexes; other cases require major nerve block or general anesthesia with endotracheal intubation. With this range of intervention in mind, several basic issues must be addressed before any anesthetic care is rendered.

Foremost is a clear plan should a medical disaster occur. The surgeon and anesthesiologist must have a plan that allows for an efficient interface between the office and a nearby emergency room. Few situations could cause more harm to the patient, or reflect more poorly on the office, than to have a patient develop a serious complication for which the practitioners have no recourse but to dial 911 and hope for a rapid response. Specific issues of how the patient will be carried from the site of care to the ambulance must be assessed. Will the stretcher fit into the elevator, and can it be negotiated around corners in the hallway? The response time for the local emergency medical service and ambulance should be determined, and the time for transport from the office to the emergency room clocked. Often these communications have political overtones, since work performed within an office reflects the decrease in hospital use. The hospital administration may not want its facility to serve as a safety net for procedures performed outside its walls. Discussions are best focused on the advantages to the particular hospital of providing medical care in an emergency situation. Although the potential for political problems in contract negotiations is daunting, this safety net should be established before the practitioner offers care.⁸⁸

The office must be properly equipped. Even if the plan of intervention calls only for mild sedation for podiatric services under local blockade, certain devices must be present and readily available.^{88,89,90,91} and ⁹² These include a reliable source of oxygen, motor-driven suction, capabilities for providing positive-pressure ventilation, and emergency airway management equipment—oral and nasal airways, a laryngoscope, and endotracheal tubes. Basic medications include sedatives, hypnotics, and opioids, as well as medications required to initiate and continue cardiac life support. Portable defibrillators are now readily available and reasonably priced. These devices and medications will be life-saving while waiting for an emergency response from the community should a medical disaster occur. Essential monitoring equipment for the least invasive cases includes a blood pressure device, pulse oximetry, and an electrocardiograph. The facility should have a backup power supply should a power failure occur during a procedure.

Patient selection is clearly an important factor for surgery performed in the office. It is always tempting to care for additional patients—patients who almost, but not quite, meet the criteria. This mirrors the evolution in care provided in ambulatory surgery centers in the 1980s. Surgical practices that initially accepted only ASA I and II patients began to care for the occasional ASA III patient. This occurred gradually as the staff became more familiar with the routines. Few data are available to assess outcomes in individual offices. Practitioners and organizations are just now looking at the care delivered. Answers to basic questions concerning quality of care in the office, as opposed to the hospital or surgical center, will be forthcoming as data are gathered and analyzed. This information will eventually determine the most desirable and cost-efficient site. For the present, most providers do not offer office anesthesia to patients whose coexisting medical conditions are likely to cause problems. No one needs the personal stress (patient, physicians), medical liability, or scheduling disruptions that follow a delay or a bad outcome. Frequent types of patients who are poor candidates for office surgery are those who have had recent cardiovascular events, are obese, or suffer medical conditions that would interfere with a rapid recovery.

Preoperative Testing

The first step in any anesthetic is the preoperative assessment. Its goal is to reduce the morbidity of surgery. When the assessment is performed in a preoperative screening clinic by an anesthesiologist, as opposed to a surgeon, requests for medical consultations are reduced by 75%.^{92,93} Cancellations of procedures because of unresolved medical problems are reduced by 80%, and the cost of laboratory tests are reduced by 55%, or approximately \$110 per patient. The advantages arise from having the anesthesiologist obtain the history and make decisions for further evaluation of the particular patient. This contrasts with the older practice of ordering batteries of blood tests for multiphasic screening.^{92,93} The process seemed logical at the time because of the ease and relatively low cost of performing the tests. However, it is now known that routine screening tests are unnecessary and very costly. Most patients, unless they have significant comorbidity, do not require any

laboratory tests prior to office surgery. A history and physical examination are the most efficient ways to determine if a patient has a disease that places them at increased risk for anesthesia.⁹⁴ Tests should be performed only if called for by the patient's medical condition.^{92,93,95}

Anesthesia in the Office

The gradations in anesthesia care from conscious sedation to general anesthesia have been described above. The definitions are fluid because the depth of sedation and anesthesia changes over time depending on the degree of stimulation. Loosely defined, "conscious" sedation is a state of medically induced and controlled depression of consciousness in which the patient is able to maintain a patent airway and make appropriate responses to verbal commands. "Deep" sedation begins when the patient may not be able to maintain the airway independently and is unable to respond appropriately to physical stimulation or a verbal command.⁹¹ Any drug used for conscious sedation can also cause deep sedation when given in excess or the level of stimulation falls. This change can, in turn, lead to hypoventilation, hypoxia, and cardiopulmonary collapse.

Routine Workloads

Unlike the work performed in hospitals and surgical centers, many of the procedures done in offices are highly routine. It is quite common for the same kind of anesthesia for the same surgical intervention to be performed over and over again. This is particularly true at office sites staffed by a few surgeons who work in one field only. For example, in an ophthalmology practice routine cataract extractions are performed sequentially. There is little or no variation in the practice from case to case. All health care professionals who work in the office know the routines of each of the other practitioners. The goal is to work quickly, efficiently, and safely. All efforts are focused on getting the patient in and out with no complication. If the nursing personnel who clean the instruments are delayed, the physicians may help clean and prepare the room. The offices encourage a team approach. Practitioners who work exclusively with ophthalmologists providing monitored anesthesia care (MAC) for eye operations develop techniques to maximize efficiency, cost savings, and patient safety. These attitudes permit the efficient use of newer medications that would otherwise be too expensive to allow for profitability.

The following, for example, is a cost-effective technique to provide sedation for cataract patients. A 1-mg vial of remifentanyl is diluted in a 100-ml bag of saline. Ten different 10-ml syringes of the diluted remifentanyl are drawn up at a concentration of $10 \mu\text{g} \cdot \text{ml}^{-1}$. Each cataract patient has a dose calculated at 0.5, 0.75, or $1.0 \mu\text{g} \cdot \text{kg}^{-1}$: the very elderly and frail receive $0.5 \mu\text{g} \cdot \text{kg}^{-1}$, the typical patient receives $0.75 \mu\text{g} \cdot \text{kg}^{-1}$, and the younger, healthier patient receives a full $1.0 \mu\text{g} \cdot \text{kg}^{-1}$. Nasal cannula are applied and the flow is set to $10 \text{ l O}_2 \cdot \text{min}^{-1}$ for 1 minute prior to a retrobulbar block. The injection of remifentanyl is given over 15 seconds; then 90 seconds elapse before the surgeon performs the block. Patients have excellent anesthesia and amnesia for the block.⁹⁶

The first two patients for the day are seen in a recovery area adjacent to the operating room, and the first two remifentanyl injections and eye blocks are performed sequentially. When the first patient is taken to the recovery area at the conclusion of the first operation, the remifentanyl injection and eye block are then administered to the third patient. This sequence continues throughout the workday. Occasionally, there is a transient decrease in the oxygen saturation, but it is rare. Within a few moments, the patient responds to verbal commands and takes deep breaths. Since only one vial is used for 10 cases each day, the cost for the agent is very low. Since patients recover from the effects of remifentanyl before the surgery is completed, they are discharged home almost immediately after the procedure.⁹⁶

Costs of Anesthesia Equipment and Supplies

It is possible to deliver a quality anesthetic to a patient in an office setting at a reasonable cost. There is a large range of fees charged in the office, and a savvy practitioner with an eye toward the bottom line can safely economize on many costs.^{96,97} The following supplies are typically consumed for an office anesthetic: alcohol wipes, cloth tape, intravenous catheter, tubing, stopcock, a bag of crystalloid, midazolam, propofol, and a short-acting opioid (remifentanyl or alfentanil). Rough costs when dealing with a discount supplier can be less than \$50. If the oxygen and/or other gases for the office must be provided, these costs must be included. If the patient is at high risk for postoperative nausea (previous experience, history of motion sickness, or in the higher-risk phase of the menstrual cycle), a preemptive antiemetic may be given, further increasing costs.

In an office limited exclusively to performing cosmetic procedures, the estimated costs can be even further reduced.^{97,98} Propofol and ketamine mixtures can be effectively infused and bolused during cosmetic surgery. The procedures performed may reflect the whole spectrum of cosmetic surgery, including face and brow lifts, blepharoplasty, rhinoplasty, otoplasty, facial resurfacing, fat transfer, breast augmentation, abdominoplasty, and liposuction. Despite the variety of surgical procedures, the anesthesia can be limited to the administration of midazolam, propofol, ketamine, and glycopyrrolate ... exclusively.^{98,99} and ¹⁰⁰ Patients are sedated but awake enough to breathe room air spontaneously. No supplemental oxygen is provided. The approach is to infuse propofol continuously and then bolus ketamine to produce a dissociative state immediately prior to the injection of local anesthetic by the surgeon. The propofol/ketamine technique is a form of monitored anesthesia care (MAC) that is most properly called dissociative anesthesia, not total intravenous anesthesia (TIVA).

As the demand for office anesthesia grows, ketamine is enjoying a resurgence.^{99,100} Ketamine differs from opioids in that it permits spontaneous ventilation. The agent enhances laryngeal reflexes (as opposed to the depression seen with opioids), making aspiration unlikely. It is not associated with postoperative nausea and vomiting. Ketamine hallucinations, as administered by the above protocol, are rarely seen.^{99,100} A possible reason is that the ketamine is given only after midazolam is administered, and all doses of ketamine are nested within the propofol infusion. Patients are awake, with a mild euphoria. In a series of 1200 cases, only two instances of intraoperative emesis occurred, neither with aspiration. SpO_2 levels remained above 90% throughout all cases.^{99,100} Patients emerged without harm, and there were no hospital admissions for nausea or pain. The majority of patients were discharged by the end of the first postoperative hour. Although some patients underwent 9-hour procedures and required 2 hours of observation before discharge, none required supplemental oxygen or support of the airway to maintain $\text{SpO}_2 > 95\%$.⁹⁹ In a 5-year review of 1264 cases at this site, the costs of the supplies and medications were approximately \$40 per hour of MAC.⁹⁷ The anesthetic technique provides an appropriate depth of sedation, yet it allows the patient to breathe air spontaneously. The monitoring equipment in the office is compact, portable, and battery-operated. Resuscitative equipment and medication are stored in the surgeon's office and maintained by the staff.

Regulations for Office-Based Procedures

There is a large body of information regarding ambulatory surgery centers; however, not very much of this can be directly applied to patient care in an office. The problem is the inherent differences between the sites. Surgery centers have several different surgeons performing disparate operations. The center must be accredited by a variety of agencies, not the least of which is the state that issues a Certificate of Need for the construction and use of the facility. Because of the strict regulations concerning usage, all centers are relatively similar in their organization and physical structure.¹⁰¹ Offices, on the other hand, run the gamut. A single site of anesthesia care within an office is currently unregulated in 47 states—all but California, Florida, and New Jersey. The range of facilities is quite broad; some are well equipped suites that mirror the operating rooms in hospitals. Others are small areas off to the side of an examining room. More importantly, the scope of the practice in an office is usually quite limited: one or two practitioners doing the same kinds of procedures repetitively. Consequently, not much of the data collected by those who work in the surgery centers can be extrapolated to the office.

There are, of course, some similarities between centers and offices; several of the basic concerns and issues overlap. Both require that a patient arrive at a site of surgical care, receive treatment, then leave to return home. Both have benefited from the advances in the fields of surgery and anesthesia. And both provide a continuum of anesthesia care to different patients. Newer induction agents, inhalational anesthetics, muscle relaxants, and opioids have allowed for specific tailoring of the anesthetic to the desired results.^{72,77} The medications allow for a more rapid onset and offset of action, such that less time is required for clearance of the drug and dissipation of the effect.

The Scope of Care Provided in the Office MAC

Monitored anesthesia care (MAC) has evolved over the past several years as new drugs have become available, older drugs are used in a more tailored fashion, and patient acceptance has increased.¹⁰² A common practice is to combine a regional or local block with the intravenous infusion of medications to alleviate anxiety and prevent pain from the needle insertion. The combination of local anesthetics with MAC is particularly well suited for the office; many surgical procedures are performed this way. To some, the term MAC implies that the degree of vigilance is lower because fewer changes are produced by the medications than during a general anesthetic. This is not true. A patient can quickly move from a minimally depressed state of consciousness to deep sedation and general anesthesia when significant doses of depressant drugs have been administered and/or the degree of surgical stimulation is decreased. All patients who receive MAC should be monitored by a designated individual who is primarily responsible for the administration of the sedative and analgesic drugs, as well as monitoring of the patient's vital signs. The same standards of anesthetic care should be provided during MAC as are required for general or regional anesthesia.

A wide range of agents has been recommended for MAC, most with iv administration. Nitrous oxide has been used in the past, and many argue that low-dose sevoflurane may provide similar advantages in this setting. An activated charcoal filter is available to scavenge inhalation agents and minimize contamination of the office. Useful iv agents include benzodiazepines, ketamine, barbiturates, propofol, and opioids. Midazolam is particularly well suited for the office because it has an

amnesic effect, and a short duration of action with a half-life of approximately 100 minutes. It is associated with less pain on injection than is diazepam, it is easy to administer, and its effects can be reversed with flumazenil $0.1 \text{ mg} \cdot \text{kg}^{-1}$. Sedation causes mild depression of the hypoxic ventilatory response, and severe respiratory depression can occur if the agent is combined with opioids. When contrasted with comparable doses of diazepam, midazolam provides more profound amnesia, sedation, and anxiolysis.^{102,103}

Fentanyl is a synthetic opioid that is approximately 100 times stronger than morphine.¹⁰⁴ It has a rapid onset and a duration of action of only 30–45 minutes. This combination makes it ideal for short or painful procedures. Unfortunately, its respiratory depressant effect is longer than its analgesic effect. Doses of $0.5\text{--}1 \mu\text{g} \cdot \text{kg}^{-1}$ are slowly titrated to effect. Respiratory depression is more pronounced when the agent is combined with a sedative. For procedures performed under regional anesthesia, a stable level of sedation can be attained by the use of a small dose of midazolam (1–2 mg) followed by an infusion of propofol $25\text{--}100 \mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. This can generally be supplemented with boluses of fentanyl (25 μg) or ketamine (5 mg) as needed. Careful titration of the agents is key to avoid respiratory depression or loss of airway reflexes.¹⁰²

Local Anesthetics and Regional Techniques

When applicable, the use of local or regional anesthesia in an office is almost always preferable to the use of a general anesthetic.^{105,106} Issues of airway trauma, bronchospasm, aspiration, prolonged sedation, paralysis, malignant hyperthermia, nausea, and vomiting are either bypassed or greatly reduced. Regional anesthesia offers fewer chances for drug interactions, cardiac or respiratory depression, or airway problems. It results in shorter time intervals to the intake of fluids, the ability to void, and to ambulate. At the end of the case, regional techniques allow for a reduced intensity of postoperative care, fewer side-effects, and, in some circumstances, a decreased recovery time. Often, they also provide excellent short-term pain control.

Regional anesthesia is the standard of care in an office devoted exclusively to patients for orthopedic procedures. In this setting, the techniques are particularly appropriate for the facility, surgeon, and patients. Those who provide the blocks are secure that the techniques will be successful a high percentage of the time. Performing a regional anesthetic can be a stress for the provider. A less than perfect block can be a public embarrassment that is evident to the surgeon, patient, and nurses. Because of this potential, it is important that the anesthesiologist maximize chances for success. It must be remembered that blocks take time to perform properly. Regional anesthesia is almost always most successful when it is the norm for the facility. Those involved with the care of the patient know that the time spent at the beginning of the case avoids delays in discharge that can follow general anesthesia. When all works well, regional techniques can allow the patient to bypass the first phase of recovery entirely, thereby decreasing the time to discharge. This is particularly evident when using intravenous regional, popliteal, brachial plexus, and retrobulbar blocks.¹⁰⁶ Central neuraxial blocks, such as spinal or epidural, tend to be long-acting and are generally not useful for rapid-turnover office procedures.

Skillfully managed regional techniques are valuable because they allow more patients to be discharged home uneventfully. Data collected from surgery centers indicate that persistent nausea, vomiting, or pain caused approximately 40% of the unanticipated hospital admissions. The rate following general anesthesia was 2.9%; after regional, the rate was less than half that number, at 1.2%.¹⁰⁷ Although the local anesthetics have a good record of clinical safety, 5% lidocaine in a hyperbaric dextrose solution has been implicated as causing a painful radicular sensation lasting for one or two days. The phenomenon has been labeled *transient radicular irritations* (TRI).^{108,109} TRI has not been associated with intrathecal bupivacaine. Surgical positioning, especially use of dorsolithotomy, is thought to contribute to the radicular pain. It is not clear why these complaints are appearing now after decades of intrathecal lidocaine use.

Lower extremity procedures can be easily performed with spinal or epidural blockade. In general, a spinal is easier to perform, has a more definite endpoint, and provides a faster onset with a denser block. Additionally, a smaller dose of anesthetic is used, and patients report fewer backaches (11% vs. 30%).^{106,110} The problem with the routine use of spinal blockade is the possibility for post-dural puncture headache, especially in younger patients. The risk can be lowered with the use of small-gauge needles (*e.g.*, 25 gauge) with pencil-point tips or attention to the orientation of the bevel on insertion.

Cost Savings with Regional Techniques. Data from nonhospital surgery centers indicate that regional anesthesia may offer savings when compared to general anesthesia.^{105,106} and ¹⁰⁷ Appropriately selected and managed regional anesthesia is usually associated with a reduced intraoperative time, a decreased need for intense postoperative care, fewer side-effects, shorter recovery times, and diminished postoperative pain. The use of regional techniques allows for persistence of postoperative analgesia and diminished needs for narcotics.¹¹¹

Are there potential disadvantages to the use of regional techniques? Yes. Some of them include systemic toxicity from the local anesthetic, PDPH, allergy to the anesthetic, pneumothorax, low back pain, nerve injury, and hematoma formation. However, the techniques are region-specific and economical. General anesthesia must always be available as a backup to a regional technique.

General Anesthesia

Propofol is widely used for induction and maintenance of general anesthesia in the office setting.^{112,113} Before propofol's introduction, thiopental was the drug of choice for induction. Thiopental, noted for its ease of administration and rapid onset, has a reasonably short period of hypnotic activity, but accumulates with repeated doses and is not appropriate for continuous infusions. It is associated with prolonged drowsiness and an increased incidence of nausea and vomiting upon emergence. Propofol, on the other hand, produces unconsciousness for a very short duration, does not accumulate, and is suitable for continuous infusions. Experience has shown that at infusion rates of $2.5\text{--}5.5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{hr}^{-1}$, patients undergoing leg surgery under spinal anesthesia were sedated/asleep but arousable with verbal commands.¹⁰² These patients were completely awake a few minutes after the propofol infusion was stopped. A low-dose infusion of propofol allows patient comfort for the performance of a nerve block or regional anesthetic, and the infusion allows sedation throughout the procedure. Propofol sedation will control restlessness and anxiety during noninvasive procedures such as MRI and radiation therapy. Its antiemetic properties and short recovery times are additional benefits. Because it is supplied in a lipid vehicle that supports microbial growth, the contents of an ampule must be used within 6 hours of opening, and syringes or infusions of propofol must be for single-patient use only.

Nitrous oxide is used in hospitals and surgery centers to supplement more potent volatile agents. Its use in office settings is less common because of the expense of delivering tanks to the facility, its low potency, and its tendency to cause nausea and vomiting.¹¹⁴ Isoflurane is the most commonly used inhalation agent in adults,⁷² but it is relatively long-acting compared to the newer inhaled anesthetics. Desflurane, an anesthetic with low blood solubility and short action, has not gained general acceptance because it is expensive, it requires a special vaporizer for administration, and it is pungent. The odor makes it difficult to use for inhalational inductions.

Sevoflurane, a newer fluorinated anesthetic with minimal apparent toxicity,⁷² is particularly well suited to office use because of its pleasant odor and rapid action. A theoretical concern is the development of vinyl ether, or compound A, when the agent is in prolonged contact with soda lime. Compound A has been implicated as causing renal tubular necrosis in laboratory animals given large doses. The potential for harm has generated dozens of papers and talks, yet no damage has been reported in patients despite extensive use of the agent in over 45 countries. The metabolism of sevoflurane results in measurable blood levels of free fluoride. Isosthenuric renal failure is another theoretical concern that has never been reported. Because sevoflurane has a pleasant odor and is easily inhaled, it is an excellent alternative to halothane for both children and adults. Patients rapidly emerge when the agent is discontinued. Effective methods for scavenging this agent in an office setting are being developed and refined.

Muscle relaxants are essential for certain types of operations. They abolish motor reflexes, ease the control of ventilation, and provide for immediate airway management. Both depolarizing drugs (succinylcholine) and nondepolarizing relaxants (mivacurium, vecuronium, atracurium, cisatracurium) are used in offices. Succinylcholine reliably and reproducibly causes complete muscle relaxation, but complications from routine use include myalgias and transient increases in intragastric and intraocular pressures. The most useful nondepolarizing relaxants are those with a short, predictable duration of action. Mivacurium has a favorable overall profile and is rapidly hydrolyzed by plasma cholinesterase. A typical intubating dose will provide onset within 2–3 minutes and 20 minutes of relaxation. Histamine release mandates a slow injection of the drug. For longer procedures, vecuronium and cisatracurium are logical choices, although they are more expensive than traditional nondepolarizing relaxants such as pancuronium. Succinylcholine, as well as all of the volatile inhalational agents, can trigger malignant hyperthermia (MH). Office-based physicians should have dantrolene immediately available. Should MH develop, treatment with dantrolene should be initiated before the patient is transported to an emergency room.

Potent, synthetic opioids have been developed that are many times stronger than morphine. These agents can be used to blunt the sympathetic response to laryngoscopy and intubation, and they can provide intense analgesia in the perioperative period. Opioids must be titrated because of their ability to cause profound hypoventilation and skeletal muscle rigidity. They can be used as the exclusive supplement to local anesthetics; however, they do not reliably cause sedation unless given in doses that can cause respiratory depression.¹⁰² Alfentanil has a very low pK_a , which allows for more bioavailability at physiologic pH. The onset of action is rapid, and the duration is brief. Sufentanil is more lipid-soluble and tends to produce more depression of the sensorium than do the other synthetic opioids. Fentanyl has continued to be widely used. Doses of 50–100 μg iv have an onset time of 3–5 minutes and a duration of effect of 45–60 minutes. Even very small doses can cause respiratory depression when combined with a sedative. The latest synthetic opioid, remifentanil, is so short-acting that it has minimal application as an adjunct for general anesthesia. Patients have little postoperative analgesia. On the other hand, remifentanil can be effective when profound analgesia is required for a very brief

period, such as during injection of local anesthetic.

Postoperative Analgesia

A major criterion for the performance of a procedure in an office setting is the ability to control the postoperative pain. Severe pain is a common reason for delayed discharge and for unanticipated hospital admission after ambulatory surgery.^{78,115} A large study examined consecutive ambulatory surgical patients. Nerve blocks and nonsteroidal anti-inflammatory agents (NSAIDs) were not routinely used as a part of the technique. Most patients received either general anesthesia or MAC. The patients were assessed for pain in the PACU, ambulatory surgical unit, and 24 hours postoperatively. Younger male adults and patients with a higher body mass index (BMI) had a higher incidence of severe pain. Those patients undergoing orthopedic procedures on the shoulder experienced the greatest incidence of severe postoperative pain. The group with severe pain had a longer stay in the PACU and in the surgical facility than did those in the group without severe pain.⁷⁸

NSAIDs have become popular for perioperative analgesia. They avoid many of the side-effects caused by opioids, particularly respiratory depression. Ketorolac is a parenterally active NSAID that can be used as the sole analgesic supplement to local anesthetic, or as an adjunct to a propofol infusion. Use of iv ketorolac as compared to fentanyl is associated with a decreased incidence of nausea, vomiting, and pruritis. Ketorolac provides dense analgesia even following invasive procedures such as arthroscopy and laparoscopy. Ketorolac, like other NSAIDs, inhibits platelet function and, in large or repeated doses, has the potential to cause renal dysfunction or gastric bleeding.¹⁰²

Postoperative Nausea

Although data on office-based outcomes are not yet available, experience in freestanding surgery centers indicate that postoperative nausea and vomiting (PONV) accounts for the majority of unanticipated admissions to the hospital. The incidence of these complications is highest with fentanyl-based anesthetics. The incidence is lower when propofol is used in place of thiopental. Several agents are available to prevent or decrease the incidence of PONV. These include promethazine, atropine, and droperidol. Ondansetron and granisetron are very effective in controlling postoperative nausea, although they are relatively costly. The additional cost is, however, easily justified if it prevents an unplanned hospital admission.

Discharge Criteria

There is now a move toward "criteria-based" recovery standards. These criteria will eliminate any mandatory time patients must spend in a recovery area. An essential aspect of care in the office is the timing for discharge home. At discharge, the patient should be clinically stable, ready to ambulate, and able to tolerate oral intake. Discharge from the facility should be to the care of a responsible adult. A post-anesthetic discharge scoring system (PADSS) has been developed that is based on five criteria: vital signs, activity and mental status, pain and nausea, surgical bleeding, and intake and output. Each of the items is graded from 0 to 2 such that a summed score of 9 or 10 indicates fitness for discharge from the office (Table 51-5). A major advantage to the use of the PADSS, as opposed to conventional criteria, is that it replaces the subjective clinical impressions with objective indicators. It indicates fitness for discharge home.¹¹⁶

| Post-Anesthesia Discharge Scoring System (PADSS) | Clinical Discharge Criteria (CDC) |
|---|---|
| 1. Vital signs 2 = within 20% of preoperative value 1 = 20-40% of preoperative value 0 = >40% of preoperative value | 1. Stable vital signs 2. Patient is alert and oriented |
| 2. Activity and mental status 2 = oriented x3 AND has a steady gait 1 = oriented x3 OR has a steady gait 0 = neither | 3. Patient is free of nausea and/or vomiting 4. Steady of gait 5. Patient has no significant bleeding |
| 3. Pain, nausea, and/or vomiting 2 = minimal 1 = moderate, having required treatment 0 = severe, requiring treatment | |
| 4. Surgical bleeding 2 = minimal 1 = moderate 0 = severe | |
| 5. Intake and output 2 = has had per fluids AND has voided 1 = has had per fluids OR has voided 0 = neither | |

Comparisons of Outcomes

Few data on specific practices and outcomes exist for office-based anesthesia. The practitioners have been too scattered and the field too ill-defined for information to have been collected. The establishment of standards is desirable for the patient, payer, and the provider. If standards are agreed upon and met, a bad clinical outcome is more likely to be seen as a complication of care as opposed to malpractice. Several guidelines already exist for the provision of anesthesia in settings outside of the traditional operating room. They address the use of sedation by nonanesthesiologists and discuss the necessary skills, supplies, and monitors that must be available. Recommendations have been published by the American Society of Anesthesiologists (1996), American Dental Society, American College of Surgeons (1994), American Academy of Pediatrics (1992), Sedation Guidelines—Pediatric Dentistry (1993), and others.^{1,2,4,5} and ^{6,89}

If we examine these guidelines, we see a pattern. They match the level of care and sophistication of monitoring to the intensity of anesthesia intervention that is needed. This continuum ranges from conscious sedation through major nerve blockade to general anesthesia. Many states have introduced legislation to regulate the anesthesia care that is provided in an office. These laws aim to address wide variations in care that are found from site to site. Specific concerns include licensing issues, transfer agreements, medical record keeping, quality assurance and quality improvement, peer review of the medical practice, credentialing of practitioners, and documentation of outcomes.¹¹⁷ The focus is on certification of the facility, not the practitioners. Some office settings "may be operating in a manner which is injurious to the public health, welfare, and safety," even though the professionals delivering health care services in those settings are licensed and qualified.¹¹⁷ In California, the intent of the law was to create regulations that impact safety; it was not intended to require standards in excess of those requirements or to require physical modification of facilities unless the modifications or standards directly affect safety and are cost-effective.¹¹⁷ Undoubtedly, new laws affecting office-based surgery will continue to evolve.¹¹⁸

The office-based surgery arena is dynamic, evolving as the country adapts to a new model of medical care delivery. Radically different trends will emerge to enhance cost-effective and safe care of patients in new and different settings. The guidelines presented by the American College of Surgeons in 1994 and reflected by Florida state legislation may emerge as universal standards. They focus on quality of care as a primary goal and follow the model of classifying surgical procedures according to the intensity of anesthesia care required. In brief, all surgical procedures are stratified into three classes according to the intensity of anesthesia care that is required.^{89,119}

Class A office surgery permits topical or local agents or both, but no drug-induced alterations of consciousness other than minimal preoperative tranquilization of the patient. No assistance from any personnel other than the operator is required. Basic life support (BLS) certification is recommended but not mandatory. Required equipment and supplies include oxygen, a positive-pressure ventilation device, epinephrine, corticosteroids, antihistamines, and atropine.

Class B office surgery encompasses those cases in which perioperative medication and sedation are required. Examples include herniorrhaphy, hemorrhoidectomy, breast biopsy, and colonoscopy. A transfer agreement between the operating physician and a local hospital is mandatory if the physician does not have privileges to perform the same procedure in the hospital. The hospital must be within a "reasonable distance" from the office, although the number of miles is not specified. Anesthetic care is limited to local injection or peripheral nerve block, including intravenous regional anesthesia (Bier block). Intravenous or intramuscular sedation is permitted. Vital reflexes are to be monitored and maintained at all times during and immediately after the procedure. The surgeon must have at least one assistant and both must be certified in BLS. It is recommended that at least one have advanced cardiac life support (ACLS) certification. In some specific situations, additional assistance may be required. Equipment and supplies include a full and current "crash cart," a defibrillator, and resuscitative medications.

Class C office surgery permits the use of preoperative sedation and general anesthesia or major nerve block. The physician must have staff privileges to perform the same procedures as are performed in the office setting at a licensed hospital within reasonable proximity. The surgeon and at least one assistant must be certified in BLS. It is recommended that at least one member of the team be certified in ACLS as well. Emergency procedures to be performed in response to serious complications should be formulated, written, periodically reviewed, practiced, updated, and posted in conspicuous locations. Equipment, medication, and post-anesthesia recovery must be available, with qualified nursing personnel. The facility, in terms of general preparation, equipment and supplies, must be comparable to a freestanding ambulatory surgical center. Equipment for patient monitoring, an operating table capable of rotation to the Trendelenburg position, and proper record

keeping are also specifically mentioned.

Future Trends

Bolder use of the office setting is inevitable. Patient demand and obvious economic incentives will move more cases to this site. More invasive and prolonged procedures will be performed. Surgeons and anesthesia providers have already tested the limits by undertaking extensive and prolonged cosmetic procedures. A 1997 U.S. Supreme Court case, *Abbott v. Bradgon*,¹²⁰ concerned an HIV-positive patient who sued a dentist who refuses to treat her in the office, despite a lack of symptoms or signs of AIDS. The dentist was concerned about the appropriateness of care and insisted that the patient check into, and pay for, a hospital stay. The advantages of an office setting, as opposed to a hospital, were developed as a part of the arguments heard. Inherent to the case is the cost savings and convenience of care in a less intensive arena. This was tested as a right.

SUMMARY

Anesthesia provided at alternative sites is economical, safe, and popular. Proper attention must be paid to the physical site, the abilities of the provider, and the patient before any case is undertaken. Backup plans have to be in place to anticipate a misadventure. For the anesthetic itself, overall experiences indicate that the least amount of anesthetic that can be used is the best dose. Local and monitored anesthesia care are preferable to regional techniques. Regional techniques are preferable to general anesthesia. The number of anesthetics provided outside of conventional operating rooms is growing rapidly. More anesthesiologists are working in these settings. Advances in surgical techniques and the development of newer anesthetic agents have made the provision of care in an office both possible and practical. The cost savings of bypassing the hospitals and dedicated surgery centers are large. Operative care in the individual office is more convenient for the patient and economically advantageous for all involved. Patients will increasingly want the services a well-trained anesthesiologist who is adept at providing care at sites far removed from hospital operating rooms.

Transplantation of a variety of tissues is now routine in clinical practice. Bone, tendon, cartilage, and fascia readily provide a partially inert framework for the ingrowth of healthy native cells. Cornea, blood vessels, heart valves, and certain endocrine tissues such as parathyroid are also, to some extent, immunologically privileged and have been successfully transplanted. Bone marrow can be used to replace the entire hematopoietic and lymphopoietic systems. More recently, transplantation of vital organs with distinct vasculature, including the kidneys, liver, heart, and lungs, has achieved the status of preferred therapeutic option for end-stage visceral disease. Technical and biologic factors have thus far prevented widespread introduction of pancreas and small bowel transplantation, but the intensity of current research suggests that important advances will be forthcoming.

The role of anesthesiologists in transplantation may involve caring for organ donors, prospective recipients, or patients who have already received transplants but require further surgery. To do so, specialized knowledge is required in a multitude of disciplines as diverse as organ preservation, biomedical ethics, transplantation immunology, and the physiology of brain death.

ANESTHESIA CARE OF ORGAN DONORS

In the United States, most viscera for transplantation are derived from brain-dead organ donors through voluntary programs established by state and federal law. To supplement these programs, many states have also enacted "required request" legislation, obliging hospital personnel to ask the family of a brain-dead patient to grant permission for organ donation. Organs are distributed through a nationwide organ and transplantation network developed, under federal contract, by the United Network for Organ Sharing (UNOS). UNOS is also responsible for collecting data, reporting statistics, and educating the public about organ donation and transplantation.¹

Brain death is usually a consequence of catastrophic neurologic injury after blunt head trauma (most often from motor vehicle accidents), penetrating head injury (from gunshot wounds), or intracranial hemorrhage (cerebrovascular accidents). In general, suitable donors will not have sustained prolonged periods of circulatory compromise or septicemia. Donors are screened for serologic evidence of hepatitis B or human immunodeficiency virus infection, as well as active toxoplasmosis, herpes, or tuberculosis. All of these infectious processes disqualify organ donation. In contrast, most transplant centers use organs obtained from donors with prior cytomegalovirus (CMV) infection for recipients with previous CMV exposure. Autoimmune disease in general has not been a criterion for disqualification of donors, despite the report that idiopathic thrombocytopenic purpura can be transmitted by liver transplantation.² Cardiac donors are usually younger than 50 years of age and without pre-existing myocardial or coronary artery disease. Myocardial contractility must be adequate as judged by echocardiography, and there should be no history of use of intracardiac injections or high doses of inotropes. Hepatic function tests are useful to screen potential liver donors who may have abused drugs or alcohol. Urinalysis and cultures, blood urea nitrogen, and creatinine levels are standard tests for potential kidney donors. However, given that there are currently 62,000 people waiting for an organ,³ and some 4000 will die while waiting this year, more compromised donor organs may make their way into patient care.

Viscera for transplantation are also obtained from living donors. Almost all viscera derived from living donors are kidneys, although partial liver and lung resections have been performed to create reduced-size allografts for relatively few recipients. Living donors must be closely related to recipients if there is to be any benefit. The

strategy underlying living-related kidney transplantation is that human leukocyte antigen (HLA) identity between donor and recipient results in significantly greater graft survival than even a partially matched organ.⁴ Discussion of the perioperative care of living donors is continued in the section on Kidney Transplantation.

Diagnosis of Brain Death

The need for a uniform definition of brain death arose with the advent of heart transplantation in the late 1960s. Before that time, retrieval of kidneys, which are tolerant of a short period of warm ischemia, was performed after cessation of the donor's heartbeat. After several legislative efforts to address the issue, a special panel of medical consultants to the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavior Research issued a report that defined brain death as "irreversible cessation of all function of the entire brain, including the cortex and brain stem, determined in accordance with accepted medical standards."⁵ The concept of brain death is now widely recognized in Western societies, although the medical standards of its determination have been the subject of much debate.^{6,7}

Cerebral cortical function is deemed absent when no spontaneous movement or response to noxious external stimuli can be elicited by an experienced physician (Table 52-1). However, studies supporting these physical findings are often obtained in accordance with local "medical standards," which may include electroencephalography or cortical blood flow determinations. An electrically silent (flat) electroencephalogram is consistent with the diagnosis of brain death, although residual activity may still be found after cessation of cerebral blood flow.⁸ Four-vessel cerebral angiography has been used to establish brain death,⁹ but less invasive methods, such as transcranial Doppler¹⁰ and xenon-enhanced computed tomography,¹¹ are gaining popularity.

| |
|---|
| LOSS OF CEREBRAL CORTICAL FUNCTION |
| No spontaneous movement |
| Unresponsive to external stimuli |
| LOSS OF BRAIN STEM FUNCTION |
| Absent respiratory reflex (apnea test) |
| Absent cranial nerve reflexes |
| Pupillary light reflex |
| Corneal reflex |
| Oculocephalic reflex |
| Oculovestibular reflex |
| Atropine resistance |
| SUPPORTING STUDIES |
| Electroencephalography |
| Cerebral flow studies |
| Angiography |
| Transcranial Doppler examination |
| Xenon computed tomography scan |

TABLE 52-1. CRITERIA FOR THE DIAGNOSIS OF BRAIN DEATH

Brain stem infarction is indicated by loss of reflexes mediated by bulbar cranial nerve and respiratory nuclei. These include the direct pupillary light reflex (absent when bright light fails to constrict the homolateral pupil); the oculocephalic reflex (absent when ocular position is fixed during rotation of the head ["doll's eyes"]); the corneal reflex (absent when lightly touching the cornea fails to elicit a blink); and the oculovestibular reflex (absent when irrigation of the external auditory canal with ice water fails to produce nystagmus ["cold caloric test"]). Respiratory reflexes are assessed by the apnea test.¹² In most protocols, after a period of mechanical ventilation on 100% oxygen, the ventilator is disconnected (although oxygen is still supplied) and respiratory effort is judged by serial determinations of PaCO₂. By this means, an accurate assessment of respiratory brain stem function can be obtained in 10 minutes of observation if the patient remains otherwise physiologically stable.¹³

Irreversibility is implicit in the diagnosis of brain death and is established by the lack of improvement in the neurologic examination for 12–24 hours. Factors that may confound this diagnosis include generalized seizures, centrally active drug effects, hypothermia, and cardiovascular or metabolic instability because all may reversibly depress brain function. Therefore, it is also important that the cause of brain death is known and sufficient to account for this diagnosis. In young children, the potential for recovery from neurologic insults may be less predictable than in adults, so it has been recommended that an experienced pediatric neurologist be consulted to evaluate these young brain-injured patients.¹⁴

Physiologic Derangements With Brain Death

Brain death is frequently accompanied by marked physiologic instability, and treatment is often necessary to maintain the viability of donor organs (Table 52-2). Hypotension, hypoxemia, or arrhythmias may be part of the pathogenesis of brain death or else a consequence of brain stem infarction. Hypotension results from the loss of descending vasomotor control and is exacerbated by hemorrhage, massive diuresis from diabetes insipidus or radiographic dyes, or dehydration therapy for cerebral edema. Treatment consists of restoration of intravascular volume with colloid and crystalloid solutions, and, if necessary, vasopressin administration (Pitressin 0.5–15 U · h⁻¹) or vasoactive drug infusion. Because phenylephrine may diminish splanchnic perfusion and thereby jeopardize abdominal donor organs, dopamine (2–5 mg · kg⁻¹ · min⁻¹) is recommended for blood pressure support in this setting. Hypoxemia may follow from overzealous fluid administration during resuscitation attempts, atelectasis, aspiration, pneumothorax, pulmonary contusion, or pneumonia. The FIO₂, minute volume of ventilation, and positive end-expiratory pressure (PEEP) are usually adjusted to maintain systemic arterial saturation in excess of 95%. Atrial and ventricular arrhythmias, as well as varying degrees of conduction blockade, have been noted after brain death.¹⁵ Etiologies include intracranial hypertension, vagal nucleus infarction, myocardial ischemia or contusion, hypothermia, and abnormal pH or serum electrolytes. Bradycardia is resistant to atropine¹⁶ but responds to direct-acting chronotropic agents (e.g., dopamine, isoproterenol).

| Condition | Cause |
|--------------------------------------|--|
| Hypotension | Hypovolemia (diabetes insipidus; hemorrhage) |
| | Neurogenic shock |
| Hypoxemia | Neurogenic pulmonary edema |
| | Pulmonary contusion |
| | Pneumonia |
| | Gastric aspiration |
| | Fluid overload |
| Hypothermia | Hypothalamic infarction |
| | Exposure |
| Dysrhythmia (especially bradycardia) | Intracranial injury or herniation |
| | Hypothermia |
| | Hypoxia |
| | Electrolyte abnormality |
| | Myocardial contusion, ischemia |

TABLE 52-2. COMMON PHYSIOLOGIC DERANGEMENTS AFTER BRAIN DEATH

Numerous endocrine responses have been associated with brain death, including diabetes insipidus. This diagnosis is confirmed when polyuria is accompanied by relative hyposmolarity of the urine (300 mOsm · l⁻¹) despite serum hyperosmolarity (310 mOsm · l⁻¹) and hypernatremia (serum sodium 150 mEq · l⁻¹). Treatment consists of replacement of free water losses while restoring normal serum electrolyte and osmolarity values, and infusion of aqueous vasopressin (Pitressin, 0.5–15 U · h⁻¹ intravenously [iv]). Infrequently, catecholamine and cortisol levels are markedly elevated, and thyroid hormone (T₃) or insulin activity reduced after brain death. However, there is no consistent pattern; therefore, replacement therapies are not routinely used.

Donor Operation

Anesthesia care for multiple organ retrieval should continue the focus on maintenance of donor organ perfusion and oxygenation begun in the intensive care unit. Although cortical and brain stem function is absent, both visceral and somatic reflexes that can lead to physiologic responses during the procedure may be present.¹⁷ For example, reflex pressor responses may accompany surgical stimuli and can jeopardize the renal microvasculature. Vasodilator infusion is sufficient treatment because general anesthetics are unnecessary under these circumstances. Reflex neuromuscular activity mediated by spinal somatic reflexes is suppressed with relaxants.

After surgical preparation in the supine position, a midline incision is made from the suprasternal notch to the pubic symphysis, followed by sternotomy. Once exposed,

the liver is freed of its ligamentous attachments to the diaphragm. To minimize warm ischemic time and surgical trauma to the harvested viscera, the typical donor operation involves regional cooling and preservation of organs *in situ*, followed by *en bloc* removal.¹⁸ Thus, after the abdominal aorta is encircled with a ligature above the celiac artery, either the splenic or inferior mesenteric vein is cannulated and the liver is flushed through the portal system with cold preservative solution. The donor is then systemically heparinized and the abdominal aorta is cannulated, cross-clamped, and perfused with cold preservative. This cools the donor's kidneys and liver, and once the ureters are dissected and divided, *en bloc* graft nephrectomy can be accomplished by transecting the aorta and inferior vena cava (IVC) above and below the renal pedicles. The hepatic artery and common bile duct are then divided and the donor liver can now be removed. Donor cardiectomy begins once *in situ* preservation of the abdominal viscera is begun; further details about the cardiac donor procedure are found in Heart Transplantation. After all donor organs are removed, ventilatory and circulatory support is discontinued and the anesthesiologist's involvement ends. Death is always certified before the donor procedure and is not considered to have occurred in the operating room.

ORGAN PRESERVATION

Organ transplantation depends on the temporary separation of a donor organ from blood supply and protection from ischemia while *ex vivo*. Organ-sharing networks are based on distant procurement, which may extend the period of ischemia to the biologically tolerable limit. The protection strategy combines hypothermia to decrease metabolism with preservative solutions of specific electrolyte composition to maintain cellular integrity. These solutions may also contain chemical additives that are cryoprotective and prevent cellular swelling, vasospasm, and buildup of toxic metabolites and provide a source of energy.

Preservation strategies are based on the control of the adverse cellular events that follow ischemia and reperfusion. Preventing these chain reactions is the rationale for using free radical scavengers (e.g., mannitol, superoxide dismutase) and synthesis blockers (allopurinol) as additives to preservative solutions.

Preservation Solutions

Collins *et al*¹⁹ first developed a series of isotonic flushing solutions for renal preservation. Their compositions usually resembled that of intracellular fluid (*i.e.*, low sodium and high potassium), which was shown to diminish renal cortical respiration. Other additives included heparin, phenoxybenzamine, and procaine, all meant to prevent agonal vasospasm and thrombosis in cadaver kidneys. Today, among the most widely used kidney flushing solutions in the United States and Europe is a modified Collins solution, termed Euro-Collins (Table 52-3). Euro-Collins solution is modestly hyperosmotic, does not contain additives, and supports kidney viability *ex vivo* for more than 48 hours.²⁰

TABLE 52-3. COMMON ORGAN PRESERVATION SOLUTIONS

The high metabolic rate of the liver makes it relatively vulnerable to ischemia, and its large bulk prevents rapid, uniform cooling during procurement. As a consequence, the most common cause of postoperative hepatic graft dysfunction is ischemic injury. UW (University of Wisconsin) solution²¹ was shown to extend hypothermic preservation of donor livers for at least 24 hours *ex vivo*, and possibly longer.^{21,22} The key additives in UW solution (see Table 52-3) include lactobionate and raffinose, which are used as impermeants to suppress hypothermia-induced cellular swelling.

Protection of the heart is based on cellular metabolic arrest and uniform cooling, both of which prevent the generation of cytotoxic free radicals.²³ Techniques that provide myocardial protection, particularly cardioplegia, developed in parallel with heart transplantation and greatly facilitated distal procurement.²⁴ Compared with other preservative regimens, cardioplegia solutions (see Table 52-3) were shown to reduce the need for inotropic support after implantation²⁴ and are now generally used for *ex vivo* myocardial preservation. Under laboratory conditions, cardioplegia is able to preserve cardiac function for up to 24 hours. However, in humans, the practical limit of ischemic time is 4–6 hours.^{24,25}

TRANSPLANTATION IMMUNOLOGY

Tissue derived from a (nontwin) donor of the same species for transplantation is termed an *allograft*. When an immunocompetent recipient is confronted with foreign antigens present on the cell surfaces of an allograft, an immune response occurs. All elements of a recipient's immune system contribute to the response provoked by transplanted tissue; these include humoral factors (immunoglobulins secreted by B lymphocytes as well as complement proteins) and cellular elements (T cells, other leukocytes, and macrophages). T lymphocytes play a primary role in the immune response by initial antigen recognition and ultimate allograft destruction. On the basis of their specific reactivity to certain monoclonal antibodies or their cell surface antigens, T lymphocytes can be subdivided into at least four subpopulations:²⁶ cytotoxic T cells, helper T cells, delayed hypersensitivity T cells, and suppressor T cells. All are important participants in the reaction to foreign tissue.

The cell surface glycoproteins that establish the immunologic identity of donor tissues are termed the *major histocompatibility complex* (MHC) antigens. Class I MHC antigens, also called HLA-A, -B, and -C, are found on all nucleated cells. These are the classic transplantation antigens as well as the primary targets for cytotoxic cells.²⁷ Class II MHC antigens, also termed HLA-DR, -DQ, and -DP, are located on activated T cells, B cells, dendritic cells, and macrophages, and are the primary targets for helper T cells.²⁸ There is an enormous diversity of alleles at the chromosomal loci encoding for the HLA antigens, and this accounts for the varying degrees of HLA matching observed. Finally, the major blood group antigens (ABO) are particularly potent transplantation antigens, such that organs transplanted into patients with known preformed isohemagglutinins against the donor blood type can be expected to provoke the most rapid form of rejection (hyperacute rejection) because of thrombosis in the microvasculature.

Mechanisms of Allograft Rejection

Unless suppressed, the immune response to transplanted tissue begins with the recognition of the donor antigens as foreign or "nonself," proceeds with proliferation of immunocompetent cells, and culminates in an effector phase. Briefly, recognition involves a binding reaction between an immunogenic histocompatibility antigen present on the surface of the allogeneic (donor) cell and a receptor on the surface of a helper or cytotoxic T cell (Fig. 52-1). After T cells are bound, accessory macrophages secrete "monokines," notably interleukin-1 (IL-1), to further enhance T cell activation. IL-2 and other lymphokines are secreted by helper T cells, promoting lymphocyte proliferation and differentiation. Differentiated lymphocytes, in turn, secrete effector molecules including γ -interferon, which activate and enlist macrophages and leukocytes to cooperate in the process of graft rejection.

Figure 52-1. Immune response to allogenic tissue. The cellular and humoral events that comprise the immune cascade are illustrated, starting with recognition of an allogenic (foreign) cell by T lymphocytes at the top of the figure. See text for details. HLA = human leukocyte antigen. (Reprinted with permission from Strom TB: Immunosuppressive agents in renal transplantation. *Kidney Int* 26:353, 1984.)

Clinical Immunology of Organ Transplantation

Hyperacute rejection of renal allografts, characterized by microvascular thrombosis rapidly followed by graft necrosis, occurs in the presence of major blood group (ABO) incompatibilities.²⁹ However, like blood transfusion, kidneys from type O donors can be transplanted into compatible, nonidentical (A, B, or AB) recipients. In some centers, ABO-incompatible, living-related donor kidney transplants are performed with good results, but only under special immunosuppression protocols that include splenectomy, plasmapheresis, donor-specific platelet transfusion, and cyclosporine administration. The importance of HLA histocompatibility matching in kidney transplantation is controversial; HLA-incompatible, living-related donor transplantation yields excellent results, but survival rates of HLA-matched cadaver allografts are superior. The presence of preformed cytotoxic antibodies to the donor's T lymphocytes (anti-lymphocyte antibodies) increases the risk of hyperacute rejection and usually precludes kidney transplantation.³⁰ One other immunologic parameter that may affect renal allograft survival is the panel-reactive antibody (PRA). In this test, cross-match testing is done between patient sera and donor cells to detect the presence of preformed antibodies. It has been reported that patients with lymphocytotoxic antibodies that react against more than 50% of the random test panel have a greater rate of rejection.³¹

Donor-specific ABO isoagglutinins may induce hyperacute reactions of cardiac allografts,³² thus, ABO matching is considered to be essential. The role of HLA matching in heart transplantation is more controversial. Some studies indicate that HLA mismatching does not correlate with the number of cardiac rejection episodes or survival,³³ whereas others find that HLA mismatching has clinically important consequences.³⁴ However, until the tolerable donor heart ischemic time is extended beyond the present 4–6 hours, full prospective histocompatibility matching and PRA screening will remain impractical and limit their application.

In contrast to the heart and kidneys, hyperacute rejection has not been reported to occur in liver allografts,³⁵ supporting the assertion that the liver is resistant to such antibody-mediated injury.³⁶ Consequently, liver transplantation is often performed despite major ABO incompatibility, although the risk of subsequent rejection is elevated.^{29,37} When ABO matching is done, short-term survival is better with ABO-identical than with ABO-compatible, nonidentical allografts,²⁹ and the longer-term trend is similar.³⁸ There does not seem to be any relation between either HLA matching or T-cell crossmatch and allograft survival.

In summary, the distribution of renal allografts depends mostly on immunologic factors such as ABO match, HLA histocompatibility, T-cell crossmatch, and PRA profile. In contrast, except for ABO matching, the distribution of donor livers and hearts depends more on factors such as size compatibility and medical urgency than on immunologic criteria.

Mechanisms of Immunosuppression

In clinical practice, the immune response must be controlled to avoid allograft rejection. Immunosuppressant drugs have been developed for this purpose, but their use is accompanied by significant morbidity. Because of side effects and toxicities (as discussed in Evaluation of Patients With a Prior Organ Transplant), immunosuppression is warranted only for grafts essential for life. For example, a thyroid allograft would be inappropriate because it is easily substituted by a medication.

Ideally, immunosuppressants should inhibit only that lymphocyte subset directed against donor-specific alloantigens, but the drugs in current use are immunologically nonspecific. Antirejection regimens usually combine low doses of several agents to provide superior immunosuppression and to minimize side effects.

Glucocorticoids

Glucocorticoids (Table 52-4) are potent anti-inflammatory agents and have been a mainstay in almost all immunosuppressive regimens. These agents decrease macrophage production of IL-1, a critical factor in helper T-cell development.³⁹ In addition, T-cell secretion of IL-2 is also diminished, preventing clonal expansion of helper and cytotoxic T cells.⁴⁰

| Agent | Main Effects ^a |
|---------------------------------|---|
| Glucocorticoids | Decrease IL-1 production from macrophages (reducing effectiveness of T-helper cells) Decrease IL-2 production from T cells (reducing clonal expansion of T-helper and cytotoxic cells) |
| Azathioprine | Inhibits DNA and RNA synthesis (reducing lymphocyte proliferation) |
| Cyclosporine | Prevents T-helper cell activation by antigen Inhibits elaboration of T-cell-derived factors, particularly IL-2 |
| Tacrolimus (FK 506) | Inhibits T-cell production of IL-2 Inhibits production of IL-2 receptors on T cells |
| Antilymphocyte globulin OKT3 | Prevents B-cell activation Diminishes populations of both T and B lymphocytes Inactivates T cells and prevents reactivation |

IL = interleukin.

TABLE 52-4. MECHANISMS OF IMMUNOSUPPRESSANT ACTION

Azathioprine

Azathioprine is an imidazole derivative of 6-mercaptopurine, an analogue of the purine hypoxanthine. Thioinosinic acid, a metabolite of azathioprine, competes with inosinic acid for conversion to xanthylic acid, an essential substrate for *de novo* purine synthesis required for production of both DNA and RNA. As a result, protein synthesis and both T- and B-lymphocyte proliferation are inhibited.⁴¹

Cyclosporine, Tacrolimus, Mycophenolate, and Rapamycin

Cyclosporine is a lipophilic undecapeptide antibiotic isolated from a soil fungus that virtually revolutionized viscera transplantation by making it feasible routinely to achieve results comparable with those obtained in transplants between identical twins. Its major target is the T cell, which is inhibited from elaborating key lymphokines such as IL-2.⁴² Cyclosporine also prevents activation of helper T cells by foreign antigens and inhibits the production of IL-1 by macrophages.

Tacrolimus (FK 506) and rapamycin are newer macrolide antibiotic immunosuppressants currently undergoing clinical trials. Both are highly potent and may have somewhat more immunospecificity and less toxicity than cyclosporine. These agents diminish activation and proliferation of T cells as well as lymphokine production, but do so through distinct intracellular signaling pathways.

Mycophenolate mofetil has shown promise in early clinical trials. It is hydrolyzed to mycophenolic acid, which inhibits the enzyme inosine monophosphate dehydrogenase. In turn, this disrupts guanosine nucleotide synthesis in T and B lymphocytes, reducing their ability to proliferate during an immune response.⁴³ Whether its immunospecificity and toxicity profiles are better than those of the aforementioned compounds remains to be seen.

Antilymphocyte Globulin and OKT3

Antilymphocyte globulin (ALG) is a polyclonal antibody produced by immunizing animals with human lymphoid cells and isolating the IgG fraction from resulting antisera. ALG seems rapidly to diminish the availability of activated T lymphocytes, interrupting the chain of events leading to rejection. ALG may also have a sustained effect on T-cell proliferation, perhaps by promoting formation of nonspecific suppressor T cells.⁴⁴ Similarly, the OKT series of murine monoclonal antibodies directed against T-cell surface antigens are added to some immunosuppression regimens to treat rejection. OKT3 is specifically directed against the T3 (CD3) complex on the

surface of mature T lymphocytes. The T3 complex is located adjacent to the T-cell receptor involved in recognition of foreign antigens; binding of OKT3 blocks the recognition of MHC antigens and, consequently, the immune response cascade.⁴⁵ Administration of OKT3 also results in removal of opsonized T cells by the reticuloendothelial system.

GENERAL PREANESTHETIC EVALUATION OF TRANSPLANT CANDIDATES

The general indication for organ transplantation is failure of medical or other surgical management to enhance the quality of life for patients with end-stage organ disease or significantly to improve their chances for long-term survival. Because major organ transplantation procedures are now associated with reasonably low perioperative mortality rates, this option is considered in virtually all such cases.

The major contraindications to organ transplantation are incurable malignancy; the presence of another systemic disease; active, poorly controlled infection; and physical or social factors that would either impede recovery or lead to recurrent disease (Table 52-5). Rather than being considered absolute, these criteria are under continuous evolution in light of new information. For example, diabetes mellitus was formerly considered to contraindicate organ transplantation, but many diabetic patients have now undergone renal transplantation and 1-year allograft survival is the same as for nondiabetic patients. Patients with diabetic nephropathy now comprise the largest segment of adults who undergo renal transplantation. Similarly, many elderly patients have undergone heart transplantation with results that are comparable with those for younger subpopulations.

| |
|---|
| Incurable malignancy |
| Other major systemic illness |
| Old ("physiologic") age |
| Active systemic or incurable infection |
| Significant obesity |
| Current alcohol, drug, or tobacco abuse |
| Evidence of emotional instability or lack of supportive social milieu |

TABLE 52-5. GENERAL CONTRAINDICATIONS TO VISCERA TRANSPLANTATION

Candidates for organ transplantation often manifest physical findings or laboratory abnormalities indicative of secondary organ involvement (e.g., hepatomegaly consequent to right ventricular failure). It is important to verify that such findings do not represent a coexistent primary disease process (which might disqualify potential recipients) and to bear in mind that compromised organs may be especially vulnerable to acute insults. Because recipients will be immunosuppressed, occult infection (e.g., tuberculosis) should assiduously be ruled out. For the same reason, it is standard to order CMV-negative blood for transfusion unless recipients are seropositive. On occasion, technical feasibility may become the overwhelming source of concern (e.g., with atypical vascular anatomy or body habitus, or multiple previous surgeries).

Because of the shortage of suitable donor organs, patients may remain on a waiting list for many months while their conditions continue to deteriorate. Interval changes, as well as corresponding alterations in their medical regimens, should be ascertained. The urgency of surgery may, by necessity, influence the acceptability of an available donor organ.

With organs for which the safe ischemic time is less than 24 hours, transplantation procedures are usually performed under emergency circumstances. The patient to receive the organ may have eaten recently and arrives in the operating room without the benefit of premedication. The remaining management considerations are specific to the particular type of transplantation procedure, as discussed in the following sections.

KIDNEY TRANSPLANTATION

Approximately 10,000 renal transplantations are performed each year in the United States. This comprises 5–10% of patients with end-stage renal disease who are otherwise dependent on dialysis. Dialysis is clearly effective in prolonging life, but considerable morbidity and mortality are associated with its use. For example, in 1988 the 1-year mortality rate after renal transplantation was 5%; in some studies the yearly mortality rate of patients on chronic dialysis is at least twice as high.⁴⁶

Renal transplantation is a highly successful procedure. According to data from the national organ procurement and transplantation network UNOS, cadaveric renal allografts have a 1-year survival rate of 81%, whereas the same statistic for living-related donor organs is 91%.⁴⁷ Studies from large centers indicate that longer-term graft survival is also comparably favorable, as are other measures of outcome. In adults with end-stage renal disease, kidney transplantation improves the quality of life⁴⁸ while remaining cost-effective,⁴⁹ and for children, transplantation provides superior growth and development.⁵⁰ For these reasons, renal transplantation has become the treatment of choice for end-stage renal disease,⁵¹ with its growth limited only by the supply of available donor organs.

Pathophysiology of End-Stage Renal Disease

End-stage renal disease can result from numerous causes (Table 52-6), all of which ultimately lead to the uremic syndrome. In uremia, patients are unable to regulate the volume and composition of their body fluids, resulting in fluid overload, acidemia, and imbalance of electrolytes such as potassium, phosphorus, magnesium, and calcium. In addition, there is usually evidence of secondary dysfunction in other organ systems (Table 52-7). Even patients maintained by dialysis may have peripheral neuropathy, pericardial or pleural effusions, renal osteodystrophy, and gastrointestinal (GI) as well as immunologic dysfunction.

| Etiology | Total Cases (%) |
|----------------------------------|-----------------|
| Diabetic glomerulonephropathy | 43.6 |
| Other glomerulonephritides | 23.2 |
| Polycystic kidney disease | 5.8 |
| Chronic pyelonephritis | 5.4 |
| Obstructive uropathy | 3.4 |
| Alport's syndrome | 2.1 |
| Lupus nephritis | 1.6 |
| Miscellaneous, including unknown | 14.9 |

TABLE 52-7. COMMON PATHOPHYSIOLOGIC CONSEQUENCES OF END-STAGE RENAL DISEASE

Specific Indications and Contraindications

A large proportion of adults with end-stage renal disease are candidates for kidney transplantation. Aside from the general contraindications to viscera transplantation (see [Table 52-5](#)), relative contraindications specific to renal transplantation are disease processes likely to recur in the transplanted kidney. Hemolytic-uremic syndrome, membranoproliferative glomerulonephritis, and metabolic derangements that produce toxic deposits in the kidney (*e.g.*, gout, oxalosis, cytinosis) fall into this group. In practice, however, patients with such disorders may derive years of benefit from transplantation, and thus at many centers are still considered eligible. Similarly, diabetic nephropathy can also recur in allografts, but diabetes mellitus is no longer considered a contraindication to renal transplantation.

Preanesthetic Considerations

Because the tolerable ischemic time for kidneys is at least 48 hours,²⁰ cadaver allografts may be transplanted semielectively. With living-related donation, renal transplantation is an elective procedure. In either case, sufficient time is available for ABO matching, cross-matching of the recipient's serum with donor lymphocytes, and, at some institutions, HLA tissue typing. Likewise, dialysis may precede transplantation to correct serious electrolyte and volume derangements. After dialysis, it is important to ascertain the net volume status of patients; the final hematocrit, electrolyte, and bicarbonate levels; and whether there is any residual heparin effect. The serum potassium should be normal, and the serum calcium supplemented if $<7 \text{ mg} \cdot \text{dl}^{-1}$ to prevent tetanus. Most uremic patients, even those on dialysis, have hemoglobin levels in the 6–8 $\text{g} \cdot \text{dl}^{-1}$ range. However, in chronically anemic patients, compensatory changes promote tissue oxygen unloading, and, on this basis alone, preoperative transfusion is not mandatory. But transfusion may enhance allograft survival; thus, it has become a standard part of the preoperative regimen at some centers. On occasion, pleural or pericardial effusions may require treatment if there is functional impairment; in patients on chronic steroids, preoperative administration of full replacement doses of glucocorticoids should be considered.

Because many adult recipients are diabetic, the possibility of coexistent ischemic heart disease is usually evaluated by exercise stress testing and, if indicated, coronary angiography.⁵² Diffuse coronary disease has not been considered a contraindication to renal transplantation, provided that ventricular function is not seriously diminished and the patient is willing to assume the added risk. In such patients, appropriate invasive monitoring (arterial and pulmonary artery catheters) is warranted; in all others, a central venous pressure catheter is sufficient to monitor intravascular volume for optimal renal perfusion. Finally, transplanted kidneys, particularly those derived from cadaver donors, may not be functional immediately, so it is vital to protect existing arteriovenous fistulas or other routes for postoperative hemodialysis or peritoneal dialysis.

Donor Procedure and Related Considerations

The procedure used for harvesting abdominal viscera from cadaver donors is reviewed in Anesthesia Care of Organ Donors. If the cadaver is brain dead but the circulation is intact, harvesting may proceed at leisure through the transperitoneal route. If the circulation fails, however, the kidneys must be rapidly removed and flushed with preservative solution to minimize warm ischemic time.

Living donors are the source of 20% of the kidneys transplanted in the United States and 60% of those in Europe. Because results with unrelated living donors are no better than those achieved with cadaver donors, living donors are virtually always close relatives. Most are healthy adults, because any significant systemic disease increases the risk of general anesthesia and surgery, giving rise to ethical conflicts. For similar reasons, donors who are 45 (male) or 50 years (female) of age usually undergo noninvasive studies to detect occult coronary ischemia. The use of living-related donors has gained widespread acceptance because the overall incidence of serious perioperative morbidity in this population is small (2%), and deaths are extremely rare.⁵³ Furthermore, long-term follow-up studies indicate that donors have no greater risk of renal failure or hypertension.⁵⁴

Before surgery, donors undergo renal arteriography and iv pyelography and are screened for ABO blood group compatibility and CMV titer. Then, 2–4 weeks before the procedure, several units of blood are donated for autologous transfusion. During the night preceding harvesting, donors are hydrated with crystalloid solutions to promote an active diuresis, and at the time of nephrectomy, a minimum urine output of $1 \text{ ml} \cdot \text{min}^{-1}$ is achieved by means of mannitol and furosemide. The timing of the donor and recipient procedures is coordinated so that the kidney's ischemic interval is minimized. Heparin is administered systemically before removal of the organ from the donor, which is then flushed free of blood with a cold crystalloid solution and transplanted immediately.

Anesthesia Induction for Recipients

Diabetic patients can have delayed gastric emptying;⁵⁵ therefore, rapid induction may be warranted. Provided the serum potassium is normal after recent dialysis, there is no contraindication to the use of succinylcholine. Drugs that are highly protein bound (*e.g.*, thiopental) should be administered in reduced dosages. Further discussion of the kinetics and dynamics of drugs in renal failure patients is found in [Chapter 36](#).

Central venous catheters are useful for the reasons discussed earlier but are usually inserted after induction. Many renal transplant recipients are moderately hypertensive and maintained on combinations of appropriate medications. Most have recently been dialyzed and are volume depleted. Thus, the possibility of synergistic interactions between strongly vasodilating anesthetics (*e.g.*, isoflurane, fentanyl), antihypertensives (*e.g.*, hydralazine, diltiazem, captopril), and hypovolemia should be considered.

Anesthesia and Surgical Procedures

Although regional anesthetic techniques have been advocated by some,⁵⁶ the use of general anesthesia is more common.⁵⁷ With general anesthesia, there is superior control of ventilation, which becomes particularly important when surgical retraction is close to the diaphragm. In addition, the duration of renal transplant procedures in most centers makes regional techniques impractical. Enflurane is seldom chosen because its biotransformation results in inorganic fluoride that is nephrotoxic. Nitrous oxide is often omitted to avoid distention of the bowel, particularly in children, so either opioids and benzodiazepines are used in combination, or a potent inhaled agent is used alone. Atracurium and vecuronium are the preferred muscle relaxants because they are least dependent on renal metabolism, although laudanosine, a metabolite of atracurium, may accumulate in patients with end-stage renal disease.⁵⁸ Laudanosine increases the minimum alveolar concentration of halothane in laboratory animals but does not seem to cause an analogous clinical effect in humans.⁵⁹ The response to vecuronium may be variable in renal failure,⁶⁰ and because it is not clear precisely when renal metabolic function is restored after transplantation, neuromuscular monitoring is highly recommended.

In adults, the kidney is implanted retroperitoneally in the upper pelvis using a paramedian lower-abdominal approach; in children weighing $<20 \text{ kg}$, abdominal implantation is the rule. Revascularization of the allograft in adults involves anastomoses of the renal vessels to an iliac vein and artery. This necessitates clamping the common iliac vessels, resulting in lower extremity ischemia, usually for less than 60 minutes. After the anastomoses are complete, the circulation is restored to the allograft and lower extremities. To promote renal perfusion, a high-normal blood pressure is achieved by reducing the depth of anesthesia, bolus administration of crystalloid, or temporary dopamine infusion. When the vascular clamps are released, renal preservative solution and the venous drainage from the legs are also released into the circulation. These effluents are relatively rich in potassium and acid metabolites, but in adults, have little systemic effect. The final stage of the procedure involves ureteral implantation for urinary drainage.

Postoperative Management

Varying periods of oliguria or anuria due to acute tubular necrosis are associated with cadaveric renal transplantation in approximately one third of cases;⁶¹ thus, fluids must be administered judiciously to reduce the risk of postoperative pulmonary edema. In contrast, the ischemic time for organs derived from living-related donors is minimal and urine flow is usually immediate. Emergence is often accompanied by both pain and hypertension, which are particularly hazardous in diabetic patients with coexistent ischemic heart disease. In such cases, preparations should be made to administer potent analgesics (e.g., by epidural catheter) and antihypertensives in the recovery room, if myocardial ischemia is to be avoided. Other early postoperative complications include atelectasis, bleeding and thrombosis of vascular anastomoses, urinary obstruction or leak, and, rarely, gastric aspiration. Hyperacute rejection may also occur and lead to anuria; definitive diagnosis requires a renal biopsy. This complication has become rare because both ABO matching and crossmatching of the recipient's serum to donor lymphocytes are routinely performed.

Immunosuppression with "triple therapy" (cyclosporine, azathioprine, prednisone) is usually begun before transplantation of living-related donor organs or after transplantation of cadaveric kidneys. Long-term complications of renal transplantation related to immunosuppression are discussed in Evaluation of Patients With a Prior Organ Transplant.

LIVER TRANSPLANTATION

Medical treatment for chronic end-stage liver disease is supportive but does little to prolong or improve the quality of life, particularly after serious complications (e.g., GI bleeding, coma, uremia) develop. In acute hepatic failure, the salvage rate with medical treatment is between 5 and 20%.⁶² In contrast, in the cyclosporine era, the overall 1-year survival rate of orthotopic liver recipients is 76%, with an allograft survival rate of 69%.⁴⁷ Longer-term survival is also comparatively high (Fig. 52-2). Moreover, the quality of life for a high proportion of transplantation survivors is markedly improved.⁶³

Figure 52-2. Survival of liver transplant recipients treated before and after the availability of cyclosporine. Data are derived from 170 "before" (solid line) and 1258 "after" (dashed line) recipients. Survival is calculated using the life-table method. (Reprinted with permission from Starzl TE, Demetris AJ, van Thiel DH: Liver transplantation. N Engl J Med 321:1014, 1092, 1989.)

The yearly rate of liver transplantations in the United States has reached approximately 2500, although it has been argued that more than twice that number are needed.⁶³ The overwhelming majority of these procedures are orthotopic, involving native hepatectomy and implantation of the donor organ in anatomic position in the right upper quadrant. Heterotopic (also called auxiliary) transplantation, where the donor liver is implanted adjacent to the native liver, which is left *in situ*, has been used on rare occasion for reversible hepatic failure and in patients too frail for the orthotopic procedure.⁶⁴

Pathophysiology of End-Stage Liver Disease

The liver has numerous synthetic and metabolic functions (see Chapter 39); thus, end-stage liver disease has ramifications that extend to virtually every other organ system (Table 52-8). In disease processes that destroy the normal hepatic architecture, portal hypertension results and extensive venous collaterals develop in the abdominal wall, mesentery, retroperitoneum, and GI tract. Aside from the significant morbidity associated with hemorrhage from esophageal varices, the extensive network of arteriovenous communications results in low systemic vascular resistance and high cardiac output. Intrapulmonary shunting is also seen frequently in patients with end-stage liver disease,⁶⁵ leading to hypoxemia that is exacerbated by pleural effusions and bibasilar atelectasis from abdominal distention. Renal function may be impaired from hepatorenal syndrome or prerenal azotemia. Ascites develops as a result of venous hypertension, decreased albumin synthesis, and sodium and water retention from a relative excess of aldosterone and antidiuretic hormone. Treatment often consists of diuretics, which in turn may cause electrolyte and acid-base derangements and intravascular volume depletion. Blood coagulation is abnormal because synthesis of the hepatically derived clotting factors (I [fibrinogen], II [prothrombin], V, VII, IX, X) and clearance of fibrinolytic factors are compromised. Hypersplenism may also markedly diminish the platelet count. Eventually, even the central nervous system is affected, resulting in a progressive toxic encephalopathy and cerebral edema, which presage death.

| Organ System | Consequence |
|------------------------|---|
| Central nervous system | Encephalopathy (mild confusion → coma) |
| Cardiovascular | Brain edema (subarachnoid hepatitis) Hyperdynamic circulation Reduced systemic resistance Increased plasma volume Pericardial effusion |
| Pulmonary | Pleural effusion Interstitial edema (hypoalbuminemia) Atelectasis Ventilation-perfusion mismatch and shunting |
| Gastrointestinal | Esophageal varices Ascites Portal hypertension Delayed gastric emptying |
| Hematologic | Reduced clotting factor levels Anemia Thrombocytopenia (hypersplenism) Reduced clearance of fibrinolytic substances and tissue plasminogen activators |
| Endocrine | Glucose intolerance Disturbed glycogen stores |
| Renal | Oliguria (hepatorenal syndrome, prerenal azotemia) Hyponatremia (diuretics, increased antidiuretic hormone activity) Hypokalemia (poor nutrition, diuretics, gastric intestinal losses) |

TABLE 52-8. COMMON PATHOPHYSIOLOGIC CONSEQUENCES OF END-STAGE LIVER DISEASE

Specific Indications and Contraindications

The decision to transplant is difficult to base on objective liver function test results because these values vary considerably according to the specific pathologic process. Instead, the degrees of medical, social, and psychological impairment are considered in combination, then balanced against the mortality associated with conservative management.⁶³ Ideally, liver transplantation is undertaken before the degree of organ failure becomes severe and the patient incapacitated,⁶² to reduce perioperative morbidity.

There is little debate that liver transplantation is indicated for nonmalignant end-stage liver disease that will not recur in the hepatic graft. Most often, this procedure is used to treat benign parenchymal diseases, including postnecrotic cirrhosis and any of the causes of acute liver failure or cholestatic processes (e.g., primary biliary cirrhosis or biliary atresia in children; Table 52-9). In all, more than 60 disease entities have now been successfully treated by liver transplantation.⁶³ Transplanting in the presence of a disease when recurrence is a possibility is somewhat more controversial, considering the limited supply of donor organs. Alcoholic cirrhosis was once considered an absolute contraindication to transplantation, but multidisciplinary care and careful selection have led to results with Laennec's cirrhosis that are comparable with those with other liver diseases.⁶⁶ Similarly, transplantation for cirrhosis from hepatitis B virus infection has proved to be beneficial for many patients⁶³ despite the inability to prevent infection in the donor liver. Advanced age was also once a contraindication, but recipients older than 50 years have been shown to have a 5-year survival rate after transplantation comparable with that of younger adults.⁶⁷

| Disease | No. of Cases |
|------------------------------------|--------------|
| PARENCHYMAL | |
| Fibrosclerotic cirrhosis | 348 |
| Alcoholic cirrhosis | 76 |
| Acute liver failure | 84 |
| Budd-Chiari syndrome | 18 |
| Congenital hepatic fibrosis | 9 |
| Cystic fibrosis | 6 |

TABLE 52-9. PREOPERATIVE PATHOLOGIC DIAGNOSES IN LIVER TRANSPLANT RECIPIENTS

Treatment of hepatic cancers by transplantation is being studied at several centers and is the subject of considerable debate. Patients with primary liver and bile duct cancers, as well as hepatic metastases from GI and endocrine tumors, have undergone liver transplantation with varying duration of remission.^{68,69} But recurrence of tumor is the rule, so transplantation is usually reserved for selected cases with isolated tumors and deteriorating liver function. If hepatic function remains preserved in the presence of a liver tumor, major hepatic resection is the recommended alternative.

Other possible contraindications relate to specific surgical obstacles, including thromboses of major abdominal veins and scarring from multiple abdominal procedures. However, the successful use of vein grafts and accumulation of practical experience with the transplantation procedure have rendered even these contraindications obsolete.

Preanesthetic Considerations

Candidates for liver transplantation present a broad clinical spectrum, ranging from chronic fatigue with mild jaundice to coma with multiorgan failure. Hepatic encephalopathy may be reversible; thus, the timing of liver transplantation can be critical to outcome. Emergency transplantation for fulminant hepatic failure can have a salvage rate of 55–75%⁷⁰ provided that symptoms have not progressed to Grade 4 encephalopathy.⁶³ Without transplantation, most causes of fulminant hepatic failure are associated with much poorer prognoses.

Certain uncommon diseases treated by liver transplantation have additional implications for anesthesiologists. For example, after transplantation for the Budd-Chiari syndrome, which typically is associated with extensive hepatic venous thrombosis, patients may require anticoagulation.⁷¹ In children with an even rarer disorder, Crigler-Najjar syndrome (bilirubin uridine diphosphate–glucuronyl transferase deficiency), drugs that interfere with bilirubin binding to albumin (e.g., barbiturates) should be avoided.⁷²

Many of the physiologic derangements associated with end-stage liver disease are not correctable until after transplantation. Therefore, the major emphasis in the preanesthetic evaluation should be on identifying the most important areas of physiologic compromise and treating only those that threaten the safe induction of anesthesia. For example, pleural effusions may be responsible for profound hypoxemia, and despite clotting abnormalities, preoperative thoracentesis may be a necessity. However, defects in coagulation are usually not corrected at this point unless there is active hemorrhage. If blood product administration is essential, but limited by oliguric hypervolemia, hemofiltration has been used in parallel to the venovenous bypass circuit.⁷³

Preparation of fluid-warming units, gas circuit humidifiers, warming blankets, and nonconductive wraps for the head and extremities is essential before induction; otherwise, hypothermia will rapidly result from transfusion, convective and evaporative losses from exposure of abdominal organs, diminished hepatic energy production, and implantation of a cold donor organ of large thermal mass. A thromboelastograph is also prepared at many centers as a relatively rapid means to elucidate a need for specific blood product replacement under conditions of massive transfusion.⁷⁴

Finally, as a result of the primary disease process or subsequent multiple transfusions, recipient serologies may be positive for hepatitis A, B, or C. The health care team should be aware of the potential for infectious contamination and take appropriate precautions.

Anesthesia Induction

Liver transplantation involves transection and reanastomosis of several major venous structures (portal vein and IVC), and the ability to transfuse rapidly is vital to successful outcome.⁷⁵ At the University of Pittsburgh, at least two large-bore peripheral venous cannulae are inserted, one of which is 8.5 French units to facilitate the use of a rapid transfusion device. Because major shifts in intravascular volume are common and reperfusion of the donor liver has been associated with hypotension,⁷⁶ invasive monitoring with arterial and pulmonary artery catheters is standard. Both radial and femoral artery catheters are often placed because distal arterial flow may be compromised by aortic clamps during hepatic artery anastomoses. The balance of the monitoring array is similar to that used for any critically ill patient undergoing a major general surgical procedure.

Patients with end-stage liver disease have numerous reasons for delayed gastric emptying, such as ascites or active upper GI bleeding. Therefore, aspiration precautions are mandatory and induction of general anesthesia should proceed by either a rapid-sequence technique or, in patients with hemodynamic instability or significant hypovolemia, awake intubation.

Anesthesia and Surgical Procedures

Anesthesia is maintained by agents that preserve splanchnic flow (e.g., opioids or isoflurane) combined with muscle relaxants, except in cases of fulminant hepatic failure in which the possibility of intracranial hypertension contraindicates potent inhaled agents. Nitrous oxide is not contraindicated but is usually avoided because of its ability to distend the bowel and increase the size of gas bubbles entrained in the circulation. Pharmacokinetic alterations associated with end-stage liver disease are complex and are described in [Chapter 39](#) and reviewed by Howrie and Burckart.⁷⁷ The net effect of these factors for nondepolarizing muscle relaxants is to increase the loading dose requirements and prolong the durations of action. In contrast, fentanyl kinetics are not markedly changed.⁷⁸ Although well preserved liver allografts can rapidly begin to metabolize drugs,⁷⁹ many of the pharmacokinetic changes (e.g., diminished serum albumin, enlarged volumes of distribution) persist beyond the transplantation procedure.

The orthotopic procedure involves replacing the diseased native liver with a cadaveric organ in the most anatomic position possible. It consists of three stages: the preanhepatic, anhepatic, and neohepatic stages⁸⁰ ([Table 52-10](#)).

| Phase | Surgical Procedures | Physiologic Changes |
|--------------|---|--|
| Preanhepatic | Dissection of porta hepatis Release of hepatic attachments | Third space losses (ascites) Hemorrhage (venous collaterals) |
| Anhepatic | Clamp hepatic aorta, portal vein Venovenous bypass (adults) Clamp IVC Retraction on diaphragm | Obstruction of venous return Oliguria (venous congestion) Atelectasis, decreased compliance |
| Neohepatic | Anastomosis of IVC Flush hepatic allograft Anastomosis of portal vein, hepatic artery Biliary drainage procedure | Hemorrhage (coagulopathy) Citrate intoxication Hyperkalemia Hypothermia Metabolic acidosis |

IVC = inferior vena cava.

TABLE 52-10. OVERVIEW OF THE ORTHOTOPIC LIVER TRANSPLANTATION PROCEDURE

The preanhepatic stage involves dissection of the structures of the porta hepatis and mobilization of the native liver. Cardiovascular instability is common during this phase because of hypovolemia from acute third-space losses (ascites) and hemorrhage from venous collaterals in the body wall and mesentery. Citrate-induced hypocalcemia,⁸¹ hyperkalemia from rapid transfusion and hemolysis, embarrassment of venous return from retraction, or precipitous drops in intra-abdominal pressure and consequent venous pooling also contribute to hemodynamic instability. During sudden volume shifts, previously asymptomatic pericardial effusions may reduce cardiac output, so they are often drained under direct vision. Hemorrhage may be exacerbated by clotting factor deficiencies or hemodilution, and fibrinolysis.⁸² These defects should be treated as specifically as is feasible using either conventional studies (prothrombin time, partial thromboplastin time, bleeding time, fibrinogen, fibrin split product levels, and platelet count) or thromboelastography. At the University of Pittsburgh, a rapid infusion system designed to deliver prewarmed fluids or blood products at a rate of up to $1.5 \text{ l} \cdot \text{min}^{-1}$ is routinely used (Fig. 52-3). Line pressure monitors, filters, air detectors, and fluid-level sensors are built into the device to minimize trauma to the blood and to prevent transfusion of air. Blood salvaging (“autotransfusion”) systems, which collect and wash extravasated blood, are also used, provided that there is no active infection or malignancy.

Figure 52-3. Rapid infusion system used during liver transplantation at the University of Pittsburgh. (Reprinted with permission from Kang YG, Martin DJ, Marquez J et al: Intraoperative changes in blood coagulation and thromboelastographic monitoring in liver transplantation. *Anesth Analg* 64:888, 1985.)

Metabolic acidosis may accompany hypotension and persist in the absence of hepatic metabolic function. Sodium bicarbonate is used for treatment, although if acidosis is severe, THAM (tromethamine [tris(hydroxymethyl)aminomethane]) is an alternative that avoids hyperosmolar hypernatremia.⁷⁵ Oliguria is also common in this phase, and once prerenal causes are ruled out, aggressive treatment with osmotic or potent loop diuretics, as well as renal-dose dopamine ($2.5 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$), is begun.

The anhepatic stage begins when the native diseased liver is removed after transection of its blood supply (hepatic artery and portal vein) as well as occlusion of the suprahepatic and infrahepatic portions of the IVC. If large esophageal varices seem at high risk for rupturing during IVC clamping, a Sengstaken-Blakemore tube may be placed temporarily. To avoid drastic decreases in venous return and cardiac output, as well as venous congestion in the lower body, bowel, and kidneys, many centers use a venovenous bypass system.⁸³ The venovenous circuit drains blood from the portal and femoral veins and routes it extracorporeally to the axillary vein. A centrifugal pump propels blood through the circuit at a flow rate 20–50% of usual total systemic flow. The circuit makes use of heparin-bonded tubing, which at the flow rates typically used obviates the need for systemic heparinization. Although venous bypass may help to preserve renal function,⁸³ it may not improve overall morbidity and mortality⁸⁴ and can lead to venous air embolism⁸⁵ and thrombosis. The use of venous bypass can also prolong the procedure and contribute to heat loss.⁸⁶ Moreover, support of cardiac output with positive inotropes may still be required.

Removal of the native liver and implantation of the allograft usually require vigorous retraction near the diaphragm, decreasing respiratory compliance and causing atelectasis and hypoventilation. Adding PEEP and raising inspiratory pressures may help minimize these effects. Because of the lack of liver metabolic function during the anhepatic phase, citrate intoxication from rapid transfusion is a more likely possibility, and calcium must be infused to maintain the ionized calcium level above $1.0 \text{ mmol} \cdot \text{l}^{-1}$. Calcium chloride is often chosen, but even in the absence of hepatic function, calcium gluconate has effectively treated ionized hypocalcemia.⁸⁷ Progressive hyperkalemia may be treated with an insulin infusion, despite the absence of liver, but metabolic acids, including lactate, remain largely uncleared during the anhepatic period.

The neohepatic or postreperfusion stage begins with reanastomoses of the major vascular structures. Before removal of all clamps, the allograft is flushed of air, debris, and preservative solution with blood released from the portal vein. Despite this, subsequent final unclamping can cause release of a large load of potassium and metabolic acids into the circulation.⁸⁸ Dysrhythmias, hypotension, and cardiac arrest may ensue, and the anesthesiologist should be prepared to treat the underlying metabolic causes specifically. Inotropic support may be needed to treat hypotension stemming from myocardial depression by putative vasoactive mediators,⁷⁶ or right heart failure from venous air embolism.^{89,90} Appearance of significant end-tidal nitrogen from venous air embolism by mass spectroscopy is useful to differentiate between these alternatives. Pulmonary thromboembolism has also been reported to be a cause of cardiovascular collapse during reperfusion.^{90,91}

Once the allograft begins to function, hemodynamic and metabolic stability is gradually restored.⁸⁰ The need for inotropic support usually diminishes, and urine output improves even in patients with prior hepatorenal syndrome.⁹² Clotting parameters can usually be normalized with specific replacement therapy, and fibrinolysis controlled with, e-aminocaproate (Amicar). The procedure ends with some form of biliary reconstruction, either direct bile duct anastomosis or a Roux-en-Y choledochojejunostomy (Fig. 52-4).

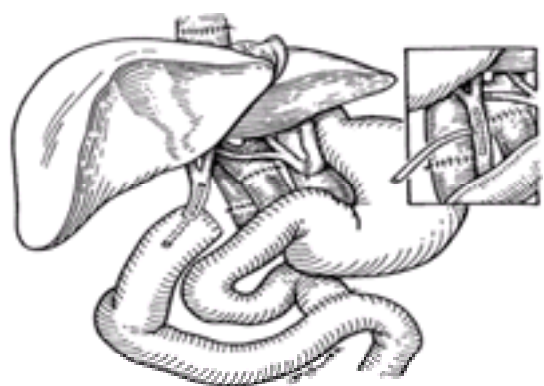

Figure 52-4. Biliary reconstruction after orthotopic liver transplantation. Biliary drainage can be accomplished via a Roux-en-Y (choledochojejunostomy) or “duct-to-duct” anastomosis (*inset*). (Reprinted with permission from Starzl TE, Demetris AJ, van Thiel DH: Liver transplantation. *N Engl J Med* 321:1014, 1092, 1989.)

Postoperative Management

In a well-functioning allograft, metabolic acids, including lactate, continue to be metabolized and systemic alkalosis may result. Meticulous postoperative pulmonary toilet is vital and may be complicated by injury to the diaphragm, nosocomial pneumonia, adult respiratory distress syndrome from massive transfusion, and weakness from nutritional deficiencies. Primary nonfunction of the allograft is now a rare complication of liver transplantation, perhaps because of the widespread use of UW solution for preservation. Recovery from primary nonfunction has occurred, but most often retransplantation has been necessary.

The full immunosuppression regimen of cyclosporine or tacrolimus, azathioprine, and prednisone is begun in the early postoperative period, yet rejection episodes are still common and may be treated with the monoclonal antibody OKT3. Other complications include biliary or vascular anastomotic leaks, abdominal abscesses, and thrombosis of the hepatic artery or portal vein. As in other patients on long-term immunosuppression with cyclosporine, recipients are also at risk for development of lymphoproliferative malignancies and opportunistic infections (see [Evaluation of Patients With a Prior Organ Transplant](#)). Cases of transplantation for hepatitis B or neoplasms may also be complicated by recurrence of the original disease.⁹³

HEART TRANSPLANTATION

It is estimated that as many as 14,000 patients per year in the United States alone could benefit from heart transplantation.⁹⁴ However, after rapid growth in the mid-1980s, the number of heart transplantations per year has now reached a plateau of approximately 3000 cases worldwide because of the limited availability of donor organs. The orthotopic procedure has accounted for the overwhelming majority of cases.⁹⁵

Growth in heart transplantation has been encouraged by dramatic increases in survival. Before the introduction of cyclosporine, the 1-year survival rate was approximately 40%. In the 1990s, cyclosporine, coupled with intensive immunologic surveillance by endomyocardial biopsy and aggressive antirejection treatment with lymphocyte-specific monoclonal antibodies, has boosted overall survival rates of orthotopic transplant recipients worldwide to >80% at 1 year, and >70% at 5 years.⁹⁵ Individual centers have reported survival rates to be as high as 90% at 4 years.⁹⁶ Other outcome variables, such as patients' quality of life, are favorable as well.

Pathophysiology of End-Stage Heart Disease

End-stage heart disease may result from either congenital or acquired diseases of the heart or vascular system. The leading causes include ischemic and valvular disease and primary cardiomyopathy. Depending on the cause, a varying period of physiologic adaptation precedes the onset of decompensation, which is usually manifested by congestive heart failure. Once this symptom is present, the overall 5-year survival rate is less than 50%, although patients with rapidly progressive symptoms seem even less likely to survive.⁹⁷ Dysrhythmias and laboratory evidence of pump failure (e.g., low ejection fraction) are also associated with a relatively poorer prognosis.

As the left ventricle fails, the main compensatory mechanism is an increase in left ventricular end diastolic volume, which enhances resting myocardial fiber length and promotes more effective fiber shortening. Such changes restore stroke volume, at the cost of increasing left atrial pressure and producing pulmonary venous congestion. Other compensations include elevation in catecholamines and increased renin production, resulting in salt and water retention.

Progression of the underlying pathophysiologic process eventually reduces ejection fraction and results in severe congestive heart failure refractory to conventional drug therapy. At this point, some patients may still be ambulatory but have little functional reserve; others are not ambulatory because of dyspnea or dependence on iv inotropes, mechanical circulatory support, or mechanical ventilation. Protracted periods of low cardiac output compromise other vital organ functions (e.g., passive congestion of the liver and prerenal azotemia) and may culminate in inadequate perfusion to the heart itself, initiating a final, irreversible downward spiral. Patients may enter a transplant program during any of these stages, or even after mechanical circulatory support with an intra-aortic balloon or ventricular assist device becomes necessary. Interestingly, survival rates remain relatively high in patients requiring mechanical circulatory support as a bridge to transplantation,⁹⁸ even in those receiving a temporary artificial heart.⁹⁹

Specific Indications and Contraindications

The indication for heart transplantation is fulfilled when New York Heart Association Class IV status (severely compromised) and prognosis (guarded despite therapy) persist despite maximal medical therapy. The typical candidate is a 40–60-year-old man with a pretransplantation diagnosis of ischemic cardiomyopathy and left ventricular ejection fraction of <20%. The other common diagnoses are idiopathic cardiomyopathy and viral cardiomyopathy, and end-stage congenital heart disease accounts for the remainder. In the latter group, the congenital defect is often associated with a cardiomyopathy secondary to long-standing cyanosis or myocardial hypertrophy, making further palliation impossible.¹⁰⁰

The list of contraindications has undergone considerable evolution in the last decade and will probably continue to do so. For example, the upper age limit was formerly 50 years. However, substantial numbers of older patients have now undergone this procedure without disproportionate morbidity, and, as a consequence, "physiologic" rather than chronologic age is now emphasized when deciding on candidacy. Diabetes mellitus had also been an absolute contraindication; however, it now seems that even insulin-dependent diabetic patients can be successfully immunosuppressed without the aid of steroids, and short-term results seem favorable. A history of cancer was once an absolute contraindication as well, but strict exclusion on this basis became obsolete as true long-term cures for certain malignancies (e.g., Hodgkin's lymphoma) were demonstrated. The presence of certain systemic diseases may also contraindicate heart transplantation; for example, the cardiomyopathy accompanying sarcoidosis could respond to medical therapy, and amyloidosis might recur in the donor organ.

Severe, irreversible pulmonary hypertension remains one of the few absolute contraindications to orthotopic heart transplantation because the right ventricle of a normal donor heart is unable acutely to cope with a markedly elevated, fixed pulmonary vascular resistance and rapidly decompensates.¹⁰¹ The precise level of pulmonary hypertension deemed unacceptable is still a matter of debate: the traditional values are 6–8 Wood units (6–8 mm Hg [l · min⁻¹], or in metric resistance units, 480–640 dyne · s⁻¹ · cm⁻⁵), or a transpulmonary gradient (mean pulmonary artery pressure—mean pulmonary capillary wedge pressure) of 10–15 mm Hg. If irreversible pulmonary hypertension is present, heterotopic heart transplantation is one option, although more recently, as long as suitable organs are available, heart–lung transplantation is preferred.

Preanesthetic Considerations

Given the candidacy criteria, the recipient's other vital organs are usually not seriously impaired. However, low cardiac output may lead to chronic passive liver congestion and oliguria, and there may be corresponding physical signs and abnormal laboratory values (Table 52-11).

| Organ System | Consequence |
|-----------------|--|
| Pulmonary | Pulmonary venous congestion Interstitial edema |
| Renal | Prerenal azotemia Oliguria |
| Hepatic | Chronic passive congestion Hepatomegaly |
| Central nervous | Asotemia |
| Endocrine | Confusion (low cardiac output) Elevated serum catecholamines Elevated renin levels |

TABLE 52-11. PATHOPHYSIOLOGIC CONSEQUENCES OF DILATED CARDIOMYOPATHY

Candidates for heart transplantation are usually maintained on oral or iv inotropes (e.g., digoxin, amrinone), vasodilators (captopril, amrinone), and diuretics, and, when appropriate, antidysrhythmics. Patients with large, dilated hearts and low cardiac output are prone to form intracardiac thrombi and therefore are anticoagulated with warfarin. In such cases, fresh-frozen plasma is required after cardiopulmonary bypass, and appropriate arrangements should be made before induction. Blood products should be CMV free for patients without antibody evidence of prior exposure, considering the likelihood and morbidity of CMV sepsis in immunosuppressed recipients.¹⁰² Bacterial pneumonia is relatively common early after heart transplantation,¹⁰³ so preparation of the anesthesia machine with a fresh, sterile breathing circuit and bacterial filter seems prudent. It has not been found necessary to sterilize tracheal intubation equipment, although at most institutions, factory-sterilized disposable endotracheal tubes are standard.

Some transplantation candidates have previously undergone coronary bypass or other thoracic or mediastinal procedures. If so, they are likely to require more than the usual time for insertion of vascular catheters and cannulation for cardiopulmonary bypass. To avoid unnecessary prolongation of donor organ ischemic times, the surgical and anesthesia teams must factor in these potential sources of delay.

Donor Procedure and Related Considerations

Cardiac harvesting is best done simultaneously with the harvesting of abdominal viscera. This approach, which involves local perfusion with preservative solutions after cross-clamping the abdominal and thoracic aortae, avoids inadvertent cardiac arrest before cardiectomy and damage to the allograft. Donor cardiectomy begins with pericardiotomy; after which the epicardial coronary arteries are grossly palpated for plaques. The aorta and both venae cavae are dissected, and after systemic

heparinization, the superior vena cava is ligated and the IVC and a pulmonary vein are transected. The heart is then exsanguinated, and cardioplegia is administered through the aortic root. After cardiac arrest the aorta is cross-clamped, the heart is topically cooled, and the remaining pulmonary veins are individually transected. Finally, the great arteries are divided, and the heart is rinsed and examined for a patent foramen ovale or valvular lesions and then placed in a sterile plastic bag containing cold saline, which, in turn, is placed inside an insulated cooler. In laboratory studies, hearts have been preserved for as long as 24 hours with excellent subsequent graft function. Currently, however, the generally accepted limit on human donor heart ischemic time (measured from the time the cross-clamp is applied, to the time of cross-clamp removal after implantation) is 4–6 hours.^{25,104} In view of this limited duration, the only immunologic matching performed prospectively is ABO compatibility.

Cardiac trauma, cardiac arrest, hypoxemia, and excessive requirement for exogenous catecholamines may render a potential donor's heart unacceptable for transplantation. However, as long as there is echocardiographic evidence of good contractility, such criteria do not necessarily mandate exclusion.¹⁰⁵ In most transplantation centers, there is no absolute age limit for eligibility as a heart donor, but in donors older than 40 years, careful physical examination at the time of harvest is essential to avoid transplanting organs with significant coronary lesions.

Anesthesia Induction

Candidates are often on the transplant list for extended periods and build up considerable apprehension. Despite this, preoperative sedation must be used judiciously because residual cardiac performance depends on elevated endogenous catecholamines. The monitoring regimen used by most heart transplantation centers includes intra-arterial and pulmonary artery pressure monitoring. Although avoidance of sepsis is important, conventional aseptic techniques for catheter insertions have proved to be sufficient.¹⁰⁶ At the University of Pittsburgh, pulmonary artery catheterization is routinely performed through the right internal jugular vein and does not seem to jeopardize access for future endomyocardial biopsies. Correct pulmonary artery catheter positioning is often more difficult in this population owing to severe orthopnea (necessitating a semisitting position), cardiac dilatation (promoting intraventricular coiling), tricuspid regurgitation, atrial fibrillation or other arrhythmias, or congenital vascular anomaly. Once the catheter is placed, a long, sterile sheath is always used because this catheter is pulled back to "central venous pressure position" before caval cannulation.

Whether already in the hospital or newly admitted through the emergency department, most of these patients have recently eaten and thus require rapid inductions. There have been numerous descriptions of anesthetic techniques under these circumstances,^{107,108} and ¹⁰⁹ all based on agents compatible with the pathophysiology of end-stage heart disease. In one study of induction regimens, a combination of etomidate $0.3 \text{ mg} \cdot \text{kg}^{-1}$, fentanyl $10 \mu\text{g} \cdot \text{kg}^{-1}$, and succinylcholine $1.5 \text{ mg} \cdot \text{kg}^{-1}$ iv was shown rapidly to produce adequate intubating conditions without significant cardiovascular depression.¹¹⁰ Anesthesia can then be maintained using a regimen compatible with extremely poor ventricular function (e.g., O_2 -fentanyl $35\text{--}75 \mu\text{g} \cdot \text{kg}^{-1}$ iv [total] + scopolamine 0.3 mg iv).

After induction, tracheal intubation is accomplished without specially sterilized laryngoscopy equipment, and broad-spectrum prophylactic antibiotics and the immunosuppressant azathioprine are infused. Patients with end-stage heart disease are often exquisitely sensitive to changes in preload or afterload; thus, hypotension may stem from relatively small degrees of hypovolemia or alterations in systemic vascular resistance. Because one or both ventricles are usually extremely noncompliant, filling pressures may not accurately reflect intracavitary volumes, so transesophageal echocardiography can be especially helpful in maintaining cardiovascular stability.

Surgery and Cardiopulmonary Bypass

In the prepump phase of the orthotopic procedure, manipulation of the heart is minimized to avoid dislodging any intracardiac thrombi. After individual cannulation of the venae cavae as well as the aorta, cardiopulmonary bypass is initiated and patients are cooled as for conventional cardiac procedures ($26\text{--}30^\circ\text{C}$). During cooling the diseased heart is excised, leaving an atrial cuff containing the caval and pulmonary venous orifices and long remnants of the aorta and pulmonary artery. The donor heart's back wall (atrium) is trimmed appropriately, then anastomosed with the recipient's atrial remnant. Special care must be taken to keep the anterior wall of the donor heart cold even during posterior wall anastomosis because warming may contribute to poor right ventricular function later. The heart is then filled with cold saline to displace most of the air, the aorta is anastomosed, and after de-airing once again, the cross-clamp is removed (ending the ischemic time). Often electromechanical activity resumes spontaneously and, finally, the pulmonary artery anastomosis is completed (Fig. 52-5). A more recently introduced variation, the complete atrioventricular heart transplantation operation, involves bicaval anastomoses with preservation of the entire donor atria. The principal advantage seems to be a lower prevalence of tricuspid regurgitation.¹¹¹

Figure 52-5. Sites of anastomoses after the mid-atrial excision orthotopic cardiac transplantation procedure. (Reprinted with permission from Reitz BA, Fowles RE, Ream AK: Cardiac transplantation. In Ream AK, Fogdall RP [eds]: Acute Cardiovascular Management, p 549. Philadelphia, JB Lippincott, 1982.)

For the heterotopic procedure (Fig. 52-6), after sternotomy, a right pleuropericardial flap is created. When cardiopulmonary bypass is initiated, the native heart undergoes cardioplegic arrest for myocardial protection, and the donor heart is placed in the right thorax anterior to the compressed lung. The donor and recipient superior venae cavae and right atria are incised and sutured together, and the donor's aorta is sutured end-to-side to the recipient's ascending aorta. The donor's pulmonary artery is then connected to the recipient's main pulmonary artery by means of a Dacron graft.

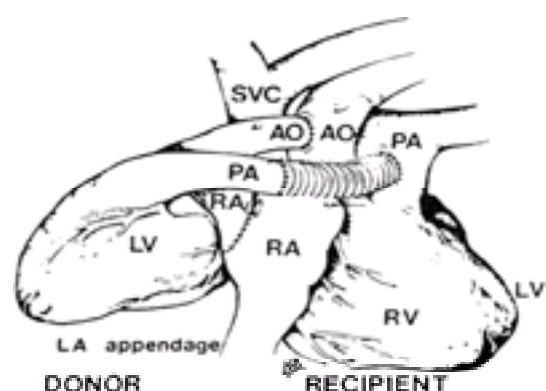

Figure 52-6. Heterotopic transplantation of a donor heart. Abbreviations are standard. (Reprinted with permission from Cooper DKC, Lanza LP: Heart Transplantation: The Present Status of Orthotopic and Heterotopic Heart Transplantation. Lancaster, United Kingdom MTP Press, 1984.)

Because many patients with end-stage heart disease are maintained on diuretics, mannitol or furosemide may be necessary to maintain a urine flow. In some cases, these patients may have markedly expanded blood volumes and benefit from hemoconcentration on bypass. At many centers, just before release of the aortic cross-clamp, to reduce the possibility of hyperacute immune response, methylprednisolone $500\text{--}1000 \text{ mg}$ iv is administered. Immediately after release of the aortic cross-clamp, slow junctional rhythms or arteriovenous nodal dysfunction is relatively common. An infusion of either isoproterenol or another catecholamine with positive chronotropic effects is often begun temporarily to support heart rate. Most of these dysrhythmias resolve, but a small percentage do persist after surgery, even in the

absence of rejection. Ultimately, approximately 5% of recipients require implantation of a permanent pacemaker, although the balance of survivors do not seem particularly prone to other serious dysrhythmias.

Immediately before weaning from cardiopulmonary bypass, the posterior anastomosis is rechecked because leaks in this area are difficult to repair later. After final de-airing, the superior vena caval cannula is removed, the pulmonary artery catheter advanced and repositioned, and the serum ionized calcium restored to normal. If heart rate is less than 60–70 beats · min⁻¹, epicardial electrodes are placed and pacing is begun.

Cardiac performance is often mildly compromised immediately after heart transplantation, and many transplantation centers routinely use inotropic infusions to wean patients from cardiopulmonary bypass. Although there have been reports of exaggerated effects, in practice, responses to catecholamine infusions seem qualitatively similar to those in other cardiac surgical patients.¹¹² Further discussion of the physiology and pharmacology of cardiac denervation is found in Evaluation of the Patient With a Prior Organ Transplant.

Markedly elevated pulmonary vascular resistance is a contraindication to orthotopic transplantation, but transient pulmonary vasospasm can occur during weaning, even in patients with previously normal pulmonary artery pressures, producing life-threatening right heart failure. Prostaglandin E₁ (PGE₁), at infusion rates of between 0.025 and 0.2 mg · kg⁻¹ · min⁻¹, has been shown effectively to unload the right heart,¹¹³ although simultaneous norepinephrine or phenylephrine infusion may be required to support systemic vascular resistance. Elevated pulmonary vascular resistance often falls within hours of the procedure,¹¹⁴ allowing PGE₁ infusions to be discontinued, but as a last resort, mechanical right ventricular assist has been used for varying periods with success.¹¹⁵

Postoperative Management

The short-term management goals in the intensive care unit include cardiovascular support and prevention of rejection and infection.¹⁰³ Most patients receive triple immunosuppression (cyclosporine–azathioprine–prednisone)⁹⁵ and, at some centers, OKT3. The sources of fever or pulmonary infiltrates are sought aggressively. Early in the postoperative period, bacterial pneumonias with typical nosocomial organisms are encountered. Later, opportunistic infection with CMV, *Pneumocystis*, or *Legionella*¹¹⁶ may occur, and transbronchoscopic brushing may be necessary to establish the etiology. There may be bradydysrhythmias or atrioventricular block in this period, with temporary pacing required. Persistently low cardiac output may result from rejection or from reperfusion injury, and endomyocardial biopsy may be the only means to establish the diagnosis.

Excessive mediastinal bleeding and coagulopathy may be encountered in patients who had previously undergone a cardiac surgical procedure, and are treated in the conventional fashion. If hemodynamic stability is maintained, evidence of mild organ compromise present before transplantation will gradually disappear. If, however, the transplanted heart functions poorly, organs with preoperative impairment may rapidly decompensate.

HEART–LUNG TRANSPLANTATION

Heart–lung transplantation is the procedure of choice for patients with end-stage lung disease complicated by irreversible right ventricular failure, or end-stage congenital heart disease with secondary pulmonary vascular involvement (Eisenmenger's syndrome). Specific pathologic diagnoses in recipients have included primary pulmonary hypertension, emphysema, multiple pulmonary emboli, cystic fibrosis, and granulomatous and fibrotic diseases of the lung. Suitable donor blocs are in extremely short supply because both the lungs and heart must fulfill the criteria for acceptability (see [Other Viscera Transplantation Procedures](#)). Such blocs consist of the entire heart and lungs, including a tracheal segment long enough to facilitate anastomosis. Distal procurement is made feasible by flushing the harvested bloc with modified Euro-Collins or UW solution, to which PGE₁ or other pulmonary vasodilators may be added.

Considerations for monitoring and induction of anesthesia are in general similar to those for heart transplantation, but air trapping during ventilation and pulmonary hypertension are additional factors that may lead to hemodynamic instability. Difficulty with the airway during induction can result in hypercarbia or hypoxia and further elevate pulmonary vascular resistance. Patients with congenital heart disease may have bidirectional intracardiac shunts, which can become predominantly right-to-left and lead to profound hypoxemia. Such shunts may also lead to paradoxical air emboli, so bubbles in iv tubing should be scrupulously avoided. Chronically cyanotic patients are often severely polycythemic (hematocrit >60%) and manifest clotting derangements. Under these circumstances, phlebotomy and hemodilution are beneficial. In all recipients, large-sized endotracheal tubes are preferred to facilitate therapeutic bronchoscopies.

In the prebypass phase, surgical dissections may be complicated by extensive pleural adhesions; however, once on bypass, *en bloc* implantation is relatively straightforward and accomplished by sequential tracheal (or bibronchial), right atrial, and aortic anastomoses. The phrenic, vagus, and recurrent laryngeal nerves may be damaged by both dissection and topical cooling, and must be protected. The tracheal anastomosis usually involves some technique to prevent dehiscence, such as a “telescope” anastomosis or wrapping the suture line with vascularized omentum. Re-expansion of transplanted lungs may require bronchoscopy to relieve mechanical obstruction by secretions; occasionally, bronchodilators are useful to treat bronchospasm. Because of the extensive mediastinal and pleural dissection, the early postbypass period may be complicated by hemorrhage leading to coagulopathy. Pulmonary compliance and gas exchange may deteriorate during this time because of pulmonary hemorrhage or inadequate preservation, and the use of PEEP is often required.

After surgery, rejection episodes are relatively common and are characterized by infiltrates, fever, and deteriorating gas exchange. Pulmonary allografts may be rejected without significant abnormalities in endomyocardial specimens,¹¹⁷ so low cardiac output is not necessarily a symptom of rejection. Recipients are also highly susceptible to bacterial pneumonia, which presents with the same clinical picture as rejection; bronchoalveolar lavage or transbronchial biopsy may be necessary for definitive diagnosis. A dreaded problem soon after heart–lung transplantation is dehiscence of the tracheal or bronchial suture lines, which can lead to fatal mediastinitis. Later, bronchiolitis obliterans develops in a significant proportion of survivors. The etiology is unknown, but this condition is associated with a progressive decline in exercise tolerance. Bronchiolitis obliterans and the physiology of transplanted lungs are discussed further in [Other Viscera Transplantation Procedures](#).

In the future, heart–lung transplantation will probably have even fewer indications, as experience with isolated lung transplantation accumulates. The latter operation will then be used in patients with end-stage lung disease before right ventricular failure becomes irreversible and necessitates the combined heart–lung procedure.

LUNG TRANSPLANTATION

End-stage lung disease from destruction of the pulmonary parenchyma or vasculature is a leading cause of disability and death among adults. Several lung transplantation operations have been developed to treat end-stage lung disease, each having certain conceptual and practical advantages. These include the heart–lung, *en bloc* double-lung, single-lung, and bilateral sequential single-lung procedures. In the setting of chronically elevated pulmonary vascular resistance with right ventricular failure, heart–lung transplantation usually is chosen. However, when cardiac performance is preserved, isolated lung transplantation has been shown to be of benefit to carefully selected patients with end-stage lung disease¹¹⁸ ([Table 52-12](#)).

| Diagnosis | No. |
|---------------------------------------|-----|
| Chronic obstructive pulmonary disease | 20 |
| α_1 -Antitrypsin deficiency | 19 |
| Cystic fibrosis | 8 |
| Pulmonary hypertension | 8 |
| Pulmonary fibrosis | 7 |
| Bronchiectasis | 2 |
| Eosinophilic granuloma | 1 |
| Lymphangiomyomatosis | 1 |

* Data derived from 66 consecutive patients who underwent lung transplantation at Barnes Hospital, St Louis, between July 1988 and January 1991. Adapted with permission from Trulock EP, Cooper JD, Kaiser LR et al: The Washington University–Barnes Hospital experience with lung transplantation. *JAMA* 266:1943, 1991.

TABLE 52-12. PATHOLOGIC DIAGNOSES IN LUNG TRANSPLANT RECIPIENTS

End-stage pulmonary parenchymal diseases are either restrictive, obstructive, or infectious. Briefly, restrictive lung diseases are characterized by interstitial fibrosis with a loss of lung elasticity and compliance. Most fibrotic diseases are idiopathic, but they may also be caused by an inhalation injury or immune process. Interstitial lung disease may affect the blood vessels as well, so pulmonary hypertension is often found. Functionally, diseases in this category are associated with diminished lung volumes and diffusion capacity, but preserved air flow rates. Respiratory muscle strength is usually excellent because the work of breathing is chronically elevated. The

most common cause of end-stage obstructive lung disease is smoking-induced emphysema, but other causes include asthma and several comparatively rare congenital disorders. Among these, α_1 -antitrypsin deficiency is associated with severe bullous emphysema in the fourth or fifth decade of life. With obstructive diseases, airway resistance is elevated, expiratory flow rates are diminished, air trapping may be prominent, and ventilation–perfusion mismatching severe. The common infectious etiologies of end-stage lung disease include cystic fibrosis and bronchiectasis. Cystic fibrosis, which occurs in 1 of every 2000 live births in the United States, produces mucus plugging of peripheral airways, chronic bronchitis, and bronchiectasis. Smoking and environmental exposures may also lead to bronchiectasis. End-stage pulmonary vascular disease may be a consequence of primary pulmonary hypertension, which is a relatively rare disease of unknown etiology characterized by marked elevation of pulmonary vascular resistance from hyperplasia of the muscular pulmonary arteries and fibrosis of smaller arterioles. Congenital heart disease with Eisenmenger's syndrome, and diffuse arteriovenous malformations, are other causes of destruction of the pulmonary arterial bed.

The general indications for transplantation with any of the end-stage lung diseases are progressive exercise intolerance, increasing oxygen requirements, and carbon dioxide retention. Other factors favoring the transplantation option are recurrent need for phlebotomy and increasing physical and social debilitation. The timing of surgery depends on the rate of functional deterioration and ability of the right ventricle to tolerate the progression of pulmonary hypertension. Considering the limited supply of donor organs, specific contraindications to lung transplantation include severe debilitation, neuromuscular disease, or mechanical ventilator dependence (because respiratory muscle strength is crucial to recovery); severe chest deformity or pleural disease (complicating surgical procedures and postoperative ventilation); advanced right ventricular failure; or glucocorticoid dependence (because healing of airway anastomoses is impeded by steroids).

The choice of lung transplantation procedure is based largely on the consequences of leaving the native lung *in situ*. For example, single-lung transplantation is not an option if infection or severe bullous emphysema is present in the contralateral lung. Infection would cross-contaminate the healthy transplanted lung, and severe bullous disease in the native lung could lead to gross ventilation–perfusion mismatching and shifting of the mediastinum. Instead, double-lung transplantation would be chosen for such cases. Similarly, double-lung transplantation may also lead to better functional outcomes in the treatment of end-stage pulmonary hypertension.^{118,119} The other major factor influencing the choice of procedure is the relative rate of perioperative complications. For example, single-lung transplantation is feasible without cardiopulmonary bypass and is seldom complicated by bleeding diatheses. In contrast, *en bloc* double-lung transplantation mandates cardiopulmonary bypass with full systemic heparinization and extensive mediastinal dissection—both risk factors for development of postoperative coagulation defects. Another advantage of single-lung transplantation is that it makes use of bronchial anastomoses, which heal with significantly fewer complications than the tracheal repairs typical of the *en bloc* double-lung procedure. Bilateral sequential lung transplantation, an alternative to *en bloc* double-lung transplantation, combines advantages by using bibronchial anastomoses and avoiding cardiopulmonary bypass.

Donor Lungs

Donor lungs may be jeopardized by massive fluid resuscitation, aspiration, contusion, and exposure to nonphysiologic oxygen tensions because most organ donors are trauma victims. Ideally, the donor's history should indicate early tracheal intubation with no evidence of aspiration, minimal fluid administration in the course of resuscitation, and absence of chest tubes, pleural diseases, or tracheostomy at any time. Suitable donors should have a minimal alveolar–arterial O_2 gradient (*i.e.*, a PaO_2 of >400 mm Hg while breathing 100% O_2 , or 100 mm Hg on 40% $O_2/5$ cm H_2O PEEP), as well as a clear chest radiograph and sputum examination within 2 hours of harvesting.¹²⁰ If bronchoscopy fails to elucidate any pathologic process, iv glucocorticoids and antibiotics are administered and the lungs harvested. Because both the heart and lungs may be harvested from the same donor, a method has been developed for cardiectomy without jeopardizing the use of the lungs.¹²¹ First, the heart is removed, but a cuff of left atrium is left attached to the donor lungs. The trachea is then stapled and divided at its midpoint, and the lungs removed *en bloc* and immersed in cold preservative solution. In some centers, before removal, the donor is treated with a pulmonary vasodilator (*e.g.*, PGE_1) to improve the distribution of a large volume of either a blood-based or intracellular-type cold crystalloid preservative solution, infused through the pulmonary artery. Finally, the lungs may be inflated before immersion in preservative solution and stored for transportation.

Preanesthetic Considerations

Preanesthetic considerations for lung recipients have been described.^{122,123,124} and ¹²⁵ Briefly, size matching is achieved by comparing the vertical and transverse radiologic chest dimensions of the donor and recipient. Organs are also matched on the basis of ABO compatibility, but because the need for histocompatibility is still unknown and the tolerable ischemic time for the lung is relatively short (approximately 4 hours), HLA matching is done only in retrospect. Preoperative pulmonary function and right heart catheterization studies, ventilation–perfusion scans, and arterial blood gas values are helpful to predict the difficulties likely to be encountered during and after induction. For example, diminished expiratory flow rates and air trapping may exacerbate hypoxemia and hypercapnia and lead to hemodynamic instability during mask ventilation and after tracheal intubation. Elevated pulmonary artery pressures may indicate a likelihood that cardiopulmonary bypass will be necessary because right ventricular failure can suddenly result when one-lung ventilation or ligation of a pulmonary artery is begun. Even in the absence of pulmonary hypertension, many centers recommend “pump standby” for these cases because gas exchange is so precarious. Clearly, both systemic and pulmonary arterial pressure monitoring are vital during lung transplantation procedures, although profound dyspnea may make internal jugular cannulation difficult before induction. Pulmonary artery catheters should be inserted through a sterile sleeve to allow withdrawal during the anastomosis and subsequent repositioning. Finally, candidates may have recently undergone weaning from glucocorticoids, but “stress doses” are avoided in the perioperative period to protect from systemic sepsis or suture line dehiscence.

Single-Lung Transplantation

The single-lung transplantation procedure involves pneumonectomy and implantation of a new lung, sometimes preceded by mobilization of omentum with its vascular pedicle for bronchial wrapping. If the native lungs are equally impaired and no pleural scarring is present, the left lung is often chosen for transplantation for technical reasons: the native right pulmonary veins are less accessible than those on the left, the recipient's left bronchus is longer, and the left hemithorax can more easily accommodate a somewhat oversized donor lung. Most surgeons prefer that the lung to be removed is collapsed during dissection; both bronchial blockers and double-lumen endobronchial tubes have been used for this purpose. Because the right upper lobe bronchial orifice is relatively close to the origin of the mainstem bronchus, left-sided endobronchial double-lumen tubes have been recommended for both right and left single-lung transplants as well as for the bilateral sequential operation.

For the induction of anesthesia by the rapid-sequence technique, drugs that do not release histamine or depress the myocardium are usually preferred (*e.g.*, etomidate, vecuronium). Nitrous oxide is avoided in patients with bullae or elevated pulmonary vascular resistance and when 100% oxygen is needed to maintain acceptable arterial saturation. Both high-dose opioids and potent inhaled agents, supplemented with long-acting relaxants, have been used successfully for the maintenance of anesthesia. With the onset of one-lung ventilation, acute deterioration in gas exchange or hemodynamics is the rule. Strategies for improving oxygenation under these circumstances, discussed in detail in [Chapter 30](#), include the use of PEEP in the dependent lung, continuous positive airway pressure or high-frequency ventilation in the nondependent lung, or ligation of the (nondependent) pulmonary artery. If pulmonary artery pressures rise sharply at this point, right ventricular failure may ensue. Vasodilators or inotropes may diminish right heart strain; if not, one-lung ventilation should be abandoned. Similarly, if hemodynamics or systemic arterial saturations deteriorate when the pulmonary artery is clamped in anticipation of pneumonectomy, cardiopulmonary bypass may be necessary.

Immediately before implantation, the donor lung is trimmed to match the size of the recipient bronchus, branch pulmonary artery, and atrial cuff containing the orifices of the pulmonary veins. While attempting to keep the allograft cold, the atrial, pulmonary artery, and bronchial anastomoses are completed in sequence. The circulation is then restored to the donor lung, ending the ischemic interval, but until ventilation to the allograft is restarted, systemic arterial saturation suffers. Flexible bronchoscopy is prudent at this stage to visualize the anastomosis directly or reinflate the allograft by removing secretions or blood from the airway. Once the anastomosis is secure, a pedicle of omentum with its blood supply intact may be brought into the chest and wrapped around the bronchial anastomosis. Finally, after the chest is closed, the supine position can be restored and the endobronchial tube exchanged for a standard endotracheal type (except if “split” ventilation is planned).

Double-Lung Transplantation

Double-lung transplantation is most often used in patients with primary pulmonary hypertension or cystic fibrosis. The *en bloc* operation is performed in the supine position, and because both lungs are replaced at once, cardiopulmonary bypass is mandatory. Cardioplegic arrest is used to accomplish anastomosis of the left atrial cuff containing all four pulmonary venous orifices. The airway is typically interrupted at the level of the trachea, so a standard endotracheal tube is suitable. Because systemic arterial supply to the trachea is permanently interrupted, an omental wrap may be added. The extensive retrocardiac dissection required often leads to cardiac denervation and postoperative bleeding that is difficult to control.¹²⁶

Bilateral sequential single-lung transplantation was introduced to treat the same spectrum of patients as the *en bloc* procedure but obviates the need for cardiopulmonary bypass and tracheal anastomosis. Access to the hilar structures is gained in the supine position through a rather extensive incision that includes a transverse sternotomy (“clamshell” incision; [Fig. 52-7](#)). Another relative disadvantage is that serial implantation results in a longer ischemic time for the second allograft.

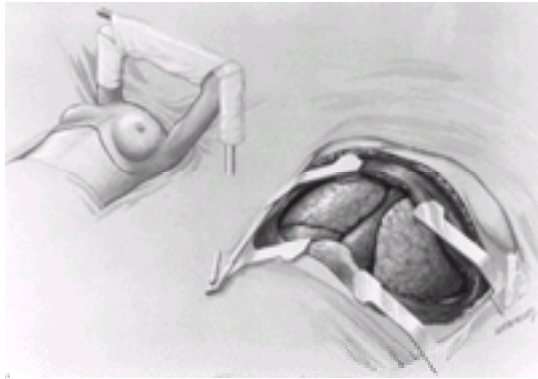

Figure 52-7. Positioning and surgical approach for bilateral sequential lung transplantation. The incision consists of bilateral anterior thoracotomies with a transverse sternotomy. After insertion of vascular catheters, the patient's arms are wrapped and suspended from the ether screen. (Reprinted with permission from Cooper JD, Patterson GA: Isolated lung transplantation. In Kapoor AS, Laks H, Schroeder JS *et al* [eds]: *Cardiomyopathies and Heart-Lung Transplantation*, p 429. New York, McGraw-Hill, 1991.)

Postoperative Management

Postoperative management of patients after isolated lung transplantation involves intensive respiratory support and differentiating between lung infection and rejection using transbronchial biopsies obtained by flexible bronchoscopy.¹²⁷ Early respiratory insufficiency may be due to pulmonary venous (anastomotic) obstruction or reperfusion injury, which is characterized by large alveolar–arterial oxygen gradients, poor pulmonary compliance, and parenchymal infiltrates despite low cardiac filling pressures. Mechanical ventilation with PEEP is essential, but in consideration of new airway anastomoses, inflation pressures are kept to a minimum. FIO_2 values are also maintained at the lowest levels compatible with acceptable oxygen saturation. After single-lung transplantation for an obstructive disease, the endobronchial tube may be left in place for several days, and special respiratory support in the form of split (individual lung) ventilation used to avoid overinflation of the native lung, gross ventilation–perfusion mismatching, and shifting of the mediastinum.¹²⁸

The lung is unique among transplanted viscera because it is exposed to the external environment. Lymphatic disruption, poor mucociliary function, and the presence of suture lines across the airway are other factors increasing the susceptibility of transplanted lungs to infection. In the first postoperative month, bacteria are the most frequent cause of pneumonia; nosocomial gram-negative organisms comprise the bulk of isolates.¹²⁹ After this period, CMV pneumonitis becomes more common, particularly if lungs from a CMV-seropositive donor are used in a seronegative recipient.¹²⁰ There is a high rate of acute rejection episodes after lung transplantation, which on clinical grounds alone are often difficult to distinguish from infection. This distinction is vital, however, because steroid boluses used to treat rejection may worsen pneumonia or promote systemic sepsis. Bronchoalveolar lavage fluid or sputum specimens obtained by fiberoptic bronchoscopy may be helpful in diagnosing an infectious etiology; transbronchial or, occasionally, open lung biopsy is needed to establish the diagnosis of rejection.¹²⁷

Hemorrhage is a complication that most frequently occurs after *en bloc* double-lung transplantation, particularly in patients with pleural disease or Eisenmenger's syndrome with extensive mediastinal vascular collaterals. The recurrent laryngeal, phrenic, and vagal nerves are jeopardized during lung transplantation, and injury complicates the process of weaning from mechanical ventilation. Primary healing occurs with most bronchial anastomoses; rarely, bronchial fistulae lead to stenoses that can be successfully treated by silicone stents and dilatation. In contrast, tracheal anastomotic leaks often lead to fatal mediastinitis. Long-term complications include lung infections with opportunistic organisms, such as *Pneumocystis carinii* and *Candida albicans*. Bronchiolitis obliterans, a pathologic condition characterized by luminal destruction of small respiratory bronchioles, has been noted after heart–lung transplantation,¹³⁰ but so far seems less common after single-lung transplantation.

Outcome results of lung transplantation series from specialized centers are promising. The Washington University Lung Transplantation Group¹¹⁸ has reported on a series of 69 procedures and found the actuarial survival at 1 year to be 90% after single-lung transplantation and 82% after the bilateral sequential operation. Pulmonary function tests, pulmonary arterial pressure and resistance, arterial blood gases, and exercise capacities all improved significantly after operation. In an earlier analogous series from Toronto, there were no ventilatory limitations noted in lung transplantation survivors or significant desaturation during exercise testing.¹¹⁹

OTHER VISCERA TRANSPLANTATION PROCEDURES

There is considerable interest in transplantation of the pancreas and small intestine, particularly in view of the sizable patient populations that stand to benefit. These are relatively fragile viscera, and optimal preservation regimens and implantation procedures have yet to be defined.

Pancreas Transplantation

There are as many as 20,000 new cases of Type 1 (juvenile-onset, insulin-dependent) diabetes mellitus in the United States each year.¹³¹ This disease destroys the insulin-producing pancreatic β cells by an inflammatory process. The microangiopathy that results from diabetes is among the leading causes of blindness and renal failure.

Pancreatic transplantation by surgical means was first attempted in the mid-1960s, and by 1989 the annual rate of such cases reported to the International Pancreas Transplantation Registry was 554.¹³² At specialized centers, the operative mortality rate was low (1%), the 1-year survival rate was at least 90%, and normoglycemia and insulin independence was achieved in 50–70% of cases at 1 year.¹³³ In many of these cases, patients received both kidney and pancreas allografts, which seemed to prevent the recurrence of diabetic nephropathy in the transplanted kidney¹³⁴ as well as some of the other microvascular complications.

Pancreatic transplantation is usually reserved for diabetic patients with the most severe and rapidly progressive complications in view of the considerable side effects of immunosuppression. Preoperative screening consists of thorough evaluation of the organ systems most affected by diabetes; metabolic studies, including a glucose tolerance test; and urine and serum C-peptide levels (“connecting” peptide is cleaved from proinsulin before secretion into the circulation); glycosylated hemoglobin levels (an index of glycemic control during preceding months); and insulin and islet cell antibodies. Ultrasonography of the gallbladder is conducted to rule out cholelithiasis. In addition to tight preoperative plasma glucose control, mechanical and antibiotic bowel preparation is usually undertaken.

Most pancreatic transplantations are accomplished using the bladder drainage technique. This involves extraperitoneal pancreatic placement and exocrine drainage by duodenocystostomy. After surgery, patients seldom require intensive care, although assiduous control of plasma glucose using an insulin infusion is recommended. Once oral feeding is resumed, insulin is unnecessary unless allograft function is lost. A major advantage of the bladder drainage technique is the ability to monitor allograft exocrine function, which deteriorates during episodes of rejection. Urinary pH may fall, reflecting a decrease in pancreatic bicarbonate secretion, and urinary amylase may diminish. Other postoperative complications include graft thrombosis and intra-abdominal infection.

Pancreatic islet transplantation, in which only the required cell type is introduced, has undergone numerous clinical trials.¹³⁵ In this procedure, which does not require surgical intervention, just the islets are isolated by cell separation techniques then infused into the portal vein. In some cases, islet cells may become fully functional over several weeks and restore insulin independence;¹³⁵ in others, insulin requirement has been reduced but not eliminated.

Multiviscera Transplantation

Simultaneous replacement of multiple digestive organs, known as the *cluster operation*, has been introduced to treat two diseases: short gut syndrome and locally confined GI tumors.¹³⁶ With short gut syndrome from any cause, parenteral feeding may lead to liver failure, and *en bloc* transplantation of the liver combined with the pancreas, stomach, duodenum, and jejunum (Fig. 52-8) has met with some success.¹³⁷ In children, multiviscera transplantation is performed primarily for short gut syndrome resulting from necrotizing enterocolitis or midgut volvulus.

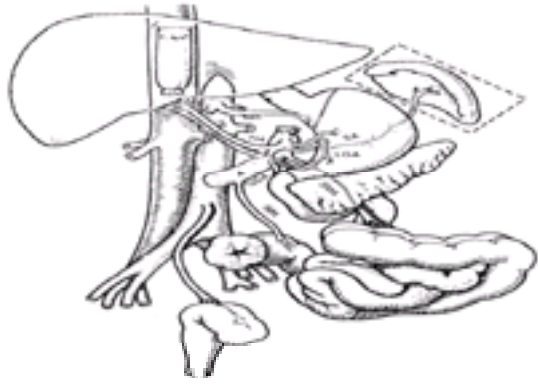

Figure 52-8. Schematic representation of the recipient procedure for multiviscera transplantation. (A = donor aorta; HA = hepatic artery; SA = splenic artery, LGA = left gastric artery; SMA = superior mesenteric artery; IMA = inferior mesenteric artery; GDA = gastroduodenal artery.) (Reprinted with permission from Starzl TE, Rowe MI, Todo S *et al*: Transplantation of multiple abdominal viscera. JAMA 261:1449, 1989.)

Tumors such as hepatomas and cholangiocarcinomas, as well as carcinomas of the proximal GI tract or pancreas, have also been treated by cluster operation after upper abdominal exenteration. Without surgery, the prognosis for these cancers is uniformly dismal, and even partial resections combined with chemotherapy or radiation offer little improvement in overall survival. In contrast, although experience is still limited, multiviscera transplantation is associated with 1-year survival rates of 70% (with sarcomas or GI-derived neuroendocrine tumors) or 44% (primary liver cancers).¹³⁸

Anesthetic management of cluster surgery has been reviewed in detail.¹³⁹ Briefly, the types and doses of previous chemotherapy should be ascertained during the preoperative visit because some agents have long-lasting toxic effects on the heart or kidneys. Hormone-secreting tumors, producing carcinoid crisis, can be suppressed with octreotide acetate, a somatostatin analogue; with ketanserin, a serotonin antagonist; or by arterial embolization. During surgery, the management issues are similar to those for liver transplantation alone, namely, massive transfusion, coagulopathies, hypothermia, electrolyte abnormalities, and the use of venovenous bypass for systemic venous return. Postoperative complications include a high incidence of rejection, particularly of the small bowel, sepsis from loss of the intestinal barrier, and graft-versus-host disease. The likelihood of graft-versus-host disease is proportional to the length of intestine transplanted, presumably reflecting the quantity of lymphoid tissue contained in the wall of this organ.

VISCERA TRANSPLANTATION IN CHILDREN

The clinical manifestations of end-stage organ disease in children are in general similar to those in adults; however, the pathologic processes leading to organ failure often differ. For example, the etiology of end-stage renal disease noted in the pediatric population (Table 52-13) differs markedly from that for the general population (see Table 52-6). During childhood, developmental anomalies and genetic defects, anatomic or functional (*i.e.*, inborn errors of metabolism), may lead to end-stage organ disease. Congenital anomalies may be confined to a single organ system (*e.g.*, reflux nephropathy) or be part of a constellation of abnormalities. For example, in Alagille's syndrome, end-stage liver disease is accompanied by congenital heart disease, hypercholesterolemia, and renal dysfunction. Clearly, awareness of such syndromes is necessary to anticipate coexistent pathologic processes in other organ systems.

| | Total Cases (%) |

TABLE 52-13. ETIOLOGY OF END-STAGE RENAL DISEASE IN CHILDREN

Ethical Considerations

The ethics of transplantation are also somewhat different in the pediatric age group. The legally adopted criteria for brain death are not universally accepted as applicable in the immediate neonatal period,¹⁴⁰ so organ donation from this population is controversial. Size considerations place additional constraints on the organ-matching process in children, exacerbating the shortages. To remedy this, procedures for living-related donation have been developed for kidney transplantation, and, more recently, liver¹⁴¹ and lung¹⁴² transplantation. Although living-related renal transplantation has gained acceptance because of its particular benefits for children, the liver and lung procedures are more controversial owing to higher morbidity and mortality in the donors. Other ethical dilemmas, such as whether transplantation can provide truly long-term survival, and whether transplanted organs grow and develop normally in children, remain unresolved. In addition, long-term immunosuppression with cyclosporine increases the risk for development of a lymphoproliferative malignancy, perhaps related to Epstein-Barr virus infection or reactivation. Although the overall incidence is reasonably low, the shift to earlier presentation of aggressive malignancies raises new concerns.¹⁴³

Renal Transplantation

Although pharmacologic agents combined with dialysis can be used to treat end-stage renal disease in children, medical management has an overall high morbidity rate and adversely affects growth and development.¹⁴⁴ Children treated medically during their maximum growth years show a marked decrease in eventual height and weight,¹⁴⁵ as well as cognitive development,¹⁴⁶ compared with control subjects. Early transplantation seems to reduce the severity of these problems,^{147,148} justifying the current recommendation "expectantly" to transplant children with progressive renal insufficiency, sometimes even before dialysis is required.

The most common diseases leading to renal transplantation in children are related to congenital anomalies; acquired nephropathies and a group of miscellaneous diseases account for the remainder (Table 52-14). Living-related renal transplantation is most often done in children and confers significant advantages: both short- and long-term mortality rates are improved, and graft survival is superior,¹⁴⁹ perhaps because the risk of minor antigenic mismatch is reduced. Organ survival in children receiving a living-related donor kidney approaches 100% at 1 year and 70% at 10 years.¹⁴⁹ Because perioperative mortality and renal rejection are greater in infants, current practice is to avoid transplantation until later in childhood.

TABLE 52-14. PATHOLOGIC DIAGNOSES IN PEDIATRIC RENAL TRANSPLANT RECIPIENTS AT THE UNIVERSITY OF MINNESOTA

In contrast to adults, pediatric renal transplantation relies on intra-abdominal placement of the organ. This allows adult-sized kidneys to be transplanted into very small children and increases the size of the donor pool. During surgery, however, placement of the allograft can acutely cause hypothermia and sequester relatively large proportions of the child's blood volume. As a consequence, hypotension can occur when adequate perfusion is critical. To prevent this, fluid boluses and vasoactive infusions are used to maintain systemic blood pressure in the high-normal range. As in adults, living-related donor kidneys usually function at once, whereas cadaver kidneys may take hours to resume urine production. Fluid management must take this into account. In either case, adult kidneys initially produce adult-sized volumes of urine, so maintenance fluids must be adjusted accordingly.

Liver Transplantation

Approximately 20% of the orthotopic liver transplantations performed worldwide are in children, and most recipients are younger than 5 years of age.¹⁵⁰ Biliary atresia is by far the most common cause of liver failure in this population (Table 52-15), followed by inborn errors of metabolism, which include disorders such as α_1 -antitrypsin deficiency, glycogen storage diseases, Wilson's disease, and tyrosinemia. The latter three conditions primarily involve biochemical defects in hepatocytes and are therefore considered cured by liver transplantation.

| | Total Cases (%) |
|--|-----------------|
| Biliary atresia | 44 |
| α_1 -Antitrypsin deficiency | 20 |
| Other inborn errors of metabolism | 10 |
| Other obstructive disease (e.g., Alagille's and Byler's syndromes) | 12 |

* Data derived from 50 pediatric orthotopic liver transplant recipients at Children's Hospital of Pittsburgh between 1981 and 1983. Adapted with permission from Botland LM, Roule M, Cook DE: Anesthesia for pediatric orthotopic liver transplantation. *Anesth Analg* 64:117, 1985.

TABLE 52-15. PATHOLOGIC DIAGNOSES IN PEDIATRIC ORTHOTOPIC LIVER TRANSPLANT RECIPIENTS

Several aspects of the orthotopic liver transplantation procedure are unique to children. For example, patients with biliary atresia have usually undergone prior decompression with a Kasai (choledochojejunostomy) procedure, and this may complicate abdominal dissection during the preanhepatic phase of liver transplantation, as well as later biliary reconstruction. Venovenous bypass is not feasible in patients weighing <20 kg, so the lower body venous congestion that accompanies portal vein and IVC occlusion often leads to oliguria and intestinal complications in this group. An oversized allograft may sequester a substantial proportion of the blood volume, increase the risk of excessive potassium release after reperfusion, and lead to severe hypothermia. In children whose temperature falls below 34°C, lavage of the peritoneal cavity with warm saline is effective in raising core temperature.

The limited availability of suitably sized organs for small patients has prompted the development of techniques for transplanting part of a liver. Figure 52-9 illustrates the technique that is used to create a reduced-size ("split") liver and enable one donor liver to be used for multiple patients. There is a significantly higher complication rate with this method, including greater blood loss,¹⁵¹ risk of organ necrosis, and diminished patient survival,^{151,152} so it is usually reserved for patients who are rapidly deteriorating. Living-related (partial) liver donation has also been promoted by the contention that up to one half of pediatric liver transplantation candidates die while awaiting a suitable organ. However, in view of the potential for donor morbidity and the relatively reduced survival of recipients of reduced-size livers, few centers offer this option.

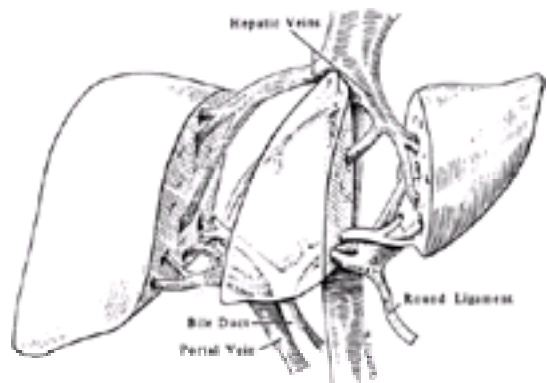

Figure 52-9. A schematic for *ex vivo* dissection of an adult liver to create reduced-size liver allografts with vascular supplies and biliary orifices. Donor iliac arteries or veins are used as needed to extend the vessels. (Adapted and reprinted with permission from Broelsch CE, Edmond JC, Whittington PF *et al*: Application of reduced-size liver transplants as split grafts, auxiliary orthotopic grafts, and living related segmental transplants. *Ann Surg* 212:368, 1990.)

The overall 1-year survival rate in children after orthotopic liver transplantation is 70–75%, but results for younger (<3 years) and smaller (<12 kg) patients are not as good (45–50% 1-year survival rate).^{150,152} This discrepancy probably stems from two factors: the greater incidence of hepatic artery thrombosis in small children, which in turn is related to arterial size, and the use of reduced-size livers.^{141,153}

Heart Transplantation

Cardiac transplantation for congenital heart disease is the major indication for this procedure in children younger than 5 years of age.¹⁵⁴ In older children, dilated cardiomyopathy remains most common. However, mortality rates for the young children remain higher than for older children and adults (25% vs. 10% 30-day mortality, respectively),¹⁵⁴ which results in lower overall survival. Cardiac-related complications are responsible for most early deaths, stemming from the presence of complex vascular anatomy, previous cardiac surgery, and elevation of pulmonary vascular resistance. The latter factor is a well recognized contraindication to heart transplantation in adults, but it is often difficult accurately to quantify the "fixed" component of pulmonary vascular resistance in infants. If pulmonary vascular resistance is fixed at a high level, the normal allograft's right ventricle cannot acutely adjust to the afterload, and refractory right-heart failure ensues. Long-term survival may be limited by an accelerated form of coronary atherosclerosis,¹⁵⁵ as is seen in adults.

Generally accepted indications for heart transplantation in newborns include aortic atresia and hypoplastic left heart syndrome. If reconstruction of the aortic arch is required, profound hypothermia and circulatory arrest are usually necessary. Positional or size discrepancies of the great vessels and abnormal arrangements of systemic or pulmonary venous return can complicate these procedures, and have so far limited overall survival rates for neonates to 66% at 1 year.¹⁵⁶

A scientifically provocative aspect of transplantation unique to neonates is that the immature immune system seems relatively tolerant of foreign antigens.¹⁵⁷ By several criteria, the neonatal immune response to allograft tissue is attenuated, although the response to infective organisms and active immunization is comparatively intact. The mechanisms responsible are unclear but may involve neonatal suppressor cells or maternal cells that enter the circulation during gestation.

Other Viscera Transplantation Procedures

Rarely, heart–lung transplantation is indicated before early adulthood for cystic fibrosis, Eisenmenger's syndrome, or primary pulmonary hypertension.¹⁵⁸ Isolated lung transplantation may offer the only chance of survival to children with severe developmental anomalies of the lung, including cystadenomatous malformations and congenital diaphragmatic hernia with pulmonary hypoplasia or, in older children, cystic fibrosis. The scarcity of suitable donor organs has led to instances of living-related lung donation,¹⁴² but the merits of this approach have yet to be fully evaluated.

Multiviscera transplantation, which combines liver and small bowel transplantation, has been tried in children with short gut syndrome (as a result of necrotizing enterocolitis or midgut volvulus) further complicated by hepatic failure after long-term hyperalimentation. So far, intra-abdominal infection and repeated episodes of bowel rejection have limited survival, and thus the approach is still considered experimental.

EVALUATION OF PATIENTS WITH A PRIOR ORGAN TRANSPLANT

Transplant recipients may return for a staged repair (e.g., bile duct reconstruction after liver transplantation) or for entirely unrelated surgery. They may also present with a surgical illness superimposed on organ rejection, where the usual signs and symptoms are masked.

Immunosuppression increases the risk of opportunistic infection, so many recipients are maintained on a fixed-dose combination of trimethoprim–sulfamethoxazole, which is effective in preventing such illnesses.¹⁵⁹ Postoperative bacterial infections are also more common in this group, so an attempt should be made to minimize exposure to nosocomial sources, such as urinary and intravascular catheters, and mechanical ventilators. Immunosuppressants also have numerous other adverse effects that can influence perioperative management.

Immunosuppressant Side Effects and Toxicities

Although immunosuppressants are usually administered in combination to diminish the risk of dose-related toxicity from any single agent, significant morbidity is still associated with their use (Table 52-16).

| Agent | Side Effect/Toxicity |
|--------------------------|---|
| Glucocorticoids | Adrenal suppression Glucose intolerance Cushingoid appearance Integument fragility Aseptic necrosis Peptic ulceration |
| Azathioprine | Anemia Thrombocytopenia Leukopenia Pancreatitis Hepatitis Decrease nondepolarizing relaxant requirement |
| Cyclosporine, tacrolimus | Glomerulosclerosis (elevation of blood urea nitrogen, creatinine) Hypertension Hepatotoxicity Neurotoxicity Enhanced renal sensitivity to insults |
| Antilymphocyte globulin | Leukopenia Thrombocytopenia Systemic symptoms |
| OKT3 | Systemic symptoms Increased susceptibility to cytomegalovirus infections |

TABLE 52-16. IMMUNOSUPPRESSANT SIDE EFFECTS AND TOXICITIES

Glucocorticoids

Glucocorticoids produce glucose intolerance, cushingoid habitus, fragility of the integument, aseptic necrosis, and exacerbation of peptic ulcer disease. Yet attempts to eliminate them from immunosuppression regimens usually have not met with success, with the possible exception of neonatal heart transplant recipients. Chronic glucocorticoid use is also associated with adrenal suppression. Although some authors advocate administration of preoperative stress doses of glucocorticoids, this was shown to be unnecessary in at least one large series of patients who underwent a surgical procedure after renal transplantation.¹⁶⁰

Azathioprine

Azathioprine is a myelosuppressant, producing anemia, thrombocytopenia, and occasionally marrow aplasia. It has also been associated with hepatitis, alopecia, and GI upset, and through an allergic mechanism, pancreatitis. Azathioprine has been reported to increase the requirement for nondepolarizing relaxants to a modest degree, probably by presynaptic inhibition of phosphodiesterase in the motor nerve terminal.¹⁶¹

Cyclosporine and Tacrolimus

Cyclosporine is both acutely and chronically nephrotoxic, producing interstitial renal fibrosis and tubular atrophy. Chronic toxicity is common, leading to elevations in blood urea nitrogen and creatinine levels, as well as systolic and diastolic hypertension.¹⁶² Management with conventional antihypertensives is usually successful, but the kidneys of such patients may be more vulnerable to acute insults, such as radiographic dye- or hypotension-induced nephropathy. Cyclosporine may be hepatotoxic, producing hyperuricemia, gingival hypertrophy, or seizures and neurotoxicity at high serum levels. The toxicity profile of tacrolimus seems to be qualitatively similar.

Antilymphocyte Globulin and OKT3

Antilymphocyte globulin is a polyclonal antibody, and as such is “contaminated” with antibodies other than those directed against lymphocytes. These may give rise to marked leukopenia and thrombocytopenia, and systemic symptoms such as fever, chills, pruritus, GI upset, and even frank serum sickness. The first dose of OKT3 is frequently followed by systemic symptoms such as fever, dyspnea, and nausea, unless patients are pretreated with hydrocortisone, acetaminophen, and diphenhydramine. Subsequent reactions are less pronounced. OKT3 has also been associated with episodes of pulmonary edema, aseptic meningitis, and an unusually high incidence of CMV infection.

Early after transplantation, bacterial infections related to wound infection, urinary catheters, and pneumonia are most common (e.g., with *Staphylococcus aureus*, *Escherichia coli*, and *Streptococcus pneumoniae*, respectively). After 1 month, immunosuppressed patients become vulnerable to opportunistic infections (*P. carinii* pneumonia, herpes zoster infections, and CMV sepsis).¹⁰² These episodes need not be fatal and can be overcome if diagnosis is rapid and treatment specific. The most common viral infection is CMV, which can occur as a primary infection from contaminated blood or allograft tissue in seronegative recipients, or as reactivated infection in seropositive patients.¹⁶³

Immunosuppressed patients are also more likely to have one of several histologically distinct types of lymphoproliferative malignancy. For example, the incidence of B-cell lymphoma in patients with renal allografts is approximately 350-fold higher than that seen in the normal age-matched population, and the same is probably true for cardiac recipients. Some studies have documented a causal role for Epstein-Barr virus,¹⁶⁴ and it is speculated that cyclosporine may diminish the cytotoxic response of suppressor T cells to autologous Epstein-Barr virus–infected B cells. Unfortunately, the mortality rate associated with these malignancies is relatively high; in one series, the 5-year mortality rate was 37%.¹⁶⁵

Other Preanesthetic Considerations

Transplant recipients depend on immunosuppressants to avoid rejection, and these regimens must be restarted soon after surgery. If oral intake is expected to be delayed, appropriate parenteral formulations should be used. Certain drugs used in the perioperative period may inhibit the cytochrome P-450 system and interfere with metabolism of cyclosporine (e.g., cimetidine), whereas others may induce the P-450 enzymes and decrease cyclosporine levels (e.g., phenobarbital and phenytoin). Cyclosporine increases the hypnotic duration of pentobarbital in laboratory animals,¹⁶⁶ but because it does not increase the requirement for inhaled agents,¹⁶⁷ such an effect may be pharmacokinetic in origin. Cyclosporine has also been reported to prolong the action of pancuronium,¹⁶⁸ but controlled data are lacking.

The transplant population is also particularly prone to bacterial pneumonia and CMV sepsis,¹⁰² so early extubation of the trachea is an important goal after any surgical procedure, and the use of CMV-negative blood is mandatory. In addition, intravascular catheterization is used only when specifically indicated, although standard aseptic cannulation techniques seem sufficient.

Anesthesia After Kidney Transplantation

Although renal transplantation is usually highly successful, some recipients still require dialysis. Thus, it is important to ascertain the degree of residual renal impairment and treat such patients accordingly. If the allograft is functional, renal excretion of drugs may be expected to be comparable with that through native kidneys.

Many of these patients are diabetic and return to the operating room for ophthalmologic or peripheral vascular procedures. Perioperative complications leading to loss of the renal allograft are uncommon,^{160,169} but sepsis is a major cause of morbidity. Management of blood glucose may be complicated by steroid immunosuppressants and fever; in such cases, insulin infusions are often necessary.

Because kidney recipients are maintained on cyclosporine, other agents with nephrotoxic potential (e.g., enflurane) are usually avoided. Cyclosporine may render allografts particularly sensitive to insults, so maintaining a brisk urine flow during anesthesia is recommended. During long procedures, this may justify the use of central venous pressure and urinary catheters.

Anesthesia After Liver Transplantation

In a well functioning liver allograft, common biochemical pathways for drug metabolism are unimpaired.¹⁷⁰ Provided that the metabolic and synthetic functions of the transplanted liver are also intact, the anesthetic care of these patients differs little from that of any other visceral transplant recipient. Within the first 2 months after liver transplantation, the most common surgical procedures are exploratory laparotomy for biliary leak or abscess drainage, or open liver biopsy. Regional anesthesia is avoided unless the coagulation profile has returned to normal, and the likelihood of ileus or elevated intra-abdominal pressure indicates the use of rapid-sequence induction. Later, patients may require biliary reconstruction procedures.

Anesthesia After Heart Transplantation

Heart transplant recipients return to the operating room for noncardiac surgery with some regularity. Such procedures do not always follow the transplantation immediately, instead occurring months or even years later. Overall, 25–30% of these patients require a general surgical procedure (Table 52-17) within 2 years of transplantation.^{171,172} Infectious causes for surgery (e.g., drainage of abscesses) can clearly be attributed to immunocompromise, but a relatively high incidence of cholecystitis is unexplained. In addition to these common general surgical problems, orthopedic procedures are frequently required secondary to joint complications arising from chronic steroid use. Despite numerous case reports of cardiac recipients undergoing noncardiac surgery,^{173,174} there are no prospective data addressing the risks of anesthesia in this physiologically unique population.

| Diagnosis | Time After Transplantation |
|---------------------------------|----------------------------|
| Perforated sigmoid diverticulum | 8 mo; 29 mo; 39 mo |
| Small bowel perforation | 4 mo; 5 mo |
| Free intraperitoneal air | 3 days; 5 wk |
| Cholecystitis | 2 wk; 21 mo |
| Vagus nerve injury | 3 mo |
| Ventral hernia | 26 mo |
| Inguinal hernia | 7 mo |
| Perirectal abscess | 20 mo |
| Pancreatitis | 18 mo; 1 mo; 2 mo |
| Diverticulitis | 18 mo |

TABLE 52-17. GENERAL SURGICAL DIAGNOSES IN PATIENTS AFTER HEART TRANSPLANTATION

During orthotopic heart transplantation, the aorta and the main pulmonary artery are transected (see Fig. 52-6). As a result, the cardiac plexus is divided, resulting in autonomic afferent and efferent denervation. Myocardial tissue obtained from hearts transplanted for as long as 12 years fails to reveal evidence of abundant reinnervation.¹⁷⁵ Some of the nerve cells present in such specimens probably represent postganglionic parasympathetics because significant amounts of acetylcholine do remain.¹⁷⁶ Although early canine studies indicated that implanted hearts underwent efferent reinnervation and thus regained autonomic control,¹⁷⁷ in humans, with rare exception,^{178,179} studies of transplanted heart rate responses to exercise and respiratory stimuli^{176,180,181} and ¹⁸² indicate that autonomic efferent denervation is permanent. Afferent reinnervation may occur in some cases, as suggested by clinical and biochemical criteria.¹⁸³

In the absence of rejection or significant pulmonary hypertension, long-term follow-up studies after heart transplantation have demonstrated that despite denervation, the resting stroke volume and indices of myocardial contractility are often normal¹⁸⁴ or only subtly reduced.¹⁸⁵ However, with demands for increased cardiac output (e.g., during exercise), the response of the denervated heart is demonstrably different (Fig. 52-10). In the normally innervated heart, immediate increases in cardiac output are mediated by elevation in heart rate with little change in stroke volume. In contrast, the denervated heart responds to such demands by increases in stroke volume rather than in heart rate. Cardiac recipients are thus preload dependent and must have adequate central volume to meet the demands of stress or anesthetic techniques that redistribute vascular volume to the periphery.

Figure 52-10. Schematic representation of the cardiac physiologic responses to moderate supine exercise in humans. Responses of normal subjects are represented on the left; those following cardiac denervation are on the right. (Reprinted with permission from Kent KIM, Cooper T: The denervated heart: A model for studying autonomic control of the heart. *N Engl J Med* 291:1017, 1974.)

The denervated heart eventually can manifest increases in heart rate, albeit with some delay (Fig. 52-11). In cardiac transplant recipients, the maximal achievable pulse rate during exercise develops more slowly than in control subjects, and the return of heart rate to baseline is slower. The delay in achieving a maximal heart rate corresponds to the time required for secretion and circulation of adrenal catecholamines, and the slow return is probably related to the absence of vagal input.

Figure 52-11. Donor heart rates during supine bicycle exercise by eight patients 1 year after heart transplantation. The rates of achieving a maximal pulse are slower than in patients with innervated hearts. “Control” refers to measurements made at the start of exercise. The postexercise scale is compressed. (Reprinted with permission from Stinson EB, Griep RB, Schroeder JS *et al*: Hemodynamic observations one and two years after cardiac transplantation in man. *Circulation* 45:1183, 1972.)

As a consequence of the mid-atrial orthotopic surgical technique, the transplant recipient retains remnants of the native atria, and the electrocardiogram may contain both donor and native P waves. Because the sinus node is normally under the continual influence of autonomic (vagal) nerves, the rate of the transplanted atria usually exceeds that of the native atria.¹⁸⁶ With parasympathetic activation (e.g., by visceral traction, including laryngoscopy or drug effects), the native atrial rate may diminish but the transplanted heart rate remains unchanged because vagal input is absent. In contrast, sympathetic stimulation (whether from hypoxemia, hypercapnia, hypotension, or pain) can still increase the donor heart's sinus rate, although, importantly, such responses are delayed. In contrast to effects on the sinoatrial node, denervation usually does not alter the arteriovenous conduction time or affect ventricular conduction.¹⁸⁷

By 3 years, approximately 30% of survivors have multivessel coronary stenoses¹⁸⁸ (Fig. 52-12). These lesions are diffuse, concentric narrowings of the coronary lumen, and are thought to arise from areas of immune-mediated endothelial damage. In some cases, lesions are amenable to angioplasty or surgical bypass, but often, myocardial ischemia and infarction limit the useful life of the allograft. Although the ability of these patients to perceive angina pectoris has been documented,¹⁸³ afferent innervation seems to be lacking in most, rendering episodes of myocardial ischemia silent. Thus, diagnostic electrocardiographic monitoring is essential throughout the perioperative period, and paroxysmal dyspnea, which may be the only indication of ischemia, should be regarded as an ominous symptom.

Figure 52-12. Life-table analysis showing the risk, in humans, for development of coronary artery disease over the first 3 years after cardiac transplantation. (Reprinted with permission of the authors and the American Heart Association. From Uretsky BF, Murali S, Reddy PS *et al*: Development of coronary artery disease in cardiac transplant patients receiving immunosuppressive therapy with cyclosporine and prednisone. *Circulation* 76:827, 1987.)

Clearly, drugs that act indirectly on the heart fail to produce their typical effects after denervation; for example, administration of atropine or pancuronium does not elevate heart rate (Table 52-18), although neostigmine can cause bradycardia in this population.¹⁸⁹ In contrast, agents that act directly on myocardium or cardiac conduction tissues manifest their usual effects; for example, isoproterenol increases contractility and heart rate, whereas propranolol has the opposite effects. Digoxin, which has mixed direct–indirect actions,¹⁹⁰ acts only directly after transplantation. An iv bolus of digoxin fails to alter either the functional or effective refractory periods of the atrioventricular node,¹⁹⁰ whereas it significantly increases the refractory period in normal patients. This suggests that digoxin's acute, chronotropic effects are vagotonic, dependent on intact autonomic innervation. When treated chronically with digoxin, cardiac transplant recipients demonstrate an inotropic response from a direct effect independent of autonomic innervation. Norepinephrine is another cardioactive drug with somewhat atypical effects in this population. Infusions at conventional doses may be accompanied by more pronounced chronotropic effects than usual, through a direct β -adrenergic receptor–mediated effect on the sinus node that is normally masked by vagal reflexes. Cardiac transplant recipients with previous long-standing heart failure may also have a persistently blunted response to α -adrenergic agonists.¹⁹¹ This probably results from adjustment of the peripheral vasculature or the baroreceptors to chronically elevated catecholamine levels. Finally, there is electrophysiologic evidence of moderate supersensitivity to adenosine after transplantation.¹⁹²

| Drug | Response |
|----------------|--|
| Atropine | No vagolytic effect |
| Pancuronium | No vagolytic effect |
| Edrophonium | No vagotonic effect |
| Ephedrine | Less cardiostimulatory effect |
| Nifedipine | No depression of nodal conduction |
| Digoxin | No acute vagotonic effect |
| Norepinephrine | Enhanced β -stimulatory effect |
| Phenylephrine | Diminished vasoconstrictive effects with long-standing heart failure |

TABLE 52-18. ALTERED RESPONSES TO COMMON CARDIOVASCULAR DRUGS AFTER CARDIAC DENERVATION

Cardiac rejection may be superimposed on the surgical illness and may be the cause of low cardiac output and dysrhythmias. Rejection can thus impair responses to the stress of surgery and anesthesia. Endomyocardial biopsy may be necessary for definitive diagnosis of rejection, and aggressive immunotherapy with high-dose steroids or antilymphocyte globulin may be started in the perioperative period.

FUTURE TRENDS

Since its inception, viscera transplantation has been limited by a shortage of suitable donor organs. For patients with end-stage renal disease, this has meant longer periods on dialysis with greater costs and morbidity, but for prospective heart and liver recipients, there is a 10–40% mortality rate while awaiting transplantation.¹⁹³ One remedy lies in further improvements in organ preservation because prolonging tolerable organ ischemic time increases the potential donor pool. The size of this pool will also increase as the criteria for donor acceptability expand (e.g., to include older donors, donors with certain systemic diseases, and terminally ill and fetal donors).³ Other approaches to deal with the limited supply of organs include cellular transplantation, where healthy allograft cells derived from one organ may be infused into multiple recipients, and xenotransplantation from genetically “humanized” animals.¹⁹⁴

Optimizing use of the available donor organs will also be important. For example, early application of isolated lung transplantation could make the heart–lung procedure obsolete and allow each heart–lung bloc to serve several patients. Accelerated atherosclerosis is a major factor limiting the useful life span of donor hearts; development of an effective therapy would represent a major breakthrough.

For the foreseeable future, immunosuppressant drugs will continue to be necessary to prevent the response to foreign tissue antigens. Development of agents with greater immunoselectivity and reduced toxicity is of the highest priority. Noninvasive methods to diagnose organ rejection would also substantially improve the quality of life for transplantation survivors. Longer-term approaches to the problem of rejection currently under investigation include induction of tolerance to foreign antigens by promoting cell migration and “chimerism;”¹⁹⁵ definition of the most critical elements for histocompatibility; and development of better “rescue” drugs once rejection has begun.

An individualized, problem-oriented approach to the assessment of surgical patients is essential to ensure appropriate postoperative recovery with minimum risk and expense. Facility design, equipment, and staffing requirements for a state-of-the-art postanesthesia care unit (PACU) are reviewed elsewhere.¹

VALUE OF POSTANESTHESIA CARE UNIT CARE

Indicators of PACU quality include not only clinical results but the “value” of care, defined as the improvement in clinical outcome per dollar spent on a PACU admission. The impact of PACU care on clinical outcomes in a surgical population varies with incidence and severity of underlying illness, the frequency, urgency, and type of surgical procedures, and the blend of surgical and anesthetic techniques used. Training, skill, and preferences of surgeons, anesthesia providers, and PACU nurses also affect how important a PACU admission might be to a patient. The effectiveness of PACU staff at recognizing complications, the quality of diagnostic and consultative services, and the efficiency with which physicians institute therapy are also important. The patient’s impressions during the PACU stay have a major impact on perception of the entire surgical episode. Friendliness and empathy from the PACU staff is an important element of patient satisfaction that contributes to a pleasant working environment.

Actual cost of PACU care incorporates space, staff, and hardware. Triage, admission, and discharge policies affect how many admissions occur and what resources each admission consumes. The greatest PACU cost is for staffing. Mix of nursing staff (e.g., amount of training and experience; salaries and benefit levels), the staffing ratios (e.g., number of patients per caregiver, number of support staff), and the duration of PACU stay determine an overall personnel cost per admission. Level of monitoring provided affects capital expenditure for equipment and operating expenditure for disposable items. Patient mix also determines expenditures for staffing and for equipment such as intravenous (iv) pumps, and ventilators. The type of physician coverage (e.g., dedicated versus on-demand coverage, response times) affects the efficiency of care. Routine postoperative diagnostic testing increases costs for securing and processing tests, and for professional interpretation. Finally, use of routine therapies (e.g., oxygen, antiemetics, respiratory therapy) increases the expenditure per patient for drugs and disposable items, and can add to the staffing resources required per patient.

Cost comparisons between institutions are difficult because factors affecting impact and cost are facility specific and vary among institutions and over time. Regulatory requirements, standards of care, and medicolegal climates also vary among regions or between facilities in the same locale. Attempts to establish national benchmarks of “cost-effectiveness” of PACU care are fraught with inaccuracy. Despite this complexity, emphasis on containment of health care expenditures forces each surgical facility to evaluate the value of its PACU care to an individual patient.

Postanesthesia care unit directors are challenged to optimize clinical results while minimizing expenditure. Innovative PACU practices can guarantee safe care, minimize cost, and fulfill regulatory requirements. Medical leaders must identify those interventions that have actual yield versus those that are “wasteful.” The actual impact of many PACU interventions on clinical outcome is not substantiated by controlled scientific analysis. Useless testing, unnecessary or unjustifiably expensive therapy, and inappropriate PACU admission should be eliminated. However, using a more expensive therapy can sometimes generate real savings by decreasing admissions or length of stay. Finally, integration of the PACU service with other elements of the surgical continuum is essential. The most important interface is between the PACU and the intraoperative anesthesiology service. In one study, 22.1% of 37,000 patients had a minor anesthesia-related event or complication that prolonged PACU stay and consumed PACU resources.² Consumption of PACU resources is definitely linked to anesthetic duration and technique,³ so close coordination between services should reduce the frequency and impact of such events.

It is important to distinguish between potential and actual cost savings. Improvements in care might create an opportunity to shorten length of stay in the PACU and discharge unit, but the actual impact is frequently reduced by transportation delays, persistence of pain or nausea, waiting for space, or surgeon discharge delays.^{4,5}

Also, administrators should beware of cost-saving measures in other areas that increase the cost of PACU care. For example, use of a cheaper, longer-acting muscle relaxant might trim cost in anesthesiology but increase length of stay, complication rates, and cost in the PACU.⁶ Also, savings are illusory unless an operational change yields an actual decrease in expenditures for staff, supplies, or equipment. Nurse staffing is the largest variable direct cost in the PACU.⁷ Innovative scheduling of operating room cases, shortening PACU length of stay, and bypassing the PACU create an opportunity for savings that is realized only if the number of paid nursing hours is reduced or if a larger number of patients is serviced with the same hours. If excess hours are consumed by ineffective scheduling, by using nurses for low-yield clerical or maintenance tasks, or by staff subterfuge, then no savings are realized. Finally, trimming costs sometimes entails an increase in risk, no matter how small. Differentiating between cost-effective postanesthetic care and unsafe clinical practice must remain a matter of professional judgment.

LEVELS OF POSTOPERATIVE CARE

For both ambulatory and inpatient surgery, the level of postoperative care a patient requires is determined by the degree of underlying illness, the duration and complexity of anesthesia and surgery, and the risk postoperative complications. As less invasive surgical techniques and shorter-duration anesthetic regimens become more prevalent, many patients exhibit minimal cardiovascular or respiratory depression after surgery. Using a less intensive postanesthesia setting for selected patients can reduce cost for a surgical procedure and allow the facility to divert scarce PACU resources to patients with greater needs. Alert patients are more satisfied when spared the unnecessary assessments and interventions and the upsetting environment of PACU care. Amenities such as recliners, reading material, television, music, and food improve perceptions without affecting quality or safety. Earlier reunion with family in lower-intensity recovery settings is desirable. This of course assumes that postoperative care is safe and appropriate.

Creation of separate PACUs for inpatients and ambulatory patients is one possible way to streamline PACU care for straightforward cases. If separation is not feasible, then linking the level of monitoring and coverage to the degree of postoperative impairment achieves similar results in one PACU. However, full-intensity PACU care must always be available, given the incidence of complications after anesthesia and surgery.⁸ As the aging population generates an increase in the complexity of surgical care in the face of dwindling resources,⁹ maintaining appropriate PACU capacity will be increasingly important.

Requirements of state and national agencies sometimes impede the implementation of innovative PACU care policies. Codes and regulations might be outdated, poorly substantiated, or interpreted by regulators with clinical experience from a different era. Flexibility and logic need to be incorporated into regulation for complete evolution of postanesthesia care to occur.

POSTOPERATIVE TRIAGE

Patients must be carefully evaluated to determine which level of postoperative care is most appropriate. Triage should be based on clinical condition and the potential for complications that require intervention. Alternatives to PACU care must be used in a nondiscriminatory fashion. Artificial triage categories based on age, American Society of Anesthesiologists classification, ambulatory versus inpatient status, or type of insurance should not be used. A wide margin of safety must be preserved, and applicable PACU standards observed when appropriate¹⁰ (see [Table 2-3](#)). If doubt exists about a patient's safety in a lower-intensity setting, the patient should be admitted to a "full-service" PACU. The clinician always errs for patient safety, regardless of cost.

After superficial procedures using local infiltration or minor blocks and sedation, patients can almost always recover with less intensive monitoring and coverage. Healthy patients undergoing more extensive procedures (e.g., hernia repairs, arthroscopic procedures, minor joint procedures) under local or plexus blockade might also bypass the PACU. Selected patients who meet the PACU discharge criteria at the end of general anesthesia can bypass the PACU and be transferred from the operating room directly to a discharge area.¹¹ Innovative anesthetic techniques and use of bispectral index monitoring help facilitate this "fast-track" postoperative care, although inadequate control of pain and postoperative nausea and vomiting (PONV) often reduces the impact of PACU bypass on resource expenditure.¹²

SAFETY IN THE PACU

The PACU medical director must ensure that the PACU environment is as safe as possible. Beyond usual policies ensuring safe clinical care, staffing levels and training must ensure that appropriate coverage and skill mix are available to deal with unforeseen crises. Ideally, all staff should have PACU certification, and staffing ratios should never fall below accepted standards.¹⁰ Each medical director must guarantee that less skilled staff are appropriately supervised and that a sufficient number of certified personnel is available to handle worst case scenarios.

The PACU staff protects patients who are temporarily incompetent. They safeguard the patient's right to informed consent for additional procedures and to observance of advanced directives. The staff is obligated to preserve each patient's privacy and dignity, and to minimize the psychological impact of unpleasant or frightening events. Medical directors must address the potential for personal assault of patients during recovery. Access to the PACU should be strictly controlled, and unobserved coverage of a PACU patient by one staff member for prolonged periods avoided, especially if there is a gender difference.

The PACU environment must also be safe for professionals. Air handling in the PACU should guarantee that personnel are not exposed to unacceptable levels of trace anesthetic gases, although trace gas monitoring is not necessary.¹³ Staff must receive appropriate vaccinations, including that for hepatitis B. All practitioners must adhere to policies for radiation safety, infection control, disposal of sharps, universal precautions for bloodborne diseases, and safeguarding against exposure to pathogens like methicillin-resistant *Staphylococcus* or tuberculosis. Masks, gloves, eye protection, and appropriate personal respiratory equipment must always be available. Staff should never risk personal injury while lifting and positioning patients or while dealing with emergence reactions because sufficient help is not available. Compulsive documentation and clear lines of clinical responsibility protect staff against unnecessary medicolegal exposure.

ADMISSION CRITERIA

Every patient admitted to a PACU should have heart rate and rhythm, systemic blood pressure, and ventilatory rate and character recorded. Assessment every 5 minutes for the first 15 minutes and every 15 minutes thereafter is a prudent minimum, with contemporaneous recording of results. Temperature should be documented at least on admission and discharge, along with level of consciousness, airway patency, and skin color. Order diagnostic tests only for specific indications.

Every patient should be monitored with a pulse oximeter and a single-lead, continuous electrocardiogram (ECG). Capnography is necessary only for patients receiving mechanical ventilation or those at risk for compromised ventilatory function. The output from invasive monitors such as central venous, systemic, or pulmonary arterial catheters must be transduced, and results from monitors recorded and timed on the record.

Anesthesiology personnel should manage the patient until PACU staff secure admission vital signs and attach appropriate monitors. A succinct but thorough report that includes sufficient information to allow rapid evaluation and intervention for postoperative complications must be legibly recorded ([Table 53-1](#)). A standardized format printed on the PACU record is useful. Document the time, amount, and route of administration of all neuromuscular relaxants, respiratory depressant medications, and reversal agents, and clearly outline orders, specific therapeutic end points, and how to contact the responsible anesthesiologist. Responsibility should never be turned over to PACU personnel until the patient's airway status, ventilation, and hemodynamics are appropriate. The anesthesiologist checks the function of indwelling cannulae, iv catheters, and monitors just before leaving.

Table 53-1. COMPONENTS OF A POSTANESTHESIA CARE UNIT ADMISSION REPORT

POSTOPERATIVE PAIN MANAGEMENT

Relief of surgical pain with minimal side effects is a primary goal of PACU care and a very high priority for both anesthesiologists and patients¹⁴ (see also [Chapter 54](#)). Inadequate postoperative analgesia is a major source of preoperative fear and postoperative dissatisfaction for surgical patients. In addition to improving patient comfort, relief of pain reduces sympathetic nervous system (SNS) response and helps avoid hypertension, tachycardia, and dysrhythmias. In hypovolemic patients who rely on SNS activity for cardiovascular homeostasis, analgesics can precipitate hypotension, especially if direct or histamine-induced vasodilation occurs. A tachycardic patient with low or normal blood pressure who complains of severe pain must be carefully assessed before analgesics are given. Eliminating pain also precipitates hypoventilation by accentuating the depressant effects of previously administered opioids or residual anesthetics.

The actual degree of postoperative pain can be difficult to establish. Severity of pain varies among different surgical procedures and anesthetic techniques. Staff are relatively ineffective at quantifying a patient's discomfort. Inexperienced nurses overestimate a patient's pain, whereas more experienced nurses tend to underestimate.¹⁵ Either error leads to inappropriate treatment. A wide divergence can exist between cognitive perception of pain and SNS response, related to psychological, cultural, and cardiovascular differences among individuals. Some perceive severe pain with minimal SNS activity, whereas others have hypertension, tachycardia, and dysrhythmias with minimal complaint of discomfort. The best barometer of adequate analgesia is usually the patient's own perception. Careful planning of analgesic requirements and medication transitions is necessary to provide seamless pain control beyond the PACU.¹⁶ In a study of postoperative pain in 10,008 ambulatory patients, 5.3% related severe pain in the PACU but only 1.7% in the discharge area. Surprisingly, 5.3% related severe pain again 24 hours after surgery¹⁷ ([Fig. 53-1](#)).

Figure 53-1. Percentage of patients experiencing severe pain in the postanesthesia care unit (PACU), the ambulatory surgery unit (ASU), and during a postanesthesia phone call at 24 hours. (From Chung F, Ritchie E, Su J: Postoperative pain in ambulatory surgery. *Anesth Analg* 85:808, 1997.)

To avoid masking signs of an unrelated condition or a surgical complication, ascertain that the nature and intensity of pain are appropriate for the surgical procedure before analgesics or sedatives are administered. The central nervous system (CNS) signs of hypoxemia, acidemia, or cerebral hypoperfusion often mimic those of pain, especially during emergence. Evaluating orientation, the level of arousal, and cardiovascular or pulmonary status usually identifies such patients. Administration of parenteral analgesics or sedatives can acutely worsen hypoventilation, airway obstruction, or hypotension, causing sudden deterioration and arrest.

Incisional pain can be effectively treated with iv opioids.¹⁸ Opioid administration in the PACU should be part of a planned analgesic continuum that begins with the induction of surgical anesthesia and continues throughout the postoperative course. During iv titration, analgesia is achieved while incremental respiratory or cardiovascular depression is assessed. Sufficient analgesia is the end point, even if large doses of opioids are necessary in tolerant patients. Short-acting iv opioids are useful to expedite discharge and minimize nausea in ambulatory settings,¹⁹ although short duration of analgesia can be a problem.²⁰ Disadvantages of the intramuscular route include larger dose requirements, delayed onset, and unpredictable uptake in hypothermic patients. Oral and transdermal analgesics have a limited role in the PACU but are helpful for ambulatory patients. Rectal analgesics are useful in children. Agonist-antagonist analgesics offer little advantage.

Ketorolac is an effective analgesic and anti-inflammatory that lowers opioid requirements, although possibility of hemorrhage due to its antiplatelet properties limits its use. Ketorolac might also decrease ischemic events in patients with coronary artery disease through analgesic and antiplatelet actions.²¹ Oral acetaminophen or ibuprofen is effective, especially when administered before surgery.^{22,23} Use of clonidine to supplement analgesic is effective but can cause hypotension.²⁴ N-methyl-D-aspartate antagonists such as dextromethorphan are claimed beneficial for inflammatory components of pain.²⁵

Fear, anxiety, and confusion often accentuate postoperative pain, especially after general anesthesia. Titration of an iv sedative such as diazepam or midazolam attenuates this psychogenic component, although analgesic requirements may increase because of effects of benzodiazepines on g-aminobutyric acid receptors. It is important to separate requirements for analgesia and for sedation. Opioids are poor sedatives, whereas benzodiazepines are poor analgesics. Interventions such as repositioning, reassurance, or extubation can also help minimize discomfort.

Other analgesic modalities provide pain relief beyond the PACU. Intravenous opioid loading in the PACU is important for smooth transition to patient-controlled analgesia. Injection of opioids into the epidural or subarachnoid space during anesthesia or in the PACU yields prolonged postoperative analgesia in selected patients.^{26,27} Epidural opioid analgesia is effective after thoracic and upper abdominal procedures and helps wean patients with obesity or chronic obstructive pulmonary disease (COPD) from mechanical ventilation. Immediate and delayed ventilatory depression can occur, related to vascular uptake and cephalad spread in cerebrospinal fluid.^{28,29} Nausea and pruritus are troubling side effects. Nausea resolves with antiemetics, whereas pruritus often responds to naloxone infusion. Ondansetron has been proposed as treatment for pruritus as well as opiate-induced nausea.³⁰ Epidural analgesia may also improve surgical outcomes after orthopedic and urologic procedures. Addition of local anesthetic or clonidine enhances analgesia and decreases the risk of side effects from epidural opioids,²⁴ although local anesthetics add risk of hypotension or motor blockade. Addition of other potentiating agents such as neostigmine is not yet widely used.

Placement of long-acting regional analgesic blocks reduces pain, controls SNS activity, and often improves ventilation. Percutaneous intercostal blocks reduce analgesic requirements after thoracic or high abdominal incision, although beneficial effects on postoperative pulmonary function are questionable. After shoulder and upper extremity procedures, interscalene block yields almost complete pain relief with only moderate inconvenience from motor impairment. Paralysis of the ipsilateral diaphragm can impair postoperative ventilation in patients with marginal reserve, although the impact is small in most.³¹ Use of more dilute anesthetic solutions might decrease the incidence of this problem.³² Suprascapular nerve block might be an alternative to avoid this very common and potentially serious side effect.³³ Caudal analgesia is effective in children after inguinal or genital procedures, whereas infiltration of local anesthetic into joints, soft tissues, or incisions decreases the intensity of pain. Instillation of opioids or neostigmine into joints is also somewhat analgesic. Input of positive suggestion during anesthesia probably has no significant influence on analgesic requirement and recovery course. Other modalities, such as transcutaneous nerve stimulation, "white noise," acupuncture, or hypnosis have limited utility for surgical pain.

Use of patient-controlled analgesia, spinal opioids, or neural blockade mandates anticipation of risk beyond the PACU. Again, the anesthesiologist must plan for extended postoperative analgesia before induction of surgical anesthesia and orient the anesthetic and PACU care toward that plan. If one analgesic modality proves inadequate, particular care must be taken implementing a second, innovative technique.

DISCHARGE CRITERIA

When possible before discharge, each patient should be sufficiently oriented to assess his or her physical condition and to summon assistance. Airway reflexes and motor function must be adequate to prevent aspiration of vomitus or secretions. Assure that ventilation and oxygenation are acceptable, with sufficient reserve to cover minor deterioration in unmonitored settings. Blood pressure, heart rate, and indices of peripheral perfusion should be relatively constant for at least 15 minutes. Achieving normal body temperature is not an absolute requirement, but resolution of shivering is. Acceptable analgesia must be achieved and vomiting appropriately controlled. Patients should be observed for at least 15 minutes after the last iv opioid or sedative is administered to assess peak effects and side effects. After reinforcement of regional anesthetics, longer observation could be appropriate. Oxygen saturation should be monitored for 15 minutes after discontinuation of supplemental oxygen to detect hypoxemia. Assess likely surgical complications (e.g., bleeding, vascular compromise, pneumothorax) or complications of underlying conditions (e.g., coronary artery disease, diabetes, hypertension, asthma). The results of postoperative diagnostic tests should be reviewed. If these generic criteria cannot be met, postponement of discharge or transfer to a specialized unit is advisable.

Fixed PACU discharge criteria must be used with caution because variability among patients is tremendous. Scoring systems that quantify physical status or establish thresholds for vital signs are useful for assessment but cannot replace individual evaluation.^{34,35} Ideally, each patient should be evaluated for discharge by an anesthesiologist using a consistent set of criteria (Table 53-2), considering the severity of underlying disease, the anesthetic and recovery course, and the level of care at the destination, especially for ambulatory patients (see Chapter 46).

| | |
|-----------------------------|---|
| General condition | Observed in PACU, stable, and physical examination |
| Respiratory status | Spontaneous breathing, adequate tidal volume, and oxygen saturation |
| Heart rate and rhythm | Stable, within normal limits, and regular |
| Vital signs and oxygenation | Stable, within normal limits, and oxygen saturation |

| Fluid balance | Stable, within normal limits, and no signs of fluid overload |
| Medication management | Stable, within normal limits, and no signs of medication toxicity |
| Discharge criteria | Stable, within normal limits, and no signs of discharge criteria |

Table 53-2. GUIDELINES FOR DISCHARGE EVALUATION FROM POSTANESTHESIA CARE UNIT

CARDIOVASCULAR COMPLICATIONS

Postoperative Hypotension

Systemic hypotension, a common postoperative complication, can cause hypoperfusion of vital organ systems. Consequent tissue hypoxia promotes inefficient anaerobic metabolism and accumulation of lactic acid, leading to unexplained metabolic acidemia. During hypotension, the SNS diverts blood flow to preserve the brain, heart, and kidneys. Symptoms of hypotension referable to these organs (e.g., disorientation, nausea, loss of consciousness, angina, reduced urine output) indicate that compensatory mechanisms have been exhausted. Complications of hypotension include ischemia or infarction of the myocardium, cerebrum, renal tubules, spinal cord, or bowel. Reduced venous flow rate increases risk of deep vein thrombosis and pulmonary embolism. Decreased hepatic oxygen delivery might change metabolic pathways for drugs, causing hepatic damage by toxic metabolites. The degree of hypotension at which risk of complications increases varies with the preoperative blood pressure, and is higher in patients with arteriosclerotic disease, stenotic vascular lesions, chronic hypertension, increased intracranial pressure, or renal failure.

Spurious Hypotension

Identifying spurious hypotension avoids unnecessary treatment and iatrogenic hypertension. A blood pressure cuff that is too large yields falsely low values. Cuff width should approximate two thirds of arm circumference. A transducer system that is improperly zeroed or excessively damped by air bubbles or catheter obstruction yields artificially low readings from an arterial catheter. Arterial constriction caused by hypothermia or α -adrenergic agonist drugs can reduce radial or brachial blood pressure below aortic pressure.

Hypovolemia

A reduction in circulating intravascular volume (“absolute” hypovolemia) decreases ventricular filling and cardiac output. SNS-mediated tachycardia, increased systemic vascular resistance (SVR), and venoconstriction might compensate for a 15–20% loss of intravascular volume. Greater deficits cause hypotension.

Failure to replace preoperative fluid deficit and fluid or blood lost during surgery frequently causes absolute hypovolemia. In the PACU, ongoing hemorrhage, sweating, and exudation of fluid into tissues (third-space losses) exacerbate hypovolemia. Blood loss is often occult, as with retroperitoneal bleeding, diffuse oozing related to coagulopathy, or hemorrhage into muscle after trauma or orthopedic procedures. Third-space losses can continue for up to 48 hours after surgery and can be massive during high-permeability pulmonary edema or accumulation of ascites. In a hypothermic, venoconstricted patient, a low intravascular volume might maintain cardiac output on PACU admission but cause hypotension when venous capacity increases during rewarming.

Sometimes, a “normal” intravascular volume is inadequate to maintain blood pressure (relative hypovolemia). Sudden decreases in endogenous SNS activity caused by relief of pain or vasovagal responses can acutely increase venous capacity, as can medications that mimic α -adrenergic receptor blockade (droperidol, chlorpromazine), release histamine (morphine), or directly dilate veins (nitrates, furosemide). Spinal or epidural anesthesia interferes with SNS regulation of venous tone, increasing venous capacitance and preventing constriction of veins in response to hemorrhage or positional changes. Compression of thoracic veins from positive intrathoracic pressure during mechanical ventilation impedes venous return, as does inferior vena caval compression from a gravid uterus or increased intra-abdominal pressure. Pericardial tamponade or air embolism also impedes ventricular filling.

On the patient’s admission to the PACU, his or her intravascular volume is estimated, considering preoperative status, type and duration of surgery, estimated blood loss, fluid replacement, and hemostasis. Monitoring urine output as an index of intravascular volume can be misleading. Surgery and anesthesia impair renal tubular concentrating ability and glycosuria causes osmotic diuresis, each falsely indicating that intravascular volume is adequate. The variation of systolic blood pressure seen on an arterial catheter or pulse oximeter trace during positive-pressure ventilation provides a qualitative warning of reduced intravascular volume.³⁶ Central venous or pulmonary arterial pressure or transesophageal ultrasound monitoring helps clarify volume status.

Ventricular Dysfunction

Postoperative hypotension caused by ventricular dysfunction usually indicates that baseline ventricular contractility is reduced. Such patients often need high left ventricular end-diastolic pressure and elevated SNS activity to maintain cardiac output. Excessive fluid administration causes ventricular dilation, decreased cardiac output, and hypotension, often complicated by hydrostatic pulmonary edema. Overhydration may not be evident. If sympathetic blockade during spinal or epidural anesthesia is treated with excessive fluids, ventricular filling pressures can be normal during early recovery despite hypervolemia. When SNS blockade resolves, a characteristically high level of SNS outflow mobilizes large fluid volumes to the central circulation, precipitating ventricular failure. Depression from residual inhalational anesthetics and opiates contributes to decreased SNS outflow and reduced ventricular contractility. Although β -adrenergic receptor–blocking drugs reduce myocardial contractility, hypotension usually occurs only in patients who rely on maximal SNS activity for cardiovascular stability. Profound metabolic or respiratory acidemia reduces ventricular performance by interfering with catecholamine–receptor interaction and by depressing central SNS outflow. Low ionized calcium levels caused by dilution, chelation, or acute alkalemia also reduce ventricular contractility. Right ventricular dysfunction caused by pulmonary thromboembolism often presents with systemic hypotension.

Myocardial Ischemia

Postoperative myocardial ischemia is often initiated in high-risk patients by tachycardia or hypotension. Among patients with coronary disease, risk is higher for those with a history of congestive heart failure, smoking, and hypertension, and those having emergency surgery.³⁷ Patients are at significant risk of ischemia after both general and regional anesthetics.³⁸ In the PACU, tachycardia caused by pain, hypotension, acidemia, anxiety, or medications decreases diastolic filling time and generates ischemia. Inadequate diastolic blood pressure also causes ischemia. Increased ventricular wall tension secondary to overhydration, hypertension, or increased SNS activity increases myocardial oxygen consumption and initiates ischemia even when diastolic pressure is adequate. Severe hypoxemia, anemia, or carbon monoxide (CO) poisoning generates ischemia independent of coronary perfusion. The lowest tolerable hematocrit is highly individualized to each patient, but usually higher in patients with vascular disease.³⁹ Most postoperative angina is truly silent, and risk of early morbidity is high.^{21,40} Postoperative anginal chest pain might be overshadowed by pain from surgical incisions and gastric distention, or masked by analgesia from residual anesthetics or opioids. The incidence of ischemic dysrhythmias is difficult to determine, given the high incidence of benign postoperative dysrhythmias. Hypotension caused by ischemic ventricular dysfunction can quickly cause irreversible infarction. Close evaluation of the hemodynamic responses to fluid challenge, the ST segment and T-wave morphology on the ECG, and the pulmonary artery (PA) pressures can sometimes uncover ischemia before hypotension occurs (Fig. 53-2). However, the predictive value of these indices is controversial. In high-risk patients, control of precipitating factors and timely therapy with analgesia, nitrates, and especially β -adrenergic blocking agents helps

decrease morbidity from postoperative myocardial ischemia.^{41,42}

Figure 53-2. Physiologic consequences of myocardial ischemia. Note that changes in ventricular pressure and compliance may precede electrocardiographic changes (ST segment). LVEDP = left ventricular end-diastolic pressure; LVEDV = left ventricular end-diastolic volume; EF = ejection fraction; STD = ST segment change; CHF = congestive heart failure. (Reproduced with permission from Barash PG: Monitoring myocardial oxygen balance: Physiologic basis and clinical application. In Barash PG, Deutsch S, Tinker J [eds]: Refresher Courses in Anesthesiology, vol 13, p 21. Philadelphia, JB Lippincott, 1985.)

Cardiac Dysrhythmia

Pre-existing myocardial disease or rhythm disturbances increase the risk of postoperative hypotension caused by a cardiac dysrhythmia. Sinus or nodal bradycardia with ventricular rates below $40 \text{ beats} \cdot \text{min}^{-1}$ decreases cardiac output and blood pressure, as do slow ventricular rhythms associated with complete heart block. A tachydysrhythmia that generates ventricular rates of $140\text{--}150 \text{ beats} \cdot \text{min}^{-1}$ can decrease cardiac output because ventricular filling time is compromised. Ventricular fibrillation, asystole, or electromechanical dissociation causes life-threatening reductions of output. Swings in autonomic nervous system activity place patients with valvular abnormalities at particular risk of hypotension from rhythm changes. An increased heart rate in patients with aortic stenosis reduces systolic ejection time, whereas tachycardia in patients with mitral stenosis impedes ventricular filling. Both decrease cardiac output and cause hypotension.

Decreased Systemic Vascular Resistance

Hypotension associated with regional anesthesia, α -adrenergic receptor–blocking drugs, blood components, or warming is caused by decreased SVR as well as by reduced venous return. Severe systemic acidemia decreases SVR by directly dilating vessels and by interfering catecholamine– α receptor interaction. Antihypertensive medications like hydralazine and nitroprusside reduce blood pressure in hypovolemic patients by interfering with arteriolar constriction. Sepsis interferes with arteriolar constriction, generating a high-output, low-resistance hypotension.

Postoperative hypotension is occasionally caused by the effects of anesthesia or surgery on baroreceptor function or by intracranial disease. Rarely, hypotension reflects steroid deficiency in patients whose adrenal axis is suppressed by exogenous steroid use. Hypotension secondary to steroid deficiency is often preceded by lethargy, fever, or nausea and by hyponatremia, hyperkalemia, and hypoglycemia.

Treatment of Postoperative Hypotension

In general, symptoms of vital organ hypoperfusion or a 20–30% reduction in systolic pressure from preoperative levels is an indication to treat. If risk for complication from hypotension is high, acceptable limits for pressure and heart rate should be defined during PACU admission.

A low blood pressure determination should be quickly validated. Auscultation of heart sounds and palpation of carotid or femoral pulses are useful qualitative indicators of central blood pressure. Supplemental oxygen should be administered and the iv infusion rate increased to maximum because hypovolemia is the most common etiology. If hypotension is spurious or caused by a reduced SVR or ischemia, the amount of fluid infused while these diagnoses are established is usually inconsequential. Check breath sounds and the cardiac rate and rhythm. Recent drug administration should be evaluated, and infusions that might cause vasodilation stopped. A 12-lead ECG, arterial blood gas determination, and chest radiography might be indicated.

Therapy is directed at the etiology of reduced systemic blood pressure, and the diagnosis reconfirmed. Simple maneuvers such as reducing airway pressure, placing pregnant patients in a lateral tilt position, or placing patients with orthostatic changes in a supine position should be used when appropriate. Tension pneumothorax must be evacuated. Infusion of crystalloid solutions is usually sufficient, although plasma expanders or blood facilitate more rapid volume expansion. Sympathomimetic α -adrenergic pressors such as phenylephrine that increase SVR and venous return temporarily maintain systemic pressure until sufficient volume can be infused. Ephedrine is less desirable because increased heart rate and contractility are usually unnecessary.

If fluid administration (300–500 ml) does not improve hypotension, myocardial dysfunction should be considered. For dysfunction not related to ischemia, drugs that augment contractility, perhaps in conjunction with systemic vasodilators, restore cardiac output and systemic pressure. If hypotension is caused by ischemia, resolution of the ischemia usually restores baseline cardiac function. Support of aortic diastolic pressure with an α receptor agonist and reduction of left ventricular end-diastolic pressure with nitroglycerin help maximize the coronary artery pressure gradient. Heart rate control with analgesics, sedatives, and especially β receptor blockers is important. Accurate diagnosis of ischemia is critical because therapy for ischemia can worsen hypotension caused by hypovolemia or other causes. PA catheterization or transthoracic echocardiography might be useful to estimate left ventricular filling and cardiac output, although the actual predictive value of PA readings is questionable.

If hypotension is caused by metabolic acidemia, iv bicarbonate or another alkalinizing agent helps restore pH while the underlying cause is remedied. Severe hypoxemia or respiratory acidemia mandates tracheal intubation and mechanical ventilation with supplemental oxygen. Sinus bradycardia unrelated to hypoxemia usually responds to iv atropine, glycopyrrolate, or ephedrine. Refractory bradycardia caused by sinus node disease or complete heart block is managed with iv epinephrine or isoproterenol, or with cardiac pacing. Digitalization or calcium channel blockade reduces the ventricular rate from acute-onset atrial fibrillation, whereas re-entrant paroxysmal atrial tachycardia often disappears with maneuvers or drugs that change cardiac conduction rates. If hypotension from a tachydysrhythmia is severe, immediate low-energy direct-current cardioversion (50J) is indicated.

Hypotension caused by a low SVR is treated with an α -adrenergic agent. Sympathectomy from regional anesthesia responds to low levels of a stimulation. During advanced sepsis or catecholamine depletion, norepinephrine infusions may be required. If decreased SVR is caused by acidemia, correction of pH is necessary before pressor therapy will be effective.

Postoperative Hypertension

A moderate elevation in systemic blood pressure is common and acceptable in well-hydrated postoperative patients.^{8,43} However, excessively high blood pressure can cause hemorrhage and third-space losses from arterial and venous sources, and might disrupt vascular suture lines. High ventricular intracavitary pressure might lead to dilation, myocardial fiber stretch, and increased wall tension, precipitating ischemia or dysrhythmias. Elevated intraocular or intracranial pressure, cerebral edema, and intracranial hemorrhage also potentially increase morbidity.

A blood pressure cuff that is too small yields erroneously high readings, especially in obese or very muscular patients. A transducing system that is improperly zeroed or exhibits excessive resonance overestimates systolic pressure. Overshoot does not significantly change the accuracy of diastolic readings.

Patients with pre-existing hypertension exhibit exaggerated blood pressure responses because they have noncompliant vasculature, elevated peripheral vascular tone, and high levels of baseline endogenous SNS activity. Baroreceptor control of heart rate is impaired,⁴⁴ especially after anticholinergic administration during reversal of neuromuscular relaxation. After carotid endarterectomy, abnormal baroreceptor function can also generate hypertension.

Enhanced SNS activity frequently causes hypertension in the PACU. Peripheral arteriolar and venous constriction mediated by α -adrenergic stimulation increases SVR and venous return, whereas increased β_1 receptor stimulation increases ventricular contractility and heart rate. Intravascular volume expansion also increases cardiac

output, especially when hypothermia leads to systemic vasoconstriction. SNS outflow most often reflects an appropriate response to noxious stimuli or adverse physiologic conditions (Table 53-3). SNS activity might also be a manifestation of exogenous sympathomimetics, monoamine oxidase inhibition, or pheochromocytoma. Cerebral vascular accidents, hypoxic encephalopathy, increased intracranial pressure, or severe osmotic changes interfere with central SNS regulation, causing autonomic dysfunction and severe hypertension.

| FACTORS INCREASING SYMPATHETIC ACTIVITY | |
|--|--|
| Noxious stimuli | |
| Pain, anxiety, cranial stimulation, full bladder, tracheal intubation | |

| Relaxants | |
| Pancuronium | |

Table 53-3. FACTORS THAT INCREASE POSTOPERATIVE CARDIAC SYMPATHETIC INFLUENCE

Indications for treatment include a systolic or diastolic pressure 20–30% above baseline, signs or symptoms of complications (*e.g.*, headache, bleeding, ocular changes, angina, ST segment depression), or an unusual risk of morbidity (*e.g.*, increased intracranial pressure, mitral regurgitation, open eye injury). In patients with chronic hypertension, achieving a “normal” systemic pressure could promote vital organ hypoperfusion, so blood pressure should be reduced toward preoperative levels. Therapy should be oriented toward causes of increased SNS activity. Administering analgesics or sedatives, correcting acidemia or hypoxemia, and ensuring ability to void are helpful. If hypertension persists, iv antihypertensive medications such as hydralazine with propranolol, labetalol, esmolol, or nicardipine yield temporary control. Incorporation of clonidine into the overall regimen is useful for both augmenting analgesia and for blood pressure control.⁴⁴ Clonidine may also blunt the postoperative SNS response to stimuli.⁴⁵ Potent vasodilators (nitroprusside, nitroglycerin) are reserved for refractory or profound hypertension.

Cardiac Dysrhythmias in the Postoperative Period

Asymptomatic Electrocardiographic Abnormalities

General anesthesia causes ECG changes in axis, intraventricular conduction, P- and T-wave morphology, and ST segments that are not related to cardiac abnormality (see Appendix). These changes reflect electrophysiologic effects of hypothermia, inhalation anesthetics, autonomic nervous system imbalance, and mild electrolyte abnormalities, and usually resolve within 3–6 hours. If persistent ECG changes indicate ischemia in a patient at risk, myocardial oxygen supply and demand should be optimized and serial ECG and enzyme determinations followed. Prolonged monitoring may be appropriate.

Bradycardia

In the PACU, increased parasympathetic nervous system (PNS) activity or decreased SNS influence promotes sinus bradycardia⁴⁶ (Table 53-4). Sick sinus syndrome, sinoatrial nodal ischemia, or severe hypoxemia also reduce sinus rate. Sinus bradycardia is benign unless it causes hypotension, usually when the rate falls below 40–45 beats · min⁻¹. Therapy involves restoring SNS/PNS balance to normal. Bradycardia caused by excess PNS activity usually responds to muscarinic-blocking drugs such as atropine or glycopyrrolate. Decreased SNS activity usually responds to a b-mimetic drug like ephedrine.

| FACTORS INCREASING PARASYMPATHETIC ACTIVITY | |
|--|--|
| Vagal reflexes | |
| Carotid sinus massage, Valsalva maneuver, gagging, rectal examination, increased ocular pressure, bladder distention, pharyngeal stimulation | |
| Parasympathomimetic medications | |
| Acetylcholinesterase inhibitors | |
| Neostigmine, edrophonium | |
| α-Adrenergic drugs | |
| Nesynephrine, norepinephrine | |
| Opioids | |
| Morphine, fentanyl | |
| Succinylcholine | |
| FACTORS DECREASING SYMPATHETIC ACTIVITY | |
| High spinal or epidural anesthesia | |
| Withdrawal of stimulus, extubation, emptying bladder | |
| Severe acidemia/hypoxemia | |
| Sympatholytic medications | |
| β Receptor blockers (propranolol) | |
| Opioids/sedatives/general anesthetics | |
| Ganglionic blockers | |
| Local anesthetics | |

Table 53-4. FACTORS THAT INCREASE POSTOPERATIVE PARASYMPATHETIC INFLUENCE

Emergence of a nodal pacemaker in the lower atrioventricular (AV) node or the bundle of His is also usually caused by autonomic imbalance. Increased PNS activity seems to suppress a dominant sinoatrial pacemaker more than other pacemaker cells, allowing a slower focus to emerge. Factors that stop sinus impulses from reaching the ventricle also promote nodal rhythms. Nodal rhythms are benign unless a low ventricular rate or lack of coordinated atrial contraction reduces cardiac output and blood pressure. If hypotension occurs, atropine or b-mimetic medications can restore a sinus rhythm. These measures sometimes only increase nodal rate, necessitating support of blood pressure until spontaneous resolution occurs.

Risk of complete heart block in patients with bifascicular block or left bundle-branch block is small but real.⁴⁷ Idioventricular bradycardia seldom generates adequate cardiac output, and usually indicates life-threatening heart block, hypoxemia, acidemia, or myocardial ischemia. Atropine might improve AV nodal conduction enough to allow supraventricular impulses to reach the ventricles with acute third-degree AV nodal block. Atropine does not increase rate of ventricular pacemaker cells because they lack PNS innervation. Epinephrine, isoproterenol, or cardiac pacing accelerate the ventricular rate.

Tachycardia

Postoperative sinus tachycardia is nearly always associated with a physiologic increase in SNS influence (see Table 53-3). Tachycardia is usually harmless, but it can precipitate acute myocardial ischemia in patients with coronary artery disease. Sinus tachycardia seldom interferes with ventricular filling, but compromises cardiac output in patients with stenotic valvular lesions. Tachycardia exacerbates hypertension and might herald acidemia, hypoxemia, or malignant hyperthermia. Sinus tachycardia is treated by controlling its underlying cause. Giving analgesics for pain, iv fluids for hypovolemia, or sedatives to calm anxiety is usually sufficient. Decompressing a full bladder is helpful. Tachycardia caused by sympathomimetic drugs resolves as drug levels fall. If SNS activity is beyond control or tachycardia presents a threat, b blockade helps control rate. Digoxin is ineffective unless ventricular failure is the underlying cause.

Sudden-onset atrial fibrillation sometimes generates ventricular rates greater than 150 beats · min⁻¹ and might appear as a fast, nearly regular supraventricular tachycardia on the ECG. Patients recovering from thoracic surgical procedures or those with mitral valvular disease or pulmonary emboli have a higher incidence.⁴⁸ Fast ventricular rate might cause hypotension or myocardial ischemia. Digoxin or calcium channel blockers decrease the number of impulses that traverse the AV node per minute. For serious hypotension, direct-current cardioversion can convert fibrillation to sinus rhythm.

Atrial flutter is rare in postoperative patients. Treatment decreases the ventricular rate and regularizes atrial electrical activity. Paroxysmal atrial tachycardia usually reflects circus re-entry in a loop of conduction tissue, although 10–15% of cases are caused by discrete, rapidly firing atrial cells. Fast rates can interfere with ventricular filling and compromise cardiac output. Treatment involves slowing conduction velocities to interrupt re-entrant synchrony by increasing PNS influence (see Table 53-4). Digoxin or calcium channel blockers are also useful. Paroxysmal atrial tachycardia caused by a rapidly firing atrial pacemaker slows with b blockade.

Postoperative ventricular tachycardia or fibrillation almost always reflects severe myocardial ischemia, systemic acidemia, or hypoxemia, although re-entrant ventricular

tachycardia does occur. Cardiopulmonary resuscitation, β -mimetic pressors, cardioversion, and control of ventilation, oxygenation, and serum pH help restore a synchronized rhythm.

Premature Contractions

An aberrant impulse arising in the atrium, AV node, or upper bundle of His generates an atrial premature contraction (APC), causing an early but otherwise normal QRS complex that often is not preceded by a P wave. In postoperative patients, APCs usually appear with increased SNS activity and seldom cause hemodynamic compromise. Control of stimuli causing increased SNS activity often eliminates APCs (see [Table 53-3](#)).

Ventricular ectopy present before surgery usually reappears in the PACU, with somewhat decreased frequency. Ectopy does not usually predict postoperative outcome.⁴⁹ In postoperative patients, abnormal ventricular complexes are almost always benign and seldom require treatment. Relatively few high-amplitude, wide, bizarre QRS complexes represent abnormal impulses that originate in ventricular conducting tissue. Most represent aberrantly conducted APCs or re-entrant rhythms. Most actual premature ventricular contractions (PVCs) are caused by nonthreatening conditions.

Actual PVCs usually occur at varying intervals from a previous normal QRS and often exhibit a full compensatory pause. In postoperative patients, benign PVCs frequently accompany excessive PNS or SNS activity. Increased PNS influence allows emergence of ventricular escape beats. Increased SNS activity accelerates ventricular automatic cells, promoting depolarization between supraventricular impulses, and fosters emergence of parasystolic foci. PVCs resolve when autonomic nervous system balance is restored. Benign postoperative PVCs can also be generated by stretch of myocardial fibers from hypertension and mechanical stimulation from central vascular catheters. PVCs that reflect digitalis toxicity, myocardial ischemia, or electrolyte disturbances are much rarer but more serious. Antidysrhythmics such as lidocaine, procainamide, and bretylium control automaticity in ischemic ventricular tissues.

An early supraventricular impulse that enters the ventricular conduction system before all pathways have recovered excitability generates asynchronous ventricular depolarization and a wide, high-amplitude ECG complex. This aberrantly conducted APC is sometimes preceded by an abnormal P wave, often exhibits a noncompensatory pause, and often resembles normal complexes in general shape. Delayed recovery of excitability after general anesthesia favors aberrant conduction.

If a sinus impulse is delayed in a ventricular conduction pathway long enough to encounter tissue that has recovered excitability, the impulse depolarizes this tissue a second time and spreads through the entire heart. This "re-entrant" depolarization generates a wide, high-amplitude QRS similar to a true PVC. Re-entrant complexes are uniform in configuration, manifest full compensatory pauses, follow the preceding normal complex by a constant interval (fixed coupling), and often appear in a bigeminal pattern. Re-entry is often seen with increased SNS activity in patients recovering from halothane anesthesia.

If ectopic beats are so frequent that cardiac output is compromised, control of autonomic nervous system imbalance usually restores a regular rhythm. Antidysrhythmics are seldom necessary, although β receptor blockade might be useful. Treatment of re-entrant impulses is based on elimination of factors that cause conduction delay or nonuniform recovery of excitability, and on control of SNS activity.

POSTOPERATIVE PULMONARY DYSFUNCTION

Mechanical, hemodynamic, and pharmacologic factors related to surgery and anesthesia impair ventilation, oxygenation, and airway maintenance.⁵⁰ Heavy smoking, obesity, sleep apnea, severe asthma, and COPD increase the risk of postoperative ventilatory events.^{43,51} Preoperative pulmonary function testing has limited predictive value for postoperative complications,^{52,53} perhaps with the exception of postoperative bronchospasm in smokers.⁵⁴

Inadequate Postoperative Ventilation

In the PACU, elevated PaCO₂ does not necessarily indicate inadequate postoperative ventilation. Inadequate ventilation should be suspected when (1) respiratory acidemia occurs coincident with tachypnea, anxiety, dyspnea, labored ventilation, or increased SNS activity; (2) hypercarbia reduces the arterial pH below 7.25; or (3) PaCO₂ progressively increases with a progressive decrease in arterial pH.

Inadequate Respiratory Drive

In PACU patients, mild respiratory acidemia is expected. Residual effects of iv or inhalational anesthetics blunt the ventilatory responses to both hypercarbia and hypoxemia.⁵⁵ Residual neuromuscular relaxants might also depress cholinergic portions of the hypoxic drive neural arc.⁵⁶ Sedatives augment depression from opioids and anesthetics, ablate the conscious will to ventilate (sometimes a significant component of ventilatory drive), and might directly depress ventilation.⁵⁷

Serious hypoventilation and hypercarbia often evolve insidiously during transfer to the PACU. Effects of intraoperative medications are usually waning, but the peak depressant effect of iv opioid given just before transfer occurs in the PACU. Parallel depression of medullary centers that regulate the SNS blunts signs of acidemia or hypoxemia such as hypertension, tachycardia, and agitation, concealing hypoventilation. Patients might communicate lucidly and even complain of severe pain while experiencing significant opioid-induced hypoventilation.⁵⁸ A balance must be struck between an acceptable level of postoperative ventilatory depression and a tolerable level of pain or agitation.⁵⁹ If hypoventilation from opioids is excessive, titration of iv naloxone reverses respiratory depression without affecting analgesia. Flumazenil directly reverses depressant effects of benzodiazepines on ventilatory drive.⁶⁰

The abrupt diminution of a noxious stimulus (e.g., tracheal extubation, regional analgesic block) may promote airway obstruction or hypoventilation by altering the balance between depression from medication and arousal from discomfort. Intracranial hemorrhage or edema sometimes presents with apnea, especially after posterior fossa craniotomy. Bilateral carotid body injury after endarterectomy can ablate peripheral hypoxic drive. Chronic respiratory acidemia from COPD alters CNS sensitivity to pH and makes hypoxic drive dominant, but hypoventilation from supplemental oxygen rarely occurs in the PACU. Patients with abnormal CO₂/pH responses from morbid obesity, chronic airway obstruction, or sleep apnea are more sensitive to respiratory depressants.⁶¹ Risk for apnea after anesthesia in preterm infants depends on type of anesthetic, postconceptual age, and preoperative anemia.⁶² Preterm infants should be monitored for at least 12 hours after surgery (see [Chapter 43](#)).

Increased Airway Resistance

High resistance to gas flow through airways increases work of breathing and CO₂ production. If inspiratory muscles cannot generate sufficient pressure gradients to overcome resistance, alveolar ventilation falls and progressive respiratory acidemia occurs.

In the PACU, high upper airway resistance is caused by obstruction in the pharynx (posterior tongue displacement, change in anteroposterior and lateral dimensions from soft tissue collapse), in the larynx (laryngospasm, laryngeal edema), or in the large airways (extrinsic compression from hematoma or tumor, tracheal stenosis).^{63,64} Weakness from residual neuromuscular relaxation⁶⁵ or myasthenia gravis⁶⁶ is often contributory, but seldom is the primary etiology of airway compromise. If the airway is clear of vomitus or foreign bodies, simple maneuvers such as lateral positioning, chin lift, mandible elevation, or placement of an oropharyngeal or nasopharyngeal airway usually relieve obstruction. A nasopharyngeal airway is better tolerated with functional gag reflexes. Improving the level of consciousness is useful.

During emergence, stimulation of the pharynx or vocal cords by secretions, foreign matter, or extubation generates laryngospasm.⁶⁷ Laryngeal constrictor muscles tightly occlude the tracheal inlet and severely reduce air flow. Children with upper respiratory infections,⁶⁸ smokers,⁵⁰ children chronically exposed to secondhand smoke,⁶⁹ patients with irritable airway conditions, and patients recovering from upper airway surgery are at highest risk. Laryngospasm can usually be overcome with gentle positive pressure in the oropharynx with 100% oxygen. Prolonged laryngospasm is relieved with a small dose of succinylcholine (e.g., 0.1 mg · kg⁻¹). An intubating dosage of succinylcholine should never be used to break postoperative laryngospasm, especially if the alveolar partial pressure of oxygen (PAO₂) has been decreased by a period of apnea. The rate of PAO₂ decline invariably causes serious hypoxemia before restoration of spontaneous ventilation unless assisted ventilation is given⁷⁰ ([Fig. 53-3](#)). If obesity or surgical factors have reduced the functional residual capacity (FRC), the decreased volume of O₂ available in the lungs accelerates the development of hypoxemia.

Figure 53-3. Rate of SpO_2 decline after onset of apnea. (From Benumof JL, Dagg R, Benumof R: Critical hemoglobin desaturation will occur before return to an unparalyzed state following 1 mg/kg intravenous succinylcholine. *Anesthesiology* 87:979, 1997.)

Acute extrinsic upper airway compression, as seen with an expanding neck hematoma, must be relieved. Soft tissue edema worsens airway obstruction, especially in children and in adults recovering from carotid endarterectomy, thyroid surgery, or other procedures on the neck.⁷¹ Nebulized vasoconstrictors help somewhat, but systemic steroids have little effect.⁷² Patients with C1 esterase inhibitor deficiency can have severe, refractory angioneurotic edema after even slight surgical trauma to the upper airway.⁷³ If airway obstruction is fixed (e.g., epiglottitis, retropharyngeal abscess, encroaching tumors), emergency tracheal intubation might be necessary. Airway manipulation is dangerous because minor trauma from intubation attempts can convert a marginal airway into a total obstruction. Use of sedatives or muscle relaxants to facilitate intubation can worsen obstruction by compromising the patient's volitional efforts to maintain the airway and by eliminating spontaneous ventilation. Equipment and personnel necessary for emergency cricothyroidotomy or tracheostomy should be available. Cricothyroidotomy using a 14-gauge iv catheter permits oxygenation and marginal ventilation until the airway can be secured (Fig. 53-4), especially if jet ventilation with 100% oxygen is used.

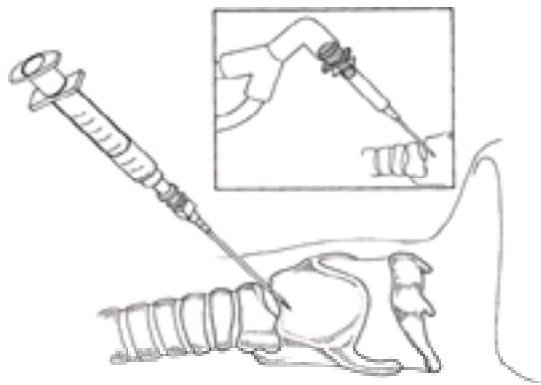

Figure 53-4. Cricothyroidotomy using a large-bore (14-gauge) intravenous catheter attached to syringe. After entry into the trachea, the needle is directed toward the carina.

Reduction of cross-sectional area in small airways increases overall airway resistance because resistance varies inversely with the fourth power of radius during laminar flow and with the fifth power during turbulent flow. In the PACU, pharyngeal or tracheal stimulation from secretions, suctioning, aspiration, or tracheal intubation can trigger a reflex constriction of bronchial smooth muscle in patients with reactive airways. Histamine release precipitated by medication or allergic reactions also increases airway smooth muscle tone. Decreased radial traction on small airways reduces cross-sectional area in patients with COPD or with decreased lung volume secondary to obesity, surgical manipulation, excessive lung water, or splinting.⁷⁴ If ventilatory requirements are increased by warming, hyperthermia, or elevated work of breathing, high flow rates convert laminar flow to higher-resistance turbulent flow.

Smokers and patients with bronchospastic conditions are at highest risk for bronchospasm after surgery.⁷⁵ Preoperative spirometric evidence of increased airway resistance predicts an increased risk of postoperative bronchospasm.⁵⁴ In postoperative patients, prolonged expiratory time or wheezing during a forced vital capacity expiration often unmasks high airway resistance. (Resistance is higher during expiration because intermediate-diameter airways are compressed by positive intrathoracic pressure.) High airway resistance does not always cause audible turbulent air flow (wheezing) because flow might be so impeded that no sound is produced. Signs of increased resistance mimic those of decreased pulmonary compliance. Spontaneously breathing patients exhibit accessory muscle recruitment, labored ventilation, and increased work of breathing with either condition. Mechanically ventilated patients exhibit high peak inspiratory pressure for a given tidal volume.

The treatment of small airway resistance is directed at an underlying etiology. Laryngeal or airway stimulation should be eliminated. Patients often respond well to their existing regimen of albuterol, pirbuterol, or salmeterol inhalers. Isoetharine or metaproterenol nebulized in oxygen resolves postoperative bronchospasm with minimal tachycardia. Intramuscular or sublingual terbutaline can be added. If ventilation is still compromised or unduly labored, an aminophylline loading dose and maintenance infusion might be administered. Bronchospasm resistant to β_2 -sympathomimetic medication may improve with an anticholinergic medication such as atropine or ipratropium. If bronchospasm is life-threatening, an iv epinephrine infusion usually yields profound bronchodilation.

Increased small airway resistance caused by mechanical factors (e.g., loss of lung volume, retained secretions, pulmonary edema) usually does not resolve with bronchodilators. Restoration of lung volume with incentive spirometry or deep tidal ventilation increases radial traction on small airways. Reducing left ventricular filling pressures might relieve airway resistance caused by increased lung water, although resistance can persist because interstitial fluid accumulation requires time to resolve. After prolonged bronchospasm, a patient might seem resistant to bronchodilators. Extended contraction of airway smooth muscle obstructs venous and lymphatic flow, leading to airway wall edema that resolves slowly.

Decreased Compliance

Extrinsic factors that reduce pulmonary compliance accentuate the work of breathing. In the extreme, low compliance causes progressive respiratory muscle fatigue, hypoventilation, and respiratory acidemia. Gas in the stomach or bowel and tight chest or abdominal dressings also reduce pulmonary compliance. Obesity affects compliance, especially when adipose tissue compresses the thoracic cage or increases intra-abdominal pressure in supine or lateral positions. An intra-abdominal tumor, hemorrhage, ascites, bowel obstruction, or pregnancy also impairs diaphragmatic excursion and reduces compliance.

Parenchymal changes affect compliance. Reduction of FRC leads to small airway closure and distal lung collapse, requiring greater energy expenditure to re-expand the lung. Pulmonary edema increases the lung's weight and inertia, making expansion more difficult. Fluid in air spaces also elevates surface tension by interfering with surfactant activity. Pulmonary contusion or hemorrhage interferes with lung expansion, as do restrictive lung diseases, skeletal abnormalities, intrathoracic lesions, hemothorax, pneumothorax, or cardiomegaly.

In the PACU, the work of breathing is improved by resolving problems that reduce compliance. Allowing patients to recover in a semisitting position (rather than supine or full sitting position) reduces work of breathing. Incentive spirometry and chest physiotherapy restore lung volume, as does positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). In patients with COPD and highly compliant lungs, positive airway pressure might force the rib cage and diaphragms toward their excursion limits, accentuating muscular effort required during inspiration.

Neuromuscular and Skeletal Problems

Postoperative airway obstruction and hypoventilation are sometimes caused by incomplete reversal of neuromuscular relaxation. Residual paralysis compromises cough, airway patency, ability to overcome airway resistance, and airway protection.⁷⁶ Intraoperative use of shorter-acting relaxants might decrease the incidence of residual paralysis, but does not eliminate the problem.⁷⁷ Marginal reversal can be more dangerous than near-total paralysis because an agitated patient exhibiting uncoordinated movements and airway obstruction is more easily identified. A somnolent patient exhibiting mild stridor and shallow ventilation from marginal

neuromuscular function might be overlooked. Insidious hypoventilation with respiratory acidemia or regurgitation with aspiration then occur later into recovery.

Patients with neuromuscular abnormalities such as myasthenia gravis, Eaton-Lambert syndrome, periodic paralysis, or muscular dystrophies exhibit exaggerated or prolonged responses to muscular relaxants. Even without relaxant administration, they can exhibit postoperative ventilatory insufficiency from inadequate neuromuscular reserve. Medications potentiate neuromuscular relaxation (e.g., antibiotics, furosemide, propranolol, phenytoin), as does hypocalcemia or hypermagnesemia.

Diaphragmatic contraction is compromised in some postoperative patients, forcing more reliance on intercostal muscles and reducing the ability to deal with decreased compliance or increased ventilatory demands.⁷⁸ Impairment of phrenic nerve function from interscalene block, trauma, or thoracic and neck operations “paralyzes” one or rarely both diaphragms.³¹ Adequate ventilation can normally be maintained with only one diaphragm and marginal ventilation by external intercostal muscles alone. However, with high work of breathing, muscle weakness, or increased ventilatory demands, a nonfunctional diaphragm impairs ventilation. Thoracic spinal or epidural blockade interferes with intercostal muscle function and reduces ventilatory reserve, especially in patients with COPD. Abnormal motor neuron function (e.g., Guillain-Barré syndrome, cervical spinal cord trauma), flail chest, or severe kyphosis or scoliosis can cause postoperative ventilatory insufficiency.

Simple bedside tests help assess mechanical ability to ventilate. Forced vital capacity of 10–12 ml · kg⁻¹ and inspiratory pressure more negative than -25 cm H₂O imply that strength of ventilatory muscles is adequate to sustain ventilation. The ability to sustain head elevation in a supine position is a rough index of muscular recovery. Tactile train-of-four assessment accurately assesses ability to ventilate. However, none of these clinical end points reliably predicts recovery of airway protective reflexes.^{79,80} Hand grip, pedal flexion, and other maneuvers are less reliable indicators. Failure on these tests does not necessarily indicate the need for assisted ventilation.

Occasionally, a clinical picture suggesting ventilatory insufficiency appears when ventilation is adequate. Voluntary limitation of chest expansion to avoid pain causes labored, rapid, shallow breathing characteristic of inadequate ventilation. This pattern seldom causes actual hypoventilation and usually regularizes with repositioning and analgesia. Ventilation with small tidal volumes due to thoracic restriction or reduced compliance generates afferent input from pulmonary stretch receptors, leading to dyspnea, labored breathing, and accessory muscle recruitment in spite of appropriate minute ventilation. (This also occurs during mechanical ventilation with low volumes.) Occasional large, “satisfying” lung expansions often relieve these symptoms. Finally, spontaneous hyperventilation to compensate for a metabolic acidemia might generate tachypnea or labored breathing, which is mistaken for ventilatory insufficiency.

Increased Dead Space

Ventilation of poorly perfused alveoli with high ventilation/perfusion (\dot{V}/\dot{Q}) ratios or of unperfused dead space is less effective in removing CO₂. Expansion of dead space volume or reduction of tidal volume increases the fraction of each breath wasted in dead space (\dot{V}_D/\dot{V}_T) and the amount of CO₂ from the previous exhalation that is rebreathed. A proportionally larger increase in total minute ventilation is also required to meet any increase in CO₂ production. Patients with high \dot{V}_D/\dot{V}_T are at greater risk for postoperative ventilatory failure.

In an occasional postoperative patient, an acute increase in dead space contributes to postoperative respiratory acidemia. Although upper airway dead space is reduced after tracheal intubation and nearly eliminated by tracheostomy, excessive tubing volume or valve reversal in breathing circuits promotes rebreathing of CO₂. PEEP or CPAP elevates anatomic dead space, especially in patients with high pulmonary compliance. Pulmonary embolization with air, thrombus, or cellular debris increases physiologic dead space, although impact on CO₂ excretion is often masked by accelerated minute ventilation from hypoxic drive or reflex responses.

Pulmonary hypotension can transiently increase \dot{V}_D/\dot{V}_T by decreasing perfusion to well ventilated, nondependent lung. Irreversible increases in dead space occur if adult respiratory distress syndrome (ARDS) related to sepsis, massive transfusion, or hypoxia destroys pulmonary microvasculature.

Dead space may appear high if an inhalation interrupts the previous exhalation and a portion of spent alveolar gas is rebreathed. This “gas trapping” occurs when high airway resistance lengthens the time required to exhale completely, or if improper inspiration/expiratory ratios or excessive ventilatory rates are used during mechanical ventilation.

Increased Carbon Dioxide Production

Carbon dioxide production varies directly with metabolic rate, body temperature, and substrate availability. During anesthesia, CO₂ production falls to approximately 60% of the normal 2–3 ml · kg⁻¹ · min⁻¹ as hypothermia lowers metabolic activity and neuromuscular relaxation reduces tonic muscle contraction. In the PACU, metabolic rate and CO₂ production can increase by 40% as they return toward normal. Shivering, high work of breathing, infection, SNS activity, or rapid carbohydrate metabolism during iv hyperalimantation also accelerate CO₂ production. Malignant hyperthermia generates CO₂ production many times greater than normal, which rapidly exceeds ventilatory reserve and causes severe respiratory acidemia.

Even mild increases of CO₂ production can precipitate respiratory acidemia if compliance, airway resistance, or neuromuscular paralysis interferes with ventilation. With the exception of adjusting hyperalimantation or treating malignant hyperthermia, there is little yield from adjusting CO₂ production in the PACU. Rarely, when increased dead space precludes delivery of adequate mechanical ventilation, deliberate hypothermia and paralysis are instituted to reduce CO₂ production in the hope that increased \dot{V}_D/\dot{V}_T is reversible.

Inadequate Postoperative Oxygenation

Systemic arterial partial pressure of oxygen (PaO₂) is the best indicator of pulmonary oxygen transfer from alveolar gas to pulmonary capillary blood. Arterial hemoglobin saturation monitored by pulse oximetry yields less information on alveolar–arterial gradients and is not helpful to assess impact of hemoglobin dissociation curve shifts or carboxyhemoglobin.⁸¹ Evaluation of metabolic acidemia or mixed venous oxygen content yields better insight into peripheral oxygen delivery and utilization. Adequate arterial oxygenation does not mean that cardiac output, arterial perfusion pressure, or distribution of blood flow will maintain tissue oxygenation. Sepsis, hypotension, anemia, hemoglobin dissociation abnormalities, or CO poisoning generate tissue ischemia in spite of adequate oxygenation.

In the PACU, the acceptable lower limit for PaO₂ varies with individual patient characteristics. A PaO₂ below 65–70 mm Hg causes significant hemoglobin desaturation, although tissue oxygen delivery might be maintained at lower levels. Maintaining PaO₂ between 80 and 100 mm Hg (saturation 93–97%) ensures adequate peripheral oxygen availability. Little benefit is derived from elevating PaO₂ above 110 mm Hg because hemoglobin is saturated and the amount of additional oxygen dissolved in plasma is negligible. During postoperative mechanical ventilation, a PaO₂ above 80 mm Hg with 0.4 FIO₂ and 5 cm H₂O PEEP or CPAP usually sustains peripheral oxygenation after tracheal extubation.

Distribution of Ventilation

Loss of dependent lung volume commonly causes \dot{V}/\dot{Q} mismatching and hypoxemia. A reduction in FRC decreases radial traction on small airways, leading to collapse and distal atelectasis that can worsen for 36 hours after surgery.⁸² Reduced ventilation in dependent lung is particularly damaging because gravity directs pulmonary blood flow to dependent areas. Certain patients are at increased risk. Obese patients sustain large decreases in FRC during surgery.⁷⁴ Older patients normally exhibit airway closure at end-expiration (Fig. 53-5). Those with COPD have more severe closure that is exacerbated by small reductions in FRC. Retraction, packing, manipulation, or peritoneal insufflation during upper abdominal surgery reduces FRC, as does compression from leaning surgical assistants.⁸³ Prone, lithotomy, or Trendelenburg positions are disadvantageous, especially in obese patients. Right upper lobe collapse secondary to partial right mainstem intubation is a frequently overlooked cause. During thoracic surgery, the weight of unsupported mediastinal contents, pressure from abdominal contents on the dependent diaphragm, and lung compression all reduce dependent lung volume. Gravity and lymphatic obstruction also promote interstitial fluid accumulation, which accentuates \dot{V}/\dot{Q} mismatching. This “down lung syndrome” may appear as unilateral pulmonary edema on the chest film.

Figure 53-5. The influence of age on PaO_2 . For any given age, the PaO_2 is lower in the postoperative period. The *dashed line* indicates range of normal individual values; the *shaded area* indicates the range of normal mean values. (Reproduced with permission from Marshall BE, Wyche MQ Jr: Hypoxemia during and after anesthesia. *Anesthesiology* 37:178, 1972.)

In the PACU, acute pulmonary edema from overhydration, ventricular dysfunction, or increased capillary permeability leads to hypoxemia by interfering with both \dot{V}/\dot{Q} matching and diffusion of oxygen. Strong inspiratory efforts against an obstructed airway decrease FRC and promote negative-pressure pulmonary edema. Small airway occlusion from extrinsic compression, retained secretions, aspirate, or mainstem intubation leads to distal hypoventilation and hypoxemia. Pneumothorax, hemothorax, pulmonary contusion, or pulmonary hemorrhage also reduce lung volume.

Conservative measures that restore lung volume often improve oxygenation. If possible, obese patients should recover in a semisitting position to reduce the pressure of abdominal contents on the diaphragms. Deep ventilation, vigorous cough, chest physiotherapy, and incentive spirometry help expand FRC, mobilize secretions, and accustom a patient to incisional discomfort. Pain with ventilation encourages rapid, shallow breathing that provides adequate ventilation but does not promote expansion. Analgesia helps maintain FRC, especially with upper abdominal or chest wall incisions.

For serious postoperative reduction of lung volume, positive pressure is effective for restoring FRC. CPAP (5–7 cm H_2O) can be delivered by face mask for several hours until factors promoting loss of lung volume resolve. If hypoxemia is severe or patient acceptance of mask CPAP is poor, tracheal intubation is usually required. Intubation for delivery of CPAP does not mandate positive-pressure ventilation. Ventilatory requirements should be assessed independently, considering PaCO_2 , arterial pH, and work of breathing. Usually, 5–10 cm H_2O of CPAP or PEEP restores lung volume and PaO_2 without risking hypotension, increased intracranial pressure, or barotrauma. If PaO_2 does not improve, the etiology must be re-evaluated. During routine postoperative care, airway pressure >10 cm H_2O is transmitted more to thoracic veins and is associated with higher incidence of barotrauma. An occasional patient with ARDS or severe pulmonary contusion might exhibit improvement in oxygenation and compliance with higher pressures.

Tracheal intubation eliminates expiratory resistance and the “physiologic PEEP” (2–5 cm H_2O) that might help maintain lung volume during spontaneous ventilation. Exposing an intubated trachea to ambient airway pressure may cause a gradual, progressive reduction in FRC. It may be helpful to allow intubated patients to exhale against a slight degree of CPAP. Healthy, slender patients left intubated without positive pressure for short periods can usually restore reduced FRC after extubation.

Distribution of Perfusion

Poor distribution of pulmonary perfusion also interferes with \dot{V}/\dot{Q} matching and oxygenation. The distribution of pulmonary blood flow is primarily determined by hydrodynamic factors (pulmonary arterial and venous pressures, arteriolar and capillary resistance), which in turn are affected by gravity, airway pressure, lung volume, and cardiovascular dynamics. Distribution of blood flow is modulated by hypoxic pulmonary vasoconstriction (HPV), which diverts flow away from air spaces that exhibit low PaO_2 .

After surgery, SNS activity increases cardiac output and pulmonary vascular resistance, elevating PA pressure. High PA pressure increases blood flow to less dependent lung and through the bronchial circulation, interfering with \dot{V}/\dot{Q} matching. Reduction in PA pressure might compromise perfusion to well ventilated midlung parenchyma. If low compliance in dependent lung simultaneously redistributes fresh ventilation to upper lung, regional \dot{V}/\dot{Q} mismatch results. Also, the effectiveness of HPV varies with PA pressure in a bimodal fashion.

Position changes affect oxygenation if gravity forces blood flow to areas with reduced ventilation. Placing a poorly ventilated lung in a dependent position can seriously reduce PaO_2 , but placing the unventilated parenchyma in a nondependent position could improve \dot{V}/\dot{Q} matching. Care should be taken when positioning a diseased lung in the “up” position to avoid draining purulent material to the unaffected lung.

Distribution of blood flow is affected by changes in airway pressure and lung volume. Positive-pressure lung inflation might increase resistance in intra-alveolar and extra-alveolar vessels, whereas negative-pressure expansion probably decreases extra-alveolar resistance. Reduced lung volume has complex effects on microvascular resistance.

Other factors affect \dot{V}/\dot{Q} matching in PACU patients. Residual inhalational anesthetics, vasodilators, and sympathomimetics alter PA pressure and directly affect vascular tone and HPV, partially explaining larger alveolar–arterial oxygen gradients after general anesthesia. (Changes in lung volume and distribution of ventilation also contribute.) Patients with cirrhosis of the liver exhibit poor \dot{V}/\dot{Q} matching caused by circulating humoral substances related to abnormal hepatic metabolism. Circulating endotoxin impairs HPV, contributing to hypoxemia in septic patients.

In the PACU, few interventions are useful to improve \dot{V}/\dot{Q} matching by changing pulmonary blood flow. Postoperative \dot{V}/\dot{Q} abnormalities are more effectively resolved by improving the distribution of ventilation. PA pressure should be maintained within an acceptable range and, when possible, placing severely diseased lung tissue in a dependent position should be avoided. Eliminating b-mimetic or vasodilatory medications may improve PaO_2 , but benefits from the medication usually outweigh drawbacks of impaired HPV.

Inadequate Alveolar PAO_2

Postoperative hypoxemia is occasionally caused by a global reduction of PAO_2 , usually from inadequate ventilation. If oxygen uptake from alveoli exceeds delivery by ventilation, PAO_2 decreases. Hypoxemia might occur if opioids or residual anesthetic levels depress ventilatory drives, or during periodic apnea. Hypoventilation must be severe to cause hypoxemia based on a reduction in oxygen delivery to alveoli. Complete apnea or airway obstruction by foreign bodies, soft tissue edema, or laryngospasm leads to rapid depletion of alveolar oxygen, as does very high small airway resistance, which precludes effective ventilation. If cessation of ventilation does occur, the rate of PAO_2 decline varies with age, body habitus, degree of underlying illness, and initial PAO_2 ⁷⁰ (see Fig. 53-3).

Partial airway obstruction does not usually reduce PAO_2 , especially when patients are receiving supplemental oxygen. Increasing the oxygen content of the FRC safeguards against hypoxemia from hypoventilation or airway obstruction. Occasionally, excessive concentrations of other gases reduce PAO_2 . At the end of general anesthesia, rapid outpouring of nitrous oxide from PA blood displaces alveolar gas and can lower PAO_2 to dangerous levels if a patient is hypoventilating or breathing ambient air. This “diffusion hypoxia” usually occurs before PACU admission unless a patient is severely hypoventilating. Volume displacement of oxygen could also occur during severe hypercarbia in a patient breathing ambient air, although respiratory acidemia is often a greater problem than hypoxemia.

Reduced Mixed Venous PO_2

Systemic venous partial pressure of oxygen ($\text{P}\bar{\text{V}}\text{O}_2$) is affected by arterial oxygen content, cardiac output, distribution of peripheral blood flow, and tissue oxygen extraction. If arterial oxygen content decreases or tissue extraction increases, $\text{P}\bar{\text{V}}\text{O}_2$ falls. The lower the $\text{P}\bar{\text{V}}\text{O}_2$ in blood that is shunted or flows through low \dot{V}/\dot{Q} units,

the greater the reduction of PaO_2 . Blood with a low $\bar{P}\text{V}\text{O}_2$ also extracts larger volumes of oxygen from alveolar gas, amplifying the effect of hypoventilation or airway obstruction on PAO_2 . Very low $\bar{P}\text{V}\text{O}_2$ increases the risk of resorption atelectasis in poorly ventilated alveoli. In PACU patients, shivering, infection, and hypermetabolism lower $\bar{P}\text{V}\text{O}_2$ by increasing peripheral oxygen extraction. Low cardiac output or hypotension also lower $\bar{P}\text{V}\text{O}_2$ by decreasing tissue oxygen delivery. Supplemental oxygen minimizes the impact of low $\bar{P}\text{V}\text{O}_2$ on alveolar oxygen extraction and on arterial oxygenation.

Carbon Monoxide Poisoning

Carbon monoxide reversibly binds to hemoglobin with 200 times the affinity of oxygen, creating carboxyhemoglobin, which impedes both the binding of oxygen and the dissociation of oxygen from oxyhemoglobin. During general anesthesia, patients can be exposed to CO generated by a reaction between inhalation anesthetics and dry CO_2 -absorbing agents. Overall risk of exposure is estimated as 0.26%, but risk increases to 0.46% for first cases of the day, and to 2.9% for first cases performed in peripheral anesthetizing locations.⁸⁴

Because CO poisoning is difficult to recognize, a PACU patient can be severely hypoxic but appear well oxygenated by routine indices. Symptoms of moderate CO exposure such as headache, nausea, vomiting, irritability, and altered visual or motor skills are nonspecific and common during recovery. CO seldom causes cyanosis. A pulse oximeter interprets carboxyhemoglobin as oxyhemoglobin, so SpO_2 reads falsely high. (A co-oximeter differentiates between carboxyhemoglobin and oxyhemoglobin.) The PaO_2 is often high, although SpO_2 is low and metabolic acidemia is significant.

Anemia

Preoperative hematocrit and intraoperative hemorrhage determine a patient's red cell mass and oxygen-carrying capacity after surgery. Reduction of hematocrit caused by dilution has less impact on oxygen-carrying capacity than reduction by hemorrhage. The hematocrit at which oxygen delivery becomes insufficient to match tissue needs varies with cardiac reserve, oxygen consumption, hemoglobin dissociation, PaO_2 , blood flow distribution, and other factors. Each patient has a minimum hematocrit below which tissues use inefficient anaerobic metabolism, generating a lactic acidemia. Patients with vascular disease are at increased risk of vital organ ischemia as hematocrit falls.

Supplemental Oxygen

The incidence of hypoxemia in postoperative patients is high. In one study of PACU patients placed on room air, 30% of patients younger than 1 year of age, 20% aged 1–3 years, 14% aged 3–14 years, and 7.8% of adults had hemoglobin saturations fall below 90%, with many falling below 85%⁸⁵ (Fig. 53-6). Clinical observation and assessment of cognitive function do not accurately screen for hypoxemia, so monitoring with oximetry is essential throughout the PACU admission.⁸¹ Predicting which patients will become hypoxemic in the PACU or when hypoxemia will occur is difficult. Patients with lung disease or obesity, those recovering from thoracic or upper abdominal procedures, and those with preoperative hypoxemia are probably at increased risk.⁸⁶ Perioperative hypoxemia occurs in children, especially those with respiratory infections or chronic adenotonsillar hypertrophy.⁸⁷ Hypoxemia occurs frequently after regional anesthesia.^{27,28}

Figure 53-6. SpO_2 versus postanesthesia care unit (PACU) time in patients spontaneously ventilating on room air after general anesthesia (Group 1 = 0–1 year of age; Group 2 = 1–3 years; Group 3 = 3–14 years; Group 4 = 14–58 years). (From Xue FS, Huang YG, Tong SY *et al*: A comparative study of early postoperative hypoxemia in infants, children, and adults undergoing elective plastic surgery. *Anesth Analg* 83:709, 1996.)

Supplemental oxygen could be administered only to patients at high risk of hypoxemia or with low SpO_2 readings.^{88,89} However, if a patient requires PACU admission (especially given evolving PACU bypass criteria), he or she should probably receive supplemental oxygen during initial recovery and perhaps during transport to the PACU.

Supplemental oxygen improves PaO_2 , although the effect is variable. The inspired concentration delivered by face masks or nasal prongs is unpredictable because ambient gas is entrained during inspiration. Use of oxygen neither consistently prevents hypoxemia nor addresses underlying causes.⁹⁰ Oxygen has a negligible effect on hypoxemia caused by shunting because shunted blood is not exposed to increased FIO_2 , whereas blood passing ventilated alveoli is already saturated. If hypoxemia is caused by low $\dot{V}\dot{Q}$, increasing oxygen content in marginally ventilated air spaces improves arterial saturation. Increased oxygen content in the FRC delays the onset of serious hypoxemia during airway obstruction or hypoventilation. If CO poisoning reduces oxygen-carrying capacity, 100% oxygen displaces CO from hemoglobin and markedly accelerates the CO elimination. Hyperbaric oxygen therapy may be indicated for severe cases.

Cost of supplemental oxygen is minimal, inconvenience to patients is minor, and risk is small. An $\text{FIO}_2 > 0.8$ promotes resorption atelectasis as inert nitrogen is replaced with oxygen in poorly ventilated alveoli. Inspiration of 100% oxygen for 24–36 hours generates early signs of pulmonary oxygen toxicity. Toxicity is accelerated in patients receiving hyperbaric oxygen therapy. If arterial oxygen saturation is adequate, PaO_2 should be maintained below 150 mm Hg. Risk of oxygen toxicity is not increased after bleomycin therapy. Although oxygen might cause minor mucosal drying, routine humidification is of little benefit unless intubation bypasses natural humidification. Oxygen apparatus might cause corneal abrasion during emergence.

Perioperative Aspiration

During anesthesia, airway reflexes are frequently ineffective, placing patients at risk for pulmonary aspiration. Pulmonary morbidity from perioperative aspiration varies with the type and volume of the aspirate. Although aspiration of gastric contents is most widely feared, surgical patients also experience other aspiration syndromes.

Aspiration of clear oral secretions during induction, face mask ventilation, or emergence is common and usually insignificant. Cough, mild tracheal irritation, or transient laryngospasm are usual sequelae, although large-volume aspiration might predispose to infection, small airway obstruction, or pulmonary edema. Aspiration of blood secondary to trauma, epistaxis, or surgery in the oropharynx or large airways generates marked changes on the chest radiograph that are out of proportion with clinical signs. Aspirated “sterile” blood causes minor airway obstruction but is rapidly cleared by mucociliary transport, resorption, and phagocytosis. Massive blood aspiration interferes with gas exchange and leads to fibrinous changes in air spaces and to pulmonary hemorrhage from iron accumulation in phagocytic cells. Secondary infection is a threat, especially if tissue or purulent matter is also aspirated.

Aspiration of food, small objects, pieces of teeth, or dental appliances causes persistent cough, diffuse reflex bronchospasm, airway obstruction with distal atelectasis, or pneumonia. Complications are often localized and treated with antibiotics and supportive care once the foreign matter is expelled or removed by bronchoscopy. Secondary thermal, chemical, or traumatic airway injury from aspirated objects may require later surgical intervention. Of course, complete upper airway or tracheal obstruction by an aspirated object is a life-threatening emergency.

Aspiration of acidic gastric contents during vomiting or regurgitation causes chemical pneumonitis characterized initially by diffuse bronchospasm, hypoxemia, and atelectasis. In serious cases, airway epithelial degeneration, interstitial and alveolar edema, and hemorrhage into air spaces rapidly progresses to ARDS with high-permeability pulmonary edema. Destruction of pneumocytes, decreased surfactant activity, hyaline membrane formation, and atelectasis or emphysematous

changes can all occur, leading to \dot{V}_Q mismatching and reductions in compliance. Destruction of pulmonary microvasculature increases pulmonary vascular resistance and \dot{V}_D/\dot{V}_T . The morbidity increases directly with volume of acid aspirate and inversely with the pH of the aspirate. Classically, aspirates above 0.4–1.0 ml · kg⁻¹ and with pH below 2.0–2.5 are most serious. Aspiration of partially digested food worsens and prolongs pneumonitis, especially if vegetable matter is present. Food particles mechanically obstruct airways and are a nidus for secondary bacterial infection.

The risk of aspiration is still high in PACU patients, although the incidence is relatively low.⁹¹ Frequency of vomiting remains high, especially if gas has accumulated in the stomach. Hypotension, hypoxemia, or acidemia cause both emesis and obtundation, increasing aspiration risk. Protective airway reflexes such as cough, swallowing, and laryngospasm are suppressed by depressant medications such as inhalation anesthetics, barbiturates, and opiates, so patients with decreased levels of consciousness in the PACU must be observed carefully. Persisting effects of laryngeal nerve blocks or topical local anesthetics used to reduce airway irritability decrease postoperative airway protection, as does residual sedation. Reflexes are also impaired by residual neuromuscular paralysis.⁷⁹ Ability to sustain airway patency and spontaneous ventilation does not indicate that neuromuscular recovery is sufficient to maintain airway protection. Patients can pass a head lift test, have a tactile train-of-four T4/T1 ratio greater than 0.7, exhibit full recovery of ventilation, and still have impaired airway reflexes from residual paralysis.⁸⁰ The T4/T1 ratio might need to exceed 0.9 before reflexes are completely competent.⁹² Risk of aspiration also increases if reversal is omitted after paralysis with short-acting relaxants.⁹³

Preventing aspiration is critical because effective therapy is limited. Evolution of guidelines for preoperative fasting and analysis of outcomes have demonstrated the safety of shorter fasting periods for clear liquids in all patients and for feedings in young children.^{94,95} For patients at high risk, preoperative administration of nonparticulate antacids such as sodium citrate increase the pH of gastric fluid without excessively increasing volume. Particulate antacids must be avoided. Histamine type 2 receptor blockers like cimetidine or ranitidine reduce the volume and increase the pH of gastric secretions. Metoclopramide increases gastroesophageal sphincter tone and accelerates gastric emptying. Inserting a nasogastric tube is often ineffective to remove particulate matter and interferes with gastroesophageal sphincter integrity.

In the PACU, vigilance for regurgitation and aspiration is important. Trendelenburg position might promote regurgitation, but aids in airway clearance if regurgitation or vomiting occurs. Head elevation in unconscious patients should be avoided because it creates a gravitational gradient from pharynx to lung. High-risk patients should not have the trachea extubated until airway reflexes are fully restored. Aspiration of acidic fluid can still occur around an inflated tracheal tube cuff. Cuff deflation should be avoided because the rigid tube impairs laryngospasm and increases. The pharynx should be completely suctioned before extubation, and extubation done at end-inspiration with positive airway pressure to promote expulsion of material trapped below the cords but above the inflated cuff. Careful observation is essential after extubation because airway reflexes might be temporarily impaired.

Postoperative anatomic distortion from mandibular fractures or airway soft tissue trauma interferes with airway protection. Mandibular fixation makes expulsion of vomitus, blood, or secretions difficult, so equipment for release of fixation must be available. Patients recovering with mandibular fixation must demonstrate cognitive and physical ability to clear the airway before the trachea is extubated.

Discovery of gastric secretions in the pharynx mandates immediate lateral head positioning (assuming cervical spine integrity) and suction of the airway. If airway reflexes are compromised, tracheal intubation is often appropriate. After intubation, the trachea is suctioned through the tracheal tube before positive-pressure ventilation; this avoids widely disseminating aspirated material into distal airways. Instillation of saline or alkalotic solutions is not recommended. Assessing the pH of tracheal aspirate is useless because buffering is immediate. Checking pharyngeal aspirate pH is more reliable but of little practical value.

Suspicion that aspiration has occurred mandates 24–48 hours of monitoring for development of aspiration pneumonitis. If likelihood of aspiration is high, the patient should be admitted to the hospital. Observation includes serial temperature checks, white blood cell counts with differential, and blood gas determination or pulmonary function testing if appropriate. Fluffy infiltrates may appear on the chest radiograph any time within 24 hours. Hypoxemia might develop quickly or evolve insidiously as lung injury progresses, so continuous pulse oximetry monitoring is important. Chest physiotherapy, incentive spirometry, and reinstatement of medications for pre-existing pulmonary conditions minimize the loss of lung volume, \dot{V}_Q mismatching, and infection. If the likelihood of aspiration is small, follow-up can be done on an outpatient basis, assuming hypoxemia, cough, wheezing, or radiographic abnormalities do not appear within 4–6 hours. Give the patient explicit instructions to contact a medical facility at the first appearance of malaise, fever, cough, chest pain, or other symptoms of pneumonitis.

If hypoxemia, increased airway resistance, consolidation, or pulmonary edema evolves, the patient is supported with supplemental oxygen, PEEP, or CPAP. Mechanical ventilation is often necessary. Therapy is similar to that for ARDS. Pulmonary edema usually reflects increased capillary permeability and should not be treated with diuretics unless high filling pressures or hypervolemia exist. Hypovolemia from fluid losses into the lung can necessitate aggressive fluid management. Steroids yield little real improvement of long-term outcome. Bacterial infection does not always follow aspiration, so prophylactic antibiotics merely promote colonization by resistant organisms. If evidence of bacterial infection appears, antibiotic therapy should be instituted based on Gram stain and culture of sputum. If culture results are equivocal, broad-spectrum antibiotics should be used with coverage for gram-negative rods and anaerobes, including *Bacteroides fragilis*.

POSTOPERATIVE RENAL COMPLICATIONS

Monitoring kidney function during recovery reduces morbidity in patients with marginal cardiovascular or renal status.

Ability to Void

The ability to void should be assessed because autonomic effects of regional anesthetics or opioids interfere with sphincter relaxation and promote urine retention.⁹⁶ Urinary retention is common after urologic, inguinal, and genital surgery, and frequently delays discharge.⁹⁷ It is reasonable to discharge inpatients to a surgical floor and selected ambulatory surgical patients from the facility before they void.⁹⁸ However, it is important to ensure that urine output is monitored after discharge from the PACU to avoid urinary retention. Give ambulatory patients who are discharged without voiding a specific time interval in which to void (*i.e.*, 10–12 hours after discharge). If retention persists, the patient is instructed to contact a health care facility. Higher-than-average return rates after urologic procedures are partially related to urinary retention.⁹⁹ An ultrasonic bladder scan is helpful to assess bladder volume before discharge, avoiding the archaic practice of “straight catheterization.” Neither the patient nor staff can estimate the need to void through sensation or palpation, respectively.¹⁰⁰ Patients with indwelling urinary catheters should have output recorded hourly. Use of urinary output to gauge intravascular volume status or renal viability can be misleading given the prevalence of osmotic diuresis and impaired renal regulatory mechanisms in recovering patients.

Renal Tubular Function

Analysis of urine yields information about postoperative renal tubular function. Urine color is not useful for assessing tubular function such as concentrating ability, but color can signal hematuria, hemoglobinuria, or pyuria. Urine osmolality (reflecting the number of particles in solution) is a more reliable index of tubular function than is specific gravity, which is affected by molecular weight. An osmolality of 450 mOsm · l⁻¹ indicates intact tubular concentrating ability. A urine sodium concentration far below or a potassium concentration above serum concentrations also indicates renal tubular viability. Acidification or alkalization of urine requires intact tubular function, so urinary pH evaluation is useful. Osmolality, electrolyte, and pH values close to those in serum may indicate poor tubular function and acute tubular necrosis.

Inorganic fluoride released during metabolism of inhalation anesthetics causes a transient reduction of maximum tubular concentrating ability after long anesthetics. Higher fluoride levels cause nephrotoxicity and renal tubular necrosis. Interaction between sevoflurane and carbon dioxide absorbents generates compound A, a vinyl ether. The amount of compound A generated varies directly with absorbent dryness and sevoflurane concentration, and inversely with flow rate. Cytochrome P-450 degrades compound A, increasing free inorganic fluoride in serum. In rats, compound A is lethal in high concentrations and nephrotoxic in lower concentrations. Although transient increases in protein excretion and decreases in concentrating ability may occur, prolonged use of sevoflurane does not have a serious impact on renal function.¹⁰¹ Given the relationship between compound A and dry CO₂ absorbents, the anesthesiologist must be aware that polyuria or proteinuria in patients who received sevoflurane during first cases or cases performed in peripheral anesthetizing locations might be related to compound A exposure.

Oliguria

Oliguria (0.5 ml · kg⁻¹ · h⁻¹) occurs frequently during recovery and usually reflects an appropriate renal response to hypovolemia or systemic hypotension. However, a decreased urine output might indicate abnormal renal function. The acceptable degree and duration of oliguria vary with underlying renal status, the surgical procedure, and the anticipated postoperative course. If intraoperative manipulations or events could jeopardize renal function (possible ureteral ligature, aortic cross-clamping, severe hypotension, massive transfusion), oliguria must be aggressively evaluated. In patients without catheters, bladder volume and interval since last voiding should be checked to help differentiate between oliguria and inability to void. Urinary catheters should be checked for kinking and for obstruction by blood clots or debris.

Patient position might also hold the catheter tip above the urinary level in the bladder.

Systemic pressure must be adequate for renal perfusion (based on preoperative pressures). A 300–500-ml iv crystalloid bolus given after urine sent for electrolyte and osmolarity determinations helps assess whether oliguria represents a renal response to hypovolemia. If output does not improve, a larger bolus or a diagnostic trial of furosemide, 5 mg iv, should be considered. Furosemide interferes with tubular resorption and increases urine output if oliguria reflects retention of fluid by the kidneys. Also, some patients on chronic diuretic therapy might require a diuretic effect to maintain brisk postoperative urine output.

Persistence of oliguria despite hydration, adequate perfusion pressure, and a furosemide challenge increases the likelihood of acute tubular necrosis, ureteral obstruction, renal artery or vein occlusion, or inappropriate antidiuretic hormone secretion. Administration of desmopressin for hematologic purposes seldom affects postoperative urinary output. Cystoscopy, iv pyelography, angiography, or radionuclide scanning may help clarify renal status. Osmotic or loop diuretics and low-dose dopamine or dobutamine are probably useful to attenuate renal damage, but consultation with a nephrologist is prudent.

Polyuria

Profuse postoperative urine output usually reflects generous intraoperative fluid administration. Osmotic diuresis caused by hyperglycemia and glycosuria is another cause, particularly if glucose-containing crystalloid solutions are infusing. Polyuria might also reflect intraoperative diuretic administration. However, sustained polyuria ($4\text{--}5\text{ ml} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) can indicate abnormal regulation of water clearance, especially if urinary losses compromise intravascular volume and systemic blood pressure. Polyuria related to diabetes insipidus occurs secondary to intracranial surgery, pituitary ablation, head trauma, increased intracranial pressure, or inadvertent omission of preoperative vasopressin. The diagnosis is made by comparing urine and serum electrolytes and osmolarity. Diagnostic or therapeutic administration of vasopressin is useful. High-output renal failure also should be considered as a cause.

METABOLIC COMPLICATIONS

Postoperative Acid–Base Disorders

Categorization of postoperative acid–base abnormalities into discrete primary and compensatory disorders is difficult because a rapidly changing pathophysiologic process often generates two or more primary disorders.

Respiratory Acidemia

Respiratory acidemia is frequently encountered in PACU patients because anesthetics, opioids, and sedatives promote hypoventilation by depressing CNS sensitivity to pH and CO₂. In awake, spontaneously breathing PACU patients receiving adequate analgesia, hypercarbia and acidemia are usually mild (PaCO₂ 45–50 mm Hg, pH 7.36–7.32). Anesthetized or deeply sedated patients exhibit more profound acidemia unless supplemental ventilation is used. Some postoperative patients cannot sustain adequate ventilation despite an appropriate CNS drive. Residual neuromuscular paralysis, increased airway resistance, or decreased pulmonary compliance might impede ventilation and lead to progressive respiratory acidemia, especially if dead space is increased. Elevated CO₂ production caused by shivering, hyperalimentation, fever, or malignant hyperthermia amplifies the problem. The kidneys require many hours to generate a compensatory metabolic alkalosis, so compensation for acute respiratory acidemia is limited.

Symptoms of respiratory acidemia include agitation, confusion, ventilatory dissatisfaction, and tachypnea. SNS responses to low pH cause hypertension, tachycardia, and dysrhythmias which increase the risk of myocardial ischemia, bleeding, or cerebrovascular accident. Respiratory acidemia caused by CNS depression often produces less intense signs of SNS activity because autonomic responses are also depressed. At very low pH, catecholamines cannot interact with adrenergic receptors, so heart rate and blood pressure decrease precipitously. Respiratory acidemia increases cerebral blood flow and potentially increases intracranial pressure in patients with head injury, intracranial tumors, or cerebral edema.

Treatment consists of correcting the imbalance between CO₂ production and alveolar ventilation. Reversal of opioids or neuromuscular relaxants and raising the level of consciousness improves ventilatory drive. Relieving airway obstruction, reducing airway resistance, or improving ventilatory mechanics is useful. If spontaneous ventilation cannot maintain CO₂ excretion, tracheal intubation and mechanical ventilation are necessary. Reducing CO₂ production by eliminating high glucose loads or controlling fever, shivering, and the work of breathing may be helpful. Extreme measures such as core cooling or paralysis are seldom useful in the PACU.

Metabolic Acidemia

Evaluation of acute postoperative metabolic acidemia is relatively straightforward. Patients with renal failure, renal tubular acidosis, or small bowel drainage usually exhibit a preoperative metabolic acidemia. Excessive saline infusion during surgery can generate a mild hyperchloremic metabolic acidemia in the PACU.¹⁰² Substituting lactated Ringer's solution helps resolve this problem. Postoperative metabolic acidemia is occasionally caused by ketoacidosis in patients with severe diabetes mellitus. Serum glucose levels are elevated, and ketones are detectable in blood or urine. Rarely, a patient manifests acidemia from toxic ingestion of phenformin, aspirin, or methanol.

Once these unusual causes are excluded, postoperative metabolic acidemia almost always represents lactic acid accumulation secondary to insufficient delivery or utilization of oxygen in peripheral tissues. Hypotension leading to peripheral hypoperfusion is often caused by low cardiac output (hypovolemia, cardiac failure, dysrhythmia) or decreased SVR (sepsis, catecholamine depletion, sympathectomy). Arteriolar constriction from hypothermia or inappropriate pressor administration reduces tissue perfusion, as does poor distribution of blood flow. Hypoxemia, severe anemia, impaired hemoglobin dissociation (alkalemia, hypothermia), and inability to utilize oxygen in the mitochondria (cyanide or arsenic poisoning) also generate lactic acidemia. When evaluating lactic acidemia after general anesthesia, the real possibility of CO poisoning must be considered, especially in early cases from peripheral locations.

A spontaneously breathing patient with intact ventilatory drive quickly generates a respiratory alkalosis to compensate for postoperative metabolic acidemia. However, anesthetics and analgesics interfere with this ventilatory response. The sympathetic response to acute metabolic acidemia is often milder than the response to respiratory acidemia because hydrogen and bicarbonate ions cross the blood–brain barrier with more difficulty than CO₂.

Treatment consists of resolving the condition causing accumulation of metabolic acid. Ketoacidosis is treated with iv potassium, insulin, and glucose. If lactic acidemia is mild and conditions causing lactate accumulation are improved, acidemia resolves through metabolism and renal excretion of hydrogen ions. Improving cardiac output or systemic blood pressure can reduce lactic acid production, as can rewarming. If acidemia is severe or progressive, iv bicarbonate or a substitute helps restore pH toward normal.

Respiratory Alkalemia

Excessive pain or anxiety during emergence causes hyperventilation and acute respiratory alkalemia. Excessive mechanical ventilation also generates respiratory alkalemia, especially if hypothermia or paralysis has decreased CO₂ production. Pathologic causes of “central” hyperventilation include sepsis, cerebrovascular accident, or paradoxical CNS acidosis (an imbalance of bicarbonate concentration across the blood–brain barrier caused by prolonged mechanical hyperventilation).

Acute respiratory alkalemia generates confusion or dizziness, atrial dysrhythmias, or mild cardiac conduction abnormalities. If the alkalemia is severe, reduced serum ionized calcium concentration precipitates muscle fasciculation or hypocalcemic tetany. Alkalemia decreases cerebral blood flow, causing hypoperfusion and even stroke in patients with cerebrovascular disease. Very high pH levels depress cardiovascular, CNS, and catecholamine receptor functions. Metabolic compensation for acute respiratory alkalemia is limited, again because renal time constants for bicarbonate excretion are large. Correction of respiratory alkalemia necessitates reducing alveolar ventilation, usually by administering analgesics and sedatives for pain and anxiety. Rebreathing of CO₂ has little application in the PACU.

Metabolic Alkalemia

Metabolic alkalemia is rare in PACU patients unless vomiting, gastric suctioning, dehydration, alkaline ingestion, or potassium-wasting diuretics caused an alkalemia that existed before surgery. Excessive intraoperative bicarbonate administration causes postoperative metabolic alkalemia, but alkalemia from metabolism of lactate or citrate usually does not appear within the first 24 hours. Respiratory compensation through retention of CO₂ is rapid but limited because hypoventilation eventually causes hypoxemia. Hydration and correction of hypochloremia and hypokalemia allow the kidney to excrete excess bicarbonate. An iv hydrochloric acid infusion is seldom necessary but can be used through a central venous catheter to treat life-threatening alkalemia.

Glucose Disorders

Serum glucose determination is superior to urine glucose measurement for managing blood sugar abnormalities. However, urine glucose concentration helps assess osmotic diuresis and estimate renal transport by comparison with serum levels.

Hyperglycemia

Glucose infusions and stress responses commonly elevate serum glucose levels after surgery. In diabetic patients, hyperglycemia may indicate insulin deficiency and potential for ketoacidosis. Moderate hyperglycemia ($200\text{--}300\text{ mg} \cdot \text{dL}^{-1}$) usually resolves spontaneously and probably has little effect on wound healing. Higher glucose levels cause glycosuria with osmotic diuresis and interfere with serum electrolyte determinations. Severe hyperglycemia increases serum osmolality to a point that cerebral disequilibrium and hyperosmolar coma occur. Titration of iv regular insulin by incremental doses or by continuous infusion allows adjustment of blood glucose without the uptake delay of subcutaneous, longer-acting insulin. Potassium replacement and serial blood glucose determinations are essential.

Hypoglycemia

Hypoglycemia in the PACU can be caused by endogenous insulin secretion or by excessive or inadvertent insulin administration. Serious postoperative hypoglycemia is rare and easily treated with iv 50% dextrose followed by glucose infusion. Both sedation and excessive SNS activity mask signs and symptoms of hypoglycemia during recovery.

Electrolyte Disorders

Hyponatremia

Postoperative hyponatremia occurs if free water is infused intravenously during surgery or if sodium-free irrigating solution is absorbed during transurethral prostatic resection or hysteroscopy. Accumulation of serum glycine or its metabolite, ammonia, might exacerbate symptoms. Free water retention is also caused by inappropriate antidiuretic hormone secretion, prolonged induction of labor with oxytocin, or respiratory uptake of nebulized droplets. Excessive intraoperative administration of isotonic saline expands extracellular volume, leading to excretion of hypertonic urine and iatrogenic hyponatremia through desalination.¹⁰³ Symptoms of moderate hyponatremia include agitation, disorientation, visual disturbances, and nausea, whereas severe hyponatremia causes unconsciousness, impaired airway reflexes, and CNS irritability that progresses to grand mal seizures. Therapy includes gradual administration of iv saline and iv furosemide to promote renal wasting of free water in excess of sodium. Infusion of hypertonic saline may be necessary for severe hyponatremia. Monitoring of sodium concentration and osmolality is essential.

Hypokalemia

Although usually inconsequential, postoperative hypokalemia might generate serious dysrhythmias, especially in patients taking digoxin. A potassium deficit from chronic diuretic therapy, nasogastric suctioning, or vomiting often underlies hypokalemia. Urinary and hemorrhagic losses, dilution, and insulin therapy generate more acute hypokalemia that worsens during respiratory alkalemia. Excess SNS activity or infusion of calcium, insulin, or b-mimetic medications exacerbates effects of hypokalemia. Addition of potassium to peripheral iv fluids usually restores serum concentration, but infusion of concentrated solutions through a central catheter may be necessary.

Hyperkalemia

Serious postoperative hyperkalemia occurs after excessive potassium administration or in patients with chronic renal failure or malignant hyperthermia. Acute acidemia exacerbates hyperkalemia. Administration of succinylcholine in the PACU could increase serum potassium to dangerous levels in patients with burns, severe trauma, or chronic neurologic injuries. Treatment with iv insulin and glucose acutely lowers serum potassium, whereas iv calcium counters myocardial effects. b-Mimetic medications might also have a role. An inexplicably high serum potassium raises the suspicion of spurious hyperkalemia from a hemolyzed specimen or from sampling near an iv containing potassium or banked blood.

Calcium and Magnesium

Although underlying parathyroid disease or massive fluid replacement reduces total-body and ionized calcium, symptomatic postoperative hypocalcemia seldom occurs in the PACU. A rare patient might exhibit hypocalcemia and upper airway obstruction after parathyroid excision. Further reduction of the ionized fraction by alkalemia may cause myocardial conduction and contractility abnormalities, decreased vascular tone, or tetany. Administration of calcium chloride or calcium gluconate to hypocalcemic patients improves cardiovascular dynamics and the response to iv fluid administration. Transfusion of blood containing chelating agents (e.g., citrate) rarely causes symptomatic hypocalcemia unless the rate of blood infusion exceeds $500\text{ ml} \cdot \text{min}^{-1}$.

Magnesium plays a key role in restoration of neuromuscular function after surgery and in maintenance of cardiac rhythm and conduction.

MISCELLANEOUS COMPLICATIONS

Nausea and Vomiting

Avoiding postoperative nausea and vomiting (PONV) is a high priority for physicians and patients.¹⁴ PONV remains a significant problem. Aside from unpleasantness for the patient and staff, PONV poses medical risks. Increased intra-abdominal pressure jeopardizes abdominal or inguinal suture lines, whereas elevated central venous pressure increases morbidity after ocular, tympanic, or intracranial procedures. Risk of aspirating gastric contents increases, especially if airway reflexes or ability to expel secretions are impaired. SNS response to emesis elevates heart rate and systemic blood pressure, increasing the risk of myocardial ischemia or dysrhythmias. Movement during PONV worsens postoperative pain and accentuates autonomic responses. Gagging and retching might also elicit parasympathetic responses with bradycardia and hypotension. Finally, PONV delays discharge or necessitates admission of ambulatory patients, reducing patient satisfaction and the efficiency of services.

The incidence of PONV varies with many factors.^{8,104} Reported incidence is lower in the PACU than over 24 to 48 hours because emesis often appears after PACU discharge. Delayed emesis may reflect timing of oral intake, waning effects of antiemetics, or greater post-discharge pain. A prospective study of 17,638 ambulatory patients revealed increased risk in younger patients.¹⁰⁴ Likelihood of PONV decreased 13% per decade of age. Women had a 3-fold higher incidence than men. Ear–nose–throat and dental procedures had a high incidence (14.3%), followed by orthopedic shoulder procedures and cosmetic surgery. The risk of PONV is very high after procedures involving extraocular muscle traction,¹⁰⁵ middle ear manipulation, peritoneal or intestinal irritation, or testicular traction. A history of postoperative emesis or motion sickness predicts PONV. Smokers have a significantly lower risk of PONV than nonsmokers.^{104,106} Undergoing a general anesthetic near menses increases the incidence in women, perhaps related to circulating E_2 estrogen levels.^{107,108}

Perioperative factors contribute to emergence of PONV. Starvation, autonomic imbalance, pain, and effects of anesthetics on the chemotactic center probably increase the incidence. Conditions that affect the gastroesophageal junction (obesity, hiatal hernia) increase the likelihood of emesis in the PACU. Swallowed blood or secretions promotes PONV, as does gas in the stomach from face mask ventilation, nitrous oxide diffusion, or esophageal intubation. Incidence of PONV is lower after regional than general anesthesia, although this difference narrows once parenteral opioids are needed to control postoperative pain. Meta-analyses reveal that exclusion of nitrous oxide from an anesthetic appears to reduce the incidence of PONV.¹⁰⁹ The incidence of nausea does not differ greatly among inhalation anesthetics, although desflurane and sevoflurane might generate slightly higher rates. Barbiturate induction seems less offensive than etomidate or ketamine, whereas propofol offers a still lower risk. Administration of opioid analgesics increases the incidence PONV when compared with “pure” inhalational techniques, especially after ambulatory surgery. Using small doses of shorter-acting opioids might decrease incidence, but short duration of analgesia offsets this advantage. Supplementation of opioids with nonopioid analgesics such as ketorolac, acetaminophen, or ibuprofen might reduce the frequency of emesis. It is unclear whether administration of neostigmine to reverse neuromuscular relaxation or physostigmine to counteract sedation also increases the incidence of PONV. The choice of anticholinergic during reversal of paralysis might also affect incidence.

Several interventions have been evaluated to prevent PONV. Evacuation of stomach contents with an orogastric tube to avoid gastric distention is of questionable value. Hydration appears to reduce the incidence of PONV,¹¹⁰ but postoperative drinking is often a triggering event. Children or high-risk patients can be appropriately

discharged before they take oral fluids.¹¹¹ Whether this decreases incidence of PONV or merely delays onset is unclear. Limiting postoperative vestibular stimulation by minimizing brisk head motion is helpful.

Studies of medications for prophylaxis and treatment of PONV reveal that droperidol and ondansetron are probably equal in efficacy, cost effectiveness, and patient satisfaction.^{105,112} whereas metoclopramide holds a weak third place.¹¹³ These antiemetics have different sites of action, so combination therapy might generate better results by simultaneously treating two or more precipitating factors.¹¹⁴

Ondansetron, a serotonin receptor blocker, is a very useful antiemetic for PONV. Optimum iv dosage in adults seems to be 4 mg administered near the end of surgery or on PACU admission.¹¹⁵ Ondansetron appears to be particularly useful for PONV related to stimulation of gastric enterochromaffin cells by blood.¹¹⁶ Ondansetron has few side effects. Bothersome headache occurs after iv administration,¹¹³ and transient liver enzyme elevation is seen in a small percentage of patients.¹¹⁷ Ondansetron is cost effective if its use shortens PACU length of stay, avoids admission, and improves patient satisfaction. Granisetron, tropisetron, dolasetron, and the newer ramosetron all are effective antiemetics, but none appears to surpass ondansetron for efficacy.

Droperidol decreases the incidence and severity of PONV, although efficacy varies among procedures and patients. A total iv dose of 1–2 $\mu\text{g} \cdot \text{kg}^{-1}$ (0.625–1.25 mg in adults) seems optimal.^{113,114} Although mild sedation might delay discharge slightly, delay from untreated PONV is usually greater. Transient restlessness and rare extrapyramidal side effects are usually inconsequential.¹¹³ Droperidol treats breakthrough nausea in patients who have received prophylaxis. α -Adrenergic blocking properties can precipitate hypotension in hypovolemic patients.

Other agents exhibit antiemetic properties. Propofol does not compare with droperidol or ondansetron as a first-line antiemetic.¹⁰⁵ Propofol has short-term antiemetic properties and is useful for anesthesia in patients at high risk for PONV.¹¹⁸ Dexamethasone has an antiemetic effect when used during upper airway procedures such as adenotonsillectomy, perhaps secondary to its anti-inflammatory properties.^{119,120} Although cimetidine decrease gastric acidity and ranitidine improves gastric emptying, neither is useful to treat PONV. Dimenhydrinate or thiethylperazine are also relatively ineffective. Intravenous scopolamine causes unacceptable psychogenic reactions, whereas transdermal scopolamine is ineffective and causes postoperative visual disturbances. Efficacy of ephedrine for treating PONV related to ambulation or motion is unclear. The antiemetic effect of midazolam in children is likely related to the relationship between vomiting and crying or agitation. Acupuncture and acupressure might reduce the incidence of PONV.¹²¹ These modalities are unlikely to gain wide acceptance unless they prove clearly superior to antiemetic medications.

Before treating PONV, more serious causes of nausea and emesis should be considered, such as hypotension, hypoxemia, hypoglycemia, intracranial pressure, or gastric bleeding.

Incidental Trauma

Ocular Injuries

Anesthetized patients sustain incidental trauma from positioning, equipment, and manipulation. Corneal abrasion caused by drying or inadvertent eye contact during face mask ventilation or intubation is a common eye injury encountered in the PACU. Corneal abrasion occurs more frequently in elderly patients, after long cases, with lateral positioning, and after head or neck surgery.¹²² Corneal injury also occurs in the PACU if a rigid oxygen face mask rides up on the eye or if the eye is rubbed with a digital pulse oximeter probe. Abrasion causes tearing, decreased visual acuity, pain, and photophobia. Fluorescein staining is useful for diagnosis. Abrasion usually heals spontaneously within 72 hours without scarring, but severe injury can cause cataract formation and impair vision. Symptomatic treatment includes artificial tears and eye closure.

Visual acuity is often impaired after anesthesia. Autonomic side effects of medications impair accommodation, and residual ocular lubricant clouds vision. Impairment of retinal perfusion by ocular compression generates postoperative visual disturbances ranging from loss of acuity to permanent blindness.¹²³ Ischemic optic atrophy also occurs in the absence of external compression.¹²⁴ Risk is higher after long procedures in the prone position, and in patients with vascular disease and anemia. The anesthesiologist must be alert for visual impairment and perform a cursory check of acuity when assessing patients at higher risk for ischemic optic atrophy.

Oral, Pharyngeal, and Laryngeal Injuries

Laryngoscopy, rigid airways, and dentition all can cause trauma of oral soft tissues. Lip, tongue, or gum abrasions heal quickly and are treated with an ice pack and analgesia. Penetrating injuries caused by tissue entrapment between teeth and a laryngoscope blade or airway may require topical antibiotics. After a traumatic tracheal intubation, hematoma or edema might cause partial airway obstruction. Nebulized racemic epinephrine often improves stridor. If damaged teeth or dental appliances are noted, it is necessary to obtain a dental consultation and observe for signs of foreign body aspiration.¹²⁵ Dental damage can also occur during emergence if a patient bites on a rigid oral airway or forcefully clenches his or her teeth.

Sore throat and hoarseness after tracheal intubation occur in 20–50% of patients, depending on the degree of trauma during laryngoscopy and oropharyngeal suctioning, the duration of intubation, and the type of tube (see also [Chapter 23](#)). Mucosal irritation often presents as an unquenchable dryness in mouth and throat. The use of local anesthetic ointments to lubricate endotracheal tubes does not help and may cause additional mucosal irritation. During surgery, impact of cuff expansion with nitrous oxide is avoided by inflating the cuff with a sample of the anesthetic mixture. Topical viscous lidocaine attenuates irritation from nasogastric tubes during recovery but may increase risk of aspiration. In children, the severity of postextubation laryngeal edema or tracheitis depends on age, intubation trauma, duration of intubation, and tube movement. Most children recover with cool mist therapy, but nebulized racemic epinephrine is also effective. Dexamethasone might also decrease edema. Laryngoscopy and intubation can also cause hypoglossal, lingual, or recurrent laryngeal nerve damage, vocal cord evulsion, desquamation of laryngeal or tracheal mucosa, airway wall edema or ulceration, and tracheal perforation. Sore throat can also occur without intubation, related to drying from unhumidified gases or trauma from airways and suctioning.

Nerve Injuries

Injuries caused by improper positioning during anesthesia generate serious long-term complications (see [Chapter 24](#)). Spinal cord injury can be caused by positioning for intubation or by hematoma accumulation after placement of regional anesthetics. Peripheral nerve compression during general or regional anesthesia sometimes causes permanent sensory and motor deficits, as do stretch injuries from hyperextension of an extremity.¹²⁶ Any bruising or skin breakdown should prompt evaluation for underlying nerve damage. Many postoperative neuropathies occur without an identifiable cause. This is particularly true for ulnar neuropathy, which may be related to subtle positioning problems,¹²⁷ pre-existing impairment,¹²⁸ or unusual sensitivity of the nerve to ischemia. Every complaint of pain, numbness, or weakness from a postoperative patient should be evaluated.

In spite of improvements in spinal needle design, postdural puncture headache often first emerges in the PACU. Positional headache is more frequent after difficult subarachnoid anesthetics with multiple attempts¹²⁹ and after dural puncture during attempted epidural placement. Subarachnoid air bubbles from loss-of-resistance testing may contribute. In the PACU, treatment is supportive with hydration, analgesics, and positioning. In severe cases, an early epidural blood patch might be considered.

Mechanical nerve injury secondary to puncture, laceration, or intraneuronal injection during placement of regional anesthesia is rare but does occur.^{126,130} In the PACU, patients complain of pain, focal numbness, residual paresthesia, or dysesthesia. Symptoms are usually transient. In one study, 6.3% of 4767 patients experienced paresthesia during placement of spinal anesthesia, but only 0.126% had persisting symptoms.¹³¹ Analgesia should be administered, and the patient reassured and closely observed to ensure that neurologic symptoms do not indicate a more serious complication.

During recovery from spinal anesthesia, some patients exhibit lower extremity discomfort, buttock pain, and other signs of sacral neurologic irritation. This problem is more common in obese patients, after procedures in lithotomy position, and after spinal anesthesia with 5% lidocaine.¹³² Symptoms are transient and treated supportively. Rarely, a patient exhibits headache and meningeal signs caused by chemical meningitis after injection of a spinal drug that is contaminated or outside the acceptable pH range.

Soft Tissue and Joint Injuries

If pressure points are improperly padded during long procedures, soft tissue ischemia and necrosis occur, especially with lateral or prone positioning. Prolonged scalp pressure causes localized alopecia, whereas entrapment of ears, breasts, genitalia, or skin folds causes inflammation or necrosis. Regional ischemia from major arterial compression is rare. Thermal, electrical, or chemical burns from cautery equipment, preparatory solutions, or adhesives also appear. Extravasation of iv medications can cause sloughing or localized chemical neuropathy; extravasation of fluid or blood can cause a compartment syndrome. Excessive joint or muscle

extension leads to postoperative backache, joint pain or stiffness, and even joint instability.

Each patient admitted to the PACU should be carefully evaluated for traumatic complications. Discovery or suspicion of a complication necessitates careful documentation, notification of physicians responsible for extended postoperative care, consultation with specialists, and follow-up.

Skeletal Muscle Pain

Postoperative muscle pain is caused by many intraoperative factors. Prolonged lack of motion or unusual muscle stretch during positioning often contributes to muscle stiffness and aching in the PACU. Fasciculation during depolarizing blockade has implicated succinylcholine as a cause of postoperative myalgias. A small dose of nondepolarizing relaxant may reduce the incidence or severity, but pretreatment with a “self-taming” dose of succinylcholine does not appear to be protective. Acute myalgia also occurs after administration of other relaxants and in patients receiving no relaxant. Delayed-onset muscle fatigue can appear days after surgery and resolve spontaneously.

Hypothermia and Shivering

Although intraoperative temperature maintenance is a standard, patients still exhibit hypothermia after surgery. Heat is lost by evaporation during skin preparation, by humidification of dry gases in the airway, and by radiation and convection from the skin and wound. Core temperature reduction is accelerated by cold iv fluids and low ambient temperatures. Thermoregulatory vasoconstriction decreases heat loss but is less effective under anesthesia. Rate of heat loss is approximately the same during general or regional anesthetics, but patients rewarm more slowly after regional anesthetics because residual vasodilation and paralysis impede heat generation and retention. Cachectic, traumatized, or burned patients experience more serious temperature reduction. Infants are at increased risk given their low ratio of body mass to surface area. Humans actively regulate body temperature once it falls below the thermoregulatory threshold temperature, which is decreased by approximately 2.5°C during general anesthesia.¹³³ Ability to maintain body temperature is compromised because paralysis and anesthesia impair shivering, and because nonshivering thermogenesis is relatively ineffective in adults.

Postoperative hypothermia increases SNS activity, elevates peripheral vascular resistance, and decreases venous capacitance.¹³⁴ Risk of myocardial ischemia is increased.¹³⁵ Severe hypothermia interferes with cardiac rhythm generation and impulse conduction, lengthens PR, QRS, or QT intervals, and generates J waves on the ECG. Risk of dysrhythmia from mechanical myocardial stimulation is increased. Spontaneous ventricular fibrillation occurs at temperatures <28°C. Hypoperfusion promotes tissue hypoxia and metabolic acidemia and jeopardizes marginal tissue grafts. The alveolar–arterial gradient for oxygen is increased even after temperature correction, and increased avidity of hemoglobin for oxygen compromises oxygenation in hypothermic tissues. Platelet sequestration, decreased platelet function, and reduced clotting factor activity contribute to coagulopathy. Moderately hyperglycemia occurs, cellular immune responses are compromised, and postoperative infection rates increase.¹³⁶ A decrease in the minimal alveolar concentration of inhalation anesthetics of 5–7% per 1°C reduction in core temperature accentuates sedation from residual inhalation anesthetics. Reduced perfusion and impaired biotransformation might increase the duration of neuromuscular relaxants and sedatives.

Hypothermia complicates care in the PACU. Vasoconstriction interferes with the reliability of pulse oximetry, intra-arterial pressure monitoring, and peripheral nerve stimulation. Duration of PACU stay averages 90 minutes longer for hypothermic patients, and 40 minutes longer if rewarming is not used as a discharge criteria.¹³⁷ To increase endogenous heat production, hypothalamic regulation accelerates metabolic activity and generates shivering during emergence.¹³⁸ Shivering increases the risk of incidental trauma or disruption of medical devices, interferes with accuracy of ECG and pulse oximetry monitoring, and makes bedside interventions more difficult. Oxygen consumption and CO₂ production increase by up to 800% during shivering. Associated increases in minute ventilation and cardiac output can precipitate ventilatory failure in patients with limited reserve, or myocardial ischemia in patients with coronary artery disease.¹³⁵ Shivering is accentuated by tremors related to emergence from inhalation anesthesia. Tremors exhibit both clonic and tonic components and likely reflect decreased cortical influence on spinal cord reflexes.

For most patients, shivering during warming from mild to moderate hypothermia is uncomfortable but self-limited, and needs no treatment other than warmth and reassurance. Many medications have been shown to suppress shivering, including meperidine, morphine, sufentanil, droperidol, physostigmine, clonidine, propofol, nalbuphine, chlorpromazine, and magnesium.¹³⁹ Withholding reversal of relaxants in ventilated, sedated patients attenuates shivering but increases rewarming time. Administration of additional relaxant to avoid shivering is seldom indicated in the PACU.

Hyperthermia

Hyperthermia is relatively uncommon in the PACU. Occasionally, a patient exhibits self-limited hyperthermia from close draping or aggressive intraoperative heat preservation. Postoperative fever sometimes reflects an existing infection exacerbated by the surgical procedure (e.g., resection of infected tonsils or appendix, abscess drainage, urinary tract manipulation) or by a previously asymptomatic condition (e.g., sinusitis, upper respiratory or urinary tract infection). Atelectasis secondary to loss of lung volume, retained secretions, or aspiration is another cause, although fever often appears after PACU discharge. Elevated temperature might indicate a drug or transfusion reaction. Muscarinic blocking agents like atropine interfere with a patient's ability to cool and might contribute to fever, but are seldom the cause. High fever occurs with malignant hyperthermia, but signs such as muscle rigidity, dysrhythmia, hyperventilation, and acidemia establish the diagnosis first. Other hypermetabolic states like thyroid storm must be considered.

Ambient cooling, chest physiotherapy, incentive spirometry, and antipyretics are usually sufficient to treat postoperative fever. Offending medications or blood products should be withheld if a drug or transfusion reaction is suspected. The physician responsible for extended care must be notified to ensure evaluation is continued beyond the PACU. Therapy for malignant hyperthermia or thyroid storm is well described elsewhere.

Persistent Sedation

The evaluation of prolonged unconsciousness after anesthesia requires an organized analysis. Because 90% of patients regain consciousness within 15 minutes of admission, unconsciousness persisting for a greater period is considered prolonged.¹⁴⁰ Even a highly susceptible patient should respond to a stimulus within 30–45 minutes after a reasonably conducted general anesthetic.

The level of preoperative responsiveness should be researched to uncover intoxication with drugs and alcohol or pre-existing mental dysfunction. The time and amount of all preoperative and intraoperative sedative medications are noted, and any unusual intraoperative events reviewed. Physical assessment should include a firm tactile stimulus such as a light skin pinch. Tactile stimulation elicits more arousal than verbal stimulation, perhaps because sensory input is amplified through the reticular activating system. The rate and character of spontaneous ventilation helps judge residual anesthesia depth, whereas the heart rate, rhythm, and systemic blood pressure qualitatively indicate adequacy of cerebral perfusion. Diagnostic value of pupillary size and response is low.

Residual sedation from inhalation anesthetics is a frequent cause of prolonged unconsciousness, especially after long procedures, in obese patients, or when high inspired concentrations are continued through the end of surgery. Sedation from intraoperative opioid or sedative administration is dose related. Long-acting sedatives used for premedication (e.g., pentobarbital, hydroxyzine, promethazine, droperidol, lorazepam, scopolamine) contribute to postoperative somnolence. To assess degree of sedation from opioids, low-dose iv naloxone is administered (0.04-mg increments every 2 minutes, up to 0.2 mg). With careful titration, respiratory depression and sedation are reversed without precipitating dangerous reversal of analgesia. If unconsciousness is related to residual opioid effects, ventilatory rate and arousal increase with 0.2 mg or less of iv naloxone unless a patient has received a massive opioid overdose. Flumazenil (0.2 mg iv per min to a total of 1.0 mg), a competitive benzodiazepine antagonist, reverses sedation from midazolam and diazepam, although duration of action is short. Administration of iv physostigmine (1.25 mg) counteracts but does not reverse sedation caused by inhalation anesthetics and other sedatives. If administration of naloxone, flumazenil, or physostigmine does not elicit a response, unconsciousness is most likely not related to residual anesthetic medications. However, it is still possible that an unrecognized, preoperative overdose with depressant oral drugs is responsible.

Profound residual neuromuscular paralysis might rarely mimic unconsciousness by precluding any motor response to stimuli. This might occur after gross overdosage, if reversal agents are omitted, in patients with unrecognized neuromuscular disease, or in patients with Phase II blockade caused by excessive succinylcholine administration or pseudocholinesterase deficiency. Observation of any purposeful motion, spontaneous ventilation, or reflex activity eliminates residual paralysis as an explanation.

Children who were exhausted before surgery are often difficult to arouse after anesthesia, especially if sleep patterns are disrupted by emergency surgery at night. Hypothermia below 33°C impairs consciousness and increases the depressant effect of medications. Core temperatures below 30°C cause fixed pupillary dilation, areflexia, and coma. A serum glucose level should be evaluated to eliminate severe hypoglycemia or hyperglycemic, hyperosmolar coma as causes. Suspicion that unresponsiveness is caused by hypoglycemia indicates an immediate empiric trial of iv 50% dextrose. Hyposmolar states (<260 mOsm · l⁻¹) such as acute hyponatremia (Na < 125 mEq · l⁻¹) are ruled out by serum electrolyte and osmolarity determination. Arterial blood gas analysis reveals CO₂ narcosis (PaCO₂ > 200–250

mm Hg). A patient may also be feigning unresponsiveness or having a hysterical reaction that presents as unconsciousness.¹⁴¹

If a diagnosis remains elusive, a neurologist should perform a neurologic evaluation. CNS depression secondary to iv local anesthetic toxicity or inadvertent subarachnoid injection can mimic postoperative coma. Occasionally unresponsiveness reflects subclinical grand mal seizures secondary to delirium tremens or an underlying seizure disorder. Cerebral anoxia from intraoperative hypotension, dysrhythmias, or hypoxemia must be considered as a potential cause. Neither adequate PaO₂ from a blood gas nor hemoglobin saturation from a pulse oximeter rules out cerebral hypoxia from CO poisoning. Laboratory co-oximetry detects carboxyhemoglobinemia. The possibility of unrecognized head trauma, intracerebral hemorrhage, or increased intracranial pressure from bleeding or edema must be considered in injured patients or those recovering from intracranial surgery. Patients sometimes awaken very slowly after long intracranial procedures.¹⁴² Paradoxical air or fat embolism through a right-to-left intracardiac shunt should be considered. Cerebral thromboembolism is another possibility after cardiac, proximal major vascular, or invasive neck surgery, or in patients who have undergone internal jugular or subclavian cannulation. Patients with atrial fibrillation, carotid bruits, or hypercoagulable states are also at increased risk of thromboembolism. Postoperative cerebrovascular accidents in other patients are very rare and usually occur after the PACU.

Altered Mental Status

Recovering patients often exhibit inappropriate mental reactions, ranging from lethargy and confusion to physical combativeness and extreme disorientation. Aside from the disturbance to staff and other patients, there are serious medical consequences. The risk of incidental trauma increases, including contusion or fracture from contact with equipment or side rails, corneal abrasion from dislodged oxygen apparatus, and sprains from violent struggling against restraints. Forceful, thrashing movements jeopardize suture lines, orthopedic fixations, vascular grafts, drains, tracheal tubes, and indwelling vascular catheters. Agitated patients manifest high levels of SNS tone. Resulting tachycardia and hypertension can cause serious medical complications. Least appreciated is the risk of injury to PACU staff struggling to protect a combative patient.

Adverse psychological responses during awakening from general anesthesia are the most frequent cause of emergence reactions. For a short period after regaining consciousness, some patients appear unable to process sensory input appropriately. Many exhibit somnolence, slight disorientation, and sluggish mental reactions that gradually clear. Others experience wide emotional swings such as uncontrollable weeping or escalating resistance to positioning and restraint.

Predicting which patients will have emergence reactions is difficult. Recovery of cognitive functions is slower in the elderly.^{143,144} Emergence reactions are more prevalent in children and young adults, especially after anesthesia with sevoflurane and desflurane.¹⁴⁵ In young children, anxiety is heightened by parental separation. Patients with mental retardation, psychiatric disorders, organic brain dysfunction, or hostile preoperative interactions manifest those problems after surgery. Inability to speak secondary to oral fixation or tracheal intubation generates frustration or fear, which exaggerates emergence reactions. Ethnic, cultural, and psychological characteristics play some role. A language barrier accentuates an emergence reaction because reassuring input from PACU staff might not be understood. The incidence of stormy emergence is probably higher after procedures that are charged with anxiety or emotional significance such as breast or testicular biopsies. Recall of intraoperative events can generate severe panic and anxiety during emergence.¹⁴⁶

Disorientation or clouded sensorium might reflect chronic use of psychogenic drugs or premedication with long-acting sedatives. Intoxication or withdrawal elicits bizarre emergence behavior in patients who abuse alcohol, opioids, cocaine, or other illicit drugs.¹⁴⁷ Disorientation, paranoia, and combativeness occur after administration of parenteral scopolamine as a premedication or antiemetic. This can be treated with iv physostigmine. Patients receiving atropine premedication or chronic meperidine therapy might exhibit anticholinergic-induced delirium. Ketamine may cause dysphoria and hallucination, although acute reactions are rare. The use of etomidate for induction contributes to restlessness.

Surgical pain amplifies agitation, confusion, and aggressive behavior during emergence.¹⁴⁸ Ensure adequate postoperative analgesia early in the PACU course. Urinary urgency or gastric distention from trapped gas generates discomfort and agitation, as do tight dressings, painful phlebotomy, and poor positioning. Pain from endotracheal or nasogastric tubes, urinary catheters, or infiltrated vascular catheters is equally discomforting. Unrecognized sources of pain such as corneal abrasion, entrapment of sensitive body parts, or small devices left beneath a patient should be checked.

Nausea and dizziness are very distressing during emergence, as is severe pruritus. Some patients struggle vigorously to move from a supine into a more comfortable semisitting position. This is common in patients with gastroesophageal reflux, pulmonary congestion, or obesity. Patients often resist physical restraint until the restraint is relaxed. Residual paralysis elicits severe agitation and violent, uncoordinated motions that make a patient appear disoriented and combative, even when ventilation is adequate. Weakness, a peculiar flapping nature of voluntary motion, and electrical nerve stimulation are helpful in the diagnosis. However, patients can appear fully recovered by train-of-four monitoring, head lift, and other bedside indices but still perceive significant impairment of swallowing, visual acuity, and overall sense of strength.⁷⁹

Combativeness, confusion, or delirium might also reflect serious respiratory dysfunction. Moderate hypoxemia often presents with clouded mentation, disorientation, and agitation resembling that caused by pain. Respiratory acidemia caused by airway obstruction or poor ventilatory mechanics elicits profound agitation. (Hypercarbia caused by ventilatory center depression generates less agitation because higher CNS functions are also depressed.) Hypercarbia without acidemia is usually asymptomatic. Limitation of inspiratory volume by chest dressings, gastric distention, or splinting evolves a vague dissatisfaction with lung inflation similar to air hunger. This also occurs during mechanical ventilation with low delivered volumes, and is probably mediated by stretch receptors in the lung. Inability to generate a forceful cough or clear secretions causes distress, as does high work of breathing. Early interstitial pulmonary edema elicits symptoms of chest fullness and air hunger before airway flooding occurs. Agitation can be profound even though ventilation and oxygenation are adequate.

Metabolic abnormalities interfere with lucidity. Lactic acidemia causes anxiety and mild disorientation, whereas acute hyponatremia clouds the sensorium. Cerebral fluid shifts also occur in patients on dialysis and after repletion of severe dehydration. Hyperosmolarity from hyperglycemia or hypernatremia clouds consciousness, whereas severe hypoglycemia causes first agitation and then diminished responsiveness. Cerebral hypoperfusion produces lethargy, disorientation, agitation, and combativeness. This is a medical emergency that requires aggressive resolution. Administration of sedative or analgesic medications for a mistaken diagnosis of anxiety or pain generates a catastrophic cardiopulmonary collapse in such a patient.

Once reversible causes of delirium or agitation are eliminated, a primary neurologic problem must be considered. Cerebral embolism, hemorrhage, or infarct may initially manifest with disorientation, inability to vocalize, or a reduced level of consciousness. Seizure activity might mimic agitation and combativeness, or disorientation and somnolence during the postictal phase. Seizures should be suspected in patients with epilepsy, head trauma, chronic alcohol intoxication, or cocaine abuse.

There are few interventions that prevent emergence reactions. Use of preoperative sedatives in children does not decrease the incidence of emergence delirium,¹⁴⁹ and preoperative suggestion or reassurance seems ineffective. Altered mental status is treated supportively because most emergence reactions disappear within 10–15 minutes as residual anesthesia dissipates. Verbal reassurances that surgery is completed and the patient is doing well are invaluable. The patient's and the surgeon's name should be used frequently, and the time and location stressed. When practical, patients can be allowed to choose their own positions. Adequate analgesia must be provided. In selected cases, light parenteral sedation relieves fear or anxiety and smooths emergence. Identifying whether a patient is reacting to pain or to anxiety is important. Benzodiazepines and barbiturates are ineffective analgesics, whereas opioids are poor sedatives. Physical restraint is used only when a patient's physical safety is jeopardized. Sedative or analgesic medications should not be administered if altered mental status reflects a physiologic abnormality (e.g., hypoxemia, hypoglycemia, hypotension, acidemia); instead, the abnormality should be resolved.

Acute postoperative pain is a complex physiologic reaction to tissue injury, visceral distention, or disease. It is a manifestation of autonomic, psychological, and behavioral responses that result in an unpleasant, unwanted sensory and emotional experience. Patients often perceive postoperative pain as one of the more ominous aspects of undergoing surgery. In the past, the treatment of postoperative pain was given a low priority by both surgeons and anesthesiologists, and pain was considered a requisite part of the postoperative experience.

With the development of an expanding awareness of the epidemiology and pathophysiology of pain, more attention has been focused on the management of pain in an effort to improve quality of care and patient outcome. The natural progression of this focus was the formation of the postoperative analgesia service or acute pain service, involving a group of individuals who specialize in pain management and who apply an ever-increasing number of modalities to control postoperative pain. This chapter reviews the pathophysiology of pain, examines some pharmacologic considerations, and compares the use of oral, parenteral, and central neuraxial analgesics. Peripheral nerve blocks that have application for postoperative pain relief are highlighted, as are some nonpharmacologic therapies. Incorporation of this knowledge into clinical practice is the basis and the rationale for the effective management of acute postoperative pain.

FUNDAMENTAL CONCEPTS

Nociception

Nociception refers to the detection, transduction, and transmission of noxious stimuli. Stimuli generated from thermal, mechanical, or chemical tissue damage may activate nociceptors, which are free nerve endings. Nociceptors can be further classified into exteroceptors, which receive stimuli from skin surfaces, and interoceptors, which are located in the walls of viscera or deeper body structures. Although nociceptors are free nerve terminals, they are adjacent to small blood vessels and mast cells, with which they operate as a functional unit.¹ In addition to nociceptors, the skin is richly innervated by specialized somatosensory receptors that are sensitive to other forms of stimulation (Table 54-1). Each sensory unit includes an end-organ receptor, accompanying axon, dorsal root ganglion, and axon terminals in the spinal cord. In contrast to other special somatosensory receptors, nociceptors exhibit high response thresholds and persistent discharge to suprathreshold stimuli without rapid adaptation and are associated with small receptive fields and small afferent nerve fiber endings.

| Receptor | Sensation Perceived |
|----------------------------------|---------------------|
| Nerve fibers on hair follicles | Touch |
| Merkel's disks | Touch |
| Meissner's corpuscles | Touch |
| Free nerve endings (nociceptors) | Pain |
| Krause's end bulbs | Cold |
| Ruffini's endings | Heat |
| Pacinian corpuscles | Pressure |
| Golgi-Mazzoni endings | Pressure |

Table 54-1. SOMATOSENSORY RECEPTORS

Peripheral Nerve Afferent Fibers

Nerve fibers were first described according to their type of covering and the presence or absence of myelination. Neural fibers may be covered with neurolemma or myelin, or both. Speed of conduction is determined by fiber size and the presence or absence of myelination. Small, unmyelinated fibers transmit at slower speed than larger myelinated afferent fibers.

With the invention of the oscilloscope, Erlanger and Gasser² were able to describe a more functional classification of peripheral nerve fibers. Nerve fibers were categorized into three groups (A, B, and C), depending on size, degree of myelination, rapidity of conduction, and distribution of fibers. A refinement of this classification is the functional subdivision of the Class A fibers into the subtypes of alpha, beta, gamma, and delta.³

Class A. These neurons, composed of large myelinated fibers, exhibit a low threshold for activation, conduct impulses at a speed of 5–100 m · sec⁻¹, and measure 1–20 μm in diameter. Class A delta fibers mediate pain sensation, whereas Class A alpha fibers transmit motor and proprioceptive impulses. Class A beta and gamma fibers are responsible for cutaneous touch and pressure as well as regulation of muscle spindle reflexes.

Class B. These neurons constitute the medium-sized myelinated fibers with a conduction velocity ranging from 3 to 14 m · sec⁻¹ and a diameter less than 3 μm. They have a higher threshold (lower excitability) than Class A fibers but a lower threshold than Class C fibers. The postganglionic sympathetic and visceral afferents belong

to this group.

Class C. These fibers are unmyelinated or thinly myelinated and have conduction velocities in the range of $0.5\text{--}2\text{ m} \cdot \text{sec}^{-1}$. This class is composed of preganglionic autonomic fibers and pain fibers. Approximately 50–80% of C fibers modulate nociceptive stimuli.

An additional classification of afferent muscle nerve fibers used by neurophysiologists divides the large myelinated fibers into three functional groups (Ia, Ib, II), placing the thinly myelinated (III) and unmyelinated fibers (IV) into separate groups. The muscle afferents of Erlanger and Gasser's Class A alpha fibers are subdivided into two groups, Ia and Ib. Fibers from the annulospiral endings of the muscle spindles compose the Ia Group, whereas Group Ib fibers emanate from the Golgi tendon organs. Group II consists of the tactile and proprioceptive fibers of Classes A beta and gamma, respectively, whereas the primary nociceptive nerve fibers of Classes A delta and C are equivalent to Groups III and IV, respectively, within this classification.⁴

Spinal Cord and Brain Pathways

The peripheral afferent neuron, termed the *first-order neuron*, has its cell body located in the dorsal root ganglion and sends axonal projections into the dorsal horn and other areas of the spinal cord. At this point, a synapse occurs with a second-order afferent neuron, which can be categorized, depending on the afferent input it receives, as a nociceptive-specific or wide-dynamic-range neuron. Nociceptive-specific neurons process afferent impulses only from nociceptive afferent fibers, whereas A beta, A delta, and C fibers communicate with wide-dynamic-range neurons. In the dorsal horn, further synaptic connections occur between first-order neurons and regulatory internuncial neurons. First-order neurons also communicate with the cell bodies of the sympathetic nervous system and ventral motor nuclei, either directly or through the internuncial neurons.⁵ The cell body of the second-order neuron lies in the dorsal horn, and axonal projections of this neuron cross to the contralateral hemisphere of the spinal cord (Fig. 54-1). This second-order afferent neuron ascends from that level in the lateral spinothalamic tract to synapse in the thalamus. Along the way, this neuron divides and sends axonal branches that synapse in the regions of the reticular formation, nucleus raphe magnus, peri-aqueductal gray, and other areas in the brain stem. In the thalamus, the second-order neuron synapses with a third-order afferent neuron, which sends axonal projections into the sensory cortex.

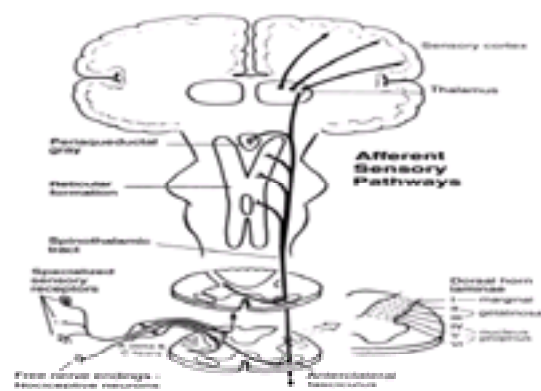

Figure 54-1. Afferent sensory pathways for detection and transmission of nociceptive impulses.

Modulation of Nociception

Even though nociceptors and the afferent sensory neural pathways detect and transmit noxious stimuli reliably, modulation occurs at several levels in the pathway before perception of the signal at the cortical levels. Modulation can occur either in the periphery or at any point where synaptic transmission occurs.

Peripheral Modulation

Peripheral modulation occurs either by the liberation or elimination of allogenic substances in the vicinity of the nociceptor. Tissue injury activates nociceptors in the periphery by causing the release of neurotransmitters such as substance P and glutamate, which directly activate nociceptors. Other allogenic mediators—such as potassium and hydrogen ions, lactic acid, serotonin, bradykinin, histamine, and the prostaglandins—further sensitize and excite nociceptors and act as mediators of inflammation. The sources of these substances include ischemic damaged cells and mast cells in the area of the injury, as well as plasma and platelets in the microcirculation surrounding the nociceptors.¹ Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and specific cyclo-oxygenase-2 (COX-2) inhibitors exert an analgesic effect by inhibiting prostaglandin synthesis and reducing prostaglandin E_1 - and E_2 -mediated sensitization of peripheral nociceptors.

Spinal Modulation

Modulation in the spinal cord results from the action of neurotransmitter substances in the dorsal horn or from spinal reflexes, which convey efferent impulses back to the peripheral nociceptive field. The excitatory amino acid transmitters L-glutamate and aspartate, and several neuropeptides, including vasoactive intestinal peptide, calcitonin gene-related peptide, and neuropeptide Y, are found in central terminals of the first-order neurons and have been shown to modulate transmission of nociceptive afferent signals.⁶ Substance P, which is found in the synaptic vesicle of unmyelinated C fibers, is also an important neuromodulator that can enhance or aggravate pain.⁷ Prostaglandins produced in response to inflammation play a role in inflammation-evoked central sensitization of spinal cord neurons.⁸

Inhibitory substances involved in the regulation of afferent impulses in the dorsal horn include the enkephalins, β -endorphins, norepinephrine, dopamine, and adenosine.⁶ Somatostatin, a neuropeptide found in cells that do not contain substance P, may represent another inhibitory neuropeptide involved in afferent modulation. Acetylcholine is also involved in afferent signal processing. Muscarinic receptors of the M_1 and M_2 subtypes have been identified on the nerve terminals of the first-order neurons in laminae II and III of the spinal cord.⁹ Cell bodies staining for choline acetyltransferase have been found in laminae III, IV, and V,¹⁰ with dendritic projections into laminae I, II, and III, sites that are primarily involved in processing of nociceptive impulses.¹¹ Cholinergic agonists have been demonstrated to produce analgesia,¹² as has neostigmine, which inhibits the breakdown of the endogenous neurotransmitter acetylcholine.¹³ Acetylcholine acts at muscarinic (M_1 or M_3) receptors that appear to mediate spinal antinociception.¹⁴ The analgesic efficacy of modulating the cholinergic system depends on the tonic release of acetylcholine at muscarinic receptors involved in afferent signal processing, because acetylcholine has actions at other spinal sites (inhibition of motor neuron activity, excitation of sympathetic outflow) that produce unwanted side effects.¹³

Afferent modulating mechanisms at the spinal level may also involve spinal reflexes in which afferent signals directly evoke somatic or sympathetic efferent impulses. These impulses discharge in the area of the efferent nociceptive signal. For example, skeletal muscle spasm in an injured area is part of a somatic efferent reflex that is induced as a result of nociceptive afferent signals. Increased skeletal muscle tone initiates more nociceptive signals in a positive feedback loop system from the muscles (Fig. 54-2). In addition, spinal reflexes may involve the discharge of efferent sympathetic signals evoked from the nociceptive impulse (see Fig. 54-2). Efferent sympathetic signals emanate from cell bodies located in the intermediolateral column of the spinal cord. These cell bodies receive internuncial projections from the dorsal horn of the gray matter. This sympathetic reflex produces smooth muscle spasm, vasoconstriction, and liberation of norepinephrine in the vicinity of the wound, thereby generating more pain. Release of norepinephrine has been shown to produce or augment pain after injury.

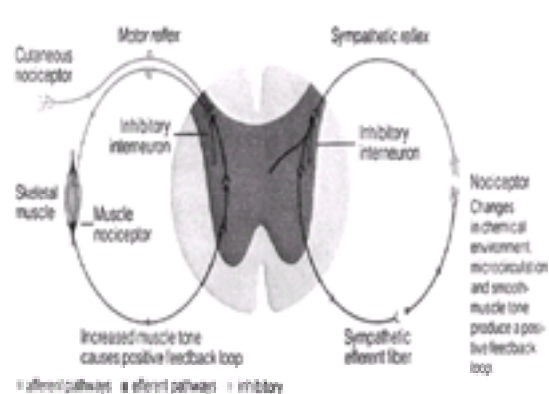

Figure 54-2. Schematic representation of spinal reflexes involved in pain modulation. (Reprinted with permission from Bonica JJ, Liebeskind JC, Albe-Fessard DG [eds]: *Advances in Pain Research and Therapy*, p 3. New York, Raven Press, 1979.)

Neuroplasticity: The Dynamic Modulation of Neural Impulses. The preceding description of the neurophysiology of afferent signal transmission and processing is based on the concept that neural connections involve isolated, unaltered transmission of a single impulse or group of impulses between neurons. Using this model, modulation of noxious efferent signals could be described by gating mechanisms, which have formed the basis for therapeutic analgesic interventions. More recently, however, the description of neural activity-dependent plasticity has enhanced our understanding of the dynamic nature of the nociceptive response to injury. As peripheral nociceptors are sensitized by local tissue mediators of injury (potassium, prostaglandins, and bradykinins), the excitability and frequency of neural discharge increase. This primary hyperalgesia permits previously subnoxious stimuli to generate action potentials and be transduced orthodromically in the spinal cord (Fig. 54-3). The facilitation of impulse transduction in the first-order neuron is partially mediated by noxious substances released from damaged tissues. In addition, axonal reflexes exaggerate this response by releasing substance P, which produces vasodilation and mast cell degranulation, liberating histamine and serotonin and effectively enlarging the peripheral receptive field to include adjacent noninjured tissue, resulting in secondary hyperalgesia.¹⁵

Figure 54-3. Schematic representation of peripheral and spinal mechanisms involved in neuroplasticity. Primary hyperalgesia results from tissue release of toxic substances, which spread to adjacent tissues, prolonging the hyperalgesic state (secondary hyperalgesia). As C-fiber terminals increase in frequency of release of neurotransmitters such as glutamate, substance P, and tachykinins, the effects of these neurotransmitters are summated, resulting in prolonged depolarizations of second-order neurons (“windup”). Function changes at the second order neuron occur as a result of neurotransmitter binding to postsynaptic receptors, which results in activity-dependent plasticity of the spinal cord. See text for details. AMPA = a-amino-3 hydroxy-5-methyl-4-isoxazole propionic acid; NK = neurokinin; NMDA = N-methyl-D-aspartate.

The increased frequency of impulse transmission to the dorsal horn reduces the gradient between the resting and the critical threshold potential of second-order neurons in the spinal cord. As peripheral nerve firing increases, other changes also occur in the excitability of spinal cord neurons, altering their response to afferent impulses. This central sensitization to afferent impulses results from a functional change in spinal cord processing, termed *neuroplasticity* (see Fig. 54-3). The temporal summation of the number and duration of action potentials elicited per stimulus that occurs in dorsal horn neurons (or in the motor neurons of the ventral horn) has been referred to as the “windup” phenomenon.¹⁶ In general, the windup phenomenon requires a minimum stimulus frequency of 0.5 Hz, arising from C fibers. Once the stimulus frequency reaches a critical threshold, the postsynaptic depolarizing responses of these second-order afferent neurons summate to produce bursts of action potential discharges instead of a single action potential. The windup phenomenon results in a persistence of action potentials for up to 60 seconds after the discontinuance of the stimulus, and results in a change in spinal cord processing that can last for 1–3 hours.¹⁷ As this process repeats, more permanent changes in these second-order neurons occur and have been termed *long-term potentiation*.

The cellular mechanisms of spinal cord sensitization involve the relatively slow-onset and long-duration synaptic potentials elicited by A delta and C fibers in dorsal horn neurons.¹⁶ These potentials persist up to 20 seconds (approximately 2000 times longer than the fast potentials of A beta fibers). These slow potentials are mediated through release by the afferent axon of the excitatory neurotransmitter glutamate and the neuropeptides substance P and neurokinin A^{16,18} (see Fig. 54-3). As peripheral afferent nerve activity increases, progressively more and longer-lasting second-order neuron depolarizations occur because of the accumulation of these excitatory neurotransmitters and summation of these slow potentials. The net result is that a few seconds of C-fiber activity can result in several minutes of postsynaptic depolarization.

Spinal cord synaptic plasticity involves the binding of glutamate to the N-methyl-D-aspartate (NMDA) receptor as well as binding of substance P and neurokinins to tachykinin receptors.^{16,19} High-frequency presynaptic activity causes release of glutamate and tachykinins from presynaptic vesicles. Binding of glutamate to NMDA receptors alters a magnesium-dependent block of ion channels, subsequently increasing cellular permeability to all cations, especially calcium and sodium. Glutamate also activates the a-amino-3 hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and metabotropic receptors on the postsynaptic cell. AMPA receptors control depolarization primarily through modulation of sodium influx into the cell. Neurokinins and substance P, through G-protein-linked receptors, increase enzymatic activity, resulting in augmented depolarization and increases in stores of secondary neurotransmitters. In aggregate, stimulation of these three receptor groups enhances the excitability of the second-order neuron (see Fig. 54-3).

In addition to modulating augmented excitability, these transmitter and cellular mechanisms mediate changes in the postsynaptic cell, leading to more permanent changes in nerve conduction, or long-term potentiation.¹⁷ Extracellular calcium influx enhances release of intracellular calcium stores, initiating a series of intracellular events that include calcium-dependent enzymatic reactions mediated by protein kinase C, calcium-calmodulin, and cyclic adenosine monophosphate-dependent protein kinase A. These enzymes phosphorylate membrane proteins, namely receptors and ion channels on the postsynaptic cell, which further increases excitability. AMPA receptors become more numerous on the postsynaptic cell membrane, and a retrograde factor is released that diffuses back to the presynaptic cell, augmenting neurotransmitter release in response to a given presynaptic action potential. Finally, changes in second messengers also activate immediate early gene products, transcription factors that can alter the expression of particular genes, which in turn can result in more persistent changes in neural processing.

Although much of the preceding discussion of altered spinal cord processing in response to nociceptive input has been derived from the study of chronic pain, similar changes in spinal cord processing occur even after a minor surgical incision.²⁰ These changes result in an increase in primary hyperalgesic response to noxious stimulus that persists for many days in the area of the incision as well as secondary hyperalgesia of shorter duration in surrounding tissues.²¹

Supraspinal Modulation

Brain Stem. Descending inhibitory tracts at the brain stem level originate from cell bodies located in the region of the periaqueductal gray, reticular formation, and nucleus raphe magnus. These inhibitory tracts descend into the dorsolateral fasciculus and synapse in the dorsal horn. Neurotransmitters act presynaptically on the first-order neuron and postsynaptically on the second-order neuron of the spinothalamic tract or on the internuncial neuron pool. Internuncial neurons can be inhibitory and can regulate synaptic transmission between primary and secondary afferent neurons in the dorsal horn. At least two groups of nerve fibers have been identified as participants in this inhibitory modulation. One group of fibers involves the opioid system and contains the neurotransmitters b-endorphin and the enkephalins, as well as other neuropeptides. Analgesia is produced during electrical stimulation of the peri-aqueductal gray, and this effect is blocked by naloxone.²² These opioid projections from the nucleus raphe magnus and reticular formation interface presynaptically with the first-order afferent neurons. Neurotransmitters released from these projections hyperpolarize Class A delta and C fibers, which serves to negate or shunt out the depolarizing current that approaches the terminal end plate, thereby diminishing the release of neurotransmitters such as substance P²³ (Fig. 54-4). In addition to this presynaptic modulation, exogenously applied opioids inhibit L-glutamate-evoked discharge of dorsal horn neurons, suggesting that opioids exert a direct postsynaptic effect.²⁴ In summary, opioids modulate transmission of afferent impulses in the dorsal horn presynaptically at the level of the first-order neuron. The enkephalinergic transmitter that is released from the descending inhibitory pathways hyperpolarizes the afferent terminals to block neurotransmitter release. Opioids also exert a direct inhibitory effect on the postsynaptic membrane potential (see Fig. 54-4).

hormone influence water and electrolyte reabsorption by promoting Na⁺ and water retention while expending potassium. This contributes to increases in the extravascular fluid compartment both peripherally and within the pulmonary parenchymal tissue. Local release of cytokines such as interleukin-2, interleukin-6, and tumor necrosis factor may contribute to abnormal physiologic responses such as alterations in heart rate, temperature, blood pressure, and ventilation.³¹ Finally, catecholamines sensitize peripheral nociceptive endings, which serve to propagate more intense pain and may contribute to a vicious pain–catecholamine release–pain cycle.³² The magnitude of these neuroendocrine and cytokine responses is related to the severity of tissue injury and correlates with outcome after injury.^{33,34}

Cardiovascular

The cardiovascular effects of pain are initiated by the release of catecholamines from sympathetic nerve endings and the adrenal medulla, of aldosterone and cortisol from the adrenal cortex, and of antidiuretic hormone from the hypothalamus, and by activation of the renin–angiotensin system. These hormones have direct effects on the myocardium and vasculature, and they augment salt and water retention, which places a greater burden on the cardiovascular system.

Angiotensin II causes generalized vasoconstriction, whereas catecholamines increase heart rate, myocardial contractility, and systemic vascular resistance. The sympathoadrenal release of catecholamines and the effects of angiotensin II may result in hypertension, tachycardia, and dysrhythmias and may lead to myocardial ischemia in susceptible patients as a consequence of increased oxygen demand. In addition, a significant proportion of perioperative myocardial ischemia is related to reductions in myocardial supply without hemodynamic aberrations. Activation of the sympathetic nervous system may trigger coronary vasoconstriction, which may result in myocardial ischemia in the presence of atherosclerotic coronary artery disease. This may occur through direct activation of cardiac sympathetic nerves³⁵ as well as through circulating catecholamines, which may contribute to hypercoagulability, a known mediator of adverse outcome in patients with ischemic heart disease. Salt and water retention secondary to aldosterone, cortisol, and antidiuretic hormone, in combination with the previously described effects of catecholamines and angiotensin II, can also precipitate congestive heart failure in patients with limited cardiac reserve.

Respiratory

Increases in extracellular lung water may contribute to ventilation-perfusion abnormalities. For surgical procedures performed on the thorax and abdomen, pain-induced reflex increases in skeletal muscle tension may lead to decreased total lung compliance, splinting, and hypoventilation. These changes then promote atelectasis, contribute to further ventilation-perfusion abnormalities, and result in hypoxemia. In major surgical procedures or in high-risk patients, these respiratory effects of pain may lead to a significant reduction in functional residual capacity ranging from 25–50% of preoperative values.³⁶ Hypoxemia stimulates increases in minute ventilation. Although tachypnea and hypocapnia are common initially, prolonged increases in the work of breathing may result in hypercapnic respiratory failure. Pulmonary consolidation and pneumonitis may occur because of hypoventilation and further aggravate the clinical scenario. These sequelae are especially significant in patients with pre-existing pulmonary disease, upper abdominal and thoracic incisions,³⁷ advanced age, or obesity.³⁶

Gastrointestinal

Pain-induced sympathetic hyperactivity may cause reflex inhibition of gastrointestinal function.³⁸ This promotes postoperative ileus, which contributes to postoperative nausea, vomiting, and discomfort and delays resumption of an enteral diet. Failure to resume early enteral feeding may be associated with postoperative morbidity, including septic complications and abnormal wound healing.³⁹

Genitourinary

An increase in sympathetic activity responses to pain causes reflex inhibition of most visceral smooth muscle, including urinary bladder tone. This can result in urinary retention with subsequent urinary tract infections and related complications.

Immunologic

The pain-related stress response suppresses both cellular and humoral immune function^{40,41} and results in lymphopenia, leukocytosis, and depression of the reticuloendothelial system. In addition, some anesthetic agents reduce chemotaxis of neutrophils and may be one factor involved in the reduction of monocyte activity. Many known mediators of the stress response are potent immunosuppressants, and both cortisol and epinephrine infusions decrease neutrophil chemotaxis.⁴² These effects can lower resistance to pathogens and may be key factors in the development of perioperative infectious complications.⁴³ In patients with neoplasms in whom surgical manipulation of the tumor causes release of tumor cells, the postoperative stress response may reduce the cytotoxicity of killer T cells. Increases in catecholamines, glucocorticoids, and prostaglandins in response to stress may impair immunologic responses important for patients with neoplasms.⁴⁴

Coagulation

Stress-related alterations in blood viscosity, platelet function, fibrinolysis, and coagulation pathways have been described.^{45,46,47} and ⁴⁸ These stress-mediated effects include increased platelet adhesiveness, diminished fibrinolysis, and promotion of a hypercoagulable state. When these effects are coupled with the microcirculatory effects of catecholamines as well as immobilization of the patient in the postoperative period, thromboembolic events are more likely to occur.

General Well-Being

Pain increases skeletal muscle tone in the area of the surgical field. This postoperative impairment of muscle function may lead to physical immobility and a delayed return to normal function. Poorly controlled pain also contributes to insomnia, anxiety, and a feeling of helplessness. These psychological factors, coupled with the immobilization that occurs because of the increased skeletal muscle tone, create a postoperative scenario feared by many patients.

Attenuation of Central Sensitization and the Stress Response

As discussed earlier, acute tissue injury results in peripheral as well as central neural sensitization. It is also evident that acute nociceptive stimulation can result in neuroplastic responses that compound the intensity of pain perception in concert with other deleterious systemic effects, including those modulated as part of the stress response. Because most of these events are not manifest until after surgery, most efforts to attenuate the cascade of events precipitated by intraoperative trauma have focused on the postoperative period. These efforts are well founded because of the need to interrupt and limit central sensitization propagated by ongoing tissue injury. However, perioperative anesthetic and analgesic strategies must also consider the temporal relation of nociceptive stimulation to the initiation of central sensitization. The ideal perioperative intervention should focus on preventive, rather than primarily therapeutic measures to control the adverse sequelae of central sensitization and the stress response. Our current understanding of the pathophysiologic consequences of tissue injury has therefore prompted the application of preoperative and intraoperative techniques that prevent or minimize this postinjury hypersensitivity, and has fostered the concept of preemptive analgesia.

The relative importance of preemptive analgesia in preventing adverse sequelae depends on several factors, including preoperative patient status and the magnitude and site of the surgical intervention. It is widely believed that preemptive analgesia has a greater impact in patients with impaired physiologic reserve than in healthier patients who can better tolerate the perturbations induced by surgery. Minor, peripheral surgical procedures performed with the use of local anesthesia usually produce minimal systemic or central neuraxial changes. The more extensive the surgical procedure, the greater the magnitude of the neuroendocrine stress response. Procedures associated with greater degrees of surgical trauma may also contribute to greater central sensitization than less invasive procedures.

From the previous discussion, it is apparent that the postoperative physiologic changes are not homeostatic mechanisms but are reproducible adverse responses to tissue injury that result in a myriad of adverse physiologic events that likely modulate perioperative outcome. Research efforts have therefore been focused on the effectiveness of various anesthetic and analgesic strategies targeted to modify the adverse neural and systemic derangements commonly observed after surgery.

Influence of Anesthesia on the Surgical Stress Response and Outcome

General Anesthesia

It has been demonstrated that general anesthesia, either with intravenous (iv) or inhalational anesthetics, does not effectively attenuate the neuroendocrine stress response.⁴⁹ One exception to this assertion is the administration of high-dose opioid anesthesia. Extremely high doses of certain opioids can inhibit some aspects of the stress response, but lower doses of opioids usually are unable to hinder the neuroendocrine effects of stress.^{50,51} The effect of opioids on immune function is controversial because both immune-suppressing and immune-enhancing effects have been described.⁵² High doses of inhalational agents (1.5 of minimum alveolar

concentration) may suppress the intraoperative catecholamine response but do not diminish the catecholamine response that develops after surgery.

Regional Anesthesia and Analgesia

Mitigation of nociception at the peripheral and central level may be accomplished through a variety of techniques. A regional anesthetic or analgesic modality is ideally suited to produce this desired effect because it diminishes the intensity of afferent impulses reaching the spinal cord. Regional anesthesia and analgesia have been shown to reduce catecholamine and other stress hormone responses during the perioperative period for certain surgical procedures.^{30,47,53} The finding that regional anesthesia and analgesia can ablate the neuroendocrine stress responses is not universal. Some studies have demonstrated that central neuraxial techniques have no significant influence on cortisol release. The differing results may be related to the level of the afferent neural blockade. Another confounding variable is the region of the body where the surgical procedure was performed. In studies where regional anesthesia did not have an influence on the cortisol response, surgery was performed in the upper abdomen, whereas in most studies that demonstrate inhibition, surgery was performed on a lower extremity or the lower abdomen. Sensory blocks below L1 usually have no effect on cortisol response. To prevent a cortisol response to surgery, all afferent pathways from the surgical site must be blocked.⁵⁴

Besides reducing the neuroendocrine stress response, regional anesthesia can reduce myocardial work and oxygen consumption by reducing heart rate, arterial pressure, and left ventricular contractility. Left ventricular ejection fraction is not significantly affected by epidural anesthesia in normal patients, whereas patients with chronic stable angina experience a modest but significant improvement in left ventricular ejection fraction and left ventricular wall motion, provided that volume loading is limited.⁵⁵ In patients with unstable angina that is refractory to treatment with nitrates, β blockers, and Ca^{2+} antagonists, thoracic epidural analgesia alleviates chest pain without changing coronary perfusion pressure, cardiac output, or systemic vascular resistance.⁵⁶ Studies evaluating regional myocardial blood flow distribution in intact animals indicate that epidurally administered local anesthetics can improve endocardial-to-epicardial blood flow ratios, shifting blood flow to the area of myocardium at greatest risk of ischemia and infarction.⁵⁷ A reduction in infarct size in experimental models of acute coronary occlusion has also been demonstrated.⁵⁷

Administration of epidural local anesthetics or opioids in the postoperative period can reduce the incidence of myocardial ischemia and dysrhythmias compared with systemic opioids.^{58,59} Beneficial effects of epidural anesthesia and analgesia on cardiac outcomes have been demonstrated only in high-risk populations undergoing major operations, perhaps because such patients experience a high incidence of complications, allowing differences to be detected in relatively small samples. Epidural anesthesia and analgesia was associated with both statistically and clinically significant reductions in serious cardiovascular morbidity compared with general anesthesia with on-demand opioid analgesia alone in a population of patients undergoing major intrathoracic, intra-abdominal, or vascular surgery,⁶⁰ as well as in a series of patients undergoing major peripheral vascular surgery (approximately 45% of operations involving the abdominal aorta).⁴⁵ Another study in abdominal aortic reconstructive surgery comparing general anesthesia with combined epidural anesthesia and general anesthesia found no differences in cardiovascular or other outcomes, although postoperative analgesia techniques were not controlled or randomized.⁶¹ In aggregate, these findings are consistent with the hypothesis that outcome improvement requires that intraoperative initiation of central neuraxial blockade be accompanied by postoperative continuation of this modality. Other studies investigating lower-risk patient populations⁶² or less invasive surgical procedures (infrainguinal revascularizations)⁶³ with a lesser magnitude of surgical insult had lower incidences of cardiac morbidity and could not demonstrate significant effects on cardiac morbidity despite other beneficial effects of epidural anesthesia and analgesia. Therefore, the benefits of epidural analgesia on cardiac morbidity remain controversial, and formation of definitive conclusions has been hindered by the absence of studies with sufficient numbers of patients and the multifactorial causation of cardiac morbidity, which mandates a tightly controlled study design. Most studies with negative results have not consistently continued the intraoperative epidural technique for postoperative analgesia.

The beneficial effects of epidural anesthesia and analgesia on some aspects of cardiovascular outcome may be intimately related to modulation of the hypercoagulable state that occurs and persists after major surgical trauma, especially in patients with atherosclerotic vascular disease and others with a predisposition to hypercoagulability.⁶⁴ General anesthesia with parenteral opioid analgesia has little effect on postoperative hypercoagulability.^{45,46,63,65} Epidural anesthesia using local anesthetics with or without opioids enhances fibrinolytic activity,^{46,66} hastens the return of antithrombin III from elevated to normal levels, and attenuates postoperative increases in platelet activity. These effects probably occur through multiple mechanisms, including block of sympathetic efferent nerves, reduced levels of circulating catecholamines and anticoagulant properties of even low levels of systemically absorbed local anesthetics. These reductions in postoperative hypercoagulability appear to reduce the incidence of thromboses of vascular grafts in patients undergoing lower extremity revascularization,^{45,63} and also reduce the incidence of deep venous thromboses and risk of pulmonary thromboembolism in patients undergoing total hip replacements. The reduced incidence of thrombotic phenomena in these settings may be related to an inhibitory effect on platelet aggregation as well as to improvements in lower limb blood flow.⁶⁷ Similar reductions in thromboembolic complications have been reported with the use of epidural anesthesia and analgesia (with local anesthetics) after other procedures, including knee arthroplasty⁶⁸ and open prostatectomy.⁶⁹ The differences in coagulability associated with epidural anesthesia and analgesia have been observed only in patients inherently at high risk for vaso-occlusive events.

Epidural analgesia is associated with improved pulmonary function after surgery compared with intramuscular (im) and iv opioid.^{36,70,71,72} and ⁷³ Diaphragmatic function is commonly impaired after abdominal or thoracic surgery, probably as a result of reflex inhibition of phrenic nerve activity.^{74,75} Although analgesia provided by parenterally or epidurally administered opioids alone does not significantly improve this dysfunction,⁷⁶ thoracic epidural analgesia with local anesthetic may improve postoperative diaphragmatic function by neural blockade of the inhibitory reflex^{74,75} as well as by changing chest wall compliance.

Although epidural and parenteral opioids are associated with similar frequencies of episodic postoperative hypoxemia,⁷⁷ epidural analgesia with local anesthetics reduces the frequency and severity of early postoperative hypoxemia. It is likely that reductions in the work of breathing and other beneficial effects of improved analgesia such as enhanced ability to cough and facilitation of chest physiotherapy also play an important role in preventing postoperative respiratory complications. The former effects may be related to improved analgesia during activity, particularly when epidural local anesthetics and opioid are combined.⁷⁸

Several studies have demonstrated reductions in the incidence of postoperative pneumonia and respiratory failure in high-risk patients undergoing thoracic or abdominal operations.^{36,45} Similar differences in pulmonary morbidity between parenteral postoperative opioids and epidural analgesia have not been observed in healthy patients undergoing low-risk operations or when postoperative analgesia was not managed using well defined protocols.^{55,79,80} and ⁸¹

In summary, epidural anesthesia and analgesia can reduce the frequency and severity of postsurgical stress-induced physiologic perturbations. The effect of epidural anesthesia and postoperative analgesia on mediators of the stress response appears to have the greatest impact on perioperative outcome in patients at high risk of complications. The relative importance of preemptive intraoperative initiation compared with postoperative application of epidural local anesthetics (versus opioid alone or in combination), as well as the cost effectiveness of these analgesic techniques compared with other modalities for management of postoperative pain, depends on the patient's preoperative status and the specific operative procedure.

PHARMACOLOGY OF POSTOPERATIVE PAIN MANAGEMENT

Drugs administered orally for postoperative pain management can be grouped by their mechanism of effect as nonopioid or opioid analgesics.

Nonopioid Analgesics

Mechanisms of Analgesic Effects

Aspirin, acetaminophen, the NSAIDs, and the selective COX-2 inhibitors are the principal nonopioid analgesics used to treat minor or moderate acute postoperative pain (Table 54-3). Although these compounds represent diverse chemical entities, their common mechanism of action is inhibition of prostaglandin-mediated amplification of chemical and mechanical irritants on the sensory pathways. Although sensitization or intensification of painful stimuli is mediated by the prostaglandins and lowers the threshold for further activation of the nociceptors, the prostaglandins directly evoke little painful response.

| Drug | Class | MOA | Relative Efficacy | Relative Safety | Relative Cost |
|---------------|-----------------|--------------------------|-------------------|-----------------|---------------|
| Aspirin | NSAID | COX inhibition | High | Low | Low |
| Acetaminophen | Non-NSAID | Central COX inhibition | Low | High | Low |
| Ibuprofen | NSAID | COX inhibition | High | Low | Low |
| Naproxen | NSAID | COX inhibition | High | Low | Low |
| Celecoxib | COX-2 inhibitor | COX-2 inhibition | High | High | High |
| Etoricoxib | COX-2 inhibitor | COX-2 inhibition | High | High | High |
| Rofecoxib | COX-2 inhibitor | COX-2 inhibition | High | High | High |
| Valdecoxib | COX-2 inhibitor | COX-2 inhibition | High | High | High |
| Paracetamol | Non-NSAID | Central COX inhibition | Low | High | Low |
| Codeine | Opioid | Mu receptor activation | High | Low | Low |
| Morphine | Opioid | Mu receptor activation | High | Low | Low |
| Fentanyl | Opioid | Mu receptor activation | High | Low | Low |
| Sufentanil | Opioid | Mu receptor activation | High | Low | Low |
| Remifentanyl | Opioid | Mu receptor activation | High | Low | Low |
| Alfentanil | Opioid | Mu receptor activation | High | Low | Low |
| Carfentanyl | Opioid | Mu receptor activation | High | Low | Low |
| Buprenorphine | Opioid | Mu receptor activation | High | High | Low |
| Nalbuphine | Opioid | Mu receptor activation | High | High | Low |
| Butorphanol | Opioid | Mu receptor activation | High | High | Low |
| Meperidine | Opioid | Mu receptor activation | High | Low | Low |
| Propofol | Anesthetic | GABA receptor activation | High | Low | Low |
| Etomidate | Anesthetic | GABA receptor activation | High | Low | Low |
| Midazolam | Anesthetic | GABA receptor activation | High | Low | Low |
| Flunitrazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Alprazolam | Anesthetic | GABA receptor activation | High | Low | Low |
| Clonazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Lorazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Oxazolone | Anesthetic | GABA receptor activation | High | Low | Low |
| Thiopental | Anesthetic | GABA receptor activation | High | Low | Low |
| Propofol | Anesthetic | GABA receptor activation | High | Low | Low |
| Etomidate | Anesthetic | GABA receptor activation | High | Low | Low |
| Midazolam | Anesthetic | GABA receptor activation | High | Low | Low |
| Flunitrazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Alprazolam | Anesthetic | GABA receptor activation | High | Low | Low |
| Clonazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Lorazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Oxazolone | Anesthetic | GABA receptor activation | High | Low | Low |
| Thiopental | Anesthetic | GABA receptor activation | High | Low | Low |
| Propofol | Anesthetic | GABA receptor activation | High | Low | Low |
| Etomidate | Anesthetic | GABA receptor activation | High | Low | Low |
| Midazolam | Anesthetic | GABA receptor activation | High | Low | Low |
| Flunitrazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Alprazolam | Anesthetic | GABA receptor activation | High | Low | Low |
| Clonazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Lorazepam | Anesthetic | GABA receptor activation | High | Low | Low |
| Oxazolone | Anesthetic | GABA receptor activation | High | Low | Low |
| Thiopental | Anesthetic | GABA receptor activation | High | Low | Low |

Table 54-3. PHARMACOKINETIC PARAMETERS/MAXIMUM DOSAGE RECOMMENDATIONS OF NON-NARCOTIC ANALGESICS

Most of these agents modulate prostaglandin synthesis through inhibition of the action of the enzyme prostaglandin endoperoxide synthase (COX), which is one of the first steps in the conversion of arachidonic acid into prostaglandins, thromboxanes, and prostacyclin. By reducing prostaglandin synthesis, COX inhibitors block the nociceptive response to endogenous mediators of inflammation such as bradykinin, acetylcholine, and serotonin. Although the exact mechanism for the participation of endogenous substances such as prostaglandins in the generation and transduction of nociceptive stimuli is unknown, the effect is greatest in tissues that have been subjected to trauma and inflammation.⁸² The prostaglandins represent a diverse group of compounds that mediate many cellular and subcellular functions. The order of the sensitizing or hyperalgesic effect that is usually observed with this group is $PGE_1 > PGE_2 > PGF_{2\alpha}$, whereas PGA_1 , PGB_2 , and PGI_2 exhibit little sensitizing effect.

Although mediation of the peripheral inflammatory response is an important component of pain modulation by this group of drugs, inhibition of central mechanisms of hyperalgesia is likely.^{83,84} Acetaminophen and ketorolac are COX inhibitors that are equipotent to aspirin in inhibiting prostaglandin synthesis in the central nervous system but much less potent in inhibiting prostaglandin synthesis at peripheral sites. The site of activity of these agents may be a result of pharmacokinetic factors such as drug distribution, but more likely it reflects differences in these enzyme systems throughout the body. Studies in mammalian cells indicate that COX exists as two unique isoenzymes, COX-1 and COX-2.⁸⁵ Major differences between these isoenzymes involve dissimilar regulation and expression, with COX-1 found in most tissues, especially platelets, vascular endothelial cells, and collecting tubules. Unlike COX-1, under basal conditions COX-2 usually is undetectable in most tissues except the brain and renal cortex.⁸⁶ The COX-1 isoform primarily produces prostaglandins that regulate renal, gastric, and vascular homeostasis. In the presence of inflammation or tissue injury, inflammatory cytokines induce the expression of the COX-2 enzyme, which generates the prostaglandins involved in pain. Both isoforms of the enzyme are membrane associated and have a long, narrow tunnel into which arachidonic acid is drawn for conversion to a prostaglandin. NSAIDs block the tunnel at approximately its midpoint. Although the enzymes are not selective for substrate, a valine amino acid substitution (for isoleucine) in the COX-2 isoform allows for the synthesis of isoform-specific inhibitors. The smaller valine amino acid exposes an area in the tunnel into which larger side-chain substitutions of the enzyme inhibitor can fit. Because of these bulkier side groups, these same drugs have much less COX-1 activity, resulting in analgesic/anti-inflammatory properties with diminished effects on platelet, gastric mucosal, and renal functions.⁸⁷

Because not all NSAIDs block COX to the same degree, membrane stabilization has also been attributed to these drugs.⁸⁸ Membrane stabilization may account for decreased prostaglandin release seen at drug concentrations that are lower than those needed for effective COX inhibition. This theory is supported by the correlation of analgesic potency with the octanol/water partition coefficient in this group.⁸⁸ Corticosteroids, which are membrane stabilizers, are known selectively to inhibit the expression of COX-2 during inflammation. NSAIDs, tricyclic antidepressants, and local anesthetics may also function through this mechanism of action, which explains some of their beneficial effects when they are used for acute pain management.

Absorption/Biotransformation/Elimination

After oral administration, nonopioid analgesics are rapidly and completely absorbed. Food usually delays absorption but does not affect absolute bioavailability. Intramuscular absorption of ketorolac is complete and occurs within 50 minutes of administration.⁸⁹ With the exception of acetaminophen, protein binding for this group exceeds 80%. Displacement of other highly protein-bound drugs, such as warfarin, may occur when these agents are administered concurrently. Biotransformation by liver enzyme systems and renal excretion of conjugated metabolites are the primary modes of elimination of these agents. Caution must be exercised in patients with renal and liver dysfunction.

Adverse Effects

Gastrointestinal discomfort and central nervous system disturbances are the most common adverse effects of short-term therapy with nonopioid analgesics. Nausea, vomiting, dyspepsia, heartburn, and epigastric discomfort occur in 5–25% of patients receiving aspirin and in 3–9% of patients receiving other NSAIDs. Selective COX-2 inhibitors have a similar incidence of prototypical NSAID gastrointestinal side effects; however, the incidence of endoscopically confirmed gastrointestinal ulceration is reduced with these drugs. Dizziness, headache, and drowsiness occur in approximately 1–9% of patients receiving NSAIDs. Prolonged bleeding is a result of the action of these drugs on COX-1 in platelets. This effect is usually reversible with the NSAIDs 24–48 hours after discontinuing therapy. It is more prolonged after discontinuation of aspirin because of the irreversible acetylation of the platelet surface. Although this effect of aspirin persists for the life of the platelet, clinical prolongation of bleeding time is thought to be reversed in approximately 1 week. More severe adverse effects include an exacerbation of bronchospasm and rhinitis induced by aspirin or other NSAIDs in patients with a history of nasal polyps, asthma, and rhinitis. Ulceration and bleeding of the gastrointestinal mucosa can occur because of direct irritation by the drug. This effect, coupled with the inhibition of prostaglandin-mediated bicarbonate and mucus secretion, allows for further erosion of the tissue. Patients with diabetes or gastric or peptic ulcers are at higher risk for gastrointestinal bleeding, ulceration, and even perforation. Misoprostol, a synthetic PGE_2 , can be used to increase bicarbonate and mucus production in high-risk patients. An acute renal insufficiency syndrome—hyperkalemia and peripheral edema—can be precipitated in elderly patients, those with congestive heart failure or renal or hepatic dysfunction, or patients on diuretic therapy. This is a result of the blockade of prostaglandin-mediated effects on renal blood flow. Proteinuria, interstitial nephritis, and papillary necrosis have been reported, but the mechanism of their association with prostaglandin inhibition is less clear. Despite its usefulness as an injectable NSAID, ketorolac should be restricted to short-term postoperative administration to limit the risk of renal dysfunction. In general, acetaminophen is free of adverse effects in dosages used for acute pain management.

Clinical Uses

Unlike the opioid analgesics, the mechanisms of analgesia with the nonopioid analgesics are not specifically involved in interrupting the transmission of the nociceptive stimulus. The effectiveness of these agents depends on the central and peripheral inflammatory responses to tissue injury, although they have little or no inhibitory effect on classic catabolic stress hormones, acute-phase protein, and other immunologic responses.⁵² The reduction in prostaglandin-mediated inflammatory response can serve to enhance the analgesic effect when these agents are combined with opioids, such as the use of acetaminophen with codeine and its congeners. Based on their pharmacologic mechanisms, it is predictable that the analgesic effect of nonopioid drugs is confined to somewhat narrow therapeutic ranges above which there is little increase in analgesia but a considerable increase in toxicity. To reduce the postoperative amplification of the nociceptive response to tissue injury, the most efficacious use of these agents is before surgery. This is because the effect of PGE_2 can last for many hours and the sensitizing effects of circulating prostaglandins are not reversed by COX inhibitors. These agents also appear to be more effective in procedures involving musculoskeletal, post-traumatic, and inflammatory pain and in conditions such as dysmenorrhea, renal colic, and biliary obstruction, in which prostaglandins are known to be involved in the pathogenesis of the pain.

Opioid Analgesics

Mechanism of Analgesic Effects

Morphine and related compounds act as agonists, producing their biologic effects by interacting with stereoselective and saturable membrane-bound receptors that are nonuniformly distributed throughout the central nervous system. The major sites of opioid activity in the central nervous system include the periaqueductal and periventricular gray, nucleus reticularis gigantocellularis, medial thalamus, mesencephalic reticular formation, lateral hypothalamus, raphe nuclei, and spinal cord. The endogenous neuromodulating peptides of the enkephalin and b-endorphin classes also bind to this family of receptors, which are collectively referred to as the *opioid receptors*. The unique properties of the individual drugs of this group are a result of their specific receptor activity and affinity. Currently, five distinct classes of opioid receptors have been identified (μ [μ], κ [κ], δ [δ], σ [σ]; and ϵ [ϵ]), as well as subtypes of the μ , κ , and σ receptors. The cellular mechanisms of these interactions have been discussed previously in this chapter. A peripheral effect of opioids that results in “local analgesia” is more pronounced in chronically inflamed tissues,^{90,91} where opioid receptors that are synthesized in the dorsal root ganglia have been transported and activated on primary afferent neurons in response to inflammation.⁹² The local analgesic effects of opioids such as morphine have been clinically useful after surgery. Application of morphine at the nerve terminal (e.g., intra-articular injections after orthopedic procedures) often produces effective, long-lasting analgesia of similar potency to conventional local anesthetics.^{93,94,95,96,97} and ⁹⁸ Peripherally acting μ -receptor agonists that do not cross the blood-brain barrier are being investigated.⁹⁹

Affinity and activity at four of the opioid receptor classes (μ , δ , κ , and σ) are responsible for the pharmacologic effects of the opiates (Table 54-4). The enkephalins and opiates have affinity and activity at the μ_1 receptor, which mediates supraspinal analgesia, prolactin release, and euphoria. Opiate-selective μ_2 receptors appear to mediate respiratory depression and physical dependence. The δ and κ receptors are at least partially responsible for spinal analgesia. Miosis and sedation are a result of κ receptor activity, whereas σ activity can produce dysphoria and hallucinations. Pure opioid agonists (Table 54-5) have affinity and exhibit at least moderate activity at the μ_1 , μ_2 , δ , and κ receptors, which explains their central and spinal analgesic effect as well as their dose-related side effects and addictive potential. The differences in potency and side effects among drugs in this class are a result of receptor selectivity, affinity, and lipophilicity of the drug.

Table 54-5. PHARMACOKINETIC PARAMETERS AND MAXIMUM DOSAGE RECOMMENDATIONS OF ORAL AND PARENTERAL OPIOID ANALGESICS

Tramadol, a synthetic 4-phenyl-piperidine analogue of codeine, is a centrally acting analgesic that possesses weak affinity for the μ opioid receptor and modifies transmission of nociceptive impulses through inhibition of monoamine (norepinephrine and serotonin) reuptake but not production. Receptor-blocking studies have demonstrated that these mechanisms work synergistically to produce the therapeutic analgesic effects of tramadol.^{100,101} and ¹⁰² Intravenous and im tramadol has been found to be approximately 1/10 as potent an analgesic as morphine in treating moderate (but not severe) pain. At similar analgesic doses, tramadol has less effect on the respiratory center than morphine and has not been associated with a high abuse potential.¹⁰³

The pharmacologic properties of the mixed agonist–antagonist analgesics are also a result of their affinity for the opioid receptors. Unlike pure agonists, however, not all of these agents produce an agonist effect when they interact with the receptor. There are two distinct groupings of the agonist–antagonist drugs based on their receptor affinity and activity. The first of these groups is characterized by high μ receptor affinity with activity less than or similar to that of morphine. Agents in this category include buprenorphine and dezocine. The second group of agonist–antagonist analgesics includes pentazocine, butorphanol, and nalbuphine. This group possesses only moderate affinity without activity at the μ receptor, high affinity with at least moderate activity at the κ receptor, and at least moderate affinity and some activity at the σ receptor, which accounts for the highly sedative effects and potential for psychomimetic reactions seen with these drugs. In addition, because of the affinity of both of these classes for the μ receptor, with activity less than that of the pure agonists, all of these drugs have the potential for reversing the effect of an agonist, including precipitation of withdrawal symptoms.

Absorption/Biotransformation/Elimination

Although opioid analgesics are well absorbed from the gastrointestinal tract, differences in analgesic equivalence between oral and parenteral doses result from significant first-pass metabolism by the liver. Codeine, oxycodone, and hydrocodone do not undergo extensive first-pass metabolism owing to the methoxy substitution of the phenolic component of the phenanthrene ring, and they have greater oral-to-parenteral equivalency than morphine. Parenteral administration results in a more rapid onset of effect compared with oral and rectal administration. Distribution depends on the lipophilicity of the drug; smaller amounts of the more hydrophobic morphine equilibrate in the brain as opposed to more lipophilic agents such as methadone, meperidine, and codeine. Biotransformation followed by renal elimination of conjugated metabolites is the primary mode of elimination. Active metabolites of morphine (morphine-6-glucuronide), codeine (morphine), meperidine (normeperidine), and propoxyphene (norpropoxyphene) add to the primary pharmacologic effect as well as to the toxicity of these drugs. Metabolism of tramadol, including production of its primary metabolite *O*-demethyl tramadol and its conjugates, is influenced by debrisoquine polymorphism.¹⁰⁴ This metabolite has a greater affinity for opioid receptors than the parent drug; however, the elimination half-life of this metabolite is not significantly greater than that of tramadol itself.¹⁰⁵ Renal elimination of the opioids and their metabolites is primarily by glomerular filtration, with small fractions of drug and metabolites excreted in the feces.

Adverse Effects

With short-term, moderate-dose therapy, central nervous system and gastrointestinal side effects predominate. Sedation, dizziness, lightheadedness, miosis, nausea, vomiting, and constipation are extensions of the pharmacologic actions of these drugs and occur in dose-dependent fashion. Tolerance to the sedative and other central nervous system effects develops rapidly over the first few days of therapy or after an increase in dosage. Constipation is a result of decreased peristalsis of the bowel and decreased secretory actions of the stomach, biliary tract, and pancreas. Spasm of the sphincter of Oddi can increase pressure in the common bile duct and contribute to epigastric distress. This effect can persist for up to 24 hours after a single therapeutic dose of an opioid. Low doses of naloxone and vasodilating agents have been used to relieve this discomfort. Biliary colic tends to occur more often in patients after morphine administration than after meperidine administration, despite the similar rise in biliary pressure seen with both these agents. The agonist–antagonists tend to produce less of a rise in biliary pressure than pure agonists. Stool softeners and laxatives are warranted in patients with severe constipation. Urinary retention may also result from the increase in sphincter tone. Physical dependence and analgesic tolerance usually are not problems in short-term use but may occur after chronic opioid therapy. Unlike the NSAIDs, opioid analgesics do not interfere with healing processes or inhibit platelet function. Ventilatory depression, apnea, cardiac arrest, circulatory collapse, coma, and death can occur after large iv doses.

Clinical Uses

Opioids remain the primary pharmacologic therapy for moderate to severe postoperative pain. Analgesia is achieved by blunting the central response to noxious stimuli without loss of consciousness or affecting tactile, visual, or auditory sensation. Dose-limiting side effects such as nausea, vomiting, constipation, urinary retention, and ventilatory depression can be overcome by proper selection of the agent and route of administration. Sedation and euphoria may be desired in the immediate postoperative period. Analgesic potency is not necessarily an advantage because at equianalgesic doses there are parallel increases in side effects. Agonist–antagonists can be effective analgesics in the postoperative period and have a ceiling effect for ventilatory depression. Unfortunately, dose escalations with these agents may also produce a ceiling for their analgesic effects while increasing their sedative and dysphoric properties.

Therapeutic approaches using on-demand administration have been replaced with continuous or regularly scheduled dosing methods. As postoperative analgesic requirements diminish, the transition from parenteral to oral opioid analgesia usually involves replacing the opioid with an opioid-NSAID combination such as acetaminophen with codeine. Codeine, hydrocodone, and oxycodone are limited in their analgesic potency because of their high incidence of side effects at equianalgesic doses compared with morphine or meperidine, and are best used for minor to moderate pain.

METHODS OF ANALGESIA

Pain relief may involve administration of analgesic drugs by various routes or nonpharmacologic application of mechanical, electrical, or psychological techniques. In any patient, the optimal combinations of these techniques depend on the type and degree of pain, the patient's perception of the pain, and the underlying medical, social, and environmental conditions in which the pain is managed.

Routes of Analgesic Delivery

Oral

Oral analgesics are usually considered less than optimal for moderate to severe acute postoperative pain management because of their lack of titratability and prolonged time to peak effect, and because they require a functional gastrointestinal system. In general, hospitalized patients receive systemically administered opioids and then are converted to oral analgesics when the need for rapid adjustments in the level of analgesia has diminished. However, with the focus on more rapid hospital discharge, early use of longer-acting, potent oral opioids facilitates transition of patients from parenteral opioids to oral therapy. Both nonopioid and opioid analgesic agents are available for oral administration, alone or in combination.

Transepithelial

With the increased number and complexity of surgical procedures being performed in the outpatient setting, there is a growing need for efficacious analgesic regimens for moderate to severe acute postoperative pain in this subset of patients. Methods of drug delivery such as transdermal¹⁰⁶ or transmucosal¹⁰⁷ administration have been evaluated as alternatives to oral analgesics. These techniques permit delivery of potent analgesics that would be less effective when administered orally because of significant first-pass metabolism. Pharmacokinetic characteristics, primarily in absorption, confer important clinical differences to these routes of administration. For example, to achieve optimal analgesic efficacy, transdermal fentanyl must be applied several hours before emergence from anesthesia, whereas transmucosal fentanyl is more rapidly absorbed. As with the oral route, titratability can be problematic and there may be unpredictability of drug absorption. Although transdermal fentanyl combined with patient-controlled analgesia (PCA) using morphine can reduce the number of demand doses, total opioid requirements as well as side effects are not decreased.¹⁰⁸

Parenteral

Parenteral administration of opioid analgesics remains the primary pharmacologic route for the treatment of moderate to severe postoperative pain. The use of computerized, patient-controlled delivery systems has played an important role in refining this method of delivery and reducing side effects of parenterally administered drugs.

Intramuscular. Intramuscular administration of postoperative analgesics produces a more rapid onset and time to peak effect than oral administration. It is also simple to administer analgesics by this route because no special infusion device is needed. However, pain at the injection site, patient apprehensiveness of needle sticks, the potential for delayed ventilatory depression, and wide variability in drug serum concentrations limit the viability of this route. Absorption from im sites depends on the lipophilicity of the agent and blood flow in the area of the injection. After im injections of morphine or meperidine, plasma concentrations may vary as much as 3-fold to 5-fold, and time to peak concentration may vary from 4 to 108 minutes among patients.¹⁰⁹ On the other hand, there is much less variability in the minimum analgesic plasma concentration for any patient.¹¹⁰ Small changes in plasma concentrations (10–20%) for a patient may represent a spectrum of effects from inadequate analgesia to complete pain relief.¹¹¹

The relationship between plasma concentrations, effect, and time is depicted in [Figure 54-6](#). Plasma concentrations after im administration of high doses of an opioid analgesic such as morphine at long dosing intervals establish a cyclic pattern of sedation, analgesia, and finally inadequate analgesia. When morphine is administered by this route on a 3- or 4-hour basis, plasma concentrations exceed or meet analgesic requirements for only approximately 35% of the dosing interval because of the delayed absorption and narrow therapeutic window. This situation is exacerbated by the dynamic nature of analgesic requirements. PCA and continuous epidural infusions circumvent many of the problems of im administration and may provide more effective analgesia with fewer side effects by maintaining tighter control of plasma levels.

Figure 54-6. Relationship between serum drug concentration, pharmacologic effect, and method of administration. (Reprinted with permission from Tuman KJ, McCarthy RJ, Ivankovich AD: Pain control in the postoperative cardiac surgery patient. *Hospital Formulary* 23:580, 1988.)

Most opioids can be administered by the im route; however, only one NSAID, ketorolac, is available for parenteral injection to manage postoperative pain. Ketorolac has efficacy equal to that of moderate doses of opioids for treatment of moderate to severe pain after general, gynecologic, or orthopedic surgeries.

Intravenous. Intermittent iv bolus infusions of opioids can be administered in situations when close continuous monitoring of the patient is feasible. With a small iv bolus, the delay until analgesic effect and the variability in plasma concentrations seen with im administration can be reduced. Rapid redistribution of the drug shortens the duration of effect after a single iv administration compared with im injections. The numerous personnel needed to supervise frequent administration of boluses and monitoring of the fluctuations seen in plasma concentrations has led to the use of continuous iv infusions.

Continuous iv infusions offer the advantages of maintaining nearly constant plasma drug concentrations and reducing the peak-and-valley effect inherent in intermittent injections. Without the use of an initial bolus loading injection, continuous infusion techniques are inadequate because of the long time required for the drug to reach steady state (four to five half-lives). Initiating therapy with a loading dose eliminates this problem but still does not allow for rapid dosage adjustments as analgesic requirements change.

Patient-Controlled Analgesia. By combining the advantages of a continuous infusion with the flexibility of interposing low bolus doses as analgesic requirements vary, PCA appears to be the answer for many patients' analgesic needs. This method has evolved as advances in computer technology have met the needs for improved drug delivery. Early PCA devices permitted a patient to titrate analgesic needs by delivering a small bolus dose of an opioid such as morphine sulfate when he or she activated a switch. Limits could be placed on the number of activations per unit time the patient was allowed and the minimum time that would have to elapse between activations (lockout interval). Refinements of this system permit administration of a continuous background infusion superimposed on patient-controlled boluses. Background infusion concomitant with intermittent PCA boluses is advantageous in maintaining serum drug levels within the analgesic range and further attenuates fluctuations in levels, resulting in improved analgesia and patient satisfaction without producing additional unwanted side effects.¹¹² In addition to combining infusion and bolus dosing, current devices record a profile of the drug administration, including number and time of bolus delivery, number of activations that did not result in drug delivery, and total amounts of the agent that were administered per unit time.

Compared with traditional methods of on-demand analgesic delivery, PCA has been shown to provide superior analgesia, with less total drug use, less sedation, fewer nocturnal sleep disturbances, and a more rapid return to physical activity.¹¹³ Most patients tend to titrate PCA to a level of pain at which they feel comfortable and taper their dosage requirements as they convalesce.¹¹⁴ In addition, patient acceptance of PCA is high because patients feel that they have significant control over their therapy.¹¹⁵

One limitation to PCA therapy is the selection of agents available for use in the PCA devices ([Table 54-6](#)). Ideally, a drug administered by PCA should be highly efficacious, have a rapid onset of action and a moderate duration of effect, should not accumulate or change pharmacokinetic properties with repeated administration, and should have a large therapeutic window. Morphine and meperidine, the drugs most widely prescribed by this route, are far from ideal, and limitations imposed by the pharmacology of the agonist-antagonist group have made their use in these devices disappointing. Despite theoretic advantages, the use of fentanyl for PCA has

not been shown to be clearly superior to morphine,¹¹⁶ although it may improve the initial PCA demand-to-delivery ratio.¹¹⁷

| Drug | Loading Dose (mg) | Intermittent Bolus Dose (mg) | Lockout Interval (min) | Continuous Infusion Rate (mg/h) | 4-Hour Limit (mg) |
|-----------------------------|-------------------|------------------------------|------------------------|---------------------------------|-------------------|
| AGONISTS | | | | | |
| Fentanyl citrate | 0.05-0.075 | 0.05-0.075 | 5-10 | 0.04-0.1 | 0.04 |
| Hydromorphone hydrochloride | 0.25-0.5 | 0.1-0.5 | 5-10 | 0.2-0.5 | 0.2-0.5 |
| Morphine hydrochloride | 1-10 | 5-10 | 10-20 | 5-10 | 20-30 |
| Nalbuphine hydrochloride | 1-2 | 0.5-1 | 10-20 | 1-2 | 2-3 |
| Sufentanil citrate | 0.005-0.01 | 0.005-0.01 | 2-5 | 0.005-0.01 | 0.01 |
| AGONISTS-ANTAGONISTS | | | | | |
| Naloxone hydrochloride | 1-2 | 1-2 | 5-10 | 1-2 | 2-3 |

*For patients using oral PCA.

Table 54-6. GUIDELINES REGARDING THE BOLUS DOSAGES, LOCKOUT INTERVALS, AND CONTINUOUS INFUSIONS FOR VARIOUS PARENTERAL ANALGESICS WHEN USING A PATIENT-CONTROLLED ANALGESIA SYSTEM

Other problems encountered with PCA therapy are primarily a result of operator or mechanical errors.¹¹⁸ Because patients titrate their own therapy, they must be capable of understanding the concepts of the device, be able to activate the trigger, and be willing to participate. This often makes the use of PCA devices more difficult in pediatric and in older and debilitated patients.

Optimum results from PCA therapy are obtained only when the patient's analgesic needs can be met within the prescribed parameters set on the device. The patient's age, surgical procedure, need for a continuous background infusion, number and amount of boluses allowed, and total analgesic requirements are considered. Anesthesiologists must incorporate some flexibility into protocols for ordering PCA therapy to account for the variability introduced by these factors.

Central Neuraxial Analgesia

The technique of spinal analgesia was described by Bier and Tuffler in 1898, and that of sacral epidural analgesia by Sicard and Cathelin in 1901. In 1949, a major advance in the application of central neuraxial analgesia was the description by Cleland¹¹⁹ of the use of a continuous catheter epidural infusion for postoperative analgesia. Analgesia was maintained for 1–5 days after surgery by administering intermittent bolus doses of a local anesthetic. Although effective analgesia was obtained, a significant sympathetic block accompanied the analgesia, and all patients required at least one dose of a vasopressor. Additional shortcomings of this technique, as with any intermittent dosing regimen, were the fluctuating levels of analgesia that occur as the effect of the bolus dissipates, and the medical staff required to reinject the patient every several hours.

Because of the shortcomings of intermittent dosing, the continuous infusion of local anesthetics along the central neuraxis was subsequently recommended as an alternative to the intermittent bolus technique. The continuous infusion of local anesthetics simplifies maintenance of analgesia, but the use of local anesthetics in concentrations sufficient to produce pain relief usually results in sensory and occasional motor blockade. These are unwanted effects in the postoperative period because sensory and motor blockade prohibit ambulation, an important factor in postoperative convalescence.

Although it has long been recognized that application of local anesthetic agents along the spinal canal could provide effective analgesia, the demonstration that opioids could produce analgesia by this route has been responsible for the widespread application of the practice of central neuraxial analgesia. The enthusiasm for this route of administration has also been a direct result of the shortcomings of im and iv therapies. By interrupting pain pathways at the level of communication between the first- and second-order neurons, a method for providing effective analgesia without the associated central nervous system depression and cyclical nature of pain associated with other parenteral routes of administration is achieved.

Intrathecal. The intrathecal administration of opioids has the advantage of providing long-lasting analgesia after a single injection. The onset of analgesic effect after the intrathecal administration of an opioid is directly proportional to the lipid solubility of the agent, whereas the duration of the effect is longer with more hydrophilic compounds. Morphine, for example, has been shown to produce peak analgesic effects in 20–60 minutes that last for 2–12 hours when doses ranging from 0.25 to 4 mg were administered intrathecally to adults.^{120,121} In routine clinical practice, 0.25–1 mg morphine can be expected to provide effective analgesia, whereas doses in the range of 0.25–0.5 mg generally maintain analgesic efficacy while minimizing the potential for ventilatory depression.¹²⁰

Intrathecal bolus injections share many of the problems of other intermittent techniques, including lack of titratability and extensive time requirements for monitoring and reinjection. In addition, the potential for infection, a greater risk of ventilatory depression owing to rostral spread of the drug, and a higher incidence of side effects make this technique less desirable than epidural administration (Table 54-7). Widespread clinical experience has shown that continuous epidural infusions may be preferable to intrathecal techniques for central neuraxial analgesia. The practical aspects of maintaining a catheter in the intrathecal space for a prolonged period and reports of cauda equina syndrome after continuous spinal anesthesia also may favor the continuous epidural technique.¹²² Although intrathecal analgesic techniques are infrequently used outside the setting of labor analgesia, the use of a combined spinal anesthesia followed by continuous epidural analgesia has gained increasing popularity because it provides the advantages of spinal anesthesia (rapid onset, dense neural blockade) while facilitating the transition to an effective and titratable postoperative analgesia method after major surgery.¹²³

| Complication | Reported Incidence (%) ^a | | Treatment |
|------------------------|-------------------------------------|----------|---|
| | Spinal | Epidural | |
| Respiratory depression | 5–7 | 0.1–2 | Support ventilation; naloxone |
| Pruritus | 60 | 1–100 | Antihistamine; naloxone |
| Nausea and vomiting | 20–30 | 20–30 | Antiemetic; transdermal scopolamine; naloxone |
| Urinary retention | 50 | 15–25 | Catheterize; naloxone |

^a Reported incidences vary widely, appear to be related to dose, and are higher with spinal than with epidural administration. Table 54-7. COMPLICATIONS OF NEURAXIAL OPIOIDS

Epidural. Epidural administration of opioids and local anesthetics has evolved in parallel with intrathecal techniques. As noted, the advantages of epidural administration of drugs such as opioids and local anesthetics include the reduced incidence of side effects and a diminished propensity for opioid-induced ventilatory depression compared with the intrathecal route. When a drug is placed in the epidural space, it must first cross the dura before it can reach the spinal cord. Besides the physical barrier presented by the dura, the epidural space is highly vascularized, and a significant redistribution of drug to the systemic circulation occurs. The epidural space also contains fat, connective tissues, a lymphatic network, and the dorsal and ventral roots of the spinal nerves, all of which can serve as a repository for lipophilic agents.¹²⁴

The influence of these factors can be demonstrated by an examination of the pharmacokinetics of epidurally administered hydrophilic (morphine) and lipophilic (fentanyl) opioids. Ten milligrams of morphine, given either iv or epidurally, produce peak serum levels and decay curves that are nearly identical (Fig. 54-7). Whereas the duration of pain relief from iv administration is short-lived (1–2 hours), epidural morphine can provide 12 or more hours of analgesia. This indicates that although much of an epidural dose is absorbed into the systemic circulation, a small fraction of the morphine dose (~2–10%) diffuses across the dura to bind spinal opiate receptors and produce analgesia. In contrast, when epidural fentanyl 200 µg is given in a similar manner, peak serum levels are only approximately 50% of those after a similar im injection. However, serum levels of fentanyl 24 hours after a continuous rate infusion are similar to those obtained from a similar iv infusion.¹²⁵ This implies that with the initial bolus of fentanyl, there is redistribution of the drug to lipophilic tissues, which become saturated after continuous administration. Therefore, only a

small fraction of a typically administered epidural dose is necessary to produce spinally mediated analgesia.

Figure 54-7. Serum concentration of morphine (mean \pm SEM) after intravenous and lumbar epidural administration of 10 mg of morphine sulfate in 10 subjects; triangles = intravenous; circles = epidural. (Reprinted with permission from Bromage PR, Camporesi EM, Durant PAC, Nielsen CH: Nonrespiratory side effects of epidural morphine. *Anesth Analg* 61:490, 1982.)

Because the diffusion of drugs across the dura is both concentration and time dependent, it is necessary to administer significantly larger amounts of drugs than those that effectively saturate spinal opiate receptors. These higher doses are more likely to produce unwanted side effects from systemic and rostral distribution of the drug, but fewer than those associated with equianalgesic intrathecal doses. When these factors are considered, the margin of therapeutic safety and the decrease in side effects with epidural administration make this route preferred for postoperative analgesia.

Intermittent epidural bolus doses of morphine sulfate (15 mg over 24 hours) have been used for postsurgical analgesia.⁷² Although this method of administration provides excellent analgesia for up to 12 hours, side effects associated with these bolus doses limits the widespread application of this technique. An intermittent bolus technique also has the disadvantage of limiting the number of usable opioids to the longer-acting drugs (e.g., morphine and hydromorphone).

In an effort to mitigate the frequency and severity of opioid-induced side effects associated with bolus techniques, El-Baz *et al*¹²⁶ described the use of a continuous epidural morphine infusion ($100 \mu\text{g} \cdot \text{h}^{-1}$) and found equivalent analgesia and fewer side effects than after epidural boluses of either bupivacaine (0.5%) or morphine (5 mg; Fig. 54-8 and Table 54-8). It is now well accepted that continuous epidural infusions of opioids provide effective analgesia while reducing the side effects associated with bolus administration.^{127,128 and 129}

Figure 54-8. Analgesic effectiveness of continuous morphine epidural infusion compared with epidural bolus doses of morphine sulfate (MS) or bupivacaine. See text for details. (Adapted from El-Baz NI, Faber LP, Jensik RJ: Continuous epidural infusion of morphine for treatment of pain after thoracic surgery: A new technique. *Anesth Analg* 63:757, 1984.)

| Side Effect | Group A (Bupivacaine 25 mg · 5 ml ⁻¹ , 0.5% Epidural Bolus) | Group B (Morphine 5 mg Epidural Bolus) | Group C (Morphine 100 $\mu\text{g} \cdot \text{h}^{-1}$ Epidural Infusion) |
|-------------------------|---|--|--|
| Urinary retention | 30 (100%) | 30 (100%) | 2 (7%) |
| Hypotension | 7 (23%) | 0 | 0 |
| Weakness of hands | 12 (40%) | 0 | 0 |
| Pruritus | 0 | 12 (40%) | 1 (7%) |
| Depressed consciousness | 0 | 8 (27%) | 0 |

Table 54-8. SIDE EFFECTS WITH POSTOPERATIVE EPIDURAL ANALGESIA

Because the laws of mass action apply to diffusion of drugs out of the epidural space to their sites of action, several hours are often required to achieve adequate analgesia when using continuous infusions alone. Effective analgesia with epidural infusions administered at a continuous rate may take as long as 3–4 hours to achieve. Delay in onset of effective analgesia can be reduced by adjusting the infusion rate to provide the equivalent of a small (5–10 ml) bolus of the epidural solution over 5–15 minutes before beginning the maintenance infusion. This allows an adequate concentration of the analgesic drug(s) to be present at their site(s) of action in a shorter time.

In addition to a reduction in adverse effects, another advantage of a continuous epidural infusion over an epidural bolus injection is the ability to titrate the amount of analgesia (Table 54-9). Although morphine usually provides 12 hours of pain relief after a single epidural injection, wide variability has been reported in the duration of effective analgesia (4–24 hours) depending on the site and extent of surgical trauma and age of the patient. Because of this variability, it becomes difficult to titrate uniform levels of analgesia. A continuous infusion provides easier analgesic titration, particularly when shorter-acting opioids such as fentanyl are used. Fentanyl has an onset of action within 4–5 minutes and a peak effect within 20 minutes.^{130,131} Because of the rapid onset, it becomes much easier to adjust dosage, observe the desired effect, and titrate to an optimal intensity of analgesia. Morphine, on the other hand, has an onset time of 30 minutes with a time to peak effect ranging from 60 to 90 minutes.

| Advantages | Disadvantages |
|--|---|
| CONTINUOUS EPIDURAL INFUSIONS 1. Low neural spread so side effects are minimized 2. Provides continuous analgesia avoiding the peaks and nadir seen with intermittent bolus 3. Allows for concurrent use of dilute local anesthetic solutions 4. Allows the use of short-acting opioids such as fentanyl or sufentanil 5. Low potential risk of concentration for injection because the catheter system has lower levels in sterile technique 6. Simple and easy maintenance; reduces the need for anesthesia personnel to inject patients periodically | 1. Need for sophisticated infusion device |
| INTERMITTENT EPIDURAL BOLUS 1. Single (providing resident or nursing staff accept the responsibility of epidural catheter injections) 2. No need for infusion device | 1. Limited number of suitable opioids 2. Higher incidence of side effects 3. Extra effort to inject catheter every 8-12 hr 4. Excludes the use of local anesthetics 5. More difficult to sterile draw |

Table 54-9. COMPARISON OF EPIDURAL ADMINISTRATION TECHNIQUES

Mirroring the evolution of PCA, a refinement in delivery of analgesics by the epidural route is the use of superimposed patient-controlled bolus doses with a continuous basal infusion. Early application of this technique for delivery of epidural analgesia used relatively large intermittent demand doses alone or combined with a low-rate continuous infusion, and the intermittent demand doses provided the preponderance of analgesia. This dosing paradigm has reduced efficacy because of fluctuations in analgesia occurring as a consequence of large intermittent bolus dosing. Using higher basal infusion rates and smaller patient-activated bolus doses, the continuous infusion maintains a more constant intensity of analgesia, whereas the bolus doses, provide supplemental analgesia for transient increases in analgesic requirements¹³² (Table 54-10). Patient-controlled epidural analgesia is particularly useful to manage dynamic changes in pain related to patient activity (e.g., coughing, chest physiotherapy).¹³³ The development of new infusion devices has allowed such combined modes of administration of epidural analgesia to be readily delivered (see Appendix 54-1).

| Agent | Bolus Dose | Analgesic Effect | | | Continuous Infusion Rate | | Patient-activated Bolus | Interval (hr) |
|--|--|--------------------|------------------------|--------------------------|--------------------------|---------------|-------------------------|---------------|
| | | Onset (min) | Peak (hr) | Duration (hr) | Range (mcg/hr) | Rate (mcg/hr) | | |
| Morphine (0.1-0.2%) + Bupivacaine 0.5% | 3 mg | 20 ± 4 | 38-48 | 12-24 | 2-8 | 5 | 1 | 12 |
| Morphine 0.2% Morphine 0.2-0.4% + Bupivacaine 0.5% | 3 mg | 20 ± 2 | 47 ± 5 | 22 ± 44 | 3-4 | 5 | 1 | 30 |

Table 54-10. EPIDURAL OPIOIDS: LATENCY AND DURATION OF POSTOPERATIVE ANALGESIA

INITIATION AND MAINTENANCE OF THERAPY Based on the preceding considerations, achievement of optimal results with a continuous epidural analgesia technique requires appropriate perioperative planning and assessment. This strategy includes identifying patients who may benefit from epidural analgesia and scheduling the epidural catheter placement as part of the anesthetic plan. At the authors' institution, epidural catheters are commonly placed while the patient is in the holding area before being taken to the operating room. This practice allows the anesthesiologist to administer a test dose of local anesthetic while the patient is still awake. The application of bolus administration followed by a continuous infusion mandates that the test dose be administered to an awake patient. This facilitates diagnosis of intrathecal, intravascular, or subdural catheter placement and allows confirmation of segmental epidural analgesia when the test dose of local anesthetic is administered. This practice also allows the continuous epidural infusion to be started during surgery. Solutions of morphine (0.1 mg · ml⁻¹) with bupivacaine (1 mg · ml⁻¹), or fentanyl (10 µg · ml⁻¹) with bupivacaine (1 mg · ml⁻¹), are most commonly used. Concentrations of opioid are reduced for patients with increased risk of serious opioid-induced side effects (see later). The infusion is begun during surgery at a rate of 4-6 ml · h⁻¹, augmenting the general anesthetic and providing sufficient time to achieve good analgesia and smooth emergence. If the surgical procedure is relatively short (1-2 hours), a 5- to 10-ml bolus of the epidural solution may be given as a rapid infusion as described earlier, to hasten the onset of analgesia. As an alternative, the patient may be given an epidural bolus of 0.5% bupivacaine combined with either fentanyl (50-100 µg) or morphine (2-5 mg). If the surgical procedure is expected to exceed 3-4 hours, bolus dosing may not be needed because sufficient time is allowed for continuous epidural infusion alone to achieve analgesia on the patient's awakening.

PLACEMENT OF EPIDURAL CATHETER Hydrophilic compounds such as morphine, when injected epidurally, result in cerebrospinal fluid concentrations of the drug that allow it to follow the rostral spread of the cerebrospinal fluid¹³⁴ (Fig. 54-9). Because of this property, epidural morphine may be infused at a lower lumbar level and still provide analgesia for surgical procedures performed on the upper abdomen and thorax. Lipophilic drugs such as fentanyl tend to provide more of a segmental analgesic effect.¹³⁵ This may in part be the result of the lipophilic compounds partitioning into lipid compartments in the spinal canal, such as epidural fat and the spinal cord. This segmental nature of analgesia mandates the need to place an epidural catheter in a location to cover the dermatomes included in the surgical field. A general guideline for the catheter locations in various types of surgery is as follows: thoracic surgery—upper to lower thoracic; upper abdominal and renal surgery—low thoracic to high lumbar; orthopedic procedures of the lower extremities and lower abdominal and gynecologic surgery—lumbar region. Alternatively, catheter placement should be approximately at the dermatomal level that corresponds to a point intersecting the upper one third and lower two thirds of the surgical incision. In general, placement of the epidural catheter at a level lower than that described previously necessitates increased epidural drug dosing to achieve effective analgesia, especially when lipophilic opioids are used, and this may lead to an increase in side effects.

Figure 54-9. Rostral spread of central neuraxial morphine. (a) Spread in small injection volumes of 1 ml after dura penetration into the intrathecal space. (b) Spread in high injection volumes of 10 ml in the intrathecal and epidural space. (Reprinted with permission from Chrubasik J: Investigations on respiratory depression. In Chrubasik J [ed]: Spinal Infusions of Opiates and Somatostatin, p 19. Obersul, Germany, Verlag Hygeineplan, 1985.)

SELECTION OF ANALGESICS The differences among the opioids used for epidural analgesia relate to their duration of action and propensity to produce side effects. Patient factors such as advanced age, small body habitus, morbid obesity, history of sleep apnea, and general debilitation should be considered when initiating epidural analgesia because these conditions are associated with a greater propensity for respiratory complications. Reduced concentrations of opioids should be used when initiating epidural analgesia in such patients (see Appendix 54-1, Appendix 54-2 and Appendix 54-3).

Pain relief lasts longer with hydrophilic agents such as morphine than with the more lipid-soluble hydromorphone or fentanyl (see Table 54-10). The relatively long duration of action of epidural or intrathecal morphine allows it to be used effectively as an intermittent bolus given every 12 hours, whereas because of a shorter duration of analgesia, fentanyl is better suited for continuous epidural infusions. Morphine can be used as a continuous epidural infusion and has been associated with

reduced side effects compared with epidural bolus injections.¹²⁶ Hydromorphone, which has a lipid solubility between that of morphine and fentanyl, is 7–10 times as potent as morphine. Intermittent epidural bolus administration of hydromorphone provides effective analgesia for 7–12 hours with a reduced incidence of pruritus and nausea compared with morphine.¹³⁶

Lipophilic compounds such as fentanyl and sufentanil and, to a lesser extent, hydromorphone partition into the spinal cord and lipid structures in the epidural space more than hydrophilic agents, which remain in the cerebrospinal fluid to a greater extent. Therefore, it may be preferable to use lipophilic opioids such as fentanyl rather than the more hydrophilic morphine to produce a more segmental level of analgesia. Although the tendency of hydrophilic drugs for rostral ascension facilitates the dermatomal distribution of analgesia, it also can result in a higher incidence of some side effects.¹³⁴

Epidural coadministration of opioids with local anesthetics takes advantage of the desirable properties of each drug. The desired result of these combinations is achievement of potentiated analgesia at lower opioid doses with a concentration of a local anesthetic that does not produce significant motor blockade. This potentiation may be a result of antinociception at different sites in the spinal cord.¹³⁷ Opioids produce analgesia by binding to opiate receptors in the substantia gelatinosa, whereas local anesthetics block transmission of afferent impulses at the nerve roots and dorsal root ganglia.¹³⁸ Another advantage of the combination using reduced doses is the concomitant decrease in the incidence and severity of side effects. Despite wide acceptance, not all studies have demonstrated analgesic potentiation when bupivacaine and fentanyl have been used in combination.¹³⁹

Receptors of the α_2 class modulate nociceptive impulses in the dorsal horn of the spinal cord as well as throughout the central nervous system. Agonists of these receptors produce antinociception with minimal ventilatory depression compared with opioids.¹⁴⁰ Clonidine has been the most widely used α_2 agonist for epidural analgesia, producing dose-dependent analgesia when given as a bolus.^{141,142} Epidural clonidine has been associated with hypotension and with bradycardia because of inhibition of preganglionic sympathetic fibers. This is most prevalent at lower doses, whereas increased doses normalize blood pressure because of systemic vasoconstriction that overrides the central hypotensive effect. Although epidural clonidine has been used as a single agent to provide postoperative analgesia,¹⁴³ it has more frequently been used in combination with local anesthetics¹⁴⁴ or opioids^{145,146} to potentiate analgesia and minimize side effects. Optimal ratios for combining α_2 agonists with opioid or local anesthetics are yet to be defined¹⁴⁷ because these drugs exhibit nonlinear synergism.¹⁴⁸ Other α_2 agonists that may be introduced into clinical pain management include dexmetomidine and tizanidine.¹⁴⁹ Dexmetomidine is an α_2 agonist with a very high α_2 -to- α_1 selectivity (1600) compared with clonidine (ratio of 200).¹⁵⁰ Tizanidine, an analogue of clonidine, produces analgesia in a manner similar to clonidine but has fewer cardiovascular effects.^{149,151}

MANAGEMENT OF INADEQUATE ANALGESIA Although epidural analgesia is usually effective, patients may occasionally experience inadequate pain relief. A systematic approach is necessary to evaluate and manage inadequate epidural analgesia. The initial step in this process is verification of the integrity of the catheter system, followed by a bolus (5–7 ml) of the epidural solution (typically a combination of dilute local anesthetic with opioid), with analgesic assessment after a short interval (15–30 minutes). If analgesia remains inadequate, a test dose of a local anesthetic solution, such as 2% lidocaine with 1:200,000 epinephrine, can be given further to evaluate epidural catheter location (Fig. 54-10). The test dose usually yields one of three results. If bilateral sensory block occurs in a few segmental dermatomes, epidural catheter location is confirmed. In this case, volume of the infusion was likely insufficient for adequate dermatomal coverage, resulting in inadequate analgesia, and increasing the rate of infusion may produce effective analgesia. A unilateral sensory block after administration of a test dose of local anesthetic is suggestive of the catheter tip residing laterally in or near a neuroforamen. Withdrawal of the catheter 1–2 cm is usually associated with a bilateral sensory block after a subsequent test dose. Once bilateral sensory blockade has been documented, adequate analgesia can be maintained with bolus administration of the epidural solution, followed by adjustments of the continuous epidural infusion or patient-controlled epidural infusion parameters.

Figure 54-10. Postoperative epidural management algorithm. The test dose, given by anesthesia personnel, is two percent lidocaine with epinephrine 1:200,000 (5 ml for lumbar catheters; 3 ml for thoracic catheters).

Finally, a lack of sensory blockade after test dose administration indicates that the epidural catheter does not reside in the epidural space. In this situation, the catheter is removed and the patient is given the option of having another epidural catheter placed or switching to PCA therapy.

SAFETY CONSIDERATIONS Serious complications that can occur with a continuous epidural technique include accidental intrathecal administration of drug, infection-related problems, epidural hematoma, and ventilatory depression. To decrease the incidence of these complications, the authors propose the following guidelines:

1. A low concentration of local anesthetic (e.g., 0.1% bupivacaine) in combination with an opioid analgesic allows subarachnoid catheter migration to be identified earlier by the onset of progressive sensory blockade. Low concentrations of local anesthetics do not interfere with neurologic assessments because they do not usually produce significant sensory or motor block when administered epidurally. If sensory or motor deficits are present, discontinuation of the infusion should allow for regression of these anesthetic effects within 2–4 hours. Persistent impairment of sensory or motor function should prompt appropriate evaluation to identify potentially serious causes of neurologic dysfunction, especially in anticoagulated patients (Fig. 54-10).
2. Catheter sites should be examined daily, temperature curves monitored, and the patient periodically evaluated for signs of meningism. Symptoms of epidural abscess include neurologic deficits, elevated body temperature, and back pain, although meningitis is uncommon.¹⁵² If any findings consistent with infection are present, the catheter is removed and cultures performed. In the authors' experience of more than 23,000 cases of postoperative epidural analgesia, only a single case of epidural abscess has been encountered, and this patient was successfully treated without neurologic compromise. In a small number of patients, infections limited to the cutaneous structures have developed and resolved with conservative therapy.
3. Epidural catheters should be placed at least 1 hour before iv heparinization in patients without preoperative coagulation defects but requiring intraoperative anticoagulation with unfractionated heparin. At least one published series has shown that if epidural catheters are placed at least 1 hour before heparinization, the incidence of clinically significant epidural hemorrhage does not appear to increase.¹⁵³
4. The risk of epidural hematoma formation related to epidural catheter placement in patients receiving certain forms of perioperative anticoagulation is controversial. Historically, concern for epidural hematoma formation with epidural catheterization has been generated primarily in the setting of intraoperative anticoagulation with unfractionated heparin. With the introduction of low-molecular-weight heparins (LMWH), increased risk of epidural hematoma formation related to epidural catheterization has been attributed to the perioperative use of such fractionated heparin compounds. Similar to unfractionated heparin, LMWH binds to antithrombin III; however, the resulting complex also diminishes thrombin generation by inhibiting factor Xa. In contrast to unfractionated heparin, the anticoagulating effects of LMWH are of longer duration and not effectively monitored with the activated clotting time or activated partial thromboplastin time.¹⁵⁴ Based on consensus opinion, after assessing the risks and benefits of epidural anesthesia/analgesia on an individual patient basis, it has been recommended that epidural catheterization (as well as removal of epidural catheters) be performed at least 10–12 hours after a dose of LMWH.¹⁵⁵ In addition, dosing of LMWH should not occur for at least 2 hours after removal of an epidural catheter to avoid manipulation during the peak anticoagulant effect.¹⁵⁵ Although some clinicians remove epidura catheters before postoperative initiation of LMWH, others continue postoperative epidural analgesia for longer than 24 hours in some patients. In such instances, LMWH administration may be delayed or alternative methods of thromboprophylaxis selected. The risks of spinal hematoma are incrementally increased when LMWH is used concomitantly with other drugs that affect hemostasis, including antiplatelet drugs, standard heparin, and dextran. The entire patient care team must be cognizant of this whenever postoperative epidural analgesia is used, and the postoperative analgesia service should interface with other managing clinicians to determine the optimal management of patients with these considerations. Whenever perioperative anticoagulation is used in patients managed with epidural analgesia, monitoring of anticoagulation and neurologic status is imperative.
5. With appropriate monitoring of coagulation status, epidural catheters may be inserted safely in patients who receive perioperative warfarin.¹⁵⁶ In patients with international normalized ratio values exceeding 1.5, neurologic checks should be continued for at least 24 hours after epidural catheter removal.¹⁵⁷
6. Respiratory rates and level of sedation should be monitored every hour for the first 24 hours of the epidural infusion and every 4 hours thereafter. Apnea monitors can be used to supplement, but cannot replace, direct patient observation. Patients at increased risk for respiratory compromise include the elderly and those with sleep apnea or any debilitating disease. In the authors' institution, an apnea monitor is usually used for the first 24 hours when epidural bolus doses of morphine 2

mg or greater are given as loading doses.

In summary, a continuous infusion technique alone or in combination with patient-controlled epidural boluses simplifies maintenance of epidural analgesia and allows greater analgesic titratability than intermittent epidural bolus dosing. Proper patient selection, catheter placement, and methods to identify and treat inadequate analgesia are important aspects of postoperative pain management. Patient safety is paramount and guidelines should be established within each facility for prevention, early diagnosis, and treatment of complications.

Caudal. Caudal nerve blocks play a minor role in acute postoperative pain management in adults. Because they are technically more difficult to perform in adults than other efficacious forms of lumbar epidural blocks, they are used less frequently in adults than in the pediatric population. Continuous caudal analgesia for postoperative pain has a limited utility because of the difficulty of securing a catheter, but it may have a role in select patients such as those who have had extensive lumbar or thoracic spine surgery. In those unusual situations where continuous caudal analgesia is used, the standard solutions for lumbar epidural analgesia may be used, although infusion rates may need to be higher than those with a lumbar epidural infusion.

Pediatric (“kiddie”) caudals have become popular for intraoperative supplementation and postoperative pain relief. Palpation of the sacral hiatus is much easier in the pediatric population, and a distinct “pop” can be heard as the needle pierces the sacrococcygeal membrane. A short, 22- or 23-gauge needle should be used; the block is usually performed with the child in the lateral position. After needle insertion, needle aspiration should be performed to avoid inadvertent injection into the intrathecal or vascular space. Volumes of local anesthetic ranging from 0.75 to 1 ml · kg⁻¹ body weight of 0.25% bupivacaine should provide analgesia to the T10 level, which is sufficient for procedures in the groin and lower extremities. Although bupivacaine usually provides 4–6 hours of effective pain relief, children receiving caudal nerve blocks at the time of surgery exhibit better pain relief and use significantly fewer supplemental opioids during the first 12 postoperative hours.

As with other combined regional and general techniques, a relatively lighter plane of general anesthesia is required to maintain adequate surgical anesthesia when this block is instituted before the surgical incision, and this may represent an advantage over the use of a caudal block placed at the conclusion of the procedure. Blocks placed before surgical incisions also allow the patient to awaken more quickly and to benefit from a smoother emergence from general anesthesia.

Peripheral Nerve Blocks

General Considerations. Peripheral application of local anesthetics to block nociceptive neural transmission can be a useful adjunct in the treatment of acute postoperative pain. Although peripheral neural blocks are simple to perform and have a historical record of safety, the relatively short duration of analgesia and the selective nature of these blocks preclude their general application to all patient populations. With proper selection of the patient and the local anesthetic, the pain relief afforded by regional nerve blocks may be superior to that achievable with systemic opioids.

MECHANISM OF ACTION OF LOCAL ANESTHETICS The electrophysiology of local anesthetics is described in detail elsewhere in this textbook (see [Chapter 17](#)). Local anesthetics produce their neuronal blocking effect by diffusing across the nerve membrane and inhibiting sodium channels, thereby preventing the normal influx of sodium ions necessary for depolarization and nerve transmission. Thus, the membrane is left in its normal polarized state, and neither local miniature endplate potentials nor action potentials are generated.

Local Infiltration. Local infiltration, the instillation of local anesthetics in the vicinity of the surgical incision, is a simple technique for providing postoperative analgesia for the first several hours after a minor surgical procedure. Needle aspiration before injection should be performed to avoid intravascular injection or perforation of deep vascular structures. Even when blood has not been aspirated before injection, it is still possible for local anesthetic to be delivered intravascularly during a local infiltration. In addition to intravascular injection, exceeding recommended total volume and dosages of local anesthetic is another factor that can be responsible for untoward reactions.

The primary advantages of the local infiltration technique are simplicity and the ability to block afferent nerve activity in the area of the incision without affecting the general sensorium. A major disadvantage is the limited duration of analgesia, which usually lasts only several hours. The most commonly used local anesthetics for this procedure are bupivacaine and ropivacaine because of their long duration of effect compared with most other local anesthetics.

A special type of local infiltration is the intra-articular injection of local anesthetics after arthroscopic procedures. This technique decreases postoperative discomfort and facilitates postsurgical recuperation.¹⁵⁸ Bupivacaine is the most commonly used local anesthetic, with doses of 100 mg providing effective analgesia while maintaining serum concentrations below toxic levels.^{158,159}

Intercostal. Intercostal blocks are useful for providing analgesia after operations of the thorax and upper abdomen. A 22- or 25-gauge needle is advanced at the midaxillary or postaxillary line until a rib is contacted. The needle is then walked off the inferior border and advanced 1 mm. When performing intercostal blocks for large thoracic incisions, it is important to identify the sensory dermatomes supplying the surgical incision so that each can be blocked. Dermatomes that supply the area where thoracostomy drainage tubes may be inserted should also be blocked. When abdominal incisions are large and lie in or extend across the midline, a large volume of local anesthetic is needed for optimal pain relief. Providing adequate analgesia for these types of incisions usually requires multiple bilateral intercostal blocks. In general, postoperative pain management for abdominal surgery is better conducted with continuous epidural infusion of opioids or with opioid and local anesthetic solutions. An additional problem with intercostal blocks is the potential for pneumothorax and respiratory compromise. Bupivacaine or bupivacaine with epinephrine is recommended for postsurgical pain relief with an intercostal nerve block. Intercostal blocks should be performed in the midaxillary or posterior axillary line. The site of the injection must be proximal or more posterior to the area of incision. This may occasionally present technical difficulties because the ribs tend to project more anteriorly as they approach the posterior midline. Adequate analgesia for a surgical incision usually requires application of local anesthetic to a minimum of two intercostal segments, and optimal analgesia usually requires that a minimum of three segments be blocked.

An alternative to the injection of local anesthetic on the intercostal nerve is the use of a cryoprobe, which is designed to produce local intercostal nerve freezing (cryoanalgesia).¹⁶⁰ This technique has been reported to produce reversible nerve disruption while preserving intraneural and peridural connective tissues. For optimal results, the cryoprobe should be applied on the intercostal nerve from within the chest by piercing the parietal pleura, and two to three levels above and below the incision should be blocked. Two to three weeks after cryoanalgesia, nerve function and structure begin to recover, with complete recovery occurring within 1–3 months. Advantages reported with this technique include a low incidence of neuritis or neuroma formation. Because of the extended period of postoperative analgesia, this technique is advantageous when prolonged effective postoperative analgesia is desirable, such as in the patient with chest trauma or significantly limited respiratory function.¹⁶¹

Ilioinguinal. An ilioinguinal nerve block is useful for pain relief after inguinal or femoral herniorrhaphy, appendectomy, or procedures involving the scrotum. A simple technique to perform ilioinguinal nerve block involves palpation of the anterior superior iliac spine.¹⁶² Next, a position is located two fingerbreadths medial and two fingerbreadths superior until an imaginary line drawn from the anterosuperior iliac spine to the umbilicus is reached. At this point, a 22-gauge, 8.75-cm spinal needle is advanced perpendicular to the skin. The needle is advanced slowly and bounced every several millimeters until a paresthesia is elicited. This is indicative of needle contact with the fascia immediately outside the external oblique muscle pierced by the ilioinguinal nerve on its path to more superficial structures. Once the needle is in this location, 10–15 ml of local anesthetic is injected after aspiration. The needle is then withdrawn by several centimeters and redirected laterally until the tip reaches the medial edge of the anterior superior iliac spine. An additional 10–15 ml of local anesthetic solution is then injected. Complications of ilioinguinal nerve blocks include hemorrhage and hematoma at the injection site. Occasionally, numbness in the distribution of the lateral femoral cutaneous nerve can be demonstrated. Ilioinguinal nerve blocks are useful for acute postoperative analgesia after outpatient procedures such as inguinal herniorrhaphy.

Penile. A penile nerve block performed with 0.25% bupivacaine can provide effective analgesia after circumcision or orchiopexy. Two techniques are described for performing this block. One involves injecting half of the volume of local anesthetic at the 10 o'clock position at the base of the penis, with the remainder at the 2 o'clock position. An alternative involves placing the local anesthetic in a ring of the subcutaneous tissue 360 degrees around the base of the penis. Epinephrine-containing local anesthetic should not be used for penile blocks because of the risk of vasoconstriction and ischemic necrosis of the skin.

Brachial Plexus. Continuous postoperative brachial plexus analgesia can be achieved using catheters placed by the infraclavicular, supraclavicular, axillary, or interscalene approach. A catheter-over-needle technique using an 18-gauge, 5-cm Teflon-coated iv catheter threaded over a 22-gauge, 8.75-cm spinal needle is one method. A nerve stimulator is essential to elicit paresthesias and identify when the neurovascular bundle is contacted. Another method for catheter placement uses the Seldinger technique. With this technique, the needle is positioned with the aid of a nerve stimulator, and after paresthesias are elicited, a guidewire is passed through the needle. Sterile alligator clips connected to the nerve stimulator can then be placed on the guidewire after the needle has been removed to confirm that the guidewire is still contacting the brachial plexus. A 20-gauge catheter is passed over the guidewire, which is then removed. For rapid sequential confirmation of correct catheter placement, the guidewire can be reinserted through the catheter at any time and a nerve stimulator used to determine if paresthesia can be elicited.

Postoperative brachial plexus analgesia has been described using bupivacaine 0.25% at rates ranging from 6 to 10 ml · h⁻¹. When infusion rates are maintained in this range, toxic serum levels are unlikely to occur. Application of this regimen does not preclude the use of any commonly used doses and volumes of local anesthetics currently recommended for surgical anesthesia with brachial plexus blockade. Patient-controlled interscalene brachial plexus analgesia has also been used in patients

after shoulder surgery.¹⁶³ One disadvantage to this technique is postoperative catheter migration, and the infraclavicular and interscalene approaches may be better suited to continuous postoperative analgesia of the upper extremity because there tends to be less catheter migration than with the axillary approach.

Intrapleural. Intrapleural regional analgesia involves the percutaneous placement of a catheter in the thoracic cage between the visceral and parietal pleurae. The procedure is usually performed with the patient in the lateral decubitus position. An intercostal space between the fifth and tenth ribs is usually chosen, and a 17-gauge Touhy needle is inserted in the posterior axillary line over the superior aspect of the rib. A saline-lubricated glass syringe filled with 3–4 ml of air is attached to the needle, and the syringe and needle unit is advanced with the needle bevel directed in a cephalad direction. Once the pleural space is entered, the negative interpleural pressure draws the syringe plunger down in a manner analogous to the hanging drop technique of Gutierrez used for locating the epidural space. An epidural catheter may then be advanced 6 cm into the pleural space, rapidly to prevent the development of a clinically significant pneumothorax. If patients are mechanically ventilated, positive-pressure ventilation should be interrupted while the needle and catheter are being inserted to prevent injury to the pulmonary parenchyma. When patients are breathing spontaneously, the needle and catheter procedure should be performed during end exhalation.

Local anesthetics placed in the pleural cavity diffuse across the parietal pleura to the intercostal neurovascular bundle, producing a unilateral intercostal nerve block at multiple levels. To achieve a more extensive block, two catheters may have to be placed in the interpleural space. Intercostal analgesia using intermittent boluses of local anesthetic may be used to provide postoperative analgesia after upper abdominal surgical procedures, such as open cholecystectomy with subcostal incision as well as laparoscopic cholecystectomy. Effective postoperative pain relief requires intermittent intrapleural injections every 6 hours with approximately 20 ml of 0.25–0.5% bupivacaine. As in other intermittent bolus techniques, peaks and valleys in intrapleural analgesia occur when sequential doses are separated by hours.

Intrapleural analgesia may be less effective for post-thoracotomy pain than after other procedures in which the pleura is intact and there are no pleural drainage tubes to divert the local anesthetic from its site of action. Certain intercostal incisions, particularly those used for anterior thoracotomies, require that pleural drainage tubes be clamped for a short time after each intermittent local anesthetic injection to allow the local anesthetic to cross the parietal pleura and provide effective analgesia. Intermittent clamping of the pleural drainage tube after injection of the local anesthetic may not be tolerated in patients with a moderate or large air leak from the pulmonary parenchyma after thoracotomy. The risk of pneumothorax and the problems of fluctuating levels of analgesia with intermittent dosing of intrapleural catheters suggest that other techniques, such as continuous thoracic epidural analgesia, may be preferable after thoracotomy when there is an anterior intercostal incision.

Other Modalities

Transcutaneous and Percutaneous Electrical Nerve Stimulation

Although transcutaneous electrical nerve stimulation (TENS) was initially prescribed for relief of chronic pain, its use has been extended to postoperative pain. TENS is a simple, conservative technique that uses electrical stimulation of the skin to provide pain relief. Two or four electropads are placed on the skin adjacent to the skin incision. These pads are then connected to a battery-operated pulse generator with varying modes, frequencies, and strengths of stimulation. Current strength can be varied from 100 to 200 mA, with mixed low 2-Hz and high 100-Hz frequencies providing a greater opioid-sparing effect than either low or high frequencies alone.¹⁶⁴ The mechanism by which TENS produces pain relief is thought to involve the release of endogenous endorphins by the electrical stimulation of afferent cutaneous nerves. The endogenous endorphin release has an inhibitory effect on the dorsal horn and augments the descending inhibitory modulating pathways. Partial reversal by naloxone of the analgesia produced by TENS supports this hypothesis. The degree of pain relief that patients experience is highly variable. Percutaneous electrical nerve stimulation is a modification of TENS in which needle electrodes are used instead of electropads. This method may reduce the interpatient variability in responses by avoiding the high resistance of the skin.

Psychological Interventions for Postoperative Analgesia

The use of various analgesic techniques involving nerve blocks and of opioids applied to the central neuraxis as well as administered by iv infusions has produced dramatic changes in the management of pain. Nevertheless, it is sometimes necessary to augment these techniques with various psychological interventions. Psychological interventions are used widely in the treatment of chronic pain, and the benefit of these behavioral strategies for the management of acute pain is now recognized. This often involves approaching the treatment of pain on a cognitive basis and using interventions such as distraction or imagery that attempt to focus attention away from the painful event. Other, simpler methods consist of educating patients about their surroundings, disease state, treatment plans, and the hospital environment in an effort to reduce fear and anxiety about unknown events or situations in the perioperative period. Despite the banality of this approach, it is a frequently overlooked element when dealing with patients who often are unfamiliar with the hospital environment. Other psychological interventions that may be effective are relaxation techniques such as deep breathing exercises or muscle relaxation training, which can reduce anxiety and muscle tension.

ORGANIZATION OF A POSTOPERATIVE ANALGESIA SERVICE

With the increasing number and complexity of modalities for treating postoperative pain, it is logical that an organized, systematic approach involving all members of the health care team has evolved in the form of the postoperative analgesia service. The anesthesiologist is uniquely qualified to lead this team because of his or her knowledge of the neurophysiology, pathophysiology, pharmacology, and anatomic pathways involved in the modulation of acute pain. Furthermore, with the postoperative analgesia service under the direction of the anesthesiologist, continuity of pain care management is enhanced because the anesthesiologist is routinely involved in the preoperative assessment, intraoperative management, and postoperative follow-up of surgical patients. Because anesthesiologists are the logical choice for managing the postoperative analgesia service, it is desirable that each department of anesthesiology assume responsibility for organizing and maintaining efficient operation of the service.

When initiating a postoperative analgesia service, it is essential that the department of anesthesiology have one or more members who will assume the position of director or co-director. This ensures that at least one person will be responsible for communication with the pharmacy, nursing, and surgical departments, development of policy and procedural protocols, and departmental representation when issues concerning postoperative pain management arise.

The delivery of central neuraxial opioid analgesia requires cooperation among the anesthesiology, nursing, surgery, and pharmacy staffs. Success of such an interdisciplinary program for postoperative analgesia often requires significant flexibility to satisfy the needs of all the parties concerned. Each institution must identify the approach that is practical and most beneficial for its patients after considering available resources. With these considerations, protocols that reflect individual practice patterns can be effectively developed. These protocols should include written policy and procedure manuals for nursing staff (see [Appendix 54-2](#) and [Appendix 54-4](#)) as well as preprinted epidural analgesia orders (see [Appendix 54-3](#)). Postoperative pain relief has generated intense interest and fostered the introduction of several new analgesic modalities. Although these techniques have been shown to provide better pain relief than conventional im administration of opioids, the complexity of these modalities requires the use of an organized approach to maximize efficacy while minimizing potentially adverse effects. The transition phase from the operating room to the recovery area and then to the patient ward is a crucial period for intervention by the postoperative analgesia service. Optimization of analgesia (while the effects of anesthesia are dissipating) and potential reduction in the incidence or severity of side effects requires proactive evaluation and management in the recovery area by personnel trained and dedicated to these aspects of patient care.

When formulating the strategy for development and initiation of an epidural analgesia service, consideration must be given to the choice of continuous infusion techniques, intermittent bolus regimens, or combinations of these methods. In addition, with the use of PCA devices, similar protocols outlining the initial parameters for starting therapy should be established to facilitate effective use when these devices are prescribed (see [Table 54-6](#)).

The basic goals of the postoperative analgesia service are (1) administering and monitoring postoperative analgesia, and (2) identifying and managing complications or side effects of postoperative analgesic techniques. Implicit in these goals is the inclusion of an active quality assurance program directed at maintaining high-quality patient care while minimizing complications. When the postoperative analgesia service is managed by anesthesiologists, quality assurance monitoring can be applied to the heterogeneous surgical population so that the goals of pain management can be refined for the individual patient. This is much more difficult to achieve when particular surgical services are charged with the management of postoperative pain. Nonetheless, successful implementation of these principles requires the cooperation and involvement of health care providers outside of the department of anesthesiology, such as surgeons, nurses, and pharmacy personnel.

The foundation of an effective postoperative analgesia service is based on education of all members of the interdisciplinary health care team. This educational process must begin within the department of anesthesiology and be directed by those physicians with special qualifications in pain management and regional anesthesia. A corollary of this educational process is the use of a standardized approach to the initiation of pain management, which may include choices among fixed medication protocols, algorithms to identify and treat inadequate analgesia, and preprinted postoperative orders. The use of such methods increases efficiency, serves as a guideline for health care providers involved with the postoperative analgesia service, and gives the postoperative analgesia service team the flexibility to individualize therapy. This approach also facilitates the education of ancillary personnel, such as nursing staff, necessary to the functioning of the service.

Ideally, all members of each anesthesia department should become well versed in the basic principles necessary for the day-to-day operation of the postoperative analgesia service. Although its management usually is the responsibility of a limited number of anesthesia personnel, education of all members of the department

ensures the smooth operation of the service when those key individuals are not available after hours or on weekends. Although patients receiving postoperative analgesia should be seen on a regular basis by the anesthesiologist, it may be necessary for nurse clinicians or anesthesiology residents to assist in performing these functions if the service is very large. It is the responsibility of the anesthesiologist to educate these people in the principles of pain management. Nurse clinicians often have excellent rapport with other nursing staff and can act as effective liaisons. In addition, nurse clinicians can facilitate the operation of the postoperative analgesia service by performing tasks such as charting daily progress notes, inspecting epidural catheter sites, removing epidural catheters when therapy is discontinued, notifying the anesthesiologist of any problems pertaining to pain management, and collecting patient data to facilitate quality assurance. The participation of anesthesiology residents in the postoperative analgesia service allows them to gain knowledge and expertise in this area of perioperative care. Depending on the size of the surgical population and the scope of the service, additional support may be required from clinical pharmacologists, nurse anesthetists, or other physicians. Developing this solid foundation is an important consideration when establishing a postoperative analgesia service.

In addition to 24-hour-a-day support from the anesthesia department, a successful postoperative analgesia service requires the cooperation and education of nursing staff so that they are responsive to the needs of the patients. In-service training of hospital nurses requires instruction in the principles of analgesic techniques, including appropriate aspects of neuroanatomy, neuropharmacology, side effects and their treatment, monitoring skills, analgesia assessment, and the technical aspects of the operation of PCA and epidural infusion devices. This instruction should be conducted under the supervision of the anesthesiologist in charge of the postoperative analgesia service but may also involve a clinical nurse specialist trained by the anesthesiology department, who may assist in solving nursing problems related to the operation of the service. To minimize dosing and medication errors and to improve patient comfort by early treatment of inadequate analgesia and complications such as pruritus, nurses must understand the use of the standardized protocols.

One additional benefit of such a model is the ability to transition patients from epidural or PCA techniques to oral or other analgesia delivery systems, facilitating postoperative discharge. This can usually be accomplished for most surgical patients by converting from the parenteral techniques to an orally administered acetaminophen–hydrocodone or acetaminophen–codeine preparation. However, some patients experience difficulty with transition from parenteral therapy and require more potent opioids and other nonopioid adjuvants. Such patients have typically received opioids chronically for pain, and have higher analgesic requirements to achieve satisfactory postoperative pain control.¹⁶⁵ Because of their experience with the principles and use of the more potent, longer-acting oral opioid preparations (in the setting of chronic pain management), anesthesiologists can facilitate the management of this complicated set of patients. For example, combining sustained-release forms of long-duration drugs such as oxycodone or morphine sulfate every 6–12 hours can be effective in the transition from parenteral analgesic therapy. Using such an approach, this transition may be accomplished more efficiently and potentially hastens postsurgical discharge in patients who have received opioids chronically for pain.

Another key aspect to the initiation of a postoperative analgesia service is the identification of patient populations that are most likely to benefit from improved postoperative pain management. Patients undergoing thoracic and upper abdominal procedures, major orthopedic operations such as hip surgery, and high-risk vascular surgical procedures are examples of groups in whom effective postoperative pain management produces the most rewarding results. It is often useful to consider a pilot program using PCA or epidural analgesia when surgeons are doubtful or hesitant about the efficacy of these methods. After the utility of the postoperative analgesia service has been demonstrated to surgeons, referring physicians, and others, the service can expand logically to patient populations in which improved analgesia will be obvious but in which the effects on outcome may be more subtle. Initiation of the service in any subset of patients also requires the education of surgical staff regarding (1) the advantages to their practice of being able to offer patients surgery with less postoperative discomfort, and (2) the potential differences in outcome when using certain methods of postoperative analgesia. Despite the lack of large-scale, randomized studies to demonstrate that improved postoperative analgesia (especially the use of epidural analgesia in high-risk patients) is definitively associated with improved outcomes (such as shorter, less expensive hospital stays, with fewer major complications), there is more than enough evidence currently in the literature to support the important role of epidural anesthesia and analgesia in clinical practice. Surgeons must understand that their patients will receive attentive care and that an essential element of the postoperative analgesia service is the maintenance of a cooperative spirit among disciplines.

Once the appropriate subsets of patients have been identified and educated, the physicians in charge of initiating the postoperative analgesia service must make plans for the provision of the capital resources necessary to operate the service. Plans must be made regarding types of equipment needed for continuous or patient-controlled iv or epidural analgesia, whether such devices are to be rented or purchased, types of monitoring equipment deemed necessary, any pharmacy-related factors necessary to prepare solutions of drugs for administration, and the printing of standard orders for the postoperative management of pain and treatment of complications. Decisions regarding funding sources for these capital expenses often must involve discussions with hospital administrators. In the present medical–economic climate, hospital administrators may be opposed to the purchase of new equipment if old methods appear to be functional. It is important to educate administrators who are reluctant to support the concept of a postoperative analgesia service about the potential benefits to some patients in terms of shorter, less complicated, less expensive hospital stays. Not only can the service be cost effective, but sometimes it can be used by hospital administrators as a marketing tool to attract surgical patients. Preprinted order forms usually require approval from the hospital's medical records/forms department. Job descriptions and resources are necessary to define and fund support staff such as nurse clinicians, psychologists, or clinical pharmacologists. Thus, a significant degree of planning, effort, and commitment is necessary to initiate a properly functioning postoperative analgesia service. When such efforts are expended, the establishment of such a service allows the anesthesiologist to play an important role in the postoperative period and to provide a valuable service to patients.

SPECIAL CONSIDERATIONS IN PEDIATRIC ACUTE PAIN MANAGEMENT

Acute pain management in the pediatric patient poses a unique challenge to the anesthesiologist. It is often more difficult to evaluate pain intensity in children because the expression of pain is manifested over a broad emotional spectrum. For instance, some children withdraw and become nonverbal with the onset of pain, whereas others become emotionally labile, with crying, screaming, and violent behavior. Psychological distress is often compounded in children by separation from their parents and inadequate understanding of their disease and its treatment. Furthermore, depending on age, lack of cognitive development makes it more difficult to communicate relevant concepts to children. In view of these difficulties, a useful monitor of analgesic efficacy in children is behavior observation. Some behavior such as crying can be easily understood, but social withdrawal and the inability to be distracted often indicate that a young patient has distressing pain.

The selection and dosing of analgesic agents also requires special attention in the pediatric patient (Table 54-11). Neonates and infants, because of immature hepatic function and reduced plasma proteins and plasma protein-binding capacity, exhibit a higher fraction of free drug in the central compartment. This effect is offset to some degree by the higher total body water and extracellular fluid, and larger blood volume in this group compared with adults. Increased susceptibility to the respiratory depressant component of opioids may be a result of the increased fraction of cardiac output to the developing brain, or reduced metabolic pathways leading to accumulation of opioids and their metabolites. Morphine exhibits an increase in half-life and respiratory depressant effect in infants younger than 1 month of age owing to immature glucuronidation pathways. The half-lives of meperidine and fentanyl are similarly increased during the first 3 months of life. The pharmacokinetics of local anesthetics exhibit a similar pattern of development in neonates and infants. Free fractions of local anesthetics approach those seen in adults by 6 months of age (Table 54-12).

| Drug | Dose (age < 1 yr) | Interval (hr) | Route | Comments |
|-------------------|-----------------------------|---------------|--------|--|
| NONOPIOIDS | | | | |
| Acetaminophen | 5–10 mg/kg ^a | 4–6 | po | Check for liver hepatotoxicity |
| Ibuprofen | 10 mg/kg ^a | 4–6 | Rectal | |
| Aspirin | 7 mg/kg ^a | 6–12 | po | |
| Ketorolac | 0.5–1 mg/kg ^a | 6 | iv/im | Resolving may be greater than with morphine |
| | 0.25 mg/kg ^a | 6 | po | Maximum dose 1 mg/kg ^a /d ^b |
| OPIOIDS | | | | |
| Codeine | 0.5–1 mg/kg ^a | 4–6 | po | Most commonly combined with acetaminophen |
| Oxycodone | 0.05–0.2 mg/kg ^a | 4–6 | po | Similar to codeine |
| Hydrocodone | 1–2 mg/kg ^a | 3–5 | iv | May cause less respiratory depression and other side effects than morphine |
| Morphine | 0.1–0.2 mg/kg ^a | 3–5 | iv | |
| | 0.05–0.1 mg/kg ^a | 2 | iv | Continuous infusion |
| | 0.1 mg/kg ^a | 12–24 | iv | Abdominal surgery |
| | 0.05–0.1 mg/kg ^a | 12–24 | iv | Thoracic surgery |
| | 0.05–0.1 mg/kg ^a | 12–24 | iv | Effect is rapid relative to several others |
| Fentanyl | 1–2 µg/kg ^a | 1–2 | iv | Maximum age 1 yr |
| | 2–4 µg/kg ^a | | iv | Continuous infusion |

^apo = oral; ^biv = intravenous; ^cim = intramuscular; ^div = intravenous; po = oral.

Table 54-11. PHARMACOLOGIC CONSIDERATIONS FOR PEDIATRIC PATIENTS

| Drug | Infant Dose (mg · kg ⁻¹): Age | Child Dose (mg · kg ⁻¹) |
|------------------------------|---|-------------------------------------|
| Lidocaine (plain) | 5: from birth on | 5 |
| Lidocaine (epinephrine) | 7: from birth on | 7 |
| Mepivacaine | 4: <6 mo | 5 |
| Bupivacaine (plain) | 2: <3 mo | 3 |
| Bupivacaine (epinephrine) | 2: <3 mo | 4 |
| Chloroprocaine (plain) | 4: <6 mo | 8 |
| Chloroprocaine (epinephrine) | 5: <6 mo | 10 |

Table 54-12. MAXIMUM LOCAL ANESTHETIC DOSES IN INFANTS AND CHILDREN

Oral Analgesics

Nonopioid

Nonsteroidal anti-inflammatory drugs are useful oral drugs for acute postoperative pain management in the pediatric population. Ibuprofen can be administered at 6- to 8-hour intervals in doses of 8 mg · kg⁻¹. Contraindications to the use of NSAIDs in the pediatric population are similar to those in adults. The most frequently encountered adverse effects are gastrointestinal. Platelet function alteration can occur, but this is usually not a significant clinical problem after short-term administration in the postoperative period. Acetaminophen has fewer side effects than ibuprofen and can be administered in doses of 5–15 mg · kg⁻¹ orally or 20 mg · kg⁻¹ rectally every 4–6 hours. Ketorolac in doses of 0.4–1.0 mg · kg⁻¹ is also useful for mild to moderate postoperative pain in children when parenteral administration is desirable, but may be associated with a greater incidence of vomiting than morphine.^{166,167}

Opioid

Codeine in combination with acetaminophen is a commonly used oral preparation for moderate postoperative pain in the pediatric population. The recommended oral dosage range is 0.5–1 mg · kg⁻¹ every 4–6 hours.

Patient-Controlled Analgesia

Patient-controlled analgesia is an opioid delivery system that has been used with increasing frequency to treat acute postoperative pain in children. Morphine sulfate given as a loading dose of 0.1–0.2 mg · kg⁻¹ and administered as small incremental boluses of 0.01–0.03 mg · kg⁻¹ can be used to initiate PCA therapy. After this, maintenance doses of morphine sulfate, 0.01–0.015 mg · kg⁻¹, given every 6–10 minutes with a 4-hour limit of 0.25 mg · kg⁻¹, are appropriate. Incorporation of a continuous infusion of 0.01–0.015 mg · kg⁻¹ · h⁻¹ into the regimen may be beneficial.¹⁶⁸ Lower doses of morphine may be used if ketorolac is used in conjunction with PCA.¹⁶⁹ Meperidine in maintenance doses of 0.15–0.20 mg · kg⁻¹ with a 4-hour limit of 2–3 mg · kg⁻¹ has been used and may be associated with fewer side effects than morphine.

Epidural Opioids

Like other methods of pain control, the use of epidural opioids has not been extensively studied in the pediatric population. Lumbar epidural analgesia has been used for young patients undergoing abdominal, urologic, or orthopedic procedures. Because lumbar epidural catheters may be more difficult to place in the pediatric patient than in adults, an alternative is to perform a “kiddie caudal” with a mixture of local anesthetic and opioid for postoperative analgesia. Morphine is the preferable drug for single-injection techniques and can be administered as a 0.05 mg · kg⁻¹ bolus, in volumes appropriate for the age and weight of the child.¹⁷⁰ Additional information on caudal analgesia is reported in earlier sections of this chapter.

RELATIONSHIP BETWEEN ACUTE AND CHRONIC PAIN

For an individual patient, the development of a chronic pain syndrome may simply be the extension of inadequately treated acute pain after trauma or surgery. Differentiation between acute and chronic pain is important in clinical practice because therapy usually is vastly different. It is generally agreed that pain persisting longer than 6 months can be viewed as chronic pain. Acute pain management techniques usually are not effective and may add to the problems when applied to chronic pain. For instance, systemic opioids for long-term use are often associated with the development of tolerance and, occasionally, drug dependency. Chronic pain is not simply the extension of acute pain as an isolated entity but involves multiple other factors such as altered mechanisms of nociceptive modulation and amplification of neural responses that account for the differences in clinical presentation and, more important, in choice of therapeutic modality.

SUMMARY

This chapter has reviewed the physiology of nociception and the production of acute postoperative pain as well as compared and contrasted various methods for analgesia. In addition, the rationale behind the development of a team of health care personnel aimed at managing postoperative pain has been addressed. Postoperative pain management requires continued study to refine, explore, and open new avenues for further improvement of current techniques.

APPENDIX 54-1

Solutions and Rates of Patient-Controlled Epidural Analgesia

Standard Solutions

Fentanyl 3000 μg with bupivacaine 300 mg in 300 ml normal saline (NS)—adults <70 yr, >50 kg

Fentanyl 1500 μg with bupivacaine 300 mg in 300 ml NS—adults \geq 70 yr, \geq 50 kg, history of sleep apnea

Maximum continuous rate 10 ml \cdot hr⁻¹ for lumbar epidural catheters (total infusion rate \leq 40 ml \cdot 4 hr⁻¹)

Examples of continuous and demand dosing combinations:

- 4 ml \cdot hr⁻¹ continuous, demand mode 1 ml q10min, 40 ml \cdot 4 hr⁻¹ lockout
- 4 ml \cdot hr⁻¹ continuous, demand mode 2 ml q20min, 40 ml \cdot 4 hr⁻¹ lockout
- 5 ml \cdot hr⁻¹ continuous, demand mode 1 ml q12min, 40 ml \cdot 4 hr⁻¹ lockout
- 6 ml \cdot hr⁻¹ continuous, demand mode 1 ml q15min, 40 ml \cdot 4 hr⁻¹ lockout
- 6 ml \cdot hr⁻¹ continuous, demand mode 2 ml q30min, 40 ml \cdot 4 hr⁻¹ lockout
- 7 ml \cdot hr⁻¹ continuous, demand mode 1 ml q20min, 40 ml \cdot 4 hr⁻¹ lockout
- 8 ml \cdot hr⁻¹ continuous, demand mode 1 ml q30min, 40 ml \cdot 4 hr⁻¹ lockout
- 8 ml \cdot hr⁻¹ continuous, demand mode 2 ml q60min, 40 ml \cdot 4 hr⁻¹ lockout
- 9 ml \cdot hr⁻¹ continuous, demand mode 1 ml q60min, 40 ml \cdot 4 hr⁻¹ lockout
- 10 ml \cdot hr⁻¹, no demand mode

Morphine 30 mg with bupivacaine 300 mg in 300 ml NS—adults <70 yr, >50 kg

Morphine 15 mg with bupivacaine 300 mg in 150 ml NS—adults \geq 70 yr, \geq 50 kg, history of sleep apnea

Maximum continuous rate 6 ml \cdot hr⁻¹ for lumbar or thoracic epidural catheters (total infusion rate \leq 24 ml \cdot 4 hr⁻¹)

Examples of continuous and demand dosing combinations:

- 3 ml \cdot hr⁻¹ continuous, demand mode 1 ml q20min, 24 ml \cdot 4 hr⁻¹ lockout
- 4 ml \cdot hr⁻¹ continuous, demand mode 1 ml q30min, 24 ml \cdot 4 hr⁻¹ lockout
- 5 ml \cdot hr⁻¹ continuous, demand mode 1 ml q60min, 24 ml \cdot 4 hr⁻¹ lockout
- 6 ml \cdot hr⁻¹ continuous, no demand mode

APPENDIX 54-2

Policy and Procedures for Initiation and Nursing Care of Patients with Postoperative Epidural Analgesia

- I. Purpose
 - A. To list guidelines for the initiating and monitoring of patients receiving postoperative epidural analgesia and to provide quality assurance and patient safety.
- II. Candidates
 - A. Postsurgical patients who have no previous history of allergy to the ordered analgesics.
 - B. Patients must not have any contraindications to the placement of an epidural catheter (e.g., sepsis, severe coagulopathy abnormality, hypovolemia, head injury).
- III. Equipment
 - A. Epidural infusion pump

- B. Cassette tubing
 - C. Epidural catheter tray
 - D. Micropore tape
 - E. Tegaderm dressing
 - F. Apnea monitor (if required—see below)
 - G. Naloxone 0.4 mg · ml⁻¹—two ampules
 - H. 3-ml syringes with needles
 - I. Alcohol wipes
 - J. Epidural solution
 1. Fentanyl 0.001%/bupivacaine 0.1%—300 ml (age <70 yr)
 2. Fentanyl 0.0005%/bupivacaine 0.1%—300 ml (age >70 yr, £50 kg, history of sleep apnea)
 3. Morphine 0.01%/bupivacaine 0.1%—300 ml (age <70 yr)
 4. Morphine 0.005%/bupivacaine 0.1%—300 ml (age >70 yr, £50 kg, history of sleep apnea)
- IV. Treatment initiation and guidelines
- A. Placement of epidural catheter is performed by the anesthesiologist.
 - B. Epidural order sheet must be completed by the anesthesiologist.
 1. Anesthesiologist's written order for epidural solution to include the name and amount of fluid, rate of infusion, name and dosage of any medications added, and supplemental intravenous/intramuscular pain medications as required.
 - C. Epidural solution must be administered by designated infusion pump.
 - D. Baseline blood pressure and respiratory rate must be documented before initiating epidural infusion.
 - E. Blood pressure, heart rate, level of consciousness, and temperature are to be monitored every 4 hours for the first 24 hours of the epidural infusion.
 - F. Respiratory monitoring
 1. An apnea monitor is required for patients who received epidural narcotic bolus of MSO₄ 32 mg. Patients may receive an epidural bolus of fentanyl 50–150 µg without the routine use of an apnea monitor.
 2. Respiratory rate to be monitored every hour for the first 24 hours of the epidural infusion.
 - a. Naloxone, syringe, and needle are to be readily available at all times.
 - G. The epidural solution bag and volumetric pump cassette are not changed unless otherwise ordered.
- V. Nursing responsibilities
- A. Record vital signs (blood pressure, level of consciousness, ambulation, temperature) every 4 hours for first 24 hours of epidural infusion, then as ordered.
 - B. Record respiratory rates every 1 hour for the first 24 hours of the epidural infusion and every 4 hours thereafter.
 1. If the respiratory rate falls below 8 per minute, notify the postoperative analgesia service (PAS) and administer naloxone as ordered.
 - C. Record all analgesic medications administered on the medication record.
 - D. Using the Visual Analog Scale, record patient's subjective level of pain with vital signs on flow sheet.
 1. Scale for pain: 0–10, with 0 = no pain and 10 = worst pain ever.
 - E. Assess epidural catheter integrity and check dressing for wetness every shift and as needed.
 1. Reinforce with dry 4 × 4 gauze if dressing is wet.
 2. Cover with clear plastic tape.
 3. Notify PAS if excessive wetness or integrity of catheter is in question.
 - a. If epidural catheter becomes dislodged or disconnected.
 - i. Notify PAS.
 - ii. If catheter is disconnected, cover end of catheter with 4 × 4 gauze (do not reconnect).
 - iii. If catheter becomes dislodged, keep for inspection by anesthesiologist.
 - F. Assess and document signs and symptoms of side effects.
 1. Pruritus with and without rash
 2. Nausea or vomiting
 3. Paresthesia, numbness, motor weakness
 4. Headache
 5. Backache
 6. Signs of infection around catheter site
 7. Urinary retention
 - G. Assess and document the following if patient is on anticoagulation medication:
 1. Notify PAS if patient receiving warfarin has an international normalized ratio (INR) >1.8.
 2. Notify PAS if a second anticoagulant is ordered.
 - H. Record any prescribed treatment administered for side effects or supplemental analgesics on patient care record.
- VI. Postoperative analgesia service responsibilities
- A. Team members will see patients daily and chart progress notes documenting adequacy of pain relief and the occurrence of side effects or problems associated with epidural use. Will adjust therapy or institute test dose algorithm if current protocol is associated with inadequate analgesia, side effects or complications. Will collect and maintain data for review by anesthesiologist on a weekly basis.
 - B. Organize and conduct inservice training of hospital nursing staff.
 - C. Review epidural medication record to ensure adequate documentation of use and disposal of medications.
 - D. Evaluate and make recommendations regarding new equipment for epidural analgesia.
 - E. Analyze data, identify problems, propose changes if any, and evaluate changes for quality assurance purposes.
 - F. Review anticoagulation medication taken along with coagulation status before epidural catheter removal.
 1. The epidural catheter should not be removed for at least 4 hours after the previous dose of subcutaneous standard heparin or discontinuation of intravenous heparin infusion. The next subcutaneous dose or the resumption of the intravenous infusion should be at least 2 hours after catheter removal.
 2. The epidural catheter should not be removed for at least 10 hours after the previous dose of a low-molecular-weight heparin. The next dose should be held for at least 2 hours after catheter removal.
 3. Patients receiving warfarin should not should have the epidural catheter removed until INR <1.8 and platelet count >80,000 per mm³. After epidural catheter removal in patients with INR >1.5, order neurosensory assessments to be made every 4 hours for the next 24 hours.
- VII. Pharmacy responsibilities
- A. Daily log of all patients receiving epidural analgesia with type of solution and amount dispensed.
 - B. Computer printout of all patients started on epidural analgesia in the last 24 hours. Printout should be available in pharmacy at 8 A.M. Monday through Saturday mornings. Patients started on epidural analgesia on Saturday or Sunday will be on the Monday morning printout. This list will be picked up by the PAS personnel to aid in identifying those patients started on epidural analgesia.
 - C. Collaborate with PAS personnel in quality assurance matters.
- VIII. Termination
- A. Epidural infusions ordinarily will be terminated by the PAS in conjunction with the primary surgical service using guidelines established for the type of surgical procedure and patients' analgesic requirements.
- IX. Questions/problems
- A. Any questions or problems regarding epidural drip or catheter are referred to the PAS between 8:00 A.M. and 4:30 P.M., or to the anesthesiologist on call after 4:00 P.M. and weekends.

APPENDIX 54-3

Postoperative Epidural Analgesia Order Sheet

(PLEASE CIRCLE ORDERS TO BE IMPLEMENTED AND COMPLETE BLANKS WHERE APPROPRIATE)

(DATE AND TIME FOR EACH PROCEDURE IS TO BE NOTED)

1. Admit to PAR or SIT, routine PAR or SIT VS.
2. Discharge from PAR per anesthesia care team.
3. On floor (circle):
 - a. Monitoring
 1. Apnea monitor
 2. Telemetry
 3. Pulse oximetry
 - b. VS q4h, respiratory rate q1h for the first 24 hours.
 - c. Tape two ampules of naloxone with syringe and needle at bedside.

- d. If respiratory rate <8 per minute, give 0.4 mg naloxone iv stat and call anesthesia.
4. Epidural solution (circle one):
- MSO₄ 15 mg with bupivacaine 300 mg in 300 ml NS, rate _____ ml · hr⁻¹ (age ≥70 yr, £50 kg, history of sleep apnea)
 - MSO₄ 30 mg with bupivacaine 300 mg in 300 ml NS, rate _____ ml · hr⁻¹
 - Fentanyl 1500 µg with bupivacaine 300 mg in 300 ml NS, rate _____ ml · hr⁻¹ (age ≥70 y, £50 kg, history of sleep apnea)
 - Fentanyl 3000 µg with bupivacaine 300 mg in 300 ml NS, rate _____ ml · hr⁻¹
 - PATIENT-ASSISTED EPIDURAL MODE _____ ml q _____ min, with _____ ml · 4 hr⁻¹ lockout
5. Supplemental medications (circle):
- MSO₄ 2 mg iv, im, or sq q2–4h prn for pain
 - Metoclopramide 10 mg im q4–6h prn for nausea
 - Nalbuphine 10 mg im or sq q4–6h prn for pruritus
 - Ketorolac 30 mg im q6h × 48 h prn for pain; if patient >65 y or <65 kg, give 15 mg im q6h × 48 h prn for pain
6. Nursing staff on floor call postoperative analgesia service × 24 hours a day if any problems arise or if catheter needs to be discontinued.
7. All other preoperative orders, medications, and diet per service with the exception of opioids and sedatives.

PAR = postanesthesia recovery; VS = vital signs; SIT = surgical intensive therapy unit; iv = intravenously; im = intramuscularly; sq = subcutaneously; NS = normal saline.

APPENDIX 54-4

Patient-Controlled Analgesia (PCA) Service Protocol for Postsurgical Pain Relief

- Purpose
 - To list guidelines to follow when PCA is ordered and to provide quality assurance and patient safety.
- Candidates
 - Postsurgical patients who have no previous history of allergy to the ordered analgesics.
 - Patients must be mentally alert, understand basic instructions, and be physically capable of operating the PCA infusion device.
- Treatment initiation
 - Treatment may be initiated by any surgical service as well as by anesthesia personnel. PCA treatment initiated by surgical services must conform to the guidelines listed below.
- Postoperative PCA guidelines
 - The physician's order for PCA must include the following:
 - Drug (only morphine and meperidine are available for routine use for postsurgical pain. Fentanyl and other drugs may be used only with the approval of the postoperative analgesia service [PAS] physician or anesthesiologist on call when the PAS service is not available)
 - Loading dose (if patient has pain when PCA is ordered)
 - Maintenance infusion (if desired)
 - Incremental or maintenance dose
 - Lockout interval
 - Four-hour limit
 - Mode of operation—PCA
 - Recommended starting parameters
 - Loading dose, morphine 1–4 mg, meperidine 10–40 mg
 - Maintenance dose, morphine 1 mg, meperidine 10 mg
 - Lockout interval, 6–10 minutes
 - Four-hour limit, morphine 20 mg, meperidine 200 mg
 - Mode of operation—PCA
- Surgical staff
 - Initiate preprinted order sheet.
 - Evaluate adequacy of therapy.
 - Contact PAS personnel if inadequate pain relief or patient has requirements for more complex PCA dosing.
 - Monitor for complications.
- Nursing responsibilities
 - Obtain and assure prompt delivery of PCA morphine/meperidine vials from pharmacy to nursing units.
 - Verify proper and patent intravenous line.
 - Monitor and record vital signs per orders.
 - Reinforce patient teaching on use of PCA, if needed.
 - Assess pain level and effectiveness of PCA.
 - Change PCA tubing every 48 hours.
 - Document accurate dosage of narcotic used or wasted in separate PCA medication sheets (two signatures needed for drug wasted).
 - Verify that PCA is programmed to deliver dosage as ordered.
 - At the change of shift, the incoming and outgoing nurses will check the PCA flow sheet, the pump readout, and the labeled syringe. The amount of drug administered in the previous 8 hours will be recorded on the PCA medication sheet.
 - Notify PAS personnel and primary surgical service if the patient experiences side effects, complications, or inadequate analgesia.
 - Assess and document signs and symptoms of side effects.
 - Pruritus with and without rash
 - Nausea or vomiting.
 - Sedation/decreased mentation
 - Decreased respiration
 - Ileus/constipation
 - Signs of infection or infiltration around catheter site
 - Urinary retention
 - Record any prescribed treatment administered for side effects or supplemental analgesics on patient care record.
- Postoperative analgesia service responsibilities
 - Instruct patients on the use of PCA when ordered by anesthesia and provide additional teaching if PCA is ordered by surgical service.
 - Team members will see patients daily and chart progress notes documenting adequacy of pain relief and the occurrence of side effects or problems associated with PCA use. Will adjust therapy or substitute with a new protocol if current therapy is associated with inadequate analgesia, side effects or complications. Will collect and maintain data for review by anesthesiologist on a weekly basis.
 - Organize and conduct inservice training of hospital nursing staff.
 - Review epidural medication record to ensure adequate documentation of use and disposal of medications.
 - Evaluate and make recommendations regarding new equipment of epidural analgesia.
 - Analyze data, identify problems, propose changes, if any, and evaluate changes for quality assurance purposes.
- Pharmacy responsibilities
 - Daily log of all patients receiving PCA with type of solution and amount dispensed.
 - Computer printout of all patients started on epidural analgesia in the last 24 hours. Printout should be available in pharmacy at 8 A.M. Monday through Saturday mornings. Patients started on PCA on Saturday or Sunday will be on the Monday morning printout. This list will be picked up by the PAS personnel to aid in identifying those patients started on epidural analgesia.
 - Collaborate with PAS personnel in quality assurance matters.
- Termination
 - Epidural infusions ordinarily will be terminated by the PAS in conjunction with the primary surgical service using guidelines established for the type of surgical procedure and patients analgesic requirements.
- Questions/problems
 - Any questions or problems regarding epidural drip or catheter are referred to the postoperative analgesia service between 8:00 A.M. and 4:30 P.M. or to the anesthesiologist on call after 4:00 P.M. and weekends.

A generation ago, when confronted by patients who failed to respond to reasonable therapeutic measures, we had few explanations for our failures. The gate control theory helped to direct our thinking away from the concept of a hardwired, straight-through pain transmission system. We have made enormous progress in delineating the peripheral and central mechanisms of pain perception, and we have developed some novel methods for managing intractable pain. However, we are still frustrated by a substantial number of patients for whom we cannot provide effective pain control. Part of our failure to manage some patients effectively is the fact that pain complaints are related to factors independent of either nociception or aberrant neuronal activity within the pain projection system. Patients with somatization disorders, dysfunctional learned behaviors, secondary-gain issues, and substance abuse problems are likely to fail physiologically directed treatment regimens. Even when psychosocial issues are adequately addressed, the pathophysiologic processes leading to the perception of pain may not be successfully managed by treatment options that are currently available. Patients with pain following spinal cord injury or stroke are notoriously resistant to treatment. Although the number of treatment options is expanding, the complexity and cost of care are increasing as well, and the resources available to pay for these therapies are shrinking.

In order to successfully manage a wide range of chronic pain problems, one must have a good understanding of the physiology and anatomy of pain perception. One must understand the endogenous mechanisms that serve to heighten or suppress the neural activity associated with pain perception. In addition, an understanding of the pathophysiology of the more common painful disorders is essential, as is an understanding of the pharmacology of a wide range of medications, many of which are not analgesic *per se*. Other required skills include physical examination and psychological assessment techniques, regional anesthesia skills, and familiarity with an increasingly complex range of interventional management techniques. The management of difficult chronic pain patients is being done increasingly by physicians with subspecialty training in this field.

PAIN PATHWAYS AND MECHANISMS

Pain is most often experienced as a result of injury. Its survival value to an organism is based on the fact that it is initiated by tissue injury or by stimuli that threaten damage and that it produces sufficient arousal and distress that it is unlikely to be ignored. It is tempting to envision pain as a straightforward receptive system, with transducers that respond to intense, tissue-threatening stimuli, and neurons that project to areas of the brain capable of processing pain information. Unfortunately, such a view of pain perception fails to explain the tremendous variation in pain sensitivity between individuals or the dramatic shifts in sensitivity that can occur in a single individual. It also fails to explain chronic pain that is experienced without any noxious stimulation. Oversimplified anatomic concepts also predispose to simplistic therapeutic interventions, such as neurectomy or rhizotomy, that may intensify pain or create new and often more distressing pain.

In reality, the nociceptive system is highly complex and highly adaptable. Sensitivity of most of its components can be reset by a variety of physiologic and pathologic conditions. Injury to neural elements may result in loss of ability to perceive pain or may cause spontaneous pain or heightened pain sensitivity.

The ability to understand acute pain requires a knowledge of the physiology of receptors that respond to tissue-threatening stimuli, the anatomy of peripheral and central nervous system (CNS) pathways that are activated, and the mechanisms by which various components of the pain projection system can be sensitized or suppressed. Mechanisms of chronic pain are even more complex. Chronic injury may lead to irreversible alterations in nociceptor sensitivity, to spontaneous firing of peripheral or central pain projection fibers, and to dramatic changes in the reaction of the CNS to sensory inputs. This section provides an overview of the anatomic pathways, the physiologic modulating mechanisms, and the pathologic alterations that are important to the perception of pain.

ANATOMIC PATHWAYS

Nociceptors

Receptors that respond exclusively to intense, potentially tissue-damaging stimuli are well characterized. Cutaneous nociceptors have been extensively studied. Considerably less is known about receptors responsive to intense stimuli found in deep somatic structures. Still less is known about the physiology of visceral pain.

Cutaneous Nociceptors

Most cutaneous nociceptors respond to both intense mechanical stimulation and to high temperatures and are termed mechano-heat nociceptors.¹ They do not respond to low-threshold mechanical stimulation (light touch, pressure) or to warm temperatures below the noxious range. C-fiber mechano-heat (CMH) nociceptors respond to temperatures above 43°C. Firing frequency increases in a roughly linear fashion as skin temperature is increased within the noxious range (Fig. 55-1). Repeated or prolonged exposure to suprathreshold stimuli may lead to a reduction in response, or habituation. However, under certain circumstances, previous exposure to a noxious stimulus may lead to an enhanced response (sensitization).

Figure 55-1. Sequence of events leading to sensitization of dorsal horn neurons following injury and intense nociceptive stimulation. Intense activation of primary afferent neuron stimulates release of glutamate (Glu) and substance P (SP). The NMDA receptor, at physiologic Mg^{2+} levels, is initially unresponsive to Glu; but following depolarization of the AMPA receptor by Glu on the metabotropic receptor it stimulates G-protein-mediated activation of phospholipase C (PLC), which catalyzes hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) to produce inositol triphosphate (IP_3) and diacylglycerol (DAG). DAG stimulates production of protein kinase C (PKC), which is activated in the presence of high levels of intracellular Ca^{2+} (Ca^{2+}). IP_3 stimulates release of intracellular Ca^{2+} from intracellular stores within the endoplasmic reticulum (Ca_{ex}^{2+}). Increased PKC induces a sustained increase in membrane permeability and, in conjunction with increased intracellular Ca^{2+} , leads to increased expression of proto-oncogenes such as *c-fos* and *c-jun*. The proteins produced by these proto-oncogenes encode a number of neuropeptides such as enkephalins (ENK), dynorphin (DYN), and tachykinins (TK). Increased Ca^{2+} also leads to activation of phospholipase A_2 (PLA_2) and to activation of nitric oxide synthase (NOS) through a calcium/calmodulin mechanism. PLA_2 catalyzes the conversion of phosphatidylcholine (PC) to prostaglandins (PG) and thromboxanes (TX) and by lipoxygenase (LO) to produce leukotrienes (LT). NOS catalyzes the production of protein kinases, such as PKC, and alterations in gene expression. NO diffuses out of the cell to the primary afferent terminal, where, through a GC/cGMP mechanism, it increases the release of glutamate. It is speculated that NO may interfere with release of inhibitory neurotransmitters from inhibitory neurons. (From Hogan QH, Abram SE: Diagnostic and prognostic neural blockade. In Cousins MJ, Bridenbaugh PO [eds]: *Neural Blockade in Clinical Anesthesia and Management of Pain*, p 837. Philadelphia, Lippincott-Raven, 1998.)

There are two types of A-fiber mechano-heat nociceptors (AMHs). Type I AMHs have a very high threshold to thermal stimuli ($53^{\circ}C$ or greater) and are considered by some investigators to be mechanical nociceptors, or high-threshold mechanoreceptors. These nociceptors are found principally in glabrous skin. While most have afferent fibers with conduction velocities in the A-delta range ($\sim 30 \text{ m} \cdot \text{sec}^{-1}$), some have conduction velocities as high as $55 \text{ m} \cdot \text{sec}^{-1}$, and would be considered A-b fibers. Type II AMHs are activated by temperatures below activation thresholds of type I AMHs and conduct at about $15 \text{ m} \cdot \text{sec}^{-1}$. These nociceptors also have a much shorter delay between stimulus onset and receptor activation. They are generally found in hairy skin and on the face.

The receptive fields for mechanical and thermal nociception are essentially identical for both CMHs and AMHs. However, there may be differences in the transducer mechanisms for mechanical versus thermal nociception. For instance, application of capsaicin to the skin produces analgesia to noxious thermal, but not mechanical stimulation. Cutaneous AMHs and CMHs are poorly responsive to cooling stimuli, and there is some evidence that afferent fibers from vascular structures are capable of signaling cold pain.²

Some cutaneous nociceptors are insensitive to noxious mechanical stimuli, and are termed mechanically insensitive afferents. Some of these may be chemically responsive, while others are responsive only to intense heat or cold. Some of these receptors develop mechanosensitivity following the development of inflammation.

A number of chemical mediators that are released following injury are capable of either activating or sensitizing both CMHs and AMHs. These substances include bradykinin, serotonin, prostaglandins, leukotrienes, histamine, and substance P. Bradykinin, which is released locally following tissue injury, is capable of evoking pain on intradermal injection, and has been shown to activate both CMHs and AMHs when administered within a nerve's receptive field. In addition, bradykinin produces hyperalgesia to heat stimuli through receptor sensitization. Serotonin can activate nociceptors and potentiates bradykinin-induced pain. Low pH is also capable of producing pain, both by nociceptor activation and by sensitization to mechanical stimuli.¹

Nociceptors in Other Somatic Structures

A large number of A-delta and C fibers found in muscle, fascia, and tendons are poorly responsive to normal stretching or contraction and are probably nociceptive in function. Many of the C fibers are responsive to chemical irritants, heat, and strong pressure.³ A few respond to strong contraction and to ischemia, whereas others fire in response to muscle stretching. Some A-delta fibers in muscle have relatively low sensitivity to mechanical stimuli, responding best to chemicals, such as bradykinin. Others, which tend to be arranged near muscle-tendon junctions, respond to local pressure, stretch, and contractions.³

Nociceptors in joints are located in the joint capsule, ligaments, periosteum, and articular fat pads, but probably not in cartilage. Small myelinated and unmyelinated fibers terminate in free nerve endings in joints, and A-delta fibers form a widespread plexus in capsules, fat pads, and ligaments.⁴ Some of the A-delta axons respond to noxious stimuli. Intracapsular bradykinin in animals produces generalized nociceptive responses that are enhanced by prostaglandins.

Corneal sensitivity serves a primarily protective function, and most stimuli to corneal epithelium are sensed as pain. Innervation is mainly from A-delta fibers, with fine terminals devoid of Schwann cell covering.³ These fibers have activation thresholds similar to low-threshold mechanoreceptors in skin,⁵ but low-intensity stimulation is capable of evoking pain. Tooth pulp afferents respond to a variety of chemical stimuli, strong heating, cooling, and pressure. Electrical stimulation produces almost exclusively painful sensations.³

Visceral Pain Receptors

Because of the infrequency with which visceral structures are exposed to potentially damaging events, it would not seem efficient to provide these structures with receptors designed solely to detect intense stimuli in the environment. Although severe pain of visceral origin is a common clinical phenomenon, there is little evidence that specialized pain receptors exist in visceral structures. Many damaging stimuli, such as cutting, burning, or clamping, produce no pain when applied to visceral structures. On the other hand, inflammation, ischemia, mesenteric stretching, or dilation or spasm of hollow viscera may produce severe pain. These stimuli are usually associated with pathologic processes, and the pain they induce may serve a survival function by promoting immobility.

For almost all intrathoracic, intra-abdominal, and pelvic viscera, pain perception is a function of visceral afferent (sometimes termed sympathetic afferent) nerve activity.³ These neurons accompany sympathetic efferent axons in the sympathetic chain and intra-abdominal and intrathoracic plexuses; but most, like other afferent fibers, have their cell bodies in the dorsal root ganglia and synapse with dorsal horn neurons.

Pain Perception in the Gut

It has been widely accepted that nociceptive-specific fibers do not exist in the gut. Pain is thought to result from intense activation of afferent fibers that serve other functions, such as stretch receptors. High-frequency activation of these visceral afferents in turn activates dorsal horn pain projection neurons, producing pain perceived within cutaneous referral sites. This referred pain is probably the result of viscerosomatic convergence, the phenomenon of a single spinothalamic tract (STT) neuron that can be activated by either visceral or somatic stimuli. Another type of convergence, reported by Bahr *et al*,⁶ is based on the existence of afferent neurons with two sensory branches, one visceral (sympathetic afferent) and one somatic. It is not possible to locate the site of a painful stimulus to the gut with any accuracy because stimulation of widely distant sites can give rise to the same referred sensations.

Cardiac Pain

Cardiac afferent fibers, conducting in the C and A-delta range, have been shown to fire at high rates in response to coronary occlusion or to intracoronary bradykinin.⁷ However, to designate these nerves as nociceptors, they should respond only to noxious stimuli and should exhibit no background discharge. Malliani⁷ has shown that these putative nociceptors are tonically active, demonstrate mechanosensitivity, and respond to normal hemodynamic events. It is likely that cardiac afferents that are responsive to tissue-threatening stimuli have physiologic functions under normal circumstances, but give rise to volleys of activity that can cause poorly localized pain

referred to somatic structures. Viscerosomatic convergence probably occurs with these fibers.

Other Visceral Structures

Pain associated with gallbladder disease is similar in character and location to angina pectoris.⁸ Mechanical stimulation of the gallbladder or the application of chemical stimuli can affect the electrical activity and contractility of the heart.⁹ Stretching of the bile ducts and gallbladder activates two populations of afferent fibers, one responding to small changes in pressure and the other responding only to high pressures (>25 mm Hg).¹⁰ The high-threshold stretch receptors may have a nociceptive function. Gallbladder distension activates spinothalamic cells in the T1–5 portion of the cord, cells that are also activated by cardiac afferents and somatic afferents from the medial aspect of the arm and the chest wall.

Pain from the upper portions of the esophagus is most likely caused by activation of vagal afferents.³ Heartburn pain may be a vagally mediated phenomenon, but little study of the activation of pain by acids in the esophagus has been carried out.

Distension of the renal pelvis or ureters is known to produce pain, but few studies have characterized afferent responses from the urinary tract. Pain of urethral origin is probably transmitted via sacral nerve roots rather than through sympathetic afferents. Urinary bladder distension is capable of producing cardiovascular responses, but, unlike gallbladder distension, is associated with reduced heart rate and contractility.

Dorsal Horn Mechanisms

The spinal dorsal horn and its analog in the medulla are exceedingly complex sensory processing areas. They contain the central terminals of peripheral afferent fibers, projection neurons of spinothalamic and other ascending tracts, local neurons that activate or inhibit projection neurons, and axon terminals of descending brain stem fibers.

As nerve roots approach the dorsal horn, segregation of fibers according to size takes place, with large myelinated afferents becoming arranged medially and small unmyelinated and thinly myelinated fibers arranged laterally. Most large myelinated fibers enter the cord medial to the dorsal horn. Many of these axons bifurcate, sending one branch rostrally in the dorsal columns. The other branch enters deeper layers of the dorsal horn, sending terminals into laminae IV and V and extensive arborizations into the substantia gelatinosa (laminae II and III).

Most unmyelinated or thinly myelinated afferents pass directly through the outer layer of lamina I, where they synapse with marginal layer cells and send a few branches into the underlying substantia gelatinosa. Some axons pass ventrally through these outer layers to terminate in laminae V and X.¹¹

There are two groups of cells in the dorsal horn that respond to noxious stimulation in the periphery. One group, located mainly in lamina I, responds exclusively to noxious stimulation. Most of these cells, termed nociceptive-specific, have relatively limited receptive fields, confined to some fraction of a dermatome. The second group of cells, termed wide dynamic range neurons, can be activated by either tactile or noxious stimuli. Most of these cells are located in lamina V. They have large, complex receptive fields that often have a central area of responsiveness to either noxious or tactile stimulation, surrounded by an area of responsiveness only to noxious stimulation. Stimulation just outside the entire receptive field may produce inhibition. It is generally accepted that wide dynamic range neurons contribute to pain perception and that their selective activation is sufficient to cause pain. It is likely that many of the neurons in laminae I and V that respond to noxious stimuli are STT neurons.

Activation of the Dorsal Horn Projection System

There is considerable evidence that excitatory amino acids (EAAs) such as glutamate and aspartate are the principal neurotransmitters responsible for activation of dorsal horn neurons following noxious stimulation. Evidence for this conclusion is based on localization of these substances in nerve terminals in the dorsal horn, detection of release of EAAs following noxious stimulation, and behavioral evidence of hyperalgesia following intrathecal (IT) administration of EAAs in animals.¹²

Several types of EAA receptors are involved in the initiation of neuronal excitation that leads to the transmission of pain information. The AMPA receptor responds briefly (tens of milliseconds) and unconditionally to the release of glutamate.¹³ Activation of the NMDA receptor results in postsynaptic potentials that may last much longer, on the order of seconds to minutes. The NMDA receptor is normally unresponsive to EAAs because of a voltage-dependent block that occurs at normal resting membrane potentials and physiologic concentrations of Mg²⁺. Following a period of depolarization of the AMPA receptor or activation of neurokinin (NK-1) receptors by substance P (which is released from nociceptive afferent terminals following intense activation), the NMDA receptor becomes responsive to EAAs and produces a relatively prolonged postsynaptic response (see Fig. 55-1). In such a way, the brief response to a short-lived stimulus is converted to a prolonged response, one likely to be perceived as pain, following prolonged repetitive stimulation. The phenomenon of “windup,”¹⁴ the progressive increase in response to repetitive, brief C-fiber intensity stimulation, appears to be NMDA receptor-mediated, and can be blocked by pretreatment with NMDA receptor antagonists. It has been proposed that the NMDA receptor is principally activated by aspartate released from excitatory interneurons in the dorsal horn, while the AMPA receptor is usually activated by glutamate released directly from afferent nerve terminals.

There is evidence for still more prolonged increases in sensitivity of spinal cord neurons to sensory inputs occurring in response to ongoing nociceptor activation. Changes in dorsal horn neural function known as long-term potentiation (LTP) can occur in the spinal cord and may last hours to days. A similar phenomenon is seen in the hippocampus, and is associated with learning and memory function. As with the spinal cord phenomenon of augmented transmission of nociceptive transmission (allodynia, hyperalgesia), LTP in the hippocampus is NMDA receptor-mediated. It has been shown that prolonged excitation and release of EAAs in certain areas of the CNS can lead to damage or loss of neurons, and that such neurotoxicity is mediated at least in part by the NMDA receptor.¹⁵ Following some types of peripheral nerve lesions in animals, the appearance of small darkly staining neurons in the substantia gelatinosa occurs coincidentally with the development of thermal hyperalgesia.¹⁶ It has been proposed that these cells represent degenerating inhibitory interneurons damaged by the large amounts of EAAs released by barrages of neural discharge from the injured nerve segment.¹³

Several neuropeptides that are released in the dorsal horn in response to noxious stimulation, including SP, neurokinin A, somatostatin, CGRP, and galanin, are thought to play a role in modulating the neural responses of dorsal horn cells sensory inputs.¹⁶ The role of SP is perhaps best understood. It activates a postsynaptic NK-1 receptor resulting in reduction of K⁺ efflux (μ -opioids and α_2 -adrenergic agonists enhance K⁺ efflux), thereby increasing neuronal excitability. Its activity is limited by rapid enzymatic degradation. Neurokinin A also acts as an NK-1 receptor agonist but is more slowly broken down and may actively enhance dorsal horn transmission for a period of many minutes to a few hours following injury.¹⁷

Intense or prolonged noxious stimulation produces sustained depolarization of dorsal horn neurons leading to a series of intracellular events that alter cellular responsiveness to subsequent sensory input. Ca²⁺ influx into dorsal horn cells is generated by both membrane depolarization and NMDA receptor activation. Ca²⁺ influx then results in a series of intracellular events. These include the activation of phospholipase A₂ (PLA₂) and increased production of intracellular arachidonic acid and the products of the prostaglandin cascade. The resultant spinal cord accumulation of prostaglandins augments the hyperalgesic state through mechanisms not yet identified. Evidence for this proposal is provided by the fact that intrathecal prostaglandins are indeed capable of inducing a hyperalgesic state,¹² and that hyperalgesia induced by IT NMDA is inhibited by IT administration of NSAIDs.¹⁹

Another mechanism by which Ca²⁺ influx enhances responsiveness to noxious stimulation is through an increase in the production of intracellular nitric oxide (NO). Intracellular Ca²⁺ activates the enzyme nitric oxide synthase (NOS) through a calcium-calmodulin mechanism. NO is produced by the action of the enzyme on L-arginine. NO, which is rapidly diffusible both within and outside the cell, activates protein kinases through a cyclic GMP mechanism, leading to enhanced release of neurotransmitters from primary afferent terminals and enhanced responsiveness of the NMDA receptor in postsynaptic neurons. IT administration of substances that block the synthesis NO has been shown to inhibit nociceptor-induced spinal sensitization.²⁰

Still other intracellular events, triggered by the action of EAAs and neuropeptides on metabotropic receptors, may lead to enhanced sensory processing. The activation of intracellular phospholipase C (PLC) stimulates the formation of inositol triphosphate (IP₃) and diacylglycerol (DAG). IP₃ stimulates release of intracellular Ca²⁺ stores, while DAG leads to increased production of protein kinase C (PKC). PKC further enhances NMDA receptor excitation and increases the expression of proto-oncogenes such as *c-fos* and *c-jun*, which control transcription of genes encoding a variety of neuropeptides that modulate responses to noxious stimuli.¹⁶ Agents that inhibit production of PLC (e.g., neomycin) or PKC (e.g., H-7) reduce the delayed hyperalgesic response to subcutaneous formalin injection in rats (see Fig. 55-1).²¹

PKC is involved in the development of opioid tolerance.²² Following prolonged occupation of opioid receptors on post-junctional dorsal horn neurons, there is translocation and activation of PKC, which in turn may uncouple the G protein that activates the potassium channel from the opioid receptor, producing tolerance. Thus activated, PKC may also enhance calcium influx through the NMDA receptor, producing sensitization of the cell as described above. In addition, PKC activated by the activity of EAAs on the NMDA receptor is capable of uncoupling the opiate receptor mechanism, reducing opioid responsiveness (see Fig. 55-2). Thus, prolonged

opioid administration can lead to spinal sensitization, and prolonged EAA release, as occurs with neuropathic pain states, can reduce responsiveness to opioids.²²

Figure 55-2. A spinal cord model of morphine tolerance. Postsynaptic opioid (μ) receptor occupation by an exogenous ligand such as morphine may initiate GTP binding protein-mediated kinase C (PKC) translocation and activation (*step 1*). PKC translocation/activation (*step 2a*) causes a removal of the Mg^{2+} blockade of the NMDA receptor (*step 2b*). With this blockade removed, even small amounts of EAA ligands, which could be released from presynaptic terminals of primary afferent fibers, supraspinal descending pathways, and/or spinal dorsal horn interneurons, could activate the NMDA receptor (*step 3*) and allow localized Ca^{2+} channel opening. An elevation of the intracellular Ca^{2+} level leads to activation of additional PKC (*step 4a*), production of NO via Ca^{2+} -calmodulin mediated activation of NO synthase (*step 4b*), as well as regulation of relevant gene expression (*step 4c*). PKC may then modulate μ -opioid activated, G-protein-coupled K^+ channels (*5a*) or uncouple the G-protein with the μ -opioid receptor (*5b*). In addition, NO may activate various protein kinases via cGMP and thus participates in the modulation of the μ -opioid activated, G-protein-coupled K^+ channels within the same cell. Perhaps more importantly, NO may diffuse out of the neuron enhancing presynaptic release of endogenous EAAs, resulting in a positive feedback (*step 6*). In this way, exogenous opiates may increase the basal level of presynaptic EAA release via the NO mechanism initiated by postsynaptic opioid action. This model suggests that morphine-induced presynaptic EAA release, postsynaptic NMDA receptor activation, and intracellular biochemical consequences are critical, and these factors operate in concert to result in the development of morphine tolerance. The role of presynaptic μ -opioid receptors in the development of morphine tolerance remains to be determined (see the text for a detailed discussion). Since many of the intracellular steps following the activation of the NMDA receptor in this proposed model of morphine tolerance are similar to those that occur following injury-induced hyperalgesia (see Fig. 55-1), it is conceivable that NMDA receptor-mediated intracellular changes initiated by exogenous opiate administration may also lead to the development of hyperalgesic states by means of increasing efficacy of the NMDA receptor-activated Na^+ channels and/or metabotropic EAA receptors. It is also likely that hyperalgesic states following the development of tolerance may contribute to signs of physical dependence in the process of opiate abstinence. Abbreviations not appearing in Fig. 55-1: μ -R = μ -opioid receptor; EXO = exogenous opiates; ENO, endogenous opioids. (From Mao J, Price DD, Mayer D: Mechanisms of hyperalgesia and morphine tolerance: A current view of their possible interactions. *Pain* 62:259, 1995.)

There are several systems capable of suppressing activity in STT neurons. There is substantial evidence that both descending and segmental neuronal inputs can inhibit activation of nociceptive-specific and wide dynamic range neurons. The amino acids glycine and γ -aminobutyric acid (GABA) are known to be inhibitors of synaptic transmission, and there is some speculation that they are important mediators of segmental inhibition of nociception. There are two known GABA recognition sites: $GABA_A$, for which muscimol and isoguvacine are agonists, and $GABA_B$, for which baclofen is an agonist. Benzodiazepines act to enhance the effect of GABA on $GABA_A$ receptors. When administered spinally, they produce a mild analgesic effect and inhibit sympathetic response to noxious stimuli.

Two pentapeptides, leucine enkephalin and methionine enkephalin, appear to be important spinal cord inhibitors of nociception. STT neurons in laminae I and V receive input from enkephalin-containing cells in the dorsal horn. It has been proposed that enkephalins are released in proximity to primary afferent terminals in the dorsal horn, activating presynaptic opiate receptors that prevent release of substance P. However, the presence of direct synaptic contact between enkephalin-containing cells and STT neurons suggests that their inhibitory mechanism is, at least in part, postsynaptic. Enkephalins are found in highest concentrations in laminae I and II but are also present in deeper laminae. Most dorsal horn enkephalins originate from intrinsic neurons.

It is not clear whether dorsal horn enkephalins function in a tonic fashion or whether their activity is stimulated for the most part by descending or peripheral segmental activity. If there is significant tonic inhibition by enkephalins, administration of naloxone should markedly increase activity in STT neurons. There is only equivocal evidence for such disinhibition. Release of enkephalins in response to descending neural activity has not been well documented. There is, however, evidence of enkephalin release in response to segmental activity.²³

Serotonin, or 5-hydroxytryptamine (5-HT) produces analgesia when injected intrathecally, and its antagonist methysergide attenuates the analgesia produced by certain pharmacologic interventions. It is likely that this neurotransmitter is involved in descending control mechanisms that originate in the midbrain and medulla. It has been speculated that the analgesic effect of some of the tricyclic antidepressants may be related to an increase in serotonin availability in the CNS. However, the class of antidepressants known as serotonin-specific reuptake inhibitors (SSRIs) appears to have little or no beneficial effect on those conditions that typically respond to tricyclics.

Norepinephrine is also an important neurotransmitter in descending inhibitory pathways. Spinally administered adrenergic agonists, such as epinephrine, have been shown to have analgesic effects in animals. This analgesic effect is mediated by α_2 -adrenergic receptors. Evidence for this is provided by the fact that α_2 agonists such as clonidine and dexmedetomidine produce analgesia when injected spinally and that α_2 antagonists such as yohimbine and idazoxan block their analgesic effects. IT clonidine is now in use for the treatment of intractable cancer pain. It appears to be helpful in some opioid-tolerant patients.

Adenosine receptors appear to play a role in the modulation of nociceptive transmission in the dorsal horn. There are two receptor subtypes: A_1 , which inhibits adenylylase activity, and A_2 , which stimulates it.²⁴ Adenosine receptors may play a role in the analgesia provided by transcutaneous electrical stimulation, as it has been demonstrated that dorsal horn inhibition induced by high-frequency stimulation is blocked by methylxanthines, which antagonize adenosine receptor activity.²⁵ The adenosine receptor may also play a role in the mediation of analgesia induced by spinally administered opiates. Adenosine agonists have been shown to reduce the tactile hyperesthesia induced by low-dose spinal strychnine, a glycine receptor antagonist, and may prove to be effective in certain hyperalgesic states.

In summary, the dorsal horn functions as a relay center for nociceptive and other sensory activity. The degree of activation of ascending pain projection systems depends on the degree of activation of segmental and descending inhibitory neurons in the dorsal horn, the pre-existing concentration of excitatory neurotransmitters, the level of activation of inhibitory neurotransmitters, the intensity of the noxious stimulus, and the degree of sensitization of nociceptors in the periphery.

Ascending Pathways

The STT has been considered for many years to be the most important pathway transmitting nociceptive stimuli to the brain. Although it is important to normal perception of pain, it is by no means the only pathway with that function. The ability of patients to perceive pain following spinothalamic tractotomy provides evidence that other pathways are involved.

Many of the neurons in laminae I and V that respond to noxious stimulation are probably cells of origin of the STT. The majority of STT fibers cross near their level of origin. There are thought to be two functionally distinct divisions of the STT: the neospinothalamic tract, whose fibers tend to be more lateral, and the paleospinothalamic tract, located in the medial portion of the pathway. The phylogenetically newer neospinothalamic tract projects to posterior nuclei of the thalamus, such as the ventral posterolateral nucleus, and is thought to be involved with discriminative functions, e.g., location, intensity, and duration of noxious stimulation.²⁶ The paleospinothalamic tract projects to medial thalamic nuclei, and its activation is probably associated with autonomic and unpleasant emotional aspects of pain. This older portion of the STT is likely to be important in pain associated with denervation dysesthesia. Stimulation of the thalamic projections of the paleospinothalamic tract in patients with denervation dysesthesia reproduces the burning pain these patients experience spontaneously.²⁷

The spinoreticular tract is likely to play a role in pain perception. Its cells of origin are unknown. It is thought to produce arousal associated with pain perception and probably contributes to neural activity underlying motivational, affective, and autonomic responses to pain.²⁸ The spinomesencephalic tract projects to the midbrain reticular formation. It probably evokes nondiscriminative painful sensations and may be important in the activation of descending antinociceptive pathways.²⁸

Following bilateral spinothalamic tractotomy, it is still possible for patients to perceive pain from peripheral stimulation. There must necessarily be pathways in the dorsal portions of the spinal cord that are capable of producing pain perception. The spinocervical tract is a likely candidate for such a function. It is located in the

dorsolateral funiculus. Its fibers ascend uncrossed to the lateral cervical nucleus, which serves as a relay, sending fibers to the contralateral thalamus.²⁸ There is also evidence that some fibers in the dorsal columns are responsive to noxious stimuli.

Descending Control

In the early 1970s several reports showed that electrical stimulation of the periaqueductal gray (PAG) area of the midbrain could produce widespread analgesia in animals and humans. The PAG was later found to have high concentrations of endogenous opiates and to be rich in opiate receptors. Microinjection of small quantities of morphine into that area produces generalized analgesia. Anatomic connections from the PAG area to the nucleus raphe magnus and to the medullary reticular formation were subsequently described. From the nucleus raphe magnus, serotonergic fibers descend via the dorsolateral funiculus to spinal cord dorsal horn cells. It is not clear whether serotonergic fibers produce a direct, postsynaptic inhibition of STT neurons or whether they act by activation of inhibitory neurons that release enkephalins or GABA.

There are also adrenergic fibers that descend in the dorsolateral funiculus that are thought to be inhibitors of pain. The cells of origin of these descending adrenergic pathways are believed to lie in the locus ceruleus and parabrachial regions of the medulla. Stimulation of spinal α_2 -adrenergic receptors produces analgesia through G-protein-mediated K^+ channel activation.

Multiple environmental factors appear to activate descending pain control mechanisms. Nociceptive inputs and various types of stress can produce generalized increases in pain threshold. Anxiety, depression, and emotional distress can reduce pain threshold. The descending control mechanisms described may respond to such factors. Under normal circumstances, inhibitory and pronociceptive neurons located in the midbrain periaqueductal gray rostral ventromedial medulla (RVM) play an important role in integrating and coordinating behavioral and autonomic responses to noxious stimuli.²⁹ Following a brief noxious stimulus, certain cells, known as "off-cells," in the RVM abruptly cease firing. It is thought that these cells produce tonic inhibition of nociceptive reflexes, and their cessation is associated with loss of such inhibition. Other cells, known as "on-cells," show a sudden burst of activity just before a behavioral response to a noxious stimulus. Their activation appears to produce a facilitatory influence on nociceptive transmission. At least some on-cells are GABAergic and exert an inhibitory influence on descending inhibitory neurons, including off-cells. On-cell activity is inhibited by local application of opioids, which block their inhibitory effect on pain-inhibitory pathways.

Pain and Nerve Injury

Spontaneous discharge of injured peripheral nerves was demonstrated by Wall and Gutnick,³⁰ who reported spontaneous neural activity originating from experimentally induced neuromas. It was later demonstrated that sympathetic stimulation or norepinephrine infusion could increase such abnormal firing.³¹ There is now considerable evidence that changes in ion channel configuration and distribution are responsible for functional changes in the behavior of injured axons. Following nerve injury, there is an increase in the occurrence of large intramembranous particles, which represent surface proteins such as receptors and channel proteins. In addition, the membrane properties of a regenerating nerve tip differ from those of intact nerves. There is disappearance of the sodium-dependent action potential and an increase in conductance to Na^+ , K^+ , and Ca^{2+} .³²

In addition to impulse generation originating from the site of injury, there is considerable evidence that impulse generation occurs at points of membrane instability proximal to the injury. Wall and Devor³³ reported spontaneous discharge originating from dorsal root ganglia in sciatic nerve-sectioned rats. They proposed that the dorsal root ganglia impulses could contribute to pain after peripheral nerve injury.

Another possible mechanism for chronic pain following peripheral nerve lesions involves the short-circuiting of action potentials (ephaptic transmission, cross-talk) across demyelinated segments. Several possible types of interaction might exist. Demyelination of large afferent fibers could cause activation of nociceptors at the site of injury in response to stimulation of mechanoreceptors by non-noxious stimuli. Injury of motor fibers could cause nociceptor activation in response to motoneuron activation. Loss of Schwann cell protection of postganglionic sympathetics could produce nociceptor firing in response to sympathetic discharge.

Intact peripheral nerve pathways are essential for normal function of pain projection neurons and inhibitory interneurons in the dorsal horn. Following loss of peripheral nerve activity, there may be an increase in sensitivity or onset of spontaneous activity in STT neurons. It has been postulated that disruption of large afferents, which send extensive arborizations into the substantia gelatinosa, decreases the activity of inhibitory neurons in those areas.

Spontaneous activity or heightened sensitivity of neurons is thought to occur at more central locations within the pain projection system as well. Thalamic cells may undergo such changes following cord injury or some cerebrovascular accidents. Sensitization of central neurons may also occur some time after peripheral nerve injuries.

Sympathetically Maintained Pain

There are several mechanisms by which the sympathetic nervous system influences the perception of pain. Interactions between sympathetic outflow and spontaneous depolarization of injured nerve segments have already been discussed. Following trauma, surgery, and certain illnesses, a syndrome of pain, hyperalgesia, autonomic dysfunction, and dystrophy, known as complex regional pain syndrome (CRPS), can occur. A common explanation is that there is interference with the normal regulatory function of the sympathetics to the affected area induced by pain or injury, hence the former name of the syndrome, reflex sympathetic dystrophy (RSD). Periods of heightened sympathetic activity are thought to result in vasoconstriction, ischemia, changes in interstitial environment, and, perhaps, release of prostaglandins, bradykinin, and other pain-sensitizing substances. This explanation is highly simplistic and is contradicted by several clinical findings: (1) early in the course of the syndrome the affected limb is usually warm and erythematous, (2) microneurographic recording studies have failed to demonstrate alterations in sympathetic outflow in the affected limb, and (3) venous catecholamine levels in the affected limb are not elevated. There may be central dysregulation of autonomic function in these patients, however. Experimental evidence for interference with sympathetic regulatory function following injury was provided by Blumberg and Janig,³⁴ who demonstrated loss of the normal reciprocity between skin and muscle vasoconstrictors in animals with peripheral nerve lesions. Skin vasoconstrictors are normally under the influence of hypothalamic centers. They are important in thermoregulation and tend to be inhibited by stimuli that activate muscle vasoconstrictors, which are under medullary control. Following peroneal nerve lesions, skin vasoconstrictors begin to respond like muscle vasoconstrictors and appear to be under medullary control.³⁴

Another possible interaction between sympathetic activity and pain perception involves ephaptic transmission, or "cross-talk," between different fiber types at injured nerve segments. Segmental loss of myelin or protective Schwann cell sheaths could lead to depolarization of nociceptor fibers by efferent sympathetic transmission. Although such segmental demyelination has been demonstrated anatomically, physiologic evidence for the phenomenon is scant.

Another proposal is the direct sensitization of nociceptor nerve endings by sympathetic nerve terminals. Again, there is little evidence that such nociceptor sensitization occurs. There is, however, considerable evidence that sympathetic fibers are in direct contact with mechanoreceptors and that sympathetic activity can sensitize mechanosensitive afferents. Roberts³⁵ has proposed that a combination of sensitization of mechanoreceptors plus disinhibition of wide dynamic range neurons could occur in certain post-traumatic states. Such a situation would lead to high-frequency firing of STT neurons and pain perception in response to non-noxious mechanical stimulation.

Several studies have demonstrated sprouting of sympathetic neurons following nerve injury. These neurons, which are not normally present in the dorsal root ganglion, invade this structure to form elaborate arborizations, known as baskets, surrounding neuronal cell bodies.³⁶ It is not known as yet whether there is synaptic contact between the sympathetic fibers and the cell bodies, nor have the types of afferents whose somata are invaded by sympathetic sprouts been characterized. Nerve growth factor (NGF) and the cytokines leukemia inhibitor factor (LIF) and interleukin 6 (IL-6) appear to contribute to the initiation of sympathetic sprouting. There is considerable speculation, though so far no proof, that the interactions between sympathetic sprouts and DRG cell bodies is responsible in part for sympathetically maintained pain in some clinical states.

PSYCHOLOGICAL MECHANISMS

No discussion of chronic pain is complete without some consideration of the psychological factors that are related to pain. In 1986, the International Association for the Study of Pain published a taxonomy of pain-related terms to promote uniformity of usage and to enhance accurate reporting of clinical and experimental phenomena.³⁷ Pain was defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." The salient features of that definition are that (1) pain is unpleasant, which is no surprise to most; (2) it may have a sensory component, also not surprising; (3) it has an emotional component, which distinguishes it from other sensory experiences such as touch, pressure, and vibration; and, most importantly, (4) it is an experience and, as such, is subjective, personal, private, and verifiable only by report of the individual suspected of suffering from pain. This last point cannot be overemphasized. While much of what a physician does when dealing with pain patients is objectively verifiable by monitors, touch, or direct vision, these clinical tools only allow us to make inferences about another's suffering. The gold standard for determining if a patient is in pain is to ask the patient if he or she hurts. Other observations may aid in

formulating a diagnostic impression, but only the patient can tell you if he or she has pain.

Psychological mechanisms can contribute to the pain experience in two general ways. A direct influence is exemplified by a situation in which psychological factors are entirely the cause of a report of pain. An example of this is psychogenic pain, which is considered to be rare. The psychological construct that is invoked to explain this involves the production of a perception of pain as a result of purely psychological factors, such as the need to suffer, as a means of assuaging guilt, or as a way to resolve some other intrapsychic conflict. This type of condition does exist but is frequently overdiagnosed. In fact, the likelihood of diagnosing psychogenic pain is inversely proportional to the skill and expertise of the physician examining the patient. The histories of these patients present no clear patterns or similarities, making a neat diagnostic algorithm impossible. Dramatic presentations or, conversely, apparent indifference, are not pathognomonic.³⁸

Other direct psychological influences are found in the somatization disorders. These are a group of psychiatric disorders that are typified by a preoccupation with bodily function or symptoms.³⁹ Hypochondriasis is a condition in which the individual is preoccupied with the notion that he or she is sick, despite continual reassurance from physicians. The exact psychological mechanism is not well understood, but this condition should be treated by a psychologist or psychiatrist. In suspecting this diagnosis, it is wise to remember that the term arose from patients describing pain below the right costal margin (hypochondriac) at a time when cholecystitis was not recognized as a bona fide medical entity. Patients with fears or convictions that they are ill do, on occasion, turn out to be right,⁴⁰ so a careful history and physical examination coupled with performance of clearly indicated tests is advisable.

Somatization disorder is characterized by an onset of physical symptoms before the age of 30 years and includes at least 12 (for men) or 14 (for women) of 37 symptoms involving various organ systems. These symptoms are of sufficient severity to cause the individual to seek medical attention, to take medicines, or to otherwise alter his or her lifestyle. These patients typically have undergone extensive investigations, usually from multiple physicians, all of which have yielded negative, equivocal, or conflicting results. Frequent surgeries, usually of an exploratory nature, are a common historical feature. These features are superimposed on any genuine somatic diseases suffered by the person, presenting a complex clinical picture. The mechanism for this disorder is not proved, but it is suspected that these persons come from families in which little credence or attention is given to display of emotion, yet care and attention are provided in response to physical symptoms. Thus, the theory goes, the patient learns that the exhibition of a physical symptom results in attention to the patient's needs. This modus operandi becomes ingrained on a subconscious level and then becomes part of the person's psychic constitution. This condition is not nearly so rare as psychogenic pain and, therefore, is likely to be seen with some frequency by a physician treating patients presenting with pain.

Factitious disorders (Munchausen's syndrome) present with reporting of symptoms and the intentional creation of signs that are intended to lead a physician to suspect a medical or surgical disorder. Patients have been known to instrument their urethra to cause hematuria and complain of flank pain or to use tourniquets to induce edema of the limb. The motivation for this behavior appears to be to occupy the role of a patient. The reasons for this goal are poorly understood.

Another similar condition is malingering, which is differentiated only by motivation. In this case, the motivation to assume the role of a patient is driven by the wish to avoid some other alternative that the individual feels is distasteful, such as military service or apprehension by the police, or to achieve financial gain. Fortunately, these charades are usually transparent to the astute physician. The incidence of this disorder in pain clinics is probably low.

Indirect psychological effects that influence the pain experience are common in chronic pain syndromes. At its most basic level, the presence of an ongoing nociceptive process that is not well relieved and produces continual suffering is bound to have some psychological sequelae that will color the whole pain experience. Such secondary effects as sleep deprivation, fatigue, irritability, and anger are commonly observed.⁴¹

The issue of depression and pain has been discussed by several authors.^{38,42,43} It is not surprising that most patients with chronic pain are likely to show signs of depression. It is difficult at times, however, to clarify the distinction between a set of depressive features that are reactive to having chronic pain and an episode of major depression because there can be so much overlap in symptoms.⁴³ The Diagnostic and Statistical Manual of Mental Diseases³⁹ includes many somatic and related symptoms in its criteria for diagnosing major depression. Most chronic pain patients will have several of these, but the genesis of the symptom (*e.g.*, insomnia) may be due to the pain itself rather than depression. It is clear, however, that a negative affective state such as depression serves to enhance the suffering of a person with chronic pain.

Another indirect influence is that of pain behavior. Pilowsky *et al*⁴⁴ have described the concept of illness behavior as it applies to pain patients. Simply stated, an illness is the individual's reaction or response to a disease. Illness behaviors arise from the patient's underlying physical condition and may consist of active behaviors, such as taking pills and visiting physicians, or passive behaviors, such as not working and lying down or sitting much of the day. In many chronic pain patients the illness behaviors must become a focus of treatment.

Behaviors of any type are subject to influence by operant factors.⁴⁵ Operant conditioning states that the likelihood of a behavior being expressed in a given situation can be altered by the consequences of the behavior. In chronic pain, for example, pain behavior (moaning) may be unwittingly reinforced by a spouse (showing attention), resulting in an increased frequency of the behavioral expression in the presence of the spouse. This is an example of positive reinforcement. By rewarding the behavior, its frequency is increased. The term *secondary gain* is often used to describe the type of paradigm wherein the individual, despite suffering with pain, does receive some benefit from it. Negative reinforcement increases the frequency of the behavior by removing a noxious condition from the environment in response to the behavior. Avoiding taking the garbage out by complaining of back pain is an example. Punishment, or the provision of undesirable consequences in response to a behavior, and extinction, the provision of no consequences, lead to decreased frequency of a behavior.

Cognitive factors also influence a pain experience. The belief that a person has about the meaning of his or her pain can substantially alter the actual perception of the pain. An important issue in this regard is the perceived degree of control over the pain. Using this fact, it is common practice for dentists to tell patients to raise their finger if anything hurts during the procedure. This granting of control allows patients to tolerate procedures with greater comfort. Contrast this with a patient suffering from poorly controlled cancer. Here, every time a pain is experienced, it reminds the patient of the cancer and the likelihood of an imminent and probably painful death.

MANAGEMENT OF COMMON CHRONIC PAIN SYNDROMES

It is beyond the scope of this chapter to consider the entire spectrum of long-term pain problems. Instead, the medical management of several painful conditions that are likely to respond to regional analgesic techniques or other modalities that anesthesiologists are likely to use are discussed. In addition, this section presents, in general terms, the use of some pharmacologic agents that are helpful in certain pain syndromes and gives a brief overview of the psychological principles that are important in managing chronic pain.

Low Back Pain

Several low back structures are innervated by nociceptors and act as sources of pain under certain pathologic conditions. The outer third of the annulus of the intervertebral disk has sensory innervation. Pain associated with annular tears is generally thought of as occurring only in the back; but during discography, distension of the annulus commonly produces pain in the thigh and lower leg.⁴⁶ There is also evidence that, in the presence of chronic degenerative or inflammatory conditions, the vertebral bodies and vertebral endplates may become sources of pain.⁴⁷ Facet joints receive sensory innervation and, particularly if there are inflammatory changes in the joint, mechanical stimulation or injection of the joint may result in pain which may be localized to the back or may radiate to the buttock, thigh, and lower leg. A study using saline-controlled diagnostic local anesthetic injections of the facet joint indicated that in 40% of patients the facet joint was a source of low back pain.⁴⁸ Similarly, the sacroiliac joint is a source of pain in some patients, and injection of the joint reproduces back and lower extremity pain in some patients who have evidence of SI joint pathology. Using a rigorous paradigm requiring pain relief after two separate joint injections, Maigne *et al*⁴⁹ concluded that only 20% of patients with clinical symptoms compatible with sacroiliac arthropathy had pain of sacroiliac joint origin. Mechanical compression or traction on a normal nerve root produces painless paresthesias. However, similar stimulation of a chronically injured or inflamed nerve root produces sciatica, or pain in the normal sensory distribution of that nerve root.⁵⁰

Lumbosacral Radiculopathy

Mechanical nerve root compression was originally presumed to be the cause of pain in discogenic radiculopathy. The lack of uniform success with surgical decompression and the fact that many asymptomatic patients demonstrate substantial disk protrusion on myelography or on subsequent postmortem examination suggests that other mechanisms must be operative as well. Following a period of mechanical nerve root compression, an acute inflammatory process may ensue, leading to intraneural accumulation of serum proteins and fluid, raised intraneural pressure, ischemia, and axonal degeneration.⁵¹ There is considerable evidence that the contents of the intervertebral disk can produce severe inflammation in the spinal canal. Gertzbein *et al*⁵² found that patients with lumbar disk disease in which sequestration of nucleus pulposus occurred were highly likely to exhibit cellular immune responses to homogenates of lumbar disk material, whereas patients who did not show sequestration were less likely to show such a response. These findings led the authors to propose an inflammatory autoimmune mechanism for the radicular pain associated with disk rupture. Marshall and Trethwie⁵³ were able to demonstrate the production of antibodies to glycoproteins from nucleus pulposus among patients who suffered from acute lumbar disk disease. They also demonstrated severe inflammatory reaction to nuclear glycoproteins following pulmonary arterial

injection in a guinea pig heart–lung preparation.

A different line of evidence for the development of inflammation in response to disk rupture was presented by Saal *et al.*⁵⁴ They collected human disk samples removed at surgery from patients with symptomatic radiculopathy and analyzed the material for PLA₂ activity. They found extremely high levels in this material, 20- to 100-fold higher than activity from human inflammatory synovial effusion. They conclude that the high PLA₂ activity leads to inflammation at the site of disk herniation by action of the enzyme to liberate arachidonic acid from cell membranes.

Cytokines, including interleukins, nerve growth factor (NGF), interferons, and tumor necrosis factor (TNF- α), are thought to play an important role in the pathophysiology of radiculopathic pain. Intrathecal administration of the interleukin IL-6 can produce touch-evoked allodynia in rats, and substances that block the effects of TNF- α are capable of blocking the hyperalgesic effect of experimental mononeuropathy or endotoxin.⁵⁵

It has been proposed that epidural or subarachnoid injection of corticosteroids provides beneficial effects by reducing the inflammation initiated by either mechanical or chemical insult to the nerve root.⁵⁷ The earliest use of epidural steroids was published by Lievre *et al.*⁵⁶ in 1957, who reported good to excellent results in 50% of patients following injection of cortisone acetate plus radiographic dye. Most subsequent series of epidural steroid injections used a combination of local anesthetic and suspensions of insoluble steroids. To determine whether local anesthetic alone provided benefit for patients with sciatica, Coomes⁵⁸ compared patients receiving bed rest plus epidural injections of procaine with patients treated with bed rest alone. He found that patients treated with procaine became ambulatory in 11 days, while it took the noninjected patients an average of 31 days to regain ambulation. Swerdlow and Sayle-Creer,⁵⁹ in a nonrandomized study, found consistently better results among chronic pain patients treated with epidural lidocaine and methylprednisolone than for patients treated with epidural saline or lidocaine injections. There was no difference in success rates among the three treatment groups for patients with acute or recurrent sciatica. Winnie *et al.*⁶⁰ compared patients treated with epidural methylprednisolone with patients treated with local anesthetic combined with the steroid. Success was close to 100% in both groups, suggesting that the steroid, rather than the local anesthetic, was providing the benefit.

Reports on more than 7000 patients appear in the English language literature attesting to the beneficial effects of epidural steroid injections for the treatment of sciatica. However, while there have been anecdotal reports or noncontrolled case series attesting to the beneficial effect of epidural steroids in several thousand patients, only thirteen controlled, randomized studies of the use of caudal or lumbar epidural steroid injections have been published. Koes *et al.*⁶¹ found that more than half of these controlled studies had substantial methodologic flaws. Of four studies that had reasonable methodologies, two reported positive (beneficial) results and two reported negative results. Watts and Silagy⁶² performed a meta-analysis of nearly the same group of studies (11 randomized studies with 907 patients). In assessing the rate of treatment success, defined as >75% improvement for up to 60 days, they found the odds ratio for success in the steroid treatment group to be 2.61 (95% CI 1.90–3.77). For long-term (>12 months) treatment success, the odds ratio for the steroid treatment group was 1.87 (95% CI 1.31–2.68). There was no significant difference in outcomes between the caudal and lumbar route of injection. A more recent controlled study, not included in either of the above reviews, compared epidural methylprednisolone acetate to epidural saline.⁶³ The steroid-treated group experienced more improvement in sensory function and flexibility, but only at the three-week assessment.

Few studies have evaluated the long-term effects of epidural steroids. Abram and Hopwood⁶⁴ compared the long-term responses of patients who initially experienced a favorable response to epidural steroid injections to those of patients who were considered treatment failures. After 6 months, patients in the initial success group were significantly more likely to rate their pain level lower, had significantly less sleep disruption, and were significantly less likely to be unemployed as a result of their pain when compared with initial failure patients.

The L5 and S1 nerve roots are most commonly affected by disk disease. Those roots pass through a narrow lateral bony recess as they exit the spinal canal, a circumstance that increases the likelihood of root compression.⁶⁵ Symptoms of lumbosacral radiculopathy consist of varying degrees of low back pain, pain radiating a varying distance into the lower extremity, and, in more severe cases, motor and sensory loss consistent with damage to the affected root. Typical signs and symptoms are listed in Table 55-1. As noted above, the pain typically associated with nerve root pathology is often in the same distribution as pain associated with lumbosacral or facet arthropathy or with annular tears without nerve root pathology. The presence of sciatic stretch signs (positive straight leg raising, Lasegue's sign) or single segment sensory, motor, or reflex changes increase the likelihood that the pain is related to radiculopathy.

| Level of Herniation | Pain Distribution | Numbness | Weakness | Reflex Changes |
|---------------------|---|--|------------------------|-------------------------------------|
| L4–L5 (L5 root) | Low back, lateral thigh, anterior calf, ankle, and occasionally leg toe | Lower anterior thigh and patella | MS (quadriceps) | Diminished (low pat) |
| L4–L5 (S1 root) | Low back, lateral thigh, calf, ankle, leg toe | Lateral calf, web space of foot and second toe | Foot (dorsiflexion) | None |
| L5–S1 (S1 root) | Low back, lateral posterior thigh, and calf | Posterior calf, lateral heel, and foot | Foot (plantar flexion) | Diminished or absent (achilles jct) |

Table 55-1. PAIN DISTRIBUTION AND PHYSICAL SIGNS ASSOCIATED WITH ACUTE DISK HERNIATION

If bowel and bladder dysfunction are present, indicative of a large midline disk, prompt surgical intervention may be indicated. Otherwise, initial treatment of acute discogenic radiculopathy consists of short periods (a few days) of immobilization and mild analgesics followed by gradual resumption in physical activity. Prolonged immobilization has been shown to be counterproductive. If severe pain persists after reasonable trials of conservative management, epidural steroids may be used.

Triamcinolone diacetate or methylprednisolone acetate are the most commonly used preparations. Injections are generally performed as close to the affected nerve root as possible. Addition of a small volume (3–4 ml) of local anesthetic will produce considerable analgesia if it reaches the affected nerve root, confirming proper drug placement. In occasional patients, particularly those with S1 pathology, the drug will not spread adequately to the affected root. In that situation, caudal injection may result in better drug access to the injured nerve. Likewise, caudal introduction of a radiopaque catheter, advanced under fluoroscopic control to the appropriate neural foramen, may provide a better result. Reassessment should be carried out 1–2 weeks after the initial treatment. If the patient has little or no pain at the time of the return visit, repeating the injection is relatively unlikely to be of benefit. However, if it was felt that the drug may not have reached the affected root at the time of the initial injection, a repeat procedure is a reasonable option. If symptoms are improved at the time of the follow-up visit, but some pain is still present, it is likely that a repeat injection will produce further improvement. A third block can be performed 1–2 weeks later if some symptoms persist. An algorithm for epidural steroid treatment is shown in Figure 55-3.

Figure 55-3. Algorithm for treatment of sciatica with epidural steroid injections.

There appears to be extremely little risk of serious complications associated with the use of epidural steroid injections. Animal studies tend to confirm the safety of

neuraxial administration of depo steroids.^{66,67} Allegations that the 3% polyethylene glycol vehicle of methylprednisolone acetate (MPA) and triamcinolone diacetate (TD) is capable of producing neurologic damage⁶⁸ are based on studies of high concentrations of propylene glycol (80–100%) and appear to be unfounded. The doses of corticosteroids commonly used for the treatment of sciatica are capable of producing adrenal suppression for up to several weeks, and there are occasional reports of cushingoid side-effects, sometimes lasting for weeks or longer. For example, a single injection of triamcinolone into the epidural space for the treatment of low back pain in adult patients has been shown to acutely suppress the hypothalamic–pituitary–adrenal (HPA) axis as reflected by decreased plasma cortisol and adrenocorticotrophic hormone levels in response to a provocative stimulus.⁶⁹ When three epidural triamcinolone injections were administered at 7-day intervals, the median suppression of the HPA axis was less than 1 month following the last injection and all patients had recovered by 3 months. Sedation with midazolam in conjunction with the epidural steroid injection accentuates the suppression of the HPA axis.⁶⁹ These observations suggest the possible need for exogenous steroid coverage in patients undergoing major stress during the period that the HPA axis may be suppressed by epidural steroids. Epidural steroid injections should be used with caution in diabetic patients, who may be at added risk for epidural infections, and whose glucose control may be compromised. Because of the immunosuppression associated with the steroid, aseptic technique should be meticulous.

Most of the literature documenting the safety of epidural steroids comes from reports on the use of a small number of injections, usually one to three, and with modest doses, usually 40–80 mg MPA or 50 mg TD. There are few data to support the safety of this treatment when higher doses are used or when treatment is extended beyond 3 or 4 injections over a period of several weeks.

There is some evidence that complications can occur following IT steroid injections. Aseptic meningitis⁷⁰ and bacterial meningitis⁷¹ appear to be uncommon but real risks. Arachnoiditis⁷² and cauda equina syndrome⁷³ have been reported, but these cases are rare and have occurred after multiple injections over a prolonged time interval. Nevertheless, some physicians are using a test dose of local anesthetic prior to injection of steroid in order to rule out intrathecal placement of the needle.

Patients with chronic radicular low back pain are much less likely to benefit from epidural steroid injections than are patients with more acute symptoms. Abram and Anderson⁷⁴ reported in a retrospective study that patients with long-standing symptoms were much less likely to experience even transient relief from epidural steroid injections. Similar findings were seen in a subsequent prospective study.⁶⁴ Patients who had undergone previous back surgery also had a much lower success rate. Several mechanisms may lead to chronic radicular pain that is unresponsive to steroid injections. Spontaneous activity or ephaptic transmission may occur from the injured, demyelinated root. Scarring of the root, with replacement of neural elements with fibrous tissue, causes inelasticity of the nerve. The nerve root can no longer stretch with leg motion, and chronic mechanical irritation ensues.⁵¹ Loss of large afferent fibers may lead to disruption of dorsal horn gating mechanisms and disinhibition of spinothalamic projection cells. Loss of disk height following herniation can lead to narrowing of intervertebral foramina, with subsequent root irritation laterally, or may cause redundancy and buckling of the posterior longitudinal ligament, which can effectively narrow the spinal canal. Loss of disk height can lead to facet joint subluxation and degeneration, producing pain from the joint itself and to osteophyte formation, which can narrow foramina or the central canal. Injury to the vertebral plate, the cartilaginous portion of the vertebral body adjacent to the disk, often accompanies disk disease and may lead to osteophytic growth into the central canal.

Lumbosacral Arthropathies

Degeneration and inflammation of the lumbar facet joints and sacroiliac joints can produce low back pain that is often difficult to distinguish from radicular pain. Both conditions may cause pain that radiates to the lower extremities. Computed tomographic scanning is a fairly reliable method of demonstrating pathology in these joints.^{75,76} Bone scans, particularly single-photon emission computed tomography (SPECT) scanning, may also be useful diagnostically.

When facet arthropathy is the suspected cause of low back pain, the diagnosis can be confirmed by injection of local anesthetic into the facet joint. The procedure can be done easily under fluoroscopic control. The patient is placed prone and the affected side is tilted upward until the joint space is visualized (Fig. 55-4). Proper needle placement can be confirmed by injection of 0.5–1 ml of nonionic contrast. The injection should transiently reproduce the patient's pain, and the dye will outline the extent of the capsule. Injection of 1 ml of local anesthetic should produce dramatic relief of arthropathic pain. Injection of a small volume of insoluble corticosteroid into an affected joint has been reported to produce analgesia lasting 6 months or longer in about one third of patients who experience relief from the local anesthetic. Nonsteroidal anti-inflammatory drugs may be of some benefit.

Figure 55-4. Right L4–5 and L5–S1 facet injections. Note the slight bending of needle at the L4–5 level, which is typical when the needle lies within the joint space.

When sacroiliac pathology is demonstrated, injection of the joint with local anesthetic will help confirm the diagnosis. In an uncontrolled study, we found that 25 of 35 patients with suspected sacroiliac disease experienced pain relief from local anesthetic injection of the joint. After injection of triamcinolone diacetate, 7 of 20 patients who were followed long-term experienced at least 6 months of moderate to complete pain relief (Abram SE, unpublished data). As noted previously, a more rigorous local anesthetic treatment paradigm showed only a 20% response to local anesthetic injection.⁴⁹

Myofascial Pain

The myofascial syndrome is an extremely common cause of somatic pain. It is associated with marked tenderness of discrete points (trigger points) within affected muscles, pain that is referred to areas some distance from the trigger point, and the appearance of tight, ropy bands of muscle. Autonomic changes, such as vasoconstriction and skin conductivity changes, may occur some distance from the affected muscle.⁷⁷ Biopsies of trigger points have been reported to show little or no change or to show degenerative changes, the severity of which corresponds to the intensity of the symptoms.⁷⁷ Although the pathophysiology of the condition has not been clearly defined, Travell and Simons⁷⁷ propose the following explanation: acute muscle strain causes disruption of sarcoplasmic reticulum and release of calcium, which in turn produces sustained or repeated contraction and fatigue. Blood flow becomes inadequate for the degree of metabolic activity occurring locally. Adenosine triphosphate becomes depleted, preventing release of myosin from actin, causing sarcomeres to become rigid and affected muscles to become taut. Nociceptor-sensitizing substances, such as prostaglandins, bradykinin, and serotonin, are released from platelets and mast cells, causing increased firing of muscle nociceptors.

Many of the commonly affected muscles, the sites of their trigger points, and their zones of referred pain have been mapped out.⁷⁸ The scapulocostal syndrome, one of the most common patterns of myofascial pain, is characterized by a trigger point located just medial and superior to the upper portion of the scapula and pain that can radiate to the occipital region, shoulder, medial aspect of the arm, or anterior chest wall.⁷⁹ Myofascial pain involving gluteal muscles produces pain referred into the posterior thigh and calf, mimicking S1 radiculopathy. Myofascial pain involving the piriformis muscle, which overlies the sciatic nerve, can produce sciatic irritation and, occasionally, hypoesthesia, again resembling radiculopathy.

The most important aspect of treatment for myofascial pain is to regain muscle length and elasticity. This is best done by maneuvers that gently stretch affected muscles. Because of the sensitization of muscle afferents, appropriate physical therapeutic maneuvers are often painful and may reinstate muscle contraction. Therapy aimed at reducing muscle pain and sensitivity should therefore be employed before stretching exercises. Trigger point injection, infiltration of local anesthetic directly into the trigger point, is a valuable initial therapy. Pain relief following injection confirms the diagnosis of myofascial syndrome, and a series of several injections performed daily or every several days can markedly reduce muscle sensitivity. Fairly vigorous therapy can be carried out during the analgesic period after each injection. Ultrasound therapy applied over the affected muscle may also produce periods of analgesia.

Trigger point injections and ultrasound require the participation of trained personnel, precluding their use on a frequent regular basis (e.g., several times per day). Several treatment modalities can be used by the patient alone or with the help of family members. Transcutaneous electrical nerve stimulation (TENS), applied directly over the trigger points, may produce analgesia during stimulation and often for some time afterward. Stimulation should be carried out for 20–30 minutes prior to

stretching exercises. Some patients who do not respond to the usual high-frequency TENS may benefit from a brief period (about 5–10 minutes) of low-frequency (2–4 Hz) high-intensity TENS. The current should be high enough to cause muscle contraction and mild discomfort. Vapocoolant spray (e.g., fluorimethane) sprayed over the affected muscle may produce transient analgesia sufficient to facilitate physical therapy. Massage of the affected muscle with ice may also be of some benefit.

Injection of myofascial trigger points with botulinum toxin, which produces a long-lasting block of acetylcholine release from peripheral nerves, has been shown to provide lasting pain relief in myofascial syndrome.⁸⁰ Pain relief begins within one to several days after injection and generally lasts several weeks. The principal side-effect is weakness in the injected and adjacent muscles.

Myofascial pain often develops in patients whose response to stress is an increase in muscle tone. This mechanism frequently contributes to the pathophysiology of tension headache. Surface measurement of electromyography in such patients will often demonstrate extremely high activity at rest. Electromyographic biofeedback is a useful added therapy for such patients and appears to be helpful in preventing future painful episodes for patients with recurrent problems.

Complex Regional Pain Syndromes

The term *reflex sympathetic dystrophy* (RSD) has been widely used to describe a group of conditions associated with burning pain in an extremity, dystrophic changes in skin, hair, nails and joints, allodynia, and signs of autonomic dysfunction, including skin temperature changes and alterations of sweat gland activity. The term *causalgia* has been used to describe a syndrome with similar clinical features following injury to a major nerve trunk. The term *sympathetically maintained pain* (SMP) has been used synonymously with both of these syndromes, implying that the autonomic nervous system is somehow involved in the pathophysiology of these conditions. While autonomic dysfunction is clearly evident in some cases of causalgia and RSD, it is not a prominent feature in some cases, and many patients with these conditions fail to respond to blockade or ablation of sympathetic fibers. Therefore, the term *complex regional pain syndrome* (CRPS) has become widely accepted.⁸¹ Complex regional pain syndrome type I (CRPS-I) is the term that has replaced the term RSD, and CRPS-II is now used in place of the term causalgia. The term *sympathetically maintained pain* describes that component of pain that is initiated or maintained by activity in the sympathetic nervous system, including both efferent sympathetic nervous system activity and circulating catecholamines. Painful conditions that are not typical of CRPS may have a sympathetically mediated component. Patients with certain types of neuropathic pain do not exhibit the typical clinical features of CRPS and yet experience significant pain relief following sympathetic blockade. Likewise, some patients with typical features of CRPS experience no relief from sympathetic denervation. Pain that does not appear to be sympathetically mediated is termed *sympathetically independent pain* (SIP).

CRPS-I

Common antecedents to the development of this syndrome include crush injuries, lacerations, fractures, sprains, and burns. Many postoperative cases occur after surgery involving the median nerve distribution, such as carpal tunnel release or palmar fasciectomy. The syndrome occasionally occurs after cerebrovascular accident or myocardial infarction. The pain is usually burning in quality and is often accompanied by diffuse tenderness and pain on light touch. The hand or foot are commonly the major sites of pain. The pain and hypersensitivity often spread beyond the original sites of pain.

Autonomic dysfunction is manifested as changes in skin temperature, cyanosis, edema, and hyperhidrosis. Early in the course of the disease, the skin may be warm and erythematous, with occasional to frequent bouts of intense vasoconstriction. As the process becomes more chronic, the involved extremity is usually cool and pale or cyanotic. The vascular phase of bone scanning often demonstrates differences in flow between the normal and the affected extremity. Thermography or local measurement of skin temperature using surface thermistors is also useful in documenting differences in regional blood flow.

Dystrophic changes become increasingly evident with time if the condition is untreated. Skin of the affected area becomes smooth and glossy. Bone demineralization takes place to a much greater extent than would be expected on the basis of reduced activity. Joints in the affected extremity become stiff and painful as a result of synovial edema, hyperplasia, fibrosis, and perivascular inflammation.

Local anesthetic blockade of the sympathetic chain is useful diagnostically, particularly when only a portion of the spectrum of possible symptoms is present. Cervicothoracic sympathetic block is usually carried out by injection of local anesthetic on the anterior tubercle of C6 (Fig. 55-5) or on the medial portion of the transverse process of C7. Unfortunately, a moderate number of patients experience a Horner's syndrome but fail to demonstrate evidence of sympathetic denervation of the upper extremity. Using MRI scans, Hogan *et al*⁸² demonstrated that solutions injected paratracheally at the C6 or C7 anterior tubercle often fail to spread to the stellate ganglion. Subsequently, he and his colleagues described a CT-guided technique for direct injection of the stellate ganglion just anterior to the head of the first rib.⁸³ Using this technique, evidence of sympathetic denervation of the extremity is often seen after injection of as little as 1 ml of local anesthetic. Lumbar sympathetic block is performed by injecting local anesthetic at the anterolateral aspect of the lumbar spine (Fig. 55-6). Placement of the needle at the lower border of the L2 vertebral body minimizes needle contact with the nerve root and places the needle tip in plane of the sympathetic chain.

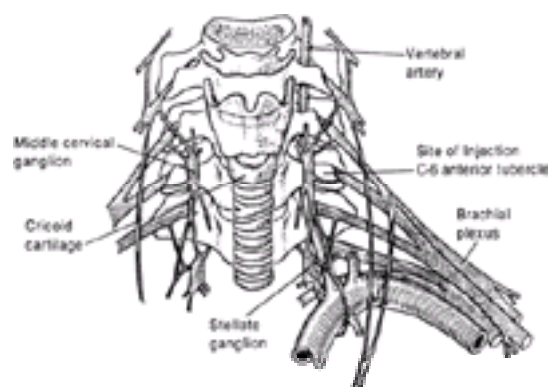

Figure 55-5. Site of injection for the C6 paratracheal approach to the cervicothoracic sympathetic chain. (From Abram SE, Boas RA: Sympathetic and visceral nerve blocks. In Benumof JL [ed]: Clinical Procedures in Anesthesia and Intensive Care, p 787. Philadelphia, JB Lippincott, 1992.)

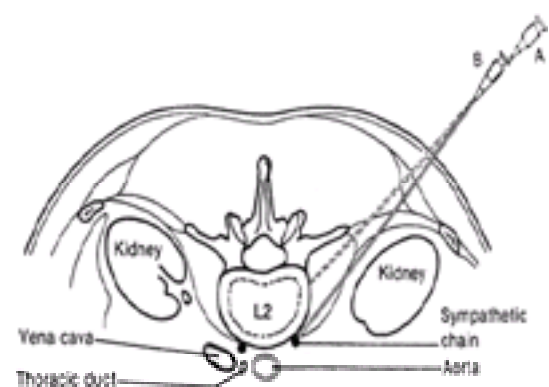

Figure 55-6. Initial needle position (A) and final needle position (B) for lumbar sympathetic block. Contact should be made at the lower portion of the L2 vertebral body, just cephalad to the L2–3 disk. (Reprinted with permission from Stanton-Hicks M, Abram SE, Nolte H: Sympathetic blocks. In Raj PP [ed]: Practical Management of Pain, p 674. Chicago, Year Book, 1986.)

Pain relief following sympathetic blockade does not guarantee that there is a sympathetically mediated component to the patient's pain. Pain relief may be the result of a placebo effect, spread of anesthetic to somatic afferent fibers, blockade of afferent fibers located in the sympathetic chain, or the systemic effect of absorbed local anesthetic.⁸⁴ Similarly, failure to achieve pain relief following sympathetic block does not guarantee that the pain is not sympathetically mediated. There may be sympathetic efferent fibers to the limb that do not travel with that portion of the sympathetic chain that has been interrupted.⁸⁴

Once it has been established that there is a sympathetically mediated component to the patient's pain, treatment consists of a series of local anesthetic sympathetic blocks. For patients with lower extremity pain, if lumbar sympathetic block is technically difficult or is particularly painful to the patient, repeated or continuous lumbar

epidural blockade can be used instead. Injections are generally continued until symptoms are minimal. Three to seven blocks are usually sufficient, but the series may occasionally be longer. Physical therapy, consisting of desensitizing techniques and active or active-assisted range of motion, is usually indicated and should be carried out immediately after each sympathetic block. Vigorous passive range of motion and heavy weights should be avoided, as they may retrigger symptoms. Patients whose condition is diagnosed and treated early are more likely to respond to sympathetic blocks. Success rates of 90% or more have been reported.⁸⁵ Unfortunately, few if any controlled studies documenting the long-term effects of sympathetic blockade exist, and the high success rates associated with early intervention may simply reflect the natural history of the process.

Hannington-Kiff⁸⁶ described an alternative technique for producing temporary sympathetic blockade using iv regional injection of guanethidine. The technique has been shown to be as effective as local anesthetic blockade⁸⁷ and has the advantage of being safer in anticoagulated patients. No reports have yet shown the technique to be superior to local anesthetic blocks. Unfortunately, injectable guanethidine is not available in some countries. Intravenous regional bretyllium has been used in a similar fashion, but there are no well-controlled studies documenting lasting benefit.

The use of systemic sympathetic blocking drugs is occasionally useful clinically. Prazosin and phenoxybenzamine, both α -adrenergic blocking agents, provide partial symptomatic relief in some patients, particularly those patients exhibiting signs of vasoconstriction. Intravenous phentolamine, given in small incremental doses up to 30 mg maximum, is helpful in predicting response to oral α -adrenergic blockers. Oral and transdermal clonidine are also occasionally useful. Other systemic medications that have been used with variable success include calcium channel blockers, tricyclic antidepressants, and anticonvulsants. Gabapentin has been used with some success, and is better tolerated than most of the older anticonvulsants.

Kozin *et al*⁸⁸ reported substantial benefit from treatment of RSD with a brief course of high-dose corticosteroids. Their success rate was 82%, which is particularly impressive in that many of their patients had experienced long-term symptoms. However, it is not clear whether improvement was permanent in these patients. In addition, their criteria for diagnosing RSD were somewhat vague and did not include response to sympathetic block, allodynia, hyperpathia, or burning pain. Sideeffects from high-dose systemic steroids are often troublesome. An alternative treatment is the intravenous regional injection of soluble steroids in the affected limb.⁸⁹ TENS can be a useful adjunctive treatment for RSD. Increased skin temperature during stimulation has been documented in patients who experience pain relief following treatment,⁹⁰ and TENS has been reported to provide substantial clinical benefit when used as the sole therapy for RSD.⁹¹

Patients with long-standing symptoms of RSD, who develop dystrophic changes and, frequently, the behavioral and psychological profiles typical of chronic pain patients, are extremely resistant to the types of intervention described previously. Surgical or neurolytic sympathectomy has been suggested as a treatment for RSD patients who respond only transiently to sympathetic blocks. It is the authors' experience, however, that most patients with chronic RSD get no relief or only a few days to weeks of benefit from sympathetic ablation. Therapy instead should be directed toward extinguishing pain behavior, increasing strength and mobility, and developing coping strategies.

CRPS-II

The term *causalgia*, which has been used to indicate a specific syndrome of burning pain and autonomic dysfunction associated with major nerve trunk injury,⁸⁵ has been replaced by the term *complex regional pain syndrome type II*, or CRPS-II. Most cases of CRPS-II are caused by gunshot wounds. Rapid, violent deformation of the nerve seems to play a major pathophysiologic role. Most cases involve partial injury to the brachial plexus, median nerve, or tibial division of the sciatic nerve proximal to the elbow or knee. Pain often begins immediately after injury and may spread to involve previously unaffected areas. There is usually severe burning pain, allodynia, and hyperpathia, often accompanied by deep shooting, crushing, or stabbing pains. The pain is aggravated by movement or any physical stimulation, such as light touch or pressure. Stimuli that increase sympathetic activity, such as a loud noise, a flash of light, or anxiety, often increase the severity of the pain. Pain may persist for many years in inadequately treated patients. There is usually evidence of reduced sympathetic activity in the affected extremity, which is generally warm, dry, and vasodilated. Vasoconstriction, hyperhidrosis, cyanosis, and edema are occasionally seen. Dystrophic changes of skin, bone, and joints, similar to those encountered in CRPS-I patients, often begin early.

Reports on the therapy of causalgia from the early 1900s described surgical destruction of peripheral nerves, which was uniformly unsuccessful. Opioid analgesics were likewise ineffective. In 1930, Spurling⁹² published encouraging results of treatment with sympathetic ganglionectomy. Since then, numerous reports have documented the efficacy of such treatment. Mayfield⁹³ reported complete relief of symptoms in 91% of 105 causalgia victims treated with surgical sympathectomy. Bonica,⁸⁵ in a review of 500 cases, found that 80% of patients responded to sympathectomy.

More recently, less invasive therapy has been undertaken in the management of CRPS-II. Neurolytic lumbar sympathetic block has been proposed as an alternative to surgical lumbar sympathectomy and has been shown to produce long-term sympathetic denervation in the large majority of patients.⁹⁴ Aggressive treatment with local anesthetic sympathetic blockade has met with some success. Bonica⁸⁵ reported success in 10 of 17 causalgia patients managed with frequent local anesthetic blocks. The authors have treated three patients with early, severe causalgia who responded dramatically to continuous-infusion lumbar epidural blockade or continuous-infusion brachial plexus block that was maintained for 5–7 days (unreported findings).

Herpes Zoster

Herpes zoster is caused by the varicella zoster virus, which, following a chicken pox infection, lies dormant in dorsal root ganglia. As immunity to the virus declines with advancing age or immunosuppression, the virus becomes active again. In patients with normal immune systems, the infection is confined to a single dermatomal segment. In immunocompromised patients, multiple segments may be involved.

Herpes zoster most commonly involves the thoracic and trigeminal dermatomes, with the ophthalmic division of the trigeminal nerve being second most common.⁹⁵ Autopsy studies have shown evidence of viral DNA in trigeminal ganglia in 87% of patients and in thoracic dorsal root ganglia in 53% of patients.

The incidence of herpes zoster in the general population is 1–2/1000 per year. It is higher among older patients, whose incidence is 5–10/1000 per year. Postherpetic neuralgia has been defined as pain persisting well beyond healing of the skin rash (4 weeks to 6 months). Overall incidence among patients with herpes zoster infection has been reported to range from 9 to 34%.⁹⁶ Incidence is considerably higher in older patients (16% in patients under 60, 47% in patients over 60).⁹⁷ Patients with severe pain during the acute phase of the disease are more likely to develop postherpetic neuralgia.

As the latent virus in the sensory ganglion becomes active, it causes a vesicular skin eruption characterized by inflammation, intranuclear inclusion bodies, and giant cell formation. Severe inflammation, hemorrhage, and necrosis occur in the dorsal root ganglia, dorsal horn, and adjacent meninges. Changes in the peripheral nerve include demyelination, Wallerian degeneration, fibrosis, and cellular infiltration.⁹⁸ Noordenbos proposed that pain of postherpetic neuralgia is associated with loss of large afferent fibers with relative preservation of C-fibers.⁹⁹ In subsequent studies, however, examination of biopsy and autopsy specimens from patients with or without persistent pain failed to show differences in populations of different fiber types.^{98,100} Some specimens showed predominantly large fiber loss, but this was seen in patients with and without postherpetic neuralgia. On the other hand, atrophy of the dorsal horn appears to be a regular autopsy feature in patients who had postherpetic neuralgia at the time of death. Persistence of inflammatory cells has been described in patients with long-standing postherpetic pain.¹⁰⁰

Because of anecdotal evidence that sympathetic blocks provide lasting pain relief in patients with acute herpes zoster,¹⁰¹ there has been speculation that intense sympathetic stimulation initiated by the virus is, at least in part, responsible for the pathologic changes that lead to postherpetic neuralgia. Winne¹⁰² has proposed that the increased sympathetic discharge initiated by the virus produces perineural ischemia that results in loss of large afferent fibers and persistence of small, unmyelinated neurons. There are several problems with the theory, including a lack of evidence that there is a local increase in sympathetic activity or that neural ischemia results from sympathetic discharge. In addition, the Noordenbos theory that pain is associated with small fiber predominance does not appear to be valid, nor is there substantial evidence that early sympathetic blockade reduces the incidence of postherpetic neuralgia.

A variety of treatments have been advocated for managing patients with acute herpes zoster. The goal of management is to control the pain associated with the acute eruption and, if possible, prevent the occurrence of persistent pain, or postherpetic neuralgia. Antiviral agents have been advocated for management of the acute stage of the disease. Acyclovir has been widely used and has been shown to modestly accelerate the rate of cutaneous healing and to reduce the severity of the acute pain, but there is little evidence that it reduces the incidence of postherpetic neuralgia.¹⁰³ On the other hand, one of the newer antiviral agents, famcyclovir, does appear to reduce the incidence and severity of postherpetic neuralgia if initiated soon after the eruption begins.¹⁰⁴

Corticosteroids have enjoyed some popularity for the treatment of the pain of acute herpes zoster. Eaglestein,¹⁰⁵ in a double-blind, controlled study, demonstrated that systemic triamcinolone reduced the duration of acute pain in patients over the age of 60. Several other studies have failed to demonstrate a reduction in the incidence of postherpetic neuralgia. Likewise, subcutaneous steroid infiltration¹⁰⁶ and epidural steroid injection¹⁰⁷ have been shown to reduce the acute pain intensity and/or duration, but there have been no controlled trials to determine whether they influence the incidence of postherpetic neuralgia. While there is some concern over the possibility that steroids may increase the risk of dissemination of the virus, there is little evidence that this is likely to occur.⁹⁵

Rosenak¹⁰⁸ was the first to report a beneficial effect of local anesthetic blocks on the pain of herpes zoster infection. He found that paravertebral sympathetic blocks or gasserian ganglion blocks with procaine resulted in dramatic relief of pain and rapid drying of vesicles. A number of subsequent uncontrolled studies also attest to the beneficial effect of sympathetic blockade. A single controlled study¹⁰⁹ attests to the ability of sympathetic blocks done early in the acute stage to prevent postherpetic neuralgia. The study contained only 10 patients in each treatment arm, and there have been no subsequent controlled studies to confirm these findings.

There is substantial evidence that local anesthetic blocks are ineffective in the management of postherpetic neuralgia. At best, they provide very temporary relief, often only for the duration of the anesthetic agent. Winnie¹⁰² recently confirmed this observation in a study that showed a very low incidence of lasting benefit from sympathetic blocks instituted more than a few months after the eruption. It is unclear whether the apparently favorable response to blocks instituted early in the course of the disease represents a real benefit from treatment or simply the natural history of the disease in the majority of patients.

The management of postherpetic neuralgia is often frustrating, as some patients respond poorly to nearly every therapy provided. Tricyclic antidepressants provide the best chance of relief with the fewest side-effects, although drowsiness, xerostomia, dysphoria, arrhythmias, and ataxia are potential problems. The onset of analgesia is slow (often requiring 2–3 weeks) and the relief is rarely complete, so many patients fail to realize they are experiencing much relief until they discontinue the drug and the pain returns to its former intensity. The addition of a second drug, such as an anticonvulsant (carbamazepine, valproic acid, phenytoin), may provide some additional benefit, but one must follow patients closely for the possibility of liver dysfunction or bone marrow depression. Gabapentin has been shown to be significantly more effective than placebo for the management of postherpetic neuralgia.¹¹⁰ The majority of patients required 3600 mg per day. Side effects of gabapentin are usually mild, there are few significant drug interactions, and it does not carry the risk of organ dysfunction seen with older anticonvulsants. Opioids rarely provide dramatic relief, and cause major problems with constipation in older patients. Most studies fail to show much benefit from epidural stimulators. TENS may help in occasional patients, but cause aggravation of pain in patients with severe allodynia and is not beneficial if there is considerable cutaneous sensory loss. Topical capsaicin is occasionally helpful, but can aggravate the pain in some individuals.

PHARMACOLOGIC TREATMENT OF CHRONIC PAIN

The long-term use of systemic opioids in patients who have noncancer pain continues to cause concern for many physicians. While most pain management physicians are comfortable with the use of opioids for patients who do not have a terminal illness, there is much disagreement regarding appropriate dosage, patient selection, and choice of drug. Among primary care practitioners, there remains much resistance to prescribing opioids for noncancer pain for a variety of reasons. These include the following concerns:

1. Addiction will occur.
2. Tolerance will develop, leading to loss of efficacy and increasing drug side effects.
3. Drug regulatory agencies will take action against the prescribing physician.
4. Patients may be diverting (selling) drugs.

The reality is that certain patients experience good pain control over long periods of time with minimal tolerance and few side-effects. Others have pain that is poorly controlled by opioids or have rapid reduction in efficacy requiring substantial dose escalation. While it is difficult to predict response to opioids in a given patient, there are some predictors of poor response. Patients with neuropathic pain are less likely to experience good pain control, and phasic pain (e.g., incident pain) is more difficult to control than constant or tonic pain. Patients with cognitive impairment or high levels of psychological distress are more likely to experience suboptimal pain control from opioids. A history of substance abuse is associated with a high risk of treatment failure and is felt by some physicians to represent a contraindication to opioid use.

The decision to prescribe opioids for patients with chronic pain should be based upon the answers to three questions:

1. Is there a history of significant substance abuse?
2. Is there a good therapeutic effect? The selected medication should provide complete or substantial analgesia. There should be minimal dose escalation over time, and there should be measurable improvement in functional activity.
3. Are there substantial side-effects? These should be minimal or tolerable.

Side effects should be monitored closely. Cognitive impairment is often insidious, and may not be recognized by the patient or family members during treatment, but becomes obvious when the medication is withdrawn. Sedation, nausea, constipation, insomnia, and sexual dysfunction are common problems.

As noted in the section on pain mechanisms, there is substantial theoretical evidence that chronic opioid use may lead to a state of hyperalgesia or sensitization of spinal pain projection systems. Persistent opioid administration may lead to loss of responsiveness to both endogenous and exogenous opioids and to hypersensitivity of systems that respond to noxious stimulation. Therefore, it is reasonable to withdraw and discontinue opioid administration for those patients who have evidence of central facilitation (allodynia hyperalgesia, hyperpathia) and who exhibit poor responsiveness to opioids. Occasionally, such patients experience gradual improvement in pain, generally beginning a few weeks after drug withdrawal. Often, they will experience a reduction in adverse effects, especially cognitive impairment, sedation, constipation, and sexual dysfunction.

Few patients with chronic pain are addicted to opioids. Addiction is defined as compulsive use of a drug or substance resulting in physical, psychological, or social harm to the user, and continued use despite that harm.¹¹¹ It may be difficult to recognize addiction in patients with persistent pain. Signs of addiction include:

1. Intense desire for the drug and unfounded concerns over availability.
2. Unsanctioned dose escalation.
3. Use of drug when pain is absent or treatment of non-pain symptoms (anxiety, depression).
4. Aberrant drug-related behaviors.

Some patients, appropriately, become concerned over the threat of drug discontinuation. When the potential loss of therapeutic benefit is anticipated, patients who are not addicted may exhibit anxiety and drug-seeking behavior. Undertreatment of pain may also result in addiction-like behaviors, which subside when pain is adequately treated. This phenomenon has been termed *pseudoaddiction*.¹¹²

Drug diversion, or sale of drugs for recreational or street use, is difficult to document or to disprove. Occasionally, an acquaintance or a family member will report such activity. Documentation depends upon a negative drug screen. The patient is asked whether he/she has taken the prescribed drug in the past several hours. If the answer is yes, a urine sample is obtained immediately and analyzed for the prescribed drug. If it is absent, diversion is likely.

When opioids are prescribed over long intervals, there should be an agreement, either informal or written, outlining the physician's obligation to continue treatment and the patient's obligation to meet several expectations of behavior. For patients who have previously failed to meet behavioral expectations, a written agreement, or "opioid contract" may be helpful. Under such a contract, the patient agrees to obtain prescriptions from one physician source and to fill prescriptions at one pharmacy, to discontinue use if there is rapid tolerance development, minimal therapeutic effect, substantial side-effects, or failure to achieve improved physical function. The patient agrees to take medications only as prescribed, and is not to request early refills. The patient agrees that no prescription will be issued in the event that drugs are lost, stolen, or accidentally destroyed. The physician, however, should be willing to adjust dosage as needed, within reason, particularly in the early stages of treatment. The patient should agree to unannounced random drug screening and to allow the physician access to all other medical records. The patient understands that violation of this agreement could result in discontinuation of opioid therapy and/or referral to an addiction specialist.

Adjuvant Analgesics

Imipramine was shown to be useful in treating chronic pain in 1960.¹¹³ Since then, the tricyclic antidepressants have come into widespread use in the management of certain chronic pain conditions, particularly neuropathic pain. The most popular explanation of the analgesic property of these drugs is that reuptake inhibition of serotonin and norepinephrine increases the levels of these inhibitory neurotransmitters in the brain stem and spinal cord.

The clinically relevant benefits to be expected from judicious use of these drugs in patients with chronic pain syndromes are normalization of sleep patterns, reduction in anxiety and depression (if present), and reduction of the patient's perception of pain. Although the antidepressant and pain-relieving effects are often delayed in onset, the improvement in sleep patterns provided by these drugs usually occurs promptly, often with the initial dose. Tricyclics suppress rapid eye movement (REM) sleep, and abrupt cessation can be associated with rebound in the form of restless sleep, with excessively vivid and pervasive dreams.

The common side-effects of the tricyclics include the antimuscarinic effects of xerostomia, impaired visual accommodation, urinary retention, and constipation.

Antihistaminic effects occur via blockade of both H₁ and H₂ receptors and include sedation and an increase in gastric pH. Orthostatic hypotension is mediated through the blockade of peripheral α₁-adrenergic receptors. Cardiac conduction effects mimic the actions of quinidine but in general are of little clinical relevance, except in the case of overdose. The lethal potential of these drugs in overdose is substantial, especially when doses exceed 2000 mg of amitriptyline or the equivalent.

Most studies of efficacy of these drugs in pain syndromes are open and are not controlled for placebo effects or for the presence of depression. Since the first double-blind placebo-controlled study by Watson *et al* in 1982,¹¹⁴ several well-designed studies have been conducted. They studied the effects of gradually increasing doses of amitriptyline in patients suffering from postherpetic neuralgia. After 3 weeks, 16 of 24 patients had obtained good to excellent relief, with doses below the norm for treatment of depression and with no change in a standard psychometric instrument assessing the presence and severity of depression. Getto *et al*¹¹⁵ reviewed 24 studies and found 19 to report some degree of benefit. Four double-blind placebo studies with a combined enrollment of 107 subjects yielded a 68% response rate with the active drug, as compared with a 13% response with placebo. Studies of a double-blind placebo crossover design included 140 subjects in five reports and revealed an aggregate response rate of 61%.

Beginning in 1987, Max *et al*^{116,117} published a series of double-blind, placebo-controlled trials that assessed the efficacy of antidepressants in certain painful syndromes. They showed that tricyclic antidepressants had analgesic effects independent of their effects on mood in neuropathic pain states (diabetic neuropathies and postherpetic neuralgia), although not all subjects had a beneficial response.

With the introduction of the serotonin-specific reuptake inhibitor (SSRI) fluoxetine, there was hope that the new class of drugs would provide pain relief at least comparable to the tricyclics. Clinical experience and research into this have yielded mixed results. In 1989, Diamond and Freitag reported their somewhat positive experience with the use of fluoxetine in the treatment of headache.¹¹⁸ This prompted numerous reports of fluoxetine use in pain, some of which purport to demonstrate some benefit.^{119,120} Max compared desipramine, amitriptyline, fluoxetine, and placebo in the treatment of diabetic neuropathy pain and found that, whereas both amitriptyline and desipramine were beneficial, fluoxetine had no more effect than placebo.¹²¹ Paroxetine has, however, been shown to be of benefit in the treatment of diabetic neuropathy pain.¹²²

As noted above, the pain-relieving effect of antidepressants has been attributed to the ability to block reuptake of serotonin and norepinephrine. Since serotonin is believed to be an important inhibitory neurotransmitter in descending pain inhibitory pathways, it was anticipated that the SSRIs would be at least as effective as the tricyclics, but with fewer side-effects. This has not generally been the case. It is now postulated that the tricyclic antidepressants may exert their analgesic and antihyperalgesic effects through other mechanisms. These drugs have been shown to bind at NMDA receptors, and can block NMDA-mediated synaptic activity.¹²³ This property, which may not be shared by many of the SSRIs, may be the principal mechanism of analgesic action.

Another class of agents said to have some efficacy in the treatment of chronic pain syndromes are the anticonvulsants. Unlike the antidepressants and neuroleptics, the pharmacology of this group varies substantially from one drug to another. The older members of this class that have some benefit in pain patients are phenytoin, valproic acid, carbamazepine, and clonazepam. The first three affect sodium, potassium, or calcium flux across the neuronal membrane, while clonazepam is a benzodiazepine and works via the benzodiazepine–GABA–chloride channel receptor complex.

The side-effect profiles of these drugs are also variable, with nausea and ataxia being commonly seen with any of them. Phenytoin can cause vitamin D and K and folate deficiencies, hirsutism, and gingival hyperplasia. Valproic acid use is associated with hepatic enzyme elevations, rare but occasionally fatal hepatic necrosis in children, and significant gastrointestinal effects that can be modified by the use of the enteric coated form of the drug. Carbamazepine can cause clinically a significant decrease in any of the blood elements selectively or can induce pancytopenia. Clonazepam is occasionally associated with disinhibition, leading to hostility and aggression or emotional lability.

Several new anticonvulsants appear to have some efficacy in treating painful conditions, particularly neuropathic pain. Gabapentin has been shown to provide significant pain relief for patients with reflex sympathetic dystrophy,¹²⁴ diabetic neuropathy,¹²⁵ and postherpetic neuralgia.¹¹⁰ It has antihyperalgesic effects in rat mononeuropathy models when administered spinally.¹²⁶ While it is a structural analog of GABA, its action does not appear to involve GABA-receptor interaction. Its mechanism of action has not been clearly defined. It has fewer side-effects and drug interaction than most of the older anticonvulsants.

Lamotrigine acts by inhibition of a sodium channel subtype, and has been shown to inhibit glutamate release. While there are a few reports of beneficial effects on neuropathic pain,¹²⁷ there are as yet no controlled studies demonstrating efficacy.

Use-dependent sodium channel blocking drugs have a role in the management of neuropathic pain. Systemically administered lidocaine is capable of suppressing spontaneous activity originating from experimentally induced neuromas at blood levels that produce no adverse effects.¹²⁸ Intravenous lidocaine and oral mexiletine have analgesic properties in some patients with neuropathic pain.¹²⁹ The analgesic effects of lidocaine are generally transient unless a continuous infusion is used. Lidocaine is commonly used to predict response to oral mexiletine, although its prognostic utility has not been well established. Lidocaine is given as a slow intravenous bolus at 1.5 mg · kg⁻¹ over 5 minutes followed by an infusion of 50 μg · kg⁻¹ · min⁻¹. The infusion is adjusted downward if symptoms of systemic toxicity become evident.

CANCER PAIN

In assessing patients with malignant disease who seek treatment for pain, it is essential to determine the specific site and mechanism of their pain. It is not enough to make a diagnosis of cancer pain. The entire range of acute and chronic pain mechanisms is encountered among patients with malignancy. It is also essential to know the stage of the patient's malignant disease. The approach to a given pain for a terminal patient may vary greatly from the approach to the same type of pain in a patient whose cancer is curable.

It is useful to determine whether the patient's pain is acute or chronic, and whether it is related to tumor progression, therapeutic intervention, or, as is occasionally the case, factors unrelated to the patient's malignant disease (arthritis, herniated disk, etc.). It is also useful to know whether the patient has a history of chronic pain or drug abuse predating the onset of malignant disease. Pain caused by tumor progression can result from compression or infiltration of peripheral nerves, nerve root, or spinal cord; infiltration of bone and soft tissue; obstruction or distension of visceral structures; and vascular occlusion. Surgical intervention may lead to scar pain, neuroma formation, sympathetic dystrophy, and venous or lymphatic obstruction. Chemotherapy may be associated with peripheral neuropathies. Therapy with steroids can cause aseptic bony necrosis or rheumatoid-like symptoms when therapy is withdrawn. Herpes zoster is associated with agents that suppress immune function. Radiation therapy sometimes results in esophagitis, plexopathy and myelopathy, and bone necrosis.

A substantial range of therapeutic options is available to the cancer patient. A major consideration in approaching the patient with severe pain is when to institute a particular modality. It is generally advisable to consider less invasive, lower-risk options initially, progressing to procedures that are more invasive, more painful to perform, and carry a higher risk of complications only when the more benign procedures are ineffective. Occasionally, it is prudent to select a more invasive procedure early in the course of management if it is thought that it will provide the patient maximum comfort or if the patient's pain level has progressed to a crisis state.

Pharmacologic Therapy

The use of oral analgesic agents is the mainstay of treatment for cancer pain. Adequate analgesia can be achieved in the large majority of patients with cancer-related pain if sound pharmacologic principles are employed. Several guidelines are essential to cancer pain management:

1. Use agents appropriate for the nature and severity of the patient's pain. Weaker opioids such as codeine may be adequate for mild to moderate pain. For severe pain, more efficacious agents such as morphine, hydromorphone, or methadone should be employed. Agonist–antagonist agents such as pentazocine and buprenorphine have a ceiling effect on their analgesic efficacy and are generally effective only for mild to moderate pain. Meperidine is a poor drug for repetitive dosing because accumulation of its metabolite normeperidine can cause CNS stimulation manifested as anxiety, tremors, or seizures. Be aware of the oral bioavailability of the drug used. The oral dose of morphine, for instance, is about three times the parenteral dose. When peripheral nociceptive processes are involved (such as bony or soft tissue invasion), the addition of nonsteroidal anti-inflammatory drugs may be very helpful.
2. Use adequate doses. The dose of opioid analgesic should be escalated until satisfactory analgesia occurs (usually the case) or until problematic side-effects occur. The dose required varies tremendously. It is not unusual for cancer patients to require 100–200 mg of oral morphine or its equivalent every 3–4 hours.
3. Maintain steady blood and tissue levels of analgesic. All analgesics should be given by the clock. As-needed administration may result in periods of inadequate relief. The time interval for administration should be consistent with the duration of action of the drug. When possible, use long-acting agents. Methadone, whose plasma half-life is 24–36 hours, can be given twice a day, avoiding the need for nighttime awakening for analgesic administration. Morphine is available in a time-release form that can be administered once or twice a day. Transdermal fentanyl provides prolonged, steady release that achieves fairly constant blood levels.
4. Consider the use of adjuvant drugs. Tricyclic antidepressants are frequently beneficial for postherpetic neuralgia, may be helpful for some patients with other types of neuralgic pain or denervation dysesthesia, and can be effective for treating concomitant depression. Some anticonvulsants may be beneficial for

neuralgic pain. Phenothiazines or butyrophenones have been shown to reduce symptoms of nausea, agitation, and pain when used in conjunction with narcotic analgesics. Corticosteroids should be considered for increased intracranial pressure, cord compression, severe bone pain, or pain from liver metastases. Calcitonin is effective in some patients with bone pain.

5. Anticipate and promptly treat side-effects. Constipation, which may become a major problem, occurs in most patients on opiates. Prophylactic management is essential. Nausea is a common opiate side-effect and concomitant administration of antiemetics may be necessary. Respiratory depression is unusual in tolerant patients. When it occurs in opioid-naïve patients, it should be treated with small incremental doses of iv naloxone (e.g., 0.05–0.1 mg) until the respiratory rate increases to an acceptable range. Large doses precipitate withdrawal, reverse much of the patient's analgesia, and initiate vomiting.

Patients who are unable to take analgesics orally can often be satisfactorily managed with parenteral opiate administration. Some patients who do not achieve satisfactory analgesia with oral drugs may have adequate control with parenteral agents, possibly because enteric absorption is poor. When the parenteral route is chosen, a constant-infusion technique or infusion plus patient-controlled analgesia (PCA) is usually superior to intermittent intramuscular injections. Many cancer patients have long-term venous access ports for chemotherapy that can be used for narcotic infusion.

When beginning opiate infusions, it is generally prudent to start with a relatively low-dose bolus injection and a modest infusion rate. If analgesia is inadequate after 1–2 hours, a small bolus is repeated and the infusion rate is increased. The process is repeated until the infusion rate is adequate. An alternative, less labor-intensive method is to use a PCA device. Once the daily opiate requirement is established, the patient can be switched to a portable, battery-powered constant-infusion device or portable PCA. When venous access is not available, portable external infusion devices can be used to deliver opiates subcutaneously through a "butterfly" type needle. The infusion site is changed every few days or when soreness occurs. When large doses are required, the use of a concentrated preparation of hydromorphone ($10 \text{ mg} \cdot \text{mL}^{-1}$) allows for longer intervals between refilling the portable infusion pump and reduces the mass of fluid injected.

Patients may experience diminishing analgesic effects from oral or parenteral opioids either from tolerance development or from increasing noxious stimulation related to tumor spread. A study by Collin *et al*¹³⁰ suggests that increasing dose requirement is nearly always associated with spread of disease. In either event, there may be a rationale for changing from morphine to a more potent drug such as fentanyl or sufentanil. This rationale is related to the concept of intrinsic activity (IA) of analgesics, *i.e.*, the fractional receptor occupancy (FRO) required to produce a given effect. A drug with relatively low IA, such as morphine or meperidine, requires a higher FRO than a drug with a high IA, such as fentanyl or sufentanil. Under conditions of tolerance, some receptors become unresponsive, and a drug with low IA may not be capable of interacting with enough of the remaining receptors to achieve adequate analgesia. Likewise, if the level of noxious stimulation increases, a greater number of receptors must be activated to produce a given analgesic effect, and a drug with a low IA may not interact with sufficient receptors to provide a reasonable analgesic response. Chronic infusion of morphine or meperidine in animals is associated with rapid development of tolerance to subsequent doses of morphine or meperidine, but not fentanyl or sufentanil.¹³¹

Transdermal fentanyl offers an alternative to parenteral opioids for patients who are unable to take medications orally. It is available in four dosage forms, which deliver 25, 50, 75, or $100 \mu\text{g} \cdot \text{h}^{-1}$ of fentanyl. The continuous use of the $100\text{-}\mu\text{g} \cdot \text{h}^{-1}$ form offers roughly the same analgesia as 360 mg of oral morphine or 60 mg of parenteral morphine per 24 hours. If higher delivery rates are required, multiple patches can be used simultaneously. Several hours are required for analgesia to develop following application of the transdermal patch and for analgesia to dissipate following its removal. An oral transmucosal preparation of fentanyl is available in doses up to 1600 μg . The onset of analgesia is much more rapid with this form of administration, with peak levels occurring at about 20 minutes.

Intraspinal Opioids

Some cancer patients do not achieve satisfactory analgesia with systemic opiates without pushing the doses to the point of marked sedation or confusion. Less conventional methods of opiate administration may be effective for some of these patients. The discovery of spinal cord opiate receptors led to speculation regarding the feasibility of intraspinal administration of opioids. Most experience with chronic intraspinal opioids administration has been with morphine, probably because it has a long duration, allowing bolus as well as continuous administration, and because it has been approved by the FDA for intraspinal use. The use of intraspinal opioids in patients who had not previously been on systemic opioids (e.g., postoperative patients and volunteers) was associated with nausea and vomiting, urinary retention, pruritus, and respiratory depression. As more experience with cancer patients accumulated, it became evident that these problems were, indeed, uncommon in this population, probably because the patients had been on systemic opioids chronically and had become tolerant to these side-effects.

Intraspinal opioids have been chronically administered by both the epidural and IT routes. IT administration has the advantage of allowing use of much lower doses, potentially minimizing systemic side-effects, but carries the risks of cerebrospinal fluid leak, headache, meningitis, and arachnoiditis. With either epidural or IT administration, the drug may be administered as a bolus, by infusion via an external pump, or by infusion via a totally implanted pump.

Percutaneous placement of an epidural catheter followed by bolus administration of opioid constitutes the simplest method of administration. The principal drawback of this technique is the risk of infection, which may spread to the epidural space. Such a technique is useful as a temporary measure to evaluate efficacy of epidural narcotics and is a reasonable method of administration for patients whose life expectancy is relatively short. The simple expedient of tunneling the catheter subcutaneously to the flank decreases the incidence of catheter dislodgement, allows the patient access to the catheter exit site to facilitate dressing changes, and may reduce the risk of epidural infection.

The decision to use an external pump is based on pharmacokinetic, technical, and financial considerations. There is some evidence that lower doses of morphine can be employed when using a continuous infusion. Coombs *et al*¹³² were able to provide good analgesia for a group of cancer pain patients using a mean dose of $2 \text{ mg} \cdot \text{day}^{-1}$ initially and $6.6 \text{ mg} \cdot \text{day}^{-1}$ at the end of 12 weeks. Reports of studies that use bolus injection describe much higher daily doses. Bolus injection produces much higher peak cerebrospinal fluid levels,¹³³ which may predispose to more cephalad migration of the drug. Another advantage to continuous-infusion techniques is the lower incidence of catheter occlusion. Inability to inject is a fairly common problem with bolus injection technique. When an obstructed catheter is removed, it is common to find fibrin material in the lumen. The use of large-bore silicone rubber catheters should minimize that possibility, however. Patients with epidural metastases may have severe pain with bolus injection but tolerate continuous infusion well. Perhaps the biggest drawback to continuous-infusion techniques is the expense. Portable pumps cost up to several thousand dollars, and the use of implantable systems adds several thousand dollars in additional physician and operating room expenses.

The totally implantable infusion pump is the most elegant, and expensive, drug delivery system. The Infusaid pump is a freon-driven device with a 50-ml, percutaneously filled drug chamber and a constant infusion rate. Pumps with a $2\text{--}3 \text{ mL} \cdot \text{day}^{-1}$ flow rate will run for 15–20 days between refills. Daily dose is adjusted by changing the drug concentration. A separate drug injection septum allows injection directly into the catheter, bypassing the drug chamber. The technique is most appropriate for patients with a relatively long life expectancy (months rather than weeks). Medtronic produces an electronically driven, externally programmable implanted pump that allows variations in rate plus the administration of intermittent bolus injections.

Perhaps the most frustrating problem associated with intraspinal opioid administration is the development of marked resistance or tolerance to the medication. While most patients develop tolerance slowly and to a limited degree, some demonstrate rapid escalation of doses. Woods and Cohen¹³⁴ reported a patient who had been on 280 mg of morphine intravenously and 90 mg of methadone orally per day who was initially comfortable on $5 \text{ mg} \cdot \text{day}^{-1}$ of epidural morphine. However, by the fifth day of epidural morphine administration, the dose had increased to $7\text{--}10 \text{ mg} \cdot \text{h}^{-1}$. One of the reported side-effects of such high doses, particularly with high-dose IT morphine, is the paradoxical development of segmental allodynia, which has been reported in patients¹³⁵ as well as in animal studies.¹³⁶

Neuraxial administration of nonopioid analgesics, either alone or in combination with opioids, may be effective when opioids alone are ineffective. Limited trials of the α_2 -agonist clonidine injected epidurally and intrathecally have proved at least temporarily effective. Animal studies suggest that there is a synergistic interaction between spinally administered α_2 -adrenergic agonists and opioids. Eisenach *et al*¹³⁷ found a dose-related analgesic effect from epidural clonidine in a series of nine cancer patients. They reported dose-related decreases in heart rate and blood pressure as well as somnolence. Seven patients were maintained on clonidine plus morphine infusions at home for periods of up to 5 months. These patients reported satisfactory analgesia and less nausea and sedation than they experienced with systemic morphine. There was minimal escalation of either clonidine or morphine during the combined infusions.

The intrathecal administration of baclofen has been used to treat patients with spasticity associated with multiple sclerosis and spinal cord injury. However, baclofen appears to have some potential as a spinal analgesic in patients without increased muscle tone who are resistant or tolerant to opioids. Intrathecal L-baclofen is antinociceptive in several animal models at doses that produce no discernible motor blockade.¹³⁸ It has been shown to produce substantial lasting analgesia in opioid-tolerant patients with neuropathic and radiculopathic pain at doses devoid of motor effects.¹³⁹

Another approach to the patient who has become resistant to neuraxial opioids is to use combinations of opioids and dilute local anesthetics. The combined use of these agents makes sense, as the local anesthetic, even at sub-blocking concentrations, can reduce the maximum firing rates of nociceptor fibers, and the opiate reduces the sensitivity of wide dynamic range and nociceptive-specific neurons in the dorsal horn to activation by nociceptors. Hogan *et al*¹⁴⁰ found that 10 of 16 patients, selected from a total of 1205 cancer admissions, required local anesthetic infusions along with epidural morphine to achieve satisfactory analgesia. Du Pen *et al*¹⁴¹ found that 68 of 375 patients (18%) failed to achieve satisfactory analgesia with neuraxial opioids alone. Sixty-one of those 68 patients experienced satisfactory

analgesia with the addition of local anesthetics.

Non-neurolytic Nerve Blocks

Myofascial pain is common among cancer patients. It is often associated with bony infiltration, neural compression, or visceral pain. Local anesthetic injections of trigger points may be surprisingly effective. Fluorimethane spray of trigger points combined with gentle stretching of affected muscles can be helpful. TENS is also likely to be of benefit.

Tumor compression of nerve roots, brachial or femoral plexus, or peripheral nerves sometimes responds dramatically to perineural injection of insoluble steroids. Pain relief can be achieved for up to 1 month in many instances. When radicular pain is caused by epidural tumor spread, epidural injections of triamcinolone diacetate are likely to be of benefit. Tumor compression of the brachial plexus may respond to brachial plexus block with a combination of depo steroid and local anesthetic. The interscalene, supraclavicular, infraclavicular, or axillary approaches may all be used, the choice depending on the site of pathology. Femoral plexopathy can be treated with a paravertebral approach (psoas compartment block) to the femoral plexus, again using depo steroids and local anesthetic. Steroid local anesthetic blocks of peripheral nerves that are irritated or compressed by tumor are occasionally beneficial, particularly if they are performed reasonably soon after the onset of pain. Patients with severe neurogenic pain should be warned that if the injections are successful in producing pain relief, they are likely to be left with some numbness, not from the injections, but from the already present neural pathology.

Acute herpes zoster is a relatively common and often debilitating source of pain in patients with malignancy. There is some evidence that local anesthetic blockade of sympathetic fibers, using either paravertebral sympathetic blocks or epidurals, will promptly relieve pain and may shorten the acute phase of the illness.¹⁰⁹ Even if the overall course of the illness is not dramatically affected, patients are usually extremely grateful for any respite from the severe pain associated with this condition.

Occasionally, patients with severe cancer pain are refractory to any opioid intervention. These patients may progress to psychological decompensation without reasonably prompt intervention. The use of continuous-infusion local anesthetic blockade may be the best answer for patients who reach such a crisis. Continuous epidurals with dilute local anesthetics can be performed at any level of the neuraxis. When upper thoracic or cervical approaches are used, close monitoring of blood pressure and respiratory function is necessary.

Neurolytic Blocks

There is a much greater willingness among anesthesiologists to perform neurolytic blocks for terminal cancer patients with pain than for patients with nonmalignant causes of pain. Reluctance to use neurolytic blocks for noncancer pain is certainly justified. The extent and duration of analgesia from neurodestructive procedures is limited by regrowth of axons and development of central pain mechanisms (denervation dysesthesia). While neurolytic blocks can produce dramatic relief for some cancer pain patients, there are some serious potential drawbacks to the technique, and overzealous use of neurodestructive procedures should be avoided.

The principal disadvantage of neurolytic blocks is the inability to precisely control the spread of the destructive agents. Loss of motor function and inability to control bowel or bladder function following neurolysis can be devastating to a patient and will greatly impair the quality of remaining life. The expected analgesia may not always result from destruction of the intended neural structures, even when prognostic local anesthetic blocks have been performed. If CNS mechanisms play a major role in a patient's pain, neurolysis is unlikely to be of benefit. In some cases, tumor progression rapidly produces pain beyond the confines of the block. With the advent of improved methods of cancer therapy, more patients survive well beyond the efficacy of the block. Overall, the incidence of fair to good results following neurolytic blockade is estimated at 50–60%.¹⁴²

Alcohol and phenol are the agents most commonly used for prolonged interruption of neural function. There is relatively little difference in overall efficacy between these agents, but there are major differences in the initial responses. Phenol produces no pain on injection, has an initial anesthetic effect, and takes about 15 minutes to exert its neurolytic effect. Alcohol causes significant pain on injection and produces neurolysis promptly. When used for intrathecal (IT) neurolysis, alcohol is hypobaric, whereas phenol in glycerine, the usual intrathecal preparation, is hyperbaric.

IT neurolysis with small volumes of alcohol or phenol requires careful positioning to place the affected sensory root uppermost (for alcohol) or in the most dependent position (for phenol). In such a way, only the involved sensory roots are affected. Patient movement during or shortly after injection can produce spread of drug to the cord, other dermatomes, or motor roots. Papo and Viscia¹⁴³ published results in a large series of patients who underwent phenol rhizotomy. They reported good results (pain-free until death) in 40% of 290 patients and fair results (reduced analgesic requirements or temporary complete relief) in 35%. Patients whose pain was localized to sacral dermatomes had the best results, whereas patients with pain in the upper thoracic area or upper or lower extremities had poor analgesia and more frequent complications. Swerdlow¹⁴⁴ reviewed 13 reports of the results of phenol and alcohol rhizotomies and found good relief of pain in about 60% of patients. In reviewing results on his own patients, he found that analgesia lasted less than 2 months in half the patients and less than 1 month in 25% of patients. Complications lasting longer than a week occurred in 15% of patients.

Patients with severe, localized perineal pain are likely to experience relief with IT blocks with phenol in glycerine. Phenol 7% in glycerine, is injected in 0.25-ml increments up to a maximum of 2 ml, with the patient in the sitting position. Injection is stopped at a lower dose if the patient experiences any lower extremity sensory changes. This treatment is limited to patients who have undergone fecal and urinary diversion procedures.

Celiac plexus block for pain associated with upper abdominal malignancy is the most successful and rewarding of the neurolytic blocks. Thompson *et al*¹⁴⁵ reported that 94% of 97 patients who underwent celiac plexus block for pain of upper abdominal cancer had good-to-excellent pain relief. Injections were performed with 50 ml of 50% alcohol. Survival from the cancer ranged from 2 days to 14 months. Fourteen patients required repeat injections for recurrent pain. Ten patients experienced transient orthostatic hypotension, and one patient had partial motor loss in one leg.

The classical technique for percutaneous injection of the celiac plexus involves bilateral placement of block needles just anterior to the body of L1 and posterior to the aorta and diaphragmatic crura. Recently, techniques have been described that involve more anterior positioning of the needle tip with computed tomographic assistance so that it lies anterior to the diaphragmatic crura.¹⁴⁶ The injected solution can be seen to spread more anteriorly, surrounding the aorta. There is much less tendency of the injected solution to spread posteriorly to the paravertebral nerve roots or sympathetic chain, minimizing risk of paresis or orthostatic hypotension. Ischia *et al*,¹⁴⁷ using such a technique, reported 93% success in relieving pain in 28 patients with cancer pain. Similar placement can be achieved with the use of biplane fluoroscopy. Five-inch 22-gauge needles are advanced from both sides at a point 7 cm from the midline, at the lower border of the 12th rib toward the midpoint of the L1 vertebral body, and advanced under anteroposterior fluoroscopy until they are just past the lateral border of the body. Under lateral fluoroscopy, the right-sided needle is advanced 1 cm beyond the anterior border of the body. It will probably lie between the aorta and vena cava. The left-sided needle is advanced the same distance, but will usually enter the aorta at this point. If so, it is advanced through the aorta until negative aspiration occurs. Half the total alcohol dose is then injected through each needle (Fig. 55-7). Alternatively, deafferentation of the upper abdominal viscera can be accomplished with the use of splanchnic block. With this technique, the neurolytic agent is injected over the anterolateral surface of the T12 and/or T11 vertebral body (Fig. 55-7). This technique may be more effective than the transcrural approach if there is dense, widespread tumor invasion around the celiac plexus.

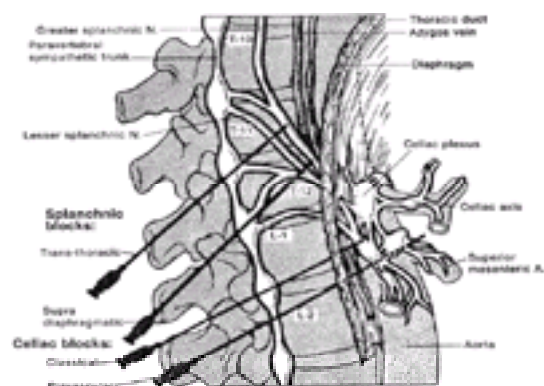

Figure 55-7. Lateral projection showing the splanchnic nerves and celiac plexus in relation to the diaphragm, vertebrae, and aortic vessels. Placement of needles for two approaches to the celiac plexus and two approaches to the splanchnic nerves is shown. (From Abram SE, Boas RA: Sympathetic and visceral nerve blocks. In Benumof JL [ed]: Clinical Procedures in Anesthesia and Intensive Care, p. 787. Philadelphia, JB Lippincott, 1992.)

Patients with pelvic pain associated with gynecologic, rectal, and genitourinary malignancies may benefit from interruption of pelvic visceral innervation at the level of the superior hypogastric plexus. The technique of needle placement just anterior to the upper portion of the sacrum originally described by Plancarte *et al*¹⁴⁸ allows for interruption of afferents from the pelvic viscera with minimal risk of somatic blockade. The block is performed by introducing bilateral needles medially and caudally through the space between the L5 spinous process and the upper border of the sacrum under fluoroscopic control. Eight milliliters of phenol introduced through each needle is generally sufficient to provide reduction in pain and opioid requirement¹⁴⁹ (Fig. 55-8). Bladder pain and spasm have been successfully treated with trans-sacral phenol injections.¹⁵⁰ If blocks are confined to one or two roots, there is little risk of disrupting bladder function.

Figure 55-8. Anterior view of the pelvis showing location of the hypogastric plexus and suggested bilateral needle placement. (Reprinted with permission from Plancarte R, Amescua C, Patt RB, Aldrete A: Superior hypogastric plexus block for pelvic cancer pain. *Anesthesiology* 73:236, 1990.)

Other Modes of Therapy

There are a number of therapeutic options that are relatively specific for the type of malignancy one is dealing with. When dealing with tumors that are extremely radiosensitive, radiation therapy is often the most effective form of intervention. If chemotherapeutic options are available, they may provide analgesia through reduction of tumor mass. Pain caused by hormonally sensitive tumors may be best treated by appropriate manipulation of the patient's hormonal environment. Surgical debulking of a large tumor will sometimes relieve pain of obstruction or abdominal distension. Stabilization of an isolated pathologic fracture can be an extremely effective pain-relieving procedure. Certain neurosurgical procedures, such as spinal cord stimulation, cordotomy, or hypophysectomy may afford months of profound relief in certain types of cases. Some patients benefit considerably from psychological interventions such as hypnosis or other cognitive strategies. With the complexity of the disease processes involved with cancer-related pain and the number of pain mechanisms and therapeutic interventions that are possible, it is essential that the full range of medical and behavioral science disciplines be made available to this group of patients.

PAIN IN HIV/AIDS

Knowledge of the syndromes in human immunodeficiency virus (HIV) disease is the fundamental prerequisite for diagnosis of HIV disease pain. HIV disease pain can be divided into three classifications: nociceptive pain, neuropathic pain, and idiopathic pain. The most common pain sources associated with HIV disease-related pain are abdominal pain 26%, peripheral neuropathy 25%, throat pain 20%, HIV disease-related headaches 17%, AZT-induced headache 16%, arthralgia 5%, back pain 5%, and herpes zoster 5%.¹⁵¹

Pain in HIV disease varies depending on the stage of HIV disease progression with acute phase evidenced by mononeuritis, brachial plexopathy, and acute demyelinating polyneuropathy, such as Guillain-Barré syndrome. As the disease progresses, pain will be associated with chronic inflammatory demyelinating polyneuropathy, herpes zoster, and mononeuritis multiplex. Late-stage HIV disease pain arises out of sensory polyneuropathy, cytomegalovirus polyradiculopathy, progressive mononeuritis multiplex, aseptic meningitis, lymphomatous meningitis, and nucleoside toxicity.

Pain at any stage is influenced by perception, by psychological, social, and even spiritual anxieties.¹⁵² The psychological sequelae of HIV disease pain are essentially similar to cancer pain, where there is the constant threat of severity and persistence. Optimal HIV disease treatment should incorporate psychological treatment strategies because patient mood, depression, and beliefs about pain as well as the significance (meaning) of pain influence pain perception.

Pharmacologic treatment for HIV disease pain should follow the World Health Organization analgesic pain treatment protocol developed for cancer beginning with acetaminophen and NSAIDs with appropriate caution related to possible drug interaction with acetaminophen and AZT. Weak opioids are next utilized including codeine, oxycodone, and hydrocodone added to acetaminophen. Concerns over use of opioid treatment in substance abusers presents difficulties that require firm limits and contractual, written agreement on the use of narcotic analgesics.

The overall course of treatment and ability of the patient to cooperate in treatment may be compromised by the impact of HIV disease dementia. As the disease progresses, the risks of associated pain and dementia increase. Some studies have found that dementia is the initial AIDS-defining illness, *viz.* 4% followed by an increased incidence of 7% after a second AIDS-defining illness and a cumulative risk of 25%.¹⁵³ Nonpharmacologic treatment such as physical therapy and psychological interventions may be difficult in the presence of apathy, psychomotor retardation, decreased attention span, and short-term memory loss.

Nerve blocks, including injection of local anesthetic or neurolytic agents, are not typically applicable to HIV disease pain. However, temporary relief from pain may facilitate physical therapy and frequently sympathetic or somatic blocks may result in relief of pain that exceeds the actual anesthetic action.

PSYCHOLOGICAL INTERVENTIONS FOR CHRONIC PAIN

Psychological input into the diagnosis and treatment of chronic pain has become an accepted part of any comprehensive team approach to the management of this class of patients. Because the psychological influences on pain experiences are myriad, the regular consultation of a specialist in behavioral medicine is invaluable. In addition to helping to understand some of the psychological influences mentioned earlier, the psychologist has at his or her disposal a number of specific techniques that prove useful as part of a multidisciplinary treatment plan for chronic pain management.

Psychodynamic approaches to the patient in chronic pain are typified by an attempt to understand the patient in terms of personality structure, biologic drives, social contexts, wishes, and expectations. This leads to a psychodynamic formulation that posits a relationship between any or all of these factors and the presenting problem. Therapy is usually done on an individual basis and is aimed at establishing a therapeutic alliance with the patient, providing an interpretation of relevant symptoms, leading the individual to new levels of understanding about the derivation of their symptoms, and enhancing symptom resolution through the patient-therapist relationship, with termination of that relationship as the ultimate goal. To engage in this sort of approach requires a knowledge of fundamental psychoanalytic and therapeutic principles, training in the particulars of psychotherapy with chronic pain patients, and the time to engage in weekly or more frequent sessions with the patient for months to years of therapy. Clearly, this is out of the realm of expertise or desire of most anesthesiologists and is typically so labor-intensive that it is not practical for many psychologists. In general, a very small proportion of patients in a given clinic population would be either amenable or appropriate to involvement in this style of therapy.

Much more common is the use of cognitive therapies. This group of strategies focuses on the cognitive or thought processes that are found in chronic pain patients. Often the thinking style of an individual has a great deal of effect on how he or she copes with pain. As mentioned earlier, the meaning of the pain experience can greatly influence the suffering. A classic example of this is the often quoted observation by Beecher¹⁵⁴ that injured soldiers on the battlefield in World War II often complained of pain far less than would be expected from the severity of their wounds. When they were safely behind the lines, however, they would complain just as loudly as anyone else when multiple venipunctures or other mildly painful procedures were required, disproving the notion that these people were stoic by nature. Beecher¹⁵⁴ reasoned that the meaning of the pain was making the difference in that a significant injury meant that one would be taken back home and, therefore, would survive the war. A common clinical example in a pain clinic would be the individual who is convinced that he or she cannot cope with a flare-up of pain. Such an individual will frequently think catastrophic thoughts such as "If this pain gets real bad, I don't know what I'll do!" These thoughts can become the focus of treatment and can, with motivation and practice on the part of the patient, be changed to more adaptive thoughts. This in time will give the individual some degree of control over the situation and will prevent him or her from engaging in self-defeating destructive thought patterns. Coping ability is thereby improved.¹⁵⁵

Behavioral therapies involve efforts to reshape behaviors, rather than the sensory or emotional conditions that underlie them. This is a direct outgrowth of the work of Fordyce *et al*,¹⁵⁶ who adapted B. F. Skinner's operant model of behavior to the human pain patient. As previously discussed, this model states that behaviors can be cued by certain stimuli and can be modified by conditions that follow the emission of the behavior. Taking this antecedent-behavior-consequence paradigm view of pain behaviors such as limping, groaning, seeking dependence on others, and taking inappropriate analgesics, Fordyce and colleagues imposed strict control on the environment into which the chronic pain patient was placed. No reinforcement of pain behaviors was forthcoming from the staff (extinction) and positive reinforcement for wellness behaviors was instituted. This resulted in a significant decrease in pain behaviors. A critique of this method was that only the behaviors were decreased, but Fordyce *et al* argue that many patients state that after a largely behavioral treatment program they perceive less pain.¹⁵⁷ The principles of behavior modification extend to the staff of a pain clinic, the patient's workplace, and the home, in that solicitous responses from a spouse in response to pain behaviors by the patient may sabotage an otherwise intact and appropriate treatment plan.

Biofeedback is the providing of information to an individual about bodily functions that are commonly held to be inaccessible to the conscious mind. Commonly used devices measure surface electromyographic activity, temperature, or electrodermal activity. When feedback from these systems is provided, a patient can frequently be taught to control those functions at will. Originally, the logical assumption was made that teaching an individual to reduce muscle tone in a specific muscle would reduce the pain by the mechanism of muscle relaxation. While the outcome is generally that which is expected, the mechanism is not universally accepted to be reduction in muscle tone, leading to decreased activation of muscle nociceptive afferent neurons. The same statement can be made for the other modes of biofeedback. This does not, however, detract from the usefulness of the techniques, and they remain a valuable psychological intervention for some patients.

Numerous strategies have evolved for the induction of a state of relaxation in chronic pain. The theory is that relaxation induces both positive mental and physical changes in the individual that promote a sense of well-being, decrease muscle tone, and enhance coping. Jacobson¹⁵⁸ developed the first standardized approach to relaxation using the progressive contraction and relaxation of muscle groups in an ascending sequence from feet to head. There have been numerous procedures since then that can be learned to induce relaxation. These techniques rely on conscious manipulation of the body to induce a relaxed state, not merely getting comfortable on the couch and propping up one's feet. Benson¹⁵⁹ studied the physiologic concomitants of a relaxed state and found commonalities to the conditions induced by a variety of methods. These included a decrease in sympathetic tone, regularity in respiratory pattern, decreased skeletal muscle tone, and a feeling of well-being. He termed this physiologic pattern the *relaxation response* and postulated that the means of achieving it was unimportant and, in fact, developed a simple and straightforward induction method. This and similar techniques find great applicability to chronic pain patients, especially those with muscular involvement such as myofascial pain syndromes.

Hypnosis has long been used to help alleviate surgical and other acute pains. It has some utility in the chronic pain population as well. For an individual to become hypnotized, several conditions must exist: (1) an ability to concentrate, (2) a belief in the process, and (3) some motivation for the process to ensue. The trance state is thought to be a naturally occurring phenomenon in most people, although there is great variability in the population with regard to frequency and ease of occurrence. Trance state can be defined as an altered state of awareness characterized by extremely focused attention, relaxation, and responsiveness to suggestion. It is thought by most modern practitioners that the hypnotist does not hypnotize the subject but rather facilitates entry into trance by directing and guiding the individual's attention. The use of hypnosis can, in the properly selected individual, be a useful adjunct to therapy of chronic pain. It has found particular utility in the treatment of patients with cancer pain, possibly because these patients are so profoundly motivated. The mechanism of analgesia associated with hypnosis is unclear, but it does not appear to be due to endogenous opiates or to be solely due to placebo effect.

Group therapy, supportive therapy, education, and family therapy are other types of psychological interventions that have utility in the management of chronic pain patients. A skilled practitioner of behavioral medicine will aid the anesthesiologist in the diagnosis, conceptualization, and treatment of patients presenting with chronic pain by selecting evaluation and therapeutic strategies that are tailored to each individual's presentation.

INTERVENTIONAL PAIN MANAGEMENT

Over the past two decades, there has been rapid technological development in the field of pain management. Reliable and sophisticated intraspinal drug delivery devices can provide complex patterns of infusion over long periods of time. Totally implanted spinal cord stimulation devices can now access multiple electrodes simultaneously. Techniques for radiofrequency denervation have been developed for many neurologic structures. Miniaturized endoscopic devices permit more accurate perineural injection of medications within the spinal canal. Systems have been developed for thermocoagulation of annular tears of intervertebral discs and for stabilization of vertebral compression fractures. While these interventional techniques are not appropriate for the majority of patients with chronic pain, they have extended our capability for managing some of the most intractable problems. The following discussion describes a few of these systems.

Intrathecal Drug Delivery Devices

The discovery of opioid receptors and endogenous opioids in the late 1970s¹⁶⁰ led to early experiences with intraspinal opioids in animals¹⁶¹ and eventually patients with chronic pain.¹⁶² The original research with spinal opioids was fueled by the search for alternatives to irreversible neurodestructive techniques. The advantage of spinal opioid analgesia was thought to lie in the potential for obtaining more potent analgesia and fewer side-effects due to higher drug concentrations at spinal opioid receptors. What made intraspinal opioids suited for continuous administration^{163,164} and eventually outpatient use was the selective nature of its action compared to local anesthetics, avoiding sensory, motor, and sympathetic blockade.

The original use of spinal narcotics for continuous drug delivery focused on cancer pain, proving its safety and efficacy in multiple studies.^{165,166} A subsequent development was the successful utilization of intrathecal baclofen for the treatment of spasticity and rigidity in patients with spinal cord injuries.^{167,168} Utilization of spinal opioids for nonmalignant pain remains controversial but is gaining acceptance.¹⁶⁹ More recent studies in this patient population seem to suggest a lower incidence of tolerance and iatrogenic addiction than first feared.¹⁶⁹

Opioids administered by the spinal route act preferentially on receptors in the dorsal horn. Pain relief is produced through modulation of incoming A-delta and C-fiber sensory input.¹⁷⁰ In part, opioids also travel rostrally and act on supraspinal opiate receptors.

In selecting patients for chronic intrathecal opioid therapy, one must distinguish between neuropathic and nociceptive pain syndromes. Nociceptive pain is generally opioid-responsive; neuropathic pain, however, may not respond, or may require much larger opioid doses.¹⁷¹ The latter may respond to the spinal administration of α_2 -receptor agonists such as clonidine¹⁷² or local anesthetic/opioid combinations.¹⁷³

Cancer pain is often dynamic, with a mixed nociceptive and neuropathic pain presentation, and may therefore require adjunct therapy. These patients may be candidates for intraspinal opioids if they have proven opioid-responsive pain but have developed either intolerable side-effects or tolerance to systemic opioids. Cost effectiveness of implantable drug delivery systems in this patient population may require a minimum of three months' survival when compared to external infusion systems.¹⁷⁴

Selection of patients with nonmalignant pain remains difficult, with no clear selection criteria identified. Prior to considering these patients for candidacy, every effort must be made to establish a diagnosis of the pain syndrome at hand. All available surgical and medical alternatives should be explored including trials of long-acting opioids. These should be escalated until side-effects are encountered or inadequate benefit is established. Psychological evaluation and psychometric testing should be considered to investigate the possibility of primary psychological pain states. Contraindications to the placement of implantable infusion devices include, among other things, the presence of sepsis, anticoagulation, severe immune suppression, and drug addiction.

Morphine continues to be the most widely used agent for long-term spinal administration. It remains the only FDA-approved intraspinal analgesic. Its high water solubility and receptor affinity provide for prolonged duration predictability and a widespread distribution throughout the cerebrospinal fluid compartment.¹⁷⁵ Substances with a higher lipid solubility, such as fentanyl, sufentanil, and meperidine, reduce supraspinal effects through limited spread but require accurate catheter placement adjacent to the spinal cord level associated with the specific pain syndrome.¹⁷⁵ Opioid rotation is commonly done in long-term use since tolerance and drug side-effects can develop. Owing to the phenomenon of incomplete cross-tolerance among opioids, a lower dose of a different opioid can often be substituted.

Intrathecal administration of baclofen has been very useful for the control of spasticity and rigidity in spinal cord injuries and multiple sclerosis, as first documented by Penn in 1987.¹⁷⁶ Since then, other studies have confirmed the usefulness of baclofen in this setting¹⁶⁸ and in certain central pain states.¹⁷⁷ Baclofen binds to GABA_B receptors, producing inhibition of synaptic transmission leading to a reduction in muscle tone. It is FDA-approved for intrathecal use for patients with spasticity. Recently, intrathecal infusions of baclofen have been shown to provide effective analgesia for patients with chronic pain that is not associated with spasticity or spinal cord injury.¹³⁹ It produced sustained benefit in several patients who had become unresponsive to intrathecal morphine.

Efficacy trials are essential to pump implantation. Different methods are in clinical use, ranging from single-shot outpatient drug administration to titration of a

continuous epidural or intrathecal infusion in the inpatient setting. Prior oral or systemic opioid needs will determine trial doses of intrathecal drugs. The patient is then observed for analgesic efficacy and drug side-effects. The minimum analgesic response is controversial, but often a minimum of 50% reduction in pain scores and a duration twice the half-life of the agent is sought. Response to placebo injections should be compared to responses to active drug. The development of early side-effects such as intractable pruritus or nausea is often discouraging even though tolerance to them may develop with longer-term administration. Efficacy of intrathecal baclofen for treatment of spasticity is assessed using the Ashworth muscle rigidity/tone scale.

Intrathecal drug delivery systems vary from simple percutaneous catheters (Type I) to totally implantable and programmable infusion pumps (Type VI). Type VI systems have gained in popularity for long-term infusions, both in cancer pain states with long survival times and in nonmalignant pain states. These systems provide for a broad range of delivery rates and modes, and hence flexibility. Refill periods range from weeks to months, depending on drug concentrations and tolerance. FDA approval has been given to Infusaid factory-preset fixed flow rate pumps (Type V) and the Medtronic Synchromed totally programmable pump systems (Type VI).

Examples of postoperative complications include bleeding, infection, seroma formation, and CSF leakage. Infection is usually localized; however, epidural or intrathecal sepsis is disastrous, requiring the removal of all hardware and administration of systemic antibiotics.¹⁷⁹ Long-term complications related to the implanted equipment include catheter disconnects, obstruction, or breakage as well as pump failure among other things. Pump malfunction is uncommon, but errors in refilling and reprogramming have resulted in serious morbidity and mortality.¹⁸⁰

Spinal Cord Stimulation

The gate control theory, introduced by Melzack and Wall in 1965, provided the theoretical foundation for the use of implanted electrical stimulation. Several years later Shealy¹⁸¹ was the first to describe what was initially known as dorsal column stimulation and eventually spinal cord stimulation (SCS). Electrical stimulation in proximity of the dorsal columns through epidural lead placement was thought convenient since sensory pathways there are segregated from motor pathways. Initially, however, poor patient selection and technological limitations led to disappointing results. Patient selection improved through work done in the late 1980s and early 1990s.¹⁸² At the same time new technology became available, including the arrival of multichannel leads, dual-lead configurations, totally implantable generators, and expanded programming options. The specific mechanism of action of SCS remains elusive. Neural and neurochemical changes, perhaps resulting from stimulation in the dorsal roots, dorsal root entry zone, or dorsal columns, have been implicated.¹⁸³ The efficacy of spinal cord stimulation is greatest for certain types of ischemic and neuropathic pain syndromes with primarily causalgic and dysesthetic features.¹⁸⁴

Conditions that have favorably responded to SCS include lumbosacral fibrosis and arachnoiditis,¹⁸⁵ complex regional pain syndromes,¹⁸⁶ and more recently ischemic pain conditions associated with peripheral vascular disease¹⁸⁷ and angina pectoris.¹⁸⁸ Failed back surgery patients with predominantly radicular pain elements have shown response rates of 50–60% at 5 years in recent studies.^{189,190} Patients with peripheral vascular disease have also responded favorably with significant limb salvage rates reported.^{187,191} Patients with medically refractory angina pectoris who were not candidates for revascularization have experienced pain relief and improvement in cardiac function and stress testing.^{188,192}

The most critical issues in patient selection consist of identifying a well founded diagnosis and the presence of specific neuropathic or ischemic pain states. A multidisciplinary approach including a psychological evaluation is recommended. High scores on the Minnesota Multiphasic Personality Inventory's depression scale have been associated with SCS failure.¹⁹³ Other contraindications such as the presence of localized infection, systemic sepsis, severe immune suppression, and coagulopathy are similar to other implantable devices.

The two systems in current use are a totally implantable generator system and a system that uses an implantable receiver and external transmitter. Either system is adaptable to multiple leads depending on the need for bilateral extremity stimulation or wider unilateral coverage. Similarly, different electrode configurations exist, varying in number and spacing of electrodes. One can also take advantage of complex programming options to fine-tune or change stimulation patterns.

Prior to permanent placement, a trial stimulation is performed. Generally, temporary percutaneous stimulator leads are used for this purpose. Once an appropriate stimulation pattern is produced, most protocols will require at least a 50% improvement in pain scores. The length of trial screening is controversial, varying from days to weeks.

Lead migration and breakage are common problems with long-term stimulation. Lead migration may produce unwanted paresthesias or diminish benefit in the original area of stimulation. This can sometimes be overcome by reprogramming of the electrode but may require lead replacement. Serious infection, bleeding, and nerve injury are uncommon complications.¹⁸⁹ Generator or transmitter failure is unlikely; however, fully implantable generators will require replacement depending on use.

Radiofrequency Lesioning

Research on the use of radiofrequency (RF) power for use in neurosurgical procedures dates back to work done by Harvey Cushing in the mid-1920s. Clinical use of this technology was first achieved through central nervous system lesions in the 1950s. The technique was further refined in the 1970s by the invention of the RF probe, leading to a variety of new applications.¹⁹⁴ Modern RF thermocoagulation has been used to ablate pain pathways in the spinal cord, dorsal root entry zone, dorsal root ganglion, trigeminal ganglion, sympathetic chain, and peripheral nerves.

An insulated probe with an uninsulated tip is placed in proximity of the target tissue and RF current is allowed to flow from a generator. As the current encounters resistance in the tissue, heat is generated, creating a lesion. Lesion size is directly proportional to tissue temperature at thermal equilibrium between the probe tip and the surrounding tissue. This equilibrium is generally achieved in 1 minute. Prior to lesioning, the target structure must be localized. This is accomplished by electrical stimulation. High frequencies and lower voltages are used to elicit a paresthesia in the desired distribution, while low frequencies and higher voltages are used to assess neuromuscular activity prior to lesioning. Temperatures specific for the target nerve can be chosen, allowing for selective interruption of small unmyelinated fibers, preserving myelinated motor innervation.

Patient selection requires a firm diagnosis verified by prognostic blocks with local anesthetics. RF lesioning is by definition neurodestructive and can be considered only after more conservative options have failed. Patients may require psychological screening and should be aware of all potential adverse sequelae, including neurologic impairment. Thorough knowledge of neuroanatomy and the use of fluoroscopy are mandatory for the pain physician.

The lumbar spine is an area where RF lesioning is often applied. Specific techniques have been developed for pain originating from the facet joints, nerve roots, annulus fibrosus, and sacroiliac joints. Approximately 50–60% of carefully selected patients with mechanical low back pain due to facet arthropathy achieve at least moderate reduction in pain following radiofrequency facet rhizotomy.^{195,196} and ¹⁹⁷ Lesions for discogenic pain are performed at the ramus communicans and intradiscally.¹⁹⁸ Owing to the complexity of disk innervation and disk pathology, this procedure is not nearly as successful. RF dorsal root gangliotomy is in use for the treatment of pain originating from the lumbar spinal nerve.¹⁹⁹ This is reserved for nonsurgical patients after diagnostic sleeve blocks of the segmental nerve have been performed. RF applications for cervical spine pain are primarily oriented toward facet joint denervation. Lesions of the sphenopalatine and trigeminal ganglia²⁰⁰ have been successfully used for select patients for the treatment of migraine headaches and trigeminal neuralgia respectively. RF neurolysis of the sympathetic chain, though not in widespread use, has been helpful in some patients with Type II complex regional pain syndrome and vasoocclusive disorders.

Patients can experience postoperative pain or dysesthesia for days to weeks after the procedure as a result of low-level heat injuries to tissue. Subsequently, judging the efficacy of the procedure is often difficult in the short term. More permanent nerve injuries and disk infections have been described.²⁰¹ Although in clinical use since the 1950s, RF is still a technique used by relatively few clinicians. It is, however, gaining in popularity since a wider range of applications and newer technologies such as pulsed RF are available now. Benefit from RF lesioning is time-limited due to nerve regeneration but the procedure may offer more prolonged analgesia than nerve blocks. Whenever possible, more conservative and less invasive treatment modalities should be entertained prior to RF procedures.

Epiduroscopy

Early experiences with endoscopic visualization of contents of the spinal canal date back to the 1930s.²⁰² With the development of fiberoptic light source technology in the 1970s, it became possible to develop endoscopes small enough for epidural insertion.²⁰³ In the early 1990s, several flexible fiberoptic systems were developed for direct imaging of epidural contents. These devices eventually featured steerability and multiple channels for irrigation, delivery of medications, and possibly instrumentation. Today's epiduroscopes carry FDA approval for diagnosis of epidural pathology, and direct delivery of normal saline and steroids. The theoretical basis for epiduroscopic injection of steroid lies in investigational data showing poor epidural spread of substances in patients with prior spine surgery.²⁰⁴ These epidural adhesions are thought to be in part responsible for failed spinal surgery. Lysis of these adhesions appears to offer some benefit for patients with certain postoperative lumbar radiculopathies.

Epidural access is achieved via the sacral hiatus, while distension of the epidural space is gained through normal saline infusions. Adhesions are then lysed through

blunt instrumentation with the endoscope, other instruments introduced through a sideport, or simply through forceful proximity injections of normal saline. The procedure is generally performed under light sedation rather than under anesthesia since a significant increase in epidural pressure due to overdistension may lead to neurologic compromise. Improvement in spread of contrast is often seen following the procedure, but may not correlate with improvement in symptoms.²⁰⁵ Contraindications to the procedure include coagulopathy, infection, raised intracranial pressure, and severe cerebrovascular disease. While the ultimate role of spinal endoscopy has yet to be established, work is under way to develop instruments that could be used for more definitive therapeutic applications. The current role of the endoscope appears to be limited to diagnosis while outcome studies on its therapeutic value have yet to be conducted.

Intradiscal Electrothermal Therapy

Intradiscal electrothermal therapy involves the percutaneous placement of a heating electrode into the intervertebral disk. The electrode is navigated circumferentially around the inner surface of the disk annulus. By then heating the electrode, annular collagen is denatured and nerve endings innervating the disk are coagulated. The patient target group for this procedure appears to be patients with internal disk disruptions secondary to small contained disk herniations, posterior annular fissures, and degenerated disk with relatively preserved disk height. This group of patients is thought likely to fail conservative therapy while discectomy and fusion surgery for these indications have shown mixed results. MRI evidence of disk disruption and a positive discogram are required for patient selection. Early studies seem to suggest moderate to good short-term results with this new technology. However, long-term efficacy trials and outcome studies have yet to be conducted.

Critical care medicine is now a clearly recognized specialty of the practice of medicine. It is a multidisciplinary specialty based in the intensive care unit (ICU), with its primary concern being care of the patient with a critical illness. Critical care medicine crosses traditional departmental and specialty lines and requires a physician whose knowledge is broad, involving all aspects of management of the critically ill patient. The core cognitive and procedural skills necessary for the practice of critical care medicine have recently been published.¹

ANESTHESIOLOGISTS AND CRITICAL CARE MEDICINE

Critical care medicine has always been an integral part of the practice of anesthesiology. Anesthesiologists have been intimately involved, indeed instrumental, in the development of critical care medicine as a specialty. Many consider the practice of operating room anesthesiology the practice of critical care medicine limited to the perioperative period. The anesthesiologist is involved daily with rapid alterations in physiologic status that require prompt recognition and early intervention, the hallmarks of critical care medicine. By virtue of training, experience, competence, and interest, the anesthesiologist brings skills and knowledge that uniquely qualify him or her to care for critically ill patients. This expertise has been recognized by the American Board of Anesthesiology (ABA), which included critical care medicine in its definition of anesthesiology, and by the American Society of Anesthesiologists (ASA), which included critical care medicine in its standards of practice. Further, training in critical care medicine is an integral part of the curriculum for residents in anesthesiology. One year of advanced training in this specialty following completion of residency training is required to be eligible to receive a certificate of special qualifications in critical care medicine by the ABA.

COST AND OUTCOME OF INTENSIVE CARE

The numbers of ICU beds required for an institution vary between 3% and 25% of the total hospital beds, with an average of 12% for major adult and general hospitals. In children's hospitals the amount of special care beds averages more than 23% and may be as high as 46%. Currently, ICU beds constitute 7–8% of all hospital beds. The number of beds required for any institution varies, depending on the patient population served. It appears, however, that with changes in the political climate and the increased preponderance of managed care networks and capitation systems only the very sickest of patients will be admitted to the hospital. Accordingly, there will be a need in the future for more critical care beds and fewer beds for elective admissions.

There is increasing concern about the cost of medical care, especially associated with critical illness. ICU beds are growing at ~6% annually, whereas other beds are closing. ICU care consumes 20% of total hospital charges. In addition, because of the intensity and stress placed on the personnel working in ICUs, the loss of personnel from these areas is disproportionately high. It has been estimated that the annual turnover of nurses from critical care units may be as high as 50%, and it is common not to be able to use all resources because of inadequate staffing.

It is still uncertain whether ICU care decreases patient morbidity and mortality. Reports in the literature are conflicting. Several early studies demonstrated a significant benefit of ICU care when specialty units were reviewed. A reduction in mortality has been reported for coronary ICU patients, burned patients, noncardiac surgical patients, trauma patients, and other selected surgical groups after the introduction of a surgical ICU teaching service and computer-based approach to patient monitoring and therapy. However, these studies and many in the literature have used historical controls. Unfortunately, this does not consider differences in treatment modalities and other factors that may have contributed to the change in morbidity and mortality. Indeed, several studies have failed to show any benefit from hospitalization in critical care units. More carefully designed, rigorously controlled trials are necessary to assess the true efficacy of ICU care.

PATIENT ASSESSMENT SYSTEMS

Because intensive care is so expensive and consumes so many resources, several attempts have been made to develop methods to predict patient outcome. In this way patient care could be optimized by limiting admission to those patients who would benefit from intensive care and withholding or removing therapy from patients

who would not. Unfortunately, the systems introduced to assess the severity of illness of patients and their need for intensive care as well as to predict outcome have met with limited success.

Illness severity scoring systems have been devised on an anatomic, therapeutic, and physiologic basis. The Clinical Classification System (CCS) was introduced as a means to assess severity of illness along with a therapeutic intervention scoring system (TISS) to measure the amount of therapy given. The therapeutic intervention scoring system serves as an indirect measure of illness severity, with the greater number of interventions occurring with sicker patients. The CCS, along with TISS, has been used to assist in appropriate use of facilities, to provide information on nurse staffing ratios, and to relate costs to extent of care given in both the adult and pediatric populations. In addition, it was an attempt to compare treatment and outcome in different ICUs, although it has been of limited utility in comparing patients who may be treated by different standards of critical care in different institutions.

The acute physiology and chronic health evaluation (APACHE) system relates the severity of a patient's illness to the degree of physiologic derangement of a series of physiologic measurements. With an assigned weight given to each measurement, it is then possible to assess preadmission health status and probability of survival. It was also proposed to control for case mix, compare outcomes between ICUs, study utilization of ICU resources, and evaluate new therapies. Attempts to simplify the APACHE system resulted in the simplified acute physiologic score (SAPS) and APACHE II.^{2,3} Because of concerns of limitations in these systems,⁴ APACHE III was developed to refine the selection and weighing of physiologic variables in the system to clarify the distinction between using the system for mortality prediction in groups as opposed to individual patients and to expand the size and diversity of the patient data base.⁵ The physiologic stability index (PSI) is an adaptation of the APACHE system for use in the pediatric population.⁶ Other scoring systems proposed to aid in the classification of the critically ill and the trauma patient include the mortality prediction model (MPM),⁷ computerized intensity intervention scores (CIIS),⁸ outcome index (OI),⁹ and a new severity characterization of trauma (ASCOT).¹⁰ Unfortunately, to date none of these systems can unequivocally predict outcome or benefit from intensive care.

CENTRAL NERVOUS SYSTEM

Assessment and treatment of critically ill patients with central nervous system (CNS) disorders require a thorough knowledge of cerebral blood flow and metabolism as well as of cerebral pharmacology, neurophysiology, and pathophysiology.

Determinants of Cerebral Blood Flow

Control of cerebral perfusion is essential in maintaining neurologic function in pathologic states. Cerebral blood flow is regulated by intracerebral and extracerebral factors. Intracerebral blood flow regulation is controlled by chemical and metabolic influences, including hydrogen ion concentration, cyclooxygenase, products of phospholipid membrane metabolism, and adenosine. In addition, neurogenic and myogenic components contribute to the regulation of cerebral blood flow.

The extracerebral determinants of blood flow include the arterial partial pressure of carbon dioxide (PaCO₂) and oxygen (PaO₂), arterial blood pressure, venous blood pressure, and pharmacologic effects of drugs. There is a linear correlation between cerebral blood flow and PaCO₂ with progressive hypercarbia. Similarly, there is a marked reduction in cerebral blood flow during hypocarbia through a pH-mediated change in arteriolar tone that results in vasoconstriction and reduced intracranial pressure (ICP). Taken to extremes, hypocarbia provides no additional benefit and may be detrimental. Therefore, current recommendations suggest maintaining PaCO₂ between 25 and 30 mm Hg. However, prolonged hypocarbia is ineffective because cerebrospinal fluid (CSF) bicarbonate adapts to the change in PaCO₂. Therefore, the long-term value of hyperventilation of the lungs for reducing ICP is offset by the normalization of CSF pH, which occurs in 6 hr.

Arterial oxygenation has a lesser effect on cerebral blood flow than does carbon dioxide. When the PaO₂ falls below 50 mm Hg, cerebral vasodilation and an increase in cerebral blood flow result, which may exacerbate intracranial hypertension. Hyperoxia generally results in small changes in cerebral blood flow until PaO₂ exceeds 300 mm Hg.

Autoregulation

Autoregulation, the ability of the brain to maintain cerebral blood flow constant despite alterations in mean arterial pressure, is functional over a mean arterial pressure range of 50–150 mm Hg. At levels below 50 mm Hg, symptoms of cerebral ischemia may appear. If the upper limit of autoregulation is exceeded, cerebral blood flow increases, which may result in cerebral edema. It is important to note that the autoregulatory curve may be shifted in the presence of chronic hypertension, intracranial tumors, head trauma, and shock states, which render the brain more susceptible to ischemic effects.

Intracranial Pressure Monitoring

ICP can normally range up to 15 mm Hg, and beyond that point any increase in ICP can result in a decrease in cerebral perfusion pressure. Once cerebral perfusion pressure falls below 40–60 mm Hg, ischemic injury to nerve cells may occur. There is a close correlation between clinical outcome and the level of ICP elevation after acute injury. Aggressive treatment of elevated ICP in the ICU is essential. The symptoms associated with increased ICP are variable, although they generally reflect effects of compression of structures around the tentorial opening. If left untreated, raised ICP leads to global cerebral ischemia, coma, and death.

Continuous monitoring of ICP can be accomplished through a ventriculostomy, a subdural bolt, or an epidural transducer. Advantages and disadvantages of each technique are outlined in [Table 56-1](#). The intraventricular catheter is inserted through a burr hole through the coronal suture. It provides an accurate and reliable reading of ICP as well as allowing withdrawal of CSF for pressure control and culture. Disadvantages of this technique include the necessity of passing through brain tissue to introduce the catheter into the ventricle. This may be difficult when the brain is distorted from trauma and edema. Further, the risk of infection is greatest with this technique as compared with the others. Indeed, positive CSF culture results have been reported in ~9% of patients monitored with intraventricular catheters.¹¹ The possibility of infection is reduced if catheterization is limited to 3 days and prophylactic antibiotics are administered.

| ICP Monitor | Advantage | Disadvantage |
|---------------------|---|---|
| Ventriculostomy | Very accurate Access to cerebrospinal fluid for pressure control and culture | Must pass through brain tissue Infection |
| Subarachnoid bolt | Easily performed Reliable procedure | Infection Less accurate |
| Epidural transducer | Easy to place Little risk of infection | Questionable accuracy and reliability |

TABLE 56-1. TECHNIQUES OF DIRECT INTRACRANIAL PRESSURE MONITORING

The subarachnoid bolt is a less invasive means of monitoring ICP. This device is inserted into the skull after the dura and arachnoid have been opened. It is easily inserted, does not require penetration of brain tissue, and can be done at the bedside. As with all invasive procedures, insertion of a subarachnoid bolt carries the risk of infection.

The epidural transducer used to monitor ICP is placed between the inner table of the skull and the dura. This device is easy to place and monitors pressures exerted by the CSF and brain on the dura. Although this technique carries little risk of infection, its accuracy and reliability for monitoring ICP are questionable.

Control of Elevated Intracranial Pressure

Treatment of increased ICP is generally recommended when levels exceed 20 mm Hg. Certainly, treatment may be indicated at a lower pressure if evidence of impaired cerebral perfusion is present. Modalities available to treat increased ICP include diuretics and fluid restriction, hyperosmotic agents, hyperventilation of the lungs, corticosteroids, barbiturates, positioning, and removal of CSF.

Once surgically correctable causes of increased ICP have been eliminated, treatment should be initiated with hyperventilation to maintain PaCO₂ between 25 and 30 mm Hg. Additional measures include drainage of CSF if an intraventricular catheter has been placed and elevation of the head to 30°, which encourages venous drainage from the brain and hence lowers ICP. Mannitol may be added in an attempt to remove brain water. This osmotic agent helps draw water from the tissues because of the transient increase in plasma osmolarity. The onset of action following intravenous (iv) administration of mannitol is 30 min, with a maximum lowering of ICP occurring within 1–2 hr and lasting 6 hr. Diuretics such as furosemide may also be used to lower ICP and are especially useful in patients with increased intravascular volume. Corticosteroids are effective in lowering ICP due to localized cerebral edema surrounding intracranial tumors. Dexamethasone is the most commonly used steroid preparation and generally causes improvement in neurologic status within 12–36 hr of therapy. Barbiturate administration can also assist in lowering ICP by a dose-related reduction in cerebral metabolic oxygen requirement as well as by decreasing cerebral blood volume. Some authors suggest barbiturate coma for cerebral protection in patients with elevated ICP.^{12,13}

Fluid and electrolyte abnormalities including hyponatremia, hypokalemia, and hypochloremia with fluid retention are common accompaniments of CNS disease. Other complications include acute respiratory failure, gastrointestinal bleeding, hypertension, cardiac dysrhythmias, and disseminated intravascular coagulation. These related complications must be recognized and treated if they occur.

Seizures

The etiology of a seizure generally depends on the age of the patient and the type of seizure. Young children frequently present with seizures associated with febrile illness. In adolescent and young adults, head trauma is a major cause of focal seizure disorders, whereas generalized seizures tend to be associated with drug or alcohol withdrawal in this age group. Brain tumors are the most common cause of seizures in patients between 30 and 50 years of age, and over 50 years of age cerebrovascular disease is the most common cause of focal or generalized seizure disorders. The initial evaluation of the patient with a seizure consists of ensuring adequate ventilation and perfusion as well as stopping the seizure. A full history and examination must be obtained. It is important to differentiate the kind of seizure to aid in determining the etiology. Treatment is directed at eliminating the cause and suppressing the seizure. Certainly, metabolic disturbances such as hypoglycemia or hypocalcemia should be sought and corrected. Structural brain lesions must be removed. Most seizure disorders are amenable to anticonvulsant medication. However, neurosurgical treatment should be considered if a structural lesion causes recurrent seizures and removal of that lesion and nearby affected brain tissue will make them easier to control or eliminate them entirely. In addition, neurosurgical ablation of epileptogenic foci may be used as a treatment modality.

Central Nervous System Trauma

Head injuries are a significant cause of morbidity and mortality, with more than 2 million injuries causing brain damage yearly. To quantitate the severity of head injury, an objective clinical scale was developed. The Glasgow Coma Scale evaluates motor response, verbal response, and eye opening (Table 56-2). It provides an estimate of the severity of neurologic dysfunction and can predict mortality. Evoked potentials are another means of assessing prognosis in patients following head injury. The accuracy of evoked potentials is greater than that of clinical observation and ICP measurements. Somatosensory evoked potentials are the most useful and can predict death or a vegetative state in ~90% of patients if they are bilaterally absent.

| Parameter | Response | Score |
|-----------------|---------------------------|-------|
| Eye opening | Spontaneously | 4 |
| | To verbal command | 3 |
| | To pain | 2 |
| Motor response | No response | 1 |
| | Obeys verbal command | 6 |
| | Localizes pain | 5 |
| | Flexion-withdrawal | 4 |
| | Decorticate rigidity | 3 |
| | Decerebrate rigidity | 2 |
| Verbal response | No response | 1 |
| | Oriented and converses | 5 |
| | Disoriented and converses | 4 |
| | Inappropriate words | 3 |
| | Incomprehensible sounds | 2 |
| | No response | 1 |

TABLE 56-2. GLASGOW COMA SCALE

Any patient who presents with severe head injury should have the airway protected and secured, ventilation and blood pressure stabilized, and attention given to life-threatening noncranial injuries followed by a full neurologic evaluation. As with any head injury, the possibility of cervical spine injury should be considered and the cervical spine should be immobilized until full evaluation is possible. Surgically treatable causes of increased ICP should be sought, including epidural or subdural hematoma and intracerebral hemorrhage. Aggressive surgical intervention may dramatically improve outcome. If, however, there are no surgically treatable lesions found on computed tomographic scan, attention should be directed toward reducing increased ICP. Direct ICP monitoring should be considered. Hypoxia, hyperthermia, hypercarbia, malpositioning of the endotracheal tube, and high mean airway pressures may exacerbate the intracranial hypertension. Persistent elevation of ICP despite conservative therapy generally portends a poor prognosis. Fluid and electrolytes should be monitored closely. Anticonvulsants and prophylaxis to prevent gastrointestinal bleeding are generally administered.

It must be remembered that patients who sustain head trauma have other associated problems. Indeed, medical complications generally dominate the intermediate-term intensive care of head trauma patients. Fluid and electrolyte balance can be a major problem following head injury. Indeed, over half of the patients who have persistent coma develop abnormalities of fluid and electrolyte balance. It is important to monitor serum osmolarity and sodium concentrations because treatment of intracranial hypertension may cause marked alterations in these parameters. Coagulation parameters must also be monitored because disseminated intravascular coagulation may accompany head trauma in 5–10% of cases.

Cerebral Protection

Common causes of acute cerebral injury include anoxic insult, traumatic injury to the brain, and stroke. The mechanism of injury in each case begins with tissue ischemia. Cell death then results from the resultant inflammation, toxicity of excitatory amino acids, and generation of free radicals. Inflammatory mediators such as platelet activating factor (PAF), interleukin-1B (IL-1B), and leukotrienes result in damage to cell membranes, leading to increased intracellular calcium and release of proteases, endonucleases, and phospholipases, which results in cell death. Similarly, excitatory amino acids also cause an increase in intracellular calcium, leading to cell death. Finally, the generation of free radicals damages cell membranes, directly leading to cell death.

Several techniques to promote neuroprotection have been tried to interrupt the pathway to cell death. Therapies for neuroprotection have included hypothermia,^{14,15} antagonists of the excitatory amino acids receptors,¹⁶ calcium channel blockers,¹⁷ corticosteroids,¹⁸ barbiturates, superoxide dismutase,¹⁹ desferoxamine mesylate,²⁰ antioxidant vitamins, antagonists of PAF, neuronal growth factors, nitric oxide, and gene therapy. Unfortunately, despite being based on sound physiologic principles and promising data in animal models, many of the neuroprotective therapies available today have yielded disappointing results in human trials. It could be that other factors influence outcome, including the timing of the intervention, gender of the patient, and dose/duration of therapy. Further investigation is necessary to determine the most effective means to provide neuroprotection following brain injury.

CARDIOVASCULAR SYSTEM

Cardiogenic Shock

Cardiogenic shock is a syndrome that results directly from severely impaired left ventricular pump function. This may be the result of end-stage cardiac disease or a catastrophic complication of acute myocardial infarction. With improvements in cardiac dysrhythmia monitoring and treatment, cardiogenic shock has emerged as the most common cause of death among patients in coronary care units. Indeed, cardiogenic shock occurs in 10–15% of patients who suffer an acute myocardial infarction. Mortality remains high despite advances in hemodynamic monitoring and newer pharmacologic drugs. Cardiogenic shock, like hypovolemic or septic shock, manifests as inadequate oxygen delivery to tissues, with failure of mitochondrial oxidative metabolism and accumulation of lactic acid. Inadequate organ perfusion in cardiogenic shock is caused by a marked reduction in the quantity of contracting myocardium. The initial insult leads to a decrease in arterial pressure with a resultant decrease in coronary blood flow. This decrease in coronary perfusion pressure further compromises myocardial function, leading to progressive circulatory deterioration. The clinical consequences of the decrease in myocardial contractility manifest as either circulatory insufficiency (forward failure) or circulatory congestion

(backward failure).

Typical signs and symptoms of patients in cardiogenic shock include restlessness and mental confusion; the skin is cool, moist, and cyanotic. Peripheral pulses are usually weak and rapid, and arterial blood pressure is decreased. However, shock can occur without severe hypotension, a relatively late indicator of inadequate reflex vasoconstriction. Nonetheless, the syndrome is usually defined by a systolic arterial pressure 80 mm Hg, with a cardiac index of $2 \text{ L} \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ and an increase in left ventricular end-diastolic pressure or pulmonary capillary wedge pressure (PCWP) to 8 mm Hg.

Because prognosis is poor and mortality is high, close monitoring and early aggressive intervention are essential for successful outcome. Certainly, any patient in shock should have continuous monitoring of arterial pressure and left ventricular filling pressures. Measurement of central venous pressure alone is inadequate and may actually be misleading because it often fails to reliably reflect left ventricular pressures. Close monitoring of urinary output is important because it gives an indication of renal artery perfusion and provides a monitor of the progress of treatment.

Successful treatment of cardiogenic shock depends on early restoration of adequate tissue perfusion to meet metabolic demands. To achieve this goal, initial resuscitation and general supportive measures should be instituted immediately. Specific pharmacologic therapy to maintain adequate blood pressure, cardiac output, and oxygenation should be initiated. Consideration should then be given to mechanical cardiac assist devices or cardiac surgical intervention, including transplantation and implantation of an artificial heart.

Drugs with positive inotropic properties improve the contractile performance of the failing heart. Sympathomimetic amines are potent positive inotropic drugs that exert their effects through action on α - and β -adrenergic receptors. Isoproterenol is rarely used in the treatment of shock. Although it increases contractility, it does so at the expense of an increase in myocardial oxygen consumption and a reduction in coronary perfusion pressure. The net increase in cardiac output seen with this drug may be limited by impairment of cardiac filling resulting from rate and rhythm changes, as well as by decreased venous return to the heart. Epinephrine is a powerful cardiac stimulant. Heart rate is increased, systole is shortened and strengthened, and cardiac work and myocardial oxygen consumption are markedly increased. The hemodynamic effects of epinephrine are dose-dependent, so that in low doses ($1\text{--}2 \mu\text{g} \cdot \text{min}^{-1}$) there is primarily β stimulation, intermediate doses ($2\text{--}10 \mu\text{g} \cdot \text{min}^{-1}$) result in mixed α and β stimulation, and high doses result primarily in α stimulation. The clinical utility of epinephrine may be limited by its peripheral vascular effects, tachycardia, and dysrhythmias. Norepinephrine is a combined α and β agent, with α properties generally dominant, causing intensive vasoconstriction. It can be useful in raising blood pressure, but the increase in afterload causes a marked increase in myocardial oxygen consumption. Dopamine has been used successfully as a positive inotropic drug with varying effects at different dosage ranges. At low doses the drug has positive chronotropic and inotropic effects, but at higher doses vasoconstriction occurs through an α -mediated response. The dopaminergic properties of the drug, which allow for increased renal blood flow, have proved useful when dopamine is added to more potent inotropic drugs to maximize renal perfusion during borderline low cardiac output states.²¹ Dobutamine is a synthetic, sympathomimetic amine with positive inotropic effects without the chronotropic or peripheral vasoconstrictive properties of dopamine. In severe congestive heart failure (CHF) dobutamine improves myocardial contractility, stroke volume, cardiac output, systemic pressures, and perfusion while decreasing ventricular filling pressures. It therefore should be used in patients without profound hypotension. Dopamine and dobutamine may also be used in combination.²² Dopexamine exerts positive inotropic effects through both direct and indirect mechanisms. It is an agonist for dopaminergic and β II receptors but has little β I and no α -adrenergic effects. It decreases systemic vascular resistance and pulmonary vascular resistance and lowers both left and right ventricular filling pressures while increasing heart rate, stroke volume, and cardiac output.

Recently, two groups of drugs that act primarily through inhibition of phosphodiesterase III have been introduced. These drugs include the bipyridine derivatives amrinone and milrinone and the imidazolones enoximone and piroximone. Amrinone causes a dose-dependent increase in cardiac output while reducing systemic vascular resistance and left ventricular filling pressures. It has been shown to increase cardiac index by 30–100% while decreasing PCWP, systemic vascular resistance (SVR), and pulmonary vascular resistance. Heart rate and blood pressure have generally remained unchanged. Milrinone is ~15 times more potent than amrinone with similar pharmacologic and hemodynamic effects.²³ Milrinone produces no increases in myocardial oxygen consumption, suggesting that cardiac performance increases without increase in myocardial oxygen demand, possibly because its vasodilator action counterbalances the increase in myocardial contractility. Enoximone is structurally different from the bipyridine derivatives but functions also as a phosphodiesterase III inhibitor. It significantly increases cardiac index and decreases SVR and PCWP with minimal increase in heart rate or change in mean arterial pressure. It alters hemodynamics primarily by vasodilation of musculoskeletal and pulmonary vascular beds along with positive inotropism and chronotropism.²⁴ Piroximone, like enoximone, improves both right and left ventricular function without causing significant changes in heart rate or blood pressure. Myocardial oxygen uptake is not altered and coronary sinus blood flow increases.²⁵ Other new agents combining phosphodiesterase inhibition with other actions are currently under investigation.²⁶

Mechanical circulatory assist devices, most commonly the intra-aortic balloon pump, have gained widespread clinical use since first introduced by Moulopoulos *et al* in 1962.²⁷ The balloon pump assist device results in a reduction in myocardial oxygen consumption, and hence myocardial ischemia. In addition, by decreasing left ventricular volume and pressure and augmenting coronary perfusion, there is a positive balance established between myocardial oxygen demand and supply. The intra-aortic balloon pump has been shown in experimental models to improve hemodynamics, augment myocardial perfusion, enhance impaired contractile function, and potentially limit infarct size. Indeed, it has been shown that an increase in coronary blood flow is seen in patients in cardiogenic shock. Unfortunately, although myocardial ischemia is relieved and heart failure lessened in most patients with intra-aortic balloon pump assist, long-term survival has not been established. In recent clinical experience, intra-aortic balloon pumping alone was associated with an overall survival rate of 30% when used in patients with cardiogenic shock. The addition of emergency cardiac surgical revascularization improved survival rates.

Although intra-aortic balloon pumping is generally a simple and relatively safe procedure, serious complications occur in 10% of patients. Complications include aortic and arterial trauma, vascular insufficiency in the catheterized limb distal to the insertion site, infection, embolic phenomena, balloon rupture with gas embolization, and thrombocytopenia. With newer assist devices available and the success of invasive cardiac procedures, temporary assistance may provide support until definitive therapy can be undertaken.

With refractory cardiogenic shock, heart transplantation should be considered. The 1-year survival for heart transplant recipients exceeds 80%, with a 5-year survival of 50–60%.²⁸ Certainly, surgical approaches should be explored when cardiogenic shock cannot otherwise be managed.

Cardiac Tamponade

The accumulation of fluid or blood in the pericardial space resulting in a fall in cardiac output due to insufficient inflow of blood to the ventricles results in tamponade. The amount of fluid necessary to cause pericardial tamponade is variable, depending on the rapidity of accumulation. Rapid accumulation of as little as 250 ml can result in tamponade, whereas 1000 ml can accumulate slowly in the pericardial space without tamponade. The most common cause of tamponade is blood in the pericardial space following cardiac surgery, trauma, tuberculosis, or tumor. However, other etiologies include acute viral or idiopathic pericarditis, postradiation pericarditis, and renal failure. Clinical manifestations of tamponade include dyspnea, jugular venous distention, and low arterial blood pressure with distant heart sounds. Electrical alternans may be seen on the electrocardiogram (ECG), and distention of the jugular veins on inspiration (Kussmaul's sign) may also be noted. Another finding suggestive of pericardial tamponade is a paradoxical occurrence of 10 mm Hg inspiratory decrease in systolic arterial pressure. Equalization of pulmonary artery wedge, right atrial, right ventricular, and pulmonary artery diastolic pressures with low cardiac output may also be seen.

Treatment of cardiac tamponade must be initiated immediately because pericardiocentesis may be lifesaving. A small catheter advanced over a needle inserted in the pericardial space allows drainage of pericardial fluid and return of cardiac function.

Pulmonary Embolism

Pulmonary embolism is a leading cause of morbidity and mortality in the United States. It has been estimated that pulmonary embolism accounts for more than 50,000 deaths annually, although most pulmonary emboli are nonfatal. The vast majority of pulmonary emboli arise in the deep venous system of the lower extremities. The three primary etiologic factors in the development of deep vein thrombosis and subsequent pulmonary embolism are venous stasis, abnormalities of the vessel wall, and alterations in blood coagulation.

Pulmonary embolism should be suspected in any patient with sudden onset of unexplained dyspnea in association with venous thrombosis. Other symptoms may include substernal chest pain, syncope, cardiac dysrhythmias, worsening of CHF, or sudden worsening of chronic obstructive lung disease. Pleuritic chest pain and hemoptysis may be present, but only when pulmonary infarction has occurred. Physical examination may be remarkably normal. Rales or wheezing may be noted on auscultation of the lungs. A pleural friction rub or effusion may be present if infarction has occurred. Findings on auscultation of the heart may include tachycardia, right ventricular gallop, wide splitting of the second heart sound, or systolic ejection murmur in the pulmonic area.

Laboratory studies may assist with the diagnosis of pulmonary embolism. The ECG is generally normal aside from tachycardia. However, there may be evidence of right axis deviation, tall peaked P waves, or ST-T wave changes consistent with right ventricular strain. Chest x-ray film findings may be subtle. Indeed, a normal chest x-ray film does not exclude the possibility of pulmonary embolism and is a common finding. Arterial blood gases associated with pulmonary embolism generally reveal

arterial hypoxemia with hypocapnia and respiratory alkalosis. However, normal arterial blood gas analysis does not exclude the possibility of thromboembolic disease.

The diagnosis of pulmonary embolism can be confirmed by radioisotope-tagged and microaggregated albumin perfusion scan along with a xenon ventilation scan. The definitive diagnosis, however, is with pulmonary angiography, which is the only means for providing anatomic information about the pulmonary vasculature. Heparin administration is the initial treatment of pulmonary thromboembolism. Fibrinolytic agents also have been used to dissolve venous thrombi in the pulmonary vasculature. Surgical therapy with formal thoracotomy and thrombectomy produces uniformly poor results.

Thrombolytic Therapy

Streptokinase (SK), urokinase (UK), and tissue plasminogen activator (tPA) are pharmacologic activators used to accelerate fibrinolysis in patients with massive pulmonary emboli, acute arterial and coronary thrombi, and peripheral venous thrombi. Streptokinase, obtained from the culture of group A *Streptococcus*, is an indirect activator that forms a complex with plasminogen and initiates fibrinolysis. It was the first thrombolytic agent available for clinical use. Urokinase, like tPA, can directly convert plasminogen to plasmin. Urokinase, which is secreted by human kidney cells, was first extracted and purified in 1957. Recombinant tissue plasminogen activator (rtPA, alteplase) peripherally activates plasminogen when it is absorbed to fibrin clots. Anistreplase (anisoylated plasminogen SK activator complex, APSAC) offered theoretical advantages over SK as did a precursor of UK, single-chain UK plasminogen activator (scuPA). Individual mortality trials of SK, APSAC, and rtPA including risks and benefits of each agent have been well described.²⁹ In general, studies comparing these agents have shown no significant differences,^{30,31} and ³² though accelerated-dose rtPA was more efficacious than SK and APSAC.^{33,34} Indeed, patients with suspected acute anterior or inferior myocardial infarctions have lower early mortality when treated with streptokinase. In particular, tPA has been used successfully with improved left ventricular function. A variety of newer agents, modifications of tPA, are under evaluation. These newer thrombolytic agents include reteplase (rPA),³⁵ tenecteplase (nPA),³⁶ and staphylokinase.³⁷

The major complication of fibrinolytic therapy is hemorrhage caused by hypofibrinogenemia and intense systemic fibrinolysis. Therefore, fibrinolytic therapy is not recommended for patients with recent surgery, indwelling cannulas, a history of neurologic lesions, or gastrointestinal bleeding. Indications for fibrinolytic therapy include massive pulmonary emboli, acute peripheral arterial embolism, and extensive iliofemoral thrombophlebitis. The fibrinolysis begins immediately after vascular injury, although clot lysis and vessel recannulation may not be complete for 7–10 days. The Fifth American College of Chest Physicians Consensus Conference on antithrombotic therapy has recently published summary recommendations.³⁸

RESPIRATORY SYSTEM

Acute Respiratory Failure

Acute respiratory failure in the critically ill patient is often synonymous with the adult respiratory distress syndrome (ARDS). This is a descriptive term applied to many acute diffuse infiltrative lung lesions with diverse etiology. However, severely diminished lung compliance, refractory hypoxemia, and diffuse radiographic abnormalities are common denominators. Regardless of the initiating event, this form of acute respiratory failure is associated with increased lung water. This type of pulmonary edema, which is associated with relatively normal cardiac function and “leaky” pulmonary capillaries, has been termed high-permeability pulmonary edema. The precise incidence of ARDS is difficult to determine, although it appears to be increasing. One third of adult deaths from shock and trauma following severe injury result from progressive respiratory failure. Although ARDS may be precipitated by many different causes, the resulting clinical syndrome is the same (Table 56-3). The mortality rate remains above 50% despite current supportive therapy and treatment modalities.

| | |
|---------------------|---------------------------|
| Shock | Fat or air embolism |
| Aspiration | Burns |
| Sepsis | Drug ingestion |
| Trauma | Uremia |
| Pancreatitis | Massive blood transfusion |
| Head injury | Cardiopulmonary bypass |
| Radiation of thorax | Drowning |

TABLE 56-3. CONDITIONS ASSOCIATED WITH ADULT RESPIRATORY DISTRESS SYNDROME

Pathophysiology

Following injury to the lung with damage of the alveolar capillary membrane, there is an increased permeability of the capillary endothelium and alveolar epithelium, with leakage of plasma and erythrocytes into the interstitial and alveolar spaces. In addition, there is proliferation of Type II pneumocytes, which probably aid in the restoration of the integrity of the capillary-endothelial lining.

Although platelet aggregation occurs, the major alterations in lung function relate to leukoaggregation on endothelial surfaces. Indeed, bronchoalveolar lavage fluid from patients with ARDS contains an accumulation of neutrophils and leukocyte elastase. These cells release mediators of inflammation such as leukotrienes, thromboxanes, and prostaglandins. These leucoagglutinins are caused by activation of complement factor C5a. Thus, complement activation, a frequent accompaniment of trauma, sepsis, and other predisposing clinical insults, may explain the leucoaggregates commonly found in the lungs of patients with ARDS. With release of toxic oxygen radicals and lysosomal proteases, these aggregated neutrophils damage the endothelial cells by destruction of structural protein and promotion of local inflammatory reactions.

In addition to leucoaggregates, microemboli are commonly found in patients with ARDS at autopsy. Indeed, platelet and coagulation abnormalities have been implicated in the pathogenesis of the syndrome. Trauma, sepsis, and other predisposing conditions can activate the coagulation system, either by release of thromboplastin from soft tissue injury or through complement activation of the coagulation cascade. This results in platelet adhesiveness and aggregation which, along with the generation of fibrin, produce microemboli that are washed into the pulmonary vasculature. These defects have been clearly demonstrated by wedge angiography and correlated with the severity of lung injury.

Clinical Manifestations

Patients may be asymptomatic immediately following insult. The earliest sign is frequently tachypnea followed by dyspnea. Arterial blood gas analysis generally reveals a respiratory alkalosis caused by hyperventilation and mild hypoxemia. At this time, administration of supplemental oxygen frequently improves arterial oxygenation. As the disease progresses, however, hypoxemia cannot be corrected by increasing inspired oxygen concentrations because hypoxemia is the result of right-to-left shunting of blood through collapsed or fluid-filled alveoli. Mechanical ventilatory support with positive airway pressure therapy is then required to maintain adequate oxygenation.

Treatment

Certainly, early recognition and prompt initiation of therapy are essential. The cornerstone of therapy is to ensure adequate tissue oxygenation. An indwelling arterial cannula is useful to monitor arterial blood pressure and allow access for measurement of arterial blood gases and other laboratory values. A pulmonary artery catheter aids immeasurably in optimizing fluid management. A Foley catheter is important to ensure close and accurate measurement of urine output. Bronchial hygiene is an important aspect of the management of these patients. Antibiotics should be used only if evidence of infection is present, and treatment should be guided by the results of cultures and antibiotic sensitivity testing. Prophylactic antibiotics are not indicated and may cause a drug-resistant infection. The use of high-dose corticosteroids in the treatment of ARDS was based on the theoretical advantages of inhibition of complement-induced granulocyte aggregation, disaggregation of neutrophils, and limitation of the increase in lung microvascular permeability. However, prospective double-blind, placebo-controlled trials of methylprednisolone therapy found no difference in mortality.³⁹

Fluid management in patients with ARDS presents a clinical dilemma. Fluid is constantly lost through the alveolar capillary membrane into the lung parenchyma, yet

adequate circulatory volume is essential to restore the perfusion important in reversal of lung damage. Therefore, it is critical that fluid administration be judicious. It is best guided by the use of a balloon-tipped, flow-directed pulmonary artery catheter. Diuretics and vasoactive agents can be used to maximize tissue oxygen delivery. Fluid replacement with crystalloid or colloid solution remains controversial. Regardless of the choice, meticulous attention must be given to fluid balance.

If adequate oxygenation cannot be maintained with an increased inspired oxygen concentration, mechanical ventilatory support should be instituted. The supportive benefits of positive end-expiratory pressure (PEEP) therapy are well documented. The clinical goals include improvement in arterial oxygenation, decrease in the work of breathing, and improvement in ventilation–perfusion inequality. With diffuse lung injury, PEEP improves functional residual capacity, compliance, and arterial oxygenation. In addition, PEEP decreases shunting, dead space ventilation, and venous admixture. This allows adequate arterial oxygenation with a lower inspired oxygen concentration.

Several criteria have been applied in attempting to define the clinical endpoint for PEEP therapy. Indices used include arterial oxygen tension, alveolar–arterial oxygen gradient, shunt fraction, compliance, and oxygen delivery.^{40,41} The usual clinical approach is to increase PEEP in increments of 3–5 cm H₂O and obtain appropriate measurements. Certainly, the optimal PEEP level chosen for any individual must fulfill the oxygenation as well as hemodynamic needs of that patient. The appropriate level depends on the degree of hypoxemia, the type of lung disorder, the functional residual capacity of the lungs, the presence of pre-existing pulmonary disease, lung compliance, the state of hydration, and the status of left ventricular function. Most recent data suggest that lower tidal volumes (6 ml · kg⁻¹) and PEEP adjusted to the beginning of the optimal compliance on the pressure–volume curve may improve prognosis. This “lung protective ventilatory strategy” may avoid volutrauma and shear stress.⁴²

Although PEEP therapy is an integral part of the treatment of acute respiratory failure, it causes complex hemodynamic effects. Changes in airway pressure can be anticipated to affect the heart and great vessels within the thorax. Potential adverse effects of PEEP include impaired venous return, decreased ventricular filling, increased pulmonary vascular resistance, interference with subendocardial blood flow, reduced left ventricular afterload, and altered configuration and compliance of the right and left ventricles. In addition to hemodynamic alterations, PEEP may cause interstitial emphysema, pneumothorax, and pneumomediastinum. Other effects of PEEP therapy include changes in ICP, alterations in renal function, and abnormalities in hepatic and gastrointestinal function.

Research on ARDS has emphasized the mechanism of lung injury in the hope of identifying a marker that would facilitate its early recognition. Current investigation is directed at altering the pathogenic sequence of increased alveolar capillary permeability and destruction of pulmonary structure. Therapeutic interventions, including anticoagulation, extracorporeal membrane oxygenation, cyclo-oxygenase inhibitors, oxygen free radical scavenger therapy, antiendotoxin antibody therapy, and prostaglandin E therapy, have not yet proved to be of definite benefit to patients with ARDS and await further prospective, controlled clinical trials.

Inhaled nitric oxide (NO) is a potential therapeutic option in patients with severe ARDS.⁴³ By decreasing pulmonary hypertension and arterial hypoxemia, inhaled NO (minimal effective inhaled NO concentration for long-term administration is 2–4 ppm) may decrease pulmonary edema, oxygen toxicity, and pulmonary barotrauma, thereby allowing the lungs to heal. A significant unresolved issue is the potential pulmonary toxicity of inhaled NO and its metabolite, nitrogen dioxide. At present, the appropriate role of inhaled NO in the treatment of ARDS remains unknown.

Mechanical Ventilation

Types of Ventilators

There are three kinds of mechanical ventilators. The simplest mechanical ventilators are those that substitute for diaphragmatic function, such as the pneumobelt or rocking bed. These devices have limited utility and are used only in patients with neuromuscular disease and normal lung function. A second kind of mechanical ventilator is the intermittent negative-pressure ventilator. These devices artificially produce a negative extrathoracic pressure during inspiration to substitute for the pleural and airway pressures normally produced by contraction of the respiratory muscles. Examples of this form of mechanical ventilation include the chest cuirass and iron lung. These devices are best suited for patients with respiratory muscle dysfunction and normal lungs.

The third kind of mechanical ventilator, and the one most commonly used today, is the intermittent positive-pressure ventilator. In this system gas is directed under positive airway pressure into the lungs. The major advantages of intermittent positive-pressure ventilation are the ability to ventilate the lungs adequately despite increased airway resistance or decreased lung compliance, patient accessibility, and access for bronchial hygiene. The mean airway pressure is positive with intermittent positive-pressure ventilation, so that venous return is compromised and cardiac performance may be impaired. Most of the positive-pressure ventilators in common clinical use today are volume ventilators that deliver a preset volume to the patient's lungs. Cycling of standard ventilators occurs whenever a certain volume or pressure is reached or at a preset time interval. When PEEP is added to intermittent positive-pressure ventilation, it is called continuous positive-pressure ventilation.

In recent years mechanical ventilators have become sophisticated and complex. The current microprocessor-based new generation of mechanical ventilators is a logical extension of earlier counterparts. The newest generation of adult mechanical ventilators offers more modes of ventilation, intrinsic microprocessors, computer-compatible monitoring or control, and extensive patient data monitoring and collection in a highly versatile and flexible ventilating device. The microprocessor control, in addition, reduces the number of moving components, enhances data management, and allows upgrading or addition of new features with a mere change in software. However, many of the new methods of ventilation available must await the results of rigorously controlled, objective, double-blind, randomized studies. The most common ventilatory modes available today with standard positive-pressure ventilators are controlled-mode ventilation, assist controlled-mode ventilation, and intermittent or synchronized intermittent mandatory ventilation. Newer ventilatory modalities include pressure support ventilation, high-frequency ventilation, extended mandatory minute ventilation, airway pressure release ventilation, pressure control ventilation, pressure control inverse ratio ventilation, and noninvasive positive pressure ventilation (Fig. 56-1).

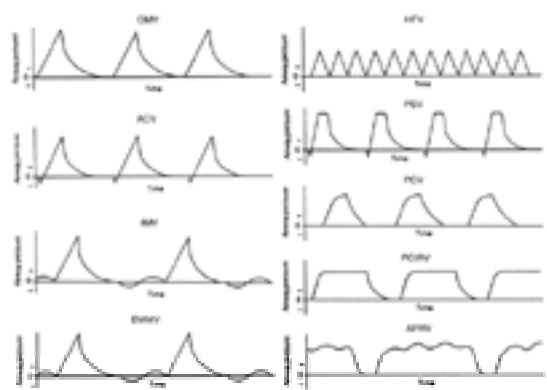

Figure 56-1. Airway pressure waveforms. CMV = controlled mechanical ventilation; ACV = assist control ventilation; IMV = intermittent mandatory ventilation; EMMV = extended mandatory minute ventilation; HFV = high-frequency ventilation; PSV = pressure support ventilation; PCV = pressure control ventilation; PCIRV = pressure control inverse ratio ventilation; APRV = airway pressure release ventilation.

Controlled Mechanical Ventilation

Controlled mechanical ventilation of the lungs is the oldest mode of intermittent positive-pressure ventilation. The ventilator obligatorily delivers a gas at a preset rate and volume independent of patient effort or response. The patient is unable to alter or influence any portion of the ventilatory cycle. Thus, a patient with an intact ventilatory drive often must be hyperventilated or given sedatives or muscle relaxants to diminish the tendency to breathe asynchronously with the ventilator. In addition, mean airway pressure is highest with this form of intermittent positive-pressure ventilation.

Assist Control Ventilation

Assist control mechanical ventilation, or assist control, is an intermittent positive-pressure ventilation mode in which the patient creates a sub-baseline pressure in the inspiratory limb of the ventilator circuit that triggers the ventilator to deliver a predetermined tidal volume. If the patient's ventilatory rate falls below a preset level, the machine automatically enters the control mode.

Intermittent Mandatory Ventilation

Intermittent mandatory ventilation (IMV) is a mode of intermittent positive-pressure ventilation in which the ventilator delivers a preset volume at a specified interval while also providing a continuous flow of gas for spontaneous ventilation. The patient spontaneously breathes gas with the same temperature, humidity, and oxygen concentration as the ventilator provides while the ventilator delivers a preset tidal volume at predetermined intervals through a parallel ventilatory circuit.

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation (SIMV) is a mode using a combination of assist control with a mechanism and circuitry that allows for independent spontaneous ventilation. In this mode the patient may spontaneously breathe through the circuit, while at a predetermined interval the spontaneous breath is assisted by the machine. Therefore, a positive-pressure breath is always in synchrony with the patient's spontaneous ventilatory pattern. In this system a pressure-sensing device located near the patient's airway detects the initiation of a spontaneous breath; this activates the ventilator or the demand flow device. The major disadvantage of the demand flow system is the delay in providing adequate gas flow, which can result in increased work of breathing.

Pressure Support Ventilation

Pressure support ventilation (PSV) is a form of ventilation that aids normal breathing with a predetermined level of positive airway pressure. PSV is similar to intermittent positive-pressure ventilation but differs in that airway pressure is held constant throughout the inspiratory period. PSV differs from conventional volume-cycled ventilation in that the clinician selects only the inspiratory pressure. The patient controls ventilatory timing and interacts with the delivered pressure to determine the inspiratory flow and tidal volume. The unique waveforms of pressure and flow produced by PSV may have an advantage by providing better support of spontaneous tidal volume and by decreasing the overall work of breathing. The objective of PSV is to increase the patient's spontaneous tidal volume by delivering airway pressure to achieve volumes equal to $10\text{--}12\text{ ml} \cdot \text{kg}^{-1}$. PSV may also decrease airway resistance by increasing air flow during inspiration and thereby decrease the work of breathing and delay muscle fatigue. Indeed, the literature suggests that PSV can reduce ventilatory workload, prevent diaphragmatic fatigue, compensate for the additional work of breathing caused by poorly functioning demand valves and undersized endotracheal tubes, improve patient-ventilator synchrony, and facilitate weaning.⁴⁴ Unfortunately, to date there are few clinical studies documenting the efficacy of this ventilatory mode, although theoretical advantages and safety of the mode in appropriately monitored patients support its use. Further studies are required to better evaluate the complex process of ventilatory reflexes and muscle conditioning during mechanical ventilation to fully establish the proper role of PSV.

Extended Mandatory Minute Ventilation

Extended mandatory minute ventilation (EMMV) provides a preset minute volume of gas either from a positive-pressure breath or from spontaneous breathing. The clinician determines the minimal accepted minute volume and selects the appropriate rate and volume. As the patient's ability to breathe spontaneously improves, less assisted ventilation is provided. Application of extended mandatory minute ventilation may enhance the weaning process by encouraging spontaneous breathing and enabling the patient to adjust to short-term changes in oxygen demand. Extended mandatory minute ventilation may also prove useful in tailoring tidal volume and respiratory rate more closely to meet patient needs. It may encourage patients who have become ventilator-dependent to use their respiratory muscles.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) was designed to augment ventilation for those patients with decreased lung compliance. The system is designed to provide alveolar ventilation as an adjunct to continuous positive airway pressure by intermittent and transient release of positive pressure, followed by restoration of pressure back to the continuous positive airway pressure level. The duration and frequency of continuous positive airway pressure release provide whatever level of ventilation is required. Because the peak airway pressure during airway pressure release ventilation equals the level of continuous positive airway pressure, cardiovascular depression, barotrauma, and ventilation-perfusion mismatch associated with conventional forms of ventilatory support may be expected to decrease. Theoretical advantages of airway pressure release ventilation over conventional positive pressure ventilatory techniques include its lower peak and mean airway pressures, improved arterial oxygenation, and smaller physiologic dead space ventilation. These advantages may lead to less depression of cardiac function as well as a decreased incidence of barotrauma. It differs from the inverse inspiratory to expiratory ratio (I:E) ventilation in that with airway pressure release ventilation, the patient breathes in an unrestricted manner during all parts of the ventilatory cycle. In contradistinction, an inverse I:E ratio requires skeletal muscle paralysis, sedation, or hyperventilation because no gas flow is available for spontaneous breathing during mechanical inspiration. Certainly, further study is necessary to better define the role of airway pressure release ventilation.

High-Frequency Ventilation

High-frequency ventilation (HFV) was originally used as a technique to provide adequate oxygenation and alveolar ventilation for rigid bronchoscopy and laryngeal surgery. Since that time, the literature has become replete with clinical applications of high-frequency ventilation. It is important to note that there are several different modalities to provide high-frequency ventilation. These ventilatory modes include high-frequency positive-pressure ventilation, high-frequency jet ventilation, high-frequency flow interrupters, and high-frequency oscillation. The common characteristic of all forms of high-frequency ventilation is ventilation at low tidal volumes (less than dead space) with high rates ($60\text{--}3000\text{ breaths} \cdot \text{min}^{-1}$). These systems enhance diffusive transport, minimize bulk transport, and improve intrapulmonary gas distribution. Hazards with high-frequency ventilation include inadequate humidification, barotrauma, necrotizing tracheobronchitis, hepatocellular injury, bronchospasm, and inadequate monitoring capabilities. Thus, although high-frequency ventilation is effective in maintaining pulmonary gas exchange at lower mean airway pressures, its precise role is yet to be determined.

Pressure Control Ventilation

Pressure control ventilation (PCV) is a patient or time-triggered, pressure-limited, time-cycled mode of ventilatory support. It is characterized by a rapid rise to peak pressure afforded by a decelerating inspiratory flow pattern. A pressure-controlled breath can be delivered in intermittent mandatory ventilation or assist mechanical ventilation instead of volume-oriented breaths, or in conjunction with pressure support ventilation. The potential advantage of pressure control ventilation is that because flow rate is geared to reach peak inspiratory pressure quickly, flow will exceed patient demand and therefore will improve patient-ventilator synchrony and decrease the work of breathing. Furthermore, pressure control ventilation might potentially improve distribution of gas within the lung by using the decelerating flow pattern and square wave air pressure pattern. The major disadvantage of pressure control ventilation is that tidal volume varies as compliance and resistance of the airways change.

Pressure Control Inverse Ratio Ventilation

Pressure control inverse ratio ventilation (PCIRV) is a time-triggered, pressure-limited, time-cycled mode of ventilation characterized by a decelerating inspiratory flow pattern, square wave air pressure pattern, and I:E ratio $\geq 1:1$. The potential advantage of this mode of ventilation is the recruitment of collapsed alveoli by prolonged inspiratory times, which allow alveolar units with slow time constants to fill. This improves both oxygenation and ventilation. Potential hazards include the development of auto-PEEP and consequent high airway pressures. Further prospective randomized controlled trials are necessary to determine the benefits to patients from the use of pressure control inverse ratio ventilation.

Noninvasive Positive Pressure Ventilation

Noninvasive positive-pressure ventilation (NPPV) provides the delivery of intermittent positive airway pressure through the upper airway and actively assists ventilation without tracheal intubation. This technique is rapidly gaining popularity because of its convenience, lower cost, and the potential significant reduction in morbidity compared with standard invasive positive-pressure ventilation. With the recent development of small, relatively inexpensive, and easily portable ventilators to be used specifically with NPPV using a nasal mask, several investigators have demonstrated successful treatment using this modality in patients with many varieties of acute^{45,46} and chronic respiratory failure.^{47,48} Most studies report a success rate of $\approx 60\%$ for NPPV in patients with acute respiratory failure caused by exacerbation of chronic obstructive pulmonary disease. Furthermore, substantial reduction in the length of intensive care unit and total hospital stays has been observed. Theoretical advantages of NPPV over traditional modes of ventilatory support include increased patient comfort, reduced need for sedation, avoidance of tracheal intubation and its attendant complications, and maintenance of airway defenses, speech, and swallowing. Limitations of this technique include the need for patient cooperation, the lack of direct access to the airway to provide bronchial hygiene, facial skin ulcers caused by mask pressure, and aerophagia. Proper patient selection for the use of this modality is an integral component for success. The precise mechanism of NPPV has not been fully elucidated. Unlike PPV through an artificial airway, NPPV can be effective only if the patient can cooperate. Patients receiving NPPV must learn to coordinate their breathing efforts with a ventilator, to allow assistance to their spontaneous breath. Properties of the ventilators may also be important in the efficacy of NPPV. The triggering mechanism, for example, may be a critical factor

because matching inspiratory airflow with the patient's inspiratory effort helps determine how much assistance a ventilator breath provides.

Several interfaces are available to provide NPPV, including nasal masks, facial masks, and lip seals. Standard nasal continuous positive-pressure masks are commonly selected because of their ease of application and ready availability. Recently, portable pressure-limited systems such as the bilevel positive airway pressure device (BiPAP; Respicorp, Inc.) have become popular. These ventilators cycle between two levels of positive airway pressure, with the higher level assisting ventilation during inspiration and the lower level maintaining airway patency during expiration. Typical pressure and volume curves with BiPAP are outlined in [Figure 56-1](#). NPPV clearly represents an important addition to the armamentarium available to manage patients with respiratory failure. However, complications, costs, and eventual outcomes have not been adequately studied. Further evaluation and refinement of the technique may provide a more widely used and valuable modality for selected patients with acute respiratory failure.

Have all the advances in technology and new ventilatory modalities had an impact on the outcome of critically ill patients in the ICU? Clearly, for select patient populations, ventilatory support has improved survival. For example, in the infant respiratory distress syndrome, this has been accomplished by the use of continuous positive airway pressure. Outcome has been similarly affected in patients with neuromuscular paralysis by the use of simple mechanical ventilation. However, despite all the newer ventilatory modalities available, little impact has been made on many other patient groups. The adult form of respiratory distress syndrome has not shown the increase in survival obtained in infants. Further, in patients with multiple organ system failure, including respiratory failure requiring mechanical support, outcome is determined more by the underlying cause than by the technique of mechanical ventilatory support. Despite an increasingly sophisticated array of mechanical support devices and detailed physiologic methodologies for augmenting support, little or no further increment of survival has been demonstrated in patients whose lungs are commonly ventilated with underlying sepsis and multiple organ failure. Certainly, ventilatory support has a place in affecting outcome in critical illness, although newer ventilatory techniques and technology must await further evaluation.

Cystic Fibrosis

Cystic fibrosis (CF) is an inherited multisystem disorder characterized by abnormalities in exocrine gland function. The most common cause of morbidity and mortality in patients with cystic fibrosis is pulmonary dysfunction. Pancreatic dysfunction is also a common accompaniment, as is hepatobiliary and genitourinary disease. The median survival time for patients with cystic fibrosis is about 20 years. However, with improvements in diagnosis and treatment, many patients survive through the third and fourth decades of life.

All levels of the respiratory tract can be involved with cystic fibrosis. Nasal polyposis, sinusitis, and lower respiratory tract disease are common findings in these patients. The common denominator is the alteration in mucus secretion. These patients have large amounts of secretion that predispose them to bacterial pneumonia, particularly with *Pseudomonas aeruginosa*.

Recently, there has been increasing interest in the use of anti-inflammatory medications to decrease airway inflammation and preserve pulmonary function in patients with CF lung disease.⁴⁹ Long-term oral corticosteroids,⁵⁰ ibuprofen,⁵¹ and inhaled corticosteroids⁵² have been shown to have a beneficial effect in slowing the progression of CF. Other agents used to reduce pulmonary inflammation include pentoxifylline,⁵³ a phosphodiesterase inhibitor, and tyloxapol,⁵⁴ a nonionic detergent and antioxidant.

Other organ systems involved with cystic fibrosis include the gastrointestinal and genitourinary systems and the sweat glands. Pancreatic insufficiency leading to protein and fat malabsorption is common, and recurrent pancreatitis may occur. Hepatobiliary disease is common in older patients with chronic cholestasis, inflammation, fibrosis, and even cirrhosis. Extrahepatic disease of the biliary system and abnormalities of the genitourinary tract are also common.

Abnormality in sweat gland function is the most reliable diagnostic test for cystic fibrosis. Examination of sweat of patients with cystic fibrosis reveals elevations of sodium, potassium, and chloride levels. This increase in electrolyte content results from a failure of reabsorption in the sweat duct.

Treatment of patients with cystic fibrosis is primarily directed at the respiratory system. Specifically, treatment has focused on the control of airway infection, secretion mobilization, and reduction of airway inflammation. Since the discovery of the CF gene, research has been directed at methods to correct the basic ion transport defects.⁵³ Every attempt must be made to increase mechanical drainage and clear secretions with chest physiotherapy and exercise programs. Control of bacterial infection with antibiotic therapy is essential. Bronchodilators should be used to reverse any bronchospastic component of the lung disease. Fluid management and general supportive measures are essential to successful treatment.

RENAL SYSTEM

Acute Renal Failure

Acute renal failure is impairment of the normal homeostatic functions of the kidney resulting in retention of nitrogenous wastes. It is a common problem, occurring in 5% of all hospitalized patients. It is particularly problematic in critically ill patients, in whom the incidence of acute renal failure is significantly higher. Despite advances in understanding the disease process, mortality remains high. Sixty percent of all cases of acute renal failure are related to surgery or trauma. The most common cause is renal ischemia with sepsis, hypovolemic shock, and nephrotoxic agents as major etiologic factors. The site of interference with renal function may be prerenal, renal, or postrenal.

Prerenal Causes

Prerenal causes of acute renal failure result from hypoperfusion of the kidneys, most commonly from extracellular fluid volume contraction. Reduced renal perfusion results from decreased effective circulating volume due to hypovolemia or redistribution of circulating volume. Reduction in cardiac output can also result in prerenal failure because of inadequate perfusion of the kidneys. This may result from primary myocardial disease, valvular heart disease, constrictive pericarditis, or cardiac tamponade. Decreased perfusion of the kidneys may also result from vascular disease of both large and small vessels. Certainly, bilateral renal artery stenosis can cause prerenal azotemia. However, although most prerenal causes of renal failure are accompanied by hypotension, renal artery stenosis is usually associated with hypertension.

Intrinsic Renal Causes

Intrinsic renal causes of acute renal failure can be divided by the component of the kidney most affected, *i.e.*, the glomeruli, blood vessels, and the tubulointerstitial region. Glomerular diseases account for 5–10% of all cases of acute renal failure and may be caused by direct immunologically mediated injury or decreased renal perfusion. Vascular disease can result in intrinsic renal failure primarily caused by either thromboembolic injury or systemic diseases.

Acute tubular necrosis is the most common cause of acute renal failure in critically ill patients and accounts for 75% of the renal causes of kidney failure. The two major causes of acute tubular necrosis are ischemia and nephrotoxins. Renal ischemia is the most common cause of acute renal failure and may be caused by a variety of clinical conditions, including volume depletion, shock, and operations that interrupt the renal circulation. It appears that prostaglandins play an important role in maintaining renal perfusion; therefore, patients taking drugs that inhibit prostaglandin synthesis may be predisposed to renal injury with hypoperfusion.

Nephrotoxic agents may also cause acute tubular necrosis. Categories of toxins include antibiotics, contrast material, anesthetic drugs, heavy metals, and organic solvents. In the past, heavy metals, organic solvents, and glycols were a common cause of acute renal failure. Today, however, aminoglycosides have supplanted them as the major nephrotoxic cause of acute renal failure. All aminoglycosides have nephrotoxic potential. Clinical nephrotoxicity, defined as a decrease in glomerular filtration rate, occurs in 5–25% of patients receiving aminoglycosides. The toxicity of these antibiotics is enhanced by advanced age, pre-existing renal dysfunction, concomitant administration of other nephrotoxic agents, and hypotension. Renal toxicity can also occur with antibiotics other than aminoglycosides, including cephalosporins, penicillins, and amphotericin B.

Toxic acute renal failure associated with the use of radiocontrast media is the second most common cause of nephrotoxic acute tubular necrosis. Patients particularly at risk for radiocontrast-induced renal failure include those with diabetes mellitus, the elderly, and those with pre-existing renal insufficiency. Dehydration compounds the risk in susceptible patients.

Anesthetic-induced nephrotoxicity is generally attributable to fluoride toxicity. Because toxicity results from high free fluoride levels in the plasma, prolonged duration of anesthesia and pre-existing renal dysfunction could put patients at risk for nephrotoxicity. Biotransformation of enflurane and sevoflurane may lead to the release of free fluoride, especially when anesthesia is prolonged, or when renal dysfunction is present. However, the usual levels of fluoride required to produce nephrotoxicity (40–50 mM) are rarely exceeded except during dramatically prolonged enflurane or sevoflurane anesthesia. Several common chemotherapeutic drugs can also cause acute tubular necrosis, including cisplatin and high-dose methotrexate. Adequate extracellular fluid volume expansion and concomitant use of diuretics may

significantly lessen nephrotoxic effects of cisplatin, and alkalization of the urine may decrease toxicity of high-dose methotrexate. Rhabdomyolysis has become an important cause of acute renal failure described in association with crush injuries, extensive burns, muscle inflammation, and a variety of settings in which muscle blood flow and metabolism are disturbed or muscle energy production is increased. The toxic effect of myoglobin causes acute tubular necrosis with rhabdomyolysis, just as hemoglobin is the toxic pigment in acute tubular necrosis associated with hemolysis from mismatched blood.

An increasing number of drugs have been associated with acute interstitial nephritis and subsequent acute renal failure. The most common cause of acute interstitial nephritis is an acute drug-induced hypersensitivity reaction. Drugs commonly implicated include β -lactam antibiotics (especially methicillin), nonsteroidal anti-inflammatory drugs, and diuretics. Acute interstitial nephritis is associated with an increased eosinophil count in blood and urine.

Postrenal Causes

Postrenal causes of acute renal failure may be asymptomatic and must be considered in any patient with renal failure. This form of acute deterioration of renal function is often reversible and occurs in up to 10% of patients with decreasing renal function. Obstruction to urine flow may occur at any level from the kidney to the bladder. Ureteral obstruction from calculi, clots, tumor, stricture, retroperitoneal fibrosis, or malignancy may cause ureteral obstruction, whereas bladder tumors or a neurogenic bladder can result in obstruction at the level of the bladder. Urethral obstruction can be caused by prostate disorders, urethral stricture, cervical carcinoma, or meatal stenosis. In most cases of possible obstruction, a combination of a flat abdominal film, renal scan, and ultrasonogram can supply as much information as excretory urography with much less risk. However, if the clinical history is suggestive of obstruction, even if the noninvasive studies are negative, cystoscopy and retrograde pyelography should be considered.

Oliguric Versus Nonoliguric Acute Renal Failure

In the past, acute renal failure was often defined by oliguria, the production of $<400 \text{ ml} \cdot \text{day}^{-1}$ of urine. However, nonoliguric acute renal failure is now recognized as a distinct clinical entity with a more favorable prognosis. Hospitalization time, complications, and mortality are less in nonoliguric patients. Drugs that increase solute excretion, such as mannitol and furosemide, may have the capacity to convert oliguric acute renal failure to the nonoliguric type. Some authors suggest that high doses of iv furosemide be given to attenuate the course of acute renal failure, whereas others claim that furosemide responders simply may have less severe renal impairment. The results are still controversial, and the efficacy of furosemide may depend on its administration in the initiation phase of acute renal failure. Nonetheless, after prerenal and postrenal factors contributing to azotemia have been corrected, a trial of furosemide $2\text{--}10 \text{ mg} \cdot \text{kg}^{-1}$ can be given in an attempt to convert an incipient oliguric renal failure to a nonoliguric state with restoration of blood volume if diuresis ensues.

Urinary Indices

Urine sediment is almost never normal in acute renal failure. A chemical profile of the urine aids immeasurably in assessing the cause of acute renal failure. In prerenal azotemia, tubular function remains relatively intact and sodium and water resorption results. There is an increase in sodium loss in the urine in patients with acute tubular necrosis because tubular function is impaired (Table 56-4). In acute oliguric renal failure, daily increases of blood urea nitrogen and serum creatinine average $10\text{--}20 \text{ mg} \cdot \text{dL}^{-1}$ and $0.5\text{--}1 \text{ mg} \cdot \text{dL}^{-1}$, respectively. If creatinine is elevated out of proportion to the blood urea nitrogen, it suggests that rhabdomyolysis may be the etiology of acute renal failure. The rapid rise in serum creatinine levels with rhabdomyolysis is attributable to the release of creatine from skeletal muscle; creatine is converted by nonenzymatic hydrolysis to creatinine.

| Parameter | Prerenal | Renal |
|---|----------|--------|
| Urinary osmolality (mOsm) | >500 | <350 |
| Urine/plasma creatinine | >30 | <20 |
| Urine sodium concentration ($\text{mEq} \cdot \text{L}^{-1}$) | <20 | >40 |
| Fractional excretion of sodium (%) | <1 | >2 |
| Renal failure index (%) | <1 | >2 |

TABLE 56-4. DIAGNOSTIC URINARY INDICES

Complications of Acute Renal Failure

Hyponatremia, edema, and pulmonary congestion can occur with oliguric acute renal failure as a result of salt and water overload. In addition, serum potassium concentration may rise because of the decreased elimination of potassium associated with acute renal failure. The usual rate of increase in serum potassium in the noncatabolic, oliguric patient is $0\text{--}0.5 \text{ mEq} \cdot 24 \text{ hr}^{-1}$. If potassium increases at a greater rate, other contributing factors should be sought and treated. Other electrolyte abnormalities present in acute renal failure include hyperphosphatemia, hypocalcemia, and mild hypermagnesemia. These abnormalities must be monitored closely and treated accordingly.

Because the kidneys can no longer eliminate the daily production of nonvolatile acid, there is a daily decrease of $1\text{--}2 \text{ mEq}$ in plasma bicarbonate levels, with a resultant anion gap metabolic acidosis. Still other complications include anemia, platelet abnormalities, and altered host defenses leading to an increased incidence of infection. Gastrointestinal complications include nausea, vomiting, and, most commonly, gastrointestinal hemorrhage, which occurs in $10\text{--}30\%$ of patients.

Treatment

Mortality rates of patients with acute renal failure vary from 30% to 60% . However, if acute renal failure follows surgery or trauma, the mortality may be as high as 70% . The first step in the management of acute renal failure is to exclude remedial causes. Specifically, identification and correction of prerenal and postrenal factors are essential. The treatment of acute renal failure includes diuresis and control of the extracellular fluid volume, treatment of hyperkalemia and acidosis, prophylaxis against infection and gastrointestinal bleeding, nutritional support, and dialysis. Because the prognosis is better with polyuria than with anuria, efforts should be made to produce and maintain a polyuric state. Intake and output must be monitored closely.

Conservative therapy is frequently ineffective for critically ill patients with acute renal failure; therefore, some form of dialytic therapy is usually indicated. The absolute indications for dialysis include symptomatic uremia, development of resistant hyperkalemia, severe acidemia or fluid overload not responsive to conservative therapy, and pericarditis. In addition, many advocate maintaining a blood urea nitrogen level of $100 \text{ mg} \cdot \text{dL}^{-1}$ and a creatinine level $8 \text{ mg} \cdot \text{dL}^{-1}$. Inadequate nutrition has recently been recognized as a reason for dialysis. Both hemodialysis and peritoneal dialysis have been used to manage acute renal failure, and survival data are similar. Each method has unique advantages and disadvantages.

Several modifications of hemodialysis have been applied to patients with acute renal failure. These include slow continuous ultrafiltration with intermittent hemodialysis, continuous arteriovenous hemodialysis, and continuous arteriovenous hemofiltration. All of these methods provide excellent hemodynamic stability. Access to blood is obtained either by percutaneous cannulation of the femoral artery and vein or via an arteriovenous shunt. No blood pump is used in this system because blood is driven by the patient's own arterial pressure. In continuous arterial venous hemofiltration, large amounts of ultrafiltrate are removed through a porous filter with the ultrafiltrate replaced by sterile iv fluid. In slow continuous ultrafiltration, much smaller volumes of ultrafiltrate are removed to correct any extracellular fluid volume expansion. However, intermittent dialysis is required to control uremia, hyperkalemia, and acidemia. With continuous arterial venous hemodialysis, dialysate flows through the dialysate compartment at $\sim 20 \text{ ml} \cdot \text{min}^{-1}$, which is sufficient to achieve a low, steady-state blood urea nitrogen and creatinine levels. Unfortunately, the various improvements in resuscitative techniques and technical advances in dialytic therapy have not significantly reduced the mortality of acute renal failure.

Hepatorenal Syndrome

Acute renal failure in the presence of severe advanced liver disease in the absence of clinical, laboratory, or anatomic evidence of other causes of renal dysfunction is known as hepatorenal syndrome. It is usually an oliguric form of renal failure with low urinary sodium concentrations. The picture appears similar to that of a prerenal

azotemia; however, it occurs in the setting of advanced liver disease. The precise mechanism for the renal failure is unknown. Currently, there is no effective treatment for hepatorenal syndrome.

INFECTIOUS DISEASES

Nosocomial Infections

Advances in technology and the use of a greater number of monitoring devices and therapeutic interventions have led to an increased number of infections. Patients in intensive care units suffer a disproportionate number of nosocomial infections compared with patients in non-critical care areas. These infections result in an increased morbidity, mortality, and cost.⁵⁵ Indeed, hospital-acquired infections have emerged as the leading cause of death in most ICUs. These infections are often polymicrobial, involve multiple resistant strains of bacteria, and do not respond to simple therapy. The incidence of nosocomial infections in ICUs is commonly 40–50%, many of which are preventable. The cost implications of prolonged hospitalization and treatment of infection are apparent.

The major determinants of the incidence and outcome of nosocomial infections include patient age, underlying disease, integrity of mucosal and integumentary surfaces, and the status of the immunologic defenses. Common sources of hospital-acquired infections in critically ill patients include the urinary tract, surgical wounds, pneumonia, intravascular devices, and sinusitis. Immunocompromised patients with a deficiency in any of the multifaceted host defenses are particularly prone to these infections and to other unusual infections. In particular, patients with acquired immunodeficiency syndrome commonly present with opportunistic infections caused by viruses, bacteria, parasites, and fungi. These patients invariably die despite transiently effective antimicrobial therapy and current attempts at immune reconstitution.

Selective Decontamination of the Digestive Tract

Selective decontamination of the digestive tract (SDD) has been proposed as a means of reducing the incidence of nosocomial infections in hospitalized patients, particularly those treated in the ICU. This method assumes that many nosocomial infections originate in the digestive tract and that it may be possible to reduce the incidence of such infections by eliminating pathogenic organisms from the digestive tract while leaving normal anaerobic flora intact. This is accomplished through the administration of both oral and parenteral antibiotics. Targeted organisms of selective decontamination include gram-negative aerobic bacilli, gram-positive aerobic cocci, and yeasts. The efficacy of this technique was first demonstrated in multiple trauma patients requiring mechanical ventilation. A dramatic reduction in the rate of infection in patients given antimicrobial decontamination from 81% to 16% was reported.⁵⁶ Since that time, several investigators have reported reduction in nosocomial infection rates using SDD.^{57,58} However, this has not been the universal experience, and other investigators have shown no change in infection rates.^{59,60} Unfortunately, to date, study design flaws have precluded a definitive conclusion on the efficacy of the technique of SDD. Additional large-scale multicenter prospective trials are needed before SDD can be confirmed as an effective method of preventing infection in critically ill patients.

Urinary Tract Infections

Urinary tract infections account for ~40% of hospital-acquired infections. Because most critically ill patients have an indwelling Foley catheter, it is not surprising that the urinary tract is a common source of infection. It is the most common site resulting in gram-negative bacteremia. The urinary tract should be considered a possible source of infection if the patient has bacteriuria and a clinical picture consistent with infection.

Wound Infections

Most surgical wound infections are caused by the introduction of bacteria directly into the tissue at the time of operation. They account for 10% of all infections in postsurgical ICU patients. Wounds should be observed for any signs of infection, and any purulent material should be sampled and sent for Gram stain and culture. Most wound infections are evident 3–7 days after surgical intervention. Wounds infected within 24 hr are generally fulminant infections caused by *Clostridium* or *b-hemolytic streptococci*. Later surgical wound infections are generally caused by gram-negative bacilli, anaerobic bacteria, and staphylococci. The administration of prophylactic antibiotics has aided immeasurably in reducing the postoperative wound infection rate.

Pneumonia

The most serious complication among hospital-acquired infections is lower respiratory tract infection. Hospital-acquired pneumonia occurs in up to 15% of ICU patients and is the leading cause of mortality in this group. The major organisms causing pneumonia in the critically ill patient population are gram-negative bacilli and *Staphylococcus aureus*. The diagnosis of pneumonia in critically ill patients who are maintained on mechanical ventilatory support can be difficult. Physical examination by itself is not an adequate screening procedure. Bacterial colonization of the upper airway is common and may not reflect lower respiratory tract disease. Nosocomial pneumonia is generally diagnosed by signs and symptoms of infection with bacteriologic verification in addition to a new pulmonary infiltrate that is unchanged by physical therapy. Unfortunately, Gram stain and culture of aspirated material through the endotracheal tube may not be reliable indicators of true lower respiratory tract infection. Antibody coating and quantitative cultures have not significantly improved diagnostic efficacy. Protected brush catheter bronchoscopy has been advocated as an effective adjunct to the diagnosis of pneumonia for patients maintained on mechanical ventilatory support.

Intravascular Devices

With advances in technology and invasive monitoring, intravascular device-related bacteremia has become a common problem, accounting for more than 25,000 cases of bacteremia annually. Contamination of intravascular devices may occur anywhere along the line from the infusate bottle to the skin entry site. Predisposition to intravascular device-related bacteremia is determined by both patient and hospital factors. The patient-related factors generally reflect the severity of underlying disease. Hospital-related factors are more controlled and include the type of catheter, site of insertion, technique of placement, and duration of cannulation. Recommendations for prevention of intravascular device-related infections should be based on the Centers for Disease Control guidelines.⁶¹

Intra-abdominal Infections

Abdominal infections generally occur in patients who have undergone prior intra-abdominal procedures. Risk factors for infection include prolonged operative time, use of foreign substances, inadequate drainage, presence of devitalized tissue, hematoma formation, and fecal contamination at the time of surgery. Acalculous cholecystitis is another potential etiology of abdominal infection in the postoperative period. Stress ulceration with significant gastrointestinal bleeding and perforation, or perforation due to mechanical causes, such as nasogastric drainage, can result in intra-abdominal infection in the absence of prior surgical intervention. The diagnosis of intra-abdominal infection relies primarily on physical examination with adjunctive radiologic evaluation including computed tomographic scan, ultrasonography, and abdominal roentgenograms.

Sinusitis

One of the recognized complications of nasotracheal intubation is the development of sinusitis. Nosocomial sinusitis accounts for 5% of all nosocomial infections in the critically ill patient population. However, this infection is frequently difficult to diagnose and often goes unrecognized. Patients may present with fever and leukocytosis but with few other signs or symptoms of overt infection. Fewer than half of the patients have purulent nasal drainage. The diagnosis of sinusitis relies on x-ray films of the paranasal sinuses. Unfortunately, these are frequently of suboptimal quality because they are taken in the critical care unit with a portable apparatus. However, if opacification of the sinuses is present or an air-fluid level is noted and aspiration reveals purulent material, the endotracheal tube should be removed and replaced using the oral route along with initiation of antibiotic therapy. Patients generally respond well and rarely require surgical drainage.

Central Nervous System Infections

Nosocomial CNS infections are uncommon in critically ill patients unless there are predisposing conditions such as neurosurgical procedures or CNS trauma. All pyogenic infections of the cranial contents originate either by hematogenous spread or extension from contiguous sites. Acute meningitis is a medical emergency that requires high-level diagnostic and therapeutic skills because it has a significant mortality rate. Patients frequently present with headache, stiff neck, seizures, and altered mental status. To differentiate bacterial meningitis from an aseptic meningitis syndrome, analysis of the CSF is necessary. All febrile patients with lethargy, headache, or confusion of sudden onset, even if only low-grade temperature is present, should be subjected to a lumbar puncture.

Brain abscess has occurred with a constant incidence even with the introduction of broad-spectrum antibiotic coverage. It is associated with a high morbidity and mortality. The most common age of patients for a brain abscess to occur is between 30 and 40 years of age, and it is frequently associated with sinusitis or otitis. Streptococci are the most common etiologic organisms. Treatment is both medical and surgical, with anaerobic antibiotic coverage and surgical drainage. Although

mortality has improved, there is still a significant incidence of neurologic residual, primarily seizure disorders.

Fungal Infections

With the use of broad-spectrum antibiotic therapy, organ transplantation, prosthetic cardiac valves, and immunosuppression from neoplasm, transplants, burns, and drugs, there has been an increased incidence of fungal infections. Clinical manifestations range from thrush to disseminated candidiasis. Organs involved with systemic disease include the kidneys, brain, myocardium, and eyes. The hallmark pathologically is diffuse microabscesses with a combined suppurative and granulomatous reaction. The diagnosis of candidemia may be difficult because serum antibodies have been uniformly disappointing and culture results are often negative. Although not all patients with candidemia require antifungal therapy, if treatment is indicated, amphotericin B is the drug of choice.

Sepsis Syndrome/Systemic Inflammatory Response Syndrome

The definition of the sepsis syndrome is based on easily acquired clinical data that can be applied to a broad population of patients. More recently, the term systemic inflammatory response syndrome (SIRS) was developed to describe a clinical response arising from a variety of insults including infection. The clinical evidence of the syndrome is based on a high index of suspicion and does not require confirmation with positive blood cultures or cultures of material from a closed space. Indeed, the sepsis syndrome can be defined in terms of the systemic response to infection expressed as tachycardia, fever or hypothermia, tachypnea, and evidence of inadequate organ perfusion. That is, the systemic response is what differentiates sepsis from simple infection or bacteremia. The object of such a broad definition is to facilitate early recognition and prompt institution of therapeutic interventions.

Sepsis has been estimated to occur in 1 of 100 hospitalized patients in the United States. Although its precise incidence is unknown, it has been estimated that up to 500,000 cases of sepsis occur each year in the United States. When the sepsis syndrome is accompanied by hypotension that is unresponsive to fluid therapy, it is often referred to as septic shock. Shock develops in ~40% of patients with sepsis. The increased survival of immunocompromised patients, those receiving organ transplants, and those with malignancy and inflammatory disease as well as the use of invasive medical devices and procedures has increased the incidence of sepsis.

The clinical response defined as SIRS includes two or more of the following: (1) temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$, (2) heart rate >90 beats $\cdot \text{min}^{-1}$, (3) respiratory rate >20 breaths $\cdot \text{min}^{-1}$ or $\text{PCO}_2 <32$ mm Hg, or (4) white blood cell count $>12.0 \times 10^9 \cdot \text{L}^{-1}$ or $<4.0 \times 10^9 \cdot \text{L}^{-1}$ or the presence of more than 0.1 immature neutrophils.⁶² The primary criteria for the diagnosis of the sepsis syndrome include (a) clinical evidence of infection such as tachycardia, tachypnea, and hyperthermia or hypothermia, and (b) evidence of altered organ perfusion or organ system dysfunction, such as alterations in mental status, arterial hypoxemia, elevated plasma lactate levels, or oliguria (Table 56-5).

| |
|---|
| Clinical evidence of infection |
| Hypothermia/hyperthermia |
| Impaired organ function or evidence of inadequate perfusion |
| Altered mentation |
| Hypoxemia |
| Elevated plasma lactate level |
| Oliguria |

TABLE 56-5. CLINICAL FEATURES OF THE SEPSIS SYNDROME

The sepsis syndrome can be identified as a systemic manifestation of presumed sepsis. Although the traditional definitions of sepsis (requiring positive blood or closed-space cultures) and of shock are frequently not present, the overall mortality rate is significant and similar to that reported by several investigators in patients with sepsis. The incidence of ARDS is also similar to that of previously published reports with sepsis. Clearly, the sepsis syndrome has a clinically significant morbidity and mortality rate. Progression from the sepsis syndrome to the associated clinical sequelae of septic shock and ARDS may be prevented by intervention at the onset of the sepsis syndrome. Identification and clinical evaluation of the criteria for the sepsis syndrome may demonstrate an appropriate point for evaluating therapeutic interventions. Recently, plasma exchange has been used as salvage therapy in severe infection in an attempt to remove bacterial products and to modulate the host inflammatory response.⁶³ While initial data suggested a lower mortality and a reduced number of organ failure in the plasma filtration patients, the differences did not reach statistical significance.⁶⁴

Septic Shock

It has been estimated that >300,000 gram-negative bacteremias occur in the United States each year. When bacteremia is caused by gram-negative bacteria, 10–20% may result in a documented period of hemodynamic instability and organ dysfunction. Mortality rates between 20% and 60% are reported for such severe cases, averaging 40% in several prospected trials.^{65,66, and 67}

Septic shock is the 13th most common cause of death in the United States and is the most common cause of death in medical and surgical intensive units. Statistics compiled by the Centers for Disease Control and Prevention indicate that the incidence of this disease has increased by 137% over the past decade. Both gram-negative and gram-positive bacteria as well as fungi and exogenous microbial components can initiate septic shock. Indeed, it has been extremely difficult to clinically differentiate between gram-positive and gram-negative infections. The gram-negative bacilli have a complex, three-layered cell wall structure. The lipopolysaccharide component of the outermost layer has been of particular interest because of its association with endotoxin properties.

Endotoxin is a complex molecule consisting of an outer core of repetitive sugar moieties, an O-antigen-specific side chain conferring serologic specificity, and an inner core linked to a structure termed lipid A. Endotoxin and other bacterial products activate cell membrane phospholipases to liberate arachidonic acid and initiate synthesis and release of leukotrienes, prostaglandins, and thromboxanes. It is these inflammatory mediators that primarily influence vasomotor tone, microvascular permeability, leukoaggregation, and the aggregation of platelets. Bacterial endotoxin can trigger a cascade of enzymatic processes, which leads to the release of vasoactive kinins, kallikreins in particular. Indeed, the physiologic changes associated with septic shock in humans result from a sophisticated interplay of mediators of cellular function and inflammation. Cytokines including tumor necrosis factor (TNF- α) and interleukins (IL-1, IL-6, and IL-8) influence cardiovascular, hemodynamic, and coagulation mechanisms. The presence of these compounds results in the production of excessive quantities of secondary mediators, which include lipids, peptides, and amines. Examples of secondary mediators include prostaglandin I_2 , thromboxane A_2 , prostaglandin E_2 , platelet-activating factor, bradykinin, angiotensin, vasoactive intestinal peptide, histamine, serotonin, and a variety of complement-derived products. Recently, apoptosis has been shown to be an important mechanism in patients with sepsis, shock, and multiple organ dysfunction.⁶⁸ Unfortunately, it remains unclear whether apoptosis is beneficial or detrimental to the host. If it is determined to be detrimental, drugs that inhibit caspase-3 may be therapeutically useful.

Monoclonal Antiendotoxin Antibodies

Several strategies have been developed to limit the effects of inflammatory mediators in septic shock. Development of new drugs to treat sepsis has been based in part on the premise that neutralizing bacterial toxins and potentially harmful host mediators could stop or slow this syndrome. Specifically, new therapies have been directed at different elements of the inflammatory cascade including endotoxin, TNF, IL-1, neutrophils, nitric oxide, eicosanoids, platelet activating factor, bradykinin, and leukotrienes. Currently, there are no antiendotoxins in clinical use, although several are under investigation. Antibodies to the O-side chain produce serotype-specific complement-dependent bactericidal activity. However, serotype specificity limits the clinical utility of O-side chain therapies. This led to investigation of antibodies directed at core and lipid A structures of endotoxin because these antibodies might cross-protect against diverse gram-negative bacteria. Core-directed antibodies are the only antiendotoxin therapies studied in clinical trials. Polyclonal core-reactive antiserum or immunoglobulin used to prevent or treat gram-negative sepsis has universally shown essentially no survival benefit.^{69,70 and 71}

Monoclonal antibodies were developed to produce a more specific antiendotoxin therapy with less risk for transmission of infection. E5, a murine IgM, has been tested in two multicenter randomized placebo-controlled clinical trials to date. Using meta-analysis and combining data from the two trials, it appeared that E5 decreased the time to recovery from organ dysfunction, and improved survival in a subgroup of patients who were not in refractory shock. HA-1A, a human IGM antibody that binds to

the lipid A domain of endotoxin, seemed initially to significantly reduce mortality in patients with sepsis and gram-negative bacteremia. However, several subsequent trials revealed a higher mortality rate in patients randomized to receive HA-1A⁷² leading to withdrawal of HA-1A from the market in European countries.

Recently, clinical trials have been initiated using neutrophil-derived bactericidal/permeability-increasing protein, high-density lipoproteins, and cationic polypeptides which may neutralize and/or enhance the clearance of endotoxin. To date, however, these antiendotoxin core-directed antibodies have shown little impact on survival in patients with septic shock.

Anticytokine Therapy

Cytokines are peptides that function as cellular signals to regulate the amplitude and duration of the host inflammatory response. Monocytes release TNF and IL-1 in response to bacterial components such as endotoxin. In animal models inhibition of TNF and IL-1 protects against endotoxin or bacteria.^{73,74} TNF and IL-1 play protective roles in the immune response to infection. Both recruit and activate neutrophils, macrophages, and lymphocytes and increase gene expression and release of acute phase proteins and granulocyte colony stimulating factors.⁷⁵ To date there have been few clinical trials of anticytokine therapy in humans, but the drugs seem to be effective in the animal model. However, a recent Phase II blinded randomized trial of recombinant human dimeric TNF receptor found no difference in mortality with low-dose anti-TNF compared with placebo; but disturbingly, patients who received medium and high doses had worse outcomes than did patients who received placebo. IL-1 antagonists have primarily been limited to the use of IL-1ra, acute phase cytokines structurally similar to IL-1, that can block the IL-1 receptor site and prevent activation of the target cell by IL-1. Clinical trials with recombinant IL-1ra have yielded conflicting results. This drug is under further investigation at present. Nonetheless, to date, anti-TNF and anti-IL-1 agents have not been shown to improve outcome in the treatment of human sepsis and septic shock and may, in fact, be potentially harmful. Whether it is clinically feasible to inhibit cytokines and limit their harmful effects while preserving their ability to perform necessary beneficial functions is unknown.

Nitric Oxide

NO is a low-molecular-weight, membrane-permeable gas that functions as a neurotransmitter, regulates vascular tone, and inhibits platelet aggregation and leukocyte adhesion.^{76,77} and ⁷⁸ At higher concentrations, NO has antitumor and antimicrobial activity. Inhibition of NO production has been proposed as a new approach to treat the hypotension of septic shock. It has been postulated that an increased production of NO during septic shock may lead to several harmful effects. NO may be largely responsible for sepsis-induced hypotension and myocardial depression.^{79,80} and ⁸¹ Further, NO may exert a proinflammatory effect during septic shock by enhancing cytokine release from phagocytic cells. Despite these potential hazards, NO may also have beneficial effects in septic shock. It appears to play a role in maintaining visceral and microvascular blood flow and may serve as a counterregulatory mechanism to maintain perfusion. In addition, its ability to block platelet aggregation and leukocyte adhesion could prevent microvascular stasis and thrombosis. NO synthase inhibitors, indeed, have been used in an attempt to improve survival in septic shock by increasing mean arterial pressure. However, to date, NO synthase inhibitors have not proved beneficial in the treatment of septic shock. In the future, however, NO synthase inhibitors that are highly selective for the induced isoform of the ionized or particular vascular beds may be developed and warrant further investigation.

Hemodynamic alterations in septic shock generally take two forms. Early in shock, the patient may have an increase in cardiac output, vasodilation, decrease in SVR, decrease in central venous pressure, and an increase in stroke volume. As shock progresses, the predominant picture is one of vasoconstriction with an increase in SVR and a decrease in cardiac output, central venous pressure, and stroke volume.

Organ systems involved in septic shock include the cardiac, renal, respiratory, and hematologic systems. Cardiac failure may develop in the setting of sepsis, primarily related to a myocardial depressant factor. Disseminated intravascular coagulation is not uncommon in septic shock. The pathogenesis probably involves the activation of the intrinsic clotting system by Hageman factor leading to activation of kallikrein. This, in turn, activates the potent vasodilator bradykinin, which promotes pooling of blood in peripheral tissues as well as increases in capillary permeability and localized tissue damage. Respiratory failure is probably the most important cause of death in patients with shock. Septic shock is an important cause of ARDS and severe respiratory failure. The kidneys are also target organs in septic shock, with resultant acute renal failure. Oliguria occurs early and probably results from inadequate renal perfusion.

Clinically, gram-negative bacteremia usually begins abruptly with chills, fever, nausea, vomiting, diarrhea, and prostration. When septic shock develops, there is in addition tachycardia, tachypnea, hypotension, cool pale extremities with peripheral cyanosis, mental obtundation, and oliguria.

Laboratory data vary greatly and depend on both the cause and extent of the shock syndrome. There is usually leukocytosis. However, the white blood cell count may be normal or even depressed. Serum bicarbonate is usually low and blood lactate level elevated. Electrolyte pattern may vary considerably, although there is a tendency to hyponatremia and hypochloremia.

Clinical treatment of septic shock is directed at two primary therapeutic goals: (1) rapid reversal of perfusion failure and (2) identification and control of infection. Certainly, every effort should be made to identify the cause of infection. However, treatment must be initiated early if it is to be successful. Indeed, antibiotic therapy should be initiated immediately and not await blood culture results. Early aggressive intervention, including antibiotics, fluid resuscitation, vasoactive drug support, mechanical ventilatory support, and surgical drainage of any infected site, is essential for successful treatment. Surgical drainage of closed space infections is mandatory, and a vigorous search for the infectious site is indicated in all patients.

Fluid resuscitation is the mainstay of treatment of septic shock. The fluid of choice for volume repletion remains controversial. Regardless of the fluid infused, however, it appears that survival can be improved if stroke volume or cardiac output improves in response to fluid challenge. If volume resuscitation and other supportive measures are inadequate in restoring perfusion, vasoactive drug support may be indicated. Because in the low-flow state of hypodynamic septic shock peripheral vascular resistances increase, drugs with predominantly α -adrenergic effects should be avoided. Dopamine and dobutamine have been used successfully in treating septic shock. These drugs have predominantly β -adrenergic effects and result in an increase in cardiac output due to an increase in both contractility and heart rate. Indeed, early data suggested an increased survival with high levels of oxygen delivery and consumption in patients with sepsis. However, a recent randomized controlled trial of the effect of treatment aimed at maximizing oxygen delivery in patients with severe sepsis or septic shock failed to show a reduction in morbidity or mortality.⁸² It is also important to maintain urine flow in an attempt to prevent renal failure. Urine output should ideally be kept higher than 30–40 ml · hr⁻¹, with fluid resuscitation and, if necessary, diuretic therapy. Corticosteroids have been advocated in the past as adjunctive therapy to the treatment of septic shock. However, more recent studies suggest that the use of high-dose corticosteroids provides no benefit in the treatment of severe sepsis and septic shock and is no longer recommended. Other areas of active investigation for the treatment of septic shock include high-dose naloxone, prostaglandin E₁, anticomplement, C5 antibodies, ibuprofen, indomethacin, and antiserum directed against cachectin.

NUTRITION

Adequate nutrition is essential to replace the nutrients used to meet the energy needs of tissues and to repair tissues being catabolized. In the critically ill or injured patient, nutrition is an essential part of treatment. For patients undergoing surgical procedures, malnutrition is well documented to be a risk factor, and perioperative nutritional support can reduce complications, mortality, morbidity, and length of hospital stay.

Nutritional Assessment

Assessment of nutrition is the first step in ensuring adequate support for the critically ill patient. Adequacy of nutrition can be assessed by anthropomorphic measurements, delayed cutaneous hypersensitivity to several antigens, and laboratory measurements reflecting severe protein and calorie malnutrition. Nitrogen balance is an important measure of nutritional status. The relationship between urea nitrogen excretion and metabolic rate is attributable to the obligatory oxidation of body cell mass that occurs with stress and starvation. Therefore, the extent of hypermetabolism can be predicted from a simple clinical determination of urea nitrogen collected in a timed urine specimen.

Estimation of Energy Requirement

The Harris-Benedict equation derived from indirect calorimetry measurements provides a reasonable estimate of basal caloric requirements (Table 56-6). Basal energy expenditure calculated in this manner correlates well with values obtained by contemporary techniques of continuous expired air analysis. The goal of nutritional support in nondepleted postoperative patients is to prevent excessive loss of lean tissue, whereas in nutritionally depleted patients it is restoration of lean tissue with concomitant restoration of fat reserves. Calculated basal energy needs should be increased by 30% with sepsis. Most of the current literature suggests the majority of critically ill patients require between 25 and 30 kcal · kg⁻¹ · day⁻¹. However, since most patients respond to overfeeding with retention of water and formation of fat and not protein, a target of providing 80% of the caloric needs in critically ill patients has been described. With the use of growth hormone protein synthesis can be achieved by providing 80% of the necessary calories and utilizing the patient's endogenous fat stores for additional energy. The exceptions to this are burn and trauma patients

who may require $40\text{--}45 \text{ kcal} \cdot \text{kg}^{-1} \cdot \text{day}^{-1}$ or patients who are calorie-depleted and need increased calories over a longer period of time to increase body fat mass.⁸³

| | |
|--------|---|
| Female | $BEE = 655 + (9.6 \times Wt) + (1.8 \times Ht) - (4.7 \times \text{age})$ |
| Male | $BEE = 66 + (13.7 \times Wt) + (5 \times Ht) - (6.8 \times \text{age})$ |

Wt = weight in kilograms; Ht = height in centimeters; age = age in years.

TABLE 56-6. HARRIS-BENEDICT EQUATIONS FOR ESTIMATION OF BASAL ENERGY EXPENDITURE (BEE)

Enteral Versus Parenteral Nutrition

The gastrointestinal tract is the route of choice for nutritional supplementation whenever possible. Intra-gastric feeding requires adequate motility and emptying; a residual greater than 150 ml is a relative contraindication to gastric feeding due to the high risk of aspiration. Small bowel feeding should be initiated under these circumstances. The presence of bowel sounds and the passage of flatus or stool is not necessary to begin postpyloric enteral feeding. There are a variety of commercially available enteral feeding formulas. With near-normal proteolytic and lipolytic activity in the gastrointestinal tract, meal replacement formulas can be used. These formulas are polymeric mixtures containing proteins, fats, and carbohydrates in high-molecular-weight forms. The lactose content is generally low, and fat content represents ~30% of the calories. Elemental diets use amino acids as the nitrogen source and usually contain little fat and no lactose. These diets also have a low viscosity, which makes them particularly useful for infusion through needle catheter jejunostomy tubes. Feeding modules are concentrated sources of one nutrient that can yield a small-volume, high-caloric mixture when added to a formula diet. This is particularly useful for patients on fluid restriction. A continuous-drip infusion of enteral feedings through a feeding tube is the preferred technique. The most common complication of enteral feedings is diarrhea. Other potential hazards include malpositioning of the feeding tube, hyperglycemia, and abnormalities in liver function tests.

Many disease-specific enteral formulas exist. "Immune-enhancing" preparations including arginine, glutamine, nucleotides, and/or omega-3 fatty acids have been used to reduce infection rates in the treatment of critically ill patients. Pulmonary formulas are designed to reduce CO_2 production and thereby ventilatory demand by providing nutrition high in fat content and low in carbohydrates. Enteral formulas used for patients with hepatic disease contain relatively large amounts of branched-chain amino acids and low quantities of aromatic amino acid. Renal formula used for enteral feeding are low in protein content and are usually calorically dense, containing up to $2 \text{ kcal} \cdot \text{ml}^{-1}$. They also are significantly lower in potassium, phosphorus, and magnesium content than the usual enteral formula. Other enteral formulations with growth hormone, selenium, vitamin C, vitamin E, and b-carotene are currently under investigation.⁸³

When the enteral route is unavailable or provides inadequate intake for the depleted patient, parenteral nutrition support should be undertaken. Contraindications to enteral feeding include diffuse peritonitis, intestinal obstruction, intractable vomiting, paralytic ileus, and severe diarrhea. Certainly, critically ill patients who are hypercatabolic, nutritionally depleted, or have multiple organ system failure should have total parenteral nutrition administered through a central line.

It is important that adequate calories be supplied to critically ill patients, and distribution of calories provided as carbohydrates, fats, and protein is equally important. Historically, caloric requirements for total parenteral nutrition were given primarily as carbohydrates, which has a respiratory quotient of 1, resulting in a large increase in carbon dioxide production and oxygen consumption. Fat emulsions supply essential fatty acids in a concentrated source of calories. Because fat emulsions are oxidized with a respiratory quotient of 0.7, carbon dioxide production and ventilatory requirements are reduced.

Although nutritional support has been shown to improve wound healing, decrease morbidity and mortality, and assist in immunocompetence, many complications have been described. Technical complications relate primarily to insertion of the central venous catheter used for access. Other complications of hyperalimentation include sepsis, metabolic abnormalities, electrolyte disturbances, acid-base disorders, hepatic dysfunction, hypercalcemia and pancreatitis, metabolic bone disease, and fluid overload.

DISORDERS OF COAGULATION

There are three essentials for a normal clotting mechanism: vascular integrity, normal platelet function, and normal coagulation factors. The initial step in normal coagulation is compensatory reduction in intravascular pressure of the severed ends of blood vessels, followed by platelets covering the damaged surfaces. They accumulate at the site, ultimately forming a hemostatic plug. The coagulation cascade is then activated with the formation of fibrin. Two distinct pathways operate to form thrombin, which then converts fibrinogen into fibrin. The intrinsic pathway produces thrombin from factors present only in the plasma, whereas the extrinsic pathway uses extraplasmic tissue factors as well as plasma factors. The final step in the normal coagulation scheme is removal of the fibrin and platelet clot by the fibrinolytic system. The end result of the activation of these pathways is the conversion of plasminogen into plasmin, which cleaves both fibrinogen and fibrin. There is an ongoing equilibrium between the activation of the coagulation system and the activation of the fibrinolytic system.

Disorders in the coagulation system lead either to bleeding or to thrombosis. Clinical evaluation of disorders of coagulation is based on history, physical examination, and laboratory studies. A history of abnormal bleeding or evidence of bleeding on physical examination may assist in making a definitive diagnosis. Laboratory screening tests for hemostatic profile are essential. Such a profile of test should include a platelet count, bleeding time, prothrombin time, partial thromboplastin time, and review of the peripheral blood smear. The prothrombin time is a measure of the efficiency of thrombin formation by the extrinsic pathway. Abnormalities in the prothrombin time can be caused by absence or impairment of any coagulation factor in the intrinsic or extrinsic clotting system. The partial thromboplastin time is used to assess the efficiency of the intrinsic clotting system. Prolongation of the partial thromboplastin time generally represents deficiency or inhibition of Factors I, II, V, VIII, IX, X, XI, or XII. Qualitative abnormalities in platelets are manifested by prolongation of the bleeding time. If platelet function is intact, bleeding abnormalities usually do not occur unless the platelet count is below $100,000 \text{ mm}^{-3}$.

Disorders of hemostasis in critically ill patients are generally complex and represent multiple acquired deficiencies. Indeed, in most critically ill patients a bleeding disorder is only one manifestation of a complex series of failing organ system interactions. Common acquired deficiencies of hemostasis include disseminated intravascular coagulation, liver disease, vitamin K deficiency, anticoagulants, and massive blood transfusion.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation is a syndrome and not a primary disease state that reflects severe underlying pathology. The coagulation cascade is activated, resulting in the deposition of small thrombi and emboli throughout the microvasculature. This phase is then followed by secondary fibrinolysis. Repetition of this cycle leads to depletion of coagulation proteins and platelets and the antihemostatic effects of fibrin degradation products. Clinical manifestations of disseminated intravascular coagulation can result in thrombosis or hemorrhage. Most commonly, bleeding is manifest from multiple sites, including venipuncture sites, nasogastric tubes, urinary catheters, or endotracheal tubes. Laboratory manifestations of disseminated intravascular coagulation include thrombocytopenia, hypofibrinogenemia, and prolongation of the prothrombin time. Abnormalities of these indicators confirm disseminated intravascular coagulation. If all are not abnormal, additional studies including partial thromboplastin time, thrombin time, and fibrin degradation products should be ordered. In addition, review of the peripheral smear may reveal a microangiopathic hemolytic anemia from cell trapping and damage within fibrin thrombi.

The treatment of disseminated intravascular coagulation is the treatment of the underlying cause. Some authors have suggested the use of heparin as supportive therapy to reduce thrombin generation and prevent further consumption of clotting proteins until the underlying disease process could be controlled. Although it remains controversial, current recommendations do not support the use of routine heparin therapy, but rather the administration of fresh-frozen plasma and cryoprecipitate to replace depleted clotting factors and of platelet concentrates to correct thrombocytopenia.

An unusual cause of bleeding can result from defects in the fibrinolytic system. Patients with α_2 plasmin inhibitor deficiency, cirrhosis of the liver, or malignancy may develop diffuse bleeding from primary fibrinolysis rather than disseminated intravascular coagulation. Laboratory data reveal relatively normal prothrombin time and partial thromboplastin time with a normal platelet count and a disproportionately low fibrinogen level. Patients with clearly established primary fibrinolysis should receive

e-aminocaproic acid and not heparin. However, if concomitant disseminated intravascular coagulation is suspected, e-aminocaproic acid should be avoided because it can cause massive, often fatal thrombosis.

POISONING

Despite preventive health programs and increased public awareness, poisoning remains a common and serious medical problem. Accidental poisonings account for about 5000 deaths per year, with suicides by chemical agents causing an additional 6000 deaths per year. Poisoning is of particular importance in the pediatric population. As many as 2 million children in the United States accidentally swallow toxic material and about 1 ingestion out of 1000 is fatal. However, poisoning is by no means a problem limited to children. One half of all poisoned patients are over the age of 20 years.

The causative agents in poisoning vary with age. Children less than 5 years of age tend to ingest household products, whereas older patients are more likely to choose drugs. Aspirin accounts for 25% of all ingestions and is reported as the most common medicine involved in poisoning.

Prompt recognition and early intervention are essential to the successful treatment of poisoning. The diagnosis of poisoning can be difficult to make because the toxic effects of many agents are nonspecific. Certainly, a high index of suspicion must be maintained when confronted with a patient presenting with seizures, coma, psychosis, acute renal or hepatic insufficiency, or bone marrow depression. However, most poisoning syndromes manifest nonspecific symptoms. Similarly, it is uncommon for the physical examination to show characteristic toxic effects of chemical substances.

Identification of the toxic agent should be attempted in every case of poisoning. Gastric fluid, urine, and blood samples should be sent to the laboratory to screen for possible poisons. Modalities available to identify the offending agents include thin-layer chromatography, gas-liquid chromatography, high-performance liquid chromatography, and spectrometry. Patients poisoned with drugs frequently take more than one agent, which can lead to drug interactions and difficulty in interpreting test results.

Treatment

Treatment of poisoning should not await toxicologic determinations. Supportive care should begin immediately, including the essentials of basic cardiopulmonary support. In addition, symptomatic treatment of neurologic, renal, and hepatic dysfunction is mandatory. Attention should then be directed to minimizing absorption of the poison. For ingested poisons this means prevention of absorption from the gastrointestinal tract by lavage, emetics, and adsorbents such as charcoal. Cathartics generally have no role in treating poisoning.

Attempts should also be made to hasten elimination of absorbed poisons. Techniques available to increase elimination of poisons include diuresis, dialysis, chelation, hemoperfusion, exchange transfusion, and antibodies. Glomerular filtration and dialysis are generally effective only with substances found in plasma water and not protein-bound poisons. Hemoperfusion is most effective if used immediately after ingestion of the poison. Exchange transfusion may be especially useful in small children in whom hemoperfusion may be technically difficult. Antibodies can also be used as a high-affinity adsorbent in the patient's bloodstream to hasten elimination.

Common Poisons

Application of the principles used for the management of acute poisonings can be exemplified by several common agents.

Acetaminophen

This aspirin substitute is a frequent cause of poisoning. Clinical manifestations are generally nonspecific. Patients may initially present with pallor, lethargy, nausea, vomiting, and diaphoresis. Hepatotoxicity may become evident 1–2 days after ingestion and can be fatal. Liver damage results when the normal metabolic pathways become saturated so that an increased fraction of drug is inactivated by the cytochrome P-450 system, glutathione stores are depleted, and the reactive intermediates bind to liver macromolecules. Treatment of acetaminophen intoxication is initiated by induction of emesis or gastric lavage followed by administration of activated charcoal. Attention is next directed toward increasing sulfhydryl donors such as glutathione to allow greater binding of the toxic acetaminophen metabolites and therefore reduce liver damage. Early administration of *N*-acetylcysteine can significantly reduce the incidence of acetaminophen-induced hepatotoxicity.

Alcohols

Although the low-molecular-weight alcohols (methanol, ethanol, ethylene glycol, and isopropanol) are relatively weak poisons, the result of their metabolism can be fatal. Ethanol depresses ventilation, decreases myocardial contractility, predisposes to hypothermia, and causes hypoglycemia, especially in children. Although there is no antidote to ethanol and no way to hasten its metabolism, it is readily removed by hemodialysis. However, usually critical care support with assisted ventilation of the lungs suffices in the treatment of ethanol intoxication. It is as important to treat associated illnesses in the patient with an ethanol overdose as it is to support the patient for the effects of the drug poisoning.

Methanol and ethylene glycol poisonings are common, yet frequently undetected. It is important to detect poisoning with these agents early because the metabolites are potent poisons and may lead to irreversible toxicity if they go unrecognized. Methanol is present in windshield washer antifreeze and solvents and in organic synthetic processes, whereas ethylene glycol is the major component in automotive antifreeze and is found in various organic solvents and cosmetics. Treatment of methanol and ethylene glycol poisoning is systemic alkalinization to decrease ocular and renal toxicity followed by hemodialysis to accelerate elimination of the alcohols and their metabolites.

Carbon Monoxide

Carbon monoxide (CO) is a colorless, odorless, tasteless, nonirritating gas produced by the incomplete combustion of carbonaceous material. It is the major cause of death in patients exposed to smoke inhalation from fires. CO is responsible for ~3500 accidental and suicidal deaths per year in the United States. It exerts its toxic effects through tissue hypoxia. The hemoglobin molecule has an affinity for CO that is 200 times greater than its affinity for oxygen. The combination of CO with hemoglobin forms carboxyhemoglobin, which is incapable of carrying oxygen. It also interferes with the release of oxygen from oxyhemoglobin, which decreases the amount of oxygen available to the tissues. In addition, because the rate of dissociation of CO from hemoglobin is extremely low, carboxyhemoglobin produces an acute decrease in blood oxygen content that is not readily reversed. The amount of carboxyhemoglobin present in blood depends on the concentration of CO in the inspired air and on the time of exposure.

Symptoms depend on the amount of carboxyhemoglobin present and the patient's activity level, tissue oxygen demands, and hemoglobin concentration. Exposure to low concentrations of CO causes irritability, altered visual and motor skills, headache, nausea, vomiting, and predisposition to angina pectoris. Severe poisoning may result in seizures, coma, respiratory failure, and death. The classic cherry red color of the skin and mucous membranes of patients with CO poisoning results from the bright red cast of carboxyhemoglobin. However, in patients with severe poisoning, cyanosis may predominate over the cherry red color.

Treatment of CO poisoning is to remove the offending agent and provide a high oxygen-enriched environment. The half-time of CO elimination can be shortened from 4 hr to 40 min by hyperventilation of the lungs with 100% oxygen. Ventilation may require mechanical support. Other treatment modalities include hyperbaric oxygen, transfusion therapy, and diuretics and steroids for the treatment of complicating cerebral edema.

LEGAL AND ETHICAL ISSUES

Brain Death

Brain death is defined as the irreversible cessation of all functions of the entire brain. This clinical definition is confirmed by autopsy studies revealing destruction of the entire brain in both the cerebral hemispheres and the brainstem. The primary insult leads to brain edema with increases in ICP. In the vast majority of brain death cases, the ICP exceeds systolic blood pressure within 12–24 hr. Currently, most states recognize brain death as a sufficient criterion for declaration of death. There have been many definitions offered of brain death. However, the broadly held consensus was reflected in *Defining Death*, a report issued in 1981 by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research.⁸⁴ In response to a congressional mandate, the commission recommended a statute, the Uniform Determination of Death Act (UDDA), which has become the most widely accepted legal formulation of the standards for determining human death. In addition, it also provided an updated formulation of the medical criteria for applying the standard.⁸⁵ Representatives of the American Bar Association, American Medical Association, National Conference of Commissioners on Uniform State Laws, and the Academy of the American Encephalographers Society agreed on the UDDA definition as follows: An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical

standards. These guidelines are now widely accepted by physicians and hospitals for clinical decision-making. This formulation of brain death is based on a clinical diagnosis with certain preconditions and confirmatory tests.^{86,87}

With advances in technology and medical capability, even seemingly clear-cut definitions, such as death, become complex and difficult to translate into law and policy. Indeed, for many years courts were slow to modify the common law definition of death, *i.e.*, cessation of all vital functions including respiration and circulation, to accept the determination of death based on irreversible cessation of all functions of the brain. The most common and familiar criteria for the diagnosis of whole brain death are the Harvard criteria published in 1968⁸⁸ by an Ad Hoc Committee of the Harvard Medical School. Tests generally used to determine brain death rely on response to stimuli, the presence of reflexes and spontaneous movements, and the electroencephalogram. There must be no evidence of hypothermia or drugs that depress brain function. The findings must persist over 24 hr. These Harvard criteria are now widely accepted by the medical profession and can be recognized legally as defining death in many states.

Indeed, organ transplantation was a major impetus for focusing public attention on the need to update standards for determining death, even though only ~15% of patients who are declared brain dead become organ donors. A special standard only for organ donors would fail to address the overwhelming majority of comatose ventilator-supported cases. This could create a separate standard of death for donors that could lead to abuse and confusion. Thus, along with the clinical diagnosis, confirmatory tests are generally required and can be dependent on normal function or intracranial blood flow.

Do Not Resuscitate (DNR) Orders

Few areas in clinical medicine generate as much controversy and debate as does the decision to withdraw or withhold treatment of critically ill patients.^{89,90} Certainly, the opinion in the Joseph Saikewicz case issued by the Massachusetts Supreme Judicial Court in November 1977 raised much controversy.⁹¹ In this case a guardian was appointed for a profoundly retarded, institutionalized 67-year-old man with acute myeloblastic monocytic leukemia and the court was asked to decide if treatment should be undertaken. It was understood that treatment would be painful and carry potential hazards with very little hope for recovery. The County Probate Court recommended withholding therapy and the Supreme Court affirmed this order. However, the Supreme Court further stated that the decision to withhold or withdraw the life-support measures in a terminally ill, incompetent patient was not within the jurisdiction of any hospital committee or panel, but rather the ultimate decision-making responsibility of the courts. Justice Paul J. Liacos, the author of the Saikewicz decision, offered a different approach to DNR orders when he suggested that they present a case for physician discretion, and that the principles of Saikewicz are inapplicable.⁹²

In a subsequent court opinion, in the matter of Dinnerstein, the legality of DNR orders was addressed. In this case, the patient was a 67-year-old woman with Alzheimer's disease, a massive stroke, and left hemiparesis. She was left in a persistent vegetative state, immobile, speechless, unable to swallow without choking, and barely able to cough. The patient's physician recommended no resuscitation in the event of cardiopulmonary arrest and the patient's family concurred. Because of the legal uncertainty surrounding "no code" orders, the physician, hospital, and family asked the court to rule about the legality of the order. The Massachusetts Appeals Court held that a DNR order in these circumstances was lawful and advance judicial approval was not necessary to write such orders. Resuscitation was not "a treatment offering hope of restoration to normal integrated functioning cognitive existence. Attempts to apply resuscitation if successful will do nothing to cure or relieve the illness, which will have brought the patient to the threshold of death."⁹³ A second Massachusetts case upholding DNR orders involved a 5-month-old infant abandoned at birth who suffered from profound congenital cardiopulmonary disease with little hope of survival. The patient's physician recommended that a DNR order be entered on the patient's medical chart, but the guardian, the Department of Social Services, refused to consent. In this case the Massachusetts Supreme Judicial Court found that a full resuscitation effort would not serve the child's interest and that the child would reject full resuscitation if the child were competent to decide.⁹⁴

The right to reject resuscitative or any lifesaving medical treatment was best outlined in the Karen Ann Quinlan case. The court stated that the constitutional right to privacy encompasses the freedom of the terminally ill but competent individual to decline medical treatment when such treatment will only prolong suffering needlessly and denigrate the quality of life.

In a recent report the Council on Ethical and Judicial Affairs of the American Medical Association outlined the guidelines for the appropriate use of DNR orders.⁹⁵ In this report the Council recommended that (1) efforts should be made to resuscitate patients who suffer cardiac or respiratory arrest except when circumstances indicate that administration of cardiopulmonary resuscitation would be futile or not in accord with the desires or best interests of the patient; (2) if a patient is incapable of rendering the decision regarding the use of cardiopulmonary resuscitation, a decision may be made by a surrogate decision maker based on the previously expressed preferences of the patient, or if such preferences are unknown, in accordance with the patient's best interest.

Withholding or withdrawing life-sustaining therapies is becoming more widely accepted. The American Hospital Association has estimated that 70% of patients who die in hospitals have some form of life-sustaining treatment terminated before death. However, perceptions by physicians regarding the legal liability have been slow to change. Indeed, physicians tend to believe that withholding life support is more acceptable than withdrawing it. Indeed, in a recent survey,⁹⁶ the majority of health care workers indicated that there is an ethical difference between withdrawing and withholding treatment, despite the unanimity in both law and philosophy that there is no intrinsic moral or legal distinction between the two. However, ICU physicians consider withholding and withdrawal ethically similar and appropriate processes, regard concerns about cost or distributive justice as unimportant in decision making, and consider patient and surrogate wishes paramount in decision making, but view these wishes in the context of their own assessment of prognosis.⁹⁷ Finally, despite a contracting health care budget that has sensitized society to the issues of resource allocation, the demand for the health care dollar has continued to expand, creating an inherent conflict between economics and bioethics.⁹⁸ This represents but one of the many complex and difficult issues that must be confronted in the care of the critically ill patient.

Treatment of cardiac and respiratory arrest is an integral part of anesthesia practice. The American Board of Anesthesiology indicates in its *Booklet of Information* that the “clinical management and teaching of cardiac and pulmonary resuscitation” are some of the activities that define the specialty of anesthesiology. The cardiopulmonary physiology and pharmacology that form the basis of anesthesia practice are applicable to treating the victim of cardiac arrest. However, there is specialized knowledge relating to blood flow, ventilation, and pharmacology under the conditions of a cardiac arrest that must be understood to maintain leadership of the modern cardiopulmonary resuscitation (CPR) team. This chapter concentrates on those aspects of CPR that are different from the more common circumstances requiring cardiovascular support, e.g., shock and dysrhythmias.

HISTORY

Anesthesiologists have contributed many of the elements of modern CPR and continue to be active investigators and teachers in the field. Discoveries leading to current CPR practice have a long history recorded in many famous works.^{1,2} The earliest reference may be the Bible story of Elisha breathing life back into the son of a Shunammite woman (II Kings 4:34). In 1543, Andreas Vesalius described tracheotomy and artificial ventilation.³ William Harvey’s manual manipulation of the heart is well known. Early teaching of resuscitation was organized by the Society for the Recovery of Persons Apparently Drowned, founded in London in 1774. The combined techniques of modern CPR developed primarily from the fortuitous assemblage of innovative clinicians and researchers in Baltimore in the 1950s and early 1960s. Building on the long history of contributions from around the world, these investigators laid the framework for current CPR practice. In the late 1950s, mouth-to-mouth ventilation was established as the only effective means of artificial ventilation.^{4,5,6} and ⁷ The internal defibrillator was developed in 1933⁸ but not applied successfully until 1947.⁹ It was another decade before general use was made possible by the development of external cross-chest defibrillation.^{10,11} Despite these advances, widespread resuscitation from cardiac arrest was not possible until Kouwenhoven *et al* described success with closed-chest cardiac massage in a series of patients.¹² The final major component of modern CPR was added in 1963 when Redding and Pearson described the improved success obtained by administering epinephrine or other vasopressor drugs.¹³

SCOPE OF THE PROBLEM

Cardiovascular disease remains the most common cause of death in the industrialized world. Although cardiovascular mortality has been declining in the United States since the mid-1960s, nearly 50% of all deaths are due to cardiovascular causes.¹⁴ Of the 1 million annual cardiovascular deaths, approximately half are related to coronary artery disease and the majority of these are sudden deaths. Thus, CPR teaching and research tend to focus on myocardial ischemia as the primary cause of cardiac arrest. However, anesthesiologists are more likely than other practitioners to deal with etiologies other than myocardial infarction. Cardiopulmonary resuscitation is symptomatic therapy, aimed at sustaining vital organ function until natural cardiac function is restored. The details of effective resuscitation technique are important. However, search for a remediable cause of the arrest must not be lost in excessive attention to mechanics.

Brain adenosine triphosphate (ATP) is depleted after 4–6 min of no blood flow. It returns nearly to normal within 6 min of starting effective CPR. Studies in animals suggest that good neurologic outcome may be possible from 10–15-min periods of normothermic cardiac arrest if good circulation is promptly restored.^{15,16} In clinical practice, the severity of the underlying cardiac disease is the major determining factor in the success or failure of resuscitation attempts. Of those factors under control of the rescuers, poor outcomes are associated with long arrest times before CPR is begun, prolonged ventricular fibrillation without definitive therapy, and inadequate coronary and cerebral perfusion during cardiac massage. Survival from out-of-hospital cardiac arrest is improved when CPR is begun by bystanders.¹⁷ Optimum outcome from ventricular fibrillation is obtained only if ventilation and closed-chest compression are begun within 4 min of arrest and defibrillation applied within 8 min.^{18,19} The importance of early defibrillation has been known for some time and it is now being emphasized in CPR practice.^{20,21} If the diagnosis of ventricular fibrillation can be established and the equipment is available, defibrillation should take precedence over all other resuscitative measures.

With an effective rapid response emergency medical system, initial resuscitation rates of 40% and survival to hospital discharge of 10–15% are reported after out-of-hospital arrests.^{19,21} A better outcome might be expected for in-hospital arrests because of rapid response times and expert personnel. However, overall rates for initial resuscitation and survival to discharge from in-hospital arrest are about 40% and 10%, respectively.²² Intercurrent illnesses of hospitalized patients reduce the likelihood of survival and the arrest victim is more likely to be elderly, a factor that may reduce survival. Within the hospital, the operating room is the location where CPR has the highest rate of success. Cardiac arrest occurs approximately 7 times for every 10,000 anesthetics.²³ The cause for the arrest is anesthesia-related, ~4.5 times for every 10,000 anesthetics, but mortality from these arrests is only 0.4 per 10,000 anesthetics. Thus, resuscitation is successful ~90% of the time in anesthesia-related cardiac arrests. Outside the operating suite, the best initial resuscitation rates are found in the intensive care unit (ICU), whereas the best survival rates are for patients arresting in the emergency department.²²

ORGANIZING A SOLUTION

Over the past 30 years, CPR has become widely practiced, facilitated by the efforts of the American Heart Association, the International Red Cross, the European Resuscitation Council, and many other organizations around the world. Specific guidelines for the teaching and practice of CPR are published periodically.²⁴ These guidelines were developed because numerous individuals with varying levels of expertise (lay public, emergency personnel, nurses, and physicians) need to be trained if CPR is to be effective in saving lives. For training to be effective, a standardized approach is needed ([Table 57-1](#)). The organizations also develop and sponsor courses at different levels of complexity for teaching CPR. The two levels of CPR care are referred to as basic life support (BLS) for ventilation and chest compressions without additional equipment and advanced cardiac life support (ACLS) for using all modalities available for resuscitation. Medical personnel need to be well versed in both levels of care. BLS is also appropriate for lay people.

-
1. Determine unresponsiveness
 2. Activate emergency medical services or team
 3. Position victim supine on firm surface
 4. Open airway
 5. Determine absence of breathing
 6. Perform ventilation: 2 breaths
 7. Determine absence of pulse
 8. Initiate chest compressions
 9. Alternate 15 compressions with 2 breaths
-

Table 57-1. STANDARD APPROACH TO THE UNCONSCIOUS PATIENT

The American Heart Association periodically coordinates a National Conference on CPR and Emergency Cardiac Care during which worldwide experts evaluate the scientific data regarding CPR. The recommendations resulting from the National Conference comprise the most complete compilation of guidelines for CPR practice.²⁴ International contributions to the most recent Conferences in 1992 and 2000 produce similar CPR practices worldwide. However, no common infrastructure exists that allows adoption of true international guidelines for CPR. The algorithms for approaching the patient with cardiac arrest published in the guidelines are familiar to all physicians and are reproduced throughout this chapter. However, the major purpose of this chapter is not to reiterate the standard approach but to provide the scientific background, where it exists, that led to adoption of the standard approach, to point out areas of continuing controversy, and to suggest areas of possible future development.

ETHICAL ISSUES: DO NOT RESUSCITATE ORDERS IN THE OPERATING ROOM

Institution of cardiopulmonary resuscitation is standard medical care when an individual is found apparently dead. In recent years, terminally ill patients have become increasingly concerned about inappropriate application of life-sustaining procedures, including CPR. Through living wills and other instruments, patients have begun placing limitations on medical treatment, including DNR—do not attempt resuscitation—orders. Such requests are generally accepted, even welcomed, by health care workers. However, the operating room is one area of the hospital where DNR orders continue to cause ethical conflicts between medical personnel and patients.^{25,26} There are ethically sound arguments on both sides of the issue as to whether DNR orders should be upheld in the operating room.

The patient's right to limit medical treatment, including refusing CPR, is firmly established in modern medical practice based on the ethical principle of respect for patient autonomy. A terminally ill patient can reject heroic measures such as resuscitation and still choose palliative therapy. If a surgical intervention will ameliorate symptoms or cure a problem that improves quality of life, there is no reason to withhold this treatment. During surgery, the patient reasonably may desire to maintain the DNR status to avoid heroic measures that serve only to prolong death. Operative intervention increases the risk of cardiac arrest, and the patient may not want the burden of surviving in a worse condition than previously. Thus, the time that the DNR order provides the greatest protection against unwanted intervention is during surgery. The possibility of death under anesthesia may be viewed as especially peaceful.

Despite these rather strong arguments for treating a DNR status in the operating room the same way it is treated elsewhere in the hospital, most operating room personnel are at least a little uneasy caring for these patients. Many surgeons require that DNR orders be suspended during the perioperative period or assume that consent to surgery includes such suspension. There are multiple reasons for the reluctance to accept DNR status during surgery and anesthesia. Approximately 75% of cardiac arrests in the operating room are related to a surgical or anesthetic complication and resuscitative attempts are highly successful.²³ Ethically, surgeons and anesthesiologists feel responsible for what happens to patients in the operating room: *primum non nocere* (first, do no harm). Although the physicians are highly diligent in monitoring and managing changes in the patient's status, complications and arrests do occur. Honoring a DNR under these circumstances is frequently viewed as failure to treat a reversible process, and hence tantamount to killing. This is an ethically sound view if the cause of arrest is readily identifiable and easily reversible and treatment is likely to allow the patient to fulfill the objectives of coming to surgery.²⁵

Institutionally, these ethical conflicts should be addressed by adoption of clear policies by hospitals.²⁷ For the individual patient, conflicts can be resolved by communication among the patient, family, and caregivers. A mutual decision can often be reached to suspend or severely limit a DNR order in the perioperative period if the patient understands the special circumstances of perioperative arrest, that interventions are brief and usually successful, and that the physicians support the patient's goals in coming to surgery and values in desiring not to prolong death. Many interventions commonly used in the operating room (mechanical ventilation, vasopressors, antidysrhythmics, blood products) may be considered forms of resuscitation in other situations. The only modalities that are not routine anesthetic care are cardiac massage and defibrillation. Therefore, the specific interventions included in a DNR status must be clarified with specific allowance made for methods necessary to perform anesthesia and surgery.

BASIC LIFE SUPPORT

Basic life support consists of those elements of resuscitation that can be performed without additional equipment: basic airway management, rescue breathing, and manual chest compressions. Common practice is to approach a victim with the airway–breathing–circulation (ABC) sequence, although the circulation–airway–breathing (CAB) sequence has been used in some countries with comparable results. [Table 57-1](#) itemizes the standard approach to an unconscious victim.

Airway Management

The problem of airway obstruction by the tongue in the unconscious patient is familiar to the anesthesiologist. The techniques used for airway maintenance during anesthesia are applicable to the cardiac arrest victim. The primary method recommended to the public is the same “head tilt–chin lift” method commonly employed in the operating room.²⁸ The head is extended by pressure applied to the brow while the mandible is pulled forward by pressure on the front of the jaw, lifting the tongue away from the posterior pharynx. The “jaw thrust” maneuver (applying pressure behind the rami of the mandible) is an effective alternative. Properly inserted oropharyngeal or nasopharyngeal airways can be useful before intubation, recognizing the danger of inducing vomiting or laryngospasm in the semiconscious victim. Tracheal intubation provides the best airway control, preventing aspiration and allowing the most effective ventilation. Intubation is indicated in any resuscitation lasting more than a few minutes, but it should not be performed until adequate ventilation (preferably with supplemental oxygen) and chest compressions have been established. A number of alternative airways designed for blind placement by individuals who are not skilled laryngoscopists have been described.²⁴ These include the laryngotracheal mask, pharyngotracheal lumen airway, esophageal obturator airway, esophageal gastric tube airway, and combination esophageal tracheal tube. None ensures airway control as well as an endotracheal tube. When other methods of establishing an airway are unsuccessful, translaryngeal ventilation or tracheotomy by cricothyroid puncture may be necessary.

Foreign Body Airway Obstruction

It is estimated that foreign body airway obstruction accounts for 1% of all sudden deaths (~3900 deaths in the United States in 1989).²⁴ Airway occlusion by a foreign object must be considered in any victim who suddenly stops breathing and becomes cyanotic and unconscious. It occurs most commonly during eating and is usually due to food, especially meat, impacting in the laryngeal inlet, at the epiglottis or in the vallecula. Sudden death in restaurants from this cause frequently is mistaken for a myocardial infarction, leading to the label “cafe coronary.”²⁹ Poorly chewed pieces of food, poor dentition or dentures, and elevated blood alcohol are the most common factors contributing to choking. The signs of total airway obstruction are the lack of air movement despite respiratory efforts and the inability of the victim to speak or cough. Cyanosis, unconsciousness, and cardiac arrest follow quickly. Partial airway obstruction will result in rasping or wheezing respirations accompanied by coughing. If the victim has good air movement and is able to cough forcefully, no intervention is indicated. However, if the cough weakens or cyanosis develops, the patient must be treated as if there were complete obstruction.

Mothers and friends have been pounding on the backs of choking victims for centuries. In 1974, Heimlich proposed abdominal thrusts as a better method of relieving airway obstruction.³⁰ In 1976, Guildner *et al* reported that sternal thrusts were just as effective.³¹ Subsequently, there were multiple studies of these maneuvers in experimental animals, anesthetized and awake humans, and even on mathematical models.^{32,33,34} and ³⁵ There is general agreement that a normal cough produces higher airway pressures and moves a larger volume of air than any artificial maneuver. Abdominal and sternal thrusts produce modest elevations in airway pressure but can produce high volumes and flows of exhaled air that may result in movement of the impacted obstruction into the pharynx. Back blows produce little flow and volume but result in instantaneous high airway pressures of short duration, considered potentially helpful in dislodging an impacted obstruction. There is no convincing evidence that any one technique is superior to the others. In clinical practice, Redding³⁴ observed that no maneuver was always successful and that each occasionally was successful when another had failed. To minimize confusion from teaching multiple techniques (especially to the lay public), the American Heart Association has elected to emphasize the abdominal thrust maneuver (with chest thrusts as an alternative for the pregnant and massively obese) and the finger sweep.²⁴ This recommendation is made on the twofold premise that the abdominal thrust is at least as effective as other techniques and that teaching one method simplifies education.

For the awake victim, abdominal thrusts are applied in the erect position (sitting or standing). The rescuer reaches around the victim from behind, placing the fist of one hand in the epigastrium between the xiphoid and umbilicus. The fist is grasped with the other hand and pressed into the epigastrium with a quick upward thrust. In the unconscious, thrusts are applied by kneeling astride the victim, placing the heel of one hand in the epigastrium and other on top of the first. Care must be taken to ensure that the xiphoid is not pushed into the abdominal contents and that the thrust is in the midline. Sternal thrusts are valuable in the massively obese or in women in advanced pregnancy. In the erect victim, the chest is encircled from behind as in the abdominal maneuver but the fist is placed in the midsternum. For the

unconscious, thrusts are applied from the side of the supine victim with a hand position the same as for external cardiac compression. Back blows are applied directly over the thoracic spine between the scapulae. They must be delivered with force. Placing the victim in a head-down position (e.g., leaning over a chair) may help move the obstruction into the pharynx.

Whatever technique is used, each individual maneuver must be delivered as if it will relieve the obstruction. If the first attempt is unsuccessful, repeated attempts should be made because hypoxia-related muscular relaxation may eventually allow success. Complications of thrust maneuvers include laceration of the liver and spleen, gastric rupture, fractured ribs, and regurgitation.

In the unconscious victim, if these maneuvers are unsuccessful, manual dislodgement of the obstruction should be tried. The mouth is opened and the tongue and jaw are grasped between the thumb and fingers and pulled forward. A finger of the other hand is inserted along the buccal mucosa attempting to dislodge the object laterally. Care must be taken not to push the foreign body deeper into the larynx. Direct visualization of the object may also be successful. In the absence of a laryngoscope and Magill forceps, ordinary instruments (such as a tablespoon and ice tongs) may be used.³³ However, blind grasping with instruments is rarely successful and may cause damage to tonsils or other tissue. Finally, if the object cannot be dislodged, a cricothyroidotomy can be life-saving.

Ventilation

The standard approach to the unresponsive victim is to follow opening the airway with ventilation (see [Table 57-1](#)). If the airway remains patent, chest compressions cause substantial air exchange. Early studies in anesthetized humans suggested that the airway would not remain open in the unconscious,^{6,7} leading to the teaching that airway control and artificial ventilation must accompany chest compressions. However, data from the Belgian CPR Registry have demonstrated that 14-day survival and neurologic outcome are the same if bystanders initiate full BLS or do only chest compressions. Both lead to substantially better survival than if the bystanders do only mouth-to-mouth ventilation or attempt no CPR.^{36,37} Studies in the more controlled setting of the animal laboratory also raise questions about the importance of ventilation during BLS. In a swine model of up to 5 min of untreated fibrillatory cardiac arrest, comparison of 10 min of standard BLS with chest compressions without airway control or ventilation demonstrated that all successfully resuscitated animals in both groups survived for 24 hr and were neurologically normal.^{38,39,40} and [41](#) A separate study using an asphyxial cardiac arrest model found a markedly improved 24-hr outcome when ventilation was added to chest compressions during BLS.⁴² These observations suggest that when arrest is witnessed, likely to be of cardiac (rather than respiratory) cause, and intubation will be available within a short time, closed-chest compressions alone may be as efficacious as compressions and mouth-to-mouth ventilation. If these preliminary studies are confirmed, BLS teaching could be considerably simplified, potentially resulting in improved rates of bystander CPR because studies show that many people are reluctant to provide mouth-to-mouth ventilation.^{43,44} and [45](#) Currently, airway management and ventilation remain the standard first steps of CPR. Mouth-to-mouth or mouth-to-nose ventilation is the most expeditious and effective method immediately available. Although inspired gas with this method will contain ~4% carbon dioxide and only ~17% oxygen (composition of exhaled air), it is sufficient to maintain viability.

Physiology of Ventilation During CPR

In the absence of an endotracheal tube, the relative impedance of flow into the lungs and stomach will determine the distribution of gas between each compartment during positive-pressure ventilation. Resistance to insufflation of the stomach is usually stated in terms of the static pressure needed to overcome the lower esophageal sphincter. Although there are no measurements during human CPR, opening pressure of the esophagus likely is no higher than it is under anesthesia (~20 cm H₂O).⁴⁶ In experimental animals, lower esophageal sphincter pressure decreases from 28 to 4 mm Hg during 15 min of cardiac arrest without CPR.⁴⁷ Resistance in the respiratory system will be determined primarily by lung–thorax compliance except in the rare case of severe bronchospasm. During 15 min of untreated arrest in a swine model, lung–thorax compliance declines by 30%.⁴⁷

Insufflation of air into the stomach during CPR leads to gastric distension, impeding ventilation and increasing the risk of regurgitation and gastric rupture. Avoiding gastric insufflation requires that peak inspiratory airway pressures stay below esophageal opening pressure. Partial airway obstruction by the tongue and pharyngeal tissues is a major cause of increased airway pressure contributing to gastric insufflation during CPR. Meticulous attention to airway management is necessary during rescue breathing. Recommended tidal volumes to cause a noticeable rise in the chest wall in most adults is 0.8–1.2 L. To achieve these tidal volumes with low inspiratory pressures, a slow inspiratory flow rate and long inspiratory time are needed, even with an open airway. Therefore, rescue breaths should be given over 1.5–2 s during a pause in chest compressions.

A useful adjunct for preventing gastric insufflation during positive pressure ventilation without an endotracheal tube is cricoid pressure (Sellick maneuver).⁴⁸ Properly applied pressure to the anterior arch of the cricoid causes the cricoid lamina to seal the esophagus and can prevent air from entering the stomach at airway pressures up to 100 cm H₂O.⁴⁹ Pressure on the thyroid cartilage is useless. Cricoid pressure should be used during rescue breathing without an endotracheal tube, but this inevitably involves the need for an additional rescuer.

Techniques of Rescue Breathing

While maintaining an open airway with the head tilt–jaw lift technique, the hand on the forehead pinches the nose, the rescuer takes a deep breath and seals the victim's mouth with the lips and exhales, watching for the chest to rise, indicating effective ventilation. For exhalation, the rescuer's mouth is removed from the victim, listening for escaping air and taking a breath. When both hands are being used in the jaw thrust maneuver of opening the airway, the cheek is used to seal the nose. For mouth-to-nose ventilation, the rescuer's lips surround the nose and the victim's lips are held closed. In some patients, the mouth must be allowed to open for exhalation with this technique. On initiation of resuscitation, two consecutive breaths should be given and breathing continued at a rate of 10–12 min⁻¹. During a one-rescuer CPR, a pause for two breaths should be made after each 15 chest compressions. When there are two rescuers, a 1.5–2-s pause after every fifth chest compression will allow a breath to be given. Exhalation can occur during subsequent compressions.

Several adjuncts to ventilation are available. An oropharyngeal airway with mouth guard and external extension mouthpiece has been used, but obtaining a good mouth seal is often difficult. Perhaps the most useful adjunct is a common mask, such as that used for anesthesia. The mask can be applied to the face and held in place with the thumbs and index fingers while the other fingers are used to apply jaw thrust. Breathing into the connector port of the mask provides ventilation. Mouth-to-mask ventilation may be more aesthetic than mouth-to-mouth ventilation and can be just as effective in trained hands. Masks are also available with one-way valves that direct the victim's exhaled gas away from the rescuer. Masks with integral nipple adapters are useful for providing supplemental oxygen. An oxygen flow of 10 L · min⁻¹ can raise the inspired concentration to 50%.

The self-inflating resuscitation bag and mask are the most common adjuncts used in rescue vehicles and hospitals. Although these devices have the advantages of noncontact and ability to use supplemental oxygen, they have been shown to be difficult for a single rescuer to apply properly, preventing substantial gas leak while maintaining a patent airway.⁵⁰ Tidal volumes with mouth-to-mouth and mouth-to-mask ventilation are often greater than with the resuscitation bag. It is now recommended that if this device is to be used, two individuals manage the airway: one to hold the mask and maintain head position and one to squeeze the bag using both hands.⁵¹ Finally, tracheal intubation provides the best control of ventilation. With a tube in place, breathing can proceed without concern for gastric distension or synchronizing ventilation with chest compressions. Blood flow during CPR slows rapidly when chest compressions are stopped and recovers slowly when they are resumed. Consequently, following intubation, no pause should be made for ventilation and ventilation should be delivered without regard for the compression cycle.

Circulation

Physiology of Circulation During Closed-chest Compression

Two theories of the mechanism of blood flow during closed-chest compression have been suggested.^{12,52} They are not mutually exclusive, and which predominates in humans continues to be the subject of controversy.

Cardiac Pump Mechanism. The cardiac pump mechanism was originally proposed by Kouwenhoven *et al.*^{12,53} According to this theory, pressure on the chest compresses the heart between the sternum and the spine. Compression raises the pressure in the ventricular chambers, closing the atrioventricular valves and ejecting blood into the lungs and aorta. During the relaxation phase of closed-chest compression, expansion of the thoracic cage causes a subatmospheric intrathoracic pressure, facilitating blood return. The mitral and tricuspid valves open, allowing blood to fill the ventricles. Pressure in the aorta causes aortic valve closure and coronary artery perfusion. Support for this mechanism comes from echocardiography studies early in CPR demonstrating a reduction in ventricular size and mitral valve closure with chest compression.⁵⁴ Additionally, CPR techniques that incorporate direct sternal compressions, compared with techniques that raise intrathoracic pressure without sternal compression, result in better tissue blood flow and 24-hr survival.^{55,56} and [57](#)

Thoracic Pump Mechanism. Some early investigators of closed-chest cardiac massage suggested that blood flow may not be due to cardiac compression because there was little difference in iliac arterial and venous pressures or in arterial and right atrial pressures during chest compressions.^{58,59} Many practitioners have

questioned the ability to depress the sternum enough to compress the heart in very large victims. In 1976, Criley *et al*⁶⁰ reported a patient undergoing cardiac catheterization who simultaneously developed ventricular fibrillation and an episode of cough-hiccups. With every cough-hiccup, a significant arterial pressure was noted. This observation of self-administered "cough CPR" prompted further investigations on the mechanism of blood flow. Taylor *et al*⁶¹ found that carotid blood flow during prolonged CPR in humans was more dependent on long compression duration than compression rate. Rudikoff *et al*⁶² demonstrated that pressures in all cardiac chambers may be equal during effective closed-chest compression and that carotid blood flow is higher during the first compression following a ventilation. These studies produced the theory of a thoracic pump mechanism for blood flow during closed-chest compressions.⁵²

According to this theory, blood flows into the thorax during the relaxation phase of chest compressions in the same manner as that described for the cardiac pump mechanism. During the compression phase, all intrathoracic structures are compressed equally by the rise in intrathoracic pressure caused by sternal depression, forcing blood out of the chest. Backward flow through the venous system is prevented by valves in the sub-clavian and internal jugular veins and by dynamic compression of the veins at the thoracic outlet by the increased intrathoracic pressure. Thicker, less compressible vessel walls prevent collapse on the arterial side, although arterial collapse will occur if intrathoracic pressure is raised enough.⁶² The heart is a passive conduit with the atrioventricular valves remaining open during chest compression. Because there is a significant pressure difference between the carotid artery and jugular vein, blood flow to the head is favored. The lack of valves in the inferior vena cava results in less resistance to backward flow, and pressures in the arteries and veins below the diaphragm are nearly equal. This is consistent with the early observations⁵⁸ and with the fact that there is little blood flow to organs below the diaphragm.^{63,64}

A number of observations and studies support the concept of the thoracic pump. With the Valsalva maneuver of coughing during ventricular fibrillation, angiographic dye can be seen moving through the left heart and into the aorta without cardiac compression.⁶⁵ Raising intrathoracic pressure by abdominal binding or ventilation simultaneous with chest compression increases arterial pressure and carotid blood flow compared with standard CPR.^{66,67} Artificial circulation adequate to maintain viability can be accomplished with simultaneous ventilation and inflation of vests surrounding the chest and abdomen in experimental animals.⁶⁵

It seems clear that fluctuations in intrathoracic pressure plays a significant role in blood flow during CPR. It is also likely that compression of the heart occurs under some circumstances. Factors that influence the mechanism probably include the compliance and configuration of the chest wall, size of the heart, force of the sternal compressions, duration of cardiac arrest, and other undiscovered factors. Which mechanism predominates varies from victim to victim and even during the resuscitation of the same victim.

Distribution of Blood Flow During CPR. Whatever the predominant mechanism, total body blood flow (cardiac output) is reduced to 10–33% of normal during experimental closed-chest cardiac massage. Similar severe reductions in flow are likely during clinical CPR in humans. Nearly all the blood flow is directed to organs above the diaphragm.^{63,64} Myocardial perfusion is 20–50% of normal, whereas cerebral perfusion is maintained at 50–90% of normal. Abdominal visceral and lower extremity flow is reduced to 5% of normal. Total flow tends to decrease with time during CPR, but the relative distribution is not altered. Changes in CPR technique and the use of epinephrine may help sustain cardiac output over time.⁶⁴ Epinephrine improves flow to the brain and heart while flow to organs below the diaphragm is unchanged or further reduced.

Gas Transport During CPR. During CPR, measurement of blood gases reveals an arterial respiratory alkalosis and a venous respiratory acidosis with a markedly elevated arteriovenous CO₂ difference.⁶⁸ The primary cause of these changes is the severely reduced cardiac output during CPR.

The no-flow state of cardiac arrest and low-flow state of CPR have severe effects on the transport of gases in the blood. To understand these changes, it is important to remember the relationship between the volume content of gas in the blood and the partial pressure of the gas. Molecules of carbon dioxide (CO₂) are produced at the tissue level, transported in the blood, and excreted by the lung. These are measured in volumes of gas, e.g., milliliters of CO₂ produced or excreted and milliliters of CO₂ · 100 ml⁻¹ of blood. The partial pressure of CO₂ (PCO₂) in the blood is directly related to CO₂ volume content, but is also related to the barometric pressure and influenced by buffers available to combine with CO₂, e.g., bicarbonate and hemoglobin. Thus, the same CO₂ content can result in different PCO₂. Under usual conditions, tissue oxygen (O₂) consumption and CO₂ production are equal to pulmonary O₂ uptake and CO₂ excretion because metabolism, circulation, and ventilation are stable. In unstable conditions, such as CPR, these relationships may not hold.

If ventricular fibrillation occurs in a patient being mechanically ventilated, the cessation of blood flow causes O₂ uptake from the inspired gas to stop and CO₂ excretion in the exhaled gas will rapidly approach zero as the functional residual capacity is washed out by continued ventilation. Because end-tidal CO₂ is a reflection of the CO₂ in the alveolar gas, it will also rapidly approach zero. At the tissue level, continued metabolism depletes meager tissue O₂ stores, resulting in a tissue O₂ deficit and CO₂ excess. Tissue pH will be reduced because of buffering of the excess CO₂. Anaerobic metabolism will contribute more CO₂ and, after many minutes, lactic acid to the acidosis.⁶⁹ Because there is no blood flow, these changes in O₂ and CO₂ at the tissue level are not reflected in arterial or venous blood. Blood gases measured during cardiac arrest without CPR are virtually unchanged from prearrest values.³⁸

If normal circulation is restored by rapid defibrillation, cellular metabolism returns to normal but the tissue O₂ deficit and CO₂ accumulation remain. More O₂ will move into the tissues from the blood than usually occurs and more CO₂ will diffuse into venous blood. Mixed venous blood will have a lower O₂ content and higher CO₂ content than normal, resulting in increased pulmonary O₂ uptake and CO₂ excretion even though tissue O₂ consumption and CO₂ production may be normal. With constant ventilation, the increase in CO₂ being returned to the lungs causes a temporary rise in alveolar, end-tidal, and arterial CO₂. Within a short time, the excess CO₂ is removed and respiratory physiologic variables return to normal.

During the low-flow state of CPR, excretion of CO₂ (ml · min⁻¹ of CO₂ in exhaled gas) is decreased from prearrest levels approximately to the same extent as cardiac output is reduced. This reduced CO₂ excretion is due primarily to shunting of blood flow away from the lower half of the body. The exhaled CO₂ reflects only the metabolism of the part of the body that is being perfused. In the nonperfused areas, CO₂ accumulates during CPR. When normal circulation is restored, the accumulated CO₂ is washed out and a temporary increase in CO₂ excretion is seen.

Although CO₂ excretion is reduced during CPR, the mixed venous partial pressure of CO₂ (PvCO₂) usually is increased and pH is decreased.^{68,69} Two factors account for this elevation. Buffering acid causes a reduction in serum bicarbonate, so that the same blood CO₂ content results in a higher PvCO₂. In addition, the mixed venous CO₂ content is frequently, but not inevitably, elevated. When flow to a tissue is reduced, all the CO₂ produced fails to be removed and CO₂ accumulates, raising the tissue partial pressure of CO₂. This allows more CO₂ to be carried in each aliquot of blood and mixed venous CO₂ content increases. If flow remains constant, a new equilibrium is established where all CO₂ produced in the tissue is removed but at a higher venous CO₂ content and partial pressure. In contrast to the venous blood, arterial CO₂ content and partial pressure (PaCO₂) usually are reduced during CPR. This reduction accounts for most of the observed increase in arterial–venous CO₂ content difference. Even though venous blood may have an increased CO₂, the marked reduction in cardiac output with maintained ventilation results in very efficient CO₂ removal. These blood gas changes with CPR are identical to those seen with any other low cardiac output (*i.e.*, shock) state.

Decreased pulmonary blood flow during CPR causes many nondependent alveoli not to be perfused. The alveolar gas of these lung units has no CO₂. Consequently, mixed alveolar CO₂ (*i.e.*, end-tidal CO₂) will be very low and correlate poorly with arterial CO₂. However, end-tidal CO₂ does correlate well with cardiac output during CPR. As flow increases, more alveoli become perfused, there is less alveolar deadspace, and end-tidal CO₂ measurements rise.

Technique of Closed-Chest Compression

In an unconscious apneic patient, cardiac arrest must be assumed in the absence of a pulse in a major artery (carotid, femoral, axillary). Because a systolic pressure of ~50 mm Hg is necessary for a palpable pulse, some circulation may remain in the "pulseless" patient with primary respiratory arrest. Opening the airway and ventilation may be sufficient for resuscitation in such circumstances. Therefore, further search for a pulse should always be made following artificial ventilation and before beginning sternal compressions.

Important considerations in performing closed-chest compressions are the position of the rescuer relative to the victim, the position of the rescuer's hands, and the rate and force of compression. The victim must be supine, the head level with the heart, for adequate brain perfusion. The victim must be on a firm surface. The rescuer should stand or kneel next to the victim's side. Compressions are performed most effectively if the rescuer's hips are on the same level, or slightly above the level of, the victim's chest.

Standard technique consists of the rhythmic application of pressure over the lower half of the sternum. The heel of one hand is placed on the lower sternum and the

other hand is placed on top of the first. Great care must be taken to avoid pressing the xiphoid into the abdomen, which can lacerate the liver. Even with properly performed CPR, costochondral separation and rib fractures are common. Applying pressure on the ribs by improper hand placement increases these complications and risks puncturing the lung. Pressure on the sternum should be applied through the heel of the hand only, keeping the fingers free of the chest wall. The direction of force must be straight down on the sternum with the arms straight and the elbows locked into position so that the entire weight of the upper body is used to apply force. During relaxation all pressure should be removed from the hands, but they should not lose contact with the chest wall.

The sternum must be depressed 3.5–5.0 cm in the average adult. Occasionally, deeper compressions are necessary to generate a palpable pulse. The duration of compression should be equal to that of relaxation and the compression rate should be 80–100 times $\cdot \text{min}^{-1}$. This rate seems to be optimal for both possible mechanisms of blood flow. The faster rate makes it easier to maintain a 50% compression–relaxation ratio, important in the thoracic pump mechanism.⁶¹ It also requires a rapid, more forceful compression that may be important in the cardiac pump mechanism.⁷⁰ A fast rate also allows time to pause for ventilations. With a single rescuer, two ventilations should be given following every 15 compressions. With two rescuers, a 1.5–2.0-sec pause for ventilation should occur every 5 compressions. With an endotracheal tube in place, ventilations at a rate of 12 breaths $\cdot \text{min}^{-1}$ should be interposed between compressions without a pause.

Alternative Methods of Circulatory Support

As currently practiced, CPR has limited success, with only ~40% of victims being admitted to hospital and 10% surviving to discharge. Despite the occasional success of prolonged resuscitation, standard CPR will sustain most patients for only 15–30 min. If return of spontaneous circulation has not been achieved in that time, the outcome is dismal. Recognition of these limits and improved understanding of circulatory physiology during CPR have led to several proposals for alternatives to the standard techniques of closed-chest compression. Most, but not all, are based on the thoracic pump mechanism of blood flow. The goals of the new methods are to provide better hemodynamics during CPR and thus improve survival and/or to extend the duration during which CPR can successfully support viability. Unfortunately, none of the alternatives has proved reliably superior to the standard technique.⁷¹

Simultaneous Ventilation–Compression CPR and Abdominal Binding. According to the thoracic pump theory, elevation of intrathoracic pressure during chest compression should improve blood flow and pressure.⁶² Abdominal binding can improve aortic pressure and carotid blood flow but also may increase traumatic visceral injury during CPR.^{67,72,73} The pneumatic antishock garment (military antishock trousers [MAST] suit) is another form of abdominal binding that impedes diaphragmatic excursion and elevates intrathoracic pressure during chest compression. Some studies have suggested that ventilation simultaneous with chest compression would raise intrathoracic pressure, aortic pressure, and carotid blood flow.^{62,67} Initial studies with these methods were encouraging because the increased aortic pressure suggested better myocardial and cerebral perfusion.^{66,67} Subsequent investigations have demonstrated that right atrial pressure and intracranial pressure are elevated as much as, or more than, the arterial pressures.^{55,74,75} and ⁷⁶ Thus, no improvement in myocardial or cerebral blood flow is found. Most importantly, survival from cardiac arrest is not improved when these techniques are compared with standard CPR in experimental animals or limited human trials.^{57,76,78,79} and ⁸⁰

Interposed Abdominal Compression CPR. Interposed abdominal compression (IAC) is fundamentally different from abdominal binding. With this technique, an additional rescuer applies abdominal compressions manually during the relaxation phase of chest compression. Abdominal pressure is released when chest compression begins.⁸¹ It has been suggested that the IAC augments aortic pressure and blood flow by counterpulsation on the abdominal aorta or by “priming” the thoracic pump.⁸² Studies have been inconsistent in demonstrating improved hemodynamics.^{83,84} Animal studies have not shown improved survival with this method.⁵⁶ One large randomized trial of out-of-hospital cardiac arrest with IAC CPR found no improvement in survival compared with standard CPR,⁸⁵ but a subsequent in-hospital study demonstrated improved outcome.⁸⁶ Although this technique remains experimental, investigations of its potential continue.

Pneumatic Vest CPR. Following the description of “cough CPR” and the development of the thoracic pump theory, a pneumatic vest device was developed that would simulate the events of vigorous coughing.^{65,87} With the original method, thoracic and abdominal vests containing pneumatic bladders inflate simultaneously with positive-pressure ventilation. Although some survival studies found no improvement in outcome when compared with standard CPR,⁵⁷ other animal studies found excellent hemodynamics and the ability to maintain viability for prolonged periods with the method.⁸⁸ The technique continues to be investigated with a number of modifications from the original method. One report used a pneumatically powered, single, circumferential thoracic vest system with a pause for ventilation after every fifth compression during 63 human cardiac arrests.⁸⁹ In this preliminary study, aortic and coronary perfusion pressure was better with the vest than with standard CPR, but survival was not significantly improved.

High-Impulse CPR. In contrast to the previously described alternative methods, a technique commonly called high-impulse CPR is based on the concept that intrathoracic cardiac and vascular compression are important determinants of blood flow during CPR.^{70,90} Relatively short compressions with moderately high force result in blood flow being directly related to rate of compressions. Laboratory investigations of this method found that the optimal rate is 120 compressions per minute to maximize coronary perfusion.⁹⁰ Some studies have shown improved survival in animals with this technique,⁷⁰ whereas others have found no difference from standard CPR.⁵⁷ This method is similar to the standard technique, and many of the studies of this method have influenced standard CPR practice. Emphasis now is placed on ensuring adequate sternal depression and compression rates have been increased to 80–100 min^{-1} .

Active Compression–Decompression CPR. The newest proposed alternative technique developed from the anecdotal report of CPR performed with a plumber’s helper applied to the anterior chest wall.⁹¹ This suggested that active decompression of the chest wall might reduce intrathoracic pressure during the relaxation phase of chest compressions, leading to improved venous return, increased stroke volume with compression, and better blood flow. A suction device that can be applied to the chest wall to enable active compression and decompression was developed.⁹² Hemodynamic studies in animals and humans with this technique have shown that coronary and cerebral perfusion may be somewhat improved with this method compared with standard CPR, although when epinephrine is used there is no difference between techniques.^{92,93} and ⁹⁴ One preliminary in-hospital clinical trial found improved immediate resuscitation but no difference in survival.⁹⁵ Two out-of-hospital trials found no difference in immediate resuscitation or survival.^{96,97}

Invasive Techniques. In contrast to the closed-chest techniques, two invasive methods have been able to maintain cardiac and cerebral viability during long periods of cardiac arrest. In animal models, open-chest cardiac massage and cardiopulmonary bypass (through the femoral artery and vein using a membrane oxygenator) can provide better hemodynamics and myocardial and cerebral perfusion than closed-chest techniques.^{74,98} Preliminary trials of percutaneous cardiopulmonary bypass for refractory human cardiac arrest have been reported.^{99,100} and ¹⁰¹ Prompt restoration of blood flow and perfusion pressure with cardiopulmonary bypass can provide resuscitation with minimal neurologic deficit after 20 min of fibrillatory cardiac arrest in canines.¹⁵ However, to be effective these techniques must be instituted relatively early (probably within 20–30 min of arrest).^{16,102} If open chest massage is begun after 30 min of ineffective closed-chest compressions, there is no better survival even though hemodynamics are improved.¹⁰³ The need to apply these maneuvers early in an arrest obviously limits the application. Before invasive procedures play a greater role in modern CPR, a method must be developed to predict, early in resuscitation, which patients will and which will not respond to closed-chest compressions.

Assessing the Adequacy of Circulation During CPR

The adequacy of closed-chest compression is usually judged by palpation of a pulse in the carotid or femoral vessels. The palpable pulse primarily reflects systolic pressure. Cardiac output correlates better with mean pressure and coronary perfusion with diastolic pressure. In the femoral area, the palpable pulse is as likely to be venous as arterial.¹⁰⁴ Despite these shortcomings, palpating the pulse remains the only monitor available during BLS.

Return of spontaneous circulation with an arrested heart is greatly dependent on restoring oxygenated blood flow to the myocardium. In experimental models, a minimum blood flow of 15–20 $\text{ml} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ of myocardium has been shown to be necessary for successful resuscitation.¹⁰⁵ Obtaining such flow depends on closed-chest compressions developing adequate cardiac output and coronary perfusion pressure. Similar to the beating heart, coronary perfusion during CPR occurs primarily in the relaxation phase (diastole) of chest compressions. Crile and Dolley suggested in 1906 that a critical coronary perfusion pressure was necessary for successful resuscitation.¹⁰⁶ This concept has been confirmed in numerous other reports.^{84,73,75,105,107,108,109,110,111,112,113} and ¹¹⁴ During standard CPR, critical myocardial blood flow is associated with aortic diastolic pressure exceeding 40 mm Hg. Because right atrial pressure can be elevated with some techniques, the aortic diastolic pressure minus the right atrial diastolic pressure is a more accurate reflection of coronary perfusion pressure. The critical coronary perfusion pressure is 15–25 mm Hg. When invasive monitoring is available during CPR, adjustments in chest compression technique and epinephrine should be used to ensure that critical perfusion pressures are exceeded. Damage to the myocardium from underlying disease may preclude survival no matter how effective the CPR efforts. However, vascular pressures below critical levels are associated with poor results even in patients who may be salvageable (Table 57-2).

| Variable | Amount |
|--|--------|
| Myocardial blood flow ($\text{ml} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$) | 15-20 |
| Aortic diastolic pressure (mm Hg) | 40 |
| Coronary perfusion pressure (mm Hg) | 15-25 |
| End-tidal carbon dioxide (mm Hg) | >10 |

Table 57-2. CRITICAL VARIABLES ASSOCIATED WITH SUCCESSFUL RESUSCITATION

Although invasive pressure monitoring may be ideal, it is rarely available during CPR. End-tidal CO_2 also has been found to be an excellent noninvasive guide to the adequacy of closed-chest compressions.¹¹⁵ Carbon dioxide excretion during CPR with an endotracheal tube in place is flow-dependent rather than ventilation-dependent. Because alveolar deadspace is large in low-flow states, end-tidal CO_2 is very low (frequently <10 mm Hg). If blood flow improves with better CPR technique, more alveoli are perfused and end-tidal CO_2 rises (usually to >20 mm Hg with successful CPR). The earliest sign of return of spontaneous circulation frequently is a sudden increase in end-tidal CO_2 to >40 mm Hg. Within a wide range of cardiac outputs during CPR, end-tidal CO_2 correlates well with cardiac output,¹¹⁶ coronary perfusion pressure,¹¹⁷ and initial resuscitation.^{118,119} End-tidal CO_2 correlates with survival in human CPR and can predict outcome.^{120,121} Patients with end-tidal $\text{CO}_2 < 10$ mm Hg will not be resuscitated successfully. In the absence of invasive monitoring, end-tidal CO_2 should be used to judge the effectiveness of chest compressions, whenever possible.¹²² Attempts should be made to maximize the measured end-tidal CO_2 by alterations in technique or drug therapy. It should be remembered that sodium bicarbonate administration liberates CO_2 into the blood and causes a temporary increase in end-tidal CO_2 . The elevation returns to baseline within 3–5 min of drug administration and end-tidal CO_2 monitoring can again be used for monitoring effectiveness of closed-chest compressions.

ADVANCED CARDIAC LIFE SUPPORT

Advanced cardiac life support (ACLS) encompasses all the cognitive and technical skills that are necessary to restore spontaneous circulatory function when simple support does not result in resuscitation. In addition to BLS skills, it includes use of adjunctive equipment and techniques for assisting ventilation and circulation, electrocardiographic (ECG) monitoring with dysrhythmia recognition and defibrillation, establishment of intravenous (iv) access, and pharmacologic therapy. A number of aspects of ACLS have been discussed in preceding sections. The following sections concentrate on electrical and drug treatment as well as the generalized ACLS algorithms. [Figure 57-1](#) demonstrates the universal algorithm for adult emergency cardiac care.

Defibrillation

Electrical Pattern and Duration of Ventricular Fibrillation

Ventricular fibrillation is the most common electrocardiographic pattern found during cardiac arrest in adults. The only consistently effective treatment is electrical defibrillation. The most important controllable determinant of failure to resuscitate a patient with ventricular fibrillation is the duration of fibrillation.¹²³ Other important factors, such as underlying disease and metabolic status, are largely beyond the control of rescuers. The fibrillating heart has high oxygen consumption, increasing myocardial ischemia and decreasing the time to irreversible cell damage. The longer ventricular fibrillation continues, the more difficult it is to defibrillate and the less likely is successful resuscitation.^{102,124} If defibrillation occurs within 1 min of fibrillation, CPR is unnecessary for resuscitation. Initial resuscitation success following out-of-hospital fibrillation and survival to hospital discharge are improved the earlier that defibrillation is accomplished.^{18,20,125}

The amplitude (coarseness) of the fibrillatory waves on the ECG may reflect the severity and duration of the myocardial insult and, thus, have prognostic significance.¹²⁶ However, the fibrillation amplitude seen on any one ECG lead varies with the orientation of that lead to the vector of the fibrillatory wave.¹²⁷ If the lead is oriented at right angles to the fibrillatory wave, a flat line can be seen. For this reason, the trace from a second lead or from a different position of paddle electrodes should always be inspected before a decision is made not to defibrillate.

Coarse (high-voltage) ventricular fibrillation is considered easier to defibrillate than fine (low-voltage) fibrillation. Increasing myocardial ischemia results in less vigorous fibrillation, reduced amplitude electrical activity, and more difficult de-fibrillation. Low-voltage fibrillation is associated with poor outcome.¹²⁶ Catecholamines with β -adrenergic activity increase the vigor of fibrillation and the amplitude of the electrical activity. Consequently, epinephrine frequently is administered to make it "easier" to defibrillate. However, experimental work has shown that manipulation of the electrical pattern with epinephrine does not influence the success of defibrillation or reduce the energy needed for defibrillation.^{124,128} Consequently, defibrillation should not be delayed for epinephrine administration or any other therapy. The algorithm for managing ventricular fibrillation–tachycardia is illustrated in [Figure 57-2](#).

Figure 57-2. Ventricular fibrillation/pulseless VT algorithm. (Reprinted with permission from American Heart Association: Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care: International consensus on science. *Circulation* 102:1-147, 2000.)

The importance of minimizing the duration of ventricular fibrillation cannot be overemphasized. Conversion of fibrillation to a rhythm capable of restoring spontaneous circulation should be the first priority of any resuscitation attempt. For out-of-hospital arrests, this problem is being addressed by improving the response times of rescue units and teaching less trained individuals to use defibrillators.^{18,19} and ²⁰ Early defibrillation has been improved recently by the development of automatic external defibrillators that recognize ventricular fibrillation, charge automatically, and give a defibrillatory shock.¹²⁹ This device has allowed the introduction of public-access defibrillation because minimally trained individuals can incorporate defibrillation into BLS skills.^{21,130} In the hospital setting, defibrillation should be carried out as soon as fibrillation is diagnosed and the equipment is available. The precordial thump, although rarely successful, can be tried while awaiting a defibrillator. It should not be used for the conscious patient with ventricular tachycardia unless a defibrillator is immediately available. It is as likely to induce fibrillation as normal rhythm. Blind defibrillation is recommended in adults if no monitoring is available. This should rarely be necessary because modern defibrillators have built-in monitoring capability using the paddles as electrodes.

Defibrillators: Energy, Current, and Voltage

Defibrillators derive power from a line source of alternating current or an integral battery. The typical defibrillator consists of a variable transformer that allows selection of a variable voltage potential, an AC/DC converter to provide a direct current that is stored in a capacitor, a switch to charge the capacitor, and discharge switches to complete the circuit from capacitor to electrodes. The output current waveform of most clinically used defibrillators is a damped half-sinusoid, although some are designed to deliver trapezoidal or near-square waves. Recently, units with biphasic waveforms have been introduced that may allow effective defibrillation at lower energy.

Defibrillation is accomplished by current passing through a critical mass of myocardium causing simultaneous depolarization of the myofibrils. However, the output of most defibrillators is indicated in energy units (joules or watt-seconds), not current (amperes). The relationships among energy, current, and impedance (resistance) are given by the following equations (standard units are indicated):

$$\text{Energy (joules)} = \text{Power (watts)} \times \text{duration (seconds)} \quad (1)$$

$$\text{Power (watts)} = \text{Potential (volts)} \times \text{current (amperes)} \quad (2)$$

$$\text{Current (amperes)} = \text{Potential (volts)} / \text{resistance (ohms)} \quad (3)$$

$$\text{Current (amperes)} = \sqrt{\text{Energy (joules)} / [\text{resistance (ohms)} \times \text{duration (seconds)}]} \quad (4)$$

From these equations, it can be determined that as the impedance between the paddle electrodes increases, the delivered energy will be reduced. Because internal resistance is low, the primary determinant of delivered energy will be transthoracic impedance. For consistency, the energy level indicated on most commercially available defibrillators is the output when discharged into a 50-ohm load. When transthoracic impedance is higher than that standard, actual delivered energy will be lower. Even at a constant delivered energy, Eq. (4) indicates that delivered current (the critical determinant of defibrillation) will be reduced as impedance increases. At high impedance and relatively low energy levels, current could be too low for defibrillation. Optimal success of defibrillation is obtained by keeping impedance as low as possible.¹³¹

Transthoracic Impedance

Transthoracic impedance has been measured at 24–109 ohms in patients undergoing cardioversion¹³² and at 15–143 ohms in human defibrillation.¹³³ The major determinants of transthoracic impedance are known and many are under the control of the rescuers. Resistance decreases with increasing electrode size, and studies suggest that optimal paddle size may be 13 cm in diameter.^{134,135} Concern has been expressed that a paddle this large may diffuse the current over too great an area for effective defibrillation. The most common paddle size remains 8–10 cm in diameter. The high impedance between metal electrode and skin can be reduced somewhat by use of saline-soaked gauze pads or creams, such as those used for recording ECGs. However, resistance is least when a gel or paste specifically designed to conduct electricity in the defibrillation setting is used.^{134,135} Self-adhesive defibrillation/monitor pads also work well when carefully applied. When paste is used, it should be applied liberally to the paddle surface, especially the edges, to prevent burns and obtain the maximum reduction in impedance. In experimental models, transthoracic impedance decreases with successive shocks.^{136,137} Although the clinical significance has been questioned,¹³³ this factor may partially explain why an additional shock of the same energy can cause defibrillation when previous shocks have failed. Transthoracic impedance is slightly, but significantly, higher during inspiration than during exhalation.¹³⁸ Air is a poor electrical conductor. Firm paddle pressure of at least 11 kg reduces resistance by improving paddle–skin contact and by expelling air from the lungs.¹³³

The average transthoracic impedance in human defibrillation is 70–80 ohms. Resistance is probably of little clinical significance when reasonably proper technique and high energy (300 J) shocks are used. For lower energy shocks, great care should be taken to minimize resistance. Defibrillators have been developed that measure transthoracic impedance prior to the shock by passing a low-voltage current through the chest during the charge cycle.^{139,140} This allows the use of low-energy shocks in appropriate patients and identification of victims needing higher energy. Although not widely used, this technology allows current-based defibrillation by adjusting the delivered energy for the measured resistance.¹⁴¹

Adverse Effects and Energy Requirements

Repeated defibrillation with high energy in animals can be associated with dysrhythmias, ECG changes suggesting myocardial damage, and morphologic evidence of myocardial necrosis.^{142,143} Whether similar injuries occur in humans is less certain. Slight elevations in creatine kinase MB fractions have been measured in patients following cardioversion with high energies.¹⁴⁴ A higher incidence of atrioventricular block has been observed in patients receiving high-energy shocks than in patients receiving low-energy shock.¹⁴⁵ It seems likely that high-energy shocks, especially if repeated at close intervals, may result in myocardial damage. Therefore, it would be prudent to keep energy levels as low as possible during defibrillation attempts. However, if energy is too low, the delivered current may be insufficient for defibrillation, especially when transthoracic impedance is high.

There is a general relationship between body size and energy requirements for defibrillation. Geddes *et al* observed that the current necessary for defibrillation in animals increased with increasing body mass.¹⁴⁶ Children need less energy than adults, perhaps as low as 0.5 J · kg⁻¹,¹⁴⁷ although the recommended dose is 2.0 J · kg⁻¹.²⁴ However, over the size range of adults, weight variability is not clinically significant and other factors are more important.¹⁴⁸ Multiple studies have demonstrated high rates of successful defibrillation using relatively low levels (160–200 J) of delivered energy.^{149,150,151} and ¹⁵² Studies of out-of-hospital and in-hospital arrests have demonstrated equal success when using £200 J initial energy compared with administering all shocks at energies ³ 300 J.^{145,153} Therefore, current recommendations are to use 200 J for the initial shock followed by a second shock at 200–300 J if the first is unsuccessful. If both fail to defibrillate the patient, additional shocks should be given at 300–360 J (see [Fig. 57-2](#)).²⁴

Pharmacologic Therapy

This discussion of drug therapy is confined to the use of drugs during CPR attempts to restore spontaneous circulation. The use of drugs to support the circulation when there is mechanical cardiac function is discussed elsewhere (see [Chapter 12](#) and [Chapter 32](#)). During cardiac arrest, drug therapy is secondary to other interventions. Chest compressions, airway management, ventilation, and defibrillation, if appropriate, should take precedence over medications. Establishing iv access and pharmacologic therapy should come after other interventions are established. The most common drugs and the appropriate adult doses are shown in [Table 57-3](#). Of the drugs given during CPR, only epinephrine is usually acknowledged as being helpful in restoring spontaneous circulation.¹⁵⁴ Asystole and pulseless electrical activity (PEA), also called electromechanical dissociation (EMD), are circumstances in which drugs are most frequently given. The standard algorithms for management of these types of cardiac arrest are shown in [Figure 57-3](#) and [Figure 57-4](#). In addition, the algorithms for the American Heart Association protocols for bradycardia, tachycardia, shock, and synchronized cardioversion are included ([Fig. 57-5](#),[Fig. 57-6](#),[Fig. 57-7](#) and [Fig. 57-8](#)).

| | Dose | Interval | Maximum |
|-------------------------|------------------------|-------------------|-------------------------|
| Epinephrine | 1 mg | Every 3-5 min | None |
| If dose fails, consider | 3-7 mg | Every 3-5 min | None |
| Amiodarone | 300 mg | Repeat in 3-5 min | 2 g |
| Lidocaine | 1.5 mg/kg ¹ | Repeat in 3-5 min | 3.0 mg/kg ¹ |
| Bretylium tosylate | 5 mg/kg ¹ | Repeat in 5 min | 10 mg/kg ¹ |
| Atropine | 1 mg | Every 3-5 min | 0.04 mg/kg ¹ |
| Sodium bicarbonate | 1 mEq/kg ¹ | As needed | Check pH! |

Routes of Administration

The preferred route of administration of all drugs during CPR is intravenous. The most rapid and highest drug levels occur with administration into a central vein. However, peripheral iv administration is also effective. The antecubital and external jugular veins are the sites of first choice for starting an infusion during resuscitation because inserting a central catheter usually necessitates stopping CPR. Because of poor blood flow below the diaphragm during CPR, drugs administered in the lower extremity may be extremely delayed or not reach the sites of action. Even in the upper extremity, drugs may require 1–2 min to reach the central circulation. Onset of action may be speeded if the drug bolus is followed by a 20–30 ml bolus of iv fluid. If iv access cannot be established, the endotracheal tube is an alternative route for administration of epinephrine, lidocaine, and atropine. (Sodium bicarbonate should not be given endotracheally.) The time to effect and drug levels achieved are inconsistent using this route during CPR. Better results may be obtained by administering 5–10 ml volumes. It is unclear whether deep injection is better than simple instillation into the endotracheal tube. Doses 2–2.5 times higher than the recommended iv dose should be administered when this route is used.

Catecholamines and Vasopressors

Mechanism of Action. Epinephrine has been used in resuscitation since the 1890s and has been the vasopressor of choice in modern CPR since the studies of Redding and Pearson in the 1960s.^{13,155} Experimental studies have shown that the efficacy of epinephrine lies entirely in its α -adrenergic properties.¹¹¹ Peripheral vasoconstriction leads to an increase in aortic diastolic pressure, causing an increase in coronary perfusion pressure and myocardial blood flow.^{64,156,157} It is tempting to invoke the β -adrenergic properties of cardiac stimulation to explain the success of epinephrine. However, animal studies have demonstrated that β -adrenergic agonists without a activity (isoproterenol, dobutamine) are no better than placebo. All strong α -adrenergic drugs (epinephrine, phenylephrine, methoxamine, dopamine, norepinephrine), regardless of β -adrenergic potency, are equally successful in aiding resuscitation, as are strong nonadrenergic vasopressors (vasopressin, endothelin-1).^{13,155,158,159} and ¹⁶⁰ α -Adrenergic blockade precludes resuscitation, whereas β -adrenergic blockade has no effect on the ability to restore spontaneous circulation.^{108,109} It is commonly believed that the ability of epinephrine to increase the amplitude of ventricular fibrillation (a β -adrenergic effect) makes defibrillation easier. Animal studies have shown that epinephrine does not improve the success of or reduce the energy necessary for defibrillation.^{124,128} Retrospective analysis of out-of-hospital CPR has found no effect of epinephrine on defibrillation success.¹²⁶

The β -adrenergic effects of epinephrine are potentially deleterious during cardiac arrest. In the fibrillating heart, epinephrine increases oxygen consumption and decreases the endocardial–epicardial blood flow ratio, an effect not seen with methoxamine.¹⁶¹ Myocardial lactate production in the fibrillating heart is unchanged after epinephrine administration during CPR, suggesting that the increased coronary blood flow does not improve the oxygen supply–demand ratio.¹⁶² Large doses of epinephrine increased deaths in swine early after resuscitation due to tachyarrhythmias and hypertension, an effect partially offset by metoprolol treatment.^{163,164} Despite these theoretical considerations, survival and neurologic outcome studies have shown no difference when epinephrine is compared with a pure α -agonist (methoxamine or phenylephrine) during CPR in animals^{155,165} or humans.¹⁶⁶ Recent animal studies^{159,160} and a small randomized clinical trial of out-of-hospital arrests¹⁶⁷ suggest that arginine vasopressin may improve outcome over epinephrine. However, vasopressin causes worse myocardial depression in the early postresuscitation phase than epinephrine.¹⁶⁸ A larger clinical trial of in-hospital arrests did not find a difference in survival when the two drugs were compared. Although epinephrine has never had a rigorous randomized human trial, there is strong animal evidence of its efficacy as well as extensive clinical experience with its use. Epinephrine remains the vasopressor of choice in CPR. It should be administered whenever resuscitation has not occurred after adequate chest compressions and ventilation have been started and defibrillation attempted, if appropriate.

Epinephrine Dose. When added to chest compressions, epinephrine helps develop the critical coronary perfusion pressure necessary to provide enough myocardial blood flow for restoration of spontaneous circulation. With invasive monitoring present during CPR, an arterial diastolic pressure of 40 mm Hg or coronary perfusion pressure of 20 mm Hg must be obtained with good chest compression technique and/or epinephrine therapy (see [Table 57-2](#)). In the absence of such monitoring, the dose of epinephrine must be chosen empirically. For many years, the standard iv dose used in animals and humans has been 0.5–1.0 mg. On a weight basis, this dose is $\sim 0.015 \text{ mg} \cdot \text{kg}^{-1}$ in humans but $0.1 \text{ mg} \cdot \text{kg}^{-1}$ in animals. In swine the human standard dose of epinephrine ($0.02 \text{ mg} \cdot \text{kg}^{-1}$) is insufficient to improve coronary perfusion pressure and blood flow, but a high dose ($0.2 \text{ mg} \cdot \text{kg}^{-1}$) improves hemodynamics to levels compatible with successful resuscitation.^{169,170} and ¹⁷¹ These animal studies suggest that higher doses of epinephrine in human CPR might improve myocardial and cerebral perfusion and improve success of resuscitation. Support for using higher doses also comes from anecdotal case reports and a series of children (with historical controls) that demonstrated return of spontaneous circulation when large doses ($0.1\text{--}0.2 \text{ mg} \cdot \text{kg}^{-1}$) of epinephrine were given to patients who had failed resuscitation with standard doses.^{172,173}

Unfortunately, outcome studies have not conclusively shown that higher doses of epinephrine will improve survival. There are two randomized, blinded animal studies comparing standard and high-dose epinephrine: one with fibrillatory arrest and one with asphyxial arrest.^{163,164} In each study, there was no difference in 24-hr survival or neurologic outcome, but more animals in the high-dose group died in the early postresuscitation period due to hyperdynamic state. There are several reports of studies comparing standard doses (1–2 mg) to high doses (5–18 mg) of epinephrine in human CPR, totaling approximately 9000 patients.^{174,175,176,177,178} and ¹⁷⁹ All are prospective, randomized, double-blind clinical trials in cardiac arrest victims, primarily out-of-hospital. Some of the studies (and the cumulative data) suggest that there may be an improvement in immediate resuscitation with high-dose epinephrine. None of the studies found improvement in survival to hospital discharge. Retrospective studies of epinephrine dosing have suggested that higher doses may be associated with impaired postresuscitation cardiovascular function and worse neurologic outcome.^{180,181} None of the prospective studies found lower survival or worse neurologic outcome with higher epinephrine dosing.

It should be noted that these outcome studies used high-dose epinephrine as initial therapy. High doses apparently are not needed early in most cardiac arrests and could be deleterious under some circumstances. The successful case reports were in patients who had failed conventional treatment. The high doses were given late in prolonged CPR when the vasculature may not be as responsive to catecholamines. Although the use of high-dose epinephrine as rescue therapy when standard doses have failed has not been rigorously studied, this may be its appropriate place in CPR practice. Current recommendations are to give 1 mg iv every 3–5 min in the adult.

If this dose seems ineffective, higher doses (3–8 mg) should be considered (see [Fig 57-2](#), [Fig 57-3](#) and [Fig 57-4](#)).

Amiodarone, Lidocaine, Bretylium

After epinephrine, the most effective drugs during CPR are those that help suppress ectopic ventricular rhythms. Amiodarone, lidocaine, and bretylium are used during cardiac arrest to aid defibrillation when ventricular fibrillation is refractory to electrical countershock therapy or when fibrillation recurs following successful conversion. Lidocaine is primarily an antiectopic agent that depresses automaticity by reducing the slope of Phase 4 depolarization and reducing the heterogeneity of ventricular refractoriness.^{182,183} In contrast, bretylium has been called a primary antifibrillatory drug. It reduces the heterogeneity of action potential duration between ischemic and normal myocardium, resulting in less disparity between refractory periods and reducing the chances for re-entry. It does not suppress automaticity or Phase 4 depolarization.¹⁸⁴ Amiodarone is a pharmacologically complex drug with sodium, potassium, calcium, and α - and β -adrenergic blocking properties that is useful for treatment of atrial and ventricular arrhythmias.

When given intravenously, lidocaine has few hemodynamic effects. Conversely, bretylium initially causes release of norepinephrine from adrenergic nerve endings.¹⁸⁴ With a normal circulation, this causes tachycardia, hypertension, and increased contractility. After ~20 min, blockade of the release and reuptake of norepinephrine from the nerve terminal occurs. This effect is maximal 45–60 min following drug administration and can lead to profound hypotension. Amiodarone can cause hypotension and bradycardia when infused too rapidly but less so than bretylium.¹⁸⁵ This can usually be prevented by slowing the rate of drug infusion, or treated with fluids, pressors, chronotropic agents or temporary pacing.

Ventricular fibrillation threshold is reduced by acute ischemia or infarction, an effect partially reversed by both lidocaine and bretylium.^{183,186,187} and ¹⁸⁸ Lidocaine has been reported to raise the defibrillation threshold; *i.e.*, more energy is needed to defibrillate.^{188,189} and ¹⁹⁰ However, peak effect does not occur until 30 min following drug administration and the clinical importance of this effect during CPR is doubtful. Amiodarone also raises the defibrillation threshold.¹⁹¹ Bretylium either reduces or does not change defibrillation threshold.^{188,189,192} These electrophysiologic considerations and anecdotal reports of chemical defibrillation¹⁹³ suggest an advantage for bretylium over amiodarone and lidocaine during CPR. However, direct comparison of the drugs in controlled randomized trials during out-of-hospital ventricular fibrillation have failed to demonstrate a difference in resuscitation success or survival.^{185,194,195} Consequently, because of the tendency for hypotension from bretylium, it is not recommended as first-line treatment during CPR. Its use should be reserved for fibrillation refractory to defibrillation, amiodarone and lidocaine, or for recurrent fibrillation uncontrolled by the other drugs. There is one randomized placebo-controlled clinical trial demonstrating improved admission alive to hospital with treatment, suggesting that amiodarone should now be first-line treatment for shock-resistant fibrillation.¹⁹⁶

When ventricular fibrillation or pulseless ventricular tachycardia is recognized, defibrillation should be attempted as soon as possible (see [Fig. 57-2](#)). No antiarrhythmic agent has been shown superior to electrical defibrillation or more effective than placebo in the treatment of ventricular fibrillation. Consequently, defibrillation should not be withheld or delayed to establish iv access or to administer drugs. When ventricular tachycardia or ventricular fibrillation has not responded to or recurred following BLS, epinephrine, and defibrillation, amiodarone should be administered. Amiodarone is usually administered as 150 mg iv over 10 min, followed by 1 mg · min⁻¹ infusion for 6 hours, and 0.5 mg · min⁻¹ thereafter. In cardiac arrest due to pulseless ventricular tachycardia or fibrillation, amiodarone is initially administered as a 300-mg rapid infusion. Supplemental infusions of 150 mg can be repeated as necessary for recurrent or resistant arrhythmias to a maximum total daily dose of 2 g. Lidocaine and bretylium are alternative therapies in refractory fibrillation. To rapidly achieve and maintain therapeutic blood levels of lidocaine during CPR, relatively large doses are necessary. An initial bolus of 1.5 mg · kg⁻¹ should be given and additional boluses of 0.5–1.5 mg · kg⁻¹ can be given every 5–10 min during CPR up to a total dose of 3 mg · kg⁻¹. Only bolus dosing should be used during CPR, but an infusion of 2–4 mg · min⁻¹ can be started after successful resuscitation. If fibrillation persists or recurs after lidocaine therapy, bretylium tosylate can be given in an initial dose of 5 mg · kg⁻¹ by iv bolus, followed by electrical defibrillation. If fibrillation persists, the dose can be increased to 10 mg · kg⁻¹ and repeated at 5-min intervals for a total dose of 30–35 mg · kg⁻¹. Once the loading dose has been given, the drug can also be given as a continuous infusion at a rate of 1–2 mg · min⁻¹.

Sodium Bicarbonate

Although sodium bicarbonate was used as commonly as epinephrine during CPR in the past, there is little evidence to support its efficacy. Its use during resuscitation is supported by the theoretical considerations that acidosis lowers fibrillation threshold¹⁹⁷ and respiratory acidosis impairs the physiologic response to catecholamines.¹⁹⁸ One older animal study found improved success of resuscitation from prolonged ventricular fibrillation when bicarbonate therapy was added to epinephrine.¹⁵⁵ Most subsequent studies have failed to demonstrate improvement in success of defibrillation or resuscitation with the use of bicarbonate.^{199,200,201} and ²⁰² The lack of effect of buffer therapy may be partially explained by the slow onset of metabolic acidosis during cardiac arrest. As measured by blood lactate or base deficit, acidosis does not become severe for 15 or 20 min of cardiac arrest.^{68,69,203}

In contrast to the lack of evidence that buffer therapy during CPR improves survival, the adverse effects of excessive sodium bicarbonate administration are well documented. In the past, metabolic alkalosis, hypernatremia, and hyperosmolarity were common after administration of bicarbonate during resuscitation attempts.^{203,204} These abnormalities are associated with low resuscitation rates and poor outcome. However, if sodium bicarbonate is given judiciously according to standard recommendations, no significant metabolic abnormalities should occur.²⁰⁵

Intravenous sodium bicarbonate combines with hydrogen ion to produce carbonic acid which dissociates into CO₂ and water. The PCO₂ in blood is temporarily elevated until the excess CO₂ is eliminated through the lungs. Tissue acidosis during CPR is caused primarily by the low blood flow and accumulation of CO₂ in the tissues.^{68,69} Therefore, concern has been expressed that the liberation of CO₂ by bicarbonate administration would only worsen the existing problem. This is of particular concern within myocardial cells and the brain. Carbon dioxide readily diffuses across cell membranes and the blood–brain barrier, whereas bicarbonate diffuses much more slowly. Thus, it is possible that sodium bicarbonate administration could result in a paradoxical worsening of intracellular and cerebral acidosis by further raising intracellular and cerebral CO₂ without a balancing increase in bicarbonate. Direct evidence for this effect has not been found. One study demonstrated an elevation in cerebral spinal fluid PCO₂ and reduction in pH could occur when very large doses of bicarbonate were given.²⁰⁶ However, with clinically relevant doses, another study found no changes in spinal fluid acid–base status.²⁰⁷ Measurement of myocardial intracellular pH during bicarbonate administration also has not detected a worsening in acidosis.²⁰⁸ Therefore, paradoxical acidosis from sodium bicarbonate therapy remains a concern primarily on theoretical grounds.

Current practice restricts the use of sodium bicarbonate primarily to arrests associated with hyperkalemia, severe pre-existing metabolic acidosis, and tricyclic or phenobarbital overdose. It may be considered for use in protracted resuscitation attempts after other modalities have been instituted. When bicarbonate is used during CPR, the usual dose is 1 mEq · kg⁻¹ initially with additional doses of 0.5 mEq · kg⁻¹ every 10 min. However, dosing of sodium bicarbonate should be guided by blood gas determination whenever possible.

Atropine

Atropine sulfate enhances sinus node automaticity and atrioventricular conduction by its vagolytic effects. Although evidence for its efficacy is weak, atropine is frequently given during cardiac arrest associated with an ECG pattern of asystole or slow PEA. One animal study found methoxamine preferable to atropine for resuscitation of asphyxia-induced PEA.²⁰⁹ Two clinical studies reported some success with atropine. Three of eight patients survived in-hospital asystolic arrest following atropine therapy.²¹⁰ In out-of-hospital asystolic arrest, atropine treatment was associated with improved resuscitation to hospital admission but not with survival to discharge.²¹¹ Other investigators have observed no response to atropine in asystolic patients²¹² or no difference in ECG rhythms or survival with or without atropine.²¹³

The predominant cause of asystole and electromechanical dissociation is severe myocardial ischemia. Excessive parasympathetic tone probably contributes little to these rhythms during cardiac arrest in adults. Even in children, it is doubtful that parasympathetic tone plays a significant role during most arrests. Therefore, the most important treatment for asystole and electromechanical dissociation is effective chest compressions, ventilation, and epinephrine to improve coronary perfusion and myocardial oxygenation. However, cardiac arrest with these rhythms has a poor prognosis.²⁴ Because atropine has few adverse effects, it is recommended in arrest with asystole or PEA and refractory to epinephrine and oxygenation. The dose is 1.0 mg iv, repeated every 3–5 min up to a total of 0.04 mg · kg⁻¹, which is totally vagolytic.^{214,215} Full vagolytic doses may be associated with fixed mydriasis following successful resuscitation confounding neurologic examination. Occasionally, a sinus tachycardia following resuscitation may be due to the use of atropine during CPR.

Calcium

With normal cardiovascular physiology, calcium increases myocardial contractility and enhances ventricular automaticity. Consequently, it has been advocated for years as a treatment for asystole and PEA. It became firmly entrenched as a treatment for these rhythms following an early report by Kay and Blalock of success in four children following open heart surgery.²¹⁶ In retrospect, it is likely that these patients were hypocalcemic. Calcium use during CPR was further bolstered by the

animal studies of Redding and Pearson showing moderate success with calcium chloride in asphyxial arrest.¹³ However, these studies also showed vasopressors to be more successful than calcium. More recent animal studies have not found calcium to influence resuscitation rates or improve electromechanical coupling with pacing.²¹⁷ In 1981, Dembo reported dangerously high serum calcium levels (up to $18.2 \text{ mg} \cdot \text{dl}^{-1}$) during CPR and questioned the efficacy of calcium in cardiac arrest.²¹⁸ Subsequently, several retrospective studies and prospective clinical trials during out-of-hospital cardiac arrest showed that calcium was no better than placebo in promoting resuscitation and survival from asystole or EMD.^{219,220,221,222,223} and ²²⁴ Consequently, because of potentially deleterious effects, calcium is not recommended during CPR unless specific indications exist. Calcium may prove useful if hyperkalemia, hypocalcemia, or calcium channel blocker toxicity is present. There are no other indications for its use during CPR. When calcium is administered, the chloride salt is recommended because it produces higher and more consistent levels of ionized calcium than other salts. The usual dose is $2\text{--}4 \text{ mg} \cdot \text{kg}^{-1}$ of the 10% solution administered slowly intravenously. Calcium gluconate contains one-third as much molecular calcium as does calcium chloride and requires metabolism of gluconate in the liver.

PEDIATRIC CARDIOPULMONARY RESUSCITATION

The principles of CPR discussed previously apply to the child in cardiac arrest. Arrest is less likely to be a sudden event and more likely related to progressive deterioration of respiratory and circulatory function in the pediatric age group. Airway and ventilation problems lead to asystole and PEA as the most common presenting rhythms. However, the consequences of myocardial and cerebral ischemia are the same as for the adult. The basic approach to the arrest victim is the same (see [Table 57-1](#)). The specific anatomic and physiologic considerations necessary for the child will be familiar to anesthesiologists. The special circumstance of neonatal resuscitation has been discussed in other chapters.

The problem of airway management in the infant is well known to the anesthesiologist. Effective ventilation is especially critical because respiratory problems are frequently the cause for arrest. Mouth-to-mouth or mouth-to-nose and mouth (for infants) can be used as well as bag-valve mask devices until intubation is possible. Cardiac compression in the infant is provided with two fingers on the midsternum or by encircling the chest with the hands and using the thumbs to provide compression. For the small child, compression can be provided with one hand on the midsternum.

The algorithm for ACLS in the pediatric patient is shown in [Figure 57-9](#) and [Figure 57-10](#). Although defibrillation is less frequently necessary in children, the same principles apply as in the adult. However, the recommended starting energy is $2 \text{ J} \cdot \text{kg}^{-1}$, which is doubled if defibrillation is unsuccessful. Considerations for drug administration are the same as for the adult except that the interosseous route in the anterior tibia provides an additional option in small children. Drug therapy is similar to the adult but plays a larger role because electrical therapy is less often needed ([Fig. 57-9, Fig. 57-10](#) and [Fig. 57-11](#)).

| Medication | Indication | Dose | Route | Notes |
|-------------------|--|--|-------|--|
| Atropine | Bradycardia with signs of poor perfusion | 1 mg/kg (0.1 mg/kg if < 6 years old) | IV/IO | Do not administer to children with narrow-angle glaucoma, obstructive pulmonary disease, or severe asthma. |
| Epinephrine | Pulseless arrest (Asystole or PEA) | 0.1 mg/kg (0.1 mg/kg if < 6 years old) | IV/IO | Do not administer to children with severe asthma or narrow-angle glaucoma. |
| Amiodarone | Refractory ventricular tachycardia or fibrillation | 5 mg/kg | IV/IO | Use 0.5 mg/kg bolus over 1-2 minutes, then 1-2 mg/kg/min infusion. |
| Lidocaine | Refractory ventricular tachycardia or fibrillation | 2 mg/kg | IV/IO | Use 1 mg/kg bolus over 1-2 minutes, then 0.5-1 mg/kg/min infusion. |
| Propofol | Refractory ventricular tachycardia or fibrillation | 1-2 mg/kg | IV/IO | Use 1 mg/kg bolus over 1-2 minutes, then 0.5-1 mg/kg/min infusion. |
| Calcium chloride | Hyperkalemia, hypocalcemia, calcium channel blocker toxicity | 2-4 mg/kg | IV/IO | Use 10% solution. |
| Calcium gluconate | Hyperkalemia, hypocalcemia, calcium channel blocker toxicity | 2-4 mg/kg | IV/IO | Use 10% solution. |

POSTRESUSCITATION CARE

The major factors contributing to mortality following successful resuscitation are progression of the primary disease and cerebral damage suffered as a result of the arrest. Active management following resuscitation appears to mitigate postischemic brain damage and improve neurologic outcome.²²⁵ Although a significant number of patients have severe neurologic deficits following resuscitation, aggressive brain-oriented support does not seem to increase the proportion surviving in vegetative states. Most severely damaged victims die of multisystem failure within 1–2 weeks.

When flow is restored following a period of global brain ischemia, three stages of cerebral reperfusion are seen in the ensuing 12 hr. Immediately following resuscitation, there are multifocal areas of the brain with no reflow. Within 1 hr there is global hyperemia followed quickly by prolonged global hypoperfusion. Elevation of intracranial pressure is unusual following resuscitation from cardiac arrest. However, severe ischemic injury can lead to cerebral edema and increased intracranial pressure in the ensuing days.

Postresuscitation support is focused on providing stable oxygenation and hemodynamics to minimize any further cerebral insult. A comatose patient should be maintained on mechanical ventilation for several hours to ensure adequate oxygenation and ventilation. Restlessness, coughing, or seizure activity should be

aggressively treated with appropriate medications including neuromuscular blockers, if necessary. Arterial PaO₂ should be maintained above 100 mm Hg and hypocapnia (PaCO₂ < 30 mm Hg) should be avoided. Blood volume should be maintained normal and moderate hemodilution to a hematocrit of 30–35% may be helpful. A brief 5-min period of hypertension to mean arterial pressure of 120–140 mm Hg may help overcome the initial cerebral no reflow. This frequently occurs secondary to the effects of epinephrine given during CPR. Because cerebral autoregulation of blood flow is severely attenuated, both prolonged hypertension and hypotension are associated with a worsened outcome. Therefore, mean arterial pressure should be maintained at 90–110 mm Hg. Hyperglycemia during cerebral ischemia is known to result in increased neurologic damage. Although it is unknown if high serum glucose in the postresuscitation period influences outcome, it seems prudent to control glucose in the 100–250 mg · dl⁻¹ range. Mild hypothermia that may occur during cardiac arrest and resuscitation should not be actively treated but induced hypothermia is not currently recommended.

In contrast to general supportive care, specific pharmacologic therapy directed at brain preservation has not been shown to have further benefit. Some animal trials of barbiturates were promising, but a large multicenter trial of thiopental found no improvement in neurologic status when this drug was given following cardiac arrest.²²⁵ Similar results were found with calcium channel blockers. Animal studies were encouraging, but a clinical trial found no improvement in outcome.²²⁶

Prognosis

For the comatose survivor of CPR, the question of ultimate prognosis is important. One retrospective study demonstrated that the admission neurologic examination of comatose victims is highly correlated with the likelihood of awakening.²²⁷ If there were no pupillary light response and no spontaneous eye movement and if the motor response to pain were absent or extensor posturing, there was only a 5% chance the patient would ever awaken. A companion study demonstrated that the chance of ever awakening fell rapidly in the days following arrest.²²⁸ If the patient was not awake by 4 days following arrest, the chance of ever awakening was 20% and all those awakening had marked neurologic deficits. Most patients who completely recover show rapid improvement in the first 48 hr. There is also a high correlation between severity of neurologic injury and the level of creatine kinase-BB found in the cerebrospinal fluid.^{229,230} Peak values of ³²S IU are associated with severe neurologic damage and are reached 48–72 hr following arrest.

THREE-LEAD SYSTEMS

| Bipolar Lead System | Electrode Placement | ECG Lead* | Advantage |
|---------------------|--|-----------------------|--------------------------------------|
| II | RA R-clavicle LA L-10th rib (midclavicular line) LL Ground | II (II) | Dysrhythmias |
| MCL 1 | RA Ground LA L-clavicle LL V ₁ | III (V ₁) | Dysrhythmias and conduction defects |
| CS 5 | RA R-clavicle LA V ₅ LL Ground | I (V ₅) | Precordial ischemia |
| CB 5 | RA R-scapula LA V ₅ LL Ground | I (V ₅) | Precordial ischemia and dysrhythmias |

MCL = modified central lead; CB = central back; CS = central subclavian.

*Selected lead on monitor: () = simulated ECG lead.

THE NORMAL ELECTROCARDIOGRAM—CARDIAC CYCLE

In this section the ECG complex is divided into the atrial (PR interval) and ventricular (QT interval) components.

ASHMAN BEATS

Rate: Variable.

Rhythm: Irregular.

PR interval: P wave may be present if supraventricular premature beat.

QT interval: QRS prolonged (>0.12 s) and altered, revealing bundle-branch pattern, most commonly right bundle. ST segment abnormal.

Note: Ashman beats are often confused with ventricular premature contractions. Ashman beats, usually seen with atrial fibrillation, have no compensatory pause and are a benign ECG finding requiring no treatment.

ATRIAL FIBRILLATION

Rate: Variable (~ 150 – 200 beats \cdot min $^{-1}$).

Rhythm: Irregular.

PR interval: No P wave, and PR interval not discernible.

QT interval: QRS normal.

Note: Must be differentiated from atrial flutter: (1) absence of flutter waves and presence of fibrillatory line; (2) flutter usually associated with higher ventricular rates (>150 beats \cdot min $^{-1}$). Loss of atrial contraction reduces cardiac output (10–20%). Mural atrial thrombi may develop. Considered controlled if ventricular rate <100 beats \cdot min $^{-1}$.

ATRIAL FLUTTER

Rate: Rapid, atrial usually regular (250–350 beats \cdot min $^{-1}$); ventricular usually regular (<100 beats \cdot min $^{-1}$).

Rhythm: Atrial and ventricular regular.

PR interval: Flutter (F) waves are saw-toothed. PR interval cannot be measured.

QT interval: QRS usually normal; ST segment and T waves are not identifiable.

Note: Carotid massage will slow ventricular response, simplifying recognition of the F waves.

ATRIOVENTRICULAR BLOCK (First-Degree)

Rate: 60–100 beats · min⁻¹.

Rhythm: Regular.

PR interval: Prolonged (>0.20 s) and constant.

QT interval: Normal.

Note: Usually clinically insignificant; may be early harbinger of drug toxicity.

ATRIOVENTRICULAR BLOCK (Second-Degree), Mobitz Type I/Wenckebach Block

Rate: 60–100 beats · min⁻¹.

Rhythm: Atrial regular; ventricular irregular.

PR interval: P wave normal; PR interval progressively lengthens with each cycle until QRS complex is dropped (dropped beat). PR interval following dropped beat is shorter than normal.

QT interval: QRS complex normal but dropped periodically.

Note: Commonly seen (1) in trained athletes and (2) with drug toxicity.

ATRIOVENTRICULAR BLOCK (Second-Degree), Mobitz Type II

Rate: <100 beats · min⁻¹.

Rhythm: Atrial regular; ventricular regular or irregular.

PR interval: P waves normal, but some are not followed by QRS complex.

QT interval: Normal but may have widened QRS complex if block is at level of bundle branch. ST segment and T wave may be abnormal, depending on location of block.

Note: In contrast to Mobitz type I block, the PR and RR intervals are constant and the dropped QRS occurs without warning. The wider the QRS complex (block lower

in the conduction system), the greater the amount of myocardial damage.

ATRIOVENTRICULAR BLOCK (Third-Degree), Complete Heart Block

Rate: $<45 \text{ beats} \cdot \text{min}^{-1}$.

Rhythm: Atrial regular; ventricular regular; no relationship between P wave and QRS complex.

PR interval: Variable because atria and ventricles beat independently.

QT interval: QRS morphology variable, depending on the origin of the ventricular beat in the intrinsic pacemaker system (atrioventricular junctional versus ventricular pacemaker). ST segment and T wave normal.

Note: Immediate treatment with atropine or isoproterenol is required if cardiac output is reduced. Consideration should be given to insertion of a pacemaker. Seen as a complication of mitral valve replacement.

ATRIOVENTRICULAR DISSOCIATION

Rate: Variable.

Rhythm: Atrial regular; ventricular regular; ventricular rate faster than atrial rate; no relationship between P wave and QRS complex.

PR interval: Variable because atria and ventricles beat independently.

QT interval: QRS morphology depends on location of ventricular pacemaker. ST segment and T wave abnormal.

Note: Digitalis toxicity can present as atrioventricular dissociation.

BUNDLE-BRANCH BLOCK—LEFT (LBBB)

V6

Rate: $<100 \text{ beats} \cdot \text{min}^{-1}$.

Rhythm: Regular.

PR interval: Normal.

QT interval: Complete LBBB (QRS $>0.12 \text{ s}$); incomplete LBBB (QRS = $0.10\text{--}0.12 \text{ s}$). Lead V_1 negative rS complex; I, aVL, V_6 wide R wave without Q or S component. ST segment and T wave deflection opposite direction of the R wave.

Note: LBBB does not occur in healthy patients and usually indicates serious heart disease with a poorer prognosis. In patients with LBBB, insertion of a pulmonary

artery catheter may lead to complete heart block.

BUNDLE-BRANCH BLOCK—RIGHT (RBBB)

Rate: $<100 \text{ beats} \cdot \text{min}^{-1}$.

Rhythm: Regular.

PR interval: Normal.

QT interval: Complete RBBB (QRS $>0.12 \text{ s}$); incomplete RBBB (QRS = $0.10\text{--}0.12 \text{ s}$). Varying patterns of QRS complex; rSR (V_1); RS, wide R with M pattern. ST segment and T wave opposite direction of the R wave.

Note: In the presence of RBBB, Q waves may be seen with a myocardial infarction.

ELECTROLYTE DISTURBANCES

| | $\downarrow \text{Ca}^{2+}$ | $\uparrow \text{Ca}^{2+}$ | $\downarrow \text{K}^+$ | $\uparrow \text{K}^+$ |
|--------------------|--|--|--|--|
| Rate | $<100 \text{ beats} \cdot \text{min}^{-1}$ | $<100 \text{ beats} \cdot \text{min}^{-1}$ | $<100 \text{ beats} \cdot \text{min}^{-1}$ | $<100 \text{ beats} \cdot \text{min}^{-1}$ |
| Rhythm | Regular | Regular | Regular | Regular |
| PR interval | Normal | Normal/increased | Normal | Normal |
| QT interval | Increased | Decreased | T flat U wave | T peaked QT decreased |

Note: ECG changes usually do not correlate with serum calcium. Hypocalcemia rarely causes dysrhythmias in the absence of hypokalemia. In contrast, abnormalities in serum potassium concentration can be diagnosed by ECG.

DIGITALIS EFFECT

Rate: $<100 \text{ beats} \cdot \text{min}^{-1}$.

Rhythm: Regular.

PR interval: Normal or prolonged.

QT interval: ST segment sloping (“digitalis effect”).

Note: Digitalis toxicity can be the cause of many common dysrhythmias (e.g., premature ventricular contractions, second-degree heart block). Verapamil, quinidine, and amiodarone cause an increase in serum digitalis concentration.

CORONARY ARTERY DISEASE—Ischemia

Rate: Variable.

Rhythm: Usually regular, but may show atrial and/or ventricular dysrhythmias.

PR interval: Normal.

QT interval: ST segment depressed; J point depression; T-wave inversion; conduction disturbances. Coronary vasospasm (Prinzmetal) ST segment elevation.

Note: Intraoperative ischemia is usually seen in the presence of “normal” vital signs (e.g., $\pm 20\%$ of preinduction values).

CORONARY ARTERY DISEASE—Myocardial Infarction

| Anteroseptal Site | Leads | ECG Changes | Coronary Artery |
|-------------------|--|-------------|--------------------------|
| Inferior | II, III, aVF | Q, ST, T | Right |
| Lateral | I, aVL, V ₅ -V ₆ | Q, ST, T | Left circumflex |
| Anterior | I, aVL, V ₁ -V ₄ | Q, ST, T | Left |
| Anteroseptal | V ₁ -V ₄ | Q, ST, T | Left anterior descending |

SUBENDOCARDIAL MYOCARDIAL INFARCTION (SEMI)

Persistent ST segment depression and/or T-wave inversion in the absence of Q wave. Usually requires additional laboratory data (e.g., isoenzymes) to confirm diagnosis.

TRANSMURAL MYOCARDIAL INFARCTION (TMI)

Q waves seen on ECG useful in confirming diagnosis. Associated with poorer prognosis and more significant hemodynamic impairment; dysrhythmias frequently complicate course.

PAROXYSMAL ATRIAL TACHYCARDIA (PAT)

Rate: 150–250 beats · min⁻¹.

Rhythm: Regular.

PR interval: Difficult to distinguish because of tachycardia obscuring P wave. P wave may precede, be included in, or follow QRS complex.

QT interval: Normal, but ST segment and T wave may be difficult to distinguish.

Note: Therapy depends on degree of hemodynamic compromise. In contrast to management of PAT in awake patients, synchronized cardioversion rather than pharmacologic treatment is preferred in hemodynamically unstable anesthetized patients.

PREMATURE ATRIAL CONTRACTION (PAC)

Rate: <100 beats · min⁻¹.

Rhythm: Irregular.

PR interval: P waves may be lost in preceding T waves. PR interval is variable.

QT interval: QRS normal configuration; ST segment and T wave normal.

Note: Nonconducted PAC appearance similar to that of sinus arrest; T waves with PAC may be distorted by inclusion of P wave in the T wave.

PREMATURE VENTRICULAR CONTRACTION (PVC)

A

B

Rate: Usually <100 beats \cdot min⁻¹.

Rhythm: Irregular.

PR interval: P wave and PR interval absent; retrograde conduction of P wave can be seen.

QT interval: Wide QRS (>0.12 s); ST segment cannot be evaluated (e.g., ischemia); T wave opposite direction of QRS with compensatory pause (A). Bigeminy: every other beat a PVC (B); trigeminy: every third beat a PVC. R-on-T occurs when PVC falls in the T wave and can lead to ventricular tachycardia or fibrillation.

Note: If compensatory pause is not seen following an ectopic beat, the complex is most likely supraventricular in origin.

SINUS TACHYCARDIA

Rate: 100–160 beats \cdot min⁻¹.

Rhythm: Regular.

PR interval: Normal; P wave may be difficult to see.

QT interval: Normal.

Note: Should be differentiated from paroxysmal atrial tachycardia (PAT). With PAT, carotid massage terminates dysrhythmia. Sinus tachycardia may respond to vagal maneuvers but reappears as soon as vagal stimulus is removed.

TORSADES DE POINTES

Rate: 150–250 beats \cdot min⁻¹.

Rhythm: No atrial component seen; ventricular rhythm regular or irregular.

PR interval: P wave buried in QRS complex.

QT interval: QRS complexes usually wide and with phasic variation twisting around a central axis (a few complexes point upward then a few point downward). ST segments and T waves difficult to discern.

Note: Type of ventricular tachycardia associated with prolonged QT interval. Seen with electrolyte disturbances (e.g., hypokalemia, hypocalcemia, and hypomagnesemia) and bradycardia. Administering standard antidysrhythmics (lidocaine, procainamide, etc.) may worsen Torsades de Pointes. Treatment includes increasing heart rate pharmacologically or by pacing.

VENTRICULAR FIBRILLATION

Rate: Absent.

Rhythm: None.

PR interval: Absent.

QT interval: Absent.

Note: "Pseudoventricular fibrillation" may be the result of a monitor malfunction (e.g., ECG lead disconnect). Always check for carotid pulse before instituting therapy.

VENTRICULAR TACHYCARDIA

Rate: 100–250 beats · min⁻¹.

Rhythm: No atrial component seen; ventricular rhythm irregular or regular.

PR interval: Absent; retrograde P wave may be seen in QRS complex.

QT interval: Wide, bizarre QRS complex. ST segment and T wave difficult to determine.

Note: In the presence of hemodynamic compromise, immediate DC synchronized cardioversion is required. If the patient is stable, with short bursts of ventricular tachycardia, pharmacologic management is preferred. Should be differentiated from supraventricular tachycardia with aberrancy (SVT-A). Compensatory pause and atrioventricular dissociation suggest a PVC. P waves and SR' (V₁) and slowing to vagal stimulus suggest SVT-A.

WOLFF-PARKINSON-WHITE SYNDROME (WPW)

Rate: <100 beats · min⁻¹.

Rhythm: Regular.

PR interval: P wave normal; PR interval short (<0.12 s).

QT interval: Duration (>0.10 s) with slurred QRS complex. Type A has delta wave, RBBB, with upright QRS complex V₁. Type B has delta wave and downward QRS-V₁. ST segment and T wave usually normal.

Note: Digoxin should be avoided in the presence of WPW because it increases conduction through the accessory bypass tract (bundle of Kent) and decreases atrioventricular node conduction; consequently, ventricular fibrillation can occur.

PACEMAKER

PACEMAKER DESIGNATIONS

| 1 | 2 | 3 | 4 | 5 |
|-------------------------------------|-------------------------------------|---|---|--|
| Chamber-Paced | Chamber-Sensed | Response | Program | Antitachy-cardia Function |
| <u>A</u> trium <u>V</u> entricle | <u>A</u> trium <u>V</u> entricle | <u>I</u> nhibit <u>T</u> rigger | <u>P</u> rogrammable (rate/output) <u>M</u> ultiprogrammable | <u>B</u> ursts <u>N</u> ormal rate <u>C</u> ompetition <u>S</u> canning <u>E</u> xternal |
| <u>D</u> ouble (A/V) | <u>D</u> ouble <u>O</u> /None | <u>D</u> ouble <u>O</u> /None <u>R</u> everse | <u>C</u> ommunicating <u>O</u> /None | |

Note: The original pacemaker designation used a three-position code. Subsequently, expanded positions were added (4, 5). For example, the presence of atrial fibrillation may require a pacemaker with the code **VVI**. This designation indicates (1) Ventricle is paced, (2) Ventricle is sensed, and the pacemaker is (3) Inhibited if a cardiac event is sensed.

EVALUATION OF THE PACEMAKER

1. Ask patient about results of last telephone check.
2. Ask patient about location of pulse generator.
3. Ask patient to exercise muscles in area of generator. Observe for inhibition of pacing.
4. If patient cannot help with 1,2,3, try to obtain ID card.
5. If 4 not possible, assume the patient has VVIR or DDDR, piezoelectric, vibratory-sensing pacemaker.
6. Observe chest x-ray for number and continuity of leads and location of electrodes.
7. Observe ECG for pacemaker dependency, failed capture, undersensing, and ventricular vs. sequential pacing.
8. Apply magnet to check for pacing capture and for rate. If magnet rate is low (≤90 beats · min⁻¹), notify cardiologist.
9. In an emergency, proceed with the surgical procedure. If the intrinsic heart rate is <50–60 beats · min⁻¹ and there are no impulses found on ECG, establish transcutaneous pacing.

ATRIAL PACING

Atrial pacing as demonstrated in this figure is used when the atrial impulse can proceed through the AV node. Examples are sinus bradycardia and junctional rhythms associated with clinically significant decreases in blood pressure.

VENTRICULAR PACING

In this tracing ventricular pacing is evident by absence of atrial wave (P wave) and pacemaker spike preceding QRS complex. Ventricular pacing is employed in the presence of bradycardia secondary to AV block or atrial fibrillation.

DDD PACING

The DDD pacemaker (generator), one of the most commonly used, paces and senses both atrium and ventricle. In the first four beats, the P waves were not followed by a QRS complex within the programmed PR interval. Therefore, a ventricular pacing spike and a ventricular paced beat occurred. In the last four beats (after the arrow), atrial activity proceeded through the AV node in the allotted amount of time; therefore, ventricular pacing was inhibited.

ATRIAL ELECTROGRAM (AEG)

The AEG is useful in differentiating various atrial dysrhythmias. The AEG is obtained from an intracardiac or esophageal lead, if P waves are not clearly seen on the surface ECG. In this trace the V lead does not have obvious P waves; however, the AEG reveals large P waves (arrows) that precede each QRS complex. Locate the QRS on the AEG by matching the R wave on the surface ECG to the AEG. The surface and AEG must be simultaneously recorded.

IMPLANTED CARDIOVERTER-DEFIBRILLATORS

Guidelines for Patient Care

- Preoperative assessment should include those procedures that are standard for patients with heart disease. Evaluate for progression of all types of heart disease.
- Question the patient regarding the number of shocks received in the few days prior to the scheduled surgery. The response will indicate the possibility of requiring therapy during the next few hours.
- Continue antiarrhythmic agents until the time of surgery. Consider discussing with the cardiologist the necessity of the administration of an additional dose of

amiodarone should the patient experience an arrhythmia during surgery. If the patient has an arrhythmia, rule out the usual causes, such as hypercarbia, to prevent the arrhythmia from recurring during surgery.

- There is no particular anesthetic technique that is clearly right or wrong for a patient who has an implanted defibrillator.
- Monitoring must include American Society of Anesthesiologists standard monitoring devices. Other monitors should be used as indicated for the individual patient.
- There are no reports concerning the use of a pulmonary arterial catheter in patients who have ICDs. If monitoring with a pulmonary arterial catheter is necessary, discuss the issues of dislodgment of the ICD with the patient and cardiologist. Document your discussions and the logic supporting the necessity for a pulmonary arterial catheter in the chart.
- Patients with transvenous devices are potentially at risk for infection when central lines are inserted without caution for aseptic technique. Consider administering an antibiotic just before inserting central lines. Maintain perfect sterile technique.
- Apply patches for external defibrillation during surgery. Assure that these external patches are as far away as possible from the device.
- Interrogate and reprogram the ICD as soon as possible after surgery.
- Always have the magnet available.

Guidelines for Electrocautery Use

- If the patient has a separately implanted pacemaker, consider programming the pacemaker to asynchronous activity (VOO or DOO) to prevent inhibition while the electrocautery is being used. Pacemaker spikes that occur when a patient's heart rate is greater than an asynchronously programmed pacemaker rate will be counted by the ICD as R waves. The ICD, therefore, could interpret a sinus tachycardia plus pacemaker spikes as a ventricular tachycardia and shock the patient.
- The electrocautery could reprogram the VVI and DDD pacing parameters of the ICD; however, the chance of reprogramming is extremely small. A magnet will not change pacing parameters in patients who require chronic pacing.
- Do not use electrocautery when the device is actively sensing and capable of delivering therapy. Program the ICD to "off." There are no reports of an ICD reprogramming to "monitor plus therapy" once it has been programmed off. Some cardiologists reprogram the ICD to "monitor only" during surgery to record arrhythmias, but the device will then monitor electrocautery signals.
- If a programming device is not available, then use the magnet to change the mode of activity. The CPI device, if it is programmed to respond to the magnet, will have changed to "monitor only" from "monitor plus therapy" once the beeping tone becomes a continuous tone. If charging starts while the surgeon is using the electrocautery, then place the magnet over the generator and the device will discharge into itself, not into the patient. The Medtronic and Intermedics devices suspend monitoring and therapy for as long as the magnet is held over the generator; therefore, if the magnet is on the generator, they will neither sense nor discharge.
- Duration criterion must be met before charging takes place. Additionally, if the patient is in ventricular tachycardia, the ICD reconfirms the arrhythmia before it delivers rapid pacing or shock therapy. These events give the device time to stop the process if an electrocautery signal is sensed as an arrhythmia. Using the electrocautery in short bursts might cause inappropriate sensing; however, sensing will not fulfill the duration criterion, therefore the device will not charge. The ICD could interpret the signal from the electrocautery as ventricular fibrillation even when the activated cautery is not in contact with the patient.
- A bipolar electrocautery has a smaller chance of causing sensing and discharge. A battery-powered electrocautery offers extra safety.
- Do not use the electrocautery within six inches of the device or leads.
- If the ICD begins to charge during the operative procedure, place the magnet over the ICD and keep it in that location. The ICD will discharge into the generator and will stop sensing. It will not stop pacing activity.
- When positioning the external defibrillator patches, assure that they are positioned perpendicular to a plane described by the generator and electrodes.

We wish to thank Dr. Malcom S. Thaler for graciously permitting reproduction of electrocardiographic tracings from his book, *The Only EKG Book You'll Ever Need* (Philadelphia, JB Lippincott, 1988).
